PREFACE

My introduction to membranes was as a graduate student in 1963. At that time membrane permeation was a sub-study of materials science. What is now called membrane technology did not exist, nor did any large industrial applications of membranes. Since then, sales of membranes and membrane equipment have increased more than 100-fold and several tens of millions of square meters of membrane are produced each year—a membrane industry has been created.

This membrane industry is very fragmented. Industrial applications are divided into six main sub-groups: reverse osmosis; ultrafiltration; microfiltration; gas separation; pervaporation and electrodialysis. Medical applications are divided into three more: artificial kidneys; blood oxygenators; and controlled release pharmaceuticals. Few companies are involved in more than one sub-group of the industry. Because of these divisions it is difficult to obtain an overview of membrane science and technology; this book is an attempt to give such an overview.

The book starts with a series of general chapters on membrane preparation, transport theory, and concentration polarization. Thereafter, each major membrane application is treated in a single 20-to-40-page chapter. In a book of this size it is impossible to describe every membrane process in detail, but the major processes are covered. However, medical applications have been short-changed somewhat and some applications—fuel cell and battery separators and membrane sensors, for example—are not covered at all.

Each application chapter starts with a short historical background to acknowledge the developers of the technology. I am conscious that my views of what was important in the past differ from those of many of my academic colleagues. In this book I have given more credit than is usual to the engineers who actually made the processes work.

Readers of the theoretical section (Chapter 2) and elsewhere in the book will see that membrane permeation is described using simple phenomenological equations, most commonly, Fick's law. There is no mention of irreversible thermodynamics. The irreversible thermodynamic approach to permeation was very fashionable when I began to work with membranes in the 1960s. This approach has the appearance of rigor but hides the physical reality of even simple processes behind a fog of tough equations. As a student and young researcher, I struggled with irreversible thermodynamics for more than 15 years before finally giving up in the 1970s. I have lived happily ever after.

Finally, a few words on units. Because a great deal of modern membrane technology originated in the United States, the US engineering units—gallons, cubic feet, and pounds per square inch—are widely used in the membrane industry. Unlike the creators of the Pascal, I am not a worshipper of mindless uniformity. Metric units are used when appropriate, but US engineering units are used when they are the industry standard.

ACKNOWLEDGMENTS FOR THE FIRST EDITION

As a school boy I once received a mark of $\frac{1}{2}$ out of a possible 20 in an end-of-term spelling test. My spelling is still weak, and the only punctuation I ever really mastered was the period. This made the preparation of a polished final draft from my yellow notepads a major undertaking. This effort was headed by Tessa Ennals and Cindi Wieselmann. Cindi typed and retyped the manuscript with amazing speed, through its numerous revisions, without complaint. Tessa corrected my English, clarified my language, unsplit my infinitives and added every semicolon found in this book. She also chased down a source for all of the illustrations used and worked with David Lehmann, our graphics artist, to prepare the figures. It is a pleasure to acknowledge my debt to these people. This book would have been far weaker without the many hours they spent working on it. I also received help from other friends and colleagues at MTR. Hans Wijmans read, corrected and made numerous suggestions on the theoretical section of the book (Chapter 2). Ingo Pinnau also provided data, references and many valuable suggestions in the area of membrane preparation and membrane material sciences. I am also grateful to Kenji Matsumoto, who read the section on Reverse Osmosis and made corrections, and to Heiner Strathmann, who did the same for Electrodialysis. The assistance of Marcia Patten, who proofed the manuscript, and Vivian Tran, who checked many of the references, is also appreciated.

ACKNOWLEDGMENTS FOR THE SECOND EDITION

Eighteen months after the first edition of this book appeared, it was out of print. Fortunately, John Wiley & Sons, Ltd agreed to publish a second edition, and I have taken the opportunity to update and revise a number of sections. Tessa Ennals, long-time editor at Membrane Technology and Research, postponed her retirement to help me finish the new edition. Tessa has the standards of an earlier time, and here, as in the past, she gave the task nothing but her best effort. I am indebted to her, and wish her a long and happy retirement. Marcia Patten, Eric Peterson, David Lehmann, Cindy Dunnegan and Janet Farrant assisted Tessa by typing new sections, revising and adding figures, and checking references, as well as helping with proofing the manuscript. I am grateful to all of these colleagues for their help.

1 OVERVIEW OF MEMBRANE SCIENCE AND TECHNOLOGY

Introduction

Membranes have gained an important place in chemical technology and are used in a broad range of applications. The key property that is exploited is the ability of a membrane to control the permeation rate of a chemical species through the membrane. In controlled drug delivery, the goal is to moderate the permeation rate of a drug from a reservoir to the body. In separation applications, the goal is to allow one component of a mixture to permeate the membrane freely, while hindering permeation of other components.

This book provides a general introduction to membrane science and technology. Chapters 2 to 4 cover membrane science, that is, topics that are basic to all membrane processes, such as transport mechanisms, membrane preparation, and boundary layer effects. The next six chapters cover the industrial membrane separation processes, which represent the heart of current membrane technology. Carrier facilitated transport is covered next, followed by a chapter reviewing the medical applications of membranes. The book closes with a chapter that describes various minor or yet-to-be-developed membrane processes, including membrane reactors, membrane contactors and piezodialysis.

Historical Development of Membranes

Systematic studies of membrane phenomena can be traced to the eighteenth century philosopher scientists. For example, Abbé Nolet coined the word 'osmosis' to describe permeation of water through a diaphragm in 1748. Through the nineteenth and early twentieth centuries, membranes had no industrial or commercial uses, but were used as laboratory tools to develop physical/chemical theories. For example, the measurements of solution osmotic pressure made with membranes by Traube and Pfeffer were used by van't Hoff in 1887 to develop his limit law, which explains the behavior of ideal dilute solutions; this work led directly to the

van't Hoff equation. At about the same time, the concept of a perfectly selective semipermeable membrane was used by Maxwell and others in developing the kinetic theory of gases.

Early membrane investigators experimented with every type of diaphragm available to them, such as bladders of pigs, cattle or fish and sausage casings made of animal gut. Later, collodion (nitrocellulose) membranes were preferred, because they could be made reproducibly. In 1907, Bechhold devised a technique to prepare nitrocellulose membranes of graded pore size, which he determined by a bubble test [1]. Other early workers, particularly Elford [2], Zsigmondy and Bachmann [3] and Ferry [4] improved on Bechhold's technique, and by the early 1930s microporous collodion membranes were commercially available. During the next 20 years, this early microfiltration membrane technology was expanded to other polymers, notably cellulose acetate. Membranes found their first significant application in the testing of drinking water at the end of World War II. Drinking water supplies serving large communities in Germany and elsewhere in Europe had broken down, and filters to test for water safety were needed urgently. The research effort to develop these filters, sponsored by the US Army, was later exploited by the Millipore Corporation, the first and still the largest US microfiltration membrane producer.

By 1960, the elements of modern membrane science had been developed, but membranes were used in only a few laboratory and small, specialized industrial applications. No significant membrane industry existed, and total annual sales of membranes for all industrial applications probably did not exceed US\$20 million in 2003 dollars. Membranes suffered from four problems that prohibited their widespread use as a separation process: They were too unreliable, too slow, too unselective, and too expensive. Solutions to each of these problems have been developed during the last 30 years, and membrane-based separation processes are now commonplace.

The seminal discovery that transformed membrane separation from a laboratory to an industrial process was the development, in the early 1960s, of the Loeb–Sourirajan process for making defect-free, high-flux, anisotropic reverse osmosis membranes [5]. These membranes consist of an ultrathin, selective surface film on a much thicker but much more permeable microporous support, which provides the mechanical strength. The flux of the first Loeb–Sourirajan reverse osmosis membrane was 10 times higher than that of any membrane then available and made reverse osmosis a potentially practical method of desalting water. The work of Loeb and Sourirajan, and the timely infusion of large sums of research and development dollars from the US Department of Interior, Office of Saline Water (OSW), resulted in the commercialization of reverse osmosis and was a major factor in the development of ultrafiltration and microfiltration. The development of electro dialysis was also aided by OSW funding.

Concurrently with the development of these industrial applications of membranes was the independent development of membranes for medical separation

processes, in particular, the artificial kidney. W.J. Kolf [6] had demonstrated the first successful artificial kidney in The Netherlands in 1945. It took almost 20 years to refine the technology for use on a large scale, but these developments were complete by the early 1960s. Since then, the use of membranes in artificial organs has become a major life-saving procedure. More than 800 000 people are now sustained by artificial kidneys and a further million people undergo open-heart surgery each year, a procedure made possible by development of the membrane blood oxygenator. The sales of these devices comfortably exceed the total industrial membrane separation market. Another important medical application of membranes is for controlled drug delivery systems. A key figure in this area was Alex Zaffaroni, who founded Alza, a company dedicated to developing these products in 1966. The membrane techniques developed by Alza and its competitors are widely used in the pharmaceutical industry to improve the efficiency and safety of drug delivery.

The period from 1960 to 1980 produced a significant change in the status of membrane technology. Building on the original Loeb–Sourirajan technique, other membrane formation processes, including interfacial polymerization and multilayer composite casting and coating, were developed for making high-performance membranes. Using these processes, membranes with selective layers as thin as $0.1\ \mu\text{m}$ or less are now being produced by a number of companies. Methods of packaging membranes into large-membrane-area spiral-wound, hollow-fine-fiber, capillary, and plate-and-frame modules were also developed, and advances were made in improving membrane stability. By 1980, micro-filtration, ultrafiltration, reverse osmosis and electrodialysis were all established processes with large plants installed worldwide.

The principal development in the 1980s was the emergence of industrial membrane gas separation processes. The first major development was the Monsanto Prism[®] membrane for hydrogen separation, introduced in 1980 [7]. Within a few years, Dow was producing systems to separate nitrogen from air, and Cynara and Separex were producing systems to separate carbon dioxide from natural gas. Gas separation technology is evolving and expanding rapidly; further substantial growth will be seen in the coming years. The final development of the 1980s was the introduction by GFT, a small German engineering company, of the first commercial pervaporation systems for dehydration of alcohol. More than 100 ethanol and isopropanol pervaporation dehydration plants have now been installed. Other pervaporation applications are at the early commercial stage.

Types of Membranes

This book is limited to synthetic membranes, excluding all biological structures, but the topic is still large enough to include a wide variety of membranes that differ in chemical and physical composition and in the way they operate. In essence, a membrane is nothing more than a discrete, thin interface that moderates the

Figure 1.1 Schematic diagrams of the principal types of membranes

permeation of chemical species in contact with it. This interface may be molecularly homogeneous, that is, completely uniform in composition and structure, or it may be chemically or physically heterogeneous, for example, containing holes or pores of finite dimensions or consisting of some form of layered structure. A normal filter meets this definition of a membrane, but, by convention, the term filter is usually limited to structures that separate particulate suspensions larger than 1 to 10 μm . The principal types of membrane are shown schematically in Figure 1.1 and are described briefly below.

Isotropic Membranes

Microporous Membranes

A microporous membrane is very similar in structure and function to a conventional filter. It has a rigid, highly voided structure with randomly distributed, interconnected pores. However, these pores differ from those in a conventional filter by being extremely small, on the order of 0.01 to 10 μm in diameter. All particles larger than the largest pores are completely rejected by the membrane.

Particles smaller than the largest pores, but larger than the smallest pores are partially rejected, according to the pore size distribution of the membrane. Particles much smaller than the smallest pores will pass through the membrane. Thus, separation of solutes by microporous membranes is mainly a function of molecular size and pore size distribution. In general, only molecules that differ considerably in size can be separated effectively by microporous membranes, for example, in ultrafiltration and microfiltration.

Nonporous, Dense Membranes

Nonporous, dense membranes consist of a dense film through which permeants are transported by diffusion under the driving force of a pressure, concentration, or electrical potential gradient. The separation of various components of a mixture is related directly to their relative transport rate within the membrane, which is determined by their diffusivity and solubility in the membrane material. Thus, nonporous, dense membranes can separate permeants of similar size if their concentration in the membrane material (that is, their solubility) differs significantly. Most gas separation, pervaporation, and reverse osmosis membranes use dense membranes to perform the separation. Usually these membranes have an anisotropic structure to improve the flux.

Electrically Charged Membranes

Electrically charged membranes can be dense or microporous, but are most commonly very finely microporous, with the pore walls carrying fixed positively or negatively charged ions. A membrane with fixed positively charged ions is referred to as an anion-exchange membrane because it binds anions in the surrounding fluid. Similarly, a membrane containing fixed negatively charged ions is called a cation-exchange membrane. Separation with charged membranes is achieved mainly by exclusion of ions of the same charge as the fixed ions of the membrane structure, and to a much lesser extent by the pore size. The separation is affected by the charge and concentration of the ions in solution. For example, monovalent ions are excluded less effectively than divalent ions and, in solutions of high ionic strength, selectivity decreases. Electrically charged membranes are used for processing electrolyte solutions in electrodialysis.

Anisotropic Membranes

The transport rate of a species through a membrane is inversely proportional to the membrane thickness. High transport rates are desirable in membrane separation processes for economic reasons; therefore, the membrane should be as thin as possible. Conventional film fabrication technology limits manufacture of mechanically strong, defect-free films to about 20 μm thickness. The development of

novel membrane fabrication techniques to produce anisotropic membrane structures was one of the major breakthroughs of membrane technology during the past 30 years. Anisotropic membranes consist of an extremely thin surface layer supported on a much thicker, porous substructure. The surface layer and its substructure may be formed in a single operation or separately. In composite membranes, the layers are usually made from different polymers. The separation properties and permeation rates of the membrane are determined exclusively by the surface layer; the substructure functions as a mechanical support. The advantages of the higher fluxes provided by anisotropic membranes are so great that almost all commercial processes use such membranes.

Ceramic, Metal and Liquid Membranes

The discussion so far implies that membrane materials are organic polymers and, in fact, the vast majority of membranes used commercially are polymer-based. However, in recent years, interest in membranes formed from less conventional materials has increased. Ceramic membranes, a special class of microporous membranes, are being used in ultrafiltration and microfiltration applications for which solvent resistance and thermal stability are required. Dense metal membranes, particularly palladium membranes, are being considered for the separation of hydrogen from gas mixtures, and supported liquid films are being developed for carrier-facilitated transport processes.

Membrane Processes

Six developed and a number of developing and yet-to-be-developed industrial membrane technologies are discussed in this book. In addition, sections are included describing the use of membranes in medical applications such as the artificial kidney, blood oxygenation, and controlled drug delivery devices. The status of all of these processes is summarized in Table 1.1.

The four developed industrial membrane separation processes are microfiltration, ultrafiltration, reverse osmosis, and electrodialysis. These processes are all well established, and the market is served by a number of experienced companies.

The range of application of the three pressure-driven membrane water separation processes—reverse osmosis, ultrafiltration and microfiltration—is illustrated in Figure 1.2. Ultrafiltration (Chapter 6) and microfiltration (Chapter 7) are basically similar in that the mode of separation is molecular sieving through increasingly fine pores. Microfiltration membranes filter colloidal particles and bacteria from 0.1 to 10 μm in diameter. Ultrafiltration membranes can be used to filter dissolved macromolecules, such as proteins, from solutions. The mechanism of separation by reverse osmosis membranes is quite different. In reverse osmosis membranes (Chapter 5), the membrane pores are so small, from 3 to 5 \AA in diameter, that they are within the range of thermal motion of the polymer

Table 1.1 Membrane technologies addressed in this book

Category	Process	Status
Developed industrial membrane separation technologies	Microfiltration Ultrafiltration Reverse osmosis Electrodialysis	Well-established unit operations. No major breakthroughs seem imminent
Developing industrial membrane separation technologies	Gas separation Pervaporation	A number of plants have been installed. Market size and number of applications served are expanding
To-be-developed industrial membrane separation technologies	Carrier facilitated transport Membrane contactors Piezodialysis, etc.	Major problems remain to be solved before industrial systems will be installed on a large scale
Medical applications of membranes	Artificial kidneys Artificial lungs Controlled drug delivery	Well-established processes. Still the focus of research to improve performance, for example, improving biocompatibility

Figure 1.2 Reverse osmosis, ultrafiltration, microfiltration, and conventional filtration are related processes differing principally in the average pore diameter of the membrane filter. Reverse osmosis membranes are so dense that discrete pores do not exist; transport occurs via statistically distributed free volume areas. The relative size of different solutes removed by each class of membrane is illustrated in this schematic

chains that form the membrane. The accepted mechanism of transport through these membranes is called the solution-diffusion model. According to this model, solutes permeate the membrane by dissolving in the membrane material and diffusing down a concentration gradient. Separation occurs because of the difference in solubilities and mobilities of different solutes in the membrane. The principal application of reverse osmosis is desalination of brackish groundwater or seawater.

Although reverse osmosis, ultrafiltration and microfiltration are conceptually similar processes, the difference in pore diameter (or apparent pore diameter) produces dramatic differences in the way the membranes are used. A simple model of liquid flow through these membranes is to describe the membranes as a series of cylindrical capillary pores of diameter d . The liquid flow through a pore (q) is given by Poiseuille's law as:

$$q = \frac{\pi d^4}{128 \mu \ell} \cdot \Delta p \quad (1.1)$$

where Δp is the pressure difference across the pore, μ is the liquid viscosity and ℓ is the pore length. The flux, or flow per unit membrane area, is the sum of all the flows through the individual pores and so is given by:

$$J = N \cdot \frac{\pi d^4}{128 \mu \ell} \cdot \Delta p \quad (1.2)$$

where N is the number of pores per square centimeter of membrane.

For membranes of equal pore area and porosity (ε), the number of pores per square centimeter is proportional to the inverse square of the pore diameter. That is,

$$N = \varepsilon \cdot \frac{4}{\pi d^2} \quad (1.3)$$

It follows that the flux, given by combining Equations (1.2) and (1.3), is

$$J = \frac{\Delta p \varepsilon}{32 \mu \ell} \cdot d^2 \quad (1.4)$$

From Figure 1.2, the typical pore diameter of a microfiltration membrane is 10 000 Å. This is 100-fold larger than the average ultrafiltration pore and 1000-fold larger than the (nominal) diameter of pores in reverse osmosis membranes. Because fluxes are proportional to the square of these pore diameters, the permeance, that is, flux per unit pressure difference ($J/\Delta p$) of microfiltration membranes is enormously higher than that of ultrafiltration membranes, which in turn is much higher than that of reverse osmosis membranes. These differences significantly impact the operating pressure and the way that these membranes are used industrially.

The fourth fully developed membrane process is electrodialysis (Chapter 10), in which charged membranes are used to separate ions from aqueous solutions under the driving force of an electrical potential difference. The process utilizes an electrodialysis stack, built on the filter-press principle and containing several hundred individual cells, each formed by a pair of anion and cation exchange membranes. The principal application of electrodialysis is the desalting of brackish groundwater. However, industrial use of the process in the food industry, for example, to deionize cheese whey, is growing, as is its use in pollution-control applications. A schematic of the process is shown in Figure 1.3.

Table 1.1 shows two developing industrial membrane separation processes: gas separation with polymer membranes (Chapter 8) and pervaporation (Chapter 9). Gas separation with membranes is the more advanced of the two techniques; at least 20 companies worldwide offer industrial, membrane-based gas separation systems for a variety of applications. Only a handful of companies currently offer industrial pervaporation systems. In gas separation, a gas mixture at an elevated pressure is passed across the surface of a membrane that is selectively permeable to one component of the feed mixture; the membrane permeate is enriched in this species. The basic process is illustrated in Figure 1.4. Major current applications

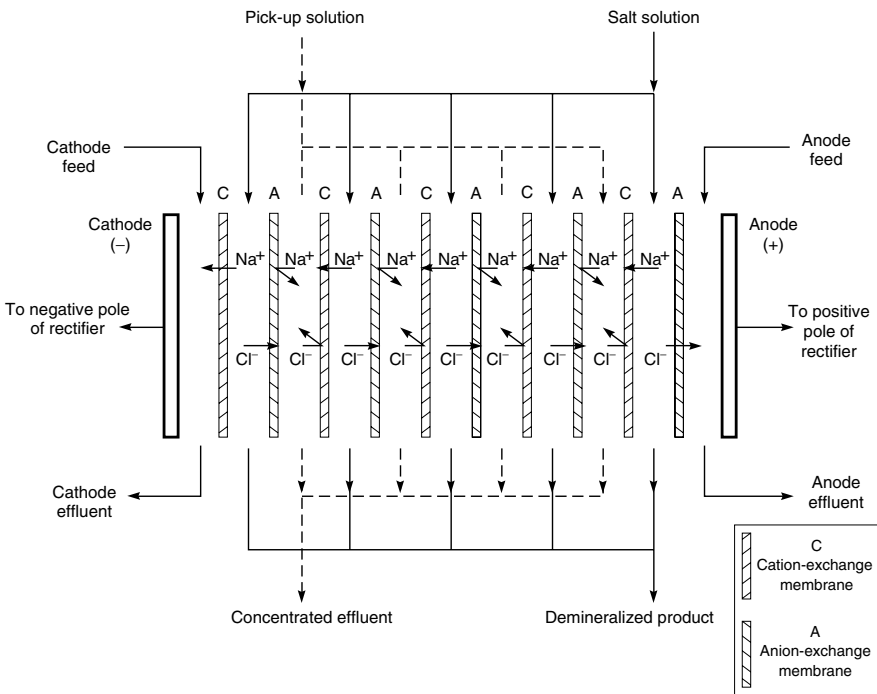

Figure 1.3 Schematic diagram of an electrodialysis process

Figure 1.4 Schematic diagram of the basic membrane gas separation process

of gas separation membranes are the separation of hydrogen from nitrogen, argon and methane in ammonia plants; the production of nitrogen from air; and the separation of carbon dioxide from methane in natural gas operations. Membrane gas separation is an area of considerable current research interest, and the number of applications is expanding rapidly.

Pervaporation is a relatively new process that has elements in common with reverse osmosis and gas separation. In pervaporation, a liquid mixture contacts one side of a membrane, and the permeate is removed as a vapor from the other. The driving force for the process is the low vapor pressure on the permeate side of the membrane generated by cooling and condensing the permeate vapor. The attraction of pervaporation is that the separation obtained is proportional to the rate of permeation of the components of the liquid mixture through the selective membrane. Therefore, pervaporation offers the possibility of separating closely boiling mixtures or azeotropes that are difficult to separate by distillation or other means. A schematic of a simple pervaporation process using a condenser to generate the permeate vacuum is shown in Figure 1.5. Currently, the main industrial application of pervaporation is the dehydration of organic solvents, in particular, the dehydration of 90–95% ethanol solutions, a difficult separation problem because of the ethanol–water azeotrope at 95% ethanol. Pervaporation membranes that selectively permeate water can produce more than 99.9% ethanol from these solutions. Pervaporation processes are also being developed for the removal of dissolved organics from water and for the separation of organic mixtures.

A number of other industrial membrane processes are placed in the category of to-be-developed technologies in Table 1.1. Perhaps the most important of these is carrier facilitated transport (Chapter 11), which often employs liquid membranes containing a complexing or carrier agent. The carrier agent reacts with one component of a mixture on the feed side of the membrane and then diffuses across the membrane to release the permeant on the product side of the membrane. The reformed carrier agent then diffuses back to the feed side of the membrane. Thus, the carrier agent acts as a shuttle to selectively transport one component from the feed to the product side of the membrane.

Figure 1.5 Schematic diagram of the basic pervaporation process

Facilitated transport membranes can be used to separate gases; membrane transport is then driven by a difference in the gas partial pressure across the membrane. Metal ions can also be selectively transported across a membrane, driven by a flow of hydrogen or hydroxyl ions in the other direction. This process is sometimes called coupled transport. Examples of carrier facilitated transport processes for gas and ion transport are shown in Figure 1.6.

Because the carrier facilitated transport process employs a reactive carrier species, very high membrane selectivities can be achieved. These selectivities are often far larger than the selectivities achieved by other membrane processes. This one fact has maintained interest in facilitated transport for the past 30 years, but no commercial applications have developed. The principal problem is the physical instability of the liquid membrane and the chemical instability of the carrier agent. In recent years a number of potential solutions to this problem have been developed, which may yet make carrier facilitated transport a viable process.

The membrane separation processes described above represent the bulk of the industrial membrane separation industry. Another process, dialysis, is not used industrially but is used on a large scale in medicine to remove toxic metabolites from blood in patients suffering from kidney failure. The first successful artificial kidney was based on cellophane (regenerated cellulose) dialysis membranes and was developed in 1945. Over the past 50 years, many changes have been made. Currently, most artificial kidneys are based on hollow-fiber membranes formed into modules having a membrane area of about 1 m^2 ; the process is illustrated in Figure 1.7. Blood is circulated through the center of the fiber, while isotonic

Figure 1.6 Schematic examples of carrier facilitated transport of gas and ions. The gas transport example shows the transport of oxygen across a membrane using hemoglobin as the carrier agent. The ion transport example shows the transport of copper ions across a membrane using a liquid ion-exchange reagent as the carrier agent

Figure 1.7 Schematic of a hollow fiber artificial kidney dialyser used to remove urea and other toxic metabolites from blood. About 100 million of these devices are used every year

saline, the dialysate, is pumped countercurrently around the outside of the fibers. Urea, creatinine, and other low-molecular-weight metabolites in the blood diffuse across the fiber wall and are removed with the saline solution. The process is quite slow, usually requiring several hours to remove the required amount of the metabolite from the patient, and must be repeated one or two times per week. In terms of membrane area used and dollar value of the membrane produced, artificial kidneys are the single largest application of membranes.

Following the success of the artificial kidney, similar devices were developed to remove carbon dioxide and deliver oxygen to the blood. These so-called artificial lungs are used in surgical procedures during which the patient's lungs cannot function. The dialysate fluid shown in Figure 1.7 is replaced with a carefully controlled sweep gas containing oxygen, which is delivered to the blood, and carbon dioxide, which is removed. These two medical applications of membranes are described in Chapter 12.

Another major medical use of membranes is in controlled drug delivery (Chapter 12). Controlled drug delivery can be achieved by a wide range of techniques, most of which involve membranes; a simple example is illustrated in Figure 1.8. In this device, designed to deliver drugs through the skin, drug is contained in a reservoir surrounded by a membrane. With such a system,

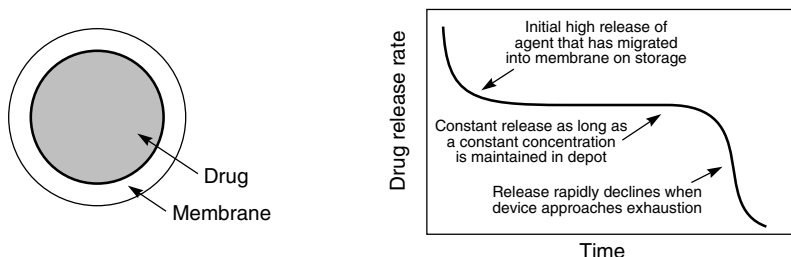

Diagram and release curve for a simple reservoir system

Figure 1.8 Schematic of transdermal patch in which the rate of delivery of drug to the body is controlled by a polymer membrane. Such patches are used to deliver many drugs including nitroglycerine, estradiol, nicotine and scopolamine

the release of drug is constant as long as a constant concentration of drug is maintained within the device. A constant concentration is maintained if the reservoir contains a saturated solution and sufficient excess of solid drug. Systems that operate using this principle are used to moderate delivery of drugs such as nitroglycerine (for angina), nicotine (for smoking cessation), and estradiol (for hormone replacement therapy) through the skin. Other devices using osmosis or biodegradation as the rate-controlling mechanism are also produced as implants and tablets. The total market of controlled release pharmaceuticals is comfortably above US\$3 billion per year.

2 MEMBRANE TRANSPORT THEORY

Introduction

The most important property of membranes is their ability to control the rate of permeation of different species. The two models used to describe the mechanism of permeation are illustrated in Figure 2.1. One is the solution-diffusion model, in which permeants dissolve in the membrane material and then diffuse through the membrane down a concentration gradient. The permeants are separated because of the differences in the solubilities of the materials in the membrane and the differences in the rates at which the materials diffuse through the membrane. The other model is the pore-flow model, in which permeants are transported by pressure-driven convective flow through tiny pores. Separation occurs because one of the permeants is excluded (filtered) from some of the pores in the membrane through which other permeants move. Both models were proposed in the nineteenth century, but the pore-flow model, because it was closer to normal physical experience, was more popular until the mid-1940s. However, during the 1940s, the solution-diffusion model was used to explain transport of gases through polymeric films. This use of the solution-diffusion model was relatively uncontroversial, but the transport mechanism in reverse osmosis membranes was a hotly debated issue in the 1960s and early 1970s [1–6]. By 1980, however, the proponents of solution-diffusion had carried the day; currently only a few die-hard pore-flow modelers use this approach to rationalize reverse osmosis.

Diffusion, the basis of the solution-diffusion model, is the process by which matter is transported from one part of a system to another by a concentration gradient. The individual molecules in the membrane medium are in constant random molecular motion, but in an isotropic medium, individual molecules have no preferred direction of motion. Although the average displacement of an individual molecule from its starting point can be calculated, after a period of time nothing can be said about the direction in which any individual molecule will move. However, if a concentration gradient of permeate molecules is formed in the medium, simple statistics show that a net transport of matter will occur

Figure 2.1 Molecular transport through membranes can be described by a flow through permanent pores or by the solution-diffusion mechanism

from the high concentration to the low concentration region. For example, when two adjacent volume elements with slightly different permeant concentrations are separated by an interface, then simply because of the difference in the number of molecules in each volume element, more molecules will move from the concentrated side to the less concentrated side of the interface than will move in the other direction. This concept was first recognized by Fick theoretically and experimentally in 1855 [7]. Fick formulated his results as the equation now called Fick's law of diffusion, which states

$$J_i = -D_i \frac{dc_i}{dx} \quad (2.1)$$

where J_i is the rate of transfer of component i or flux ($\text{g}/\text{cm}^2 \cdot \text{s}$) and dc_i/dx is the concentration gradient of component i . The term D_i is called the diffusion coefficient (cm^2/s) and is a measure of the mobility of the individual molecules. The minus sign shows that the direction of diffusion is down the concentration gradient. Diffusion is an inherently slow process. In practical diffusion-controlled separation processes, useful fluxes across the membrane are achieved by making the membranes very thin and creating large concentration gradients in the membrane.

Pressure-driven convective flow, the basis of the pore flow model, is most commonly used to describe flow in a capillary or porous medium. The basic equation covering this type of transport is Darcy's law, which can be written as

$$J_i = K' c_i \frac{dp}{dx} \quad (2.2)$$

where dp/dx is the pressure gradient existing in the porous medium, c_i is the concentration of component i in the medium and K' is a coefficient reflecting the nature of the medium. In general, convective-pressure-driven membrane fluxes are high compared with those obtained by simple diffusion.

The difference between the solution-diffusion and pore-flow mechanisms lies in the relative size and permanence of the pores. For membranes in which transport is best described by the solution-diffusion model and Fick's law, the free-volume elements (pores) in the membrane are tiny spaces between polymer chains caused by thermal motion of the polymer molecules. These volume elements appear and disappear on about the same timescale as the motions of the permeants traversing the membrane. On the other hand, for a membrane in which transport is best described by a pore-flow model and Darcy's law, the free-volume elements (pores) are relatively large and fixed, do not fluctuate in position or volume on the timescale of permeant motion, and are connected to one another. The larger the individual free volume elements (pores), the more likely they are to be present long enough to produce pore-flow characteristics in the membrane. As a rough rule of thumb, the transition between transient (solution-diffusion) and permanent (pore-flow) pores is in the range 5–10 Å diameter.

The average pore diameter in a membrane is difficult to measure directly and must often be inferred from the size of the molecules that permeate the membrane or by some other indirect technique. With this caveat in mind membranes can be organized into the three general groups shown in Figure 2.2:

- Ultrafiltration, microfiltration and microporous Knudsen-flow gas separation membranes are all clearly microporous, and transport occurs by pore flow.
- Reverse osmosis, pervaporation and polymeric gas separation membranes have a dense polymer layer with no visible pores, in which the separation occurs. These membranes show different transport rates for molecules as small as 2–5 Å in diameter. The fluxes of permeants through these membranes are also much lower than through the microporous membranes. Transport is best described by the solution-diffusion model. The spaces between the polymer chains in these membranes are less than 5 Å in diameter and so are within the normal range of thermal motion of the polymer chains that make up the membrane matrix. Molecules permeate the membrane through free volume elements between the polymer chains that are transient on the timescale of the diffusion processes occurring.
- Membranes in the third group contain pores with diameters between 5 Å and 10 Å and are intermediate between truly microporous and truly solution-diffusion membranes. For example, nanofiltration membranes are intermediate between ultrafiltration membranes and reverse osmosis membranes. These membranes have high rejections for the di- and trisaccharides sucrose and raffinose with molecular diameters of 10–13 Å, but freely pass the monosaccharide fructose with a molecular diameter of about 5–6 Å.

Figure 2.2 Schematic representation of the nominal pore size and best theoretical model for the principal membrane separation processes

In this chapter, permeation through dense nonporous membranes is covered first; this includes permeation in reverse osmosis, pervaporation, and gas separation membranes. Transport occurs by molecular diffusion and is described by the solution-diffusion model. The predictions of this model are in good agreement with experimental data, and a number of simple equations that usefully rationalize the properties of these membranes result. In the second part of the chapter, transport in microporous ultrafiltration and microfiltration membranes is covered more briefly. Transport through these membranes occurs by convective flow with some form of sieving mechanism producing the separation. However, the ability of theory to rationalize transport in these membranes is poor. A number of factors concurrently affect permeation, so a simple quantitative description of the process is not possible. Finally, a brief discussion of membranes that fall into the 'intermediate' category is given.

Solution-diffusion Model

Molecular Dynamics Simulations

The solution-diffusion model applies to reverse osmosis, pervaporation and gas permeation in polymer films. At first glance these processes appear to be very

different. Reverse osmosis uses a large pressure difference across the membrane to separate water from salt solutions. In pervaporation, the pressure difference across the membrane is small, and the process is driven by the vapor pressure difference between the feed liquid and the low partial pressure of the permeate vapor. Gas permeation involves transport of gases down a pressure or concentration gradient. However, all three processes involve diffusion of molecules in a dense polymer. The pressure, temperature, and composition of the fluids on either side of the membrane determine the concentration of the diffusing species at the membrane surface in equilibrium with the fluid. Once dissolved in the membrane, individual permeating molecules move by the same random process of molecular diffusion no matter whether the membrane is being used in reverse osmosis, pervaporation, or gas permeation. Often, similar membranes are used in very different processes. For example, cellulose acetate membranes were developed for desalination of water by reverse osmosis, but essentially identical membranes have been used in pervaporation to dehydrate alcohol and are widely used in gas permeation to separate carbon dioxide from natural gas. Similarly, silicone rubber membranes are too hydrophobic to be useful in reverse osmosis but are used to separate volatile organics from water by pervaporation and organic vapors from air in gas permeation.

The advent of powerful computers has allowed the statistical fluctuations in the volumes between polymer chains due to thermal motion to be calculated. Figure 2.3 shows the results of a computer molecular dynamics simulation calculation for a small-volume element of a polymer. The change in position of individual polymer molecules in a small-volume element can be calculated at short enough time intervals to represent the normal thermal motion occurring in a polymeric matrix. If a penetrant molecule is placed in one of the small-free-volume microcavities between polymer chains, its motion can also be calculated. The simulated motion of a carbon dioxide molecule in a 6FDA-4PDA polyimide matrix is shown in Figure 2.3 [8]. During the first 100 ps of the simulation, the carbon dioxide molecule bounces around in the cavity where it has been placed, never moving more than about 5 Å, the diameter of the microcavity. After 100 ps, however, a chance thermal motion moves a segment of the polymer chains sufficiently for the carbon dioxide molecule to jump approximately 10 Å to an adjacent cavity where it remains until another movement of the polymer chains allows it to jump to another cavity. By repeating these calculations many times and averaging the distance moved by the gas molecule, its diffusion coefficient can be calculated.

An alternative method of representing the movement of an individual molecule by computational techniques is shown in Figure 2.4 [9]. This figure shows the movement of three different permeate molecules over a period of 200 ps in a silicone rubber polymer matrix. The smaller helium molecule moves more frequently and makes larger jumps than the larger methane molecule. Helium, with a molecular diameter of 2.55 Å, has many more opportunities to move from one

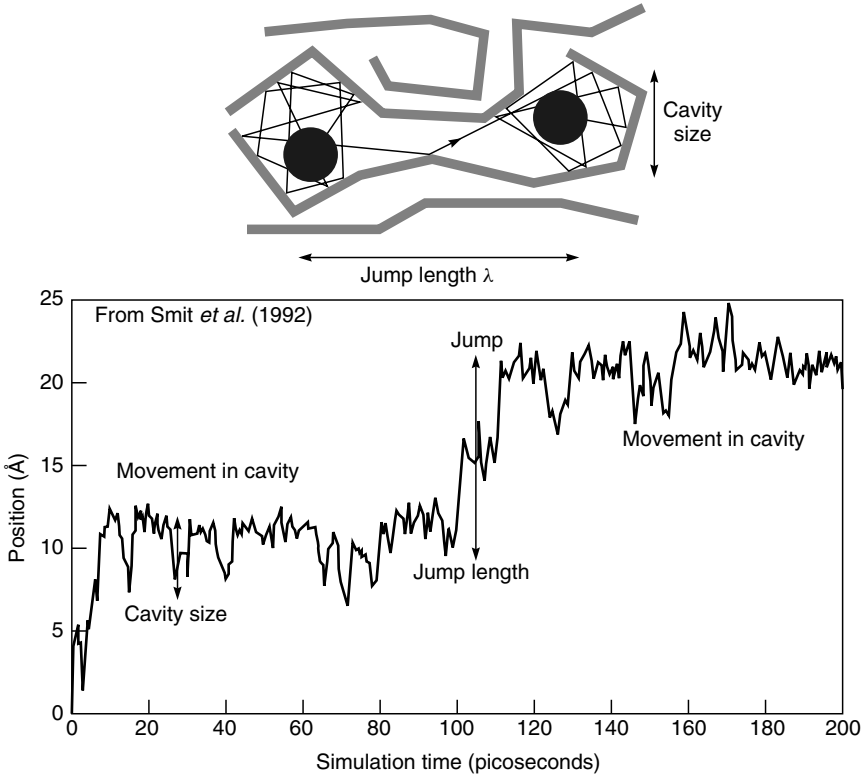

Figure 2.3 Motion of a carbon dioxide molecule in a 6FDA-4PDA polymer matrix [8]. Reprinted from *J. Membr. Sci.* **73**, E. Smit, M.H.V. Mulder, C.A. Smolders, H. Karrenbeld, J. van Eerden and D. Feil, Modeling of the Diffusion of Carbon Dioxide in Polyimide Matrices by Computer Simulation, p. 247, Copyright 1992, with permission from Elsevier

position to another than methane, with a molecular diameter of 3.76 Å. Oxygen, with a molecular diameter of 3.47 Å, has intermediate mobility. The effect of polymer structure on diffusion can be seen by comparing the distance moved by the gas molecules in the same 200-ps period in Figures 2.3 and 2.4. Figure 2.3 simulates diffusion in a glassy rigid-backbone polyimide. In 200 ps, the permeate molecule has made only one large jump. Figure 2.4 simulates diffusion in silicone rubber, a material with a very flexible polymer backbone. In 200 ps, all the permeants in silicone rubber have made a number of large jumps from one microcavity to another.

Molecular dynamics simulations also allow the transition from the solution-diffusion to the pore-flow transport mechanism to be seen. As the microcavities become larger, the transport mechanism changes from the diffusion process

Figure 2.4 Simulated trajectories of helium, oxygen and methane molecules during a 200-ps time period in a poly(dimethylsiloxane) matrix [9]. Reprinted with permission from S.G. Charati and S.A. Stern, *Diffusion of Gases in Silicone Polymers: Molecular Dynamic Simulations*, *Macromolecules* **31**, 5529. Copyright 1998, American Chemical Society

simulated in Figures 2.3 and 2.4 to a pore-flow mechanism. Permanent pores form when the microcavities are larger than about 10 Å in diameter.

However, molecular dynamics calculations are at an early stage of development. Current estimates of diffusion coefficients from these simulations are generally far from matching the experimental values, and enormous computing power and a better understanding of the interactions between the molecules of polymer chains will be required to produce accurate predictions. Nonetheless, the technique demonstrates the qualitative basis of the solution-diffusion model in a very graphic way. Currently, the best quantitative description of permeation uses phenomenological equations, particularly Fick's law. This description is given in the section that follows, which outlines the mathematical basis of the solution-diffusion model. Much of this section is adapted from a 1995 *Journal of Membrane Science* article written with my colleague, Hans Wijmans [10].

Concentration and Pressure Gradients in Membranes

The starting point for the mathematical description of diffusion in membranes is the proposition, solidly based in thermodynamics, that the driving forces of pressure, temperature, concentration, and electrical potential are interrelated and that the overall driving force producing movement of a permeant is the gradient in its chemical potential. Thus, the flux, J_i (g/cm² · s), of a component, i , is

described by the simple equation

$$J_i = -L_i \frac{d\mu_i}{dx} \quad (2.3)$$

where $d\mu_i/dx$ is the chemical potential gradient of component i and L_i is a coefficient of proportionality (not necessarily constant) linking this chemical potential driving force to flux. Driving forces, such as gradients in concentration, pressure, temperature, and electrical potential can be expressed as chemical potential gradients, and their effect on flux expressed by this equation. This approach is extremely useful, because many processes involve more than one driving force, for example, both pressure and concentration in reverse osmosis. Restricting the approach to driving forces generated by concentration and pressure gradients, the chemical potential is written as

$$d\mu_i = RT d \ln(\gamma_i n_i) + v_i dp \quad (2.4)$$

where n_i is the mole fraction (mol/mol) of component i , γ_i is the activity coefficient (mol/mol) linking mole fraction with activity, p is the pressure, and v_i is the molar volume of component i .

In incompressible phases, such as a liquid or a solid membrane, volume does not change with pressure. In this case, integrating Equation (2.4) with respect to concentration and pressure gives

$$\mu_i = \mu_i^o + RT \ln(\gamma_i n_i) + v_i(p - p_i^o) \quad (2.5)$$

where μ_i^o is the chemical potential of pure i at a reference pressure, p_i^o .

In compressible gases, the molar volume changes with pressure. Using the ideal gas laws in integrating Equation (2.4) gives

$$\mu_i = \mu_i^o + RT \ln(\gamma_i n_i) + RT \ln \frac{p}{p_i^o} \quad (2.6)$$

To ensure that the reference chemical potential μ_i^o is identical in Equations (2.5) and (2.6), the reference pressure p_i^o is defined as the saturation vapor pressure of i , $p_{i,\text{sat}}$. Equations (2.5) and (2.6) can then be rewritten as

$$\mu_i = \mu_i^o + RT \ln(\gamma_i n_i) + v_i(p - p_{i,\text{sat}}) \quad (2.7)$$

for incompressible liquids and the membrane phase, and as

$$\mu_i = \mu_i^o + RT \ln(\gamma_i n_i) + RT \ln \frac{p}{p_{i,\text{sat}}} \quad (2.8)$$

for compressible gases.

Several assumptions must be made to define any permeation model. Usually, the first assumption governing transport through membranes is that the fluids on

either side of the membrane are in equilibrium with the membrane material at the interface. This assumption means that the gradient in chemical potential from one side of the membrane to the other is continuous. Implicit in this assumption is that the rates of absorption and desorption at the membrane interface are much higher than the rate of diffusion through the membrane. This appears to be the case in almost all membrane processes, but may fail in transport processes involving chemical reactions, such as facilitated transport, or in diffusion of gases through metals, where interfacial absorption can be slow.

The second assumption concerns the pressure and concentration gradients in the membrane. The solution-diffusion model assumes that when pressure is applied across a dense membrane, the pressure throughout the membrane is constant at the highest value. This assumes, in effect, that solution-diffusion membranes transmit pressure in the same way as liquids. Consequently, the solution-diffusion model assumes that the pressure within a membrane is uniform and that the chemical potential gradient across the membrane is expressed only as a concentration gradient [5,10]. The consequences of these two assumptions are illustrated in Figure 2.5, which shows pressure-driven permeation of a one-component solution through a membrane by the solution-diffusion mechanism.

In the solution-diffusion model, the pressure within the membrane is constant at the high-pressure value (p_o), and the gradient in chemical potential across the membrane is expressed as a smooth gradient in solvent activity ($\gamma_i n_i$). The flow that occurs down this gradient is expressed by Equation (2.3), but because no pressure gradient exists within the membrane, Equation (2.3) can be rewritten by combining Equations (2.3) and (2.4). Assuming γ_i is constant, this gives

$$J_i = -\frac{RT L_i}{n_i} \cdot \frac{dn_i}{dx} \quad (2.9)$$

Figure 2.5 Pressure driven permeation of a one-component solution through a membrane according to the solution-diffusion transport model

In Equation (2.9), the gradient of component i across the membrane is expressed as a gradient in mole fraction of component i . Using the more practical term concentration c_i (g/cm^3) defined as

$$c_i = m_i \rho n_i \quad (2.10)$$

where m_i is the molecular weight of i (g/mol) and ρ is the molar density (mol/cm^3), Equation (2.9) can be written as

$$J_i = -\frac{RTL_i}{c_i} \cdot \frac{dc_i}{dx} \quad (2.11)$$

Equation (2.11) has the same form as Fick's law in which the term RTL_i/c_i can be replaced by the diffusion coefficient D_i . Thus,

$$J_i = -D_i \frac{dc_i}{dx} \quad (2.12)$$

Integrating over the thickness of the membrane then gives¹

$$J_i = \frac{D_i(c_{i_{o(m)}} - c_{i_{\ell(m)}})}{\ell} \quad (2.13)$$

By using osmosis as an example, concentration and pressure gradients according to the solution-diffusion model can be discussed in a somewhat more complex situation. The activity, pressure, and chemical potential gradients within this type of membrane are illustrated in Figure 2.6.

Figure 2.6(a) shows a semipermeable membrane separating a salt solution from the pure solvent. The pressure is the same on both sides of the membrane. For simplicity, the gradient of salt (component j) is not shown in this figure, but the membrane is assumed to be very selective, so the concentration of salt within the membrane is small. The difference in concentration across the membrane results in a continuous, smooth gradient in the chemical potential of the water (component i) across the membrane, from μ_{i_ℓ} on the water side to μ_{i_o} on the salt side. The pressure within and across the membrane is constant (that is, $p_o = p_m = p_\ell$) and the solvent activity gradient ($\gamma_{i(m)} n_{i(m)}$) falls continuously from the pure water (solvent) side to the saline (solution) side of the membrane. Consequently, water passes across the membrane from right to left.

Figure 2.6(b) shows the situation at the point of osmotic equilibrium, when sufficient pressure has been applied to the saline side of the membrane to bring the flow across the membrane to zero. As shown in Figure 2.6(b), the pressure

¹In the equations that follow, the terms i and j represent components of a solution, and the terms o and ℓ represent the positions of the feed and permeate interfaces, respectively, of the membrane. Thus the term c_{i_o} represents the concentration of component i in the fluid (gas or liquid) in contact with the membrane at the feed interface. The subscript m is used to represent the membrane phase. Thus, $c_{i_{o(m)}}$ is the concentration of component i in the membrane at the feed interface (point o).

Dense solution-diffusion membrane

Figure 2.6 Chemical potential, pressure, and solvent activity profiles through an osmotic membrane following the solution-diffusion model. The pressure in the membrane is uniform and equal to the high-pressure value, so the chemical potential gradient within the membrane is expressed as a concentration gradient

within the membrane is assumed to be constant at the high-pressure value (p_o). There is a discontinuity in pressure at the permeate side of the membrane, where the pressure falls abruptly from p_o to p_ℓ , the pressure on the solvent side of the membrane. This pressure difference ($p_o - p_\ell$) can be expressed in terms of the chemical potential difference between the feed and permeate solutions.

The membrane in contact with the permeate-side solution is in equilibrium with this solution. Thus, Equation (2.7) can be used to link the two phases in terms of their chemical potentials, that is

$$\mu_{i_{\ell(m)}} = \mu_{i_{\ell}} \quad (2.14)$$

and so

$$RT \ln(\gamma_{i_{\ell(m)}} n_{i_{\ell(m)}}) + v_i p_o = RT \ln(\gamma_{i_{\ell}} n_{i_{\ell}}) + v_i p_{\ell} \quad (2.15)$$

On rearranging, this gives

$$RT \ln(\gamma_{i_{\ell(m)}} n_{i_{\ell(m)}}) - RT \ln(\gamma_{i_{\ell}} n_{i_{\ell}}) = -v_i (p_o - p_{\ell}) \quad (2.16)$$

At osmotic equilibrium $\Delta(\gamma_i n_i)$ can also be defined by

$$\Delta(\gamma_i n_i) = \gamma_{i_{\ell}} n_{i_{\ell}} - \gamma_{i_{\ell(m)}} n_{i_{\ell(m)}} \quad (2.17)$$

and, since $\gamma_{i_{\ell}} n_{i_{\ell}} \approx 1$, it follows, on substituting Equation (2.17) into (2.16), that

$$RT \ln[1 - \Delta(\gamma_i n_i)] = -v_i (p_o - p_{\ell}) \quad (2.18)$$

Since $\Delta(\gamma_i n_i)$ is small, $\ln[1 - \Delta(\gamma_i n_i)] \approx -\Delta(\gamma_i n_i)$, and Equation (2.18) reduces to

$$\Delta(\gamma_i n_i) = \frac{-v_i (p_o - p_{\ell})}{RT} = \frac{-v_i \Delta\pi}{RT} \quad (2.19)$$

Thus, the pressure difference, $(p_o - p_{\ell}) = \Delta\pi$, across the membrane balances the solvent activity difference $\Delta(\gamma_i n_i)$ across the membrane, and the flow is zero.

If a pressure higher than the osmotic pressure is applied to the feed side of the membrane, as shown in Figure 2.6(c), then the solvent activity difference across the membrane increases further, resulting in a flow from left to right. This is the process of reverse osmosis.

The important conclusion illustrated by Figures 2.5 and 2.6 is that, although the fluids on either side of a membrane may be at different pressures and concentrations, within a perfect solution-diffusion membrane, there is no pressure gradient—only a concentration gradient. Flow through this type of membrane is expressed by Fick's law, Equation (2.13).

Application of the Solution-diffusion Model to Specific Processes

In this section the solution-diffusion model is used to describe transport in dialysis, reverse osmosis, gas permeation and pervaporation membranes. The resulting equations, linking the driving forces of pressure and concentration with flow, are then shown to be consistent with experimental observations.

The general approach is to use the first assumption of the solution-diffusion model, namely, that the chemical potential of the feed and permeate fluids are

in equilibrium with the adjacent membrane surfaces. From this assumption, the chemical potential in the fluid and membrane phases can be equated using the appropriate expressions for chemical potential given in Equations (2.7) and (2.8). By rearranging these equations, the concentrations of the different species in the membrane at the fluids interface ($c_{i_{o(m)}}$ and $c_{i_{\ell(m)}}$) can be obtained in terms of the pressure and composition of the feed and permeate fluids. These values for $c_{i_{o(m)}}$ and $c_{i_{\ell(m)}}$ can then be substituted into the Fick's law expression, Equation (2.13), to give the transport equation for the particular process.

Dialysis

Dialysis is the simplest application of the solution-diffusion model because only concentration gradients are involved. In dialysis, a membrane separates two solutions of different compositions. The concentration gradient across the membrane causes a flow of solute and solvent from one side of the membrane to the other.

Following the general procedure described above, equating the chemical potentials in the solution and membrane phase at the feed-side interface of the membrane gives

$$\mu_{i_o} = \mu_{i_{o(m)}} \quad (2.20)$$

Substituting the expression for the chemical potential of incompressible fluids from Equation (2.7) gives

$$\mu_i^o + RT \ln(\gamma_{i_o}^L n_{i_o}) + v_i(p_o - p_{i_{\text{sat}}}) = \mu_i^o + RT \ln(\gamma_{i_{o(m)}} n_{i_{o(m)}}) + v_{i_{o(m)}}(p_o - p_{i_{\text{sat}}}) \quad (2.21)$$

which leads to²

$$\ln(\gamma_{i_o}^L n_{i_o}) = \ln(\gamma_{i_{o(m)}} n_{i_{o(m)}}) \quad (2.22)$$

and thus

$$n_{i_{o(m)}} = \frac{\gamma_{i_o}^L}{\gamma_{i_{o(m)}}} \cdot n_{i_o} \quad (2.23)$$

or from Equation (2.10)

$$c_{i_{o(m)}} = \frac{\gamma_{i_o} \rho_m}{\gamma_{i_{o(m)}} \rho_o} \cdot c_{i_o} \quad (2.24)$$

Hence, defining a sorption coefficient K_i^L as

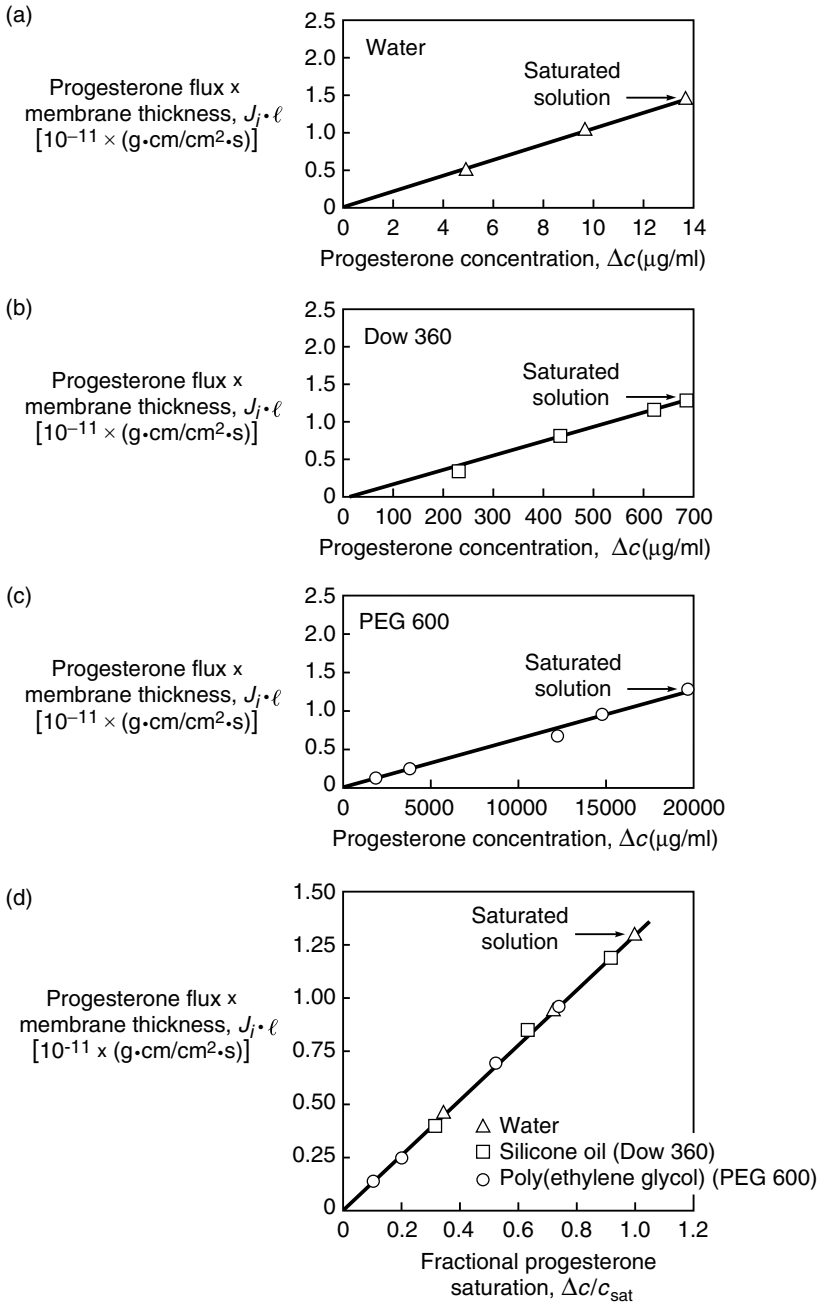

$$K_i^L = \frac{\gamma_{i_o} \rho_m}{\gamma_{i_{o(m)}} \rho_o} \quad (2.25)$$

Equation (2.24) becomes

$$c_{i_{o(m)}} = K_i^L \cdot c_{i_o} \quad (2.26)$$

²The superscripts G and L are used here and later to distinguish between gas phase and liquid phase activity coefficients, sorption coefficients and permeability coefficients.

From Theeuwes *et al.* (1978)

On the permeate side of the membrane, the same procedure can be followed, leading to an equivalent expression

$$c_{i\ell(m)} = K_i^L \cdot c_{i\ell} \quad (2.27)$$

The concentrations of permeant within the membrane phase at the two interfaces can then be substituted from Equations (2.26) and (2.27) into the Fick's law expression, Equation (2.13), to give the familiar expression describing permeation through dialysis membranes:

$$J_i = \frac{D_i K_i^L}{\ell} (c_{i_o} - c_{i\ell}) = \frac{P_i^L}{\ell} (c_{i_o} - c_{i\ell}) \quad (2.28)$$

The product $D_i K_i^L$ is normally referred to as the permeability coefficient, P_i^L . For many systems, D_i , K_i^L , and thus P_i^L are concentration dependent. Thus, Equation (2.28) implies the use of values for D_i , K_i^L , and P_i^L that are averaged over the membrane thickness.

The permeability coefficient P_i^L is often treated as a pure materials constant, depending only on the permeant and the membrane material, but in fact the nature of the solvent used in the liquid phase is also important. From Equations (2.28) and (2.25), P_i^L can be written as

$$P_i^L = D_i \cdot \gamma_i^L / \gamma_{i(m)} \cdot \frac{\rho_m}{\rho_o} \quad (2.29)$$

The presence of the term γ_i^L makes the permeability coefficient a function of the solvent used as the liquid phase. Some experimental data illustrating this effect are shown in Figure 2.7 [11], which is a plot of the product of the progesterone flux and the membrane thickness, $J_i \ell$ against the concentration difference across the membrane, $(c_{i_o} - c_{i\ell})$. From Equation (2.28), the slope of this line is the permeability, P_i^L . Three sets of dialysis permeation experiments are reported, in which the solvent used to dissolve the progesterone is water, silicone oil and poly(ethylene glycol) MW 600 (PEG 600), respectively. The permeability calculated from these plots varies from 9.5×10^{-7} cm²/s for water to 6.5×10^{-10} cm²/s for PEG 600. This difference reflects the activity term γ_i^L in Equation (2.28). However, when the driving force across the membrane is

Figure 2.7 Permeation of progesterone through polyethylene vinyl acetate films. The thickness-normalized progesterone flux ($J_i \cdot \ell$) is plotted against the progesterone concentration across the membrane, Δc [11]. The solvents for the progesterone are (a) water, (b) silicone oil and (c) poly(ethylene glycol) (PEG 600). Because of the different solubilities of progesterone in these solvents, the permeabilities calculated from these data through Equation (2.28) vary 1000-fold. All the data can be rationalized onto a single curve by plotting the thickness-normalized flux against fractional progesterone saturation as described in the text and shown in (d). The slope of this line, $P_i^L c_{\text{sat}}$ or $D_i m_i \rho_m / \gamma_{i(m)}$ is a materials property dependent only on the membrane material and the permeant and independent of the solvent

represented not as a difference in concentration but as a difference in fractional saturation between the feed and permeate solution, all the data fall on a single line as shown in Figure 2.7(d). The slope of this line is the term $P_i^L c_{\text{sat}}$. This result is also in agreement with Equation (2.29), which when combined with the approximation that, for dilute solutions, the activity of component i can be written as

$$\gamma_i^L = \frac{1}{n_{i,\text{sat}}} = \frac{m_i \rho_o}{c_{i,\text{sat}}} \quad (2.30)$$

yields

$$P_i^L c_{i,\text{sat}} = \frac{D_i m_i \rho_m}{\gamma_{i(m)}} \quad (2.31)$$

The terms $D_i m_i \rho_m / \gamma_{i(m)}$ and, therefore, $P_i^L c_{\text{sat}}$ are determined solely by the permeant and the membrane material and are thus independent of the liquid phase surrounding the membrane.

Reverse Osmosis

Reverse osmosis and normal osmosis (dialysis) are directly related processes. In simple terms, if a selective membrane (i.e., a membrane freely permeable to water, but much less permeable to salt) separates a salt solution from pure water, water will pass through the membrane from the pure water side of the membrane into the side less concentrated in water (salt side) as shown in Figure 2.8. This process is called normal osmosis. If a hydrostatic pressure is applied to the salt side of the membrane, the flow of water can be retarded and, when the applied pressure is sufficient, the flow ceases. The hydrostatic pressure required to stop

Figure 2.8 A schematic illustration of the relationship between osmosis (dialysis), osmotic equilibrium and reverse osmosis

the water flow is called the osmotic pressure ($\Delta\pi$). If pressures greater than the osmotic pressure are applied to the salt side of the membrane, then the flow of water is reversed, and water begins to flow from the salt solution to the pure water side of the membrane. This process is called reverse osmosis, which is an important method of producing pure water from salt solutions.

Reverse osmosis usually involves two components, water (i) and salt (j). Following the general procedure, the chemical potentials at both sides of the membrane are first equated. At the feed interface, the pressure in the feed solution and within the membrane are identical (as shown in Figure 2.6c). Equating the chemical potentials at this interface gives the same expression as in dialysis [cf. Equation (2.26)]

$$c_{i_o(m)} = K_i^L \cdot c_{i_o} \quad (2.32)$$

A pressure difference exists at the permeate interface (as shown in Figure 2.6c) from p_o within the membrane to p_ℓ in the permeate solution. Equating the chemical potentials across this interface gives

$$\mu_{i_\ell} = \mu_{i_\ell(m)} \quad (2.33)$$

Substituting the appropriate expression for the chemical potential of an incompressible fluid to the liquid and membrane phases [Equation (2.7)] yields

$$\mu_i^o + RT \ln(\gamma_{i_\ell}^L n_{i_\ell}) + v_i(p_\ell - p_{i_{\text{sat}}}) = \mu_i^o + RT \ln(\gamma_{i_\ell(m)} n_{i_\ell(m)}) + v_i(p_o - p_{i_{\text{sat}}}) \quad (2.34)$$

which leads to

$$\ln(\gamma_{i_\ell}^L n_{i_\ell}) = \ln(\gamma_{i_\ell(m)}^L n_{i_\ell(m)}) + \frac{v_i(p_o - p_\ell)}{RT} \quad (2.35)$$

Rearranging and substituting for the sorption coefficient, K_i^L [Equations (2.10) and (2.25)], gives the expression

$$c_{i_\ell(m)} = K_i^L \cdot c_{i_\ell} \cdot \exp\left[\frac{-v_i(p_o - p_\ell)}{RT}\right] \quad (2.36)$$

The expressions for the concentrations within the membrane at the interface in Equations (2.32) and (2.36) can now be substituted into the Fick's law expression, Equation (2.13), to yield

$$J_i = \frac{D_i K_i^L}{\ell} \left\{ c_{i_o} - c_{i_\ell} \exp\left[\frac{-v_i(p_o - p_\ell)}{RT}\right] \right\} \quad (2.37)$$

Equation (2.37) and the equivalent expression for component j give the water flux and the salt flux across the reverse osmosis membrane in terms of the pressure and concentration difference across the membrane. There is an analytical expression for Equation (2.37) for a two-component feed mixture that allows the performance of the membrane to be calculated for known permeabilities, $D_i K_i^L/\ell$ and $D_j K_j^L/\ell$, and feed concentrations, c_{i_o} and c_{j_o} . However, more commonly

Equation (2.37) is simplified by assuming that the membrane selectivity is high, that is, $D_i K_i^L / \ell \gg D_j K_j^L / \ell$. This is a good assumption for most of the reverse osmosis membranes used to separate salts from water. Consider the water flux first. At the point at which the applied hydrostatic pressure balances the water activity gradient, that is, the point of osmotic equilibrium in Figure 2.6(b), the flux of water across the membrane is zero. Equation (2.37) becomes

$$J_i = 0 = \frac{D_i K_i^L}{\ell} \left\{ c_{i_o} - c_{i_e} \exp \left[\frac{-v_i(\Delta\pi)}{RT} \right] \right\} \quad (2.38)$$

and, on rearranging

$$c_{i_e} = c_{i_o} \exp \left[\frac{v_i(\Delta\pi)}{RT} \right] \quad (2.39)$$

At hydrostatic pressures higher than $\Delta\pi$, Equations (2.37) and (2.39) can be combined to yield

$$J_i = \frac{D_i K_i^L c_{i_o}}{\ell} \left(1 - \exp \left\{ \frac{-v_i[(p_o - p_e) - \Delta\pi]}{RT} \right\} \right) \quad (2.40)$$

or

$$J_i = \frac{D_i K_i^L c_{i_o}}{\ell} \left\{ 1 - \exp \left[\frac{-v_i(\Delta p - \Delta\pi)}{RT} \right] \right\} \quad (2.41)$$

where Δp is the difference in hydrostatic pressure across the membrane ($p_o - p_e$). A trial calculation shows that the term $-v_i(\Delta p - \Delta\pi)/RT$ is small under the normal conditions of reverse osmosis. For example, in water desalination, when $\Delta p = 100$ atm, $\Delta\pi = 10$ atm, and $v_i = 18$ cm³/mol, the term $v_i(\Delta p - \Delta\pi)/RT$ is about 0.06.

Under these conditions, the simplification $1 - \exp(x) \rightarrow x$ as $x \rightarrow 0$ can be used, and Equation (2.41) can be written to a very good approximation as

$$J_i = \frac{D_i K_i^L c_{i_o} v_i (\Delta p - \Delta\pi)}{\ell RT} \quad (2.42)$$

This equation can be simplified to

$$J_i = A(\Delta p - \Delta\pi) \quad (2.43)$$

where A is a constant equal to the term $D_i K_i^L c_{i_o} v_i / \ell RT$. In the reverse osmosis literature, the constant A is usually called the *water permeability constant*.

Similarly, a simplified expression for the salt flux, J_j , through the membrane can be derived, starting with the equivalent to Equation (2.37)

$$J_j = \frac{D_j K_j^L}{\ell} \left\{ c_{j_o} - c_{j_e} \exp \left[\frac{-v_j(p_o - p_e)}{RT} \right] \right\} \quad (2.44)$$

Because the term $-v_j(p_o - p_\ell)/RT$ is small, the exponential term in Equation (2.44) is close to one, and Equation (2.44) can then be written as

$$J_j = \frac{D_j K_j^L}{\ell} (c_{j_o} - c_{j_\ell}) \quad (2.45)$$

or

$$J_j = B(c_{j_o} - c_{j_\ell}) \quad (2.46)$$

where B is usually called the *salt permeability constant* and has the value

$$B = \frac{D_j K_j^L}{\ell} \quad (2.47)$$

Predictions of salt and water transport can be made from this application of the solution-diffusion model to reverse osmosis (first derived by Merten and co-workers) [12,13]. According to Equation (2.43), the water flux through a reverse osmosis membrane remains small up to the osmotic pressure of the salt solution and then increases with applied pressure, whereas according to Equation (2.46), the salt flux is essentially independent of pressure. Some typical results are shown in Figure 2.9. Also shown in this figure is a term called the rejection coefficient, \mathbb{R} , which is defined as

$$\mathbb{R} = \left(1 - \frac{c_{j_\ell}}{c_{j_o}}\right) \times 100\% \quad (2.48)$$

The rejection coefficient is a measure of the ability of the membrane to separate salt from the feed solution.

For a perfectly selective membrane the permeate salt concentration, $c_{j_\ell} = 0$ and $\mathbb{R} = 100\%$, and for a completely unselective membrane the permeate salt concentration is the same as the feed salt concentration, $c_{j_\ell} = c_{j_o}$ and $\mathbb{R} = 0\%$. The rejection coefficient increases with applied pressure as shown in Figure 2.9, because the water flux increases with pressure, but the salt flux does not.

Hyperfiltration

By convention, the term reverse osmosis is used to describe the separation of an aqueous salt solution by pressure-driven flow through a semipermeable membrane. Recently, the same type of process has been applied to the separation of organic mixtures. For example, Mobil Oil has installed a large plant to separate methyl ethyl ketone (MEK) from MEK–oil mixtures created in the production of lubricating oil [14] as described in Chapter 5. Separation of this type of mixture is probably best called hyperfiltration.

Figure 2.9 Flux and rejection data for a model seawater solution (3.5 % sodium chloride) in a good quality reverse osmosis membrane (FilmTec Corp. FT 30 membrane) as a function of pressure [10]. The salt flux, in accordance with Equation (2.44), is essentially constant and independent of pressure. The water flux, in accordance with Equation (2.43), increases with pressure, and, at zero flux, meets the pressure axis at the osmotic pressure of seawater ~350 psi

The mathematical description of this process is identical to that of reverse osmosis given in Equations (2.37) and (2.44) and leads to expressions for the solute and solvent fluxes

$$J_i = \frac{D_i K_i^L}{\ell} \left\{ c_{i_o} - c_{i_e} \exp \left[\frac{-v_i (p_o - p_e)}{RT} \right] \right\} \quad (2.49)$$

and

$$J_j = \frac{D_j K_j^L}{\ell} \left\{ c_{j_o} - c_{j_\ell} \exp \left[\frac{-v_j (p_o - p_\ell)}{RT} \right] \right\} \quad (2.50)$$

With the advent of the personal computer, the numerical solution to these equations is straightforward even for multicomponent mixtures. Figure 2.10 shows an example calculation for the separation of a 20 wt% solution of *n*-decane in MEK. In these calculations, the ratio of the permeabilities of MEK

Figure 2.10 Flux and rejection curves calculated using Equations (2.49) and (2.50) for a 20 wt% *n*-decane solution in methyl ethyl ketone (MEK). MEK is assumed to be 10 times more permeable than *n*-decane

and *n*-decane, $D_i K_i / D_j K_j$, is set at 10. The curves have essentially the same form as the salt solution flux data in Figure 2.9. At high pressures, the rejection approaches a limiting value of 90 %, and the limiting Equations (2.43) for the solvent (MEK) flux and (2.47) for the solute flux apply.

Gas Separation

In gas separation, a gas mixture at a pressure p_o is applied to the feed side of the membrane, while the permeate gas at a lower pressure (p_ℓ) is removed from the downstream side of the membrane. As before, the starting point for the derivation of the gas separation transport equation is to equate the chemical potentials on either side of the gas/membrane interface. This time, however, the chemical potential for the gas phase is given by Equation (2.8) for a compressible fluid, whereas Equation (2.7) for an incompressible medium is applied to the membrane phase. Substitution of these equations into Equation (2.20) at the gas/membrane feed interface yields³

$$\mu_i^o + RT \ln(\gamma_{i_o}^G n_{i_o}) + RT \ln \frac{p_o}{p_{i_{\text{sat}}}} = \mu_i^o + RT \ln(\gamma_{i_{o(m)}} n_{i_{o(m)}}) + v_i(p_o - p_{i_{\text{sat}}}) \quad (2.51)$$

which rearranges to

$$n_{i_{o(m)}} = \frac{\gamma_{i_o}^G}{\gamma_{i_{o(m)}}} \cdot \frac{p_o}{p_{i_{\text{sat}}}} \cdot n_{i_o} \exp \left[\frac{-v_i(p_o - p_{i_{\text{sat}}})}{RT} \right] \quad (2.52)$$

Because the exponential term is again very close to one,⁴ even for very high pressures (p_o), Equation (2.52) reduces to

$$n_{i_{o(m)}} = \frac{\gamma_{i_o}^G n_{i_o}}{\gamma_{i_{o(m)}}} \cdot \frac{p_o}{p_{i_{\text{sat}}}} \quad (2.53)$$

The term $n_{i_o} p_o$ is the partial pressure of *i* in the feed gas, p_{i_o} . Equation (2.53) then simplifies to

$$n_{i_{o(m)}} = \frac{\gamma_{i_{(o)}}^G}{\gamma_{i_{o(m)}}} \cdot \frac{p_{i_o}}{p_{i_{\text{sat}}}} \quad (2.54)$$

or

$$c_{i_{o(m)}} = m_i \rho_m \frac{\gamma_{i_o}^G p_{i_o}}{\gamma_{i_{o(m)}} p_{i_{\text{sat}}}} \quad (2.55)$$

³At this point the superscript G is introduced to denote the gas phase. For example γ_i^G , the activity of component *i* in the gas phase, and K_i^G , the sorption coefficient of component *i* between the gas and membrane phases [Equation (2.56)].

⁴In evaluating this exponential term (the Poynting correction), it is important to recognize that v_i is not the molar volume of *i* in the gas phase, but the molar volume of *i* dissolved in the membrane material, which is approximately equal to the molar volume of liquid *i*.

By defining a gas phase sorption coefficient K_i^G as

$$K_i^G = \frac{m_i \rho_m \gamma_{i_o}^G}{\gamma_{i_o(m)} P_{i_{\text{sat}}}} \quad (2.56)$$

the concentration of component i at the feed interface of the membrane can be written as

$$c_{i_o(m)} = K_i^G \cdot p_{i_o} \quad (2.57)$$

In exactly the same way, the concentration of component i at the membrane/permeate interface can be shown to be

$$c_{i_\ell(m)} = K_i^G \cdot p_{i_\ell} \quad (2.58)$$

Combining Equations (2.57) and (2.58) with the Fick's law expression, Equation (2.13), gives

$$J_i = \frac{D_i K_i^G (p_{i_o} - p_{i_\ell})}{\ell} \quad (2.59)$$

The product $D_i K_i^G$ is often abbreviated to a permeability coefficient, P_i^G , to give the familiar expression

$$J_i = \frac{P_i^G (p_{i_o} - p_{i_\ell})}{\ell} \quad (2.60)$$

Equation (2.60) is widely used to accurately and predictably rationalize the properties of gas permeation membranes.

The derivation of Equation (2.60) might be seen as a long-winded way of arriving at a trivial result. However, this derivation explicitly clarifies the assumptions behind this equation. First, a gradient in concentration occurs within the membrane, but there is no gradient in pressure. Second, the absorption of a component into the membrane is proportional to its activity (partial pressure) in the adjacent gas, but is independent of the total gas pressure. This is related to the approximation made in Equation (2.52), in which the Poynting correction was assumed to be 1.

The permeability coefficient, P_i^G , equal to the product $D_i K_i^G$ can be expressed from the definition of K_i^G in Equation (2.56) as

$$P_i^G = \frac{\gamma_i^G D_i m_i \rho_m}{\gamma_{i(m)} \cdot P_{i_{\text{sat}}}} \quad (2.61)$$

In Equation (2.60) the membrane flux, J_i , is a mass flux ($\text{g}/\text{cm}^2 \cdot \text{s}$), whereas the gas separation literature predominantly uses a molar flux, typically expressed in the units $\text{cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s}$. The molar flux, j_i , can be linked to the mass flux, J_i , by the expression

$$j_i = J_i \frac{v_i^G}{m_i} \quad (2.62)$$

where v_i^G is the molar volume of gas i ($\text{cm}^3(\text{STP})/\text{mol}$). Similarly the mass permeability unit P_i^G , defined in Equation (2.60), can be linked to the molar gas permeability \mathcal{P}_i^G , usually in the units $\text{cm}^3(\text{STP}) \cdot \text{cm}/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$, as

$$\mathcal{P}_i^G = \frac{P_i^G v_i^G}{m_i} \quad (2.63)$$

Equation (2.60) can then be written as

$$j_i = \frac{\mathcal{P}_i^G}{\ell} (p_{i_o} - p_{i_t}) \quad (2.64)$$

and combining Equations (2.61) and (2.63) gives

$$\mathcal{P}_i^G = \frac{\gamma_i^G D_i v_i^G \rho_{(m)}}{\gamma_{i(m)} P_{i_{\text{sat}}}} \quad (2.65)$$

Equation (2.65) is not commonly used as an expression for gas-phase membrane permeability, but is of interest because it shows that large permeability coefficients are obtained for compounds with a large diffusion coefficient (D_i), a limited affinity for the gas phase (large γ_i^G), a high affinity for the membrane material (small $\gamma_{i(m)}$), and a low saturation vapor pressure ($p_{i_{\text{sat}}}$). The molar gas permeation permeability (\mathcal{P}_i^G) is close to being a materials constant, relatively independent of the composition and pressure of the feed and permeate gases. This is in sharp contrast to the permeability constant for liquids as described in the discussion centered on Figure 2.7 earlier, but, even for gases, the concept of permeability as a materials constant must be treated with caution. For example, the permeability of vapors at partial pressures close to saturation often increases substantially with increasing partial pressure. This effect is commonly ascribed to plasticization and other effects of the permeant on the membrane, changing D_i and $\gamma_{i(m)}$ in Equation (2.65). However, significant deviations of the vapor's activity coefficient, γ_i^G , from ideality can also occur at high partial pressures.

Equation (2.65) is also a useful way to rationalize the effect of molecular weight on permeability. The permeant's saturation vapor pressure ($p_{i_{\text{sat}}}$) and diffusion coefficient both decrease with increasing molecular weight, creating competing effects on the permeability coefficient. In glassy polymers, the decrease in diffusion coefficient far outweighs other effects, and permeabilities fall significantly as molecular weight increases [15]. In rubbery polymers, on the other hand, the two effects are more balanced. For molecular weights up to 100, permeability generally increases with increasing molecular weight because $p_{i_{\text{sat}}}$ is the dominant term. Above molecular weight 100, the molecular weight term gradually becomes dominant, and permeabilities fall with increasing molecular weight of the permeant. Some data illustrating this behavior for permeation of simple alkanes in silicone rubber membranes are shown in Figure 2.11. As the molecular weight increases from CH_4 to C_5H_{12} , the effect of the decrease in $p_{i_{\text{sat}}}$

Figure 2.11 Permeability coefficient, P_i^G , of n-alkanes in poly(dimethylsiloxane) as a function of saturation pressure ($p_{i,sat}$)

is larger than the effect of increasing size or D_i . Above pentane, however, the trend is reversed.

Pervaporation

Pervaporation is a separation process in which a multicomponent liquid is passed across a membrane that preferentially permeates one or more of the components. A partial vacuum is maintained on the permeate side of the membrane, so that the permeating components are removed as a vapor mixture. Transport through the membrane is induced by maintaining the vapor pressure of the gas on the permeate side of the membrane at a lower vapor pressure than the feed liquid. The gradients in chemical potential, pressure, and activity across the membrane are illustrated in Figure 2.12.

At the liquid solution/membrane feed interface, the chemical potential of the feed liquid is equilibrated with the chemical potential in the membrane at the same pressure. Equation (2.7) then gives

$$\mu_i^o + RT \ln(\gamma_{i_o}^L n_{i_o}) + v_i(p_o - p_{i,sat}) = \mu_i^o + RT \ln(\gamma_{i_o(m)} n_{i_o(m)}) + v_i(p_o - p_{i,sat}) \quad (2.66)$$

which leads to an expression for the concentration at the feed side interface

$$c_{i_o(m)} = \frac{\gamma_{i_o}^L \rho_m}{\gamma_{i_o(m)} \rho_o} \cdot c_{i_o} = K_i^L \cdot c_{i_o} \quad (2.67)$$

Figure 2.12 Chemical potential, pressure, and activity profiles through a pervaporation membrane following the solution-diffusion model

where K_i^L is the liquid-phase sorption coefficient defined in Equation (2.26) in the dialysis section.

At the permeate gas/membrane interface, the pressure drops from p_o in the membrane to p_ℓ in the permeate vapor. The equivalent expression for the chemical potentials in each phase is then

$$\mu_i^o + RT \ln(\gamma_{i_\ell}^G n_{i_\ell}) + RT \ln\left(\frac{p_\ell}{p_{i_{\text{sat}}}}\right) = \mu_i^o + RT \ln(\gamma_{i_{\ell(m)}} n_i) + v_i(p_o - p_{i_{\text{sat}}}) \quad (2.68)$$

Rearranging Equation (2.68) gives

$$n_{i_{\ell(m)}} = \frac{\gamma_{i_\ell}^G}{\gamma_{i_{\ell(m)}}} \cdot \frac{p_\ell}{p_{i_{\text{sat}}}} \cdot n_{i_\ell} \cdot \exp\left[\frac{-v_i(p_o - p_{i_{\text{sat}}})}{RT}\right] \quad (2.69)$$

As before, the exponential term is close to unity; thus, the concentration at the permeate side interface is

$$n_{i_{\ell(m)}} = \frac{\gamma_{i_\ell}^G}{\gamma_{i_{\ell(m)}}} \cdot n_{i_\ell} \cdot \frac{p_\ell}{p_{i_{\text{sat}}}} \quad (2.70)$$

The product $n_{i_\ell} p_\ell$ can be replaced by the partial pressure term p_{i_ℓ} , thus

$$n_{i_{\ell(m)}} = \frac{\gamma_{i_\ell}^G}{\gamma_{i_{\ell(m)}}} \cdot \frac{p_{i_\ell}}{p_{i_{\text{sat}}}} \quad (2.71)$$

or, substituting concentration for mole fraction from Equation (2.10),

$$c_{i_{\ell(m)}} = m_i \rho_m \cdot \frac{\gamma_{i_\ell}^G p_{i_\ell}}{\gamma_{i_{\ell(m)}} p_{i_{\text{sat}}}} = K_i^G p_{i_\ell} \quad (2.72)$$

where K_i^G is the gas-phase sorption coefficient defined in Equation (2.56) in the gas separation section.

The concentration terms in Equations (2.67) and (2.72) can be substituted into Equation (2.13) (Fick's law) to obtain an expression for the membrane flux.

$$J_i = \frac{D_i(K_i^L c_{i_o} - K_i^G p_{i_\ell})}{\ell} \quad (2.73)$$

However, the sorption coefficient in Equation (2.67) is a liquid-phase coefficient, whereas the sorption coefficient in Equation (2.72) is a gas-phase coefficient. The interconversion of these two coefficients can be handled by considering a hypothetical vapor in equilibrium with a feed solution. This vapor–liquid equilibrium can then be written

$$\mu_i^o + RT \ln(\gamma_i^L n_i^L) + v_i(p - p_{i_{\text{sat}}}) = \mu_i^o + RT \ln(\gamma_i^G n_i^G) + RT \ln\left(\frac{p}{p_{i_{\text{sat}}}}\right) \quad (2.74)$$

where the superscripts L and G represent the liquid and the gas phases. By following the same steps as were taken from Equation (2.68) to (2.72), Equation (2.74) becomes

$$n_i^L = \frac{\gamma_i^G p_i}{\gamma_i^L p_{i_{\text{sat}}}} \quad (2.75)$$

Substituting for concentration with Equation (2.10) gives

$$c_i^L = m_i \rho \frac{\gamma_i^G p_i}{\gamma_i^L p_{i_{\text{sat}}}} \quad (2.76)$$

and so

$$c_i^L = \frac{K_i^G}{K_i^L} \cdot p_i \quad (2.77)$$

This expression links the concentration of component i in the liquid phase, c_i^L with p_i , the partial vapor pressure of i in equilibrium with the liquid. Substitution of Equation (2.77) into Equation (2.73) yields

$$J_i = \frac{D_i K_i^G (p_{i_o} - p_{i_\ell})}{\ell} \quad (2.78)$$

where p_{i_o} and p_{i_ℓ} are the partial vapor pressures of component i on either side of the membrane. Equation (2.67) can also be written as

$$J_i = \frac{p_i^G}{\ell} (p_{i_o} - p_{i_\ell}) \quad (2.79)$$

This equation explicitly expresses the driving force in pervaporation as the vapor pressure difference across the membrane, a form of the pervaporation process

derived first by Kataoka *et al.* [16]. Equation (2.77) links the concentration of a sorbed vapor in the liquid phase (c_i^L) with the equilibrium partial pressure of the vapor. This is known as Henry's law and is usually written as⁵

$$H_i \cdot c_i^L = p_i \quad (2.80)$$

From Equations (2.77) and (2.80) it follows that the Henry's law coefficient, H_i , can be written as

$$H_i = \frac{K_i^L}{K_i^G} = \frac{\gamma_i^L P_{i,\text{sat}}}{m_i \rho \gamma_i^G} \quad (2.81)$$

These expressions can be used to write Equation (2.73) as

$$J_i = \frac{P_i^G}{\ell} (c_{i_o} H_i - p_{i_e}) \quad (2.82)$$

or

$$J_i = \frac{P_i^L}{\ell} (c_{i_o} - p_{i_e}/H_i) \quad (2.83)$$

Equation (2.79) expresses the driving force in pervaporation in terms of the vapor pressure. The driving force could equally well have been expressed in terms of concentration differences, as in Equation (2.83). However, in practice, the vapor pressure expression provides much more useful results and clearly shows the connection between pervaporation and gas separation, Equation (2.60). Also, P_i^G , the gas phase coefficient, is much less dependent on temperature than P_i^L . The reliability of Equation (2.79) has been amply demonstrated experimentally [17,18]. Figure 2.13, for example, shows data for the pervaporation of water as a function of permeate pressure. As the permeate pressure (p_{i_e}) increases, the water flux falls, reaching zero flux when the permeate pressure is equal to the feed-liquid vapor pressure ($p_{i,\text{sat}}$) at the temperature of the experiment. The straight lines in Figure 2.13 indicate that the permeability coefficient (P_i^G) of water in silicone rubber is constant, as expected in this and similar systems in which the membrane material is a rubbery polymer and the permeant swells the polymer only moderately.

Greenlaw *et al.* [18] have studied the effect of feed and permeate pressure on pervaporation flux in some detail; some illustrative results are shown in

⁵In Equation (2.80), the Henry's law coefficient H_i has the units atm · cm³/g. More commonly, Henry's law is written in terms of mole fraction:

$$H_i' \cdot n_i^L = p_i$$

where H_i' has the units atm/mol fraction. Using Equation (2.10), the two coefficients are linked by the expression

$$H_i = \frac{H_i'}{m_i \cdot p_i}$$

Figure 2.13 The effect of permeate pressure on the water flux through a silicone rubber pervaporation membrane. The arrows on the lower axis represent the saturation vapor pressures of the feed solution at the temperature of these experiments as predicted by Equation (2.79) [15]

Figure 2.14. As Figure 2.14(a) shows, the dependence of flux on permeate pressure in pervaporation is in accordance with Equation (2.79). The flux decreases with increasing permeate pressure, reaching a minimum value when the permeate pressure equals the saturation vapor pressure of the feed. The curvature of the line in Figure 2.14(a) shows that the permeability coefficient decreases with decreasing permeate pressure, that is, P_{hexane}^G decreases as hexane concentration in the membrane decreases. This behavior is typical of membranes that are swollen significantly by the permeant. If, on the other hand, as shown in Figure 2.14(b), the permeate pressure is fixed at a low value, the hydrostatic pressure of the feed liquid can be increased to as much as 20 atm without any significant change in the flux. This is because increased hydrostatic pressure produces a minimal change in the partial pressure of the feed liquid partial pressure (p_{i_0}), the true

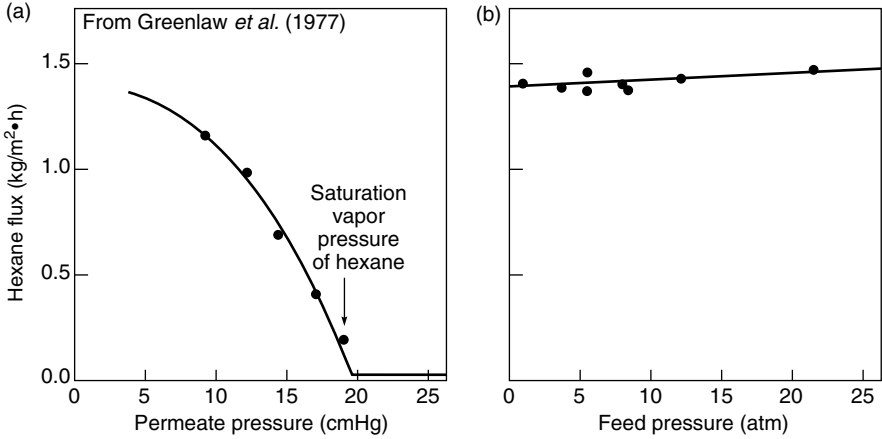

Figure 2.14 The effect of feed and permeate pressure on the flux of hexane through a rubbery pervaporation membrane. The flux is essentially independent of feed pressure up to 20 atm but is extremely sensitive to permeate pressure [18]. The explanation for this behavior is in the transport equation (2.79). Thompson, Dependence of Diffusive Permeation Rates by Upstream and Downstream Pressures, p. 141, Copyright 1977, with permission from Elsevier

driving force shown in Equation (2.79). Thus, the properties of pervaporation membranes illustrated in Figures 2.13 and 2.14 are easily rationalized by the solution-diffusion model but are much more difficult to explain by a pore-flow mechanism, although this has been tried.

Evidence for the Solution-diffusion Model

In the discussion above, the solution-diffusion model was used to derive equations that predict the experimentally observed performance of the membrane processes of dialysis, gas separation, reverse osmosis, and pervaporation. It was not necessary to resort to any additional process-specific model to obtain these results. This agreement between theory and experiment is good evidence for the validity of the solution-diffusion model. Moreover, the large body of permeability, diffusion, and partition coefficient data obtained over the past 20 years for these membrane processes are in good numerical agreement with one another. This universality and the simplicity of the solution-diffusion model are its most useful features and are a strong argument for the validity of the model. Finally, a number of direct experimental measurements can be made to distinguish between the solution-diffusion model and other models, such as the pore-flow model.

One prediction of the solution-diffusion model, controversial during the 1970s, is that the action of an applied pressure on the feed side of the membrane is to

decrease the concentration of the permeant on the low pressure side of the membrane. This counterintuitive effect is illustrated by Figures 2.5 and 2.6. A number of workers have verified this prediction experimentally with a variety of polymer membranes, ranging from diffusion of water in glassy cellulose acetate membranes to diffusion of organics in swollen rubbers [19–21]. Convincing examples of this type of experiment are the results of Rosenbaum and Cotton shown in Figure 2.15 [20]. In these experiments, four thin cellulose acetate films were laminated together, placed in a high pressure reverse osmosis cell, and subjected

Figure 2.15 Measurements of Rosenbaum and Cotton [20] of the water concentration gradients in a laminated reverse osmosis cellulose acetate membrane under applied pressures of 68 and 136 atm. Reprinted from *Steady-state Distribution of Water in Cellulose Acetate Membrane*, S. Rosenbaum and O. Cotton, *J. Polym. Sci.* 7, 101; Copyright © 1969. This material is used by permission of John Wiley & Sons, Inc.

to feed pressures of 68 or 136 atm. The permeate was maintained at atmospheric pressure. After permeation through the membrane laminate had reached a steady state, the membrane was quickly removed from the cell, and the water concentration in each laminate measured. As predicted by the solution-diffusion model and shown in Figure 2.15, the applied pressure decreases the concentration of water on the permeate side of the membrane. Also, the concentration difference across the membrane at 136 atm applied pressure is about twice that observed at 68 atm, and the measured concentration on the permeate side is within 20 % of the expected value calculated from Equation (2.36).

Another series of papers by Paul and co-workers [4–6,19,22] focuses on the same phenomenon using rubbery membranes and permeation of organic solvents such as hexane, benzene and carbon tetrachloride. Such membranes are highly swollen by the organic solvents and, when operated in reverse osmosis mode,

Figure 2.16 Pressure permeation (reverse osmosis) of iso-octane and methyl ethyl ketone through crosslinked 265- μm -thick natural rubber membranes. The change in the concentration gradient in the membrane as the applied pressure is increased is illustrated by the inserts. At high applied pressures, the concentration gradient and the permeation fluxes approach their limiting values [4]. large concentration gradients develop through the membrane even at relatively modest applied pressures. This means that the concentration in the membrane on the permeate side approaches zero and the flux through the membrane reaches a limiting value as the feed pressure is increased. Representative data are shown in Figure 2.16.

Paul and Paciotti [19] took this work a step further by measuring the flux of a liquid (hexane) through a membrane both in pervaporation experiments with atmospheric pressure on the feed side of the membrane and a vacuum on the permeate side, and in reverse osmosis experiments with liquid at elevated pressures on the feed side and at atmospheric pressure on the permeate side. The hexane flux obtained in these two sets of experiments is plotted in Figure 2.17 against the hexane concentration difference in the membrane ($c_{i_{o(m)}} - c_{i_{\ell(m)}}$). The concentrations, $c_{i_{o(m)}}$ and $c_{i_{\ell(m)}}$, were calculated from Equations (2.26), (2.36) and (2.72).

Figure 2.17 Flux of *n*-hexane through a rubbery membrane as a function of the hexane concentration difference in the membrane. Data taken from both reverse osmosis (●) and pervaporation (○) experiments. Feed-side and permeate-side membrane concentrations, $c_{i_{o(m)}}$ and $c_{i_{\ell(m)}}$, calculated from the operating conditions through Equations (2.26), (2.36) and (2.76). Maximum flux is obtained at the maximum concentration difference, when the permeate-side membrane concentration ($c_{i_{\ell(m)}}$), equals zero [19]. Reprinted from Driving Force for Hydraulic and Pervaporation Transport in Homogeneous Membranes, D.R. Paul and D.J. Paciotti, *J. Polym. Sci., Polym. Phys. Ed.* **13**, 1201; Copyright © 1975. Sorption data were used to obtain values for K_f^L . As pointed out by Paul and Paciotti, the data in Figure 2.17 show that reverse osmosis and pervaporation obey one unique transport equation—Fick's law. In other words, transport follows the solution-diffusion model. The slope of the curve decreases at the higher concentration differences, that is, at smaller values for $c_{i(m)}$ because of decreases in the diffusion coefficient, as the swelling of the membrane decreases.

The results illustrated in Figure 2.16 show that the solvent flux tends towards a limiting value at very high pressures. This value is reached when the concentration of sorbed solvent at the permeate side of the membrane reaches zero, the limiting value.

Structure–Permeability Relationships in Solution-diffusion Membranes

In the preceding section the effect of concentration and pressure gradient driving forces on permeation through membranes was described in terms of the solution-diffusion model and Fick's law. The resulting equations all contain a permeability term, P , that must be experimentally determined. This section describes how the nature of the membrane material affects permeant diffusion and sorption coefficients, which in turn determine membrane permeability. This is a difficult subject. By analyzing the factors that determine membrane permeability, useful correlations and rules of thumb can be derived to guide the selection of membrane materials with the optimum flux and selectivity properties. Most of the experimental data in this area have been obtained with gas-permeable membranes. However, the same general principles apply to all polymeric solution-diffusion membranes.

The problem of predicting membrane permeability can be divided into two parts because permeability is the product of the diffusion coefficient and the sorption coefficient:

$$P = D \cdot K \quad (2.84)$$

The sorption coefficient (K) in Equation (2.84) is the term linking the concentration of a component in the fluid phase with its concentration in the membrane polymer phase. Because sorption is an equilibrium term, conventional thermodynamics can be used to calculate solubilities of gases in polymers to within a factor of two or three. However, diffusion coefficients (D) are kinetic terms that reflect the effect of the surrounding environment on the molecular motion of permeating components. Calculation of diffusion coefficients in liquids and gases is possible, but calculation of diffusion coefficients in polymers is much more difficult. In the long term, the best hope for accurate predictions of diffusion in polymers is the molecular dynamics calculations described in an earlier section. However, this technique is still under development and is currently limited to calculations of the diffusion of small gas molecules in amorphous polymers; the

Figure 2.18 Diffusion and sorption coefficients plotted for gases in a family of 18 related polyimides. Data of Tanaka *et al.* [23]

agreement between theory and experiment is modest. In the meantime, simple correlations based on polymer free volume must be used.

As a general rule, membrane material changes affect the diffusion coefficient of a permeant much more than the sorption coefficient. For example, Figure 2.18 shows some typical gas permeation data taken from a paper of Tanaka *et al.* [23]. The diffusion and sorption coefficients of four gases in a family of 18 related polyimides are plotted against each other. Both sorption and diffusion coefficients

are fairly well grouped for each gas. However, for any one gas the difference in diffusion coefficient from the highest to lowest value is approximately 100-fold, whereas the spread in sorption coefficient is only 2- to 4-fold. Changes in polymer chemistry affect both the sorption and diffusion coefficients, but the effect on the diffusion coefficient is much more profound.

More detailed examination of the data shown in Figure 2.18 shows that the relative position of each polymer within the group of 18 is approximately the same for all gases. That is, the polymer with the highest diffusion coefficient for methane also has the highest diffusion coefficient for nitrogen, carbon dioxide and hydrogen. The trend for the solubility coefficients is similar. As a general rule, changes in polymer chemistry and structure that change the diffusion coefficient or sorption coefficient of one gas change the properties of other gases in the same way. This is why membrane permeabilities can be easily varied by orders of magnitude by changing the membrane material, whereas changing membrane selectivities (proportional to the ratio of permeabilities) by more than a factor of two or three is difficult.

In the following sections the factors that determine the magnitude of diffusion and solubility coefficients in polymers are discussed.

Diffusion Coefficients

The Fick's law diffusion coefficient of a permeating molecule is a measure of the frequency with which the molecule moves and the size of each movement. Therefore, the magnitude of the diffusion coefficient is governed by the restraining forces of the medium on the diffusing species. Isotopically labeled carbon in a diamond lattice has a very small diffusion coefficient. The carbon atoms of diamond move infrequently, and each movement is very small—only 1 to 2 Å. On the other hand, isotopically labeled carbon dioxide in a gas has an extremely large diffusion coefficient. The gas molecules are in constant motion and each jump is of the order of 1000 Å or more. Table 2.1 lists some representative values of diffusion coefficients in different media.

Table 2.1 Typical diffusion coefficients in various media (25 °C)

Permeant/material	Diffusion coefficient, D (cm ² /s)
Oxygen in air (atmospheric pressure)	1×10^{-1}
Salt in water	1.5×10^{-5}
Albumin (MW 60 000) in water	6×10^{-7}
Oxygen in silicone rubber	1×10^{-5}
Oxygen in polysulfone	4×10^{-8}
Sodium atoms in sodium chloride crystals	1×10^{-20}
Aluminum atoms in metallic copper	1×10^{-30}

The main observation from Table 2.1 is the enormous range of values of diffusion coefficients—from 10^{-1} to 10^{-30} cm^2/s . Diffusion in gases is well understood and is treated in standard textbooks dealing with the kinetic theory of gases [24,25]. Diffusion in metals and crystals is a topic of considerable interest to the semiconductor industry but not to membrane permeation. This book focuses principally on diffusion in liquids and polymers in which the diffusion coefficient can vary from about 10^{-5} to about 10^{-10} cm^2/s .

Diffusion in Liquids

Liquids are simple, well defined systems and provide the starting point for modern theories of diffusion. An early and still fundamentally sound equation was derived by Einstein who applied simple macroscopic hydrodynamics to diffusion at the molecular level. He assumed the diffusing solute to be a sphere moving in a continuous fluid of solvent, in which case it can be shown that

$$D = \frac{kT}{6\pi a\eta} \quad (2.85)$$

where k is Boltzmann's constant, a is the radius of the solute and η is the solution viscosity. This is known as the Stokes–Einstein equation. The equation is a good approximation for large solutes with radii greater than 5–10 Å. But, as the solute becomes smaller, the approximation of the solvent as a continuous fluid becomes less valid. In this case there may be slip of solvent at the solute molecule's surface. A second limiting case assumes complete slip at the surface of the solute sphere; in this case

$$D = \frac{kT}{4\pi a\eta} \quad (2.86)$$

Thus, the Stokes–Einstein equation is perhaps best expressed as

$$D = \frac{kT}{n\pi a\eta} \quad 4 \leq n \leq 6 \quad (2.87)$$

An important conclusion to be drawn from the Stokes–Einstein equation is that the diffusion coefficient of solutes in a liquid only changes slowly with molecular weight, because the diffusion coefficient is proportional to the reciprocal of the radius, which in turn is approximately proportional to the cube root of the molecular weight.

Application of the Stokes–Einstein equation requires a value for the solute radius. A simple approach is to assume the molecule to be spherical and to calculate the solute radius from the molar volume of the chemical groups making up the molecule. Using values for the solute radius calculated this way along with measured and known diffusion coefficients of solutes in water, Edward [26]

Figure 2.19 Value of the coefficient n in the Stokes–Einstein equation [Equation (2.87)] required to achieve agreement between calculation and experimental solute diffusion coefficients in water. [26]. Reprinted with permission from the *Journal of Chemical Education* **47**, No. 4, 1970, pp. 261–270, Figure 12, copyright © 1970, Division of Chemical Education, Inc.

constructed the graph of the coefficient n in the Stokes–Einstein equation, Equation (2.87), as a function of solute radius as shown in Figure 2.19. With large solutes, n approaches 6, that is, Einstein’s application of normal macroscopic fluid dynamics at the molecular level is a valid approximation. However, when the solute radius falls below about 4 Å water can no longer be regarded as a continuous fluid, and n falls below 6. Nonetheless, that an equation based on macroscopic hydrodynamic theory applies to molecules to the 4 Å level is an interesting result.

The Stokes–Einstein equation works well for diffusion of solutes in simple liquids but fails in more complex fluids, such as a solution of a high-molecular-weight polymer. Dissolving a polymer in a liquid increases the solvent’s viscosity, but the solute’s diffusion coefficient is not significantly affected. For example, as the concentration of poly(vinyl pyrrolidone) dissolved in water is changed from 0 to 20 wt %, the viscosity of the solution increases by several orders of magnitude. However, the diffusion coefficient of sucrose in these solutions only changes by a factor of four [27]. The long polymer chains of dissolved poly(vinyl pyrrolidone) molecules link distant parts of the aqueous solution and change the viscosity of the

fluid substantially, but, in the fluid immediately surrounding the diffusing sucrose molecule, the effect of polymer chain length is much less noticeable. This result illustrates the difference between the microscopic viscosity in the immediate environment of the diffusing solute and the macroscopic viscosity measured by conventional viscometers. In simple liquids the macroscopic and microscopic viscosities are the same, but in liquids containing dissolved macromolecules, or in gels and polymer films, the microscopic viscosity and the macroscopic viscosity differ significantly.

Diffusion in Polymers

The concept that the local environment around the permeating molecule determines the permeate's diffusion coefficient is key to understanding diffusion in polymer membranes. Polymers can be divided into two broad categories—rubbery and glassy. In a rubbery polymer, segments of the polymer backbone can rotate freely around their axis; this makes the polymer soft and elastic. Thermal motion of these segments also leads to high permeant diffusion coefficients. In a glassy polymer, steric hindrance along the polymer backbone prohibits rotation of polymer segments; the result is a rigid, tough polymer. Thermal motion in this type of material is limited, so permeant diffusion coefficients are low. If the temperature of a glassy polymer is raised, a point is reached at which the increase in thermal energy is sufficient to overcome the steric hindrance restricting rotation of polymer backbone segments. At this temperature, called the *glass transition temperature* (T_g), the polymer changes from a glass to a rubber.

Figure 2.20 shows a plot of diffusion coefficient as a function of molecular weight for permeants diffusing through a liquid (water), two soft rubbery polymers (natural rubber and silicone rubber), and a hard, stiff glassy polymer (polystyrene) [28]. For very small molecules, such as helium and hydrogen, the diffusion coefficients in all of the media are comparable, differing by no more than a factor of two or three. These very small molecules only interact with one or two atoms in their immediate proximity. The local environment for these small solutes in the three polymers is not radically different to that in a liquid such as water. On the other hand, larger diffusing solutes with molecular weights of 200 to 300 and above have molecular diameters of 6 to 10 Å. Such solutes are in quite different local environments in the different media. In water, the Stokes–Einstein equation applies, and the resistance to movement of the solute is not much larger than that of a very small solute. In polymer membranes, however, several segments of the polymer chain are involved in each movement of the diffusing species. This type of cooperative movement is statistically unlikely; consequently, diffusion coefficients are much smaller than in liquid water. Moreover, the differences between the motion of polymer segments in the flexible rubbery membranes and in the stiff polystyrene membrane are large. The polymer chains in rubbers are considerably more flexible and rotate more easily than

Figure 2.20 Permeant diffusion coefficient as a function of permeant molecular weight in water, natural rubber, silicone rubber and polystyrene. Diffusion coefficients of solutes in polymers usually lie between the value in natural rubber, an extremely permeable polymer, and the value in polystyrene, an extremely impermeable material [28]

those in polystyrene. One manifestation of this difference in chain flexibility is the difference in elastic properties; another is the difference in diffusion coefficient.

An example of the change in diffusion coefficient as the matrix material changes is illustrated by Figure 2.21. In this example, the polymer matrix material is changed by plasticization of the polymer, ethyl cellulose, by the permeant, dichloroethane [29]. The resulting change in the diffusion coefficient is shown in the figure. The concentration of dichloroethane in the polymer matrix increases from very low levels (<1 % dichloroethane) to very high levels (>90 % dichloroethane). As the concentration of dichloroethane increases, the polymer changes from a glassy polymer to a rubbery polymer, to a solvent-swollen gel, and finally to a dilute polymer solution. Ethyl cellulose is a glassy polymer with a glass transition of about 45–50 °C. At low concentrations of dichloroethane (below about 5 vol %) in the polymer, the ethyl cellulose matrix is glassy, and the dichloroethane diffusion coefficient is in the range 1 to 5 × 10⁻⁹ cm²/s. As

Figure 2.21 Changes in the diffusion coefficient of dichloroethane in ethyl cellulose as a function of the volume fraction of dichloroethane dissolved in the polymer matrix. Data of Artsis *et al.* [29]

the dichloroethane concentration increases to above 5 vol %, enough solvent has dissolved in the polymer to reduce the glass transition temperature to below the temperature of the experiment. The polymer chains then have sufficient freedom to rotate, and the polymer becomes rubbery. As the dichloroethane concentration increases further, the polymer chain mobility also increases as does the diffusion coefficient of dichloroethane. At 20% dichloroethane, the diffusion coefficient is $1 \times 10^{-7} \text{ cm}^2/\text{s}$, 100 times greater than the diffusion coefficient in the glassy polymer. Above 20 vol % dichloroethane, sufficient solvent is present to allow relatively large segments of the polymer chain to move. In this range, between 20 and 70 vol % dichloroethane, the matrix is best characterized as a solvent-swollen

gel, and the diffusion coefficient of dichloroethane increases from 1×10^{-7} to 2×10^{-6} cm²/s. Finally, at dichloroethane concentrations above 70 vol %, sufficient solvent is present for the matrix to be characterized as a polymer solution. In this final solvent concentration range, the increase in diffusion coefficient with further increases in dichloroethane concentration is relatively small.

Figures 2.20 and 2.21 show the significant difference between diffusion in liquids and in rubbery and glassy polymers. A great deal of work has been performed over the last two decades to achieve a quantitative link between the structure of polymers and their permeation properties. No such quantitative structure–property relationship is at hand or even in sight. What has been achieved is a set of semiempirical rules that allow the permeation properties of related families of polymers to be correlated based on small changes in their chemical structures. The correlating tool most generally used is the polymer's *fractional free volume* v_f (cm³/cm³), usually defined as

$$v_f = \frac{v - v_o}{v} \quad (2.88)$$

where v is the specific volume of the polymer (cm³/g), that is, the reciprocal of the polymer density, and v_o is the volume occupied by the molecules themselves (cm³/g). The free volume of a polymer is the sum of the many small spaces between the polymer chains in these amorphous, noncrystalline materials.

The free volume of a polymer can be determined by measuring the polymer's specific volume, then calculating the occupied volume (v_o) of the groups that form the polymer. Tables of the molar volume of different chemical groups have been prepared by Bondi [30] and Van Krevelen [31]. By summing the molar volume of all the groups in the polymer repeat unit, the occupied molar volume of the polymer can be calculated. The occupied volume obtained in this way is about 1.3 times larger than the Van der Waals volume of the groups. The factor of 1.3 occurs because some unoccupied space is inevitably present even in crystals at 0 K. The fractional free volumes of a number of important membrane materials are given in Table 2.2.

The concept of polymer free volume is illustrated in Figure 2.22, which shows polymer specific volume (cm³/g) as a function of temperature. At high temperatures the polymer is in the rubbery state. Because the polymer chains do not pack perfectly, some unoccupied space—free volume—exists between the polymer chains. This free volume is over and above the space normally present between molecules in a crystal lattice; free volume in a rubbery polymer results from its amorphous structure. Although this free volume is only a few percent of the total volume, it is sufficient to allow some rotation of segments of the polymer backbone at high temperatures. In this sense a rubbery polymer, although solid at the macroscopic level, has some of the characteristics of a liquid. As the temperature of the polymer decreases, the free volume also decreases. At the glass transition temperature, the free volume is reduced to a point at which the

Table 2.2 Calculated fractional free volume for representative membrane materials at ambient temperatures (Bondi method)

Polymer	Polymer type	Glass transition temperature, T_g ($^{\circ}\text{C}$)	Fractional free volume (cm^3/cm^3)
Silicone rubber	Rubber	-129	0.16
Natural rubber	Rubber	-73	0.16
Polycarbonate	Glass	150	0.16
Poly(phenylene oxide)	Glass	167	0.20
Polysulfone	Glass	186	0.16
6FDA-ODA polyimide	Glass	300	0.16
Poly(4-methyl-2-pentyne) (PMP)	Glass	>250	0.28
Poly(1-trimethylsilyl-1-propyne) (PTMSP)	Glass	>250	0.34

**Figure 2.22** The change in specific volume as a function of temperature for a typical polymer

polymer chains can no longer rotate freely. Segmental motion then ceases, and the remaining free volume elements between the polymer chains are essentially frozen into the polymer matrix. As the polymer temperature is reduced further, its occupied volume will continue to decrease as the vibrational energy of the groups forming the polymer decreases, but the free volume elements remain essentially constant. Therefore, a glassy polymer contains both the normal free volume elements caused by the incomplete packing of the groups making up the polymer chains and the excess free volume elements frozen into the polymer matrix because the polymer chains cannot rotate.

Figure 2.23 Structure of two high-free-volume substituted polyacetylenes, PTMSP and PMP. The carbon-carbon double bond is completely rigid, and depending on the size of the substituents, rotation around the carbon-carbon single bond can be very restricted also. The result is very stiff-backed, rigid polymer chains which pack very poorly, leading to unusually high fractional free volumes

The fractional free volume of most materials is quite small and the value depends on the methods used for the calculation. For rubbers, the volume calculated by the Bondi method is generally about 10 to 15 % and for glassy polymers slightly higher, generally in the range 15 to 20 % because of the excess free volume contribution. Recently, a number of substituted polyacetylene polymers with extraordinarily rigid polymer backbones have been prepared. The structures of two such polymers are shown in Figure 2.23. Their glass transition temperatures are very high, and their free volumes are correspondingly unusually high—as much as 25 to 35 % of the polymers' volume is unoccupied space.

Correlation of the permeation properties of a wide variety of polymers with their free volume is not possible [32]. But, within a single class of materials, there is a correlation between the free volume of polymers and gas diffusion coefficients; an example is shown in Figure 2.24 [33]. The relationship between the free volume and the sorption and diffusion coefficients of gases in polymers, particularly glassy polymers, has been an area of a great deal of experimental and theoretical work. The subject has recently been reviewed in detail by Petropoulos [34] and by Paul and co-workers [35,36].

Sorption Coefficients in Polymers

The second key factor determining permeability in polymers is the sorption coefficient. The data in Figure 2.18 show that sorption coefficients for a particular gas are relatively constant within a single family of related materials. In fact, sorption coefficients of gases in polymers are relatively constant for a wide range of chemically different polymers. Figure 2.25 plots sorption and diffusion coefficients of methane in Tanaka's fluorinated polyimides [23], carboxylated polyvinyl trimethylsiloxane [37] and substituted polyacetylenes [38], all amorphous glassy polymers, and a variety of substituted siloxanes [39], all rubbers. The diffusion

Figure 2.24 Correlation of the oxygen permeability coefficient for a family of related polysulfones with inverse fractional free volume (calculated using the Bondi method) [33]. Copyright 1992, American Chemical Society

coefficients of methane in the different polymers vary by more than 100 000, showing the extraordinary sensitivity of the permeant diffusion coefficients to changes in the packing of the polymer chains and to their flexibility. In contrast, sorption coefficients vary by only a factor of 10 around a mean value of about $15 \times 10^{-3} \text{ cm}^3(\text{STP})/\text{cm}^3 \cdot \text{cmHg}$.

The sorption coefficients of gases in polymers remain relatively constant because sorption in polymers behaves as though the polymers were ideal fluids. Gas sorption in a polymer is expressed from Equation (2.57) as

$$c_{i(m)} = K_i^G p_i \quad (2.89)$$

By substituting for the sorption coefficient K_i^G from Equation (2.56), Equation (2.89) can be written as

$$c_{i(m)} = m_i \rho_m \frac{\gamma_i^G p_i}{\gamma_{i(m)} p_{i,\text{sat}}} \quad (2.90)$$

From the conversion of concentration to mole fraction [Equation (2.10)], it follows that

$$c_{i(m)} = m_i \rho_m n_{i(m)} \quad (2.91)$$

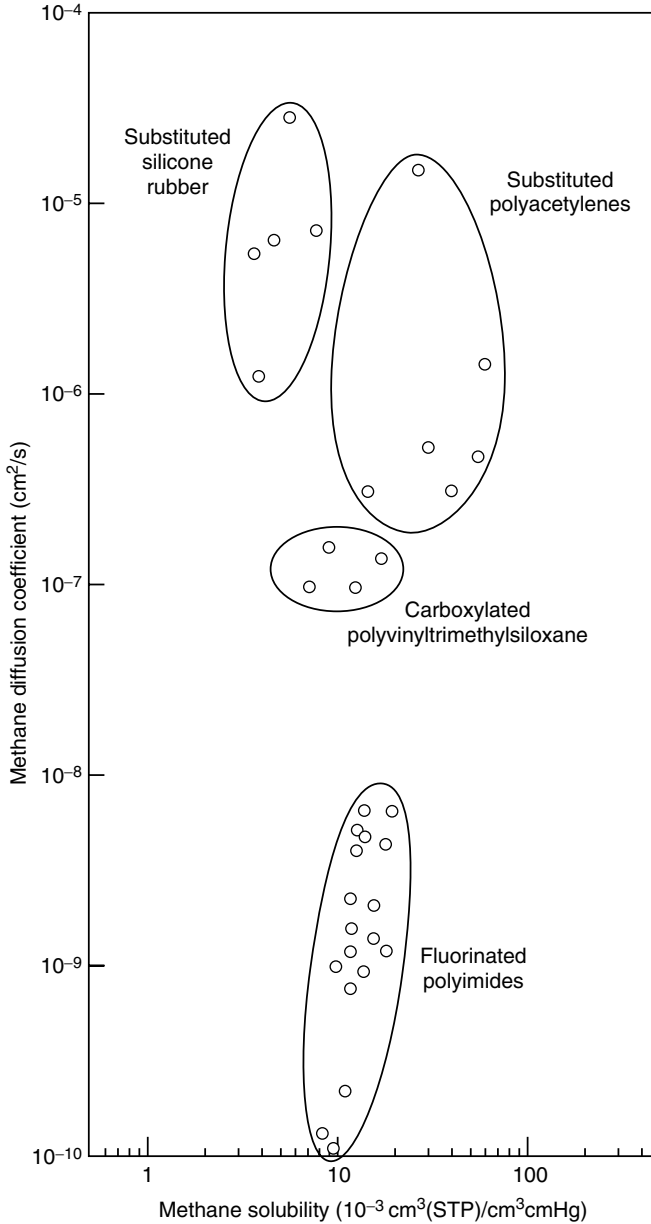

Figure 2.25 Diffusion and sorption coefficients of methane in different families of polymer materials. Diffusion coefficients change over a wide range but sorption coefficients are relatively constant. Data from references [23,35–37]

and so Equation (2.90) can be written as

$$\frac{c_{i(m)}}{\rho_m m_i} = n_{i(m)} = \frac{\gamma_i^G p_i}{\gamma_{i(m)} p_{i\text{sat}}} \quad (2.92)$$

For an ideal gas dissolving in an ideal liquid, γ_i^G and $\gamma_{i(m)}$ are both unity, so Equation (2.92) can be written as

$$n_{i(m)} = \frac{p_i}{p_{i\text{sat}}} \quad (2.93)$$

where $n_{i(m)}$ is the mole fraction of the gas sorbed in the liquid, p_i is the partial pressure of the gas, and $p_{i\text{sat}}$ is the saturation vapor pressure at the pressure and temperature of the liquid. To apply Equation (2.93), the gas saturation vapor pressure must be determined. This can be done by extrapolating from available vapor pressure data to the ambient range using the Clausius–Clapeyron equation. For some gases the vapor pressure thereby obtained does not correspond to a stable gas–liquid equilibrium because the gas is supercritical at ambient temperatures. However, the calculated value is adequate to calculate the sorption coefficient using Equation (2.93) [40]. At 25 °C the saturation vapor pressure of methane extrapolated in this way is 289 atm. Thus, from Equation (2.93) the mole fraction of methane dissolved in an ideal liquid is 1/289 or 0.0035. The ideal solubility and measured solubilities of methane in a number of common liquids are given in Table 2.3. Although there is some spread in the data, particularly for small polar solvent molecules such as water or methanol, the overall agreement is remarkably good. A more detailed discussion of the solubility of gases in liquids is given in the book by Fogg and Gerrard [41].

To apply the procedure outlined above to a polymer, it is necessary to use the Flory–Huggins theory of polymer solution, which takes into account the entropy of mixing of solutes in polymers caused by the large difference in molecular size

Table 2.3 Mole fraction of methane in various solvents at 25 °C and 1 atm. The solubility of methane in an ideal liquid under these conditions is 0.0035 [40]

Liquid	Methane solubility (mole fraction)
Ethyl ether	0.0045

between the two components. The Flory–Huggins expression for the free energy of mixing of a gas in polymer solution can be written [42]

$$\Delta G = RT \ln \frac{p_i}{p_{i,\text{sat}}} = RT \left[\ln V_i + \left(1 - \frac{v_i}{v_j} \right) (1 - V_i) \right] \quad (2.94)$$

where v_i and v_j are the molar volumes of the gas i and the polymer j respectively, and V_i the volume fraction of the polymer j occupied by the sorbed gas i . When $v_i \approx v_j$, that is, the gas and polymer molecules are approximately the same size, Equation (2.94) reduces to Equation (2.93), the ideal liquid case. When $v_i \ll v_j$, that is, when the molar volume of a gas (v_i) is much smaller than the molar volume of the polymer (v_j), then $v_i/v_j \rightarrow 0$ and Equation (2.94) becomes

$$\ln \frac{p_i}{p_{i,\text{sat}}} = \ln V_i + (1 - V_i) \quad (2.95)$$

Equation (2.95) can be rearranged to

$$V_i = \frac{p_i/p_{i,\text{sat}}}{\exp(1 - V_i)} \quad (2.96)$$

and since V_i is small, $\exp(1 - V_i)$ is approximately $\exp(1) \approx 2.72$, Equation (2.95) then becomes

$$V_i = \frac{p_i/p_{i,\text{sat}}}{2.72} \quad (2.97)$$

Comparing Equations (2.93) and (2.97), we see that the volume fraction of gas sorbed by an ideal polymer is $1/2.72$ of the mole fraction of a gas sorbed in an ideal liquid.⁶

The results of such a calculation are shown in Table 2.4. In Figure 2.26, the calculated sorption coefficients in an ideal polymer from Table 2.4 are plotted against the average sorption coefficients of the same gases in Tanaka's polyimides [23]. The calculated values are within a factor of two of the experimental values, which is extremely good agreement considering the simplicity of Equation (2.97). A more detailed discussion of sorption of gases in polymers is given in a review by Petropoulos [34].

As shown above, thermodynamics can qualitatively predict the sorption of simple gases in polymers to within a factor of two. Moreover, Equation (2.97) predicts that all polymers should have about the same sorption for the same gas and that sorption is inversely proportional to saturation vapor pressure.

Another way of showing the same effect is to plot gas sorption against some convenient measure of saturation vapor pressure, such as the gas boiling point

⁶ V_i is the volume fraction of the gas sorbed in the polymer. To calculate the amount of gas sorbed in cm^3 (STP)/ cm^3 , the molar density of the sorbed gas must be known. We assume this density is $1/MW$ (mol/cm^3).

Table 2.4 Solubility of gases in an ideal liquid and an ideal polymer (35 °C)

or critical temperature. Figure 2.27 shows a plot of this type for a typical glassy polymer (polysulfone), a typical rubber (silicone rubber), and the values for the ideal solubility of a gas in a polymer calculated using Equation (2.97) [43]. The figure shows that the difference in gas sorptions of polymers is relatively small and the values are grouped around the calculated value.

Although all of these predictions are qualitatively correct, the differences between the behavior of an ideal polymer and an actual polymer are important in selecting the optimum material for a particular separation. The usual starting point for this fine-tuning is the dual-sorption model originally proposed by Barrer *et al.* [44]. This model has since been extended by Michaels *et al.* [45], Paul *et al.* [46], Koros *et al.* [47] and many others.

Figure 2.27 Solubilities as a function of critical temperature (T_c) for a typical glassy polymer (polysulfone) and a typical rubbery polymer (silicone rubber) compared with values for the ideal solubility calculated from Equation (2.97)[43]

According to the dual-sorption model, gas sorption in a polymer (c_m) occurs in two types of sites. The first type is filled by gas molecules dissolved in the equilibrium free volume portion of material (concentration c_H). In rubbery polymers this is the only population of dissolved gas molecules, but in glassy polymers a second type of site exists. This population of dissolved molecules (concentration c_D) is dissolved in the excess free volume of the glassy polymer. The total sorption in a glassy polymer is then

$$c_m = c_D + c_H \quad (2.98)$$

The number of molecules (c_D) dissolved in the equilibrium free volume portion of the polymer will behave as in normal sorption in a liquid and can be related to the pressure in the surrounding gas by a linear expression equivalent to Equation (2.89)

$$c_D = K_D p \quad (2.99)$$

This fraction of the total sorption is equivalent to the value calculated in Equation (2.97). The other fraction (c_H) is assumed to be sorbed into the excess

free volume elements, which are limited, so sorption will cease when all the sites are filled. Sorption in these sites is best approximated by a Langmuir-type absorption isotherm

$$c_H = \frac{c'_H b p}{1 + b p} \quad (2.100)$$

At high pressures $c_H \rightarrow c'_H$, where c'_H is the saturation sorption concentration at which all excess free volume sites are filled.

From Equations (2.99) and (2.100) it follows that the total sorption can be written as

$$c_m = K_D p + \frac{c'_H b p}{1 + b p} \quad (2.101)$$

The form of the sorption isotherm predicted from the dual sorption model is shown in Figure 2.28. Because the expressions for sorption contain three adjustable parameters, good agreement between theory and experiment is obtained.

Often, much is made of the particular values of the constants c'_H , b , and K . However, these constants should be treated with caution because they depend totally on the starting point of the curve-fitting exercise. That is, starting with an arbitrary value of c'_H , the other constants b and K can usually be adjusted to obtain good agreement of Equation (2.101) with experiment. If the starting value for c'_H is changed, then equally good agreement between theory and experiment can still be obtained but with different values of b and K [48].

Figure 2.28 An illustration of the two components that contribute to gas sorption in a glassy polymer according to the dual sorption model. Henry's law sorption occurs in the equilibrium free volume portion of the polymer. Langmuir sorption occurs in the excess free volume between polymer chains that exists in glassy polymers

Permeation of gases in glassy polymers can also be described in terms of the dual sorption model. One diffusion coefficient (D_D) is used for the portion of the gas dissolved in the polymer according to the Henry's law expression and a second, somewhat larger, diffusion coefficient (D_H) for the portion of the gas contained in the excess free volume. The Fick's law expression for flux through the membrane has the form

$$J = -D_D \frac{dc_D}{dx} - D_H \frac{dc_H}{dx} \quad (2.102)$$

Pore-flow Membranes

The creation of a unified theory able to rationalize transport in the dense membranes used in reverse osmosis, pervaporation and gas separation occurred over a 20-year period from about 1960 to 1980. Development of this theory was one of the successes of membrane science. The theory did not form overnight as the result of one single breakthrough but rather as the result of a series of incremental steps. The paper of Lonsdale *et al.* [12] applying the solution-diffusion model to reverse osmosis for the first time was very important.⁷ Also important was the series of papers by Paul and co-workers showing the connection between hydraulic permeation (reverse osmosis) and pervaporation [4–6, 19] and providing the experimental support for the solution-diffusion model as applied to these processes. Unfortunately no equivalent unified theory to describe transport in microporous membranes has been developed. Figure 2.29 illustrates part of the problem, namely the extremely heterogeneous nature of microporous membranes. All of the microporous membranes shown in this figure perform approximately the same separation, but their porous structure and the mechanism of the separation differ significantly. The nucleation track membrane (Figure 2.29a) and the asymmetric Loeb–Sourirajan membrane (Figure 2.29d) both separate particles by molecular sieving. The cellulose acetate/cellulose nitrate membrane (Figure 2.29c) is a depth filter which captures particles within the interior of the membrane by adsorption. The expanded film membrane (Figure 2.29b) captures particles by both methods. The materials from which these membranes are made also differ, ranging from polyethylene and polysulfone, both hydrophobic, low-surface-energy materials, to cellulose acetate, a hydrophilic material that often carries charged surface groups.

The parameters available to characterize the complexity of microporous membranes are also imperfect. Some widely used parameters are illustrated in Figure 2.30. The membrane porosity (ε) is the fraction of the total membrane

⁷This paper was initially submitted by its three industrial authors for publication to the *Journal of Physical Chemistry* and was rejected as insufficiently fundamental. More than 30 years after it was finally published in the *Journal of Applied Polymer Science*, it remains one of the most cited papers on membrane transport theory.

volume that is porous. Typical microporous membranes have average porosities in the range 0.3–0.7. This number can be obtained easily by weighing the membrane before and after filling the pores with an inert liquid. The average porosity obtained this way must be treated with caution, however, because the porosity of a membrane can vary from place to place. For example, anisotropic membranes, such as the Loeb–Sourirajan phase separation membrane shown in Figure 2.29(d), often have an average porosity of 0.7–0.8, but the porosity of the skin layer that performs the actual separation may be as low as 0.05.

The membrane tortuosity (τ) reflects the length of the average pore compared to the membrane thickness. Simple cylindrical pores at right angles to the membrane surface have a tortuosity of one, that is, the average length of the pore is the

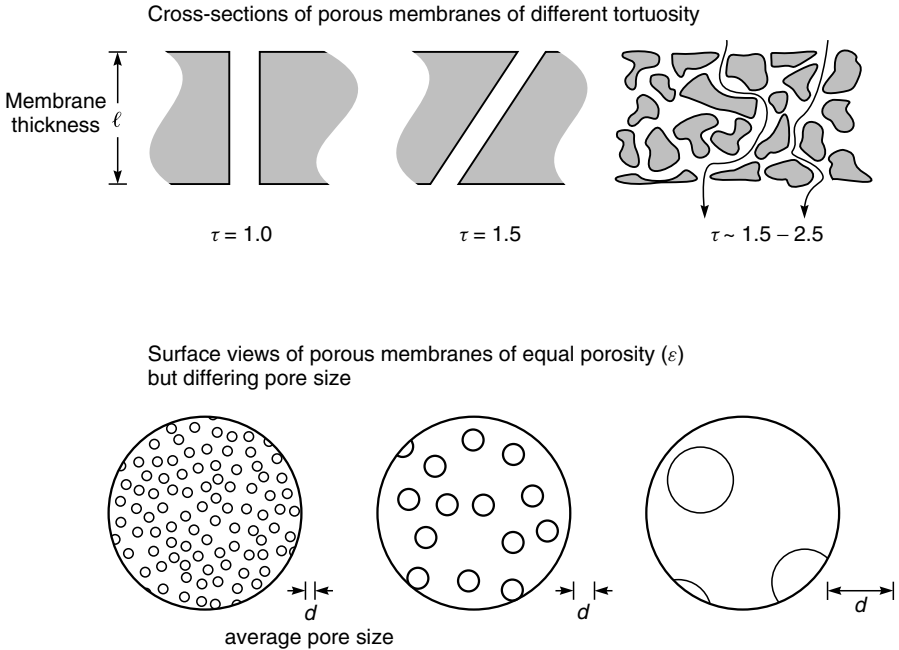

Figure 2.30 Microporous membranes are characterized by their tortuosity (τ), their porosity (ϵ), and their average pore diameter (d)

membrane thickness. Usually pores take a more meandering path through the membrane, so typical tortuosities are in the range 1.5–2.5.

The most important property characterizing a microporous membrane is the pore diameter (d). Some of the methods of measuring pore diameters are described in Chapter 7. Although microporous membranes are usually characterized by a single pore diameter value, most membranes actually contain a range of pore sizes. In ultrafiltration, the pore diameter quoted is usually an average value, but to confuse the issue, the pore diameter in microfiltration is usually defined in terms of the largest particle able to penetrate the membrane. This nominal pore diameter can be 5 to 10 times smaller than the apparent pore diameter based on direct microscopic examination of the membrane.

Permeation in Ultrafiltration and Microfiltration Membranes

Microporous ultrafiltration and microfiltration membranes used to filter particulates from liquids fall into the two general categories illustrated in Figure 2.31. The first category (a) is the surface or screen filter; such membranes contain surface pores smaller than the particles to be removed. Particles in the permeating

Figure 2.31 Separation of particulates can take place at the membrane surface according to a screen filtration mechanism (a) or in the interior of the membrane by a capture mechanism as in depth filtration (b)

fluid are captured and accumulate on the surface of the membrane. These membranes are usually anisotropic, with a relatively finely microporous surface layer on a more open microporous support. Particles small enough to pass through the surface pores are not normally captured in the interior of the membrane. Most ultrafiltration membranes are screen filters.

The second category of microporous membranes is the depth filter (b), which captures the particles to be removed in the interior of the membrane. The average pore diameter of a depth filter is often 10 times the diameter of the smallest particle able to permeate the membrane. Some particles are captured at small constrictions within the membrane, others by adsorption as they permeate the membrane by a tortuous path. Depth filters are usually isotropic, with a similar pore structure throughout the membrane. Most microfiltration membranes are depth filters.

Screen Filters

The mechanism of particle filtration by screen filters has been the subject of many studies because it is relatively easily described mathematically; Bungay has published a review of this work [49]. Ferry [50] was the first to model membrane retention by a screen filter; in his model pores were assumed to be equal circular capillaries with a large radius, r , compared to the solvent molecule radius. Therefore, the total area of the pore is available for transport of solvent. A solute molecule whose radius, a , is an appreciable fraction of the pore radius cannot approach nearer than one molecular radius of the pore overall. The model is illustrated in Figure 2.32.

The area, A , of the pore available for solute transport is given by the equation

$$\frac{A}{A_o} = \frac{(r - a)^2}{r^2} \quad (2.103)$$

Figure 2.32 Illustration of the Ferry mechanical exclusion model of solute transport in small pores

where A_o is the area of the pore available for solvent molecules. Later, Renkin [51] showed that Equation (2.103) has to be modified to account for the parabolic velocity profile of the fluid as it passes through the pore. The effective fractional pore area available for solutes in this case is

$$\left(\frac{A}{A_o}\right)' = 2\left(1 - \frac{a}{r}\right)^2 - \left(1 - \frac{a}{r}\right)^4 \quad (2.104)$$

where $(A/A_o)'$ is equal to the ratio of the solute concentration in the filtrate (c_ℓ) to the concentration in the feed (c_o), that is,

$$\left(\frac{A}{A_o}\right)' = \left(\frac{c_\ell}{c_o}\right) \quad (2.105)$$

It follows that from Equation (2.105) and the definition of solution rejection [Equation (2.48)] that the rejection of the membrane is

$$\mathbb{R} = \left[1 - 2 \left(1 - \frac{a}{r} \right)^2 + \left(1 - \frac{a}{r} \right)^4 \right] \times 100 \% \quad (2.106)$$

The Ferry–Renkin equation can be used to estimate the pore size of ultrafiltration membranes from the membrane’s rejection of a solute of known radius. The rejections of globular proteins by four typical ultrafiltration membranes plotted against the cube root of the protein molecular weight (an approximate measure of the molecular radius) are shown in Figure 2.33(a). The theoretical curves

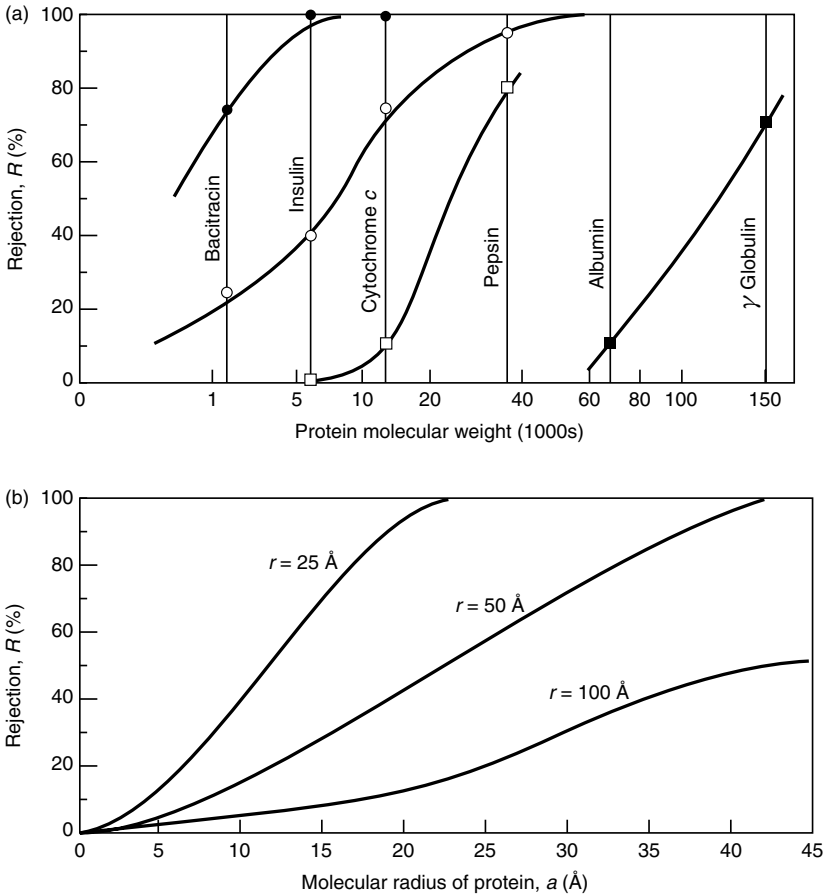

Figure 2.33 (a) Rejection of globular proteins by ultrafiltration membranes of increasing pore size; (b) calculated rejection curves from the Ferry–Renkin equation (2.106) plotted on the same scale [52]

Table 2.5 Marker molecules used to characterize ultrafiltration membranes

Species	Molecular weight ($\times 1000$)	Estimated molecular diameter (\AA)

Bovine albumin	67	64
Aldolase	142	82
γ -Globulin	150	84

calculated from Equation (2.106) are shown directly in Figure 2.33(b) [52]. The abscissae of both figures have been made comparable because the radius of gyration of albumin is approximately 30 \AA . A pore size that appears to be reasonable can then be obtained by comparing the two graphs. This procedure for obtaining an approximate pore size from membrane retention measurements shown in Figure 2.33 has been widely used. Globular proteins are usually the basis for this work because their molecular weights and molecular diameter can be calculated precisely. A list of some commonly used molecular markers is given in Table 2.5.

Depth Filters

The mechanism of particle capture by depth filtration is more complex than for screen filtration. Simple capture of particles by sieving at pore constructions in the interior of the membrane occurs, but adsorption of particles on the interior surface of the membrane is usually at least as important. Figure 2.34 shows four mechanisms that contribute to particle capture in depth membrane filters. The most obvious mechanism, simple sieving and capture of particles at constrictions in the membrane, is often a minor contributor to the total separation. The three other mechanisms, which capture particles by adsorption, are inertial capture, Brownian diffusion and electrostatic adsorption [53,54]. In all cases, particles smaller than the diameter of the pore are captured by adsorption onto the internal surface of the membrane.

In inertial capture, relatively large particles in the flowing liquid cannot follow the fluid flow lines through the membrane's tortuous pores. As a result, such particles are captured as they impact the pore wall. This capture mechanism is

Figure 2.34 Particle capture mechanism in filtration of liquid solutions by depth micro-filters. Four capture mechanisms are shown: simple sieving; electrostatic adsorption; inertial impaction; and Brownian diffusion

more frequent for larger diameter particles. In experiments with colloidal gold particles and depth filtration membranes with tortuous pores approximately $5\ \mu\text{m}$ in diameter, Davis showed that 60 % of $0.05\text{-}\mu\text{m}$ -diameter particles were captured [55]. Nucleation track membranes with $5\text{-}\mu\text{m}$, almost straight-through pores and no tortuosity retained less than 1 % of the particles. The retention of the small particles by the depth filter was caused by the greater tortuosity which led to inertial capture.

The second mechanism is capture by Brownian diffusion, which is more of a factor for smaller particles. Small particles are easily carried along by the moving fluid. However, because the particles are small, they are subject to random Brownian motion that periodically brings them into contact with the pore walls. When this happens, capture by surface adsorption occurs.

The third mechanism is capture of charged particles by membranes having surface-charged groups. Many common colloidal materials carry a slight negative charge, so membranes containing an excess of positive groups can provide enhanced removals. Several microfiltration membrane manufacturers produce this type of charged membrane. One problem is that the adsorption capacity of the charged group is exhausted as filtration proceeds, and the retention falls.

Figure 2.35 Gas-borne particle penetration through an ultrathin PVDF membrane [55,56]

In filtration of gas-borne aerosol particles by microfiltration membranes, capture by adsorption is usually far more important than capture by sieving. This leads to the paradoxical result that the most penetrating particle may not be the smallest one. This is because capture by inertial interception is most efficient for larger particles, whereas capture by Brownian motion is most efficient for smaller particles. As a result the most penetrating particle has an intermediate diameter, as shown in Figure 2.35 [55,56].

Knudsen Diffusion and Surface Diffusion in Microporous Membranes

Essentially all industrial gas separation membranes involve permeation through dense polymeric membranes. But the study of gas permeation through finely microporous membranes has a long history dating back to Graham's work in the 1850s. To date, the only application of these membranes has been the separation of U^{235}F_6 and U^{238}F_6 in the Manhattan project. More recently finely microporous membranes made by carbonizing poly(vinylidene chloride) and other polymers have been developed and taken to the pilot plant scale.

If the pores of a microporous membrane are $0.1 \mu\text{m}$ or larger, gas permeation will take place by normal convective flow described by Poiseuille's law. As

the pore radius (r) decreases it can become smaller than the mean free path (λ) of the gas. (At atmospheric pressure the mean free path of common gases is in the range 500–2000 Å.) When this occurs the ratio of the pore radius to the gas mean free path (r/λ) is less than one. Diffusing gas molecules then have more collisions with the pore walls than with other gas molecules. Gas permeation in this region is called Knudsen diffusion. At every collision with the pore walls, the gas molecules are momentarily adsorbed and then reflected in a random direction. Molecule–molecule collisions are rare, so each gas molecule moves independently of all others. Hence with gas mixtures in which the different species move at different average velocities, a separation is possible. The gas flow in a membrane made of cylindrical right capillaries for Knudsen diffusion is given by Equation (2.103)

$$j = \frac{4r\varepsilon}{3} \cdot \left(\frac{2RT}{\pi m} \right)^{1/2} \cdot \frac{p_o - p_\ell}{\ell \cdot RT} \quad (2.107)$$

where m is the molecular weight of the gas, j is the flux in $\text{gmol}/\text{cm}^2 \cdot \text{s}$, ε is the porosity of the membrane, r is the pore radius, ℓ is the pore length and p_o and p_ℓ are the absolute pressures of the gas species at the beginning of the pore ($x = 0$) and at the end ($x = \ell$).

The equivalent equation for permeation by Poiseuille flow is

$$j = \frac{r^2\varepsilon}{8\eta} \cdot \frac{[p_o - p_\ell][p_o + p_\ell]}{\ell \cdot RT} \quad (2.108)$$

where η is the viscosity of the gas. Equation (2.108) differs from the more familiar Poiseuille equation for liquids by the additional term $[p_o + p_\ell]$ which arises from the expansion of a gas as it moves down the pressure gradient.

Figure 2.36 shows the effect of the ratio r/λ on the relative proportions of Knudsen to Poiseuille flow in a cylindrical capillary [57]. When r/λ is greater than one, Poiseuille flow predominates. Because the mean free path of gases at atmospheric pressure is in the range of 500–2000 Å, for Knudsen flow to predominate and a separation to be obtained, the membrane pore radius must be less than 500 Å.

It follows from Equation (2.107) that the permeability of a gas (i) through a Knudsen diffusion membrane is proportional to $1/\sqrt{m_i}$. The selectivity of this membrane ($\alpha_{i/j}$), proportional to the ratio of gas permeabilities, is given by the expression

$$\alpha_{i/j} = \sqrt{\frac{m_j}{m_i}} \quad (2.109)$$

This result was first observed experimentally by Graham and is called Graham's law of diffusion. Knudsen diffusion membranes have been used to separate gas isotopes that are difficult to separate by other methods, for example tritium from

Figure 2.36 Illustration of the proportion of Knudsen to Poiseuille flow as a function of r/λ (after Barrer) [57]

hydrogen, $C^{12}H_4$ from $C^{14}H_4$ and most importantly $U^{235}F_6$ from $U^{238}F_6$. The membrane selectivity for $U^{235}F_6/U^{238}F_6$ mixtures is only 1.0043, so hundreds of separation stages are required to produce a complete separation. Nevertheless, at the height of the Cold War, the US Atomic Energy Commission operated three plants fitted with microporous metal membranes that processed almost 20 000 tons/year of uranium.

When the pore diameter of a microporous membrane decreases to the 5–10 Å range, the pores begin to separate gases by a molecular sieving effect. The difficulty of making these membranes defect-free has so far prevented their application to industrial separations. However, in the laboratory, spectacular separations have been reported for gases that differ in size by only 0.1 Å. Figure 2.37 shows some data for permeation through microporous silica membranes [58]. No polymeric membranes can match this separation.

Surface adsorption and diffusion add a second contribution to gas permeation that can occur in small-pore-diameter membranes. This phenomenon is shown schematically in Figure 2.38. Adsorption onto the walls of the small pores becomes noticeable when the pore diameter drops below about 100 Å. At this pore diameter the surface area of the pore walls is in the range 100 m²/cm³ of material. Significant amounts of gas then adsorb onto the pore walls, particularly if the gas is condensable. Often the amount of gas sorbed on the pore walls is much greater than the amount of nonsorbed gas. Sorbed gas molecules are mobile and can move by a process of surface diffusion through the membrane according

Figure 2.37 Permeability coefficients as a function of the gas kinetic diameter in microporous silica hollow fine fibers [58]. Reprinted from *J. Membr. Sci.* **75**, A.B. Shelekhin, A.G. Dixon and Y.H. Ma, Adsorption, Permeation, and Diffusion of Gases in Microporous Membranes, 233, Copyright 1992, with permission from Elsevier

to a Fick's law type of expression

$$J_s = -D_s \frac{dc_s}{dx} \quad (2.110)$$

where J_s is the contribution to permeation by surface diffusion of the sorbed gas c_s and D_s is a surface diffusion coefficient. At room temperature, typical surface diffusion coefficients are in the range $1 \times 10^{-3} - 1 \times 10^{-4}$ cm²/s, intermediate between the diffusion coefficients of molecules in gases and liquids [59]. Although these coefficients are less than the diffusion coefficients for nonsorbed gas, surface diffusion still makes a significant contribution to total permeation.

Some typical results illustrating the effect of surface diffusion are shown in Figure 2.39 for permeation of gases through microporous glass [60]. The expected permeability normalized for gas molecular weight, $\mathcal{P}\sqrt{m}$, is constant, but only the very low boiling gases, helium, hydrogen and neon, approach this value. As the condensability of the gas increases (as measured by boiling point or critical temperature) the amount of surface adsorption increases and the contribution of surface diffusion to gas permeation increases. For butane, for example, 80% of the total gas permeation is due to surface diffusion.

In experiments with mixtures of condensable and noncondensable gases, adsorption of the condensable gas component can restrict or even completely block permeation of the noncondensable gas [61,62]. This effect was first noticed by Barrer and Pope in experiments with sulfur dioxide/hydrogen mixtures [63]; some of the data are shown in Figure 2.40. Sorption of sulfur dioxide on the pore walls

and capillary condensation

Figure 2.38 Permeation of noncondensable and condensable gas mixtures through finely microporous membranes. With noncondensable gases molecular sieving occurs when the pore wall reaches the 5- to 10-Å diameter range. With gas mixtures containing condensable gases surface diffusion increases as the pore diameter decreases and the temperature decreases (increasing adsorption)

of the microporous carbon membrane inhibits the flow of hydrogen. If adsorption is increased by increasing the sulfur dioxide partial pressure or by lowering the temperature, sufficient sulfur dioxide is adsorbed to cause capillary condensation of sulfur dioxide in the membrane pores, completely blocking permeation of hydrogen. At this point the membrane only permeates sulfur dioxide.

Hwang and K. Kammermeyer; A. Weissberger (ed.); Copyright © 1975. This material is used by permission of John Wiley & Sons, Inc.

Microporous carbonized hollow fibers were developed over a period of 20 years by Soffer, Koresh, and others (64) at Carbon Membranes Ltd. and were brought to the small module scale. Spectacular separations were reported, but the membranes were difficult to make defect-free and were relatively sensitive to fouling and breaking. More recently, Rao, Sirkar, and others at Air Products tried to use microporous membranes to separate hydrogen/light hydrocarbon gas mixtures found in refinery waste gas streams [65,66]. They also used microporous carbon membranes, this time formed by vacuum carbonization of polymer films cast onto microporous ceramic supports. The adsorbed hydrocarbons permeate the membranes by surface diffusion while permeation of hydrogen in the gas phase is blocked by capillary condensation in the membrane pores. The process was tried at the pilot-plant scale, but eventually abandoned in part because of blocking of the membranes by permanently adsorbed higher hydrocarbons in the feed gas.

Despite these failures, microporous carbon membranes continue to be a subject of research by a number of groups [67–70]. The selectivities obtained are often very good, even for simple gas mixtures such as oxygen/nitrogen or carbon dioxide/methane. However long-term, it is difficult to imagine carbon membranes

Figure 2.40 Blocking of hydrogen in hydrogen/sulfur dioxide gas mixture permeation experiments with finely microporous membranes [63] as a function of the amount of sulfur dioxide adsorbed by the membrane. As sulfur dioxide sorption increases the hydrogen permeability is reduced until at about 140 cm³(SO₂)(STP)/g, the membrane is completely blocked and only sulfur dioxide permeates. Data obtained at several temperatures fall on the same master curve (●, 0°C; ▲, -10°C; □, -20.7°C; △, -33.6°C). Reprinted from R. Ash, R.M. Barrer and C.G. Pope, Flow of Adsorbable Gases and Vapours in Microporous Medium, *Proc. R. Soc. London, Ser. A*, **271**, 19 (1963) with permission from The Royal Society

competing with polymeric membranes for these separations. Carbon membranes are likely to be 10 to 100 times more expensive than equivalent polymeric membranes. This cost differential can only be tolerated in applications in which polymeric membranes completely fail to make the separation. Such applications might be the high-temperature separation of hydrocarbon vapor/vapor mixtures; the chemical and physical stability of ceramic and carbon membranes is a real advantage in this type of separation.

Although the literature of gas separation with microporous membranes is dominated by inorganic materials, polymer membranes have also been tried with some success. The polymers used are substituted polyacetylenes, which can have an extraordinarily high free volume, on the order of 25 vol %. The free volume is so high that the free volume elements in these polymers are probably interconnected. Membranes made from these polymers appear to function as finely microporous materials with pores in the 5 to 15 Å diameter range [71,72]. The two most

widely studied polyacetylenes are poly(1-trimethylsilyl-1-propyne) (PTMSP) and poly(4-methyl-2-pentyne) (PMP), with the structures shown in Figure 2.23. Gas permeabilities in these materials are orders of magnitude higher than those of conventional, low-free-volume glassy polymers, and are even substantially higher than those of poly(dimethylsiloxane), for many years the most permeable polymer known. The extremely high free volume provides a sorption capacity as much as 10 times that of a conventional glassy polymer. More dramatically, diffusion coefficients are 10^3 to 10^6 times greater than those observed in conventional glassy polymers. This combination of extraordinarily high permeabilities, together with the very high free volume, hints at a pore-flow contribution. Nonetheless, the ratio of the diffusion coefficients of oxygen and nitrogen (D_{O_2}/D_{N_2}) is 1.4, a small value for a glassy polymer membrane but still more than would be expected for a simple Knudsen diffusion membrane.

These high-free-volume polymers also have unusual permeability characteristics with mixtures of condensable and noncondensable gases. For example, in the presence of as little as 1200 ppm of a condensable vapor such as the perfluorocarbon FC-77 (a perfluoro octane-perfluoro decane mixture), the nitrogen permeability of PTMSP is 20 times lower than the pure nitrogen permeability [71], as shown in Figure 2.41. When the condensable vapor is removed from the feed gas the nitrogen permeability rapidly returns to its original value. The best

Figure 2.41 The change in nitrogen flux through a PTMSP membrane caused by the presence of a condensable vapor in the feed gas [71]. This behavior is characteristic of extremely finely porous microporous ceramic or ultrahigh-free-volume polymeric membranes such as PTMSP. The condensable vapor adsorbs in the 5- to 15-Å-diameter pores of the membrane, blocking the flow of the noncondensable nitrogen gas

explanation for these unusual vapor permeation properties is that PTMSP, because of its very high free volume, is an ultra-microporous membrane in which pore-flow transport occurs. The FC-77 vapor causes capillary condensation in which the pores are partially or completely blocked by the adsorbed vapor, preventing the flow of noncondensed gases (nitrogen) through the membrane.

The Transition Region

The transition between pore-flow and solution-diffusion transport seems to occur with membranes having very small pores. Ultrafiltration membranes that reject sucrose and raffinose but pass all micro-ions are clearly pore-flow membranes, whereas desalination-grade sodium-chloride-rejecting reverse osmosis membranes clearly follow the solution-diffusion model. Presumably, the transition is in the nanofiltration range, with membranes having good rejections to divalent ions and most organic solutes, but rejection of monovalent ions in the 20–70 % range. The performance of a family of nanofiltration membranes of this type is illustrated in Table 2.6 [73]. The FT30 membrane is clearly a good reverse osmosis membrane, whereas the XP-20 is a very small pore flow ultrafiltration membrane. The XP-45 membrane is intermediate in character.

The transition between reverse osmosis membranes with a salt rejection of more than 95 % and molecular weight cutoffs below 50 and ultrafiltration membranes with a salt rejection of less than 10 % and a molecular weight cutoff of more than 1000 is shown in Figure 2.42 [74]. The very large change in the pressure-normalized flux of water that occurs as the membranes become more retentive is noteworthy. Because these are anisotropic membranes, the thickness of the separating layer is difficult to measure, but clearly the permeability of

water through the pores of ultrafiltration membranes is orders of magnitude higher than permeability through dense solution-diffusion reverse osmosis membranes. Gas permeation also places high-free-volume substituted polyacetylene polymer membranes in the transition area between solution-diffusion and pore flow.

Conclusions and Future Directions

During the last 30 years the basis of permeation through membranes has become much clearer. This is particularly true for reverse osmosis, gas permeation and pervaporation for which the solution-diffusion model is now almost universally accepted and well-supported by a body of experimental evidence. This model provides simple equations that accurately link the driving forces of concentration and pressure with flux and selectivity. The solution-diffusion model has been less successful at providing a link between the nature of the membrane material and the membrane permeation properties. This link requires an ability to calculate membrane diffusion and sorption coefficients. These calculations require knowledge of the molecular level of interactions of permeant molecules and their motion in the polymer matrix that is not yet available. Only semiempirical correlations such as the dual sorption model or free volume correlations are available. The best hope for future progress towards *a priori* methods of calculating permeant sorption and diffusion coefficients lies in computer-aided molecular dynamic simulations, but accurate predictions using this technique are years—perhaps decades—away.

The theory of permeation through microporous membranes in ultrafiltration and microfiltration is much less developed and it is difficult to see a clear path forward. Permeation through these membranes is affected by a variety of hard-to-compute effects and is also very much a function of membrane structure and composition. Measurements of permeation through ideal uniform-pore-diameter membranes made by the nucleation track method are in good agreement with theory. Unfortunately, industrially useful membranes have nonuniform tortuous pores and are often anisotropic as well. Current theories cannot predict the permeation properties of these membranes.

3 MEMBRANES AND MODULES

Introduction

The surge of interest in membrane separation processes that began in the late 1960s was prompted by two developments: first, the ability to produce high flux, essentially defect-free membranes on a large scale and second, the ability to form these membranes into compact, high-surface-area, economical membrane modules. These breakthroughs in membrane technology took place in the 1960s to early 1970s, as part of the development of reverse osmosis and ultrafiltration. Adaptation of the technology to other membrane processes took place in the 1980s.

Several factors contribute to the successful fabrication of a high-performance membrane module. First, membrane materials with the appropriate chemical, mechanical and permeation properties must be selected; this choice is very process-specific. However, once the membrane material has been selected, the technology required to fabricate this material into a robust, thin, defect-free membrane and then to package the membrane into an efficient, economical, high-surface-area module is similar for all membrane processes. Therefore, this chapter focuses on methods of forming membranes and membrane modules. The criteria used to select membrane materials for specific processes are described in the chapters covering each application.

In this chapter membrane preparation techniques are organized by membrane structure: isotropic membranes, anisotropic membranes, ceramic and metal membranes, and liquid membranes. Isotropic membranes have a uniform composition and structure throughout; such membranes can be porous or dense. Anisotropic (or asymmetric) membranes, on the other hand, consist of a number of layers each with different structures and permeabilities. A typical anisotropic membrane has a relatively dense, thin surface layer supported on an open, much thicker microporous substrate. The surface layer performs the separation and is the principal barrier to flow through the membrane. The open support layer provides mechanical strength. Ceramic and metal membranes can be either isotropic or anisotropic.

However, these membranes are grouped separately from polymeric membranes because their preparation methods are so different.

Liquid membranes are the final membrane category. The selective barrier in these membranes is a liquid phase, usually containing a dissolved carrier that selectively reacts with a specific permeant to enhance its transport rate through the membrane. Liquid membranes are used almost exclusively in carrier facilitated transport processes, so preparation of these membranes is covered in that chapter (Chapter 11).

The membrane classification scheme described above works fairly well. However, a major membrane preparation technique, phase separation, also known as phase inversion, is used to make both isotropic and anisotropic membranes. This technique is covered under anisotropic membranes.

Isotropic Membranes

Isotropic Nonporous Membranes

Dense nonporous isotropic membranes are rarely used in membrane separation processes because the transmembrane flux through these relatively thick membranes is too low for practical separation processes. However, they are widely used in laboratory work to characterize membrane properties. In the laboratory, isotropic (dense) membranes are prepared by solution casting or thermal melt-pressing. The same techniques can be used on a larger scale to produce, for example, packaging material.

Solution Casting

Solution casting is commonly used to prepare small samples of membrane for laboratory characterization experiments. An even film of an appropriate polymer solution is spread across a flat plate with a casting knife. The casting knife consists of a steel blade, resting on two runners, arranged to form a precise gap between the blade and the plate onto which the film is cast. A typical hand-held knife is shown in Figure 3.1. After casting, the solution is left to stand, and the solvent evaporates to leave a thin, uniform polymer film. A detailed description of many types of hand casting knives and simple casting machines is given in the book by Gardner and Sward [1].

The polymer solution used for solution casting should be sufficiently viscous to prevent it from running over the casting plate, so typical polymer concentrations are in the range 15–20 wt%. Preferred solvents are moderately volatile liquids such as acetone, ethyl acetate and cyclohexane. Films cast from these solutions are dry within a few hours. Solvents with high boiling points such as dimethyl formamide or *N*-methyl pyrrolidone are unsuitable for solution casting, because their low volatility requires long evaporation times. During an extended solvent evaporation time, the cast film can absorb sufficient atmospheric water to

Figure 3.1 A typical hand-casting knife. (Courtesy of Paul N. Gardner Company, Inc., Pompano Beach, FL)

precipitate the polymer, producing a mottled, hazy surface. Very volatile solvents such as methylene chloride can also cause problems. Rapid evaporation of the solvent cools the casting solution, causing gelation of the polymer. The result is a film with a mottled, orange-peel-like surface. Smooth films can be obtained with rapidly evaporating solvents by covering the cast film with a glass plate raised 1 to 2 cm above the film to slow evaporation. When the solvent has completely evaporated the dry film can be lifted from the glass plate. If the cast film adheres to the plate, soaking in a swelling non-solvent such as water or alcohol will usually loosen the film.

Solution-cast film is produced on a larger scale for medical applications, battery separators, or other specialty uses with machinery of the type shown in Figure 3.2 [2]. Viscous film is made by this technique. The solution is cast onto the surface of a rotating drum or a continuous polished stainless steel belt. These machines are generally enclosed to control water vapor pickup by the film as it dries and to minimize solvent vapor losses to the atmosphere.

Melt Extruded Film

Many polymers, including polyethylene, polypropylene, and nylons, do not dissolve in appropriate solvents at room temperature, so membranes cannot be made by solution casting. To prepare small pieces of film, a laboratory press

Figure 3.2 Machinery used to make solution-cast film on a commercial scale

as shown in Figure 3.3 can be used. The polymer is compressed between two heated plates. Typically, a pressure of 2000–5000 psi is applied for 1–5 min, at a plate temperature just below the melting point of the polymer. Melt extrusion is also used on a very large scale to make dense films for packaging applications, either by extrusion as a sheet from a die or as blown film. Detailed descriptions of this equipment can be found in specialized monographs. A good overview is given in the article by Mackenzie in the *Encyclopedia of Chemical Technology* [2].

Isotropic Microporous Membranes

Isotropic microporous membranes have much higher fluxes than isotropic dense membranes and are widely used as microfiltration membranes. Further significant uses are as inert spacers in battery and fuel cell applications and as the rate-controlling element in controlled drug delivery devices.

The most important type of microporous membrane is formed by one of the phase separation techniques discussed in the next section; about half of the isotropic microporous membrane used is made in this way. The remaining types are made by various proprietary techniques, the more important of which are described below.

Track-etch Membranes

Track-etch membranes were developed by the General Electric Corporation Schenectady Laboratory [3]. The two-step preparation process is illustrated in Figure 3.4. First, a thin polymer film is irradiated with fission particles from a nuclear reactor or other radiation source. The massive particles pass through the film, breaking polymer chains and leaving behind a sensitized track of damaged polymer molecules. These tracks are much more susceptible to chemical attack than the base polymer material. So when the film is passed through a solution

Figure 3.3 A typical laboratory press used to form melt-pressed membranes. (Courtesy of Carver, Inc., Wabash, IN)

that etches the polymer, the film is preferentially etched along the sensitized nucleation tracks, thereby forming pores. The exposure time of the film to radiation determines the number of membrane pores; the etch time determines the pore diameter [4]. A feature of the track-etch preparation technique is that the pores are uniform cylinders traversing the membrane at right angles. The

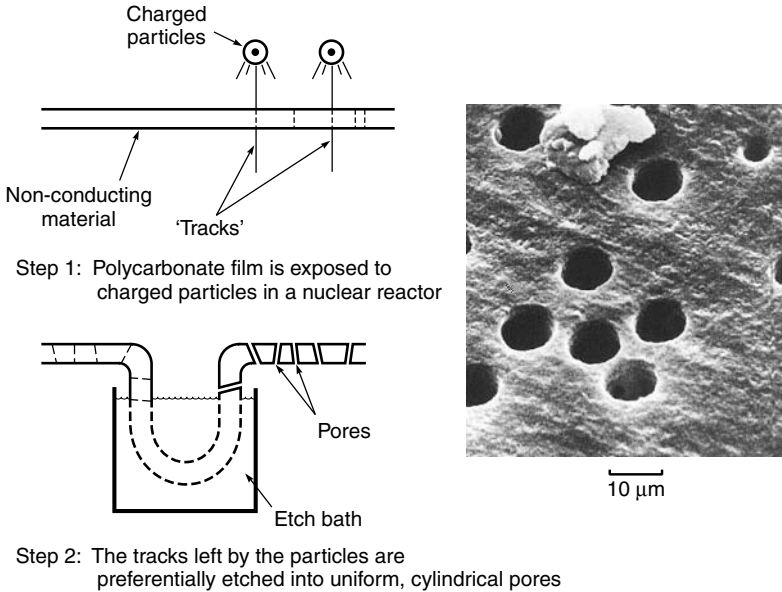

Figure 3.4 Diagram of the two-step process to manufacture nucleation track membranes [4] and photograph of resulting structure. (Photograph courtesy of Whatman plc, Maidstone, Kent, UK)

membrane tortuosity is, therefore, close to one, and all pores have the same diameter. These membranes are almost a perfect screen filter; therefore, they are widely used to measure the number and type of suspended particles in air or water. A known volume of fluid is filtered through the membrane, and all particles larger than the pore diameter are captured on the surface of the membrane so they can be easily identified and counted. To minimize the formation of doublet holes produced when two nucleation tracks are close together, the membrane porosity is usually kept relatively low, about 5% or less. This low porosity results in low fluxes. General Electric, the original developers of these membranes, assigned the technology to a spin-off company, the Nuclepore Corporation, in 1972 [5]. Nuclepore® membranes remain the principal commercially available track-etch membranes. Polycarbonate or polyester films are usually used as the base membrane material and sodium hydroxide as the etching solution. Other materials can also be used; for example, etched mica has been used in research studies.

Expanded-film Membranes

Expanded-film membranes are made from crystalline polymers by an orientation and annealing process. A number of manufacturers produce porous membranes

by this technique. The original development was due to a group at Celanese, which made microporous polypropylene membranes by this process under the trade name Celgard® [6]. In the first step of the process, a highly oriented film is produced by extruding polypropylene at close to its melting point coupled with a very rapid drawdown. The crystallites in the semi-crystalline polymer are then aligned in the direction of orientation. After cooling and annealing, the film is stretched a second time, up to 300%. During this second elongation the amorphous regions between the crystallites are deformed, forming slit-like voids, 200 to 2500 Å wide, between the polymer crystallites. The pore size of the membrane is controlled by the rate and extent of the second elongation step. The formation process is illustrated in Figure 3.5. This type of membrane is also made from poly(tetrafluoroethylene) film by W.L. Gore and sold under the

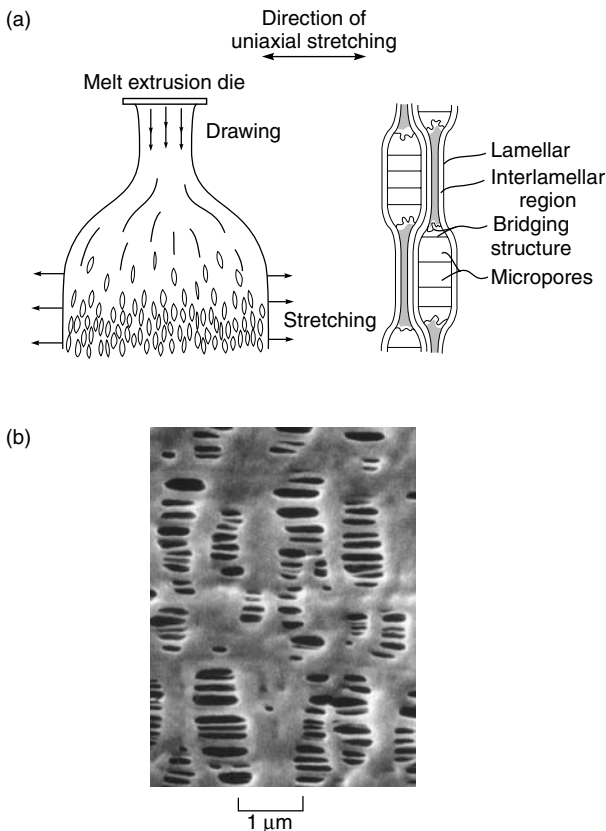

Figure 3.5 (a) Preparation method of a typical expanded polypropylene film membrane, in this case Celgard®. (b) Scanning electron micrograph of the microdefects formed on uniaxial stretching of films [6]

trade name Gore-Tex[®] [7]. Expanded film membrane was originally produced as rolled flat sheets. More recently the process has also been adapted to the production of hollow fibers [8]; Membrana produces this type of fiber on a large scale for use in blood oxygenator equipment (Chapter 12) and membrane contactors (Chapter 13). Gore-Tex poly(tetrafluoroethylene) film is widely used as a water-vapor-permeable (that is, breathable) but liquid-water-impermeable fabric. The commercial success of these membranes has motivated a number of other companies to produce similar materials [9,10].

Template Leaching

Template leaching is another method of producing isotropic microporous membranes from insoluble polymers such as polyethylene, polypropylene and poly(tetrafluoroethylene). In this process a homogeneous melt is prepared from a mixture of the polymeric membrane matrix material and a leachable component. To finely disperse the leachable component in the polymer matrix, the mixture is often homogenized, extruded, and pelletized several times before final extrusion as a thin film. After formation of the film, the leachable component is removed with a suitable solvent, and a microporous membrane is formed [11–13]. The leachable component can be a soluble, low-molecular-weight solid, a liquid such as liquid paraffin, or even a polymeric material such as polystyrene. A drawing of a template leaching membrane production machine is shown in Figure 3.6.

Anisotropic Membranes

Anisotropic membranes are layered structures in which the porosity, pore size, or even membrane composition change from the top to the bottom surface of the membrane. Usually anisotropic membranes have a thin, selective layer supported on a much thicker, highly permeable microporous substrate. Because the selective layer is very thin, membrane fluxes are high. The microporous substrate

Figure 3.6 Flow schematic of a melt extruder system used to make polypropylene membranes by template leaching [13]

provides the strength required for handling the membrane. The importance of anisotropic membranes was not recognized until Loeb and Sourirajan prepared the first high-flux, anisotropic reverse osmosis membranes by what is now known as the Loeb–Sourirajan technique [14]. Hindsight makes it clear that some of the membranes produced in the 1930s and 1940s were also anisotropic. Loeb and Sourirajan's discovery was a critical breakthrough in membrane technology. Their anisotropic reverse osmosis membranes were an order of magnitude more permeable than the isotropic membranes produced previously from the same materials. For a number of years the Loeb–Sourirajan technique was the only method of making anisotropic membranes, but the demonstrated benefits of the anisotropic structure encouraged the development of other methods. Improvements in anisotropic membrane preparation methods and properties were accelerated by the availability in the late 1960s of the scanning electron microscope (SEM), which allowed the effects of changes in the membrane formation process on structure to be assessed easily.

Membranes made by the Loeb–Sourirajan process consist of a single membrane material, but the porosity and pore size change in different layers of the membrane. Anisotropic membranes made by other techniques and used on a large scale often consist of layers of different materials which serve different functions. Important examples are membranes made by the interfacial polymerization process discovered by Cadotte [15] and the solution-coating processes developed by Ward [16], Francis [17] and Riley [18]. The following sections cover four types of anisotropic membranes:

- *Phase separation membranes.* This category includes membranes made by the Loeb–Sourirajan technique involving precipitation of a casting solution by immersion in a nonsolvent (water) bath. Also covered are a variety of related techniques such as precipitation by solvent evaporation, precipitation by absorption of water from the vapor phase, and precipitation by cooling.
- *Interfacial polymerization membranes.* This type of anisotropic membrane is made by polymerizing an extremely thin layer of polymer at the surface of a microporous support polymer.
- *Solution-coated composite membranes.* To prepare these membranes, one or more thin, dense polymer layers are solution coated onto the surface of a microporous support.
- *Other anisotropic membranes.* This category covers membranes made by a variety of specialized processes, such as plasma deposition, in the laboratory or on a small industrial scale to prepare anisotropic membranes for specific applications.

Phase Separation Membranes

The Loeb–Sourirajan technique is now recognized as a special case of a more general class of membrane preparation process, best called the phase separation

Table 3.1 Phase separation membrane preparation procedures

Procedure	Process
Water precipitation (the Loeb–Sourirajan process)	The cast polymer solution is immersed in a nonsolvent bath (typically water). Absorption of water and loss of solvent cause the film to rapidly precipitate from the top surface down
Water vapor absorption	The cast polymer solution is placed in a humid atmosphere. Water vapor absorption causes the film to precipitate
Thermal gelation	The polymeric solution is cast hot. Cooling causes precipitation
Solvent evaporation	A mixture of solvents is used to form the polymer casting solution. Evaporation of one of the solvents after casting changes the solution composition and causes precipitation

process, but sometimes called the phase inversion process or the polymer precipitation process. The term phase separation describes the process most clearly, namely, changing a one-phase casting solution into two separate phases. In all phase separation processes, a liquid polymer solution is precipitated into two phases: a solid, polymer-rich phase that forms the matrix of the membrane and a liquid, polymer-poor phase that forms the membrane pores.

Precipitation of the cast liquid polymer solution to form the anisotropic membrane can be achieved in several ways, as summarized in Table 3.1. Precipitation by immersion in a bath of water was the technique discovered by Loeb and Sourirajan, but precipitation can also be caused by absorption of water from a humid atmosphere. A third method is to cast the film as a hot solution. As the cast film cools, a point is reached at which precipitation occurs to form a microporous structure; this method is called thermal gelation. Finally, evaporation of one of the solvents in the casting solution can be used to cause precipitation. In this technique the casting solution consists of a polymer dissolved in a mixture of a volatile good solvent and a less volatile nonsolvent (typically water or alcohol). When a film of the solution is cast and allowed to evaporate, the volatile good solvent evaporates first, the film then becomes enriched in the nonvolatile nonsolvent, and finally precipitates. Many combinations of these processes have also been developed. For example, a cast film placed in a humid atmosphere can precipitate partly because of water vapor absorption but also because of evaporation of one of the more volatile components.

Polymer Precipitation by Water (the Loeb–Sourirajan Process)

The first phase separation membrane was developed at UCLA from 1958 to 1960 by Sidney Loeb, then working on his Master's degree, and Srinivasa Sourirajan, then a post-doctoral researcher. In their process, now called the Loeb–Sourirajan technique, precipitation is induced by immersing the cast film of polymer solution

in a water bath. In the original Loeb–Sourirajan process, a solution containing 20 to 25 wt% cellulose acetate dissolved in a water-miscible solvent was cast as a thin film on a glass plate. The film was left to stand for 10–100 s to allow some of the solvent to evaporate, after which the film was immersed in a water bath to precipitate the film and form the membrane. The membrane was usually post-treated by annealing in a bath of hot water. The steps of the process are illustrated in Figure 3.7.

The Loeb–Sourirajan process remains by far the most important membrane-preparation technique. The process is part of the overall membrane preparation procedure for almost all reverse osmosis and ultrafiltration and for many gas separation membranes. Reverse osmosis and gas separation membranes made by this technique consist of a completely dense top surface layer (the skin) on top of a microporous support structure. Ultrafiltration membranes, support membranes for solution coating, and interfacial polymerization membranes have the same general anisotropic structure, but the skin layer is very finely microporous, typically with pores in the 10- to 200-Å diameter range. Also, the porous substrate of ultrafiltration membranes is usually more open, often consisting of large finger-like cavities extending from just under the selective skin layer to the bottom surface of the membrane. Scanning electron micrographs of typical sponge-structure reverse-osmosis type and finger-structure ultrafiltration-type membranes are shown in Figure 3.8 [19]. These photographs show how small

Figure 3.7 Process scheme used to form Loeb–Sourirajan water precipitation phase separation membranes [14]

(b) Finger structure cast from 18 wt% Nomex in dimethylacetamide

Figure 3.8 Scanning electron micrographs of aromatic polyamide (Nomex, Du Pont) Loeb–Sourirajan membranes cast from 22 and 18 wt% Nomex in dimethylacetamide [19]

changes in the casting solution can produce major differences in membrane properties. Both membranes are prepared from a Nomex[®] (DuPont, Wilmington, DE) polyamide-dimethylacetamide casting solution, but the polymer concentration in the solutions is different.

The Loeb–Sourirajan water precipitation membranes shown in Figure 3.8 were made by casting the membranes onto glass plates. This procedure is still used in the laboratory, but for commercial production large casting machines produce rolls of membrane up to 5000 m long and 1 to 2 m wide. A diagram of a small casting machine is shown in Figure 3.9. The polymer solution is cast onto a moving nonwoven paper web. The cast film is then precipitated by immersion in a water bath. The water precipitates the top surface of the cast film rapidly,

Figure 3.9 Schematic of Loeb–Sourirajan membrane casting machine used to prepare reverse osmosis or ultrafiltration membranes. A knife and trough are used to coat the casting solution onto a nonwoven paper web. The coated web then enters the water-filled gel tank, where the casting solution precipitates. After the membrane has formed, it is washed thoroughly to remove residual solvent before being wound up on the take-up roll

forming the dense, selective skin. This skin slows entry of water into the underlying polymer solution, which precipitates much more slowly and forms a more porous substructure. Depending on the polymer, the casting solution, and other parameters, the thickness of the dense skin varies from 0.1 to 1.0 μm . Casting machine speeds vary from as low as 1 to 2 m/min for slowly precipitating casting solutions, such as cellulose acetate, to 10 m/min for rapidly precipitating casting solutions, such as polysulfone. A listing of some typical casting solutions and precipitation conditions for membranes made by the Loeb–Sourirajan technique is given in Table 3.2 [14,20–23].

Since the discovery of the Loeb–Sourirajan technique in the 1960s, development of the technology has proceeded on two fronts. Industrial users of the technology have generally taken an empirical approach, making improvements in the technique based on trial and error experience. Concurrently, theories of membrane formation based on fundamental studies of the precipitation process have been developed. These theories originated with the early industrial developers of membranes at Amicon [19,22,24] and were then taken up at a number of academic centers. Unfortunately, much of the recent academic work is so complex that many industrial producers of phase separation membranes no longer follow this literature.

Table 3.2 Historically important examples of conditions for preparation of solution-precipitation (Loeb–Sourirajan) membranes

Casting solution composition	Precipitation conditions	Application and comments
22.2 wt% cellulose acetate (39.8 wt% acetyl polymer) 66.7 wt% acetone 10.0 wt% water 1.1 wt% magnesium perchlorate	3 min evaporation, precipitate into 0 °C water, anneal for 5 min at 65–85 °C	The first Loeb–Sourirajan reverse osmosis membrane [14]
25 wt% cellulose acetate (39.8 wt% acetyl polymer) 45 wt% acetone 30 wt% formamide	0.5–2 min evaporation, cast into 0 °C water, anneal for 5 min at 65–85 °C	The Manjikian formulation widely used in early 1970s for reverse osmosis membranes [20]
8.2 wt% cellulose acetate (39.8 wt% acetyl polymer) 8.2 wt% cellulose triacetate (43.2 wt% acetyl polymer) 45.1 wt% dioxane 28.7 wt% acetone 7.4 wt% methanol 2.5 wt% maleic acid	Up to 3 min evaporation at –10 °C, precipitation into an ice bath, anneal at 85–90 °C for 3 min	A high-performance reverse osmosis cellulose acetate blend membrane [21]
15 wt% polysulfone (Udell P 1700) 85 wt% <i>N</i> -methyl-2-pyrrolidone	Cast into 25 °C water bath. No evaporation or annealing step necessary	An early ultrafiltration membrane formulation [22]. Similar polysulfone-based casting solutions are still widely used
20.9 wt% polysulfone 33.2 wt% dimethyl formamide 33.2 wt% tetrahydrofuran 12.6 wt% ethanol	Forced evaporation with humid air 10–15 s. Precipitate into 20 °C water	A high-performance gas separation membrane with a completely dense nonporous skin ~1000Å thick [23]

Empirical Approach to Membrane Formation by Water Precipitation

Over the years several rules of thumb have developed to guide producers of solution precipitation membranes. These rules can be summarized as follows:

Choice of Polymer. The ideal polymer is a tough, amorphous, but not brittle thermoplastic with a glass transition temperature more than 50 °C above the expected use temperature. A high molecular weight is important. Commercial polymers made for injection molding have molecular weights in the 30 000

to 40 000 Dalton range, but, for solution precipitation, polymers with higher molecular weights are usually preferable. If the polymer is crystalline or a rigid glass, the resulting membrane may be too brittle and will break if bent during later handling. The polymer must also be soluble in a suitable water-miscible solvent. Polymers that meet these specifications include cellulose acetate, polysulfone, poly(vinylidene fluoride), polyetherimide and aromatic polyamides.

Choice of Casting Solution Solvent. Generally the best casting solution solvents are aprotic solvents such as dimethyl formamide, *N*-methyl pyrrolidone and dimethyl acetamide. These solvents dissolve a wide variety of polymers, and casting solutions based on these solvents precipitate rapidly when immersed in water to give porous, very anisotropic membranes. Casting solutions using low-solubility-parameter solvents, such as tetrahydrofuran, acetone, dioxane and ethyl formate, are generally not appropriate. Such casting solutions precipitate slowly and give relatively nonporous membranes. However, small amounts of these solvents may be added as casting solution modifiers (see below). Figure 3.10 illustrates the apparent correlation between solvent solubility parameter and membrane porosity as demonstrated by So *et al.* [25].

Figure 3.10 The porosity of cellulose acetate membranes cast from 15-wt% solutions with various solvents. The same trend of high porosity and rapid precipitation with high solubility-parameter solvents was seen with a number of other membrane materials [25]

Increasing the polymer casting solution concentration always reduces the porosity and flux of the membrane. Typical concentrations for porous ultrafiltration membranes are in the range 15–20 wt%. Polymer casting solution concentrations for reverse osmosis or gas separation membranes are higher, generally about 25 wt%, and casting solutions used to make hollow fiber membranes by spinning a hot solution at 60 to 80 °C may contain as much as 35 % polymer.

Precipitation Medium. Water is almost always the casting solution precipitation medium. Some work has been done with organic solvents, particularly to form hollow fiber membranes for which the mechanical and safety problems of handling an organic solvent precipitation bath and limiting atmospheric emissions are more easily controlled than in flat sheet casting. In general, the results obtained with nonaqueous precipitation baths have not justified the increased complexity of the process. Organic-based solvent precipitation media such as methanol or isopropanol almost always precipitate the casting solution more slowly than water, and the resulting membranes are usually denser, less anisotropic, and lower flux than membranes precipitated with water.

The temperature of the water used to precipitate the casting solution is important; this temperature is controlled in commercial membrane plants. Generally low-temperature precipitation produces lower flux, more retentive membranes. For this reason chilled water is frequently used to prepare cellulose acetate reverse osmosis membranes.

Casting Solution Modifiers. Membrane properties are often tailored by adding small amounts of modifiers to the casting solution. The casting solutions shown in Table 3.2 contain two to four components, but modern commercial casting solutions may be more complex. Even though the solution may contain only 5 to 20 wt% modifiers, these modifiers can change the membrane performance significantly. This aspect of membrane preparation is a black art, and most practitioners have their preferred ingredients. Addition of low solubility solvents such as acetone, tetrahydrofuran or dioxane will normally produce denser, more retentive membranes. Increasing the polymer concentration of the casting solution will also make the membrane more dense. Addition of salts such as zinc chloride and lithium chloride usually gives more open membranes. Polymeric additives may also be used—commonly poly(vinyl pyrrolidone) and poly(ethylene glycol); generally these polymers make the membrane more porous. Also, although most of these water-soluble polymers and salts are removed during precipitation and washing of the membrane, a portion remains trapped, making the final membrane more hydrophilic.

When developing membranes from a new polymer, practitioners of the empirical approach usually prepare a series of trial casting solutions based on past experience with similar polymers. Membrane films are made by casting onto glass plates and precipitation in a water bath. The casting solutions most likely

to yield good membranes are often immediately apparent. The rate of precipitation is important. Slow precipitation produces dense, more isotropic membranes; rapid precipitation produces porous, anisotropic membranes. The appearance and mechanical properties of the membrane surface—shine, brittleness and thickness—compared to casting solution thickness also provide clues to the membrane structure. Based on these trials one or more casting solutions will be selected for systematic parametric development.

Theoretical Approach to Membrane Formation

Over the years several approaches have been used to rationalize the formation of Loeb–Sourirajan (solution precipitation) and other phase inversion membranes. Most have involved the polymer–solvent–precipitation medium phase diagrams popularized by Michaels [22], Strathmann [19,24,26] and Smolders [27–29]. In this approach the change in composition of the casting solution as membrane formation takes place is tracked as a path through the phase diagram. The path starts at a point representing the original casting solution and finishes at a point representing the composition of the final membrane. The casting solution composition moves to the final membrane composition by losing solvent and gaining water.

A typical three-component phase diagram for the components used to prepare Loeb–Sourirajan membranes is shown in Figure 3.11. The corners of the

Figure 3.11 Schematic of the three-component phase diagram often used to rationalize the formation of water-precipitation phase separation membranes

triangle represent the three pure components—polymer, solvent, and nonsolvent (water); points within the triangle represent mixtures of the three components. The diagram has two principal regions: a one-phase region, in which all components are miscible; and a two-phase region, in which the system separates into a solid (polymer-rich) phase and a liquid (polymer-poor) phase. During precipitation of the membrane casting solution, the solution loses solvent and gains water. The casting solution moves from a composition in the one-phase region to a composition in the two-phase region.

Although the one-phase region in the phase diagram is thermodynamically continuous, for practical purposes it can be conveniently subdivided into a liquid polymer solution region, a polymer gel region, and a glassy solid polymer region. Thus, in the low-polymer-concentration region, typical of the original casting solution, the compositions are viscous liquids. But, if the concentration of polymer is increased, the viscosity of compositions in the one-phase region increases rapidly, reaching such high values that the system can be regarded as a solid gel. The transition between the liquid and gel regions is arbitrary but can be placed at a polymer concentration of 30 to 40 wt%. If the one-phase solution contains more than 90 wt% polymer, the swollen polymer gel may become so rigid that the polymer chains can no longer rotate. The polymer gel then becomes a solid polymer glass.

During the precipitation process, the casting solution enters the two-phase region of the phase diagram by crossing the so-called binodal boundary. This brings the casting solution into a metastable two-phase region. Polymer solution compositions in this region are thermodynamically unstable but will not normally precipitate unless well nucleated. The metastable region in the phase diagrams of low-molecular-weight materials is very small, but can be large for high-molecular-weight materials. As more solvent leaves the casting solution and water enters the solution, the composition crosses into another region of the phase diagram in which a one-phase solution is always thermodynamically unstable. In this region, polymer solutions spontaneously separate into two phases with compositions linked by tie lines. The boundary between the metastable and unstable regions is called the spinodal boundary.

Thus, the membrane precipitation process is a series of steps. First, solvent exchange with the precipitation medium occurs. Then, as the composition enters the two-phase region of the phase diagram, phase separation or precipitation begins. The time taken for solvent–water exchange before precipitation occurs can be measured because the membrane turns opaque as soon as precipitation begins. Depending on the casting solution composition, the time to first precipitation may be almost instantaneous to as long as 30–60 s. Initially, the polymer phase that separates on precipitation may be a liquid or semi-liquid gel, and the precipitation domains may be able to flow and agglomerate at this point. In the final step of the precipitation process, desolvation of the polymer phase converts the polymer to a relatively solid gel phase, and the membrane structure

is fixed. The solid polymer phase forms the matrix of the final membrane, and the liquid solvent–nonsolvent phase forms the pores. The precipitation behavior of polymer–solvent mixtures is further complicated by slow kinetics caused by the viscosity of polymer solutions and by thermodynamic effects that allow metastable solutions to exist for a prolonged time without precipitating. Much has been made of these effects in a number of theoretical papers, but application to concretely predicting membrane permeation properties has proved difficult.

The original approach of Strathmann *et al.* [24] was to present the process of membrane formation as a line through the phase diagram. This approach is shown in Figure 3.12. During membrane formation, the composition changes from a composition A, which represents the initial casting solution composition, to a composition D, which represents the final membrane composition. At composition D, the two phases are in equilibrium: a solid (polymer-rich) phase, which forms the matrix of the final membrane, represented by point S, and a liquid (polymer-poor) phase, which constitutes the membrane pores filled with precipitant, represented by point L. The position of composition D on the line S-L determines the overall porosity of the membrane. The entire precipitation process is represented by the path A-D, along which the solvent is exchanged by the precipitant. The point B along the path is the concentration at which the

Figure 3.12 Membrane formation in water-precipitation membranes was first rationalized as a path through the three-component phase diagram from the initial polymer casting solution (A) to the final membrane (D) [24]

polymer initially precipitates. As precipitation proceeds, more solvent is lost, and precipitant is imbibed by the polymer-rich phase, raising the viscosity. At some point, the viscosity is high enough for the precipitated polymer to be regarded as a solid. This composition is at C in Figure 3.12. Once the precipitated polymer solidifies, further bulk movement of the polymer is hindered.

The precipitation path in Figure 3.12 is shown as a single line representing the average composition of the whole membrane. In fact, the rate of precipitation and the precipitation path through the phase diagram differ at different points in the membrane. When the cast film of polymer solution is exposed to the precipitation medium, the top surface begins to precipitate first. This surface layer precipitates rapidly, so the two phases formed on precipitation do not have time to agglomerate. The resulting structure is finely microporous. However, the precipitated surface layer then becomes a barrier that slows further loss of solvent and imbibition of nonsolvent by the cast film. The result is increasingly slow precipitation from the top surface to the bottom surface of the film. As precipitation slows, the average pore size increases because the two phases formed on precipitation have more time to separate. The differences between the precipitation rates and the pathway taken by different places in the casting solution mean that the precipitation process is best represented by the movement of a line through the phase diagram rather than a single point. This concept was developed in a series of papers on phase-separation membranes by Smolders and co-workers at Twente University [27–29]. The movement of this line is illustrated in Figure 3.13 [27]. At time t_2 , for example, a few seconds after the precipitation process has begun, the top surface of the polymer film has almost completely precipitated, and the composition of this surface layer is close to the polymer nonsolvent axis. On the other hand, at the bottom surface of the film where precipitation has only just begun, the composition is close to that of the original casting solution.

In Figure 3.13 the precipitation pathway enters the two-phase region of the phase diagram above the critical point at which the binodal and spinodal lines intersect. This is important because it means that precipitation will occur as a liquid droplet in a continuous polymer-rich phase. If dilute casting solutions are used, in which the precipitation pathway enters the two-phase region of the phase diagram below the critical point, precipitation produces polymer gel particles in a continuous liquid phase. The membrane that forms is then weak and powdery.

The simplified treatment of membrane formation using the three-component phase diagram given above is about as far as this approach can be usefully taken. Experimental measurement of the path taken by the membrane during the formation process is difficult. Recently, much effort has been made to calculate these pathways through the phase diagrams and to use them to predict the effect of membrane formation variables on the fine membrane structure. As quantitative predictors of membrane performance this approach has failed. However, as a tool to qualitatively rationalize the complex interplay of factors determining membrane performance, the phase diagram approach has proved useful. Many of the

Figure 3.13 The surface layer of water-precipitation membranes precipitates faster than the underlying substrate. The precipitation pathway is best represented by the movement of a line through the three-component phase diagram [27]

recent papers describing the application of the phase diagram approach to membrane formation are a heavy read for industrial membrane producers faced with real-world problems. This literature is reviewed in detail elsewhere [27,30–32].

Polymer Precipitation by Cooling

Perhaps the simplest solution-precipitation membrane preparation technique is thermal gelation, in which a film is cast from a hot, one-phase polymer/solvent solution. As the cast film cools, the polymer precipitates, and the solution separates into a polymer matrix phase containing dispersed pores filled with solvent. Because cooling is usually uniform throughout the cast film, the resulting membranes are relatively isotropic microporous structures with pores that can be controlled within 0.1–10 μm .

The precipitation process that forms thermal gelation membranes can be represented by the phase diagram shown in Figure 3.14 and described in an early Akzo patent of Castro [33]. This is a simplified drawing of the actual phase diagram, which was described later in papers by Lloyd *et al.* [34], Vadalía *et al.* [35] and Caneba and Soong [36]. The phase diagram shows the metastable region

and polypropylene form a clear solution at temperatures above 100–150 °C. Upon cooling, the solvent and polymer phases separate to form a microporous structure. If the solution is cooled slowly, an open cell structure of the type shown in Figure 3.15(a) results. The interconnecting passageways between cells are generally in the micrometer range. If the solution is cooled and precipitated

Lloyd (ed.), ACS Symposium Series Number 269, Washington, DC. Copyright 1985, American Chemical Society and American Pharmaceutical Association

rapidly, a much finer structure is formed, as shown in Figure 3.15(b). The rate of cooling is, therefore, a key parameter determining the final structure of the membrane. The anisotropy of the membranes can be increased by cooling the top and bottom surface of the cast film at different rates.

A schematic diagram of a commercial-scale thermal gelation polymer precipitation process is shown in Figure 3.16. The hot polymer solution is cast onto a water-cooled chill roll, which cools the solution, causing the polymer to precipitate. The precipitated film is passed through an extraction tank containing methanol, ethanol or isopropanol to remove the solvent. Finally, the membrane is dried, sent to a laser inspection station, trimmed and rolled up.

Polymer Precipitation by Solvent Evaporation

This technique, one of the earliest methods of making microporous membranes, was used by Bechhold, Elford, Pierce, Ferry and others in the 1920s and 1930s [39–43]. In the simplest form of the method, a polymer is dissolved in a two-component solvent mixture consisting of a volatile solvent, such as methylene chloride or acetone, in which the polymer is readily soluble, and a less volatile nonsolvent, typically water or an alcohol. The polymer solution is cast onto a glass plate. As the volatile solvent evaporates, the casting solution is enriched in the nonvolatile solvent, so the polymer precipitates, forming the membrane structure. The process can be continued until the membrane has completely formed, or it

can be stopped, and the membrane structure fixed, by immersing the cast film in a precipitation bath of water or other nonsolvent. The precipitation process used to form these membranes is much slower than precipitation by immersion into liquid water (the Loeb–Sourirajan process). As a result membranes formed by solvent evaporation are only modestly anisotropic and have large pores. Scanning electron micrographs of some membranes made by this process are shown in Figure 3.17 [44].

Many factors determine the porosity and pore size of membranes formed by the solvent evaporation method. As Figure 3.17 shows, if the membrane is immersed in a nonsolvent after a short evaporation time, the resulting structure will be finely microporous. If the evaporation step is prolonged before fixing the structure by immersion in water, the average pore size will be larger. In general, increasing the nonsolvent content of the casting solution, or decreasing the polymer concentration, increases porosity. It is important for the nonsolvent to be completely incompatible with the polymer. If partially compatible nonsolvents

Figure 3.17 SEM photomicrographs of the bottom surface of cellulose acetate membranes cast from a solution of acetone (volatile solvent) and 2-methyl-2,4-pentanediol (nonvolatile nonsolvent). The evaporation time before the structure is fixed by immersion in water is shown [44]. Reprinted from *J. Membr. Sci.*, **87**, L. Zeman and T. Fraser, Formation of Air-cast Cellulose Acetate Membranes, p. 267, Copyright 1994, with permission from Elsevier

are used, the precipitating polymer phase contains sufficient residual solvent to allow it to flow, and the pores will collapse as the solvent evaporates. The result is a dense rather than a microporous film.

Polymer Precipitation by Absorption of Water Vapor

Preparation of microporous membranes by solvent evaporation alone is not widely practiced. However, a combination of solvent evaporation and absorption of water vapor from a humid atmosphere is an important method of making microfiltration membranes. The processes involve proprietary casting formulations not normally disclosed by membrane developers. However, during the development of composite membranes at Gulf General Atomic, Riley *et al.* prepared this type of membrane and described the technology in some detail in a series of Office of Saline Water Reports [45]. These reports remain the best published description of the technique. Casting solutions used to prepare these membranes are complex and often contain 5 to 10 components. For example, a typical casting solution composition taken from Riley's report [45] comprises 8.1 wt% cellulose nitrate, 1.3 wt% cellulose acetate, 49.5 wt% acetone (a volatile good solvent), 22.3 wt% ethanol and 14.7 wt% *n*-butanol (nonvolatile poor solvents), 2.6 wt% water (a nonsolvent), 0.5 wt% Triton X-100 (a surfactant solution modifier), and 1.2 wt% glycerin (a polymer plasticizer).

The type of equipment used by Riley *et al.* is shown in Figure 3.18. The casting solution is cast onto a moving stainless steel belt. The cast film then passes through a series of environmental chambers. Warm, humid air is usually circulated through the first chamber, where the film loses the volatile solvent by evaporation and simultaneously absorbs water. A key issue is to avoid formation of a dense surface skin on the air side of the membrane. Dense skin formation is

Figure 3.18 Schematic of casting machine used to make microporous membranes by water vapor absorption. A casting solution is deposited as a thin film on a moving stainless steel belt. The film passes through a series of humid and dry chambers, where the solvent evaporates from the solution, and water vapor is absorbed. This precipitates the polymer, forming a microporous membrane that is taken up on a collection roll [45]

generally prevented by incorporating sufficient polymer nonsolvent in the casting solution. Polymer precipitation and formation of two phases then occur when even a small portion of the volatile solvent component in the mixture evaporates. The total precipitation process is slow, taking about 10–30 min to complete. Typical casting speeds are of the order of 1 to 5 ft/min. To allow higher casting speeds the casting machine must be very long—commercial machines can be up to 100 feet. The resulting membrane structure is more isotropic and more microporous than membranes precipitated by immersion in water. After precipitation in the environmental chambers, the membrane passes to a second oven, through which hot, dry air is circulated to evaporate the remaining solvent and dry the film. The formed membrane is then wound onto a take-up roll. This type of membrane is widely used in microfiltration. Membranes made by the water vapor absorption-solvent evaporation precipitation process often have the characteristic nodular form shown in Figure 3.19. A discussion of some of the

Figure 3.19 Characteristic structure of a phase-separation membrane made by water vapor absorption and solvent evaporation. (Courtesy of Millipore Corporation, Billerica, MA)

practical considerations involved in making this type of membrane is given in a recent book by Zeman and Zydney [46].

Interfacial Polymerization Membranes

The production by Loeb and Sourirajan of the first successful anisotropic membranes spawned numerous other techniques in which a microporous membrane is used as a support for a thin, dense separating layer. One of the most important of these was interfacial polymerization, an entirely new method of making anisotropic membranes developed by John Cadotte, then at North Star Research. Reverse osmosis membranes produced by this technique had dramatically improved salt rejections and water fluxes compared to those prepared by the Loeb–Sourirajan process. Almost all reverse osmosis membranes are now made by the interfacial polymerization process, illustrated in Figure 3.20. In this method, an aqueous solution of a reactive prepolymer, such as a polyamine, is first deposited in the pores of a microporous support membrane, typically a polysulfone ultrafiltration membrane. The amine-loaded support is then immersed in a water-immiscible solvent solution containing a reactant, such as a diacid chloride in hexane. The amine and acid chloride react at the interface of the two immiscible

Figure 3.20 Schematic of the interfacial polymerization process. The microporous film is first impregnated with an aqueous amine solution. The film is then treated with a multivalent crosslinking agent dissolved in a water-immiscible organic fluid, such as hexane or Freon-113. An extremely thin polymer film forms at the interface of the two solutions [47]. Reprinted from L.T. Rozelle, J.E. Cadotte, K.E. Cobian, and C.V. Knopp, Jr, Non-poly-saccharide Membranes for Reverse Osmosis: NS-100 Membranes, in *Reverse Osmosis and Synthetic Membranes*, S. Sourirajan (ed.), National Research Council Canada, Ottawa, Canada (1977) by permission from NRC Research Press

solutions to form a densely crosslinked, extremely thin membrane layer. The first membrane made by Cadotte was based on polyethyleneimine crosslinked with toluene-2,4-diisocyanate, to form the structure shown in Figure 3.21 [47]. The process was later refined by Cadotte *et al.* at FilmTec Corp. [15,48], Riley *et al.* at UOP [49], and Kamiyama *et al.* [50] at Nitto in Japan.

Membranes made by interfacial polymerization have a dense, highly crosslinked polymer layer formed on the surface of the support membrane at the interface of the two solutions. A less crosslinked, more permeable hydrogel layer forms under this surface layer and fills the pores of the support membrane. The dense, crosslinked polymer layer, which can only form at the interface, is extremely thin, on the order of $0.1 \mu\text{m}$ or less, so the membrane permeability is high. Because the polymer is highly crosslinked, its selectivity is also high. Although the crosslinked interfacial polymer layer determines membrane selectivity, the nature of the microporous support film affects membrane flux

Figure 3.21 Idealized structure of polyethyleneimine crosslinked with toluene 2,4-diisocyanate. This was called the NS-100 membrane. The chemistry was first developed by Cadotte to make interfacial reverse osmosis membranes with almost twice the water flux and one-fifth the salt leakage of the best reverse osmosis membranes then available. Even better membranes have since been developed by Cadotte and others [47]

significantly. The film has to be very finely porous to withstand the high pressures applied but must also have a high surface porosity so it is not a barrier to flow. The first reverse osmosis membranes made by the interfacial polymerization method were five times less salt-permeable than the best cellulose acetate Loeb–Sourirajan membranes but had better water fluxes. Since then interfacial polymerization chemistry has been refined. The first membrane produced by this method (and shown in Figure 3.21) was based on the reaction of a polyethyleneimine (in water) and toluene-2,4-diisocyanate or isophthaloyl chloride (in hexane). These NS-100 membranes had very good permeation properties but were very sensitive to even trace amounts (ppb levels) of chlorine commonly used as an antibacterial agent in water. The chlorine caused chain cleavage of the polymer at the amide bonds resulting in loss of salt rejection. A number of other chemistries have been developed over the years; the FT-30 membrane produced by reaction of phenylenediamine with trimesoyl chloride, also developed by Cadotte when at FilmTec (Dow Chemical), is particularly important. This membrane, which has a high water flux and consistent salt rejections of greater than 99.5% with seawater [51], made single-pass seawater desalination with anisotropic membranes possible. A more detailed description of the chemistry of interfacial composite membranes is given in the discussion of reverse osmosis membranes in Chapter 5 and in a review by Petersen [48].

Production of interfacial polymerization membranes in the laboratory is relatively easy, but development of equipment to produce these membranes on a large scale required some ingenuity. The problem is the fragility of the interfacial surface film, which cannot be handled once formed. One solution to this problem is illustrated in Figure 3.22. The polysulfone or other material used as the support film is first immersed in an aqueous amine bath. On leaving this bath the membrane passes to a second organic acid chloride bath and then through a drying/curing oven. The transfer rollers are arranged so that the surface layer of the polymer on which the membrane forms never contacts a roller. On leaving the oven, the interfacial membrane is completely formed. This membrane is then coated with a protective solution of a water-soluble polymer such as poly(vinyl alcohol). When this solution is dried, the membrane is wound onto a take-up roll. The poly(vinyl alcohol) layer protects the membrane from damage during subsequent handling as it is formed into spiral-wound modules. When the module is used for the first time, the feed water washes off the water-soluble poly(vinyl alcohol) layer to expose the interfacial polymerized membrane, and the module is ready for use.

Interfacial polymerization membranes are widely used in reverse osmosis and nanofiltration but not for gas separation because of the water-swollen hydrogel that fills the pores of the support membrane. In reverse osmosis, this layer is hydrated and offers little resistance to water flow, but when the membrane is dried for use in gas separation the gel becomes a rigid glass with very low gas permeability. This glassy polymer fills the membrane pores and, as a result, defect-free

Figure 3.22 Schematic of the type of machinery used to make interfacial composite membranes

interfacial composite membranes usually have low gas fluxes, although their selectivities can be good.

Solution-coated Composite Membranes

Another important group of anisotropic composite membranes is formed by solution-coating a thin ($0.5\text{--}2.0\ \mu\text{m}$) selective layer on a suitable microporous support. Membranes of this type were first prepared by Ward, Browall, and others at General Electric [52] and by Forester and Francis at North Star Research [17,53] using a type of Langmuir trough system. In this system, a dilute polymer solution in a volatile water-insoluble solvent is spread over the surface of a water-filled trough.

The apparatus used to make small sections of water-cast composite membranes is shown in Figure 3.23. The dilute polymer solution is cast on the surface between two Teflon rods. The rods are then moved apart to spread the film. The thin polymer film formed on the water surface is picked up on a microporous support. The main problem with this method is the transfer of the fragile, ultrathin film onto the microporous support. This is usually done by sliding the support

Figure 3.23 Schematic of the apparatus developed by Ward *et al.* [52] to prepare water-cast composite membranes. Reprinted from *J. Membr. Sci.*, **1**, W.J. Ward, III, W.R. Browall and R.M. Salemme, *Ultrathin Silicone Rubber Membranes for Gas Separations*, p. 99, Copyright 1976, with permission from Elsevier

membrane under the spread film. With care, small pieces of membrane as thin as 200 \AA can be made.

The water-casting procedure was scaled up to produce continuous composite membrane films at General Electric. Figure 3.24 shows a schematic of the system used to produce composite polycarbonate-silicone copolymer membranes for small air separation units to produce oxygen-enriched air for medical use. The polymer casting solution added to the surface of the water bath spreads as a thin film and is picked up on the moving microporous support membrane. Membranes as thin as $0.1\text{--}0.2 \text{ }\mu\text{m}$ can be made. This water-casting technique was used at General Electric and its spinoff, the Oxygen Enrichment Company, to make gas separation membranes for several years in the 1970s. The technique has also been adapted to coat hollow fiber membranes for gas separation applications [54,55].

Currently, most solution-coated composite membranes are prepared by the method first developed by Riley and others [45,56,57]. In this technique, a polymer solution is cast directly onto the microporous support. The support must be clean, defect-free and very finely microporous, to prevent penetration of the coating solution into the pores. If these conditions are met, the support can be coated with a liquid layer $50\text{--}100 \text{ }\mu\text{m}$ thick, which after evaporation leaves a thin selective film $0.5\text{--}2 \text{ }\mu\text{m}$ thick. A schematic drawing of the meniscus-coating technique is shown in Figure 3.25 [58]. Obtaining defect-free films by this technique requires considerable attention to the preparation procedure and the coating solution.

Figure 3.24 Method developed by Ward, Browall and others at General Electric to make multilayer composite membranes by the water casting technique [55]

The characteristics of the microporous support are very important. Because the selective layer is extremely thin, the support layer can contribute significantly to the total resistance to transport through the membrane. Not only does the resistance of the support decrease the flux through the membrane, but it can affect the separation [32,59]. To achieve the intrinsic selectivity of the selective membrane layer, the flux of the uncoated support material must be at least 10 times that of the coated support. This ensures that more than 90% of the resistance to flow lies within the selective coating layer. As well as having a high flux, the surface layer of the microporous support material must also be very finely microporous. The pores must be small enough to support the thin selective layer under high pressure, and must also be close together so the permeating components do not take a long tortuous path to reach the pore. When the selective layer is only a few tenths of a micrometer thick this requirement may be difficult to meet. One solution to the problem is an intermediate gutter layer of a highly permeable polymer between the microporous support and the selective layer. The gutter layer material is much more permeable than the thin selective layer and acts as a conduit to transport material to the support membrane pores. Finally, because the selective layer of the composite membrane is often very thin and correspondingly delicate, such membranes are often protected by a sealing layer, also formed from a highly permeable material, to protect the membrane from damage during handling. A schematic of a multilayer composite membrane of this type is shown in Figure 3.26 together with a scanning electron micrograph. A discussion of the issues involved in preparing this type of membrane is found in the review by Koros and Pinnau [32].

Figure 3.25 Schematic diagram of a film coating apparatus [58]

Other Anisotropic Membranes

Most anisotropic membranes are produced by solution precipitation, interfacial polymerization or solution coating. A number of other techniques developed in the laboratory are reviewed briefly below; none are used on a large scale.

Plasma Polymerization Membranes

Plasma polymerization of films was first used to form electrical insulation and protective coatings, but a number of workers have also prepared selective membranes by this method [60–63]. A simple plasma polymerization apparatus is

Figure 3.26 Schematic and scanning electron micrograph of a multilayer composite membrane on a microporous support. (Courtesy of Membrane Technology and Research, Inc.)

shown in Figure 3.27. Most workers used radio frequency fields at frequencies of 2–50 MHz to generate the plasma. In a typical plasma experiment helium, argon, or another inert gas is introduced at a pressure of 50–100 mTorr and a plasma is initiated. Monomer vapor is then introduced to bring the total pressure to 200–300 mTorr. These conditions are maintained for a period of 1–10 min, during which a thin polymer film is deposited on the membrane sample held in the plasma field.

Figure 3.27 Simple bell jar plasma coating apparatus

Monomer polymerization proceeds by a complex mechanism involving ionized molecules and radicals and is completely different from conventional polymerization reactions. In general, the polymer films are highly crosslinked and may contain radicals that slowly react on standing. The stoichiometry of the film may also be quite different from the original monomer due to fragmentation of monomer molecules during the plasma polymerization process. The susceptibility of monomers to plasma polymerization or the characteristics of the resulting polymer film are difficult to predict. For example, many vinyl and acrylic monomers polymerize very slowly, whereas unconventional monomers such as benzene and hexane polymerize readily. The vapor pressure of the monomers, the power and voltage used in the discharge reaction, and the type and temperature of the substrate all affect the polymerization reaction. The inert gas used in the plasma may also enter into the reaction. Nitrogen and carbon monoxide, for example, are particularly reactive. In summary, the products of plasma polymerization are ill-defined and vary according to the experimental procedures. However, the resulting films can be very thin and have been shown to be quite selective.

The most extensive studies of plasma-polymerized membranes were performed in the 1970s and early 1980s by Yasuda, who tried to develop high-performance reverse osmosis membranes by depositing plasma films onto microporous poly-sulfone films [60,61]. More recently other workers have studied the gas permeability of plasma-polymerized films. For example, Stancell and Spencer [62] were able to obtain a gas separation plasma membrane with a hydrogen/methane selectivity of almost 300, and Kawakami *et al.* [63] have reported plasma membranes

with an oxygen/nitrogen selectivity of 5.8. Both selectivities are good compared to those of other membranes, and the plasma films were also quite thin. However, in both cases the plasma film was formed on a substrate made from a thick (25–100 μm), dense polymer film, so the flux through the composite membrane was still low. Scale-up of plasma polymerization is likely to prove difficult, so the process will remain a laboratory technique until membranes with unique properties are produced.

Dynamically Formed Membranes

In the late 1960s and early 1970s, much attention was devoted to preparing dynamically formed anisotropic membranes, principally by Johnson, Kraus and others at Oak Ridge National Laboratory [64,65]. The general procedure is to form a layer of inorganic or polymeric colloids on the surface of a microporous support membrane by filtering a solution containing suspended colloid through the support membrane. A thin colloidal layer is laid down on the membrane surface and acts as a semipermeable membrane. Over time the colloidal surface layer is lost, and membrane performance falls. The support membrane is then cleaned, and a new layer of colloid is deposited. In the early development of this technique a wide variety of support membranes were used. Recently, microporous ceramic or porous carbon tubes have become the most commonly used materials. Typical colloidal materials used to make the selective membrane layer are polyvinyl methyl ether, acrylic acid copolymers or hydrated metal oxides such as zirconium hydroxide.

Dynamically formed membranes were pursued for many years for reverse osmosis because of their high water fluxes and relatively good salt rejection, especially with brackish water feeds. However, the membranes proved to be unstable and difficult to reproduce reliably and consistently. For these reasons, and because high-performance interfacial composite membranes were developed in the meantime, dynamically formed reverse osmosis membranes fell out of favor. A small application niche in high-temperature nanofiltration and ultrafiltration remains, and Rhône Poulenc continues their production. The principal application is poly(vinyl alcohol) recovery from hot wash water produced in textile dyeing operations.

Reactive Surface Treatment

Recently several groups have tried to improve the properties of anisotropic gas separation membranes by chemically modifying the surface selective layer. For example, Langsam at Air Products and Paul *et al.* at the University of Texas, Austin have treated films and membranes with dilute fluorine gas [66–71]. In this treatment fluorine chemically reacts with the polymer structure. By careful

Table 3.3 Effect of fluorination on the carbon dioxide/methane selectivity of various glassy membrane materials

Base polymer	Carbon dioxide/methane selectivity	
	Before fluorination	After fluorination
Poly(1-trimethylsilyl-1-propyne) (PTMSP) [69]	2.0	48
Poly(phenylene oxide) [71]	15	50–60
Poly(4-methyl-1-pentene) [70]	5.4	30–40

control of the process conditions, the reaction can be limited to a 100- to 200-Å surface layer. The dramatic improvements in selectivity produced by this surface treatment are illustrated by the data in Table 3.3. Scaling up this process for safe operation on a large scale will be difficult, but several groups are studying the approach. Ozone has also been suggested as a possible reactive surface treatment agent [72].

Repairing Membrane Defects

In preparing anisotropic membranes, the goal is to make the selective layer that performs the separation as thin as possible, but still defect free. Over the past 20 years, a great deal of work has been devoted to understanding the factors that determine the properties and thickness of the selective layer. The selective layer can be dense, as in reverse osmosis or gas separation membranes, or finely microporous with pores in the 100- to 500-Å diameter range, as in ultrafiltration membranes. In good quality membranes a thickness as low as 500–1000 Å can be achieved, but with layers as thin as this, formation of minute membrane defects is a problem. The defects, caused by gas bubbles, dust particles and support fabric imperfections, can be very difficult to eliminate. Such defects may not significantly affect the performance of anisotropic membranes used in liquid separation processes, such as ultrafiltration and reverse osmosis, but can be disastrous in gas separation applications. Browall [55] solved this problem by overcoating defective solution-cast composite membranes with a second thin coating layer of a highly permeable polymer to seal defects, as shown in Figure 3.28.

Later Henis and Tripodi [73] showed that membrane defects in anisotropic Loeb–Sourirajan membranes could be overcome in a similar way by coating the membrane with a thin layer of a relatively permeable material such as silicone rubber. A sufficiently thin coating does not change the properties of the underlying selective layer but does plug defects, through which simple convective gas flow can occur. Henis and Tripodi's membrane is illustrated in Figure 3.29. The silicone rubber layer is many times more permeable than the selective layer and

Figure 3.28 Method developed by Ward, Browall and others at General Electric to seal membrane defects in composite membranes made by the water coating technique [55]

(a) Defective Loeb-Sourirajan anisotropic membrane

(b) Henis and Tripodi silicone rubber-coated membrane

Figure 3.29 Schematic of (a) Loeb–Sourirajan and (b) Henis and Tripodi gas separation membranes [73]

does not function as a selective barrier but rather plugs defects, thereby reducing non-diffusive gas flow. The flow of gas through the portion of the silicone rubber layer over the pore is high compared to the flow through the defect-free portion of the membrane. However, because the area of membrane defects is very small, the total gas flow through these plugged defects is negligible. When this coating technique is used, the polysulfone skin layer of the Loeb–Sourirajan membrane no longer has to be completely defect free; therefore, the membrane can be made with a thinner skin than is possible with an uncoated membrane. The increase in flux obtained by decreasing the thickness of the selective skin layer more than compensates for the slight reduction in flux due to the silicone rubber sealing layer.

Metal Membranes and Ceramic Membranes

Metal Membranes

Metal membranes, particularly palladium-based, have been considered for hydrogen separation for a long time. In the 1950s and 1960s, Union Carbide installed and operated a palladium membrane plant to separate hydrogen from a refinery off-gas stream [74]. The plant produced 99.9% pure hydrogen in a single pass through 25- μm -thick palladium membranes. However, even at a feed pressure of 450 psi, the membranes had to be operated at 370 °C to obtain a useful trans-membrane hydrogen flux. A further problem was the very high membrane cost; a 25- μm -thick palladium membrane requires approximately 250 g palladium/m² of membrane. At current palladium costs of US\$20/g, the metal cost alone is US\$5000/m² of membrane, which is 50 times the total cost of typical polymeric membranes used for gas separations. Small-scale palladium membrane systems, to produce ultrapure hydrogen for specialized applications, are marketed by Johnson Matthey and Company. These systems use palladium/silver alloy membranes based on those developed by Hunter [75,76].

If noble metal membranes are ever to be used on a large scale their cost must be reduced. One approach [77,78] is to sputter-coat a 500- to 1000-Å film of the metal on a polymer support. Because the film is extremely thin these membranes have extremely high hydrogen fluxes even at room temperature. Another approach, used by Buxbaum [79,80], is to coat a thin layer of palladium on a tantalum or vanadium support film. Tantalum and vanadium are also quite permeable to hydrogen and much less expensive than palladium. These metals cannot be used alone because they easily form an impenetrable oxide surface film. However, protected by a thin palladium layer, these membranes are quite permeable at high temperatures. Edlund [81,82] is pursuing a similar approach. A detailed discussion of hydrogen permeation in metals is given in the book by Alefeld and Völkl [83].

Ceramic Membranes

Metal Oxide Membranes

Several companies have developed inorganic ceramic membranes for ultrafiltration and microfiltration. These microporous membranes are made from aluminum, titanium or silica oxides. Ceramic membranes have the advantages of being chemically inert and stable at high temperatures, conditions under which polymer membranes fail. This stability makes ceramic microfiltration/ultrafiltration membranes particularly suitable for food, biotechnology and pharmaceutical applications in which membranes require repeated steam sterilization and cleaning with aggressive solutions. Pore diameters in ceramic membranes for microfiltration and ultrafiltration range from 0.01 to 10 μm ; these membranes are generally made by a slip coating-sintering procedure. Other techniques, particularly sol-gel methods, are used to produce membranes with pores from 10 to 100 \AA . Sol-gel membranes are the subject of considerable research interest particularly for gas separation applications, but so far have found only limited commercial use. A number of reviews covering the general area of ceramic membrane preparation and use have appeared recently [84,85].

In the slip coating-sintering process a porous ceramic support tube is made by pouring a dispersion of a fine-grain ceramic material and a binder into a mold and sintering at high temperature. The pores between the particles that make up this support tube are large. One surface of the tube is then coated with a suspension of finer particles in a solution of a cellulosic polymer or poly(vinyl alcohol) which acts as a binder and viscosity enhancer to hold the particles in suspension. This mixture is called a slip suspension; when dried and sintered at high temperatures, a finely microporous surface layer remains. Usually several slip-coated layers are applied in series, each layer being formed from a suspension of progressively finer particles and resulting in an anisotropic structure. Most commercial ceramic ultrafiltration membranes are made this way, generally in the form of tubes or perforated blocks. A scanning electron micrograph of the surface of this type of multilayer membrane is shown in Figure 3.30.

The slip coating-sintering procedure can be used to make membranes with pore diameters down to about 100–200 \AA . More finely porous membranes are made by sol-gel techniques. In the sol-gel process slip coating is taken to the colloidal level. Generally the substrate to be coated with the sol-gel is a microporous ceramic tube formed by the slip coating-sintering technique. The solution coated onto this support is a colloidal or polymeric gel of an inorganic hydroxide. These solutions are prepared by controlled hydrolysis of metal salts or metal alkoxides to hydroxides.

Sol-gel methods fall into two categories, depending on how the colloidal coating solution is formed. The processes are shown schematically in Figure 3.31

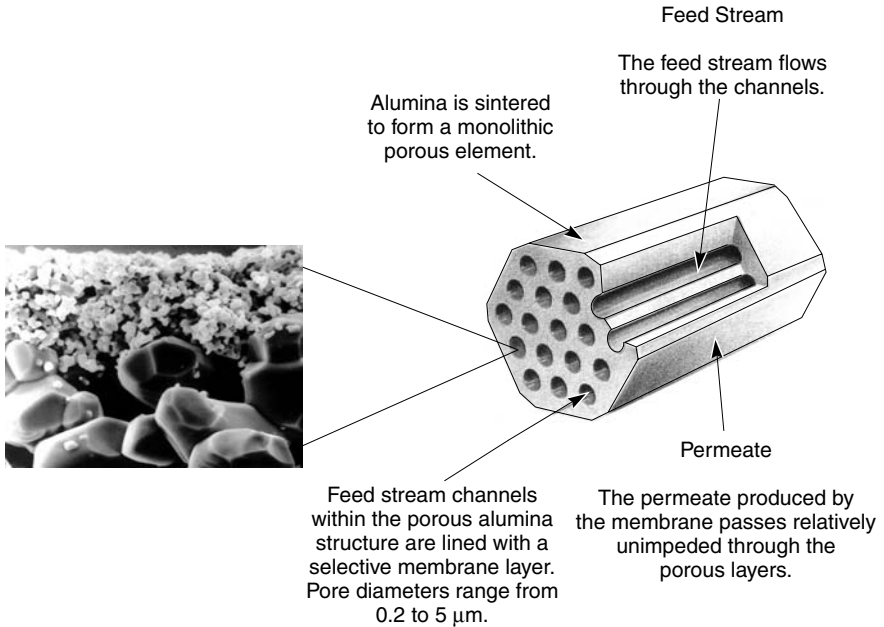

Figure 3.30 Cross-sectional scanning electron micrograph of a three-layered alumina membrane/support (pore sizes of 0.2, 0.8 and 12 μm , respectively). (Courtesy of Pall Corporation, Filterite Division, Timonium, MD)

[86–88]. In the particulate-sol method a metal alkoxide dissolved in alcohol is hydrolyzed by addition of excess water or acid. The precipitate that results is maintained as a hot solution for an extended period during which the precipitate forms a stable colloidal solution. This process is called peptization from the Greek *pep*—to cook (not a misnomer; many descriptions of the sol-gel process have a strong culinary flavor). The colloidal solution is then cooled and coated onto the microporous support membrane. The layer formed must be dried carefully to avoid cracking the coating. In the final step the film is sintered at 500–800 $^{\circ}\text{C}$. The overall process can be represented as:

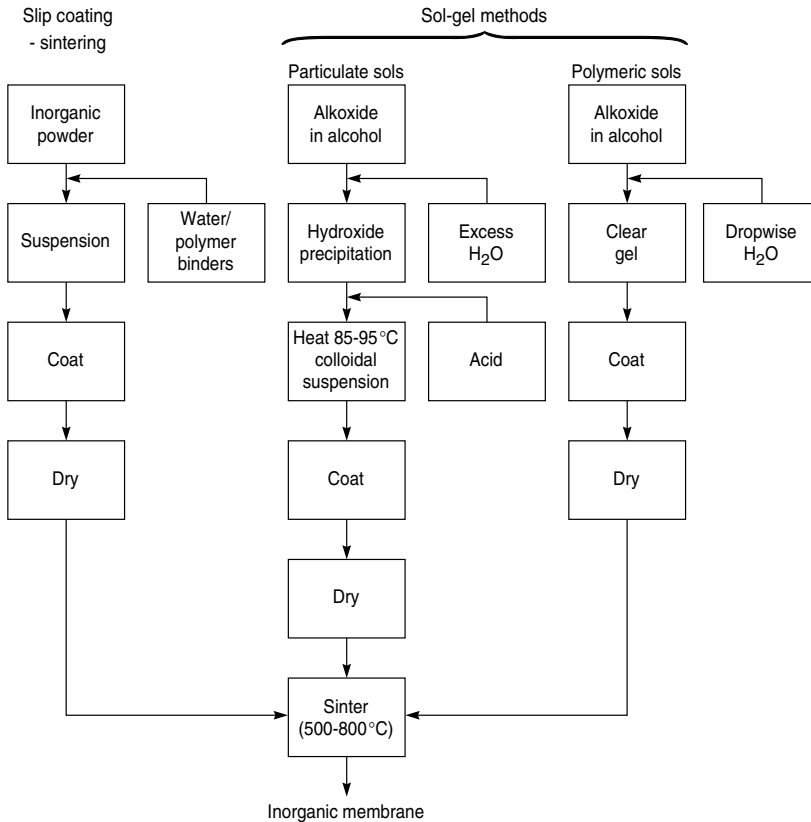

Figure 3.31 Slip coating-sintering and sol-gel processes used to make ceramic membranes

In the polymeric sol-gel process, partial hydrolysis of a metal alkoxide dissolved in alcohol is accomplished by adding the minimum of water to the solution. The active hydroxyl groups on the alkoxides then react to form an inorganic polymer molecule that can then be coated onto the ceramic support. On drying and sintering, the metal oxide film forms. Chemically the polymeric sol-gel process can be represented as:

Depending on the starting material and the coating procedure, a wide range of membranes can be made by the sol-gel process. The problem of cracking the films on drying and sintering can be alleviated by adding small amounts of a polymeric binder to the coating solution. The coating process may also be repeated several times to give a defect-free film. With care, membranes with pore sizes in the 10- to 100-Å range can be made by this method. In principle these membranes could be useful in a number of processes—membrane reactors, for example. Currently the technology is still at the laboratory stage.

Microporous Carbon Membranes

The first microporous carbon membranes were produced by Barrer in the 1950s and 1960s by compressing high-surface-area carbon powders at very high pressures [89,90]. The resulting porous plugs had pores of 5- to 30-Å diameter and were used to study diffusion of gases and vapors. More recently, practical ways of producing microporous carbon membranes have been developed by Koresh and Soffer [91], Hayashi *et al.* [92] and at Air Products by Rao and Sirkar [93]. All three groups are producing extremely finely microporous carbon membranes by pyrolyzing preformed polyimide or polyacrylonitrile membranes in an inert atmosphere or vacuum at 500 to 800 °C. Under these conditions the polymer is converted to carbon. Permeation properties show that the carbon membranes have pores from 10 to 20 Å diameter. The Air Products membranes are made as thin films coated onto a ceramic support. The membranes of Koresh and Soffer are made as hollow fine fibers. These membranes are brittle and difficult to produce on a large scale, but have exceptional separation properties for some gas mixtures.

Microporous Glass Membranes

Microporous glass membranes in the form of tubes and fibers have been made by Corning, PPG, and Schott. Currently only the Corning membranes are still available, under the trade name Vycor®. The leaching process used to make this type of membrane has been described by Beaver [94]. The starting material is a glass containing 30–70 % silica, as well as oxides of zirconium, hafnium or titanium and extractable materials. The extractable materials comprise one or more boron-containing compounds and alkali metal oxides and/or alkaline earth metal oxides. Glass hollow fibers produced by melt extrusion are treated with dilute hydrochloric acid at 90 °C for 2–4 h to leach out the extractable materials, washed to remove residual acid, and then dried.

Liquid Membranes

Liquid membranes containing carriers to facilitate selective transport of gases or ions were the subject of a considerable research effort in the 1970s and 1980s.

A number of published reviews summarize this work [95,96]. Although these membranes are still being studied in a number of laboratories, improvements in selective conventional polymer membranes have diminished interest in processes using liquid membranes. The preparation and use of these membranes are described in Chapter 11.

Hollow Fiber Membranes

The membrane preparation techniques described so far were developed to produce flat-sheet membranes. However, these techniques can be adapted to produce membranes in the form of thin tubes or fibers. An important advantage of hollow fiber membranes is that compact modules with very high membrane surface areas can be formed. However, this advantage is offset by the generally lower fluxes of hollow fiber membranes compared to flat-sheet membranes made from the same materials. Nonetheless, the development of hollow fiber membranes by Mahon and the group at Dow Chemical in 1966 [97] and their later commercialization by Dow, Monsanto, Du Pont, and others represents one of the major events in membrane technology. A good review of the early development of hollow fiber membranes is given by Baum *et al.* [98]. Reviews of more recent developments are given by Moch [99] and McKelvey *et al.* [100].

The diameter of hollow fibers varies over a wide range, from 50 to 3000 μm . Fibers can be made with a uniformly dense structure, but preferably are formed as a microporous structure having a dense selective layer on either the outside or the inside surface. The dense surface layer can be either integral with the fiber or a separate layer coated onto the porous support fiber. Many fibers must be packed into bundles and potted into tubes to form a membrane module; modules with a surface area of even a few square meters require many kilometers of fibers. Because a module must contain no broken or defective fibers, hollow fiber production requires high reproducibility and stringent quality control.

The types of hollow fiber membranes in production are illustrated in Figure 3.32. Fibers of 50- to 200- μm diameter are usually called hollow fine fibers. Such fibers can withstand very high hydrostatic pressures applied from the outside, so they are used in reverse osmosis or high-pressure gas separation applications in which the applied pressure can be 1000 psig or more. The feed fluid is applied to the outside (shell side) of the fibers, and the permeate is removed down the fiber bore. When the fiber diameter is greater than 200–500 μm , the feed fluid is commonly applied to the inside bore of the fiber, and the permeate is removed from the outer shell. This technique is used for low-pressure gas separations and for applications such as hemodialysis or ultrafiltration. Fibers with a diameter greater than 500 μm are called capillary fibers.

Two methods are used to prepare hollow fibers: solution spinning and melt spinning [98,99]. The most common process is solution spinning or wet spinning, in which a 20–30 wt% polymer solution is extruded and precipitated

Figure 3.32 Schematic of the principal types of hollow fiber membranes

into a nonsolvent, generally water. Fibers made by solution spinning have the anisotropic structure of Loeb–Sourirajan membranes. This technique is generally used to make relatively large, porous hemodialysis and ultrafiltration fibers. In the alternative technique of melt spinning, a hot polymer melt is extruded from an appropriate die and is then cooled and solidified in air prior to immersion in a quench tank. Melt-spun fibers are usually denser and have lower fluxes than solution-spun fibers, but, because the fiber can be stretched after it leaves the die, very fine fibers can be made. Melt-spun fibers can also be produced at high speeds. The technique is usually used to make hollow fine fibers for high-pressure reverse osmosis and gas separation applications and is also used with polymers such as poly(trimethylpentene), which are not soluble in convenient solvents and are difficult to form by wet spinning. The distinction between solution spinning and melt spinning has gradually faded over the years. To improve fluxes, solvents and other additives are generally added to melt spinning dopes so spinning temperatures have fallen considerably. Many melt-spun fibers are now produced from spinning dopes containing as much as 30 to 60 wt% solvent, which requires the spinner to be heated to only 70–100 °C to make the dope flow. These fibers are also often cooled and precipitated by spinning into a water bath, which also helps to form an anisotropic structure.

The first hollow fiber spinneret system was devised by Mahon at Dow [97]. Mahon's spinneret consists of two concentric capillaries, the outer capillary

having a diameter of approximately $400\ \mu\text{m}$, and the central capillary having an outer diameter of approximately $200\ \mu\text{m}$ and an inner diameter of $100\ \mu\text{m}$. Polymer solution is forced through the outer capillary, while air or liquid is forced through the inner one. The rate at which the core fluid is injected into the fibers relative to the flow of polymer solution governs the ultimate wall thickness of the fiber. Figure 3.33 shows a cross-section of this type of spinneret, which is widely used to produce the large-diameter fibers used in ultrafiltration. Experimental details of this type of spinneret can be found elsewhere [101–103]. A complete hollow fiber spinning system is shown in Figure 3.34.

Figure 3.33 Twin-orifice spinneret design used in solution-spinning of hollow fiber membranes. Polymer solution is forced through the outer orifice, while bore-forming fluid is forced through the inner capillary

Figure 3.34 A complete hollow fiber solution-spinning system. The fiber is spun into a coagulation bath, where the polymer spinning solution precipitates forming the fiber. The fiber is then washed, dried, and taken up on a roll

The evaporation time between the solution exiting the spinneret and entering the coagulation bath is a critical variable, as are the compositions of the bore fluid and the coagulation bath. The position of the dense anisotropic skin can be adjusted by varying the bath and bore solutions. For example, if water is used as the bore fluid and the coagulation bath contains some solvent, precipitation will occur first and most rapidly on the inside surface of the fiber. If the solutions are reversed so that the bore solution contains some solvent and the coagulation bath is water, the skin will tend to be formed on the outside surface of the fiber, as shown in Figure 3.35. In many cases precipitation will begin on both surfaces of the fiber, and a dense layer will form on both inside and outside surfaces. This ability to manipulate the position of the dense skin is important because the skin should normally face the feed fluid.

Generally, the spinning dope used in solution spinning has a higher polymer concentration and is more viscous than the casting solutions used to form equivalent flat sheet membranes. This is because hollow fiber membranes must be able not only to perform the separation required but also to withstand the applied pressure of the process without collapsing. The mechanical demands placed on the microporous substructure of hollow fiber membranes are more demanding than for their flat-sheet equivalents. Consequently, a finer, stronger, and higher density microporous support structure is required. Because more concentrated casting solutions are used, the thickness of the skin layer of hollow fiber membranes is also greater than their flat-sheet equivalents. Usually lower membrane fluxes result. However, the low cost of producing a large membrane area in hollow fiber form compensates for the poorer performance.

Hollow fiber spinning dopes and preparation procedures vary over a wider range than their flat-sheet equivalents, but some representative dopes and spinning conditions taken from the patent literature [98,103,104] are given in Table 3.4.

Recently some interest in forming more complex hollow fibers has developed; for example, composite hollow fibers in which the microporous shell of the fiber provides the mechanical strength, but the selective layer is a coating of a

Figure 3.35 Depending on the bore fluid and the composition of the coagulation bath, the selective skin layer can be formed on the inside, the outside or both sides of the hollow fiber membrane

Table 3.4 Preparation parameters for various hollow fiber membranes

Casting dope	Bore fluid	Precipitation bath	Membrane type
37 wt% polysulfone (Udel P3500) 36 wt% <i>N</i> -methyl pyrrolidone 27 wt% propionic acid (spun at 15–100 °C)	Water	Water 25–50 °C	Gas separation fiber α_{O_2/N_2} 5.2, ≈ 50 μm diameter, anisotropic outside-skinned fibers, finely microporous substrate [103]

different material. Ube, Praxair, Air Products and Medal all produce this type of fiber for gas separation applications. Various techniques are described in the patent literature [105–107]. A device proposed by Air Products is shown in Figure 3.36. The preformed hollow fiber support membrane is drawn through a volatile solution of the coating polymer. The thickness of the film formed on the outer surface of the fiber is controlled by the concentration of polymer in the casting solution and the diameter of the orifice in the coating die. The solvent is evaporated and the fiber wound up.

Another method of producing composite hollow fibers, described by Kusuki *et al.* at Ube [108] and Kopp *et al.* at Memtec [109], is to spin double-layered fibers with a double spinneret of the type shown in Figure 3.37. This system allows different spinning solutions to be used for the outer and inner surface of the fibers and gives more precise control of the final structure. Often, two different polymers are incorporated into the same fiber. The result is a hollow fiber composite membrane equivalent to the flat sheet membrane shown in Figure 3.26. A reason for the popularity of composite hollow fiber membranes is that different polymers can be used to form the mechanically strong support and the selective layer. This can reduce the amount of selective polymer required. The tailor-made polymers developed for gas separation applications can cost as much as

Figure 3.36 Apparatus to make composite hollow fiber membranes by coating a hollow fiber support membrane with a thin selective coating [105]

Figure 3.37 A double capillary spinneret sometimes used to produce two-layer hollow fibers. After Kopp *et al.* [109]

US\$5–10/g. Single-layer hollow fiber membranes contain 10–20 g of polymer per square meter of membrane, for a material cost alone of US\$50–200/m². Thus, using a composite structure consisting of a relatively inexpensive core polymer material coated with a thin layer of the expensive selective polymer reduces the overall membrane material cost significantly.

Membrane Modules

Industrial membrane plants often require hundreds to thousands of square meters of membrane to perform the separation required on a useful scale. Before a membrane separation can be performed industrially, therefore, methods of economically and efficiently packaging large areas of membrane are required. These packages are called membrane modules. The development of the technology to produce low-cost membrane modules was one of the breakthroughs that led to commercial membrane processes in the 1960s and 1970s. The earliest designs were based on simple filtration technology and consisted of flat sheets of membrane held in a type of filter press: these are called plate-and-frame modules. Membranes in the form of 1- to 3-cm-diameter tubes were developed at about the same time. Both designs are still used, but because of their relatively high cost they have been largely displaced in most applications by two other designs—the spiral-wound module and the hollow fiber module.

Despite the importance of membrane module technology, many researchers are astonishingly uninformed about module design issues. In part this is because module technology has been developed within companies, and developments are only found in patents, which are ignored by many academics. The following sections give an overview of the principal module types, followed by a section summarizing the factors governing selection of particular types for different membrane processes. Cost is always important, but perhaps the most important issues are membrane fouling and concentration polarization. This is particularly true for reverse osmosis and ultrafiltration systems, but concentration polarization issues also affect the design of gas separation and pervaporation modules.

Plate-and-frame Modules

Plate-and-frame modules were one of the earliest types of membrane system. A plate-and-frame design proposed by Stern [110] for early Union Carbide plants to recovery helium from natural gas is shown in Figure 3.38. Membrane, feed spacers, and product spacers are layered together between two end plates. The feed mixture is forced across the surface of the membrane. A portion passes through the membrane, enters the permeate channel, and makes its way to a central permeate collection manifold.

Figure 3.38 Early plate-and-frame design developed by Stern *et al.* [110] for the separation of helium from natural gas. Reprinted with permission from S.A. Stern, T.F. Sinclair, P.J. Gareis, N.P. Vahldieck and P.H. Mohr, Helium Recovery by Permeation, *Ind. Eng. Chem.* **57**, 49. Copyright 1965, American Chemical Society and American Pharmaceutical Association

Plate-and-frame units have been developed for some small-scale applications, but these units are expensive compared to the alternatives, and leaks through the gaskets required for each plate are a serious problem. Plate-and-frame modules are now only used in electrodialysis and pervaporation systems and in a limited number of reverse osmosis and ultrafiltration applications with highly fouling feeds. An example of one of these reverse osmosis units is shown in Figure 3.39 [111].

Tubular Modules

Tubular modules are now generally limited to ultrafiltration applications, for which the benefit of resistance to membrane fouling due to good fluid hydrodynamics outweighs their high cost. Typically, the tubes consist of a porous paper or fiberglass support with the membrane formed on the inside of the tubes, as shown in Figure 3.40.

The first tubular membranes were between 2 and 3 cm in diameter, but more recently, as many as five to seven smaller tubes, each 0.5–1.0 cm in diameter, are nested inside a single, larger tube. In a typical tubular membrane system a large number of tubes are manifolded in series. The permeate is removed from each tube and sent to a permeate collection header. A drawing of a 30-tube system is shown in Figure 3.41. The feed solution is pumped through all 30 tubes connected in series.

Figure 3.39 Schematic of a plate-and-frame module. Plate-and-frame modules provide good flow control on both the permeate and feed side of the membrane, but the large number of spacer plates and seals lead to high module costs. The feed solution is directed across each plate in series. Permeate enters the membrane envelope and is collected through the central permeate collection channel [111]

Spiral-wound Modules

Spiral-wound modules were used in a number of early artificial kidney designs, but were fully developed for industrial membrane separations by Gulf General Atomic (a predecessor of Fluid Systems, Inc.). This work, directed at reverse osmosis membrane modules, was carried out under the sponsorship of the Office of Saline Water [112–114]. The design shown in Figure 3.42 is the simplest, consisting of a membrane envelope of spacers and membrane wound around a perforated central collection tube; the module is placed inside a tubular pressure vessel. Feed passes axially down the module across the membrane envelope. A portion of the feed permeates into the membrane envelope, where it spirals towards the center and exits through the collection tube.

Small laboratory spiral-wound modules consist of a single membrane envelope wrapped around the collection tube, as shown in Figure 3.42. The membrane area of these modules is typically 0.2 to 1.0 m². Industrial-scale modules contain several membrane envelopes, each with an area of 1–2 m², wrapped around the central collection pipe. The multi-envelope design developed at Gulf General Atomic by Bray [113] and others is illustrated in Figure 3.43. Multi-envelope

Figure 3.40 Typical tubular ultrafiltration module design. The membrane is usually cast on a porous fiberglass or paper support, which is then nested inside a plastic or steel support tube. In the past, each plastic housing contained a single 2- to 3-cm-diameter tube. More recently, several 0.5- to 1.0-cm-diameter tubes, nested inside single housings, have been introduced. (Courtesy of Koch Membrane Systems)

designs minimize the pressure drop encountered by the permeate fluid traveling towards the central pipe. If a single membrane envelope were used in a large-membrane-area module, the path taken by the permeate to reach the central collection pipe would be several meters long, depending on the module diameter. Such a long permeate path would result in a large pressure drop in the permeate collection channel. By using multiple short envelopes the pressure drop in any one envelope is kept at a manageable level. The standard industrial spiral-wound module has an 8-in. diameter and is 40 in. long. Twelve-inch-diameter modules up to 60 in. long have been made and offer some economy of scale. There is, therefore, a trend towards increasing the module diameter for larger plants. The approximate membrane area and number of membrane envelopes used in industrial 40-in.-long spiral-wound modules are given in Table 3.5.

Four to six spiral-wound membrane modules are normally connected in series inside a single pressure vessel (tube). A typical 8-in.-diameter tube containing six modules has 100–200 m² of membrane area. An exploded view of a membrane tube containing two modules is shown in Figure 3.44 [115]. The end of each module is fitted with an anti-telescoping device (ATD) which is designed to

Figure 3.41 Exploded view of a tubular ultrafiltration system in which 30 tubes are connected in series. Permeate from each tube is collected in the permeate manifold

prevent the module leaves shifting under the feed-to-residue pressure difference required to force feed fluid through the module. The ATD is also fitted with a rubber seal to form a tight connection between the module and the pressure vessel. This seal prevents fluid bypassing the module in the gap between the module and the vessel wall.

In some applications of reverse osmosis and ultrafiltration spiral-wound modules in the food industry, it may be desirable to allow a small portion of the feed solution to bypass the module to prevent bacteria growing in the otherwise stagnant fluid. One way to achieve this bypass is by perforating the ATD as illustrated in Figure 3.45 [115].

Hollow Fiber Modules

Hollow fiber membrane modules are formed in two basic geometries. The first is the shell-side feed design illustrated in Figure 3.46(a) and used, for example, by Monsanto in their hydrogen separation systems and by Du Pont in their reverse osmosis systems. In such a module, a loop or a closed bundle of fibers is contained in a pressure vessel. The system is pressurized from the shell side; permeate passes through the fiber wall and exits through the open fiber ends. This design is easy to make and allows very large membrane areas to be contained in an economical system. Because the fiber wall must support considerable hydrostatic pressure, the fibers usually have small diameters and thick walls, typically 50- μm internal diameter and 100- to 200- μm outer diameter.

Spiral-Wound Module Cross Section

Figure 3.42 Exploded view and cross-section drawings of a spiral-wound module. Feed solution passes across the membrane surface. A portion passes through the membrane and enters the membrane envelope where it spirals inward to the central perforated collection pipe. One solution enters the module (the feed) and two solutions leave (the residue and the permeate). Spiral-wound modules are the most common module design for reverse osmosis and ultrafiltration as well as for high-pressure gas separation applications in the natural gas industry

Figure 3.43 Multi-envelope spiral-wound module [113], used to avoid excessive pressure drops on the permeate side of the membrane. Large-diameter modules may have as many as 30 membrane envelopes, each with a membrane area of 1–2 m²

Table 3.5 Typical membrane area and number of membrane envelopes for 40-in.-long industrial spiral-wound modules. The thickness of the membrane spacers used for different applications causes the variation in membrane area

Module diameter (in.)	4	6	8	12
Number of membrane envelopes	4–6	6–10	15–30	30–40
Membrane area (m ²)	3–6	6–12	20–40	30–60

The second type of hollow fiber module is the bore-side feed type illustrated in Figure 3.46(b). The fibers in this type of unit are open at both ends, and the feed fluid is circulated through the bore of the fibers. To minimize pressure drop inside the fibers, the diameters are usually larger than those of the fine fibers used in the shell-side feed system and are generally made by solution spinning. These so-called capillary fibers are used in ultrafiltration, pervaporation, and some low-to-medium-pressure gas applications. Feed pressures are usually limited to below 150 psig in this type of module.

In bore-side feed modules, it is important to ensure that all of the fibers have identical fiber diameters and permeances. Even fiber variation as small as $\pm 10\%$ from the average fiber can lead to large variations in module performance [116,117]. The flow of fluid through the fiber bore is proportional to the fiber

Figure 3.44 Schematic of a spiral-wound module [115] installed in a multimodule pressure vessel. Typically four to six modules are installed in a single pressure vessel. Reprinted from *Reverse Osmosis Technology*, B.S. Parekh (ed.), Marcel Dekker, New York (1988), p. 81, by courtesy of Marcel Dekker, Inc.

Figure 3.45 By perforating the antitelescoping device, a small controlled bypass of fluid past the module seal is achieved to eliminate the stagnant area between the reverse osmosis module and the pressure vessel walls. This device is used in food and other sanitary applications of spiral-wound modules [115]. Reprinted from *Reverse Osmosis Technology*, B.S. Parekh (ed.), Marcel Dekker, New York (1988), p. 359, by courtesy of Marcel Dekker, Inc.

Figure 3.46 Two types of hollow-fiber modules used for gas separation, reverse osmosis, and ultrafiltration applications. Shell-side feed modules are generally used for high-pressure applications up to 1000 psig. Fouling on the feed side of the membrane can be a problem with this design, and pretreatment of the feed stream to remove particulates is required. Bore-side feed modules are generally used for medium-pressure feed streams up to 150 psig, for which good flow control to minimize fouling and concentration polarization on the feed side of the membrane is desired

diameter to the fourth power, whereas the membrane area only changes by the second power. The effect is particularly important in the production of nitrogen from air and in hollow-fiber kidney modules, in which high levels of removal of the permeable component in a single pass are desired. If the fibers have different diameters, a few overly large or overly small fibers can significantly affect the removal achieved by the module.

Concentration polarization is well controlled in bore-side feed modules. The feed solution passes directly across the active surface of the membrane, and no stagnant dead spaces are produced. This is far from the case in shell-side feed modules in which flow channeling and stagnant areas between fibers, which cause significant concentration polarization problems, are difficult to avoid [118]. Any suspended particulate matter in the feed solution is easily trapped in these stagnant areas, leading to irreversible fouling of the membrane. Baffles to direct the feed flow have been tried [119,120], but are not widely used. A more common method of minimizing concentration polarization is to direct the feed flow normal to the direction of the hollow fibers as shown in Figure 3.47. This produces a cross-flow module with relatively good flow distribution across the fiber surface. Several membrane modules may be connected in series, so high feed solution velocities can be used. A number of variants on this basic design have been patented [121,122] and are reviewed by Koros and Fleming [123].

A second problem in shell-side feed hollow fine fibers is permeate side parasitic pressure drops. The permeate channel in these fibers is so narrow, and presents such a resistance to fluid passage, that a significant pressure drop develops along the length of the permeate channel, reducing the pressure difference across the membrane that provides the driving force for permeation. In applications involving separation of mixtures of relatively impermeable components, such as oxygen and nitrogen in air, the pressure drop that develops is small

Figure 3.47 A cross-flow hollow fiber module used to obtain better flow distribution and reduce concentration polarization (the Tyobo Hollosep reverse osmosis module). Feed enters through the perforated central pipe and flows towards the module shell

and unimportant. But in separations of more permeable gas mixtures, such as hydrogen or carbon dioxide from methane, the pressure drop can be a significant fraction of the total applied pressure. Permeate-side pressure drops also tend to develop in spiral-wound modules. However, because the permeate channels are wider in this type of module, pressure drops are usually smaller and less significant.

The greatest single advantage of hollow fiber modules is the ability to pack a very large membrane area into a single module. The magnitude of this advantage can be gauged by the membrane area per module data shown in Table 3.6. This table shows the calculated membrane area contained in an 8-in.-diameter, 40-in.-long module; a spiral-wound module of this size would contain about 20–40 m² of membrane area. The equivalent hollow fiber module, filled with fibers with a diameter of 100 μm, will contain approximately 300 m² of membrane area, 10 times the area in a spiral-wound module. As the diameter of the fibers in the module increases, the membrane area decreases. Capillary ultrafiltration membrane modules have almost the same area as equivalent-sized spiral-wound modules.

Table 3.6 also shows the huge numbers of hollow fibers required for high-surface-area modules. A hollow fine fiber module with an area of 300 m² will contain 1000 km of fiber. Expensive, sophisticated, high-speed automated spinning and fiber handling and module fabrication equipment is required to produce these modules. A typical hollow fiber spinning operation will have 50–100 spinnerets. In general the capital investment for a hollow fine fiber production plant is so large that the technology can only be considered when large numbers of modules are being produced on a round-the-clock basis. The technology is maintained as a trade secret within the handful of companies that produce this type of module. A clue to the type of machinery involved can be obtained from the patent literature. Figure 3.48, for example, shows a module winding machine from an old Du Pont patent [124]. Fibers from several bobbins are wound around a porous paper sheet, laying down the bundle that ultimately becomes the module insert.

Table 3.6 Effect of fiber diameter on membrane area and the number of fibers in a module 20 cm (8 in.) in diameter and 1 m (40 in.) long. Twenty-five percent of the module volume is filled with fiber. A spiral-wound module of this size contains approximately 20–40 m² of membrane area and has a packing density of 6–13 cm²/cm³

Module use	High-pressure reverse osmosis and gas separation	Low-pressure gas separation	Ultrafiltration		
Fiber diameter (μm)	100	250	500	1000	2000
Number of fibers/module (thousands)	1000	250	40	10	2.5
Membrane area (m ²)	315	155	65	32	16
Packing density (cm ² /cm ³)	100	50	20	10	5

Figure 3.48 Hollow fiber module winding apparatus from a 1972 Du Pont patent [124]. Machines of this general type are still used to produce hollow fiber modules

Vibrating and Rotating Modules

In all of the module designs described thus far, the fluid to be separated (gas or liquid) is pumped across the surface of the membrane at high velocity to control concentration polarization. A few vibrating or rotating modules, in which the membrane moves, and moves much faster than the fluid flowing across its surface, have been developed. One such design, a vibrating module, from New Logic International, is shown in Figure 3.49 [125,126]. Vibration of the membrane at high speed creates interior agitation directly at the membrane surface. These modules have proved to be able to ultrafilter extremely concentrated, viscous solutions that could not be treated by conventional module designs. Currently the modules are extremely expensive—in the range US\$2000–5000/m² membrane—compared to alternative designs. This limits their application to high-value separations that cannot be performed by other processes.

Figure 3.49 New Logic International vibrating plate-and-frame module design [125]. A motor taps a metal plate (the seismic mass) supported by a rubber mount at 60 times/s. A bar that acts as a torsion spring connects the vibrating mass to a plate-and-frame membrane module, which then vibrates by 1–2 in. at the same frequency. By shaking the membrane module, high turbulence is induced in the pressurized feed fluid flowing through the module. The turbulence occurs directly at the membrane surface, providing good control of membrane fouling

Module Selection

The choice of the most suitable membrane module type for a particular membrane separation must balance a number of factors. The principal module design parameters that enter into the decision are summarized in Table 3.7.

Cost, always important, is difficult to quantify because the actual selling price of the same module design varies widely, depending on the application. Generally, high-pressure modules are more expensive than low-pressure or vacuum

Table 3.7 Parameters for membrane module design

Parameter	Hollow fine fibers	Capillary fibers	Spiral-wound	Plate-and-frame	Tubular
Manufacturing cost (US\$/m ²)	5–20	10–50	5–100	50–200	50–200
Concentration polarization fouling control	Poor	Good	Moderate	Good	Very good
Permeate-side pressure drop	High	Moderate	Moderate	Low	Low
Suitability for high-pressure operation	Yes	No	Yes	Yes	Marginal
Limited to specific types of membrane material	Yes	Yes	No	No	No

modules. The total volume of product likely to be produced to satisfy a particular application is a key issue. For example, spiral-wound modules for reverse osmosis are produced by three or four manufacturers in large volumes, resulting in severe competition and low prices. Similar modules used in ultrafiltration are produced in much lower numbers and so are much more expensive. Hollow fiber modules are significantly cheaper, per square meter of membrane, than spiral-wound or plate-and-frame modules but can only be economically produced for very high volume applications that justify the expense of developing and building the spinning and module fabrication equipment. This cost advantage is often offset by the lower fluxes of the membranes compared with their flat-sheet equivalents. An estimate of module manufacturing cost is given in Table 3.7; the selling price is typically two to five times higher.

Two other major factors determining module selection are concentration polarization control and resistance to fouling. Concentration polarization control is a particularly important issue in liquid separations such as reverse osmosis and ultrafiltration. In gas separation applications, concentration polarization is more easily controlled but is still a problem with high-flux, highly selective membranes. Hollow fine fiber modules are notoriously prone to fouling and concentration polarization and can be used in reverse osmosis applications only when extensive, costly feed solution pretreatment removes all particulates. These fibers cannot be used in ultrafiltration applications at all.

Another factor is the ease with which various membrane materials can be fabricated into a particular module design. Almost all membranes can be formed into plate-and-frame, spiral-wound and tubular modules, but many membrane materials cannot be fabricated into hollow fine fibers or capillary fibers. Finally, the suitability of the module design for high-pressure operation and the relative

magnitude of pressure drops on the feed and permeate sides of the membrane can be important factors.

The types of modules generally used in some of the major membrane processes are listed in Table 3.8.

In reverse osmosis, the commonly used modules are spiral-wound. Plate-and-frame and tubular modules are limited to a few applications in which membrane fouling is particularly severe, for example, in food applications or processing heavily contaminated industrial wastewater. The hollow fiber reverse osmosis modules used in the past have now been almost completely displaced by spiral-wound modules, which are inherently more fouling resistant, and require less feed pretreatment.

For ultrafiltration applications, hollow fine fibers have never been seriously considered because of their susceptibility to fouling. If the feed solution is extremely fouling, tubular systems are still used. Recently, however, spiral-wound modules with improved resistance to fouling have been developed; these modules are increasingly displacing the more expensive tubular systems. This is particularly the case with clean feed solutions, for example, in the ultrafiltration of boiler feed water or municipal water to make ultrapure water for the electronics industry. Capillary systems are also used in some ultrafiltration applications.

Table 3.8 Module designs most commonly used in the major membrane separation processes

Application	Module type
Reverse osmosis: seawater	Spiral-wound modules. Only one hollow fiber producer remains
Reverse osmosis: industrial and brackish water	Spiral-wound modules used almost exclusively; fine fibers too susceptible to scaling and fouling
Ultrafiltration	Tubular, capillary and spiral-wound modules all used. Tubular generally limited to highly fouling feeds (automotive paint), spiral-wound to clean feeds (ultrapure water)
Gas separation	Hollow fibers for high volume applications with low flux, low selectivity membranes in which concentration polarization is easily controlled (nitrogen from air) Spiral-wound when fluxes are higher, feed gases more contaminated and concentration polarization a problem (natural gas separations, vapor permeation)
Pervaporation	Most pervaporation systems are small so plate-and-frame systems were used in the first systems Spiral-wound and capillary modules being introduced

For high-pressure gas separation applications, hollow fine fibers have a major segment of the market. Hollow fiber modules are clearly the lowest cost design per unit membrane area, and their poor resistance to fouling is not a problem in many gas separation applications because gaseous feed streams can easily be filtered. Also, gas separation membrane materials are often rigid glassy polymers such as polysulfones, polycarbonates and polyimides, which are easily formed into hollow fine fibers. Spiral-wound modules are used to process natural gas streams, which are relatively dirty, often containing oil mist and condensable components that would foul hollow fine fiber modules rapidly.

Spiral-wound modules are much more commonly used in low-pressure or vacuum gas separation applications, such as the production of oxygen-enriched air or the separation of organic vapors from air. In these applications, the feed gas is at close to ambient pressure, and a vacuum is drawn on the permeate side of the membrane. Parasitic pressure drops on the permeate side of the membrane and the difficulty in making high-performance hollow fine fiber membranes from the rubbery polymers used to make them both work against hollow fine fiber modules for such applications.

Pervaporation operates under constraints similar to those for low-pressure gas separation. Pressure drops on the permeate side of the membrane must be small, and many pervaporation membrane materials are rubbery, so both spiral-wound modules and plate-and-frame systems are in use. Plate-and-frame systems are competitive in this application despite their high cost, primarily because they can be operated at high temperatures with relatively aggressive feed solutions, conditions under which spiral-wound modules might fail.

Conclusions and Future Directions

The technology to fabricate ultrathin high-performance membranes into high-surface-area membrane modules has steadily improved during the modern membrane era. As a result the inflation-adjusted cost of membrane separation processes has decreased dramatically over the years. The first anisotropic membranes made by Loeb–Sourirajan processes had an effective thickness of 0.2–0.4 μm . Currently, various techniques are used to produce commercial membranes with a thickness of 0.1 μm or less. The permeability and selectivity of membrane materials have also increased two to three fold during the same period. As a result, today's membranes have 5 to 10 times the flux and better selectivity than membranes available 30 years ago. These trends are continuing. Membranes with an effective thickness of less than 0.05 μm have been made in the laboratory using advanced composite membrane preparation techniques or surface treatment methods.

As a result of these improvements in membrane performance, the major factors determining system performance have become concentration polarization and membrane fouling. All membrane processes are affected by these problems, so

membrane modules with improved fluid flow to minimize concentration polarization and modules formed from membranes that can be easily cleaned if fouled are likely to become increasingly important development areas.

4 CONCENTRATION POLARIZATION

Introduction

In membrane separation processes, a gas or liquid mixture contacts the feed side of the membrane, and a permeate enriched in one of the components of the mixture is withdrawn from the downstream side of the membrane. Because the feed mixture components permeate at different rates, concentration gradients form in the fluids on both sides of the membrane. The phenomenon is called concentration polarization. Figure 4.1 illustrates a dialysis experiment in which a membrane separates two solutions containing different concentrations of dissolved solute. Solute (i) diffuses from right to left; solvent (j) diffuses from left to right. Unless the solutions are extremely well stirred, concentration gradients form in the solutions on either side of the membrane. The same phenomenon occurs in other processes that involve transport of heat or mass across an interface. Mathematical descriptions of these processes can be found in monographs on heat and mass transfer, for example, the books by Carslaw and Jaeger [1], Bird *et al.* [2] and Crank [3].

The layer of solution immediately adjacent to the membrane surface becomes depleted in the permeating solute on the feed side of the membrane and enriched in this component on the permeate side. Equivalent gradients also form for the other component. This concentration polarization reduces the permeating component's concentration difference across the membrane, thereby lowering its flux and the membrane selectivity. The importance of concentration polarization depends on the membrane separation process. Concentration polarization can significantly affect membrane performance in reverse osmosis, but it is usually well controlled in industrial systems. On the other hand, membrane performance in ultrafiltration, electrodialysis, and some pervaporation processes is seriously affected by concentration polarization.

Figure 4.1 also shows the formation of concentration polarization gradients on both sides of the membrane. However, in most membrane processes there is a bulk flow of liquid or gas through the membrane, and the permeate-side composition

Figure 4.1 Concentration gradients formed when a dialysis membrane separates two solutions of different concentrations

depends only on the ratio of the components permeating the membrane. When this is the case, concentration gradients only form on the feed side of the membrane.

Two approaches have been used to describe the effect of concentration polarization. One has its origins in the dimensional analysis used to solve heat transfer problems. In this approach the resistance to permeation across the membrane and the resistance in the fluid layers adjacent to the membrane are treated as resistances in series. Nothing is assumed about the thickness of the various layers or the transport mechanisms taking place.

Using this model and the assumption that concentration polarization occurs only on the feed side of the membrane, the flux J_i across the combined resistances of the feed side boundary layer and the membrane can be written as

$$J_i = k_{ov}(c_{i_b} - c_{i_p}) \quad (4.1)$$

where k_{ov} is the overall mass transfer coefficient, c_{i_b} is the concentration of component i in the bulk feed solution, and c_{i_p} is the concentration of component i in the bulk permeate solution. Likewise, the flux across the boundary layer is also J_i and can be written as

$$J_i = k_{bl}(c_{i_b} - c_{i_o}) \quad (4.2)$$

where $k_{b\ell}$ is the fluid boundary layer mass transfer coefficient, and c_{i_o} is the concentration of component i in the fluid at the feed/membrane interface, and the flux across the membrane can be written as

$$J_i = k_m(c_{i_o} - c_{i_p}) \quad (4.3)$$

where k_m is the mass transfer coefficient of the membrane.

Since the overall concentration drop ($c_{i_b} - c_{i_p}$) is the sum of the concentration drops across the boundary layer and the membrane, a simple restatement of the resistances-in-series model using the terms of Equations (4.1–4.3) is

$$\frac{1}{k_{ov}} = \frac{1}{k_m} + \frac{1}{k_{b\ell}} \quad (4.4)$$

When the fluid layer mass-transfer coefficient ($k_{b\ell}$) is large, the resistance $1/k_{b\ell}$ of this layer is small, and the overall resistance is determined only by the membrane. When the fluid layer mass-transfer coefficient is small, the resistance term $1/k_{b\ell}$ is large, and becomes a significant fraction of the total resistance to permeation. The overall mass transfer coefficient (k_{ov}) then becomes smaller, and the flux decreases. The boundary layer mass transfer coefficient is thus an arithmetical fix used to correct the membrane permeation rate for the effect of concentration polarization. Nothing is revealed about the causes of concentration polarization.

The boundary layer mass-transfer coefficient is known from experiment to depend on many system properties; this dependence can be expressed as an empirical relationship of the type

$$k_{b\ell} = \text{constant } Q^\alpha h^\beta D^\gamma T^\delta \dots \quad (4.5)$$

where, for example, Q is the fluid velocity through the membrane module, h is the feed channel height, D is the solute diffusion coefficient, T is the feed solution temperature, and so on. Empirical mass-transfer correlations obtained this way can be used to estimate the performance of a new membrane unit by extrapolation from an existing body of experimental data [4–7]. However, these correlations have a limited range of applicability and cannot be used to obtain a priori estimates of the magnitude of concentration polarization. This approach also does not provide insight into the dependence of concentration polarization on membrane properties. A more detailed and more sympathetic description of the mass-transfer approach is given in Cussler's monograph [8].

The second approach to concentration polarization, and the one used in this chapter, is to model the phenomenon by assuming that a thin layer of unmixed fluid, thickness δ , exists between the membrane surface and the well-mixed bulk solution. The concentration gradients that control concentration polarization form in this layer. This boundary layer film model oversimplifies the fluid hydrodynamics occurring in membrane modules and still contains one adjustable parameter,

the boundary layer thickness. Nonetheless this simple model can explain most of the experimental data.

Boundary Layer Film Model

The usual starting point for the boundary layer film model is illustrated in Figure 4.2, which shows the velocity profile in a fluid flowing through the channel of a membrane module. The average velocity of the fluid flowing down the channel is normally of the order 1–5 m/s. This velocity is far higher than the average velocity of the fluid flowing at right angles through the membrane, which is typically 10–20 $\mu\text{m/s}$. However, the velocity in the channel is not uniform. Friction at the fluid–membrane surface reduces the fluid velocity next to the membrane to essentially zero; the velocity increases as the distance from the membrane surface increases. Thus, the fluid flow velocity in the middle of the channel is high, the flow there is often turbulent, and the fluid is well mixed. The velocity in the boundary layer next to the membrane is much lower, flow is laminar, and mixing occurs by diffusion. Concentration gradients due to concentration polarization are assumed to be confined to the boundary layer.

Figure 4.1 shows the concentration gradients that form on either side of a dialysis membrane. However, dialysis differs from most membrane processes in that the volume flow across the membrane is usually small. In processes such as reverse osmosis, ultrafiltration, and gas separation, the volume flow through the membrane from the feed to the permeate side is significant. As a result the permeate concentration is typically determined by the ratio of the fluxes of the components that permeate the membrane. In these processes concentration polarization gradients form only on the feed side of the membrane, as shown in Figure 4.3. This simplifies the description of the phenomenon. The few membrane processes in which a fluid is used to sweep the permeate side of the membrane,

Figure 4.2 Fluid flow velocity through the channel of a membrane module is nonuniform, being fastest in the middle and essentially zero adjacent to the membrane. In the film model of concentration polarization, concentration gradients formed due to transport through the membrane are assumed to be confined to the laminar boundary layer

to change the permeate-side concentration from the value set by the ratio of permeating components, are discussed in the final section of this chapter.

In any process, if one component is enriched at the membrane surface, then mass balance dictates that a second component is depleted at the surface. By convention, concentration polarization effects are described by considering the concentration gradient of the minor component. In Figure 4.3(a), concentration polarization in reverse osmosis is represented by the concentration gradient of salt, the minor component rejected by the membrane. In Figure 4.3(b), which illustrates dehydration of aqueous ethanol solutions by pervaporation, concentration polarization is represented by the concentration gradient of water, the minor component that preferentially permeates the membrane.

Figure 4.3 Concentration gradients formed as a result of permeation through a selective membrane. By convention, concentration polarization is usually represented by the gradient of the minor component—salt in the reverse osmosis example and water in the pervaporation example (dehydration of an ethanol solution)

In the case of desalination of water by reverse osmosis illustrated in Figure 4.3(a), the salt concentration c_{i_o} adjacent to the membrane surface is higher than the bulk solution concentration c_{i_b} because reverse osmosis membranes preferentially permeate water and retain salt. Water and salt are brought toward the membrane surface by the flow of solution through the membrane J_v .¹ Water and a little salt permeate the membrane, but most of the salt is rejected by the membrane and retained at the membrane surface. Salt accumulates at the membrane surface until a sufficient gradient has formed to allow the salt to diffuse to the bulk solution. Steady state is then reached.

In the case of dehydration of ethanol by pervaporation illustrated in Figure 4.3(b), the water concentration c_{i_o} adjacent to the membrane surface is lower than the bulk solution concentration c_{i_b} because the pervaporation membrane preferentially permeates water and retains ethanol. Water and ethanol are brought towards the membrane surface by the flow of solution through the membrane. Water and a little ethanol permeate the membrane, but most of the ethanol is retained at the membrane surface. Ethanol accumulates at the membrane surface until a sufficient gradient has formed to allow it to diffuse back to the bulk solution. An equal and opposite water gradient must form; thus, water becomes depleted at the membrane surface.

The formation of these concentration gradients can be expressed in mathematical form. Figure 4.4 shows the steady-state salt gradient that forms across a reverse osmosis membrane.

The salt flux through the membrane is given by the product of the permeate volume flux J_v and the permeate salt concentration c_{i_p} . For dilute liquids the permeate volume flux is within 1 or 2% of the volume flux on the feed side of the membrane because the densities of the two solutions are almost equal. This means that, at steady state, the net salt flux at any point within the boundary layer must also be equal to the permeate salt flux $J_v c_{i_p}$. In the boundary layer this net salt flux is also equal to the convective salt flux towards the membrane $J_v c_i$ minus the diffusive salt flux away from the membrane expressed by Fick's law ($D_i dc_i/dx$). So, from simple mass balance, transport of salt at any point within the boundary layer can be described by the equation

$$J_v c_i - D_i dc_i/dx = J_v c_{i_p} \quad (4.6)$$

where D_i is the diffusion coefficient of the salt, x is the coordinate perpendicular to the membrane surface, and J_v is the volume flux in the boundary layer generated by permeate flow through the membrane. The mass balance equation (4.6) can be integrated over the thickness of the boundary layer to give the well-known polarization equation first derived by Brian [9] for reverse osmosis:

$$\frac{c_{i_o} - c_{i_p}}{c_{i_b} - c_{i_p}} = \exp(J_v \delta / D_i) \quad (4.7)$$

¹In this chapter, the term J_v is the volume flux ($\text{cm}^3/\text{cm}^2 \cdot \text{s}$) through the membrane measured at the feed-side conditions of the process.

In the boundary layer $J_v c_i - \frac{D_i dc_i}{dx} = J_v c_{i_p}$

Figure 4.4 Salt concentration gradients adjacent to a reverse osmosis desalination membrane. The mass balance equation for solute flux across the boundary layer is the basis of the film model description of concentration polarization

In this equation, c_{i_o} is the concentration of solute in the feed solution at the membrane surface, and δ is the thickness of the boundary layer. An alternative form of Equation (4.7) replaces the concentration terms by an enrichment factor E , defined as c_{i_p}/c_{i_b} . The enrichment obtained in the absence of a boundary layer E_o is then defined as c_{i_p}/c_{i_o} , and Equation (4.7) can be written as

$$\frac{1/E_o - 1}{1/E - 1} = \exp(J_v \delta / D_i) \tag{4.8}$$

In the case of reverse osmosis, the enrichment factors (E and E_o) are less than 1.0, typically about 0.01, because the membrane rejects salt and permeates water. For other processes, such as dehydration of aqueous ethanol by pervaporation, the enrichment factor for water will be greater than 1.0 because the membrane selectively permeates the water.

The increase or decrease of the permeate concentration at the membrane surface c_{i_o} , compared to the bulk solution concentration c_{i_b} , determines the extent of concentration polarization. The ratio of the two concentrations, c_{i_o}/c_{i_b} is called the

concentration polarization modulus and is a useful measure of the extent of concentration polarization. When the modulus is 1.0, no concentration polarization occurs, but as the modulus deviates farther from 1.0, the effect of concentration polarization on membrane selectivity and flux becomes increasingly important. From the definitions of E and E_o , the concentration polarization modulus is equal to E/E_o and, from Equations (4.7) and (4.8), the modulus can be written as

$$\frac{c_{i_o}}{c_{i_b}} = \frac{\exp(J_v \delta / D_i)}{1 + E_o [\exp(J_v \delta / D_i) - 1]} \quad (4.9)$$

Depending on the enrichment term (E_o) of the membrane, the modulus can be larger or smaller than 1.0. For reverse osmosis E_o is less than 1.0, and the concentration polarization modulus is normally between 1.1 and 1.5; that is, the concentration of salt at the membrane surface is 1.1 to 1.5 times larger than it would be in the absence of concentration polarization. The salt leakage through the membrane and the osmotic pressure that must be overcome to produce a flow of water are increased proportionately. Fortunately, modern reverse osmosis membranes are extremely selective and permeable, and can still produce useful desalted water under these conditions. In other membrane processes, such as pervaporation or ultrafiltration, the concentration polarization modulus may be as large as 5 to 10 or as small as 0.2 to 0.1, and may seriously affect the performance of the membrane.

Equation (4.9) shows the factors that determine the magnitude of concentration polarization, namely the boundary layer thickness δ , the membrane enrichment E_o , the volume flux through the membrane J_v , and the diffusion coefficient of the solute in the boundary layer fluid D_i . The effect of changes in each of these parameters on the concentration gradients formed in the membrane boundary layer are illustrated graphically in Figure 4.5 and discussed briefly below.

Of the four factors that affect concentration polarization, the one most easily changed is the boundary layer thickness δ . As δ decreases, Equation (4.9) shows that the concentration polarization modulus becomes exponentially smaller. Thus, the most straightforward way of minimizing concentration polarization is to reduce the boundary layer thickness by increasing turbulent mixing at the membrane surface. Factors affecting turbulence in membrane modules are described in detail in the review of Belfort *et al.* [10]. The most direct technique to promote mixing is to increase the fluid flow velocity past the membrane surface. Therefore, most membrane modules operate at relatively high feed fluid velocities. Membrane spacers are also widely used to promote turbulence by disrupting fluid flow in the module channels, as shown in Figure 4.6 [11]. Pulsing the feed fluid flow through the membrane module is another technique [12]. However, the energy consumption of the pumps required and the pressure drops produced place a practical limit to the turbulence that can be obtained in a membrane module.

Figure 4.5 The effect of changes in boundary layer thickness δ , membrane enrichment E_o , membrane flux J_v , and solute diffusion D_i on concentration gradients in the stagnant boundary layer

The membrane's intrinsic enrichment E_o also affects concentration polarization. If the membrane is completely unselective, $E_o = 1$. The relative concentrations of the components passing through the membrane do not change, so concentration gradients are not formed in the boundary layer. As the difference in permeability between the more permeable and less permeable components increases, the intrinsic enrichment E_o achieved by the membrane increases, and the concentration gradients that form become larger. As a practical example, in pervaporation of organics from water, concentration polarization is much more important when the solute is toluene (with an enrichment E_o of 5000 over water) than when the solute is methanol (with an enrichment E_o less than 5).

Another important characteristic of Equation (4.9) is that the enrichment E_o produced by the membrane, not the intrinsic selectivity α , determines the

Figure 4.6 Flow dynamics around the spacer netting often used to promote turbulence in a membrane module and reduce concentration polarization

membrane separation performance and the concentration polarization modulus. Enrichment and intrinsic selectivity are linked but are not identical. This distinction is illustrated by the separation of hydrogen from inert gases in ammonia plant purge gas streams, which typically contain 30% hydrogen. Hydrogen is 100 to 200 times more permeable than the inert gases nitrogen, methane, and argon, so the intrinsic selectivity of the membrane is very high. The high selectivity means that the membrane permeate is 97% hydrogen; even so, the enrichment E_o is only $97/30$, or 3.3, so the concentration polarization modulus is small. On the other hand, as hydrogen is removed, its concentration in the feed gas falls. When the feed gas contains 5% hydrogen, the permeate will be 90% hydrogen and the enrichment $90/5$ or 18. Under these conditions, concentration polarization can affect the membrane performance.

Equation (4.9) shows that concentration polarization increases exponentially as the total volume flow J_v through the membrane increases. This is one of the reasons why modern spiral-wound reverse osmosis membrane modules are operated at low pressures. Modern membranes have two to five times the water permeability, at equivalent salt selectivities, of the first-generation cellulose acetate reverse osmosis membranes. If membrane modules containing these new membranes were operated at the same pressures as early cellulose acetate modules, two to five times the desalted water throughput could be achieved with the same

number of modules. However, at such high fluxes, spiral-wound modules suffer from excessive concentration polarization, which leads to increased salt leakage and scale formation. For this reason, modern, high permeability modules are operated at about the same volume flux as the early modules, but at lower applied pressures. This reduces energy costs.

The final parameter in Equation (4.9) that determines the value of the concentration polarization modulus is the diffusion coefficient D_i of the solute away from the membrane surface. The size of the solute diffusion coefficient explains why concentration polarization is a greater factor in ultrafiltration than in reverse osmosis. Ultrafiltration membrane fluxes are usually higher than reverse osmosis fluxes, but the difference between the values of the diffusion coefficients of the retained solutes is more important. In reverse osmosis the solutes are dissolved salts, whereas in ultrafiltration the solutes are colloids and macromolecules. The diffusion coefficients of these high-molecular-weight components are about 100 times smaller than those of salts.

In Equation (4.9) the balance between convective transport and diffusive transport in the membrane boundary layer is characterized by the term $J_v\delta/D_i$. This dimensionless number represents the ratio of the convective transport J_v and diffusive transport D_i/δ and is commonly called the Peclet number. When the Peclet number is large ($J_v \gg D_i/\delta$), the convective flux through the membrane cannot easily be balanced by diffusion in the boundary layer, and the concentration polarization modulus is large. When the Peclet number is small ($J_v \ll D_i/\delta$), convection is easily balanced by diffusion in the boundary layer, and the concentration polarization modulus is close to unity.

Wijmans *et al.* [13] calculated the concentration polarization modulus using Equation (4.9) as a function of the Peclet number $J_v\delta/D_i$ that is, the varying ratio of convection to diffusion. The resulting, very informative plot is shown in Figure 4.7. This figure is divided into two regions depending on whether the concentration polarization modulus, c_{i_o}/c_{i_b} , is smaller or larger than 1. The polarization modulus is smaller than 1 when the permeating minor component is enriched in the permeate. In this case, the component becomes depleted in the boundary layer, for example, in the dehydration of ethanol by pervaporation shown in Figure 4.3(b). The polarization modulus is larger than 1 when the permeating minor component is depleted in the permeate. In this case, the component is enriched in the boundary layer, for example, in the reverse osmosis of salt solutions shown in Figure 4.3(a). As might be expected, the concentration polarization modulus deviates increasingly from unity as the Peclet number increases. At high values of the ratio $J_v\delta/D_i$, the exponential term in Equation (4.9) increases toward infinity, and the concentration polarization modulus c_{i_o}/c_{i_b} approaches a limiting value of $1/E_o$.

A striking feature of Figure 4.7 is its asymmetry with respect to enrichment and rejection of the minor component by the membrane. This means that, under comparable conditions, concentration polarization is much larger when the minor

Figure 4.7 Concentration polarization modulus c_{i_o}/c_{i_b} as a function of the Peclet number $J_v\delta/D_i$ for a range of values of the intrinsic enrichment factor E_o . Lines calculated through Equation (4.9). This figure shows that components that are enriched by the membrane ($E_o > 1$) are affected more by concentration polarization than components that are rejected by the membrane ($E_o < 1$) [13]

component of the feed is preferentially permeated by the membrane than when it is rejected. This follows from the form of Equation (4.9). Consider the case when the Peclet number $J_v\delta/D_i$ is 1. The concentration polarization modulus expressed by Equation (4.9) then becomes

$$\frac{c_{i_o}}{c_{i_b}} = \frac{\exp(1)}{1 + E_o[\exp(1) - 1]} = \frac{2.72}{1 + E_o(1.72)} \quad (4.10)$$

For components rejected by the membrane ($E_o \leq 1$) the enrichment E_o produced by the membrane lies between 1 and 0. The concentration polarization modulus c_{i_o}/c_{i_b} then lies between 1 (no concentration polarization) and a maximum value of 2.72. That is, the flux of the less permeable component cannot be more than 2.72 times higher than that in the absence of concentration polarization. In contrast, for a component enriched by the membrane in the permeate ($E_o \geq 1$), no such limitation on the magnitude of concentration polarization exists. For dilute solutions (c_{i_b} small) and selective membranes, the intrinsic enrichment can be 100 to 1000 or more. The concentration polarization modulus can then change from 1 (no concentration polarization) to close to zero (complete concentration polarization). These two cases are illustrated in Figure 4.8.

Determination of the Peclet Number

Equation (4.9) and Figure 4.7 are powerful tools to analyze the importance of concentration polarization in membrane separation processes. However, before

Figure 4.8 Concentration gradients that form adjacent to the membrane surface for components (a) rejected or (b) enriched by the membrane. The Peclet number, characterizing the balance between convection and diffusion in the boundary layer, is the same $J_v \delta / D_i = 1$. When the component is rejected, the concentration at the membrane surface c_{i_o} cannot be greater than $2.72 c_{i_b}$, irrespective of the membrane selectivity. When the minor component permeates the membrane, the concentration at the membrane surface can decrease to close to zero, so the concentration polarization modulus becomes very small

these tools can be used, the appropriate value to be assigned to the Peclet number $J_v \delta / D_i$ must be determined. The volume flux J_v through the membrane is easily measured, so determining the Peclet number then becomes a problem of measuring the coefficient D_i / δ .

One approach to the boundary layer problem is to determine the ratio D_i / δ experimentally. This can be done using a procedure first proposed by Wilson [14]. The starting point for Wilson’s approach is Equation (4.8), which can be written as

$$\ln \left(1 - \frac{1}{E} \right) = \ln \left(1 - \frac{1}{E_o} \right) - J_v \delta / D_i \tag{4.11}$$

The boundary layer thickness δ in Equation (4.11) is a function of the feed solution velocity u in the module feed flow channel; thus, the term δ / D_i can be expressed as

$$\frac{D_i}{\delta} = k_o u^n \tag{4.12}$$

where u is the superficial velocity in the feed flow channel and k_o and n are constants. Equation (4.11) can then be rewritten as

$$\ln \left(1 - \frac{1}{E} \right) = \ln \left(1 - \frac{1}{E_o} \right) - \frac{J_v}{k_o u^n} \quad (4.13)$$

Equation (4.13) can be used to calculate the dependence of pervaporation system performance on concentration polarization. One method is to use data obtained with a single module operated at various feed solution velocities. A linear regression analysis is used to fit data obtained at different feed velocities to obtain an estimate for k_o and E_o ; the exponent n is adjusted to minimize the residual error. Figure 4.9 shows some data obtained in pervaporation experiments with dilute aqueous toluene solutions and silicone rubber membranes [15]. Toluene is considerably more permeable than water through these membranes. In Figure 4.9, when the data were regressed, the best value for n was 0.96. The values of E_o , the intrinsic enrichment of the membrane, and k_o obtained by regression analysis are 3600 and 7.1×10^{-4} , respectively. The boundary layer coefficient, D_i/δ is given by

$$\frac{D_i}{\delta} = 7.1 \times 10^{-4} u^{0.96} \quad (4.14)$$

where u is the superficial velocity in the module.

Figure 4.9 Derivation of the mass transfer coefficient by Wilson's method. Toluene/water enrichments are plotted as a function of feed solution superficial velocity in pervaporation experiments. Enrichments were measured at different feed solution superficial velocities with spiral-wound membrane modules [15]

A second method of determining the coefficient (D_i/δ) and the intrinsic enrichment of the membrane E_o is to use Equation (4.11). The term $\ln(1 - 1/E)$ is plotted against the permeate flux measured at constant feed solution flow rates but different permeate pressures or feed solution temperatures. This type of plot is shown in Figure 4.10 for data obtained with aqueous trichloroethane solutions in pervaporation experiments with silicone rubber membranes.

The coefficients D_i/δ obtained at each velocity in Figure 4.10 can then be plotted as a function of the feed superficial velocity. The data show that the ratio D_i/δ varies with the superficial velocity according to the equation

$$D_i/\delta = 9 \times 10^{-4} u^{0.8} \tag{4.15}$$

From Equations (4.14) and (4.15), the value of the term D_i/δ at a fluid velocity of 30 cm/s is $1.6\text{--}1.8 \times 10^{-2}$ cm/s. Based on a trichloroethane diffusion coefficient in the boundary layer of 2×10^{-5} cm²/s, this yields a boundary layer thickness of 10–15 μm. This boundary layer thickness is in the same range as values calculated for reverse osmosis with similar modules.

Figure 4.10 Trichloroethane enrichment $[\ln(1 - 1/E)]$ as a function of permeate flux J_v in pervaporation experiments with silicone rubber membranes in spiral-wound modules using solutions of 100 ppm trichloromethane in water [15]. Feed solution flow rates are shown

Concentration Polarization in Liquid Separation Processes

The effect of concentration polarization on specific membrane processes is discussed in the individual application chapters. However, a brief comparison of the magnitude of concentration polarization is given in Table 4.1 for processes involving liquid feed solutions. The key simplifying assumption is that the boundary layer thickness is 20 μm for all processes. This boundary layer thickness is typical of values calculated for separation of solutions with spiral-wound modules in reverse osmosis, pervaporation, and ultrafiltration. Tubular, plate-and-frame, and bore-side feed hollow fiber modules, because of their better flow velocities, generally have lower calculated boundary layer thicknesses. Hollow fiber modules with shell-side feed generally have larger calculated boundary layer thicknesses because of their poor fluid flow patterns.

Table 4.1 shows typical enrichments and calculated Peclet numbers for membrane processes with liquid feeds. In this table it is important to recognize the difference between enrichment and separation factor. The enrichments shown are calculated for the minor component. For example, in the dehydration of ethanol, a typical feed solution of 96% ethanol and 4% water yields a permeate containing about 80% water; the enrichment, that is, the ratio of the permeate to feed concentration, is about 20. In Figure 4.11, the calculated Peclet numbers and enrichments shown in Table 4.1 are plotted on the Wijmans graph to show the relative importance of concentration polarization for the processes listed.

Table 4.1 Representative values of the concentration polarization modulus calculated for a variety of liquid separation processes. For these calculations a boundary layer thickness of 20 μm , typical of that in most spiral-wound membrane modules, is assumed

Process	Typical enrichment, E_o	Typical flux [in engineering units and as J_v (10^{-3} cm/s)]	Diffusion coefficient (10^{-6} cm ² /s)	Peclet number, $J_v \delta / D_i$	Concentration polarization modulus [Equation (4.9)]
Reverse osmosis					
Seawater desalination	0.01	30 gal/ft ² · day(1.4)	10	0.28	1.3
Brackish water desalination	0.01	50 gal/ft ² · day(2.3)	10	0.46	1.5

Pervaporation					
Ethanol dehydration	20	0.1 kg/m ² · h(0.003)	20	0.0003	1.0
VOC from water	2000	1.0 kg/m ² · h(0.03)	20	0.003	0.14
Coupled transport					
Copper from water	1000	60 mg/cm ² · min(0.001)	10	0.0002	0.8

Figure 4.11 Peclet numbers and intrinsic enrichments for the membrane separation processes shown in Table 4.1 superimposed on the concentration polarization plot of Wijmans *et al.* [13]

In coupled transport and solvent dehydration by pervaporation, concentration polarization effects are generally modest and controllable, with a concentration polarization modulus of 1.5 or less. In reverse osmosis, the Peclet number of 0.3–0.5 was calculated on the basis of typical fluxes of current reverse osmosis membrane modules, which are 30- to 50-gal/ft² · day. Concentration polarization modulus values in this range are between 1.0 and 1.5.

Figure 4.11 shows that ultrafiltration and pervaporation for the removal of organic solutes from water are both seriously affected by concentration polarization. In ultrafiltration, the low diffusion coefficient of macromolecules produces a concentration of retained solutes 70 times the bulk solution volume at the membrane surface. At these high concentrations, macromolecules precipitate, forming a gel layer at the membrane surface and reducing flux. The effect of this gel layer on ultrafiltration membrane performance is discussed in Chapter 6.

In the case of pervaporation of dissolved volatile organic compounds (VOCs) from water, the magnitude of the concentration polarization effect is a function of the enrichment factor. The selectivity of pervaporation membranes to different VOCs varies widely, so the intrinsic enrichment and the magnitude of concentration polarization effects depend strongly on the solute. Table 4.2 shows experimentally measured enrichment values for a series of dilute VOC solutions treated with silicone rubber membranes in spiral-wound modules [15]. When these values are superimposed on the Wijmans plot as shown in Figure 4.12, the concentration polarization modulus varies from 1.0, that is, no concentration polarization, for isopropanol, to 0.1 for trichloroethane, which has an enrichment of 5700.

Table 4.2 Enrichment factors measured for the pervaporation of VOCs from dilute solutions with silicone rubber spiral-wound modules

Solute	Enrichment (E_o)
Trichloroethylene	5700
Toluene	3600
Ethyl acetate	270
Isopropanol	18

Figure 4.12 A portion of the Wijmans plot shown in Figure 4.7 expanded to illustrate concentration polarization in pervaporation of dilute aqueous organic solutions. With solutes such as toluene and trichloroethylene, high intrinsic enrichments produce severe concentration polarization. Concentration polarization is much less with solutes such as ethyl acetate (enrichment 270), and is essentially eliminated with isopropanol (enrichment 18) [15]

Concentration Polarization in Gas Separation Processes

Concentration polarization in gas separation processes has not been widely studied, and the effect is often assumed to be small because of the high diffusion coefficients of gases. However, the volume flux of gas through the membrane is also high, so concentration polarization effects are important for several processes.

In calculating the expression for the concentration polarization modulus of gases, the simplifying assumption that the volume fluxes on each side of the

membrane are equal cannot be made. The starting point for the calculation is the mass-balance Equation (4.6), which for gas permeation is written

$$J_{v_f} c_i - \frac{D_i dc_i}{dx} = J_{v_p} c_{i_p} \quad (4.16)$$

where J_{v_f} is the volume flux of gas on the feed side of the membrane and J_{v_p} is the volume flux on the permeate side. These volume fluxes ($\text{cm}^3/\text{cm}^2 \cdot \text{s}$) can be linked by correcting for the pressure on each side of the membrane using the expression

$$J_{v_f} p_o = J_{v_p} p_\ell \quad (4.17)$$

where p_o and p_ℓ are the gas pressures on the feed and permeate sides of the membrane. Hence,

$$J_{v_f} \frac{p_o}{p_\ell} = J_{v_f} \varphi = J_{v_p} \quad (4.18)$$

where φ is the pressure ratio p_o/p_ℓ across the membrane. Substituting Equation (4.18) into Equation (4.16) and rearranging gives

$$-D_i \frac{dc_i}{dx} = J_{v_f} (\varphi c_{i_p} - c_i) \quad (4.19)$$

Integrating across the boundary layer thickness, as before, gives

$$\frac{c_{i_o}/\varphi - c_{i_p}}{c_{i_b}/\varphi - c_{i_p}} = \exp\left(\frac{J_{v_f} \delta}{D}\right) \quad (4.20)$$

For gases, the enrichment terms, E and E_o , are most conveniently expressed in volume fractions, so that

$$E_o = \frac{c_{i_p} p_o}{p_\ell c_{i_o}} = \frac{c_{i_p}}{c_{i_o}} \varphi \quad (4.21)$$

and

$$E = \frac{c_{i_p}}{p_\ell} \cdot \frac{p_o}{c_{i_b}} = \frac{c_{i_p}}{c_{i_b}} \cdot \varphi \quad (4.22)$$

Equation (4.20) can then be written as

$$\exp\left(\frac{J_{v_f} \delta}{D_i}\right) = \frac{1 - 1/E_o}{1 - 1/E} \quad (4.23)$$

which on rearranging gives

$$E/E_o = c_{i_o}/c_{i_b} = \frac{\exp(J_{v_f} \delta/D_i)}{1 + E_o[\exp(J_{v_f} \delta/D_i) - 1]} \quad (4.24)$$

Figure 4.13 A portion of the Wijmans plot shown in Figure 4.7 expanded to illustrate concentration polarization in some important gas separation applications

Equation (4.24) has the same form as the expression for the concentration polarization modulus of liquids, Equation (4.9).

Equation (4.24) can be used to calculate the expected concentration polarization modulus for some of the better-known gas separation applications. The results of the calculations are tabulated in Table 4.3 and shown on a Wijmans plot in Figure 4.13. To obtain agreement between these calculations and industrial experience [16,17], it is necessary to assume the boundary layer thickness in gases is far greater than in liquids. In the calculations of Peclet numbers listed in Table 4.3 a boundary layer thickness of 2000 μm is used, 100 times larger than the value used in similar calculations for the Peclet number for liquid separation processes given in Table 4.1. A boundary layer thickness this large does not seem physically reasonable and in some cases is more than the membrane channel width. The reason for this huge difference between gases and liquids may be related to the difference in the densities of these fluids. Channeling, in which a portion of the feed gas completely bypasses contact with the membrane through some flow maldistribution in the module, can also reduce module efficiency in a way that is difficult to separate from concentration polarization. Channeling is much more noticeable in gas permeation modules than in liquid permeation modules.

Table 4.3 Calculated Peclet numbers for several important gas separations. The boundary layer thickness is assumed to be 2000 μm . Permeant diffusion coefficients in the gas boundary layer are taken from tables for ambient pressure diffusion coefficients in Cussler [8] and corrected for pressure. Membrane enrichments E_o are calculated using Equation (4.21)

Gas separation process	Pressure-normalized flux, P/ℓ [$10^{-6} \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$]	Pressure feed/permeate (atm/atm)	Volume flux at feed pressure, J_{o_f} ($10^{-3} \text{ cm}^3/\text{cm}^2 \cdot \text{s}$)	Membrane selectivity, α	Enrichment, E_o	Feed gas diffusion coefficient at feed pressure ($10^{-3} \text{ cm}^2/\text{s}$)	Peclet number, $J_{o_f} \delta/D_l (\times 10^4)$	Concentration polarization modulus [Equation (4.24)]

Cross-flow, Co-flow and Counter-flow

In the discussion of concentration polarization to this point, the assumption is made that the volume flux through the membrane is large, so the concentration on the permeate side of the membrane is determined by the ratio of the component fluxes. This assumption is almost always true for liquid separation processes, such as ultrafiltration or reverse osmosis, but must be modified in a few gas separation and pervaporation processes. In these processes, a lateral flow of gas is sometimes used to change the composition of the gas on the permeate side of the membrane. Figure 4.14 illustrates a laboratory gas permeation experiment using this effect. As the pressurized feed gas mixture is passed over the membrane surface, certain components permeate the membrane. On the permeate side of the membrane, a lateral flow of helium or other inert gas sweeps the permeate from the membrane surface. In the absence of the sweep gas, the composition of the gas mixture on the permeate side of the membrane is determined by the flow of components from the feed. If a large flow of sweep gas is used, the partial

Figure 4.14 (a) Flow schematic of permeation using a permeate-side sweep gas sometimes used in laboratory gas separation and pervaporation experiments. (b) The concentration gradients that form on the permeate side of the membrane depend on the volume of sweep gas used. In laboratory experiments a large sweep-gas-to-permeate-gas flow ratio is used, so the concentration of permeate at the membrane surface is very low

pressure of the permeating components on the permeate side of the membrane is reduced to a low value. The difference in partial pressure of the permeating gases from the feed to the permeate side of the membrane is thereby increased, and the flow across the membrane increases proportionately. Sweep gases are sometimes used in gas permeation and pervaporation laboratory experiments. The sweep gas is generally helium and the helium/permeate gas mixture is fed to a gas chromatograph for analysis.

The drawback of using an external permeate-side sweep gas to lower the partial pressure on the permeate side of the membrane for an industrial process is that the sweep gas and permeating component must subsequently be separated. In some cases this may not be difficult; some processes that have been suggested but rarely used are shown in Figure 4.15. In these examples, the separation of the sweep gas and the permeating component is achieved by condensation. If the permeating gas is itself easily condensed, an inert gas such as nitrogen can be used as the sweep [18]. An alternative is a condensable vapor such as steam [19–21].

In the examples illustrated in Figures 4.14 and 4.15, the sweep gas is an inert gas that is unlike the permeating components. However, the sweep gas could be a mixture of the permeating components at a different composition. An example of this type of process is shown schematically in Figure 4.16, which illustrates the separation of nitrogen from air using a membrane that preferentially permeates oxygen. The feed air, containing approximately 20 vol% oxygen, is introduced under pressure at one end of the module. The permeate gas at this end of the module typically contains about 50 vol% oxygen (at a lower pressure). As the feed gas travels down the membrane module it becomes increasingly depleted in oxygen (enriched in nitrogen) and leaves the module as a residue gas containing 99% nitrogen. The permeate gas at this end of the module contains about 5 vol% oxygen and 95 vol% nitrogen. If this gas is directed to flow counter to the incoming feed gas, as shown in Figure 4.16, the effect is to sweep the permeate side of the membrane with a flow of oxygen-depleted, nitrogen-enriched gas. This is beneficial because the oxygen gradient through the membrane is increased, which increases its flux through the membrane. Simultaneously the nitrogen gradient is decreased, which decreases its flux through the membrane. An opposite negative result would result if the permeate gas were moved in the same direction as the feed gas (that is co-flow). This would have the effect of sweeping the permeate side of the membrane with oxygen-enriched gas.

The cross-, co- and counter-flow schemes are illustrated in Figure 4.17, together with the concentration gradient across a median section of the membrane. It follows from Figure 4.17 that system performance can be improved by operating a module in an appropriate flow mode (generally counter-flow). However, such improvements require that the concentration at the membrane permeate surface equals the bulk concentration of the permeate at that point. This condition cannot be met with processes such as ultrafiltration or reverse osmosis in which the permeate is a liquid. In these processes, the selective side of the membrane faces the

Figure 4.15 Sweep gas systems proposed for industrial processes

feed solution, and a microporous support layer faces the permeate. Concentration gradients easily build up in this boundary layer, completely outweighing the benefit of counter-flow. Thus, counter-flow (sweep) module designs are limited to gas separation and pervaporation processes. In these processes the permeate is a gas, and permeate-side concentration gradients are more easily controlled because diffusion coefficients in gases are high.

Figure 4.16 An illustration of a counter-flow module for the separation of nitrogen from air. Directing the permeate to flow counter to the feed sweeps the permeate side of the membrane with a flow of oxygen-depleted gas. This increases the oxygen flux and decreases the nitrogen flux through the membrane

Figure 4.17 (a) Cross-, (b) co- and (c) counter-flow schemes in a membrane module and the changes in the concentration gradients that occur across a median section of the membrane

The benefit obtained from counter-flow depends on the particular separation, but it can often be substantial, particularly in gas separation and pervaporation processes. A comparison of cross-flow, counter-flow, and counter-flow/sweep for the same membrane module used to dehydrate natural gas is shown in Figure 4.18. Water is a smaller molecule and much more condensable than methane, the main component of natural gas, so membranes with a water/methane selectivity of 400–500 are readily available. In the calculations shown in Figure 4.18, the membrane is assumed to have a pressure-normalized

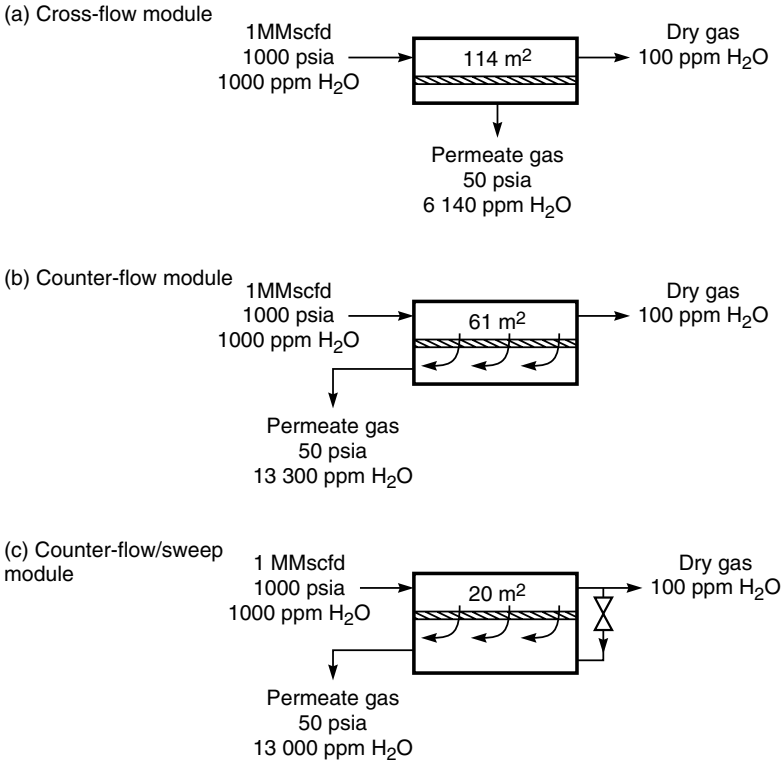

Figure 4.18 Comparison of (a) cross-flow, (b) counter-flow and (c) counter-flow sweep module performance for the separation of water vapor from natural gas. Pressure-normalized methane flux: $5 \times 10^{-6} \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$; membrane selectivity, water/methane: 200

methane flux of $5 \times 10^{-6} \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$ and a water/methane selectivity of 200. Counter-flow/sweep modules have a substantial advantage in this separation because the separation is completely pressure-ratio-limited.²

²The importance of the pressure ratio in separating gas mixtures can be illustrated by considering the separation of a gas mixture with component concentrations (mol%) n_{i_o} and n_{j_o} at a feed pressure of p_o . A flow of component across the membrane can only occur if the partial pressure of component i on the feed side of the membrane, $n_{i_o} p_o$, is greater than the partial pressure of component i on the permeate side of the membrane, $n_{i_\ell} p_\ell$. That is

$$n_{i_o} p_o > n_{i_\ell} p_\ell$$

It follows that the maximum enrichment achieved by the membrane can be expressed as

$$\frac{n_{i_\ell}}{n_{i_o}} \leq \frac{p_o}{p_\ell}$$

In the cross-flow module illustrated in Figure 4.18(a) the average concentration of water on the feed side of the membrane as it decreases from 1000 to 100 ppm is 310 ppm (the log mean). The pooled permeate stream has a concentration of 6140 ppm. The counter-flow module illustrated in Figure 4.18(b) performs substantially better, providing a pooled permeate stream with a concentration of 13 300 ppm. Not only does the counter-flow module perform a two-fold better separation, it also requires only about half the membrane area.

In the case of the counter-flow/sweep membrane module illustrated in Figure 4.18(c) a portion of the dried residue gas stream is expanded across a valve and used as the permeate-side sweep gas. The separation obtained depends on how much gas is used as a sweep. In the calculation illustrated, 5% of the residue gas is used as a sweep; even so the result is dramatic. The concentration of water vapor in the permeate gas is 13 000 ppm, almost the same as the perfect counter-flow module shown in Figure 4.18(b), but the membrane area required to perform the separation is one-third of the counter-flow case. *Mixing separated residue gas with the permeate gas improves the separation!* The cause of this paradoxical result is illustrated in Figure 4.19 and discussed in a number of papers by Cussler *et al.* [16].

Figure 4.19(a) shows the concentration of water vapor on the feed and permeate sides of the membrane module in the case of a simple counter-flow module. On the high-pressure side of the module, the water vapor concentration in the feed gas drops from 1000 ppm to about 310 ppm halfway through the module and to 100 ppm at the residue end. The graph directly below the module drawing shows the theoretical maximum concentration of water vapor on the permeate side of the membrane. This maximum is determined by the feed-to-permeate pressure ratio of 20 as described in the footnote to page 186. The actual calculated permeate-side concentration is also shown. The difference between these two lines is a measure of the driving force for water vapor transport across the membrane. At the feed end of the module, this difference is about 1000 ppm, but at the permeate end the difference is only about 100 ppm.

Figure 4.19(b) shows an equivalent figure for a counter-flow module in which 5% of the residue gas containing 100 ppm water vapor is expanded to 50 psia and introduced as a sweep gas. The water vapor concentration in the permeate gas at the end of the membrane then falls from 1900 ppm to 100 ppm, producing a dramatic increase in water vapor permeation through the membrane at the residue end of the module. The result is a two-thirds reduction in the size of the module.

This means that the enrichment can never exceed the pressure ratio of p_o/p_t , no matter how selective the membrane. In the example above, the maximum water vapor enrichment across the membrane is 20 (1000 psia/50 psia) even though the membrane is 200 times more permeable to water than methane.

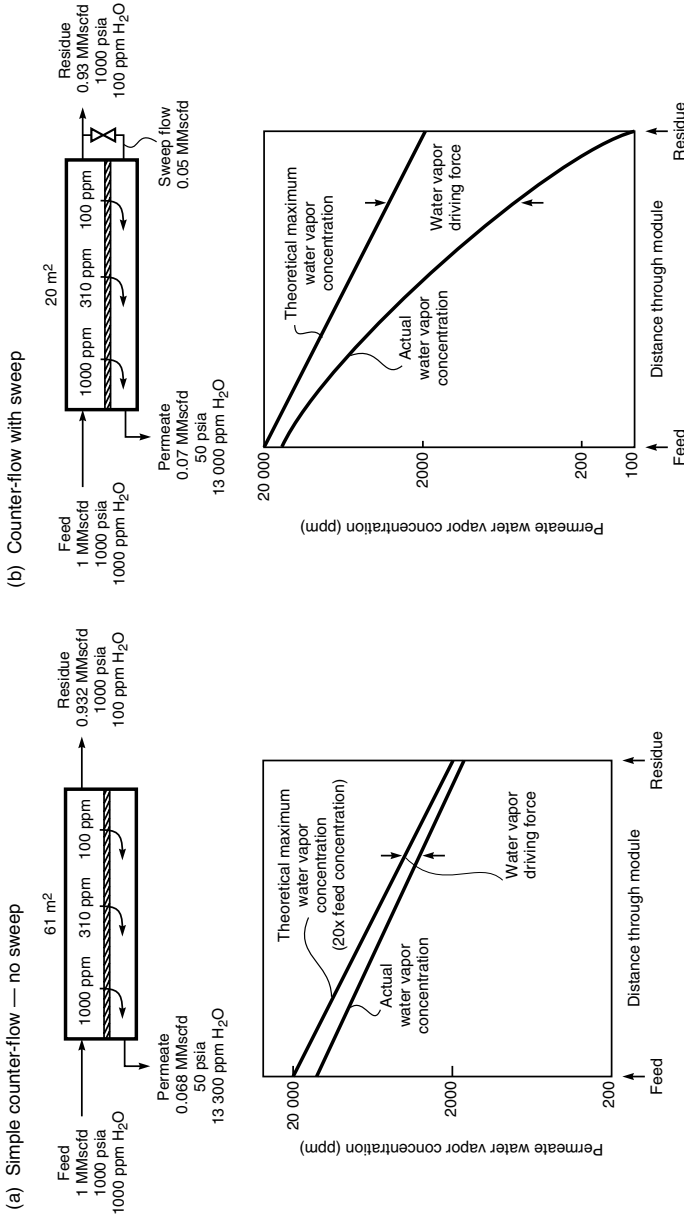

Figure 4.19 The effect of a small permeate-side, counter-flow sweep on the water vapor concentration on the permeate side of a membrane. In this example calculation, the sweep flow reduces the membrane area by two-thirds

Conclusions and Future Directions

Few membrane processes are unaffected by concentration polarization, and the effect is likely to become more important as membrane materials and membrane fabrication techniques improve. As membrane flux and selectivity increase concentration polarization effects become exponentially larger. In the laboratory, concentration polarization is controlled by increasing the turbulence of the feed fluid. However, in industrial systems this approach has practical limits. In ultrafiltration and electro dialysis, for example, liquid recirculation pumps are already a major portion of the plant's capital cost and consume 20 to 40 % of the power used for the separation. The best hope for minimizing concentration polarization effects lies in improving membrane module design, understanding the basis for the choice of channel spacer materials, and developing methods of controlling the feed fluid flow in the module. Unfortunately, this type of work is generally performed in membrane system manufacturing companies and is not well covered in the open literature.

5 REVERSE OSMOSIS

Introduction and History

Reverse osmosis is a process for desalting water using membranes that are permeable to water but essentially impermeable to salt. Pressurized water containing dissolved salts contacts the feed side of the membrane; water depleted of salt is withdrawn as a low-pressure permeate. The ability of membranes to separate small solutes from water has been known for a very long time. Pfeffer, Traube and others studied osmotic phenomena with ceramic membranes as early as the 1850s. In 1931 the process was patented as a method of desalting water, and the term reverse osmosis was coined [1]. Modern interest dates from the work of Reid and Breton, who in 1959 showed that cellulose acetate films could perform this type of separation [2]. Their films were 5–20 μm thick so fluxes were very low but, by pressurizing the feed salt solution to 1000 psi, they obtained salt removals of better than 98 % in the permeate water. The breakthrough discovery that made reverse osmosis a practical process was the development of the Loeb–Sourirajan anisotropic cellulose acetate membrane [3]. This membrane had 10 times the flux of the best membrane of Reid and Breton and equivalent rejections. With these membranes, water desalination by reverse osmosis became a potentially practical process, and within a few years small demonstration plants were installed. The first membrane modules were tubular or plate-and-frame systems, but Westmoreland, Bray, and others at the San Diego Laboratories of Gulf General Atomics (the predecessor of Fluid Systems Inc.) soon developed practical spiral-wound modules [4,5]. Later, Du Pont [6], building on the earlier work of Dow, introduced polyamide hollow fine fiber reverse osmosis modules under the name Permassep[®].

Anisotropic cellulose acetate membranes were the industry standard through the 1960s to the mid-1970s, until Cadotte, then at North Star Research, developed the interfacial polymerization method of producing composite membranes [7]. Interfacial composite membranes had extremely high salt rejections, combined with good water fluxes. Fluid Systems introduced the first commercial interfacial composite membrane in 1975. The construction of a large seawater desalination plant at Jiddah, Saudi Arabia using these membranes was a milestone in reverse

osmosis development [8]. Later, at FilmTec, Cadotte developed a fully aromatic interfacial composite membrane based on the reaction of phenylene diamine and trimesoyl chloride [9,10]. This membrane has become the new industry standard. The most recent development, beginning in the mid-1980s, was the introduction of low-pressure nanofiltration membranes by all of the major reverse osmosis companies [11,12]. These membranes are used to separate trace amounts of salts and other dissolved solutes from already good-quality water to produce ultrapure water for the electronics industry. An important recent advance by Grace Davison working with Mobil Oil, now ExxonMobil, is the development of a reverse osmosis (hyperfiltration) process to separate a solution of methyl ethyl ketone and lube oil. A plant installed at a Beaumont, Texas, refinery in 1998 was the first large-scale use of pressure-driven membranes to separate organic solvent mixtures.

Currently, approximately one billion gal/day of water are desalted by reverse osmosis. Half of this capacity is installed in the United States, Europe, and Japan, principally to produce ultrapure industrial water. The remainder is installed in the Middle East and other desert regions to produce municipal drinking water from brackish groundwater or seawater. In recent years, the interfacial composite membrane has displaced the anisotropic cellulose acetate membrane in most applications. Interfacial composite membranes are supplied in spiral-wound module form; the market share of hollow fiber membranes is now less than

Figure 5.1 Milestones in the development of reverse osmosis

10% of new installed capacity and shrinking [13]. Tubular and plate-and-frame systems, which are only competitive for small niche applications involving particularly highly fouling water, have less than 5% of the market. Some of the milestones in the development of the reverse osmosis industry are summarized in Figure 5.1.

Theoretical Background

Salt and water permeate reverse osmosis membranes according to the solution-diffusion transport mechanism are described in Chapter 2. The water flux, J_i , is linked to the pressure and concentration gradients across the membrane by the equation

$$J_i = A(\Delta p - \Delta\pi) \quad (5.1)$$

where Δp is the pressure difference across the membrane, $\Delta\pi$ is the osmotic pressure differential across the membrane, and A is a constant. As this equation shows, at low applied pressure, when $\Delta p < \Delta\pi$, water flows from the dilute to the concentrated salt-solution side of the membrane by normal osmosis. When $\Delta p = \Delta\pi$, no flow occurs, and when the applied pressure is higher than the osmotic pressure, $\Delta p > \Delta\pi$, water flows from the concentrated to the dilute salt-solution side of the membrane.

The salt flux, J_j , across a reverse osmosis membrane is described by the equation

$$J_j = B(c_{j_o} - c_{j_e}) \quad (5.2)$$

where B is the salt permeability constant and c_{j_o} and c_{j_e} , respectively, are the salt concentrations on the feed and permeate sides of the membrane. The concentration of salt in the permeate solution (c_{j_e}) is usually much smaller than the concentration in the feed (c_{j_o}), so equation (5.2) can be simplified to

$$J_j = Bc_{j_o} \quad (5.3)$$

It follows from these two equations that the water flux is proportional to the applied pressure, but the salt flux is independent of pressure. This means that the membrane becomes more selective as the pressure increases. Selectivity can be measured in a number of ways, but conventionally, it is measured as the salt rejection coefficient \mathbb{R} , defined as

$$\mathbb{R} = \left[1 - \frac{c_{j_e}}{c_{j_o}} \right] \times 100\% \quad (5.4)$$

The salt concentration on the permeate side of the membrane can be related to the membrane fluxes by the expression

$$c_{j_e} = \frac{J_j}{J_i} \times \rho_i \quad (5.5)$$

where ρ_i is the density of water (g/cm^3). By combining equations (5.1) to (5.5), the membrane rejection can be expressed as

$$\mathbb{R} = \left[1 - \frac{\rho_i \cdot B}{A(\Delta p - \Delta \pi)} \right] \times 100\% \quad (5.6)$$

The effects of the most important operating parameters on membrane water flux and salt rejection are shown schematically in Figure 5.2 [14]. The effect of feed pressure on membrane performance is shown in Figure 5.2(a). As predicted by Equation (5.1), at a pressure equal to the osmotic pressure of the feed (350 psi), the water flux is zero; thereafter, it increases linearly as the pressure is increased. The salt rejection also extrapolates to zero at a feed pressure of 350 psi as predicted by Equation (5.6), but increases very rapidly with increased pressure to reach salt rejections of more than 99% at an applied pressure of 700 psi (twice the feed solution osmotic pressure).

The effect of increasing the concentration of salt in the feed solution on membrane performance is illustrated in Figure 5.2(b). Increasing the salt concentration effectively increases the osmotic pressure term in Equation (5.1); consequently, at a constant feed pressure, the water flux falls with increasing salt concentration at a feed pressure of 1000 psi. The water flux approaches zero when the salt concentration is about 10 wt%, at which point the osmotic pressure equals the applied hydrostatic pressure. The salt rejection also extrapolates to zero rejection at this point but increases rapidly with decreasing salt concentration. Salt rejections of more than 99% are reached at salt concentrations below 6%, corresponding to a net applied pressure of about 400 psi.

The effect of temperature on salt rejection and water flux illustrated in Figure 5.2(c) is more complex. Transport of both salt and water represented by Equations (5.1) and (5.3) is an activated process, and both increase exponentially with increasing temperature. As Figure 5.2(c) shows, the effect of temperature on the water flux of membranes is quite dramatic: the water flux doubles as the temperature is increased by 30°C. However, the effect of temperature on the salt flux is even more marked. This means that the salt rejection coefficient, proportional to the ratio B/A in Equation (5.6), actually declines slightly as the temperature increases.

Measurements of the type shown in Figure 5.2 are typically obtained with small laboratory test cells. A typical test system is illustrated in Figure 5.3. Such systems are often used in general membrane quality control tests with a number of cells arranged in series through which fluid is pumped. The system is usually operated with a test solution of 0.2 to 1.0% sodium chloride at pressures ranging from 150 to 600 psi. The storage tank and flow recirculation rate are made large enough that changes in concentration of the test solution due to loss of permeate can be ignored.

Some confusion can occur over the rejection coefficients quoted by membrane module manufacturers. The intrinsic rejection of good quality membranes measured in a laboratory test system might be in the range 99.5 to 99.7%, whereas

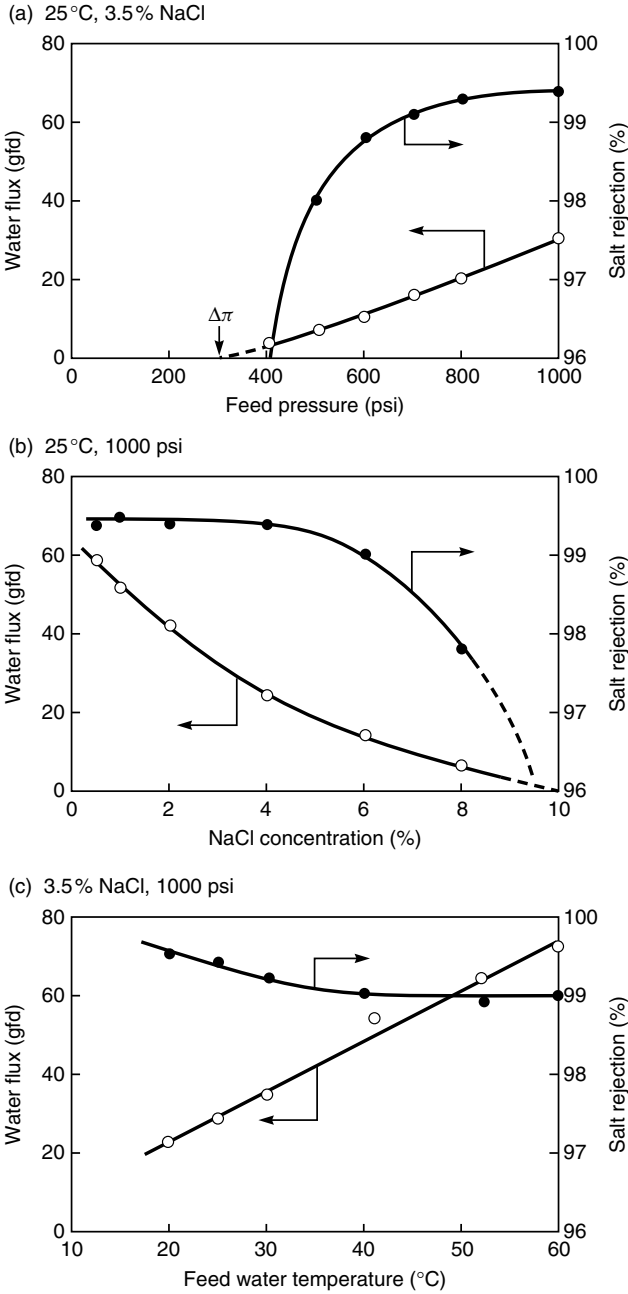

Figure 5.2 Effect of pressure, feed salt concentration and feed temperature on the properties of good quality seawater desalination membranes (SW-30) [14]

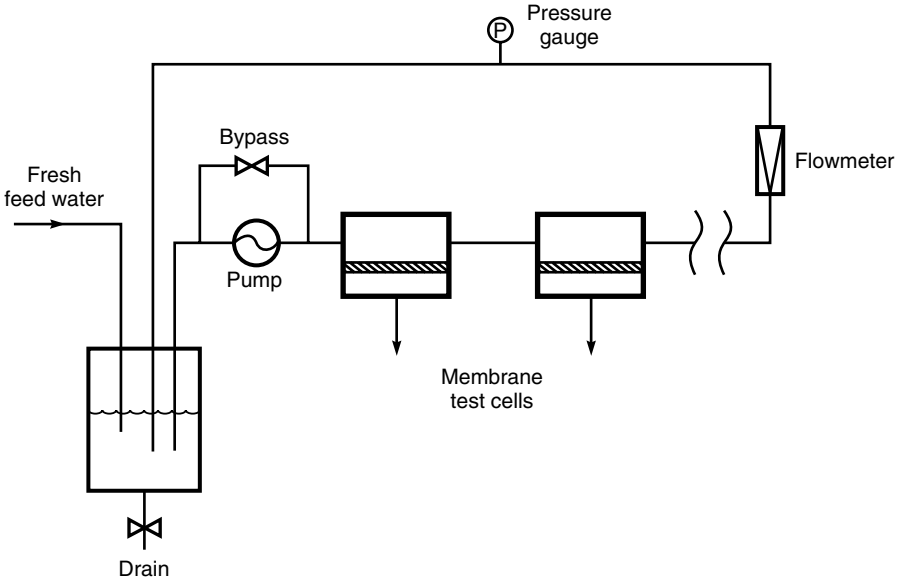

Figure 5.3 Flow schematic of a high-pressure laboratory reverse osmosis test system

the same membrane in module form may have a salt rejection of 99.4 to 99.5%. This difference is due to small membrane defects introduced during module production and to concentration polarization, which has a small but measurable effect on module rejection. Manufacturers call the module value the nominal rejection. However, manufacturers will generally only guarantee a lower figure, for example, 99.3% for the initial module salt rejection to take into account variations between modules. To complicate matters further, module performance generally deteriorates slowly during the 1- to 3-year guaranteed module lifetime due to membrane compaction, membrane fouling, and membrane degradation from hydrolysis, chlorine attack, or membrane cleaning. A decrease in the membrane flux by 20% over the 3-year lifetime of typical modules is not unusual, and the rejection can easily fall by 0.2–0.3%. Reverse osmosis system manufacturers allow for this decline in performance when designing systems.

Membranes and Materials

A number of membrane materials and membrane preparation techniques have been used to make reverse osmosis membranes. The target of much of the early work was seawater desalination (approximately 3.5 wt% salt), which requires membranes with salt rejections of greater than 99.3% to produce an acceptable permeate containing less than 500 ppm salt. Early membranes could only meet

this target performance when operated at very high pressures, up to 1500 psi. As membrane performance has improved, this pressure has dropped to 800–1000 psi. Recently, the need for desalination membranes has shifted more to brackish water feeds with salt concentrations of 0.2–0.5 wt%. For this application, membranes are typically operated at pressures in the 150–400 psi range with a target salt rejection of about 99%. With the growth of the electronics industry the demand for ultrapure water to wash silicon wafers has increased. The feed to an ultrapure water reverse osmosis plant is often municipal drinking water, which may only contain 100 to 200 ppm dissolved salts, mostly divalent ions. The target membrane performance in this case may be 98–99% sodium chloride rejection but more than 99.5% divalent ion rejection. These membranes are operated at low pressures, typically in the 100–200 psi range. Many manufacturers tailor the properties of a single membrane material to meet the requirements of different applications. Invariably a significant trade-off between flux and rejection is involved.

A brief description of the commercially important membranes in current use follows. More detailed descriptions can be found in specialized reviews [13,15,16]. Petersen's review on interfacial composite membranes is particularly worth noting [17].

Cellulosic Membranes

Cellulose acetate was the first high-performance reverse osmosis membrane material discovered. The flux and rejection of cellulose acetate membranes have now been surpassed by interfacial composite membranes. However, cellulose acetate membranes still maintain a small fraction of the market because they are easy to make, mechanically tough, and resistant to degradation by chlorine and other oxidants, a problem with interfacial composite membranes. Cellulose acetate membranes can tolerate up to 1 ppm chlorine, so chlorination can be used to sterilize the feed water, a major advantage with feed streams having significant bacterial loading.

The water and salt permeability of cellulose acetate membranes is extremely sensitive to the degree of acetylation of the polymer used to make the membrane [2,18,19]. The effect of degree of acetylation on salt and water permeability is illustrated in Figure 5.4 [20]. Fully substituted cellulose triacetate (44.2 wt% acetate) has an extremely high water-to-salt permeability ratio, reflecting its very high selectivity. Unfortunately the water permeability is low so these membranes have low water fluxes. Nonetheless, cellulose triacetate hollow fine fiber membranes are still produced for some seawater desalination plants because salt rejections of about 99.5% with a seawater feed are attainable. However, most commercial cellulose acetate membranes use a polymer containing about 40 wt% acetate with a degree of acetylation of 2.7. These membranes generally achieve 98–99% sodium chloride rejection and have reasonable fluxes. The permeability

Figure 5.4 Permeabilities of cellulose acetate to water and sodium chloride as a function of acetyl content at 25 °C. Data from Lonsdale *et al.* [20]

data shown in Figure 5.4 can be replotted to show expected salt rejections, as shown in Figure 5.5.

The data in Figure 5.5 show that thick films of cellulose acetate made from 39.8 wt% acetate polymer should reject 99.5 % sodium chloride. In practice, this theoretical rejection is very difficult to obtain with practical thin membranes [21]. Figure 5.6 shows the salt rejection properties of 39.8 wt% acetate membranes made by the Loeb–Sourirajan process [22]. The freshly formed membranes have very high water fluxes of almost 200 gal/ft² · day (gfd) but almost no rejection of sodium chloride. The membranes appear to have a finely microporous structure and are permeable to quite large solutes such as sucrose. The rejection of these membranes can be greatly improved by heating in a bath of hot water for a few minutes. Apparently, this annealing procedure, used with all cellulose acetate membranes, modifies the salt rejection layer of the membrane by eliminating the micropores and producing a denser, more salt-rejecting skin. The water flux decreases, and the sodium chloride rejection increases. The temperature of this

Figure 5.5 Water permeability as a function of sodium chloride permeability for membranes made from cellulose acetate of various degrees of acetylation. The expected rejection coefficients for these membranes, calculated for dilute salt solutions using Equation (5.6), are shown

Figure 5.6 The effect of annealing temperatures on the flux and rejection of cellulose acetate membranes. The annealing temperature is shown on the figure. (Cellulose diacetate membranes tested at 1500 psig with 0.5 M NaCl) [22]. Reprinted with permission from Elsevier

annealing step determines the final properties of the membrane. A typical rejection/flux curve for various annealed membranes is shown in Figure 5.6. Because their properties change on heating, cellulose acetate membranes are generally not used above about 35 °C. The membranes also slowly hydrolyze over time, so the feed water is usually adjusted to pH 4–6, the range in which the membranes are most stable [23].

Throughout the 1960s considerable effort was expended on understanding the Loeb–Sourirajan membrane production process to improve the quality of the membranes produced. The casting solution composition is critically important. Other important process steps are the time of evaporation before precipitation, the temperature of the precipitation bath, and the temperature of the annealing step. Most of the early membranes were made of 39.8 wt% acetate polymer because this material was readily available and had the most convenient solubility properties. By the 1970s, however, a number of workers, particularly Saltonstall and others at Envirogenics, had developed better membranes by blending the 39.8 wt% acetate polymer with small amounts of triacetate polymer (44.2 wt% acetate) or other cellulose esters such as cellulose acetate butyrate [24]. These blends are generally used to form current cellulose acetate membranes. Good-quality blend membranes with seawater salt rejections of 99.0–99.5 %, close to the theoretical salt rejection determined by thick film measurements, can be made, but the flux of these membranes is modest. However, most applications of cellulose acetate membranes do not require such high salt rejections, so the typical commercial cellulose acetate membrane has good fluxes and a sodium chloride rejection of about 96 %.

Noncellulosic Polymer Membranes

During the 1960s and 1970s the Office of Saline Water sponsored development of noncellulosic reverse osmosis membranes. Many polymers were evaluated as Loeb–Sourirajan membranes but few matched the properties of cellulose acetate. Following the development of interfacial composite membranes by Cadotte, this line of research was abandoned by most commercial membrane producers.

Nonetheless a few commercially successful noncellulosic membrane materials were developed. Polyamide membranes in particular were developed by several groups. Aliphatic polyamides have low rejections and modest fluxes, but aromatic polyamide membranes were successfully developed by Toray [25], Chemstrad (Monsanto) [26] and Permasep (Du Pont) [27], all in hollow fiber form. These membranes have good seawater salt rejections of up to 99.5 %, but the fluxes are low, in the 1 to 3 gal/ft² · day range. The Permasep[®] membrane, in hollow fine fiber form to overcome the low water permeability problems, was produced under the names B-10 and B-15 for seawater desalination plants until the year 2000. The structure of the Permasep B-15 polymer is shown in Figure 5.7. Polyamide membranes, like interfacial composite membranes, are susceptible to degradation by chlorine because of their amide bonds.

Figure 5.7 Aromatic polyamide used by Du Pont in its Permasep B-15 hollow fine fibers [27]

Figure 5.8 Membranes based on sulfonated polysulfone and substituted poly(vinyl alcohol) are produced by Hydranautics (Nitto) for nanofiltration applications

Loeb–Sourirajan membranes based on sulfonated polysulfone and substituted poly(vinyl alcohol) produced by Hydranautics (Nitto) have also found a commercial market as high-flux, low-rejection membranes in water softening applications because their divalent ion rejection is high. These membranes are also chlorine-resistant and have been able to withstand up to 40 000 ppm · h of chlorine exposure without degradation.¹ The structures of the polymers used by Hydranautics are shown in Figure 5.8.

Interfacial Composite Membranes

Since the discovery by Cadotte and his co-workers that high-flux, high-rejection reverse osmosis membranes can be made by interfacial polymerization [7,9,10], this method has become the new industry standard. Interfacial composite membranes have significantly higher salt rejections and fluxes than cellulose acetate membranes. The first membranes made by Cadotte had salt rejections in tests with 3.5 % sodium chloride solutions (synthetic seawater) of greater than 99 % and fluxes of 18 gal/ft² · day at a pressure of 1500 psi. The membranes could also be operated at temperatures above 35 °C, the temperature ceiling for Loeb–Sourirajan cellulose acetate membranes. Today's interfacial composite membranes are significantly better. Typical membranes, tested with 3.5 % sodium chloride solutions,

¹The ability of a reverse osmosis membrane to withstand chlorine attack without showing significant loss in rejection is measured in ppm · h. This is the product of chlorine exposure expressed in ppm and the length of exposure expressed in hours. Thus, 1000 ppm · h is 1 ppm chlorine for 1000 h or 10 ppm chlorine for 100 h or 1000 ppm chlorine for 1 h, and so on.

have a salt rejection of 99.5 % and a water flux of 30 gal/ft² · day at 800 psi; this is less than half the salt passage of the cellulose acetate membranes and twice the water flux. The rejection of low-molecular-weight dissolved organic solutes by interfacial membranes is also far better than cellulose acetate. The only drawback of interfacial composite membranes, and a significant one, is the rapid, permanent loss in selectivity that results from exposure to even ppb levels of chlorine or hypochlorite disinfectants [28]. Although the chlorine resistance of interfacial composite membranes has been improved, these membranes still cannot be used with feed water containing more than a few ppb of chlorine.

The chemistry and properties of some of the important interfacial composite membranes developed over the past 25 years are summarized in Table 5.1 [10,12,29,30]. The chemistry of the FT-30 membrane, which has an all-aromatic structure based on the reaction of phenylene diamine and trimesoyl chloride, is widely used. This chemistry, first developed by Cadotte [9] and shown in Figure 5.9, is now used in modified form by all the major reverse osmosis membrane producers.

For a few years after the development of the first interfacial composite membranes, it was believed that the amine portion of the reaction chemistry had to be polymeric to obtain good membranes. This is not the case, and the monomeric amines, piperazine and phenylenediamine, have been used to form membranes with very good properties. Interfacial composite membranes based on urea or amide bonds are subject to degradation by chlorine attack, but the rate of degradation of the membrane is slowed significantly if tertiary aromatic amines are used and the membranes are highly crosslinked. Chemistries based on all-aromatic or piperazine structures are moderately chlorine tolerant and can withstand very low level exposure to chlorine for prolonged periods or exposure to ppm levels

Figure 5.9 Chemical structure of the FT-30 membrane developed by Cadotte using the interfacial reaction of phenylene diamine with trimesoyl chloride

Table 5.1 Characteristics of major interfacial polymerization reverse osmosis membranes

Membrane	Developer	Properties
NS100 Polyethylenimine crosslinked with toluene 2,4-diisocyanate	Cadotte [29] North Star Research	The first interfacial composite membrane achieved seawater desalination characteristics of >99 % rejection, 18 gal/ft ² · day at 1500 psi with seawater
PA 300/RC-100 Epamine (epichlorohydrin- ethylenediamine adduct) crosslinked with isophthalyl or toluene 2,4-diisocyanate	Riley <i>et al.</i> [30] Fluid Systems, San Diego	The PA 300, based on isophthalyl chloride, was introduced first but RC-100, based on toluene 2,4-diisocyanate, proved more stable. This membrane was used at the first large reverse osmosis seawater desalination plant (Jiddah, Saudia Arabia)
NF40 and NTR7250 Piperazine crosslinked with trimesoyl chloride	Cadotte FilmTec [10] and Kamiyama Nitto Denko [12]	The first all-monomeric interfacial membrane. Only modest seawater desalination properties but is a good brackish water membrane. More chlorine-tolerant than earlier membranes because of the absence of secondary amine bonds
FT-30/SW-30 <i>m</i> -Phenylenediamine crosslinked with trimesoyl chloride	Cadotte FilmTec [10]	An all-aromatic, highly crosslinked structure giving exceptional salt rejection and very high fluxes. By tailoring the preparation techniques, brackish water or seawater membranes can be made. Seawater version has a rejection 99.3–99.5 % at 800 psi. Brackish water version has >99 % salt rejection at 25 gal/ft ² · day and 225 psi. All the major reverse osmosis companies produce variations of this membrane

for a few days. Early interfacial composite membranes such as the NS100 or PA300 membrane showed significant degradation at a few hundred ppm · h. Current membranes, such as the fully aromatic FilmTec FT-30 or the Hydranautics ESPA membrane, can withstand up to 1000 ppm · h chlorine exposure. A number of chlorine tolerance studies have been made over the years; a discussion of the literature has been given by Glater *et al.* [31]. Heavy metal ions such as iron appear to strongly catalyze chlorine degradation. For example, the FT-30 fully aromatic membrane is somewhat chlorine resistant in heavy-metal-free water, but in natural waters, which normally contain heavy metal ions, chlorine resistance is low. The rate of chlorine attack is also pH sensitive.

Other Membrane Materials

An interesting group of composite membranes with very good properties is produced by condensation of furfuryl alcohol with sulfuric acid. The first membrane of this type was made by Cadotte at North Star Research and was known as the NS200 membrane [32]. These membranes are not made by the interfacial composite process; rather a polysulfone microporous support membrane is contacted first with an aqueous solution of furfuryl alcohol and then with sulfuric acid. The coated support is then heated to 140 °C. The furfuryl alcohol forms a polymerized, crosslinked layer on the polysulfone support; the membrane is completely black. The chemistry of condensation and reaction is complex, but a possible polymerization scheme is shown in Figure 5.10.

These membranes have exceptional properties, including seawater salt rejections of up to 99.6% and fluxes of 23 gal/ft² · day at 800 psi. Unfortunately, they are even more sensitive to oxidants such as chlorine or dissolved oxygen than the polyamide/polyurea interfacial composites. The membranes lose their excellent properties after a few hundred hours of operation unless the feed water is completely free of dissolved chlorine and oxygen. A great deal of work was devoted to stabilizing this membrane, with little success.

Later, Kurihara and co-workers [33] at Toray produced a related membrane, using 1,3,5-tris(hydroxy ethyl) isocyanuric acid as a comonomer. A possible reaction scheme is shown in Figure 5.11. This membrane, commercialized by Toray under the name PEC-1000, has the highest rejection of any membrane developed,

Figure 5.10 Formation of the NS200 condensation membrane

Figure 5.11 Reaction sequence for Toray's PEC-1000 membrane

with seawater rejections of 99.9% and fluxes of 12 gal/ft² · day at 1000 psi. The membrane also shows the highest known rejections to low-molecular-weight organic solutes, typically more than 95% from relatively concentrated feed solutions [34]. Unfortunately these exceptional selectivities are accompanied by the same sensitivity to dissolved oxidants as the NS200 membrane. This problem was never completely solved, so the PEC-1000 membrane, despite its unsurpassed properties, is no longer commercially available.

Reverse Osmosis Membrane Categories

Reverse osmosis membranes can be grouped into three main categories:

- Seawater and brackish water desalination membranes operated with 0.5 to 5 wt% salt solutions at pressures of 200–1000 psi.
- Low-pressure nanofiltration membranes operated with 200–5000 ppm salt solutions at pressures of 100–200 psi.
- Hyperfiltration membranes used to separate solutes from organic solvent solutions.

Seawater and Brackish Water Desalination Membranes

The relative performances of membranes produced for the desalination market are shown in Figure 5.12, a plot of sodium chloride rejection as a function of

Figure 5.12 Performance characteristics of membranes operating on seawater at 56 kg/cm² (840 psi) and 25 °C [13]

membrane flux. The figure is divided into two sections by a dotted line at a rejection of 99.3%. This salt rejection is generally considered to be the minimum sodium chloride rejection that can produce potable water from seawater in a practical single-stage reverse osmosis plant. Membranes with lower sodium chloride rejections can be used to desalinate seawater, but at least a portion of the product water must be treated in a second-stage operation to achieve the target average permeate salt concentration of less than 500 ppm. Two-stage operation is generally not competitive with alternative desalination technologies.

As Figure 5.12 shows, Toray's PEC-1000 crosslinked furfuryl alcohol membrane has by far the best sodium chloride rejection combined with good fluxes. This explains the sustained interest in this membrane despite its extreme sensitivity to dissolved chlorine and oxygen in the feed water. Hollow fine fiber membranes made from cellulose triacetate by Toyobo or aromatic polyamides by PermaSep (Du Pont) are also comfortably in the one-stage seawater desalination performance range, but the water fluxes of these membranes are low. However, because large-surface-area, hollow fine fiber reverse osmosis modules can be

produced very economically, these membranes remained competitive until 2000, when DuPont finally ceased production. Currently, all new seawater desalination plants are based on interfacial composite membranes of the fully aromatic type, such as the SW-30 membrane of FilmTec (Dow) or the SWC membrane of Hydranautics (Nitto). Even the best Loeb–Sourirajan cellulose acetate membranes are not suitable for one-stage seawater desalination because their maximum salt rejection is less than 99 %.

Brackish water generally has a salt concentration in the 2000–10 000 ppm range. Groundwater aquifers with these salt levels must be treated to make the water useful. The objective of the desalination plant is to convert 80–90 % of the feed water to a desalted permeate containing 200–500 ppm salt and a concentrated brine that is reinjected into the ground, sent to an evaporation pond, or discharged to the sea. In this application, membranes with 95–98 % sodium chloride rejection are usually adequate. For this reason some brackish water plants still use cellulose acetate membranes with salt rejections of 96–98 %, although interfacial composite membranes are more common. The fluxes and rejections of the composite membranes at the same operating pressures are usually greater than those of cellulose acetate membranes. Therefore, composite membranes are always preferred for large operations such as municipal drinking water plants, which can be built to handle the membrane's chlorine sensitivity. Some small system operators, on the other hand, still prefer cellulose acetate membranes because of their greater stability. The membranes are often operated at higher pressures to obtain the required flux and salt rejection.

The comparative performance of high-pressure, high-rejection reverse osmosis membranes, medium-pressure brackish water desalting membranes, and low-pressure nanofiltration membranes is shown in Table 5.2. Generally, the performance of a membrane with a particular salt can be estimated reliably once the

Table 5.2 Properties of current good-quality commercial membranes

Parameter	Seawater membrane (SW-30)	Brackish water membrane (CA)	Nanofiltration membrane (NTR-7250)
Pressure (psi)	800–1000	300–500	100–150
Solution concentration (%)	1–5	0.2–0.5	0.05
Rejection (%)			
NaCl	99.5	97	60
MgCl ₂	99.9	99	89
MgSO ₄	99.9	99.9	99
Na ₂ SO ₄	99.8	99.1	99
NaNO ₃	90	90	45
Ethylene glycol	70	—	—
Glycerol	96	—	—
Ethanol	—	20	20
Sucrose	100	99.9	99.0

performance of the membrane with one or two marker salts, such as sodium chloride and magnesium sulfate, is known. The rejection of dissolved neutral organic solutes is less predictable. For example, the PEC-1000 membrane had rejections of greater than 95 % for almost all dissolved organics, but the rejections of even the best cellulose acetate membrane are usually no greater than 50–60 %.

Nanofiltration Membranes

The goal of most of the early work on reverse osmosis was to produce desalination membranes with sodium chloride rejections greater than 98 %. More recently membranes with lower sodium chloride rejections but much higher water permeabilities have been produced. These membranes, which fall into a transition region between pure reverse osmosis membranes and pure ultrafiltration membranes, are called loose reverse osmosis, low-pressure reverse osmosis, or more commonly, nanofiltration membranes. Typically, nanofiltration membranes have sodium chloride rejections between 20 and 80 % and molecular weight cutoffs for dissolved organic solutes of 200–1000 dalton. These properties are intermediate between reverse osmosis membranes with a salt rejection of more than 90 % and molecular weight cut-off of less than 50 and ultrafiltration membranes with a salt rejection of less than 5 %.

Although some nanofiltration membranes are based on cellulose acetate, most are based on interfacial composite membranes. The preparation procedure used to form these membranes can result in acid groups attached to the polymeric backbone. Neutral solutes such as lactose, sucrose and raffinose are not affected by the presence of charged groups and the membrane rejection increases in proportion to solute size. Nanofiltration membranes with molecular weight cut-offs to neutral solutes between 150 and 1500 dalton are produced. Typical rejection curves for low molecular weight solutes by two representative membranes are shown in Figure 5.13 [35].

The rejection of salts by nanofiltration membranes is more complicated and depends on both molecular size and Donnan exclusion effects caused by the acid groups attached to the polymer backbone. The phenomenon of Donnan exclusion is described in more detail in Chapter 10. In brief, charged groups tend to exclude ions of the same charge, particularly multivalent ions while being freely permeable to ions of the opposite charge, particularly multivalent ions.

Some results obtained by Peters *et al.* that illustrate the type of results that can be produced are shown in Figure 5.14 [36], in which the permeation properties of neutral, positively charged and negatively charged membranes are compared.

The neutral nanofiltration membrane rejects the various salts in proportion to molecular size, so the order of rejection is simply

The anionic nanofiltration membrane has positive groups attached to the polymer backbone. These positive charges repel positive cations, particularly divalent

Figure 5.13 Rejection of neutral solutes by two membrane types spanning the range of commonly available nanofiltration membranes [35]

cations such as Ca^{2+} , while attracting negative anions, particularly divalent anions such as SO_4^{2-} . The result is an order of salt rejection

The cationic nanofiltration membrane has negative groups attached to the polymer backbone. These negative charges repel negative anions, such as SO_4^{2-} , while attracting positive cations, particularly divalent cations such as Ca^{2+} . The result is an order of salt rejection

Many nanofiltration membranes follow these rules, but oftentimes the behavior is more complex. Nanofiltration membranes frequently combine both size and Donnan exclusion effects to minimize the rejection of all salts and solutes. These so-called low-pressure reverse osmosis membranes have very high rejections and high permeances of salt at low salt concentrations, but lose their selectivity at salt concentrations above 1000 or 2000 ppm salt in the feed water. The membranes are therefore used to remove low levels of salt from already relatively clean water. The membranes are usually operated at very low pressures of 50–200 psig.

Hyperfiltration Organic Solvent Separating Membranes

A promising new application of reverse osmosis in the chemical industry is the separation of organic/organic mixtures. These separations are difficult because of the high osmotic pressures that must be overcome and because they require

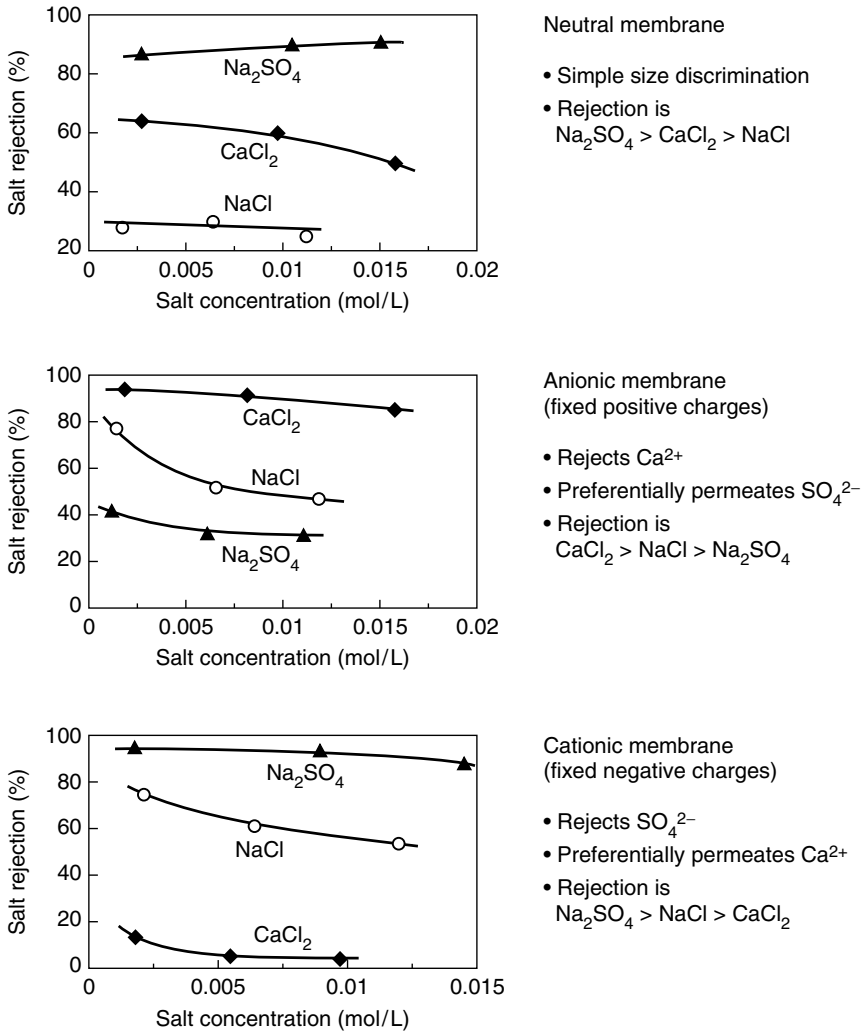

Figure 5.14 Salt rejection with neutral, anionic and cationic nanofiltration membranes showing the effect of Donnan exclusion and solute size on relative rejections. Data of Peters *et al.* [36]

membranes that are sufficiently solvent-resistant to be mechanically stable, but are also sufficiently permeable for good fluxes to be obtained. Nonetheless this is an area of keen industrial interest, and from 1988 to 2002 more than 70 US patents covering membranes and membrane systems for these applications were issued.

Developing membranes for processing organic solvent solutions is more difficult than conventional reverse osmosis because different membranes must be

developed for each category of solvent. In the 1980s, Nitto Denko developed polyimide-based ultrafiltration membranes that found a small use in the recovery of acetone, toluene, ethyl acetate and hexane and other solvents from waste paint and polymer solutions [37]. These were microporous membranes with a molecular weight cut-off of 2000–6000. The first dense, solution-diffusion, hyperfiltration membranes did not appear until the late 1990s. Kiryat Weitzman, Ltd, now part of Koch (Abcor), produced crosslinked silicone composite membranes that have some uses in the hyperfiltration of nonpolar solvents [38,39]. The flux of different simple solvents through these membranes is shown in Figure 5.15. These membranes can be used as nanofiltration membranes to separate large dyes or catalyst solutes from solvents. However, because the membranes are made from rubbers that are easily swollen and plasticized by most solvents, they show poor selectivity when used to separate simple solvent mixtures.

The first, and currently only, successful solvent-permeable hyperfiltration membrane is the Starmem[®] series of solvent-resistant membranes developed by W.R. Grace [40]. These are asymmetric polyimide phase-inversion membranes prepared from Matrimid[®] (Ciba-Geigy) and related materials. The Matrimid polyimide structure is extremely rigid with a T_g of 305 °C and the polymer remains glassy and unswollen even in aggressive solvents. These membranes found their first large-scale commercial use in Mobil Oil's processes to separate lube oil from methyl ethyl ketone–toluene solvent mixtures [41–43]. Scarpello *et al.* [44] have also achieved rejections of >99% when using these membranes to separate dissolved phase transfer catalysts (MW ~ 600) from tetrahydrofuran and ethyl acetate solutions.

Membrane Selectivity

Rautenbach and Albrecht [45] have proposed some general guidelines for membrane selectivity that can be summarized as follows:

1. Multivalent ions are retained better than monovalent ions. Although the absolute values of the salt rejection vary over a wide range, the ranking for the

different salts is the same for all membranes. In general, the order of rejection of ions by reverse osmosis membranes is as shown below.

For cations:

For anions:

2. Dissolved gases such as ammonia, carbon dioxide, sulfur dioxide, oxygen, chlorine and hydrogen sulfide always permeate well.
3. Rejection of weak acids and bases is highly pH dependent. When the acid or base is in the ionized form the rejection will be high, but in the nonionized form rejection will be low [46,47]. Data for a few weak acids are shown in Figure 5.16. At pHs above the acid pKa, the solute rejection rises significantly, but at pHs below the pKa, when the acid is in the neutral form, the rejection falls.
4. Rejection of neutral organic solutes generally increases with the molecular weight (or diameter) of the solute. Components with molecular weights above 100 are well rejected by all reverse osmosis membranes. Although differences between the rejection of organic solutes by different membranes are substantial, as the data in Figure 5.17 show, the rank order is generally consistent between membranes. Caprolactam rejection, for example, is better than ethanol rejection for all reverse osmosis membranes. The dependence of solute rejection on molecular weight is shown for three different membranes in Figure 5.18.
5. Negative rejection coefficients, that is, a higher concentration of solute in the permeate than in the feed are occasionally observed, for example, for phenol and benzene with cellulose acetate membranes [48].

Membrane Modules

Currently, 8-in.-diameter, 40-in.-long spiral-wound modules are the type most commonly used for reverse osmosis. Five to seven modules are housed inside a filament-wound, fiber-glass-reinforced plastic tube. Larger modules, up to 12 in. diameter and 60 in. length, are produced by some manufacturers but have not been widely adopted. The module elements can be removed from the pressure vessels and exchanged as needed. A photograph of a typical skid-mounted system is shown in Figure 5.19. A typical spiral-wound 8-in.-diameter membrane module will produce 8000–10 000 gal/day of permeate, so the 75-module plant shown in Figure 5.19 has a capacity of about 700 000 gal/day.

Number	Name	Number	Name
1	Formaldehyde	12	Ethyl acetate
2	Methanol	13	Phenol
3	Acetonitrile	14	<i>n</i> -Methyl-2-pyrrolidone
4	Acetaldehyde	15	ϵ -Caprolactam
5	Formic acid	16	D,L-aspartic acid
6	Ethanol	17	Tetrachloroethylene
7	Acetic acid	18	<i>o</i> -Phenyl phenol
8	Urea	19	Butyl benzonate
9	Ethylene glycol	20	Trichlorobenzene
10	Methyl ethyl ketone	21	Dimethyl phthalate
11	Glycine	22	Citric acid

Hollow fine fiber modules made from cellulose triacetate or aromatic polyamides were produced in the past for seawater desalination. These modules incorporated the membrane around a central tube, and feed solution flowed rapidly outward to the shell. Because the fibers were extremely tightly packed inside the pressure vessel, flow of the feed solution was quite slow. As much as 40–50% of the feed could be removed as permeate in a single pass through the module. However, the low flow and many constrictions meant that extremely good pretreatment of the feed solution was required to prevent membrane fouling from scale or particulates. A schematic illustration of such a hollow fiber module is shown in Figure 3.47.

Membrane Fouling Control

Membrane fouling is the main cause of permeant flux decline and loss of product quality in reverse osmosis systems, so fouling control dominates reverse osmosis system design and operation. The cause and prevention of fouling depend greatly on the feed water being treated, and appropriate control procedures must be

devised for each plant. In general, sources of fouling can be divided into four principal categories: scale, silt, bacteria, and organic. More than one category may occur in the same plant.

Fouling control involves pretreatment of the feed water to minimize fouling as well as regular cleaning to handle any fouling that still occurs. Fouling by particulates (silt), bacteria and organics such as oil is generally controlled by a suitable pretreatment procedure; this type of fouling affects the first modules in the plant the most. Fouling by scaling is worse with more concentrated feed solutions; therefore, the last modules in the plant are most affected because they are exposed to the most concentrated feed water.

Scale

Scale is caused by precipitation of dissolved metal salts in the feed water on the membrane surface. As salt-free water is removed in the permeate, the concentration of ions in the feed increases until at some point the solubility limit is exceeded. The salt then precipitates on the membrane surface as scale. The proclivity of a particular feed water to produce scale can be determined by performing an analysis of the feed water and calculating the expected concentration factor in the brine. The ratio of the product water flow rate to feed water flow rate is called the recovery rate, which is equivalent to the term stage-cut used in gas separation.

$$\text{Recovery Rate} = \frac{\text{product flow rate}}{\text{feed flow rate}} \quad (5.9)$$

Assuming all the ions remain in the brine solution, the concentration factor is given by

$$\text{Concentration factor} = \frac{1}{1 - \text{recovery rate}} \quad (5.10)$$

The relationship between brine solution concentration factor and water recovery rate is shown in Figure 5.20. With plants that operate below a concentration factor of 2, that is, 50 % recovery rate, scaling is not normally a problem. However, many brackish water reverse osmosis plants operate at recovery rates of 80 or 90 %. Salt concentrations on the brine side of the membrane may then be far above the solubility limit. In order of importance, the salts that most commonly form scale are:

- calcium carbonate;
- calcium sulfate;
- silica complexes;
- barium sulfate;

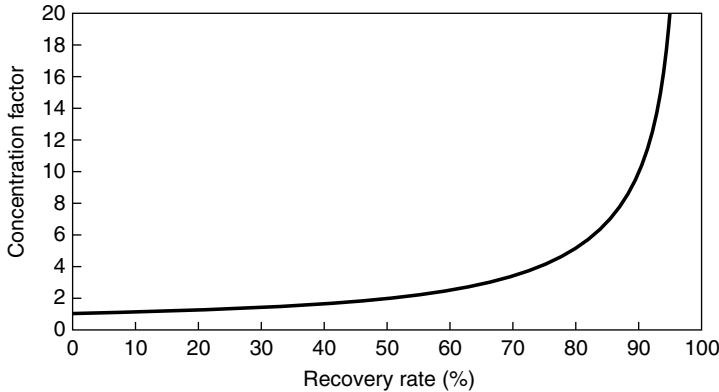

Figure 5.20 The effect of water recovery rate on the brine solution concentration factor

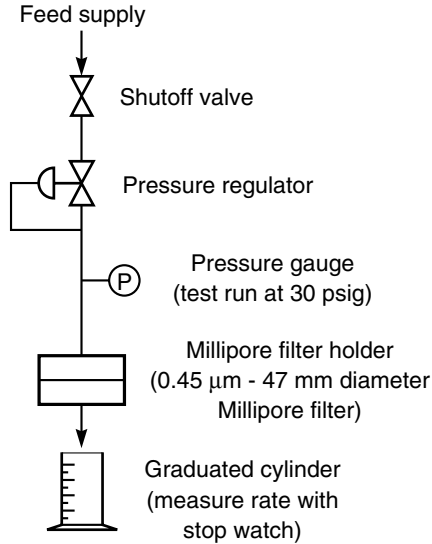

- strontium sulfate;
- calcium fluoride.

Scale control is complex; the particular procedure depends on the composition of the feed water. Fortunately, calcium carbonate scale, by far the most common problem, is easily controlled by acidifying the feed or by using an ion exchange water softener to exchange calcium for sodium. Alternatively, an antiscalant chemical such as sodium hexametaphosphate can be added. Antiscalants interfere with the precipitation of the insoluble salt and maintain the salt in solution even when the solubility limit is exceeded. Polymeric antiscalants may also be used, sometimes in combination with a dispersant to break up any flocs that occur.

Silica can be a particularly troublesome scalant because no effective antiscalant or dispersant is available. The solubility of silica is a strong function of pH and temperature, but in general the brine should not exceed 120 ppm silica. Once formed, silica scale is difficult to remove.

Silt

Silt is formed by suspended particulates of all types that accumulate on the membrane surface. Typical sources of silt are organic colloids, iron corrosion products, precipitated iron hydroxide, algae, and fine particulate matter. A good predictor of the likelihood of a particular feed water to produce fouling by silt is the silt density index (SDI) of the feed water. The SDI, an empirical measurement (ASTM Standard D-4189-82, 1987), is the time required to filter a fixed volume of

- (1) Measure the amount of time required for 500 ml of feed water to flow through a 0.45 micrometer Millipore filter (47 mm in diameter) at a pressure of 30 psig.
- (2) Allow the feed water to continue flowing at 30 psig applied pressure and measure the time required for 500 ml to flow through the filter after 5, 10 and 15 minutes.
- (3) After completion of the test, calculate the SDI by using the equation below.

$$SDI = \frac{100 (1 - T_i/T_f)}{T_t}$$

- where SDI = Silt Density Index
- T_t = Total elapsed test time (either 5, 10 or 15 minutes)
- T_i = Initial time in seconds required to collect the 500 ml sample
- T_f = Time in seconds required to collect the second 500 ml sample after test time T_t (normally after 15 minutes).

Figure 5.21 The silt density index (SDI) test [49]. Reprinted with permission from Noyes Publications

water through a standard 0.45- μm pore size microfiltration membrane. Suspended material in the feed water that plugs the microfilter increases the sample filtration time, giving a higher SDI. The test procedure is illustrated in Figure 5.21 [49].

An SDI of less than 1 means that the reverse osmosis system can run for several years without colloidal fouling. An SDI of less than 3 means that the system can run several months between cleaning. An SDI of 3–5 means that particulate fouling is likely to be a problem and frequent, regular cleaning will be needed. An SDI of more than 5 is unacceptable and indicates that additional pretreatment is required to bring the feed water into an acceptable range. The maximum tolerable SDI also varies with membrane module design. Spiral-wound modules generally require an SDI of less than 5, whereas hollow fine fiber modules are more susceptible to fouling and require an SDI of less than 3.

To avoid fouling by suspended solids, some form of feed water filtration is required. All reverse osmosis units are fitted with a 0.45- μm cartridge filter in front of the high-pressure pump, but a sand filter, sometimes supplemented by addition of a flocculating chemical such as alum or a cationic polymer, may be required. The target SDI after filtration is normally less than 3–5. Groundwaters usually have very low SDI values, and cartridge filtration is often sufficient. However, surface or seawater may have an SDI of up to 200, requiring flocculation, coagulation, and deep-bed multimedia filtration before reverse osmosis treatment.

Biofouling

Biological fouling is the growth of bacteria on the membrane surface. The susceptibility of membranes to biological fouling is a strong function of the membrane composition. Cellulose acetate membranes are an ideal nutrient for bacteria and can be completely destroyed by a few weeks of uncontrolled bacterial attack. Therefore, feed water to cellulose acetate membranes must always be sterilized. Polyamide hollow fibers are also somewhat susceptible to bacterial attack, but thin-film composite membranes are generally quite resistant. Periodic treatment of such membranes with a bactericide usually controls biological fouling. Thus, control of bacteria is essential for cellulose acetate membranes and desirable for polyamides and composite membranes. Because cellulose acetate can tolerate up to 1 ppm chlorine, sufficient chlorination is used to maintain 0.2 ppm free chlorine. Chlorination can also be used to sterilize the feed water to polyamide and interfacial composite membranes, but residual chlorine must then be removed because the membranes are chlorine-sensitive. Dechlorination is generally achieved by adding sodium metabisulfate. In ultrapure water systems, water sterility is often maintained by UV sterilizers.

Organic Fouling

Organic fouling is the attachment of materials such as oil or grease onto the membrane surface. Such fouling may occur accidentally in municipal drinking

Figure 5.22 Flow scheme showing the pretreatment steps in a typical seawater reverse osmosis system [50]

water systems, but is more common in industrial applications in which reverse osmosis is used to treat a process or effluent stream. Removal of the organic material from the feed water by filtration or carbon adsorption is required.

An example of a complete pretreatment flow scheme for a seawater reverse osmosis plant is shown in Figure 5.22 [50]. The water is controlled for pH, scale, particulates and biological fouling. The feed water is first treated with chlorine to sterilize the water and to bring it to a pH of 5–6. A polyelectrolyte is added to flocculate suspended matter, and two multilayer depth filters then remove suspended materials. The water is dechlorinated by dosing with sodium bisulfite followed by passage through an activated carbon bed. As a final check the pH is adjusted a second time, and the water is filtered through a 1- to 5- μm cartridge filter before being fed to the reverse osmosis modules. Obviously, such pretreatment is expensive and may represent as much as one-third of the operating and capital cost of the plant; however, it is essential for reliable long-term operation.

Membrane Cleaning

A good pretreatment system is essential to achieve a long reverse osmosis membrane life, but pretreatment must be backed up by an appropriate cleaning schedule. Generally this is done once or twice a year, but more often if the feed is a problem water. As with pretreatment, the specific cleaning procedure is a function of the feed water chemistry, the type of membrane, and the type of fouling. A typical cleaning regimen consists of flushing the membrane modules by recirculating the cleaning solution at high speed through the module, followed by a soaking period, followed by a second flush, and so on. The

chemical cleaning agents commonly used are acids, alkalis, chelatants, detergents, formulated products, and sterilizers.

Acid cleaning agents such as hydrochloric, phosphoric, or citric acids effectively remove common scaling compounds. With cellulose acetate membranes the pH of the solution should not go below 2.0 or else hydrolysis of the membrane will occur. Oxalic acid is particularly effective for removing iron deposits. Acids such as citric acid are not very effective with calcium, magnesium, or barium sulfate scale; in this case a chelatant such as ethylene diamine tetraacetic acid (EDTA) may be used.

To remove bacteria, silt or precipitates from the membrane, alkalis combined with surfactant cleaners are often used. Biz[®] and other laundry detergents containing enzyme additives are useful for removing biofoulants and some organic foulants. Most large membrane module producers now distribute formulated products, which are a mixture of cleaning compounds. These products are designed for various common feed waters and often provide a better solution to membrane cleaning than devising a cleaning solution for a specific feed.

Sterilization of a membrane system is also required to control bacterial growth. For cellulose acetate membranes, chlorination of the feed water is sufficient to control bacteria. Feed water to polyamide or interfacial composite membranes need not be sterile, because these membranes are usually fairly resistant to biological attack. Periodic shock disinfection using formaldehyde, peroxide or peracetic acid solutions as part of a regular cleaning schedule is usually enough to prevent biofouling.

Repeated cleaning gradually degrades reverse osmosis membranes. Most manufacturers now supply membrane modules with a 1- to 2-year limited warranty depending on the application. Well designed and maintained plants with good feed water pretreatment can usually expect membrane lifetimes of 3 years, and lifetimes of 5 years or more are not unusual. As membranes approach the end of their useful life, the water flux will normally have dropped by at least 20%, and the salt rejection will have begun to fall. At this point operators may try to 'rejuvenate' the membrane by treatment with a dilute polymer solution. This surface treatment plugs microdefects and restores salt rejection [51]. Typical polymers are poly(vinyl alcohol)/vinyl acetate copolymers or poly(vinyl methyl ether). In this procedure the membrane modules are carefully cleaned and then flushed with dilute solutions of the rejuvenation polymer. The exact mechanism of rejuvenation is unclear.

Applications

Approximately one-half of the reverse osmosis systems currently installed are desalinating brackish or seawater. Another 40% are producing ultrapure water for the electronics, pharmaceutical, and power generation industries. The remainder are used in small niche applications such as pollution control and food processing. A review of reverse osmosis applications has been done by Williams *et al.* [52].

Figure 5.23 Comparative costs of the major desalination technologies as a function of salt concentration. These costs should be taken as a guide only; site-specific factors can affect costs significantly [53]

The relative cost of reverse osmosis compared with other desalting technologies (ion exchange, electrodialysis, and multi-effect evaporation) is shown in Figure 5.23. The operating costs of electrodialysis and ion exchange scale almost linearly in proportion to the salt concentration in the feed. Therefore, these technologies are best suited to low-salt-concentration feed streams. On the other hand, the cost of multi-effect evaporation is relatively independent of the salt concentration and is mainly proportional to the mass of water to be evaporated. Thus, desalination by evaporation is best performed with concentrated salt solution feeds. Reverse osmosis costs increase significantly with salt concentration but at a lower rate than electrodialysis does. The result is that reverse osmosis is the lowest-cost process for streams containing between 3000 and 10 000 ppm salt. However, site-specific factors or plant size often make the technology the best approach for more dilute feed water or for streams as concentrated as seawater (35 000 ppm salt).

The approximate operating costs for brackish and seawater reverse osmosis plants are given in Table 5.3. These numbers are old, but improvements in membrane technology have kept pace with inflation so the costs remain reasonably current.

Table 5.3 Operating costs for large brackish water and seawater reverse osmosis plants [49]. Capital costs are approximately US\$1.25 per gal/day capacity for the brackish water plant and US\$4–5 per gal/day capacity for the seawater plant

	Brackish water (US\$/1000 gal product)	Seawater (US\$/1000 gal product)
Energy (US\$0.06/kWh)	0.36	1.80
Chemicals	0.09	0.14
Labor	0.12	0.19
Maintenance	0.05	0.22
Membrane replacement	0.10	0.90
Amortization (12%/20 years)	0.48	1.75
Total	1.20	5.00

Brackish Water Desalination

The salinity of brackish water is usually between 2000 and 10 000 mg/L. The World Health Organization (WHO) recommendation for potable water is 500 mg/L, so up to 90 % of the salt must be removed from these feeds. Early cellulose acetate membranes could achieve this removal easily, so treatment of brackish water was one of the first successful applications of reverse osmosis. Several plants were installed as early as the 1960s.

The osmotic pressure of brackish water is approximately 11 psi per 1000 ppm salt, so osmotic pressure effects do not generally limit water recovery significantly. Limitations are generally due to scaling. Typical water recoveries are in the 70–90 % range, which means the brine stream leaving the system is up to 10 times more concentrated in calcium, sulfate and silica ions present in the feed. If scaling occurs, the last modules in the system must be replaced first.

A simplified flow scheme for a brackish water reverse osmosis plant is shown in Figure 5.24. In this example, it is assumed that the brackish water is heavily contaminated with suspended solids, so flocculation followed by a sand filter and a cartridge filter is used to remove particulates. The pH of the feed solution might be adjusted, followed by chlorination to sterilize the water to prevent bacterial growth on the membranes and addition of an anti-scalant to inhibit precipitation of multivalent salts on the membrane. Finally, if chlorine-sensitive interfacial composite membranes are used, sodium sulfite is added to remove excess chlorine before the water contacts the membrane. Generally, more pretreatment is required in plants using hollow fiber modules than in plants using spiral-wound modules. This is one reason why hollow fiber modules have been displaced by spiral-wound systems for most brackish water installations.

A feature of the system design shown in Figure 5.24 is the staggered arrangement of the module pressure vessels. As the volume of the feed water is reduced as water is removed in the permeate, the number of modules arranged in parallel is also reduced. In the example shown, the feed water passes initially through

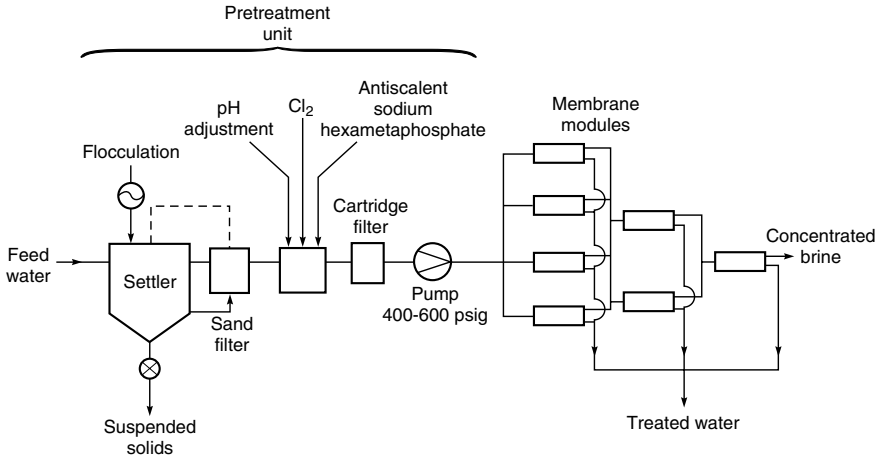

Figure 5.24 Flow schematic of a typical brackish water reverse osmosis plant. The plant contains seven pressure vessels each containing six membrane modules. The pressure vessels are in a ‘Christmas tree’ array to maintain a high feed velocity through the modules

four modules in parallel, then through two, and finally through a single module in series. This is called a ‘Christmas tree’ or ‘tapered module’ design and provides a high average feed solution velocity through the modules. As the volume of the feed water is reduced by removing water as permeate, the number of modules arranged in parallel is reduced also.

The operating pressure of brackish water reverse osmosis systems has gradually fallen over the past 20 years as the permeability and rejections of membranes have steadily improved. The first plants operated at pressures of 800 psi, but typical brackish water plants now operate at pressures in the 200- to 300-psi range. Capital costs of brackish water plants have stayed remarkably constant for almost 20 years; the rule of thumb of US\$1.00 per gal/day capacity is still true. Accounting for inflation, this reflects a very large reduction in real costs resulting from the better performance of today’s membranes.

Seawater Desalination

Seawater has a salt concentration of 3.2–4.0%, depending on the region of the world. Because of this high salinity, only membranes with salt rejections of 99.3% or more can produce potable water in a single pass. Application to seawater desalination of the first-generation cellulose acetate membranes, with rejections of 97–99%, was limited. With the development of the polyamide hollow fine fibers and interfacial composites, suitable seawater membranes became available, and many plants have been installed. In general, membranes are not

Figure 5.25 Effect of water recovery on the seawater feed osmotic pressure and net driving pressure of a plant operating at 1000 psi

competitive for large seawater desalination plants—multistage flash evaporation is usually used for plants larger than 10 million gal/day capacity. Often these plants are powered by waste steam from an adjacent electric power generation unit. A number of these very large plants have been installed in the Middle East. In the 1–10 million gal/day range membranes are more competitive, and the flexibility of membrane systems as well as their easy start-up/shut-down and turndown capability are advantages.

Early seawater reverse osmosis plants operated at very high pressures, up to 1500 psi, but as membranes improved, operating pressures dropped to 800–1000 psi. The osmotic pressure of seawater is about 350 psi, and the osmotic pressure of the rejected brine can be as much as 600 psi, so osmotic pressure affects the net operating pressure in a plant markedly. This effect is illustrated in Figure 5.25. Typical seawater plants do not operate at a recovery rate of more than 35–45 % because of the high brine osmotic pressure; at this modest recovery rate, more than half of the feed water leaves the plant as pressurized brine. Because of the high pressures involved in seawater desalination, recovery of compression energy from the high-pressure brine stream is almost always worthwhile. This can be achieved with a hydro-turbine linked to the high-pressure feed water pump, lowering total power costs by as much as 30 %.

Raw seawater requires considerable pretreatment before it can be desalinated (Figure 5.22), but these pretreatment costs can be reduced by using shallow sea-front wells as the water source. The SDI of this water is usually quite low, and little more than a sand filter may be required for particulate control. However, sterilization of the water and addition of antiscalants will still be necessary.

Ultrapure Water

Production of ultrapure water for the electronics industry is an established and growing application of reverse osmosis [54,55]. The usual feed is municipal

Table 5.4 Ultrapure water specifications for typical wafer manufacturing process and levels normally found in drinking water

	Ultrapure water	Typical drinking water
Resistivity at 25 °C (megohm-cm)	18.2	—
TOC (ppb)	<5	5000
Particles/L by laser >0.1 μm	<100	—
Bacteria/100 mL by culture	<0.1	<30
Silica, dissolved (ppb)	<3	3000
Boron (ppb)	<1	40
Ions (ppb)		
Na ⁺	<0.01	3000
K ⁺	<0.02	2000
Cl ⁻	<0.02	10 000
Br ⁻	<0.02	—
NO ₃ ⁻	<0.02	—
SO ₄ ²⁻	<0.02	15 000
Total ions	<0.1	<100 000

drinking water, which often contains less than 200 ppm dissolved solids. However, the electronics industry requires water of extraordinarily high purity for wafer production, so extensive treatment of municipal water is required. Table 5.4 shows the target water quality required by a modern electronics plant compared to that of typical municipal drinking water.

The first ultrapure water reverse osmosis system was installed at a Texas Instruments plant in 1970 as a pretreatment unit to an ion exchange process. These systems have increased in complexity as the needs of the industry for better quality water have increased. The flow scheme for a typical modern ultrapure water treatment system is shown in Figure 5.26. The plant comprises a complex array of operations, each requiring careful maintenance to achieve the necessary water quality. As the key part of the process, the reverse osmosis plant typically removes more than 98 % of all the salts and dissolved particulates in the feed water. Because the feed water is dilute, these systems often operate at very high recovery rates—90 % or more. Carbon adsorption then removes dissolved organics, followed by ion exchange to remove final trace amounts of ionic impurities. Bacterial growth is a major problem in ultrapure water systems; sterility is maintained by continuously recirculating the water through UV sterilizers and cartridge microfilters.

Wastewater Treatment

In principle, pollution control should be a major application for reverse osmosis. In practice, membrane fouling, causing low plant reliability, has inhibited its widespread use in this area. The most common applications are special situations

Figure 5.26 Flow schematic of an ultrapure water treatment system [54]

Figure 5.27 Flow scheme showing the use of a reverse osmosis system to control nickel loss from rinse water produced in a countercurrent electroplating rinse tank

in which the chemicals separated from the water are valuable. An example is the recovery of nickel from nickel-plating rinse tanks, shown schematically in Figure 5.27. Watts nickel-plating baths contain high concentrations of nickel and other plating chemicals. After plating, a conveyor belt moves the parts through a series of connected rinse tanks. Water circulates through these tanks to rinse the part free of nickel for the next plating operating. A typical countercurrent rinse tank produces a waste stream containing 2000–3000 ppm nickel; the water is a pollution problem and valuable material is lost. This is an ideal application for reverse osmosis because the rinse water is at nearly neutral pH, in contrast to many plating rinse waters which are very acidic [56,57]. The reverse osmosis unit produces permeate water containing only 20–50 ppm nickel that can be reused and a small nickel concentrate stream that can be sent to the plating tank. Although the concentrate is more dilute than the plating tank drag-out, evaporation from the hot plating bath tank compensates for the extra water.

In the early days of membrane development, membranes were expected to be widely used in the tertiary treatment of water to produce drinking water from sewage. At a cost of US\$2–3 per 1000 gal, this idea makes good economic sense in many water-limited regions of the world. However, psychological barriers have inhibited its widespread adoption. A few small plants have been introduced in Japan and at least one large plant in the US. This plant, called Water Factory 21,

is in Orange County, California, an arid region where the principal local surface water source, the Colorado River, has a total salinity of 750 ppm. Operation of this 5-million-gal/day system is described in detail by Nusbaum and Argo [58]. The system treats secondary sewage to produce good-quality water, which is reinjected into the aquifer below the county. The water is then mixed with natural groundwater before being removed and used as a drinking water supply elsewhere in the county. Apparently, confusing the source of the water supply in this way makes the process acceptable.

Nanofiltration

Nanofiltration membranes usually have high rejections to most dissolved organic solutes with molecular weights above 100–200 and good salt rejection at salt concentrations below 1000–2000 ppm salt. The membranes are also two- to five-fold more permeable than brackish and sea water reverse osmosis membranes, so they can be operated at pressures as low as 50–150 psig and still produce useful fluxes. For these reasons, their principal application has been in the removal of low levels of contaminants from already relatively clean water. For example, nanofiltration membranes are widely used as point-of-use drinking water treatment units in southern California and the southwestern United States. The water in this region contains on the order of 700 ppm dissolved salt and trace amounts of agricultural run-off contaminants. Many households use small 0.5-m² spiral-wound nanofiltration modules (under-the-sink modules) to filter this water using the 30- to 50-psig tap water pressure to provide the driving force. On a larger scale, similar membranes are used to soften municipal water by removing sulfate and divalent cations or as an initial pretreatment unit for an ultrapure water treatment plant.

Organic Solvent Separation

The use of membranes to separate organic solvent solutions is still at a very early stage. One application that has already become commercial is the separation of small solvent molecules from larger hydrocarbons in mixtures resulting from the extraction of vacuum resid oil in refineries [41–43]. Figure 5.28(a) shows a simplified flow diagram of a refining lube oil separation process—these operations are very large. In a 100 000–200 000-barrel/day refinery, about 15 000–30 000 barrels/day of the oil entering the refinery remain as residual oil. A large fraction of this oil is sent to the lube oil plant, where the heavy oil is mixed with 3–10 volumes of a solvent such as methyl ethyl ketone and toluene. On cooling the mixture, the heavy wax components precipitate out and are removed by a drum filter. The light solvent is then stripped from the lube oil by vacuum distillation and recycled through the process. The vacuum distillation step is very energy intensive because of the high solvent-to-oil ratios employed.

(a) Conventional solvent dewaxing process

(b) Mobil Oil's solvent dewaxing process

Figure 5.28 Simplified flow schemes of (a) a conventional and (b) Mobil Oil's membrane solvent dewaxing processes. Refrigeration economizers are not shown. The first 3 million gallon/day commercial unit was installed at Mobil's Beaumont refinery in 1998. Polyimide membranes in spiral-wound modules were used [41–43]

A hyperfiltration process developed by Mobil Oil, now ExxonMobil, for this separation is illustrated in Figure 5.28(b). Polyimide membranes formed into spiral-wound modules are used to separate up to 50% of the solvent from the dewaxed oil. The membranes have a flux of 10–20 gal/ft² day at a pressure of 450–650 psi. The solvent filtrate bypasses the distillation step and is recycled directly to the incoming oil feed. The net result is a significant reduction in the refrigeration load required to cool the oil and in the size and energy consumption of the solvent recovery vacuum distillation section.

ExxonMobil is now licensing this technology to other refineries. Development of similar applications in other operations is likely. Initially, applications will probably involve relatively easy separations such as the separation of methyl ethyl ketone/toluene from lube oil described above or soybean oil from hexane in food oil production. Long-term, however, the technology may become sufficiently advanced to be used in more important refining operations, such as fractionation

of linear from branched paraffins, or the separation of benzene and other aromatics from paraffins and olefins in the gasoline pool.

Conclusions and Future Directions

The reverse osmosis industry is now well established. The market is divided between three or four large manufacturers, who between them produce 70 % of the membrane modules, and a much larger number of system builders. The system builders buy modules almost as commodities from the various suppliers according to their particular needs. A handful of companies serving various niche markets produce both modules and systems. Total membrane module sales in 1998 were about US\$200 million worldwide; system sales were another US\$200 million. Short-term prospects for future growth are good. The demand for reverse osmosis systems to produce ultrapure water for the electronics and pharmaceutical industries is very strong. Municipalities in arid regions of the world are also continuing to buy brackish water and some seawater desalination units.

The industry is extremely competitive, with the manufacturers producing similar products and competing mostly on price. Many incremental improvements have been made to membrane and module performance over the past 20 years, resulting in steadily decreasing water desalination costs in inflation-adjusted dollars. Some performance values taken from a paper by Furukawa are shown in Table 5.5. Since 1980, just after the introduction of the first interfacial composite membranes, the cost of spiral-wound membrane modules on a per square meter basis has decreased seven-fold. At the same time the water flux has doubled, and the salt permeability has decreased seven-fold. Taking these improvements into account, today's membranes are almost 100 times better than those of the 1980s. This type of incremental improvement is likely to continue for some time.

The key short-term technical issue is the limited chlorine resistance of interfacial composite membranes. A number of incremental steps made over the past 10–15 years have improved resistance, but current chlorine-resistant interfacial composites do not have the rejection and flux of the best conventional membranes.

Table 5.5 Advances in spiral-wound module reverse osmosis performance

Year	Cost normalized (1980 US\$)	Productivity normalized (to 1980)	Reciprocal salt passage normalized (to 1980)	Figure of merit ^a
1980	1.00	1.00	1.00	1.0
1985	0.65	1.10	1.56	2.6
1990	0.34	1.32	2.01	7.9
1995	0.19	1.66	3.52	30.8
2000	0.14	1.94	7.04	99.3

^aFigure of merit = (productivity) × (reciprocal salt passage/cost).

Source: Dave Furukawa.

All the major membrane manufacturers are working on this problem, which is likely to be solved in the next few years. Three longer-term, related technical issues are fouling resistance, pretreatment, and membrane cleaning. Current membrane modules are subject to fouling by particulates and scale; this fouling can only be controlled by good (and expensive) feed water pretreatment and by membrane cleaning. In some large potential reverse osmosis markets, such as municipal wastewater reclamation and industrial process water treatment, the complexity, expense, and low reliability due to membrane fouling limit expansion significantly.

A further long-term area of research is likely to be the development of reverse osmosis membranes to recover organic solutes from water. This chapter has focused almost entirely on the separation of ionic solutes from water, but some membranes (such as the PEC-1000 membrane) have excellent organic solute rejections also. The PEC-1000 membrane was chemically unstable, but it demonstrated what is achievable with membranes. A stable membrane with similar properties could be used in many wastewater applications.

6 ULTRAFILTRATION

Introduction and History

Ultrafiltration uses a finely porous membrane to separate water and microsolute from macromolecules and colloids. The average pore diameter of the membrane is in the 10–1000 Å range. The first synthetic ultrafiltration membranes were prepared by Bechhold from collodion (nitro cellulose) [1]. Bechhold was probably the first to measure membrane bubble points, and he also coined the term ‘ultrafilter’. Other important early workers were Zsigmondy and Bachmann [2], Ferry [3] and Elford [4]. By the mid-1920s, collodion ultrafiltration and microfiltration membranes were commercially available for laboratory use. Although collodion membranes were widely used in laboratory studies, no industrial applications existed until the 1960s. The crucial breakthrough was the development of the anisotropic cellulose acetate membrane by Loeb and Sourirajan in 1963 [5]. Their goal was to produce high-flux reverse osmosis membranes, but others, particularly Michaels at Amicon, realized the general applicability of the technique. Michaels and his coworkers [6] produced ultrafiltration membranes from cellulose acetate and many other polymers including polyacrylonitrile copolymers, aromatic polyamides, polysulfone and poly(vinylidene fluoride). These materials are still widely used to fabricate ultrafiltration membranes.

In 1969, Abcor (now a division of Koch Industries) installed the first commercially successful industrial ultrafiltration system equipped with tubular membrane modules [7] to recover electrocoat paint from automobile paint shop rinse water. The economics were compelling, and within a few years many similar systems were installed. Shortly thereafter (1970), the first cheese whey ultrafiltration system was installed. Within a decade, 100 similar systems had been sold worldwide. These early systems used tubular or plate-and-frame modules, which were relatively expensive, but lower cost designs were gradually introduced. Hollow fiber (capillary) modules were first sold by Romicon in 1973, and spiral-wound modules, adapted to ultrafiltration applications by Abcor, became a commercial item by 1979–1980. Over the last 20 years, the ultrafiltration industry has grown steadily. The principal problem inhibiting wider application of the technology is membrane fouling. The problem is controlled, but not eliminated, by module

Figure 6.1 Milestones in the development of ultrafiltration

and system design and by regular membrane cleaning protocols. Development of membranes with surface properties designed to minimize fouling has also helped. Recently, several companies have developed ceramic-based ultrafiltration membranes. Although much more expensive than their polymeric equivalents, these have found a place in applications that require resistance to high temperatures or require regular cleaning with harsh solutions to control membrane fouling. Some of the milestones in the development of ultrafiltration membranes are charted in Figure 6.1.

Characterization of Ultrafiltration Membranes

Ultrafiltration membranes are usually anisotropic structures made by the Loeb–Sourirajan process. They have a finely porous surface layer or skin supported on a much more open microporous substrate. The finely porous surface layer performs the separation; the microporous substrate provides mechanical strength. The membranes discriminate between dissolved macromolecules of different sizes and are usually characterized by their molecular weight cut-off, a loosely defined term generally taken to mean the molecular weight of the globular protein molecule that is 90 % rejected by the membrane. Ultrafiltration and microfiltration are related processes—the distinction between the two lies in the pore size of the membrane. Microfiltration membranes have larger pores and are used to separate particles in the 0.1–10 μm range, whereas ultrafiltration is generally considered to be limited to membranes with pore diameters from 10 to 1000 \AA .

Batch stirred cell

Flow recirculation system: flow-through cells

Figure 6.2 Laboratory ultrafiltration test systems

Laboratory-scale ultrafiltration experiments are performed with small, stirred batch cells or flow-through cells in a recirculation system. Diagrams of the two types of system are shown in Figure 6.2. Because ultrafiltration experiments are generally performed at pressures below 100 psi, plastic components can be used. Stirred batch cells are often used for quick experiments, but flow-through systems are preferred for systematic work. In flow-through systems, the feed solution can be more easily maintained at a constant composition, and the turbulence at the membrane surface required to control membrane fouling is high and easily reproducible. This allows reliable comparative measurements to be made.

The cut-off of ultrafiltration membranes is usually characterized by solute molecular weight, but several other factors affect permeation through these membranes. One important example is the shape of the molecule to be retained. When membrane retention measurements are performed with linear, water-soluble molecules such as polydextran, poly(ethylene glycol) or poly(vinyl pyrrolidone), the measured rejection is much lower than the rejection measured for proteins of the same molecular weight. It is believed that linear, water-soluble polymer molecules are able to snake through the membrane pores, as illustrated in Figure 6.3. Protein molecules, however, exist in solution as tightly wound globular coils held together by hydrogen bonds. These globular molecules cannot deform to pass through the membrane pores and are therefore rejected. Some results showing the rejection of different molecules for a polysulfone ultrafiltration membrane are listed in the table accompanying Figure 6.3 [8]. The membrane shows significant rejection to globular protein molecules as small as pepsin (MW 35 000) and cytochrome *c* (MW 13 000) but is completely permeable to a flexible linear polydextran, with an average molecular weight of more than 100 000.

The pH of the feed solution is another factor that affects permeation through ultrafiltration membranes, particularly with polyelectrolytes. For example,

Solute	Globular Proteins		Linear Polymer
	Pepsin	Cytochrome <i>c</i>	Polydextran
MW (1000s)	35	13	100
Rejection (%)	90	70	0

Figure 6.3 Ultrafiltration membranes are rated on the basis of nominal molecular weight cut-off, but the shape of the molecule to be retained has a major effect on retentivity. Linear molecules pass through a membrane, whereas globular molecules of the same molecular weight may be retained. The table shows typical results obtained with globular protein molecules and linear polydextran for the same polysulfone membrane [8]

poly(acrylic acid) is usually very well rejected by ultrafiltration membranes at pH 5 and above, but is completely permeable through the same membrane at pH 3 and below. This change in rejection behavior with pH is related to the change in configuration of the polyacid. In solutions at pH 5 and above, poly(acrylic acid) is ionized. In the ionized form, the negatively charged carboxyl groups along the polymer backbone repel each other; the polymer coil is then very extended and relatively inflexible. In this form, the molecule cannot readily permeate the small pores of an ultrafiltration membrane. At pH 3 and below, the carboxyl groups along the poly(acrylic acid) polymer backbone are all protonated. The resulting neutral molecule is much more flexible and can pass through the membrane pores.

Concentration Polarization and Membrane Fouling

A key factor determining the performance of ultrafiltration membranes is concentration polarization, which causes membrane fouling due to deposition of retained colloidal and macromolecular material on the membrane surface. A number of reviews have described the process in detail [9–13]. The pure water flux of ultrafiltration membranes is often very high—greater than $1 \text{ cm}^3/\text{cm}^2 \cdot \text{min}$ ($350 \text{ gal}/\text{ft}^2 \cdot \text{day}$). However, when membranes are used to separate macromolecular or colloidal solutions, the flux falls within seconds, typically to $0.1 \text{ cm}^3/\text{cm}^2 \cdot \text{min}$. This immediate drop in flux is caused by the formation of a gel layer of retained solutes on the membrane surface due to concentration polarization. This gel layer forms a secondary barrier to flow through the membrane, as illustrated in Figure 6.4 and described in detail below. This first decline in flux is determined by the composition of the feed solution and its fluid hydrodynamics. Sometimes the resulting flux is constant for a prolonged period, and when the membrane is retested with pure water, its flux returns to the original value. More commonly, however, a further slow decline in flux occurs over a period of hours to weeks, depending on the feed solution. Most of this second decrease in flux is caused by slow consolidation of the secondary layer formed by concentration polarization on the membrane surface. Formation of this consolidated gel layer, called membrane fouling, is difficult to control. Control techniques include regular membrane cleaning, back flushing, or using membranes with surface characteristics that minimize adhesion. Operation of the membrane at the lowest practical operating pressure also delays consolidation of the gel layer.

A typical plot illustrating the slow decrease in flux that can result from consolidation of the secondary layer is shown in Figure 6.5 [14]. The pure water flux of these membranes is approximately $50 \text{ gal}/\text{min}$ but, on contact with an electrocoat paint solution containing 10–20% latex, the flux immediately falls to about $10\text{--}12 \text{ gal}/\text{min}$. This first drop in flux is due to the formation of the gel layer of latex particles on the membrane surface, as shown in Figure 6.4. Thereafter, the flux declines steadily over a 2-week period. This second drop in flux is caused by slow densification of the gel layer under the pressure of the

Figure 6.4 Schematic representation of fouling on an ultrafiltration membrane. *Surface fouling* is the deposition of solid material on the membrane that consolidates over time. This fouling layer can be controlled by high turbulence, regular cleaning and using hydrophilic or charged membranes to minimize adhesion to the membrane surface. Surface fouling is generally reversible. *Internal fouling* is caused by penetration of solid material into the membrane, which results in plugging of the pores. Internal membrane fouling is generally irreversible

system. In this particular example, the densified gel layer could be removed by periodic cleaning of the membrane. When the cleaned membrane is exposed to the latex solution again, the flux is restored to that of a fresh membrane.

If the regular cleaning cycle shown in Figure 6.5 is repeated many times, the membrane flux eventually does not return to the original value on cleaning. Part of this slow, permanent loss of flux is believed to be due to precipitates on the membrane surface that are not removed by the cleaning procedure. A further cause of the permanent flux loss is believed to be internal fouling of the membrane by material that penetrates the membrane pores and becomes lodged in the interior of the membrane, as illustrated in Figure 6.4. Ultrafiltration membranes are often used to separate colloids from water and microsolute. In this case the tendency is to use relatively high-molecular-weight cut-off membranes, but the higher fluxes of these membranes can be transitory because they are more susceptible to internal fouling. A membrane with a lower molecular weight cut-off, even

Figure 6.5 Ultrafiltration flux as a function of time of an electrocoat paint latex solution. Because of fouling, the flux declines over a period of days. Periodic cleaning is required to maintain high fluxes [14]. Reprinted from R. Walker, Recent Developments in Ultrafiltration of Electrocoat Paint, *Electrocoat* **82**, 16 (1982) with permission from Gardner Publications, Inc., Cincinnati, OH

though it may have a lower pure water flux, often provides a more sustained flux with the actual feed solutions because less internal fouling occurs.

As described above, the initial cause of membrane fouling is concentration polarization, which results in deposition of a layer of material on the membrane surface. The phenomenon of concentration polarization is described in detail in Chapter 4. In ultrafiltration, solvent and macromolecular or colloidal solutes are carried towards the membrane surface by the solution permeating the membrane. Solvent molecules permeate the membrane, but the larger solutes accumulate at the membrane surface. Because of their size, the rate at which the rejected solute molecules can diffuse from the membrane surface back to the bulk solution is relatively low. Thus their concentration at the membrane surface is typically 20–50 times higher than the feed solution concentration. These solutes become so concentrated at the membrane surface that a gel layer is formed and becomes a secondary barrier to flow through the membrane. The formation of this gel layer on the membrane surface is illustrated in Figure 6.6. The gel layer model was developed at the Amicon Corporation in the 1960s [8].

The formation of the gel layer is easily described mathematically. At any point within the boundary layer shown in Figure 6.6, the convective flux of solute to the membrane surface is given by the volume flux, J_v , of the solution through the membrane multiplied by the concentration of the solute, c_i . At steady state, this

Figure 6.6 Illustration of the formation of a gel layer of colloidal material on the surface of an ultrafiltration membrane by concentration polarization

convective flux within the laminar boundary layer is balanced by the diffusive flux of retained solute in the opposite direction. This balance is expressed by the equation

$$J_v c_i = D_i \frac{dc_i}{dx} \tag{6.1}$$

where D_i is the diffusion coefficient of the macromolecule in the boundary layer. Once the gel layer has formed, the concentrations of solute at both surfaces of the boundary layer are fixed. At one surface the concentration is the feed solution concentration c_{ib} ; at the other surface it is the concentration at which the solute forms an insoluble gel (c_{gel}). Integration of Equation (6.1) over the boundary layer thickness (δ) then gives

$$\frac{c_{gel}}{c_{ib}} = \exp\left(\frac{J_v \delta}{D_i}\right) \tag{6.2}$$

where c_{gel} is the concentration of retained solute at the membrane surface where the solute gels and c_{ib} is the concentration in the bulk solution. In any particular ultrafiltration test, the terms c_{ib} , c_{gel} , D_i and δ in Equation (6.2) are fixed because the solution and the operating conditions of the test are fixed. From Equation (6.2) this means that the volume flux J_v through the membrane is also fixed and quite independent of the intrinsic permeability of the membrane. In physical terms, this is because a membrane with a higher intrinsic permeability only causes a thicker

gel layer to form on the surface of the membrane. This lowers the membrane flux until the rate at which solutes are brought toward the membrane surface and the rate at which they are removed are again balanced, as expressed in Equation (6.1).

The formation of a gel layer of colloidal material at the ultrafiltration membrane surface produces a limiting or plateau flux that cannot be exceeded at any particular operating condition. Once a gel layer has formed, increasing the applied

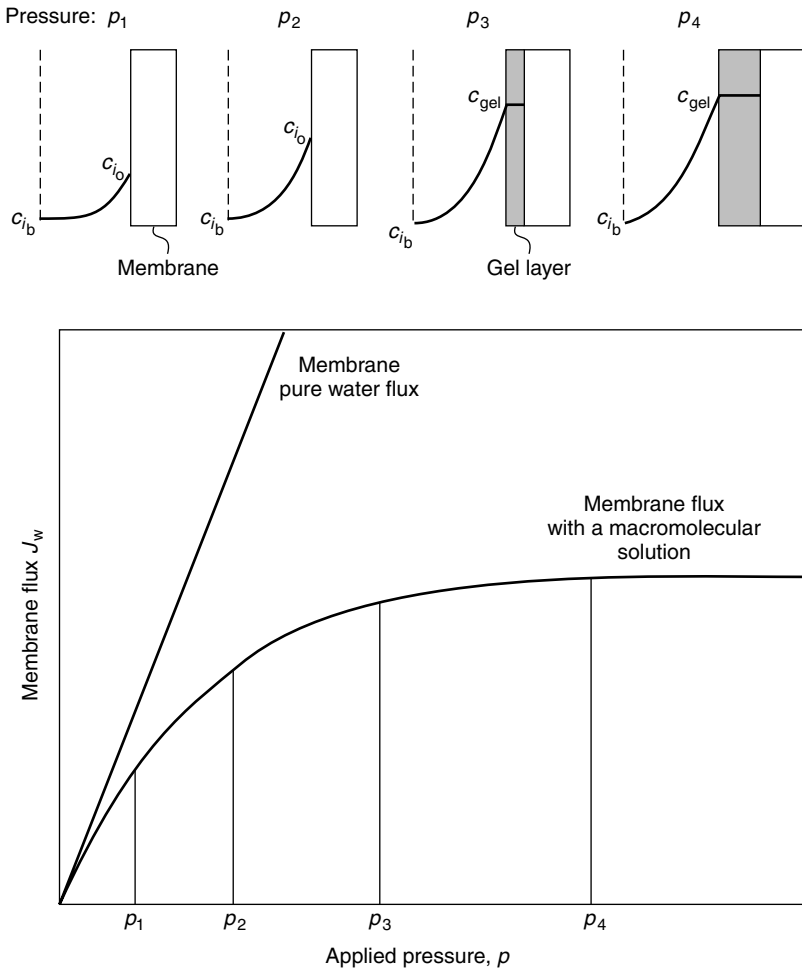

Figure 6.7 The effect of pressure on ultrafiltration membrane flux and the formation of a secondary gel layer. Ultrafiltration membranes are best operated at pressures between p_2 and p_3 at which the gel layer is thin. Operation at high pressures such as p_4 leads to formation of thick gel layers, which can consolidate over time, resulting in permanent fouling of the membrane

pressure does not increase the flux but merely increases the gel thickness. This is also shown in Equation (6.2), which contains no term for the applied pressure.

The effect of the gel layer on the flux through an ultrafiltration membrane at different feed pressures is illustrated in Figure 6.7. At a very low pressure p_1 , the flux J_v is low, so the effect of concentration polarization is small, and a gel layer does not form on the membrane surface. The flux is close to the pure water flux of the membrane at the same pressure. As the applied pressure is increased to pressure p_2 , the higher flux causes increased concentration polarization, and the concentration of retained material at the membrane surface increases. If the pressure is increased further to p_3 , concentration polarization becomes enough for the retained solutes at the membrane surface to reach the gel concentration c_{gel} and form the secondary barrier layer. This is the limiting flux for the membrane. Further increases in pressure only increase the thickness of the gel layer, not the flux.

Experience has shown that the best long-term performance of an ultrafiltration membrane is obtained when the applied pressure is maintained at or just below the plateau pressure p_3 shown in Figure 6.7. Operating at higher pressures does not increase the membrane flux but does increase the thickness and density of retained material at the membrane surface layer. Over time, material on the membrane surface can become compacted or precipitate, forming a layer of deposited material that has a lower permeability; the flux then falls from the initial value.

A series of experimental results obtained with latex solutions illustrating the effect of concentration and pressure on flux are shown in Figure 6.8. The point at which the flux reaches a plateau value depends on the concentration of the latex in the solution: the more concentrated the solution, the lower the plateau flux. The exact relationship between the maximum flux and solute concentration can be obtained by rearranging Equation (6.2) to obtain

$$J_{\text{max}} = -\frac{D}{\delta}(\ln c_{i_b} - \ln c_{\text{gel}}) \quad (6.3)$$

where J_{max} is the plateau or limiting flux through the membrane.

Plots of the limiting flux J_{max} as a function of solution concentration for latex solution data are shown in Figure 6.9 for a series of latex solutions at various feed solution flow rates. A series of straight line plots is obtained, and these extrapolate to the gel concentration c_{gel} at zero flux. The slopes of the plots in Figure 6.9 are proportional to the term D/δ in Equation (6.3). The increase in flux resulting from an increase in the fluid recirculation rate is caused by the decrease in the boundary layer thickness δ .

Plots of maximum flux as a function of solute concentration for different solutes using the same membrane under the same conditions are shown in Figure 6.10 [15]. Protein or colloidal solutions, which easily form precipitated gels, have low fluxes and extrapolate to low gel concentrations. Particulate

Figure 6.8 The effect of pressure on membrane flux for styrene-butadiene polymer latex solutions in a high-turbulence, thin-channel test cell [13]

Figure 6.9 Ultrafiltration flux with a latex solution at an applied pressure of 60 psi (in the limiting flux region) as a function of feed solution latex concentration. These results were obtained in a high-turbulence, thin-channel cell. The solution recirculation rate is shown in the figure [13]

Figure 6.10 Effect of solute type and concentration on flux through the same type of ultrafiltration membrane operated under the same conditions [15]. Reproduced from M.C. Porter, Membrane Filtration, in *Handbook of Separation Techniques for Chemical Engineers*, P.A. Schweitzer (ed.), p. 2.39, Copyright © 1979, with permission of McGraw-Hill, New York, NY

suspensions, pigments, latex particles, and oil-in-water emulsions, which do not easily form gels, have higher fluxes at the same concentration and operating conditions and generally extrapolate to higher gel concentrations.

Studies of concentration polarization such as those illustrated in Figures 6.8–6.10 are usually performed during the first few hours of the membrane use. Compaction of the secondary membrane layer has then only just begun, and membrane fluxes are often high. Fluxes obtained in industrial processes, which must operate for days or weeks without cleaning, are usually much lower.

The gel layer model described above is very appealing and is widely used to rationalize the behavior of ultrafiltration membranes. Unfortunately a number of issues cannot be easily explained by this simple form of the model:

- The flux of many macromolecular colloidal and particulate solutions is too high (sometimes by an order of magnitude) to be rationalized by a reasonable value of the diffusion coefficient and the boundary layer thickness in Equation (6.2).
- In the plateau region of the flux–pressure curves of the type shown in Figure 6.8, different solutes should have fluxes proportional to the value

of their diffusion coefficients D in Equation (6.3). This is not the case, as shown in Figure 6.10. For example, latex and particulate solutes with very small diffusion coefficients typically have higher ultrafiltration limiting fluxes than protein solutions measured with the same membranes under the same conditions. This is the opposite of the expected behavior.

- Experiments with different ultrafiltration membranes and the same feed solution often yield very different ultrafiltration limiting fluxes. But according to the model shown in Figure 6.6 and represented by Equation (6.2), the ultrafiltration limiting flux is independent of the membrane type.

Contrary to normal experience that falling bread always lands jam-side down, the trend of these observations is that experiment produces a better result than theory predicts. For this reason the observations are lumped together and called the flux paradox [9]. The best working model seems to be that, in addition to simple diffusion, solute is also being removed from the membrane surface as undissolved gel particles by a scouring action of the feed fluid [16]. This explains why protein solutions that form tough adherent gels have lower fluxes under the same conditions than pigment and latex solutions that form looser gels. The model also explains why increasing the hydrophilicity of the membrane surface or changing the charge on the surface can produce higher limiting fluxes. Decreased adhesion between the gel and the membrane surface allows the flowing feed solution to remove gel particles more easily.

Figure 6.11 illustrates how turbulent eddies caused by the high velocity of the solution passing through the narrow channel of a spiral-wound module might remove gel particles from the membrane surface. Because of the high velocity of the feed solution and the feed spacer netting used in ultrafiltration modules, the feed liquid is normally very turbulent. Although a relatively laminar boundary layer may form next to the membrane surface, as described by the film model, periodic turbulent eddies may also occur. These eddies can dislodge gel from the membrane surface, carrying it away with the feed solution.

The most important effect of concentration polarization is to reduce the membrane flux, but it also affects the retention of macromolecules. Retention data obtained with dextran polysaccharides at various pressures are shown in Figure 6.12 [17]. Because these are stirred batch cell data, the effect of increased concentration polarization with increased applied pressure is particularly marked. A similar drop of retention with pressure is observed with flow-through cells, but the effect is less because concentration polarization is better controlled in such cells. With macromolecular solutions, the concentration of retained macromolecules at the membrane surface increases with increased pressure, so permeation of the macromolecules also increases, lowering rejection. The effect is particularly noticeable at low pressures, under which conditions increasing the applied pressure produces the largest increase in flux, and hence concentration polarization, at the membrane surface. At high pressure, the change in flux with

Figure 6.11 An illustration of the channel of a spiral-wound module showing how periodic turbulent eddies can dislodge deposited gel particles from the surface of ultrafiltration membranes

Figure 6.12 Rejection of 1% dextran solutions as a function of pressure using Dextran 20 (MW 20 000), Dextran 40 (MW 40 000), and Dextran 80 (MW 80 000). Batch cell experiments performed at a constant stirring speed [17]

increased pressure is smaller, so the decrease in rejection by the membrane is less apparent.

Concentration polarization can also interfere with the ability of an ultrafiltration membrane to fractionate a mixture of dissolved macromolecules. Figure 6.13 [8] shows the results of experiments with a membrane with a molecular weight

Figure 6.13 The retention of albumin (MW 65 000) in the presence of varying concentrations of γ -globulin (MW 156 000) by a membrane with a nominal molecular weight cut-off based on one-component protein solutions of MW 200 000. As the concentration of γ -globulin in the solution increases, the membrane water flux decreases, and the albumin rejection increases from 25 % at 0.01 wt% γ -globulin to 80 % rejection at 0.1 wt% γ -globulin [8]

cut-off of about 200 000 used to separate albumin (MW 65 000) from γ -globulin (MW 156 000). Tests with the pure components show that albumin passes through the membrane almost completely unhindered, but rejection of γ -globulin is significant. However, addition of even a small amount of γ -globulin to the albumin causes almost complete rejection of both components. The increased rejection is accompanied by a sharp decrease in membrane flux, suggesting that rejected globulin forms a secondary barrier layer. The secondary layer is eliminated only at very low γ -globulin concentrations, resulting in partial fractionation of the two proteins. Unfortunately, at such low dilutions the separation is no longer of commercial interest.

Because of the effect of the secondary layer on selectivity, ultrafiltration membranes are not commonly used to fractionate macromolecular mixtures. Most commercial ultrafiltration applications involve processes in which the membrane completely rejects all the dissolved macromolecular and colloidal material in the feed solution while completely passing water and dissolved microsolute. Efficient fractionation by ultrafiltration is only possible if the species differ in molecular weight by a factor of 10 or more.

Membrane Cleaning

Several cleaning methods are used to remove the densified gel layer of retained material from the membrane surface. The easiest is to circulate an appropriate cleaning solution through the membrane modules for 1 or 2 h. The most common ultrafiltration fouling layers—organic polymer colloids and gelatinous

materials—are best treated with alkaline solutions followed by hot detergent solutions. Enzymatic detergents are particularly effective when the fouling layer is a proteinaceous gel. Calcium, magnesium, and silica scales, often a problem with reverse osmosis membranes, are generally not a problem in ultrafiltration because these ions permeate the membrane (ultrafiltration of cheese whey, in which high calcium levels can lead to calcium scaling, is an exception). Because many feed waters contain small amounts of soluble ferrous iron salts, hydrated iron oxide scaling is a problem. In the ultrafiltration system these salts are oxidized to ferric iron by entrained air. Ferric iron is insoluble in water, so an insoluble iron hydroxide gel forms and accumulates on the membrane surface. Such deposits are usually removed with a citric or hydrochloric acid wash.

Regular cleaning is required to maintain the performance of all ultrafiltration membranes. The period of the cleaning cycle can vary from daily for food applications, such as ultrafiltration of whey, to once a month or more for ultrafiltration membranes used as polishing units in ultrapure water systems. A typical cleaning cycle is as follows:

1. Flush the system several times with hot water at the highest possible circulation rate.
2. Treat the system with an appropriate acid or alkali wash, depending on the nature of the layer.
3. Treat the system with a hot detergent solution.
4. Flush the system thoroughly with water to remove all traces of detergent; measure the pure water flux through the membrane modules under standard test conditions. Even after cleaning, some degree of permanent flux loss over time is expected. If the restoration of flux is less than expected, repeat steps 1–3.

Ultrafiltration systems should never be taken off line without thorough flushing and cleaning. Because membrane modules are normally stored wet, the final rinse solutions should contain a bacteriostat such as 0.5% formaldehyde to inhibit bacterial growth.

In addition to regular cleaning with chemical solutions, mechanical cleaning of the membrane may be used, particularly if chemical cleaning does not restore the membrane flux. Early electrocoat paint systems used 1-in.-diameter tubular membrane modules. These tubes could be effectively cleaned by forcing sponge balls with a slightly larger diameter than the tube through the tube—the balls gently scraped the membrane surface, removing deposited material. Sponge-ball cleaning is an effective but relatively time-consuming process, so it is performed rather infrequently. However, automatic equipment for sponge-ball cleaning has been devised and has found a limited use.

Backflushing is another way of cleaning heavily fouled membranes. The method is widely used to clean capillary and ceramic membrane modules that can withstand a flow of solution from permeate to feed without damaging the

membrane. Backflushing is not usually used for spiral-wound modules because the membranes are too easily damaged. In a backflushing procedure a slight over-pressure is applied to the permeate side of the membrane, forcing solution from the permeate side to the feed side of the membrane. The flow of solution lifts deposited materials from the surface. Backflushing must be done carefully to avoid membrane damage. Typical backflushing pressures are 5–15 psi.

One method of achieving a backflushing effect used with capillary ultrafiltration modules is initiated by closing the permeate port from the membrane module, as shown in Figure 6.14 [18]. In normal operation a pressure drop of 5–10 psi occurs between the feed and residue side of a membrane module. This pressure difference is required to drive the feed solution through the module. If the permeate port from the module is closed, the pressure on the permeate side of the membrane will increase to a pressure intermediate between those of the feed and residue streams. This produces a slight positive pressure difference at one end of the module and a slight negative pressure difference on the other end of the module, as shown in Figure 6.14(b). The pressure difference sets up a backflushing condition in which permeate-quality water that has permeated one-half of the module becomes a backflushing solution in the other half of the module. Deposited materials lifted from the membrane surface in the back-flushed area are swept away by the fast feed flow. If the direction of the feed flow is reversed, as shown in Figure 6.14(c), the other half of the module is then back-flushed. This *in-situ* backflushing technique is used in capillary ultrafiltration modules in which the feed-to-residue pressure drop is quite large. An advantage of the procedure is that it can be done without stopping normal operation of the ultrafiltration system.

Because of the challenging environment in which ultrafiltration membranes are operated and the regular cleaning cycles, membrane lifetime is significantly shorter than that of reverse osmosis membranes. Ultrafiltration module lifetimes are rarely more than 2–3 years, and modules may be replaced annually in cheese whey or electrocoat paint applications. In contrast, reverse osmosis membranes are normally not cleaned more than once or twice per year and can last 4–5 years.

Membranes and Modules

Membrane Materials

Most of today's ultrafiltration membranes are made by variations of the Loeb–Sourirajan process. A limited number of materials are used, primarily polyacrylonitrile, poly(vinyl chloride)–polyacrylonitrile copolymers, polysulfone, poly(ether sulfone), poly(vinylidene fluoride), some aromatic polyamides, and cellulose acetate. In general, the more hydrophilic membranes are more fouling-resistant than the completely hydrophobic materials. For this reason water-soluble

Figure 6.14 Backflushing of membrane modules by closing the permeate port. This technique is particularly applicable to capillary fiber modules

polymers such as poly(vinyl pyrrolidone) or poly(vinyl methyl ether) are often added to the membrane casting solutions used for hydrophobic polymers such as polysulfone or poly(vinylidene fluoride). During the membrane precipitation step, most of the water-soluble polymer is leached from the membrane, but enough remains to make the membrane surface hydrophilic.

Figure 6.15 Effect of membrane surface charge on ultrafiltration flux decline. These membranes were used to ultrafilter cathodic electrocoat paint, which has a net negative charge. Electrostatic repulsion made the negatively charged membrane significantly more resistant to fouling than the similar positively charged membrane [13]

The charge on the membrane surface is important. Many colloidal materials have a slight negative charge from carboxyl, sulfonic or other acid groups. If the membrane surface also has a slight negative charge, adhesion of the colloidal gel layer to the membrane is reduced, which helps to maintain a high flux and inhibit membrane fouling. The effect of a slight positive charge on the membrane is the opposite. Charge and hydrophilic character can be the result of the chemical structure of the membrane material or can be applied to a preformed membrane surface by chemical grafting or surface treatment. The appropriate treatment depends on the application and the feed solution.

The importance of membrane surface characteristics on performance is illustrated by Figure 6.15. The feed solution in this example was a cathodic electrocoat paint solution in which the paint particulates had a net positive charge. As a result, membrane flux declined rapidly with the positively charged membranes but much more slowly with essentially identical membranes that had been treated to give the surface a net negative charge [13].

Ultrafiltration Modules

The need to control concentration polarization and membrane fouling dominates the design of ultrafiltration modules. The first commercially successful

ultrafiltration systems were based on tubular and plate-and-frame modules. Over the years, many improvements have been made to these module designs, and they are still used for highly fouling solutions. The lower cost of spiral-wound and capillary modules has resulted in a gradual trend to replace tubular and plate-and-frame systems with these lower-cost modules. In relatively non-fouling applications, such as the use of ultrafiltration as part of a treatment train to produce ultrapure water, spiral-wound modules are universally used. Spiral-wound and capillary modules are also used in some food applications, such as ultrafiltration of cheese whey and clarification of apple juice.

Because of their large diameter, tubular ultrafiltration modules can be used to treat solutions that would rapidly foul other module types. In a number of demanding applications, such as treatment of electrocoat paint, concentration of latex solutions, or separation of oil–water emulsions, the fouling resistance and ease of cleaning of tubular modules outweighs their high cost, large volume, and high energy consumption. In a typical tubular module system, 5- to 8-ft-long tubes are manifolded in series. The feed solution is circulated through the module array at velocities of 2–6 m/s. This high solution velocity causes a pressure drop of 2–3 psi per module or 10–30 psi for a module bank. Because of the high circulation rate and the resulting pressure drop, large pumps are required, so tubular modules have the highest energy consumption of any module design. Most tubular ultrafiltration plants use 30–100 kWh of energy per 1000 gallons of permeate produced. At an electrical energy cost of US\$0.06/kWh, this corresponds to an energy cost of US\$2–6 per 1000 gallons of permeate, a major cost factor.

The diameter of the early tubular membrane modules was 1 in. Later, more energy-efficient, higher-membrane-area modules were produced by nesting four to six smaller-diameter tubes inside a single housing (see Chapter 3). Typical tubular module costs vary widely but are generally from US\$200 to 500/m². Recently ceramic tubular modules have been introduced; these are more expensive, typically from US\$1000 to 2000/m². This high cost limits their use to a few applications with extreme feed operating conditions.

Plate-and-frame units compete with tubular units in some applications. These modules are not quite as fouling resistant as tubular modules but are less expensive. Most consist of a flat membrane envelope with a rubber gasket around the outer edge. The membrane envelope, together with appropriate spacers, forms a plate that is contained in a stack of 20–30 plates. Typical feed channel heights are 0.5–1.0 mm, and the system operates in high-shear conditions. Plate-and-frame systems can be operated at higher pressures than tubular or capillary modules—operating pressures up to 150 psi are not uncommon. This can be an advantage in some applications. The compact design, small hold-up volume, and absence of stagnant areas also makes sterilization easy. For these reasons plate-and-frame units are used in several types of food industry operations, particularly

Figure 6.16 Horizontal DDS plate-and-frame ultrafiltration system. Courtesy of Alfa Laval Nakskov A/S, Naksvov, Denmark

in Europe where Rhône Poulanc and De Danske Sukkerfabrikker (DDS) [now Alfa Laval] pioneered these applications in the 1970s. A photograph of an Alfa Laval plate-and-frame system is shown in Figure 6.16.

Capillary hollow fiber modules were introduced by Romicon in the early 1970s. A typical capillary module contains 500–2000 fibers with a diameter of 0.5–1.0 mm housed in a 30-in.-long, 3-in.-diameter cartridge. Modules have a membrane area of 2–10 m². Feed solution is pumped down the bore of the fibers. Operating pressures are quite low, normally not more than 25 psi (to avoid breaking the fibers). This low operating pressure is a disadvantage in the treatment of some clean feed solutions for which high-pressure operation would be advantageous. The normal feed-to-residue pressure drop of a capillary module is 10–15 psi. Under these conditions, capillary modules achieve good throughputs with many solutions. High-temperature sanitary systems are available; this, combined with the small hold-up volume and clean flow path, has encouraged the use of these modules in biotechnology applications in which small volumes of

expensive solutions are treated. A major advantage of capillary fiber systems is that the membrane can be cleaned easily by backflushing. With capillary modules it is important to avoid 'blinding' the fibers with particulates caught at the fiber entrance. Prefiltration to remove all particulates larger than one-tenth of the fiber's inside diameter is required to avoid blinding.

The use of spiral-wound modules in ultrafiltration applications has increased recently. This design was first developed for reverse osmosis modules in which the feed channel spacer is a fine window-screen material. In ultrafiltration a coarser feed spacer material is used, often as much as 45 mil thick. This coarse spacer prevents particulates from lodging in the spacer corners. However, prefiltration of the ultrafiltration feed down to 5–10 μm is still required for long-term operation. In the past, spiral-wound modules were limited to ultrafiltration of clean feed waters, such as preparation of ultrapure water for the electronics or pharmaceutical industries. Development of improved pretreatment and module spacer designs now allows these modules to be used for more highly fouling solutions such as cheese whey. In these food applications, the stagnant volume between the module insert and the module housing is a potentially unsterile area. To eliminate this dead space, the product seal is perforated to allow a small bypass flow to continuously flush this area.

In the last few years a number of companies, most notably New Logic International (Emeryville, CA), have introduced plate-and-frame modules in which the membrane plate is vibrated or rotated. Thus, control of concentration polarization at the membrane surface is by movement of the membrane rather than by movement of the feed solution [19]. Moving the membrane concentrates most of the turbulence right at the membrane surface, where it is most needed. These modules achieve very high turbulence at the membrane surface at a relatively low energy cost. The fluxes obtained are high and stable. Vibrating–rotating modules are considerably more expensive than cross-flow modules so the first applications have been with high-value, highly fouling feed solutions that are difficult to treat with standard modules.

System Design

Batch Systems

The simplest type of ultrafiltration system is a batch unit, shown in Figure 6.17. In such a unit, a limited volume of feed solution is circulated through a module at a high flow rate. The process continues until the required separation is achieved, after which the concentrate solution is drained from the feed tank, and the unit is ready to treat a second batch of solution. Batch processes are particularly suited to the small-scale operations common in the biotechnology and pharmaceutical industries. Such systems can be adapted to continuous use but this requires automatic controls, which are expensive and can be unreliable.

Figure 6.17 Flow schematic of a batch ultrafiltration process

The easiest way to calculate the performance of a batch system is to assume the membrane is completely retentive for the solute of interest. That is,

$$\mathbb{R} = \left(1 - \frac{c_p}{c_b} \right) = 1 \tag{6.4}$$

where c_p is the solute concentration in the permeate and c_b is the solute concentration in the feed. It follows that the increase in concentration of the solute in the feed tank from the initial concentration $c_b(o)$, to the concentration at time t , $c_b(t)$ is proportional to the volume of solution remaining in the feed tank, that is,

$$\frac{c_b(t)}{c_b(o)} = \frac{V(o)}{V(t)} \tag{6.5}$$

where the volume of solution removed in the permeate is $V(o) - V(t)$. If, as is often the case, the membrane is slightly permeable to the solute ($\mathbb{R} < 1$), the concentration ratio achieved can be written as

$$\ln \left[\frac{c_b(t)}{c_b(o)} \right] = \mathbb{R} \ln \left(\frac{V(o)}{V(t)} \right) \tag{6.6}$$

When the rejection coefficient equals one, Equation (6.6) reduces to Equation (6.5). A plot of the concentration ratio of retained solute as a function of the volume reduction for membranes with varying rejection coefficients is shown in Figure 6.18. This figure illustrates the effect of partially retentive membranes on loss of solute.

Figure 6.18 Increase in concentration of the retained feed solution as a function of volume reduction of the feed for membranes of different solute rejections. The difference between these lines and the $R = 1$ line represents loss of solute through the membrane

Continuous Systems

Continuous ultrafiltration processes, in which modules are arranged in series to obtain the separation required in a single pass, are relatively common. This is because high feed solution flow rates are required to control concentration polarization; a single-pass process would not achieve the required removal under these conditions. Solution velocities in ultrafiltration modules are 5–10 times higher than in reverse osmosis. For these reasons, feed-and-bleed systems are commonly used in large ultrafiltration plants. Figure 6.19 shows one-, two- and three-stage feed-and-bleed systems. In these systems a large volume of solution is circulated continuously through a bank of membrane modules. Concurrently, a small volume of feed solution enters the recirculation loop just before the recirculation pump, and an equivalent volume of more concentrated solution is removed (or bled) from the recirculation loop just after the membrane module. The advantage of feed-and-bleed systems is that a high feed solution velocity through the modules is easily maintained independent of the volume of solution being treated. In most plants the flow rate of solution in the recirculation loop is 5–10 times the feed solution flow rate. This high circulation rate means that the concentration of retained material in the circulating solution is close to the concentration of the bleed solution and is significantly higher than the feed solution concentration. Because the flux of ultrafiltration membranes decreases with increasing concentration, more membrane area is required to produce the required separation than in a batch or a once-through continuous system operated at the same feed solution velocity.

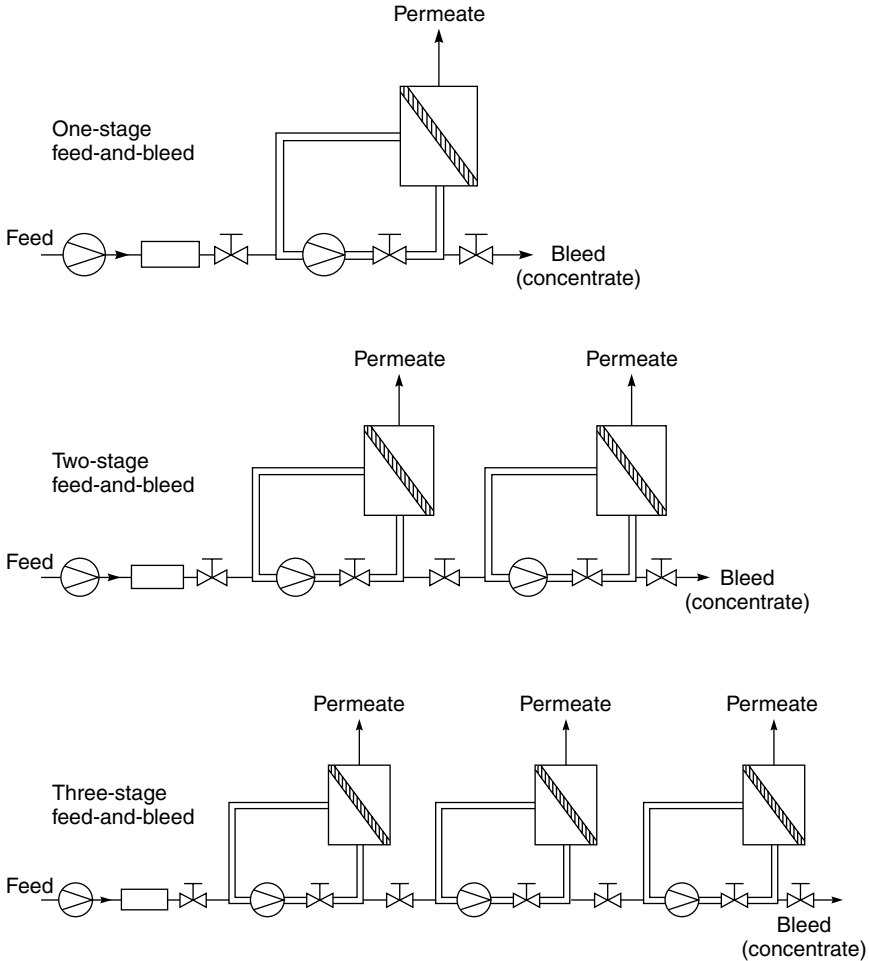

Figure 6.19 One-, two- and three-stage feed-and-bleed systems. In general, the most efficient design is achieved when all stages have approximately the same membrane area. As the number of stages is increased, the average concentration of the solution circulating through the membrane modules decreases, and the total membrane area of the system is significantly less than for a one-stage design

To overcome the inefficiency of one-stage feed-and-bleed designs, industrial systems are usually divided into multiple stages, as shown in Figure 6.19. By using multiple stages, the difference in concentration between the solution circulating in a stage and the feed solution entering the stage is minimized. The following numerical values illustrate this point. In this example, the membrane is assumed to be completely retentive and the goal is to concentrate the feed solution

from 1 to 8%. If this is done in a one-stage feed-and-bleed system, the average concentration of the solution passing through the modules is 8%, and the flux is proportionately low. In a more efficient two-stage feed-and-bleed system, the first stage concentrates the solution from 1 to 3%, and the second stage concentrates the solution from 3 to 8%. Approximately three-quarters of the permeate is removed in the first stage, and the rest in the second stage. Because the modules in the first stage operate at a concentration of 3% rather than 8%, these modules have a higher membrane flux than in the one-stage unit. In fact, the membrane area of each stage is about equal although the volume of permeate produced by each stage is very different. The two-stage feed-and-bleed design has about 60% of the area of the one-stage system. The three-stage system, which concentrates the solution in three equal-area stages—from 1 to 2% in the first stage, from 2 to 4% in the second stage, and from 4 to 8% in the third stage—is even more efficient. In this case the total membrane area is about 40% of the area of a one-stage system performing the same separation.

Because of the significantly lower membrane areas of multistage feed-and-bleed systems, most large plants have between three and five stages. The limit to the number of stages is reached when the reduction in membrane area does not offset the increase in complexity of the system. Also, because of the high fluid circulation rates involved in feed-and-bleed ultrafiltration plants, the cost of pumps can rise to 30 to 40% of the total cost of the system. Electricity to power the pumps is a significant operating expense.

Applications

In the 1960s and early 1970s it was thought that ultrafiltration would be widely used to treat industrial wastewater. This application did not materialize. Ultrafiltration is far too expensive to be generally used for this application, however, it is used to treat small, concentrated waste streams from particular point sources before they are mixed with the general sewer stream. Ultrafiltration is also used if the value of the components to be separated is sufficient to offset the cost of the process. Examples exist in food processing, in which the ultrafiltered concentrate is used to produce a high-value product, or in the production of ultrapure water in the electronics industry.

The cost of ultrafiltration plants varies widely, depending on the size of the plant, the type of solution to be treated, and the separation to be performed. In general, ultrafiltration plants are much smaller than reverse osmosis systems. Typical flow rates are 10 000–100 000 gal/day, one-tenth that of the average reverse osmosis plant. Rogers [20] compiled the costs shown in Figure 6.20 that, adjusted for inflation, still seem reasonable. For typical plants treating 10 000–100 000 gal/day of feed solution, the capital cost is in the range US\$2–5 gal/day capacity. The typical breakdown of these costs is shown in Table 6.1 [21]. Operating costs will normally be US\$3–4/1000 gal/day capacity,

Figure 6.20 Purchase price in 2003 US dollars for ultrafiltration plants as a function of plant capacity. Data of Rogers corrected for inflation [20]. Reprinted from *Synthetic Membrane Processes*, A.N. Rogers, Economics of the Application of Membrane Processes, p. 454, G. Belfort (ed.), Copyright 1984, with permission from Elsevier

Table 6.1 Typical ultrafiltration capital and operating cost breakdown [21]

Capital costs	%
Pumps	30
Membrane modules	20
Module housings	10
Pipes, valves, frame	20
Controls/other	20
Total	100
Operating costs	
Membrane replacement	30–50
Cleaning costs	10–30
Energy	20–30
Labor	15
Total	100

with membrane module replacement costs about 30–50 %, and energy costs for the recirculation pumps 20–30 %, depending on the system design.

The current ultrafiltration market is approximately US\$200 million/year but because the market is very fragmented, no individual segment is more than about US\$10–30 million/year. Also, each of the diverse applications uses membranes, modules, and system designs tailored to the particular industry served. The result is little product standardization, many custom-built systems, and high costs compared to reverse osmosis. The first large successful application was the recovery

of electrocoat paint in automobile plants. Later, a number of significant applications developed in the food industry [22,23], first in the production of cheese, then in the production of apple and other juices and, more recently, in the production of beer and wine. Industrial wastewater and process water treatment is a growing application, but high costs limit growth. Early plants were all tubular or plate-and-frame systems, but less expensive capillary and specially configured spiral-wound modules are now used more commonly. An overview of ultrafiltration applications is given in Cheryan and Alvarez's review article [23] and Cheryan's book [24].

Electrocoat Paint

In the 1960s, automobile companies began to use electrodeposition of paint on a large scale. The paint solution is an emulsion of charged paint particles. The metal piece to be coated is made into an electrode of opposite charge to the paint particles and is immersed in a large tank of the paint. When a voltage is applied between the metal part and the paint tank, the charged paint particles migrate under the influence of the voltage and are deposited on the metal surface, forming a coating over the entire wetted surface of the metal part. After electrodeposition, the piece is removed from the tank and rinsed to remove excess paint, after which the paint is cured in an oven.

The rinse water from the washing step rapidly becomes contaminated with excess paint, while the stability of the paint emulsion is gradually degraded by ionic impurities carried over from the cleaning operation before the paint tank. Both of these problems are solved by the ultrafiltration system shown in Figure 6.21. The ultrafiltration plant takes paint solution containing 15–20% solids and produces a clean permeate containing the ionic impurities but no paint particles, which is sent to the counter-current rinsing operation, and a slightly concentrated paint to be returned to the paint tank. A portion of the ultrafiltration permeate is bled from the tank and replaced with water to maintain the ionic balance of the process.

Electrocoat paint is a challenging feed solution for an ultrafiltration process. The solids content of the solution is high, typically 15–20 wt%, so a gel layer easily forms on the membrane. The gel formation results in relatively low fluxes, generally 10–15 gal/ft² · day. However, the value of the paint recovered from the rinse water and elimination of other rinse-water cleanup steps made the ultrafiltration process an immediate success when introduced by Abcor. Tubular modules were used in the first plants [7] and are still installed in many electrocoat operations, although capillary and some spiral-wound modules are used in newer plants. The first electrocoat paint was anionic because the latex emulsion particles carried a negative charge. These emulsions were best treated with membranes having a slight negative charge to minimize fouling. Cationic latex paints carrying

Figure 6.21 Flow schematic of an electrocoat paint ultrafiltration system. The ultrafiltration system removes ionic impurities from the paint tank carried over from the chromate/phosphate cleaning steps and provides clean rinse water for the counter-current rinsing operation

a positive charge were introduced in the late 1970s. Ultrafiltration of these paints required development of membranes carrying a slight positive charge.

Food Industry

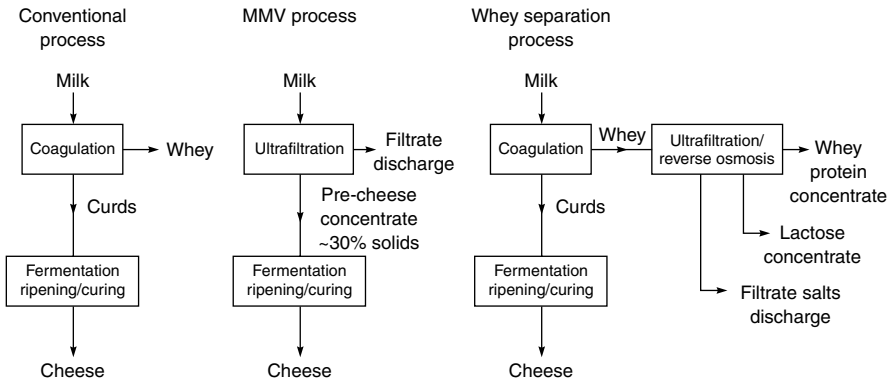

Cheese Production

Ultrafiltration has found a major application in the production of cheese; the technology is now widely used throughout the dairy industry. During cheese production the milk is coagulated (or curdled) by precipitation of the milk proteins. The solid that forms (curd) is sent to the cheese fermentation plant. The supernatant liquor (whey) represents a disposal problem. The compositions of milk and whey are shown in Table 6.2. Whey contains most of the dissolved salts and sugars present in the original milk and about 25% of the original protein. In the past, whey was often discharged to the sewer because its high salt and lactose content makes direct use as a food supplement difficult. Now about half of the whey produced in the United States is processed to obtain additional value and avoid a troublesome waste disposal problems. The traditional cheese production process and two newer processes using ultrafiltration membranes are shown in Figure 6.22.

The objective of the two membrane processes shown in Figure 6.22 is to increase the fraction of milk proteins used as cheese or some other useful product and to reduce the waste disposal problem represented by the whey. In the MMV

Table 6.2 Composition of milk and cheese whey

Component (wt%)	Milk	Whey
Total solids	12.3	7.0
Protein	3.3	0.9
Fat	3.7	0.7
Lactose/other carbohydrates	4.6	4.8
Ash	0.7	0.6

**Figure 6.22** Simplified flow schematic showing the traditional cheese production method, and two new methods using ultrafiltration to increase the recycle of useful product

process, named after the developers Maubois, Mocquot and Vassal [25], whole or skimmed milk is concentrated three- to five-fold to produce a pre-cheese concentrate that can be used directly to produce soft cheeses and yogurt. Typically, the total solids level of the concentrate is about 30–35%, containing 12–17% protein. This protein concentration is sufficient for soft cheeses (Camembert, Mozzarella and Feta) but cannot be used directly to produce hard cheeses (Cheddar and Swiss), for which protein levels of 25% are required. When ultrafiltration can be used, increased milk protein utilization increases cheese production by approximately 10%, so the process is widely used.

The second whey separation process uses both ultrafiltration and reverse osmosis to obtain useful protein from the whey produced in the traditional cheese manufacturing process. A flow schematic of a combined ultrafiltration–reverse osmosis process is shown in Figure 6.23. The goal is to separate the whey into three streams, the most valuable of which is the concentrated protein fraction stripped of salts and lactose. Because raw whey has a high lactose concentration, before the whey protein can be used as a concentrate, the protein concentration must be increased to at least 60–70% on a dry basis and the lactose content

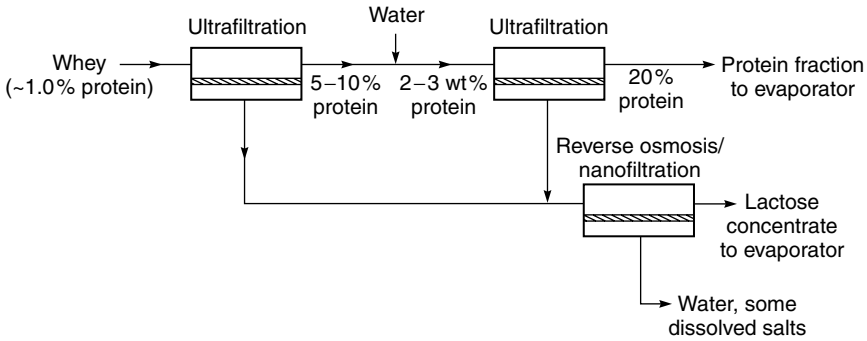

Figure 6.23 Simplified flow schematic of an ultrafiltration/reverse osmosis process to extract valuable components from cheese whey

reduced by 95%. The objective of the ultrafiltration membrane step is to concentrate the protein as much as possible to minimize evaporator drying costs and to simultaneously remove the lactose. These two objectives are difficult to meet in a single ultrafiltration step because of the reduction in flux at the very high volume reduction required to achieve sufficient lactose removal. Therefore, whey plants commonly use an ultrafiltration step to achieve a 5- to 10-fold volume reduction and remove most of the lactose, after which the feed is diluted with water and reconcentrated in a second step which removes the remaining lactose. Most whey plants use spiral-wound ultrafiltration modules in multistage feed-and-bleed systems. Sanitary spiral-wound module designs are used to eliminate stagnant areas in the module housing, and the entire plant is sterilized daily with hot high- and low-pH cleaning solutions. This harsh cleaning treatment significantly reduces membrane lifetime.

Although whey protein products have several food uses, the lactose contained in the permeate is less valuable, and many plants discharge the permeate to a biological wastewater treatment plant. A few plants recover lactose as dry lactose sugar, as shown in Figure 6.23. Some plants also ferment the lactose concentrate to make ethanol. An introduction to membrane ultrafiltration in cheese production is given by Kosikowski [26].

Clarification of Fruit Juice

Apple, pear, orange and grape juices are all clarified by ultrafiltration. Ultrafiltration of apple juice is a particularly successful application. Approximately 200 plants have been installed, and almost all US apple juice is clarified by this method. In the traditional process, crude filtration was performed directly after crushing the fruit. Pectinase was added to hydrolyze pectin, which reduced the viscosity of the juice before it was passed through a series of decantation and

Figure 6.24 Ultrafiltration flux in apple juice clarification as a function of the volumetric feed-to-residue concentration factor. Tubular polysulfone membranes at 55 °C [27]. Reprinted from R.G. Blanck and W. Eykamp, Fruit Juice Ultrafiltration, in *Recent Advances in Separation Techniques-III*, N.N. Li (ed.), AIChE Symposium Series Number 250, 82 (1986). diatomaceous filtration steps to yield clear juice with a typical yield of about 90 %. By replacing these final filtration steps with ultrafiltration, a very good-quality, almost-sterile product can be produced with a yield of almost 97 % [26,27].

Ultrafiltration membranes with a molecular weight cut-off of 10 000–50 000, packaged as tubular or capillary hollow fiber modules, are generally used. The initial feed solution is quite fluid, but in this application almost all of the feed solution is forced through the membrane, and overall concentration factors of 50 are normal. This means that the final residue solution is concentrated and viscous so the solution is usually filtered at 50–55 °C. Operation at this temperature also reduces bacterial growth. A flux versus concentration factor curve produced in this type of application is shown in Figure 6.24. As the concentration of the residue rises, the flux falls dramatically.

Oil–Water Emulsions

Oil–water emulsions are widely used in metal machining operations to provide lubrication and cooling. Although recycling of the fluids is widely practiced, spent waste streams are produced. Using ultrafiltration to recover the oil component and allow safe discharge of the water makes good economic sense, and

this application covers a wide volume range. In large, automated machining operations such as automobile plants, steel rolling mills, and wire mills, a central ultrafiltration system may process up to 100 000 gal/day of waste emulsion. These are relatively sophisticated plants that operate continuously using several ultrafiltration feed-and-bleed stages in series. At the other end of the scale are very small systems dedicated to single machines, which process only a few gallons of emulsion per hour. The principal economic driver for users of small systems is the avoided cost of waste hauling. For larger systems the value of the recovered oil and associated chemicals can be important. In both cases, tubular or capillary hollow fiber modules are generally used because of the high fouling potential and very variable composition of emulsified oils. A flow diagram of an ultrafiltration system used to treat large machine oil emulsions is shown in Figure 6.25. The dilute, used emulsion is filtered to remove metal cuttings and is then circulated through a feed-and-bleed ultrafiltration system, producing a concentrated emulsion for reuse and a dilute filtrate that can be discharged or reused.

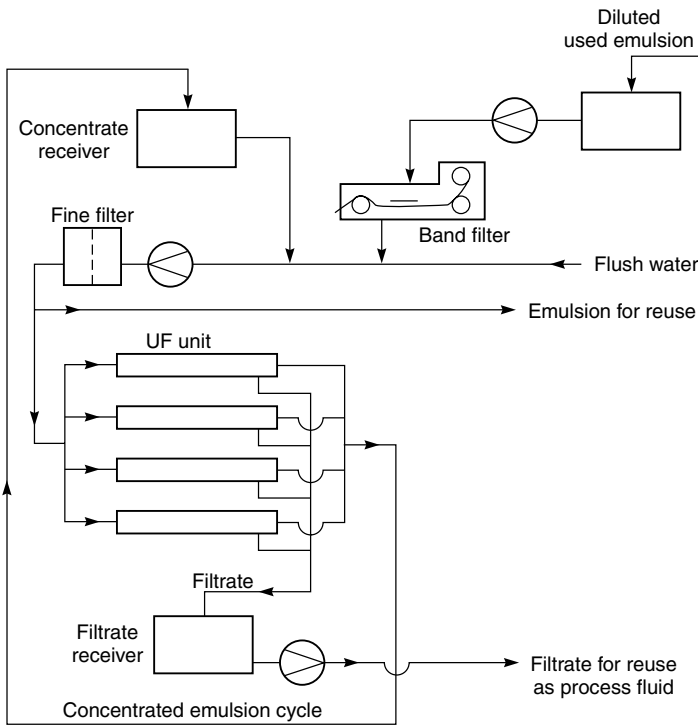

Figure 6.25 Flow diagram of a feed-and-bleed ultrafiltration unit used to concentrate a dilute oil emulsion

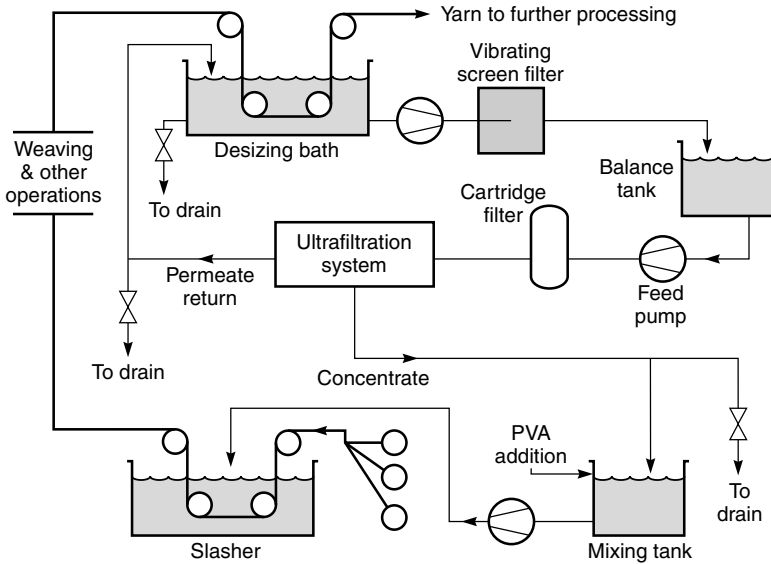

Process Water and Product Recycling

Ultrafiltration has been applied to a number of process and product recycling operations. Typical applications include cleaning and recycling hot water used in food processing applications, recovery of latex particles contained in wastewater produced in production of latex paints [28,29] and recovery of poly(vinyl alcohol) sizing agents used as process aids in synthetic fabric weaving operations [28]. The economic driving force for the applications can come from a number of sources:

- **Water recovery.** Depending on the plant's location, reduced municipal water costs can produce savings in the US\$1.00–2.00/1000 gal range.
- **Heat recovery.** Many process streams are hot. Ultrafiltration usually works better with hot feeds so hot feed solutions are not a problem. If the hot, clean permeate can be recycled without cooling, the energy savings can be considerable. If the water is 50 °C above ambient temperature, the energy savings amount to about US\$4.00/1000 gal.
- **Avoided water treatment costs.** These costs will vary over a wide range depending on the process. For a food processing plant they are likely to be relatively modest—perhaps only US\$1/1000 gal or less—but treating latex emulsion plant effluents (called white water) can cost as much as US\$10/1000 gal or more.
- **Product recovery value.** If the product concentrated by the ultrafiltration process can be recovered and reused in the plant, this is likely to be the most important credit.

A typical example of a process water and product recycling application, shown in Figure 6.26, is the recovery of poly(vinyl alcohol) sizing agent. In this application, all the above economic drivers contribute to the total plant economics. The feed stream is produced in fabric weaving when the fiber is dipped in a solution of poly(vinyl alcohol) to increase its strength. After weaving, the poly(vinyl alcohol) is removed in a desizing wash bath. The solution produced in this bath is hot (55 °C) and contains 0.5–1.0 % poly(vinyl alcohol). The purpose of the ultrafiltration unit is to concentrate the poly(vinyl alcohol) so it can be recycled to the sizing bath and to send the reclaimed, hot clean permeate stream back to the desizing step. After filtration the poly(vinyl alcohol) solution is relatively particulate-free and quite viscous, so spiral-wound modules are used to reduce costs. For very small plants with flows of less than 5 gal/min, batch systems are used. However, most plants are in the 10- to 100-gal/min range and are multistage feed-and-bleed systems, as shown in Figure 6.26. The environment is challenging for the membranes, which must be cleaned weekly with detergents to remove waxy deposits and with citric acid to remove iron scale. Even so, modules must be replaced every 12–18 months, representing a major operating cost.

Biotechnology

Many applications exist for ultrafiltration in the biotechnology industry. A typical application is the concentration and removal of products from fermentation operations used in enzyme production, cell harvesting, or virus production. Most of the systems are small; the volume processed is often only 100 to 1000 gal/day, but the value of products is often very high. Batch systems are commonly used.

Because of the glamour of biotechnology, these applications have received a disproportionate interest by academic researchers. However, this is not a major market for ultrafiltration equipment, and many of the plants use little more than bench-scale equipment.

Conclusions and Future Directions

The high cost per gallon of permeate produced limits the expansion of ultrafiltration into most large wastewater and industrial process stream applications. Costs are high because membrane fluxes are modest, large amounts of energy are used to circulate the feed solution to control fouling, membrane modules must be cleaned frequently, and membrane lifetimes are short. These are all different aspects of the same problem—membrane fouling.

Unfortunately, membrane fouling and gel layer formation are inherent features of ultrafiltration. Only limited progress in controlling these problems has been made in the last 20 years and, barring an unexpected breakthrough, progress is likely to remain slow. Development of inherently fouling-resistant membranes by changing the membrane surface absorption characteristics or charge is a promising approach. By reducing adhesion of the deposited gel layer to the surface, the scrubbing action of the feed solution can be enhanced. Another approach is to develop inherently more fouling-resistant modules. In principle, bore-side-feed capillary fiber modules offer high membrane areas, good flow distribution, and the potential for simple automatic flushing to clean the membrane. The capillary fibers used to date have generally been limited to relatively small diameters and low operating pressures. Development of economical ways to produce 2- to 3-mm-diameter capillary fiber modules, able to operate at 50–100 psi, could lead to lower energy consumption and higher, more stable membrane fluxes. Monolithic ceramic membrane modules have all of these features, but for these to be widely accepted, costs must be reduced by an order of magnitude from today's levels, that is, to less than US\$100–200/m². If this cost reduction were achieved, ceramics might replace polymeric membranes in many applications. Vibrating membrane modules have been introduced recently and, although costs are high, their performance is very good. Cost reductions could make this type of module more generally applicable in the future.

7 MICROFILTRATION

Introduction and History

Microfiltration refers to filtration processes that use porous membranes to separate suspended particles with diameters between 0.1 and 10 μm . Thus, microfiltration membranes fall between ultrafiltration membranes and conventional filters. Like ultrafiltration, microfiltration has its modern origins in the development of collodion (nitrocellulose) membranes in the 1920s and 1930s. In 1926 Membranfilter GmbH was founded and began to produce collodion microfiltration membranes commercially. The market was very small, but by the 1940s other companies, including Sartorius and Schleicher and Schuell, were producing similar membrane filters.

The first large-scale application of microfiltration membranes was to culture microorganisms in drinking water; this remains a significant application. The test was developed in Germany during World War II, as a rapid method to monitor the water supply for contamination. The existing test required water samples to be cultured for at least 96 h. Mueller and others at Hamburg University devised a method in which a liter of water was filtered through a Sartorius microfiltration membrane. Any bacteria in the water were captured by the filter, and the membrane was then placed on a pad of gelled nutrient solution for 24 h. The nutrients diffused to the trapped bacteria on the membrane surface, allowing them to grow into colonies large enough to be easily counted under a microscope. After the war there was no US supplier of these membranes, so in 1947 the US Army sponsored a program by Goetz at CalTech to duplicate the Sartorius technology. The membranes developed there were made from a blend of cellulose acetate and nitrocellulose, and were formed by controlled precipitation with water from the vapor phase. This technology was passed to the Lowell Chemical Company, which in 1954 became the Millipore Corporation, producing the Goetz membranes on a commercial scale. Over the next 40 years Millipore became the largest microfiltration company. Membranes made from a number of noncellulosic materials, including poly(vinylidene fluoride), polyamides, polyolefins, and poly(tetrafluoroethylene), have been developed over the last 40 years by Millipore

and others. Nonetheless, the cellulose acetate/cellulose nitrate blend membrane remains a widely used microfilter.

Until the mid-1960s, the use of microfiltration membranes was confined to laboratory or to very small-scale industrial applications. The introduction of pleated membrane cartridges by Gelman in the 1970s was an important step forward and made possible the use of microfiltration membranes in large-scale industrial applications. In the 1960s and 1970s, microfiltration became important in biological and pharmaceutical manufacturing, as did microfiltration of air and water in the production of microelectronics in the 1980s. The production of low-cost, single-use, disposable cartridges for pharmaceutical and electronics processes now represents a major part of the microfiltration industry. In most applications of microfiltration in these industries, trace amounts of particles are removed from already very clean solutions. The most widely used process design, illustrated in Figure 7.1(a), is dead-end or in-line filtration, in which the entire fluid flow is forced through the membrane under pressure. As particles accumulate on the membrane surface or in its interior, the pressure required to maintain the required flow increases, until at some point the membrane must be replaced. In

Figure 7.1 Schematic representation of (a) in-line and (b) cross-flow filtration with microfiltration membranes. The equipment used for in-line filtration is simple, but retained particles plug the membrane rapidly. The equipment required for cross-flow filtration is more complex, but the membrane lifetime is longer

the 1970s, an alternative process design known as cross-flow filtration, illustrated in Figure 7.1(b), began to be used.

In cross-flow systems, the feed solution is circulated across the surface of the filter, producing two streams: a clean particle-free permeate and a concentrated retentate containing the particles. The equipment required for cross-flow filtration is more complex, but the membrane lifetime is longer than with in-line filtration. The commercial availability of ceramic tubular cross-flow filters from Membralox (now a division of US Filter), starting in the mid-1980s, has increased the application of cross-flow filtration, particularly for solutions with high particle concentrations. Streams containing less than 0.1 % solids are almost always treated with in-line filters; streams containing 0.5 % solids are almost always treated with cross-flow filters. Between these two limits, both in-line and cross-flow systems can be used, depending on the particular characteristics of the application.

In the last few years, a third type of microfiltration operating system called semi-dead-end filtration has emerged. In these systems, the membrane unit is operated as a dead-end filter until the pressure required to maintain a useful flow across the filter reaches its maximum level. At this point, the filter is operated in cross-flow mode, while concurrently backflushing with air or permeate solution. After a short period of backflushing in cross-flow mode to remove material deposited on the membrane, the system is switched back to dead-end operation. This procedure is particularly applicable in microfiltration units used as final bacterial and virus filters for municipal water treatment plants. The feed water has a very low loading of material to be removed, so in-line operation can be used for a prolonged time before backflushing and cross-flow to remove the deposited solids is needed.

Beginning in 1990–1993, the first microfiltration/ultrafiltration systems began to be installed to treat municipal drinking water obtained from surface water. The US EPA and European regulators are implementing rules requiring this water to be treated to control giardia, coliform bacteria, and viruses. Large plants using back-flushable hollow fiber membrane modules are being built by a number of companies: US Filter (Memtec), Norit (X-Flow), Koch (Romicon), and Hydranautics.

Some of the important milestones in the development of microfiltration are charted in Figure 7.2.

Background

Types of Membrane

The two principal types of microfiltration membrane filter in use—depth filters and screen filters—are illustrated in Figure 7.3. Screen filters have small pores in their top surface that collect particles larger than the pore diameter on the surface of the membrane. Depth filters have relatively large pores on the top

Figure 7.2 Milestones in the development of microfiltration

surface so particles pass to the interior of the membrane. The particles are then captured at constrictions in the membrane pores or by adsorption onto the pore walls. Screen filter membranes rapidly become plugged by the accumulation of retained particles at the top surface. Depth filters have a much larger surface area available for collection of the particles, providing a larger holding capacity before fouling. The mechanism of particle capture by these membranes is described in more detail in Chapter 2.

Depth membrane filters are usually preferred for in-line filtration. As particles are trapped within the membrane, the permeability falls, and the pressure required to maintain a useful filtrate flow increases until, at some point, the membrane must be replaced. The useful life of the membrane is proportional to the particle loading of the feed solution. A typical application of in-line depth microfiltration membranes is final polishing of ultrapure water just prior to use. Screen membrane filters are preferred for the cross-flow microfiltration systems shown in Figure 7.1(b). Because screen filters collect the retained particles on the surface of the membrane, the recirculating fluid helps to keep the filter clean.

Membrane Characterization

Microfiltration membranes are often used in applications for which penetration of even one particle or bacterium through the membrane can be critical. Therefore, membrane integrity, that is, the absence of membrane defects or oversized pores,

Cross-sectional Comparison

Figure 7.3 Surface scanning electron micrograph and schematic comparison of nominal 0.45-μm screen and depth filters. The screen filter pores are uniform and small and capture the retained particles on the membrane surface. The depth filter pores are almost 5–10 times larger than the screen filter equivalent. A few large particles are captured on the surface of the membrane, but most are captured by adsorption in the membrane interior

is extremely important. Several tests are used to characterize membrane pore size and pore size distribution.

Characterizing the pore size of microfiltration membranes is a problem for manufacturers. Most microfiltration membranes are depth filters, so electron micrographs usually show an image similar to that in Figure 7.3. The average pore diameter of these membranes appears to be about $5\ \mu\text{m}$, yet the membranes are complete filters for particles or bacteria of about $0.5\text{-}\mu\text{m}$ diameter. Therefore, most manufacturers characterize their membranes by the size of the bacteria that are completely filtered by the membrane. The ability of a membrane to filter bacteria from solutions depends on the pore size of the membrane, the size of the bacteria being filtered, and the number of organisms used to challenge the membrane. Some results of Elford [1] that illustrate these effects are shown in Figure 7.4. Elford found that membranes with relatively large pores could completely filter bacteria from the challenge solution to produce a sterile filtrate, providing the challenge concentration was low. If the organism concentration was increased, breakthrough of bacteria to the filtrate occurred. However, if the membrane pore size was small enough, a point was reached at which no breakthrough of bacteria to the filtrate occurred no matter how concentrated the challenge solution. This point is taken to be the pore size of the membrane.

Figure 7.4 Membrane pore diameter from bubble point measurements versus *Bacillus prodigiosus* concentration [1]. Reprinted from W.J. Elford, *The Principles of Ultrafiltration as Applied in Biological Studies*, *Proc. R. Soc. London, Ser. B* **112**, 384 (1933) with permission from The Royal Society, London, UK

The industry has adopted two bacterial challenge tests to measure pore size and membrane integrity [2]. The tests are based on two bacteria: *Serratia marcescens*, originally thought to have a diameter of $0.45\ \mu\text{m}$, and *Pseudomonas diminuta*, originally thought to have a diameter of $0.22\ \mu\text{m}$. In fact, both organisms are ellipsoids with an aspect ratio of about 1.5:1. These tests have changed several times over the years, but by convention a membrane is designated $0.45\text{-}\mu\text{m}$ pore size if it is completely retentive when challenged with 10^7 *S. marcescens* organisms per cm^2 and $0.22\text{-}\mu\text{m}$ pore size if it is completely retentive when challenged with 10^7 *P. diminuta* organisms per cm^2 . Most commercial microfiltration membranes are categorized as 0.22- or $0.45\text{-}\mu\text{m}$ -diameter pore size based on these tests. Membranes with larger or smaller pore sizes are classified by the penetration tests with latex particle or bubble point measurements described below, relative to these two primary standard measurements.

Currently, most bacterial challenge tests are performed with *P. diminuta*. This organism has an average size of $0.3\text{--}0.4\ \mu\text{m}$, although the size varies significantly with the culture conditions. In a rich culture medium, the cells can form much larger clumps. Thus, to obtain consistent results, the culture characteristics must be carefully monitored and control experiments performed with already qualified 0.45- and $0.22\text{-}\mu\text{m}$ filters to confirm that no clumping has occurred. The ASTM procedure is illustrated in Figure 7.5 [2]. Factors affecting this test are discussed in detail by Meltzer [3].

Figure 7.5 Apparatus for testing the microbial retention characteristics of membrane filters. The whole apparatus is sterilized, and initially the flask contains 140 mL of double-strength culture medium. The culture to be tested (100 mL) is passed through the filter with clamp 1 open and clamp 2 closed. The sides of the filter apparatus are washed with two 20 mL portions of sterile broth. Clamp 2 is then opened, the vacuum released, and clamp 1 closed. The filter apparatus is replaced by a sterile rubber stopper and the flask incubated. Absence of turbidity in the flask indicates that the filter has retained the test organism. From Brock [4]. Courtesy of Thomas D. Brock

The performance of membranes in bacterial challenge tests is often quantified by a log reduction value (LRV), defined as

$$LRV = \log_{10} \left(\frac{c_f}{c_p} \right) \quad (7.1)$$

where c_f is the concentration of bacteria in the challenge solution and c_p is the concentration in the permeate. It follows that at 99 % rejection, c_f/c_p is 100 and the LRV is 2; at 99.9 % rejection, the LRV is 3; and so on. In pharmaceutical and electronic applications, an LRV of 7 or 8 is usually required. In municipal water filtration, an LRV of 4 or 5 is the target.

Latex Challenge Tests

Bacterial challenge tests require careful, sterile laboratory techniques and an incubation period of several days before the results are available. For this reason, secondary tests based on filtration of suspensions of latex particles of precise diameters have been developed. In such a test, a monodisperse latex suspension with particle diameters from 0.1 to 10 μm is used. The test solution is filtered through the membrane, and the number of particles permeating the membrane is determined by filtering the permeate solution a second time with a tight membrane screen filter. The membrane screen filter captures the latex particles for easy counting. Although the latex challenge test has been used in fundamental studies of microfiltration membrane properties, it is not widely used by membrane producers. The bubble point test described below, backed by correlating the bubble point to the primary bacterial challenge test results, is more commonly used.

Bubble Point Test

The bubble point test is simple, quick and reliable and is by far the most widely used method of characterizing microfiltration membranes. The membrane is first wetted with a suitable liquid, usually water for hydrophilic membranes and methanol for hydrophobic membranes. The membrane is then placed in a holder with a layer of liquid on the top surface. Air is fed to the bottom of the membrane, and the pressure is slowly increased until the first continuous string of air bubbles at the membrane surface is observed. This pressure is called the *bubble point pressure* and is a characteristic measure of the diameter of the largest pore in the membrane. Obtaining reliable and consistent results with the bubble point test requires care. It is essential, for example, that the membrane be completely wetted with the test liquid; this may be difficult to determine. Because this test is so widely used by microfiltration membrane manufacturers, a great deal of work has been devoted to developing a reliable test procedure to address this and other issues. The use of this test is reviewed in Meltzer's book [3].

The bubble point pressure can be related to the membrane pore diameter, r , by the equation

$$\Delta p = \frac{2\gamma \cos \theta}{r} \quad (7.2)$$

where Δp is the bubble point pressure, γ is the fluid surface tension, and θ is the liquid–solid contact angle. For completely wetting solutions, θ is 0° so $\cos \theta$ equals 1. Properties of liquids commonly used in bubble point measurements are given in Table 7.1.

Microfiltration membranes are heterogeneous structures having a distribution of pore sizes. The effect of the applied gas pressure on the liquid in a bubble test is illustrated schematically in Figure 7.6. At pressures well below the bubble point, all pores are completely filled with liquid so gas can only pass through the membrane by diffusion through the liquid film. Just below the bubble point pressure, liquid begins to be forced out of the largest membrane pores. The diffusion rate then starts to increase until the liquid is completely forced out of the largest pore. Bubbles of gas then form on the membrane surface. As the gas pressure is increased further, liquid is forced out of more pores, and general convective flow of gas through the membrane takes place. This is sometimes called the ‘foam all over pressure’ and is a measure of the average pore size of the membrane.

The apparatus used to measure membrane bubble points is shown in its simplest form in Figure 7.7 [4]. Bubble point measurements are subjective, and different operators can obtain different results. Nonetheless the test is quick and simple and is widely used as a manufacturing quality control technique. Bubble point measurements are also used to measure the integrity of filters used in critical pharmaceutical or biological operations.

Bubble point measurements are most useful to characterize sheet stock or small membrane filters. The technique is more difficult to apply to formed membrane cartridges containing several square feet of membrane because diffusive flow of

Table 7.1 Properties of liquids commonly used in bubble point measurements. The conversion factor divided by the bubble pressure (in psi) gives the maximum pore size (in μm)

Figure 7.7 Bubble point measurements; (a) exploded view of filter holder; (b) test apparatus; and (c) typical bubble patterns produced. From Brock [4]. Courtesy of Thomas D. Brock

gas through the liquid film masks the bubble point. To test cartridges, the applied pressure is set at a few psi below the bubble point, typically at 80 % of the bubble point pressure. The diffusive flow of gas through the wetted cartridge filter is then measured [5]. This provides a good integrity test of large-area cartridge filters because even a small membrane defect increases gas flow significantly above the norm for defect-free cartridges.

Although bubble point measurements can be used to determine the pore diameter of membranes using Equation (7.1), the results must be treated with caution. Based on Equation (7.1), a 0.22- μm pore diameter membrane should have a bubble point of about 200 psig. In fact, based on the bacterial challenge test, a 0.22- μm pore diameter membrane has a bubble point pressure of 40–60 psig, depending on the membrane. That is, the bubble point test indicates that the membranes has a pore diameter of about 1 μm .

Figure 7.8 shows typical results comparing microbial challenge tests using 0.22- μm *P. diminuta* with membrane bubble points for a series of related membranes [6]. In these tests at a microbial reduction factor of 10^8 – 10^9 , the membrane has a bubble point pressure of only 40 psig, far below the theoretical

Figure 7.8 Correlation of *P. diminuta* microbial challenge and bubble point test data for a series of related membranes [6]. Reprinted from T.J. Leahy and M.J. Sullivan, Validation of Bacterial Retention Capabilities of Membrane Filters, *Pharm. Technol.* 2, 65 (1978) with permission from Pharmaceutical Technology, Eugene, OR

value of 200 psig for a 0.22- μm pore diameter membrane. Such discrepancies are sometimes handled by a correction factor in Equation (7.1) to account for the shape of the membrane pores, but no reasonable shape factor can account for the four-fold discrepancy seen here. There are two possible reasons why the bubble point test overestimates the minimum pore size of the membrane. First, the test is a measure of the pore size of the membrane. However, a one-to-one relationship between the diameter of the bacteria able to penetrate the membrane and the pore diameter assumes that the only method of bacterial capture is direct filtration of the test organism somewhere in the membrane. If no organisms penetrate the membrane even at a high concentration, the conclusion is that no pores larger than the organism's diameter exist. However, this ignores other capture mechanisms, such as adsorption and electrostatic attraction, that can remove the organism even though the pore diameter is larger than the particle. As a result, although a small fraction of the membrane pores may be larger than 0.22 μm , leading to a low bubble point pressure, bacteria still cannot travel through these pores in a normal challenge test.

A second explanation, proposed by Williams and Meltzer [7], is illustrated in Figure 7.9. In liquid flow, all flow through the membrane is from the high-pressure (top) to the low-pressure (bottom) side of the membrane. In a bubble point test the membrane is filled with liquid, and gas is used to displace liquid from the large pores. The bubble point is reached when the first contiguous series of large pores through the membrane is formed. This path can be long and tortuous and may not follow the path taken by liquid flow.

(a) Liquid flow in a microbial challenge test

(b) Gas flow at the bubble point of a wet membrane

Figure 7.9 An illustration of the model of Williams and Meltzer [7] to explain the discrepancy between membrane pore diameter measurements based on the microbial challenge test and the bubble point test. Technol.* 7 (5), 36 (1983) with permission from Pharmaceutical Technology, Eugene, OR

Microfiltration Membranes and Modules

The first major application of microfiltration membranes was for biological testing of water. This remains an important laboratory application in microbiology and biotechnology. For these applications the early cellulose acetate/cellulose nitrate phase separation membranes made by vapor-phase precipitation with water are still widely used. In the early 1960s and 1970s, a number of other membrane materials with improved mechanical properties and chemical stability were developed. These include polyacrylonitrile–poly(vinyl chloride) copolymers, poly(vinylidene fluoride), polysulfone, cellulose triacetate, and various nylons. Most cartridge filters use these membranes. More recently poly(tetrafluoroethylene) membranes have come into use.

In the early 1960s and 1970s, the in-line plate-and-frame module was the only available microfiltration module. These units contained between 1 and 20 separate membrane envelopes sealed by gaskets. In most operations all the membrane envelopes were changed after each use; the labor involved in disassembly and reassembly of the module was a significant drawback. Nonetheless these systems are still widely used to process small volumes of solution. A typical plate-and-frame filtration system is shown in Figure 7.10.

Figure 7.10 Sterile filtration of a small-volume pharmaceutical solution with a 142 mm plate-and-frame filter used as a prefilter in front of a small disposable cartridge final filter. From Gelman Science

More recently, a variety of cartridges that allow a much larger area of membrane to be incorporated into a disposable unit have become available. Disposable plate-and-frame cartridges have been produced, but by far the largest portion of the market is for pleated cartridges, first introduced in the early 1970s. A disposable cartridge filter of this type is shown in Figure 7.11. A typical cartridge is 10 in. long, has a diameter of 2–2.5 in., and contains about 3 ft² of membrane. Often the membrane consists of several layers: an outer prefilter facing the solution to be filtered, followed by a finer polishing membrane filter.

In these units, the membrane is pleated and then folded around the permeate core. The cartridge fits inside a specially designed housing into which the feed solution enters at a pressure of 10–120 psi. Pleated membrane cartridges, which are fabricated with high-speed automated equipment, are cheap, disposable, reliable, and hard to beat if the solution to be filtered has a relatively low particle level. Ideal applications are production of aseptic solutions in the pharmaceutical industry or ultrapure water for wafer manufacture in the electronics industry. The low particle load of these feed solutions allows small in-line cartridges to filter large volumes of solution before needing replacement. Manufacturers produce cartridge holders that allow a number of cartridges to be connected in series

Figure 7.11 Cut-away view of a simple pleated cartridge filter. By folding the membrane a large surface area can be contacted with the feed solution producing a high particle loading capacity. (From Membrana product literature)

Figure 7.12 Standard-size disposable cartridges can be connected in series or parallel to handle large flows. This unit consists of nine cartridges arranged in a 3×3 array. (From Sartorius product literature)

or in parallel to handle large solution flows. A multicartridge unit is shown in Figure 7.12.

However, the short lifetime of in-line cartridge filters makes them unsuitable for microfiltration of highly contaminated feed streams. Cross-flow filtration, which overlaps significantly with ultrafiltration technology, described in Chapter 6, is used in such applications. In cross-flow filtration, long filter life is achieved by sweeping the majority of the retained particles from the membrane surface before they enter the membrane. Screen filters are preferred for this application, and an ultrafiltration membrane can be used. The design of such membranes and modules is covered under ultrafiltration (Chapter 6) and will not be repeated here.

Process Design

A typical in-line cartridge filtration application is illustrated in Figure 7.13. A pump forces liquid through the filter, and the pressure across the filter is measured by a pressure gauge. Initially, the pressure difference measured by the gauge is small, but as retained particles block the filter, the pressure difference increases until a predetermined limiting pressure is reached, and the filter is changed.

To extend its life, a microfiltration cartridge may contain two or more membrane filters in series, or as shown in Figure 7.13, a coarse prefilter cartridge

Figure 7.13 Typical in-line filtration operation using two cartridge filters in series. The prefilter removes all of the large particles and some of the smaller ones. The final polishing filter removes the remaining small particles

before the final polishing filter. The prefilter captures the largest particles, allowing smaller particles to pass and be captured by the following finely porous membrane. The use of a prefilter extends the life of the microfiltration cartridge significantly. Without a prefilter the fine microfiltration membrane would be rapidly blinded by accumulation of large particles on the membrane surface. The correct combination of prefilter and final membrane must be determined for each application. This can be done by placing the prefilter on top of the required final filter membrane in a small test cell, or better yet, with two test cells in series. With two test cells the pressure drop across each filter can be measured separately.

The objective of a prefilter is to extend the life of the final filter by removing the larger particles from the feed, allowing the final filter to remove the smaller particles. The results obtained with different prefilters are shown in Figure 7.14 [8]. Figure 7.14(a) shows the rate of pressure rise across the fine filter alone. The limited dirt-holding capacity of this filter means that it is rapidly plugged by a surface layer of large particles. Figure 7.14(b) shows the case when a too coarse prefilter is used. In this case, the pressure difference across the prefilter remains small, whereas the pressure difference across the final filter increases as rapidly as before because of plugging by particles passing the prefilter. Little improvement in performance is obtained. Figure 7.14(c) shows the case where the prefilter is too fine. This situation is the opposite of 7.14(a)—the pressure difference across

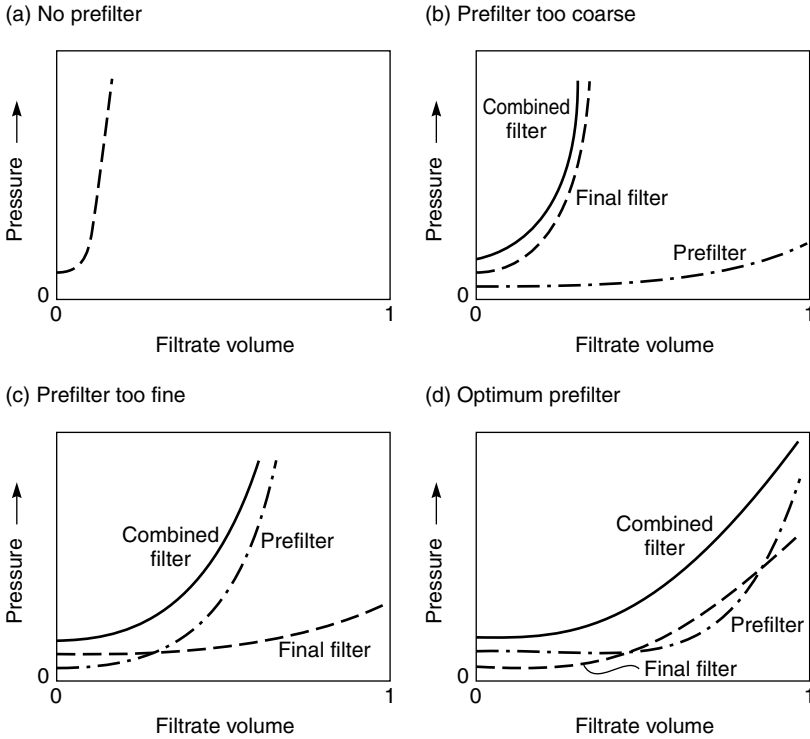

Figure 7.14 The pressure difference across the prefilter, the final filter and the combined filters for various combinations of prefilter and final filter. The optimum prefilter distributes the particle load evenly between the two filters so both filters reach their maximum particle load at the same time. This maximizes the useful life of the combination

the prefilter increases rapidly, and the lifetime of the combination filter is limited by this filter. Figure 7.14(d) shows the optimum combination in which the pressure difference is uniformly distributed across the prefilter and final filter. This condition maximizes the lifetime of the filter combination.

Recently, some membrane manufacturers have attempted to produce anisotropic microfiltration membranes in which the open microporous support is a built-in prefilter. Unlike most other applications of anisotropic membranes, these membranes are oriented with the coarse, relatively open pores facing the feed solution, and the most finely microporous layer is at the bottom of the membrane. The goal is to increase filter life by distributing the particle load more evenly across the filter than would be the case with an isotropic porous membrane.

Cartridge microfiltration is a stable area of membrane technology—few changes in cartridge design or use have occurred in the past 20 years. Most changes have focused on improving resistance to higher temperatures, solvents

and extremes of pH, to allow application of these filters in more challenging environments.

Recent innovation in microfiltration has mainly concerned the development of cross-flow filtration technology and membranes. The design of these processing systems closely follows that of ultrafiltration described in Chapter 6. In cross-flow filtration, the membrane must retain particles at the membrane surface; therefore, only asymmetric membranes or screen filters with their smallest pores facing the feed solutions can be used. Ceramic filters of the type made by Membralox (now part of US Filter) and others are being used increasingly in this type of application. A ceramic microfiltration cross-flow filter is shown in Figure 7.15. Capillary hollow fiber membrane modules similar to those originally developed for ultrafiltration applications are also now being widely used for cross-flow microfiltration applications.

The key innovation that has led to the increased use of cross-flow microfiltration membrane modules in the last few years has been the development of back-pulsing or backflushing to control membrane fouling [9–11]. In this procedure, the water flux through the membrane is reversed to remove any particulate and fouling material that may have formed on the membrane surface. In microfiltration several types of backflushing can be used. Short, relatively frequent flow reversal lasting a few seconds and applied once every few minutes is called

Figure 7.15 Monolithic ceramic microfilter. The feed solution passes down the bores of the channels formed in a porous ceramic block. The channel walls are coated with a finely porous ceramic layer

back-pulsing. Longer flow reversal, lasting 1 or 2 min and applied once every 1 or 2 h, is called backflushing. The balance between the duration of back pulses and their frequency depends on the particular application.

Direct observations illustrating the efficiency of back-pulsing have been made by Mores and Davis [9] using a transparent test cell and cellulose acetate microfiltration membranes fouled with yeast cells. Figure 7.16(a) shows a photograph of the membrane surface after 2 h of operation with a yeast solution. The membrane surface is completely covered with yeast cells. Figure 7.16(b–d) shows the effect of back-pulsing for different times. Back-pulsing for 0.1 s removes about half the yeast, back-pulsing for 1 s removes about 90%, and back-pulsing for 180 s removes all but a few yeast cells.

Microfiltration cross-flow systems are often operated at a constant applied transmembrane pressure in the same way as the reverse osmosis and ultrafiltration systems described in Chapters 5 and 6. However, microfiltration membranes tend to foul and lose flux much more quickly than ultrafiltration and reverse osmosis membranes. The rapid decline in flux makes it difficult to control system operation. For this reason, microfiltration systems are often operated as constant flux systems, and the transmembrane pressure across the membrane is slowly increased to maintain the flow as the membrane fouls. Most commonly the feed pressure is fixed at some high value and the permeate pressure

Figure 7.16 An illustration of the efficiency of back-pulsing in removing fouling materials from the surface of microfiltration membranes. Direct microscopic observations of Mores and Davis [9] of cellulose acetate membranes fouled with a 0.1 wt% yeast suspension. The membrane was backflushed with permeate solution at 3 psi for various times. Reprinted from *J. Membr. Sci.* **189**, W.D. Mores and R.H. Davis, Direct Visual Observation of Yeast Deposition and Removal During Microfiltration, p. 217, Copyright 2001, with permission from Elsevier

is set at a value just below the feed pressure. As the membrane is used, its permeability slowly decreases because of fouling. This decrease in permeability is compensated for by lowering the permeate pressure and so increasing the pressure driving force. When the permeate pressure reaches some predetermined value, the module is taken off-line and cleaned or backflushed to restore its permeability.

Some results illustrating the operation of microfiltration membranes using the constant-flux procedure are illustrated in Figure 7.17 [12]. The target flux of the module was set by choosing the initial pressure difference across the membrane. As the membrane fouled, the pressure difference increased until it reached the limiting pressure difference of 6–9 psi. In the example shown, modules set to produce a flux of $50 \text{ L/m}^2 \cdot \text{h}$ were completely fouled within 20 h. Reducing the flux to $40 \text{ L/m}^2 \cdot \text{h}$ increased the useful lifetime of the membrane three-fold; reducing the flux to $30 \text{ L/m}^2 \cdot \text{h}$ achieved a very long lifetime. Just as in ultrafiltration, the membranes perform best when operated at conditions where membrane fouling is controlled by the flow of liquid across the surface. Operating at high flux or high transmembrane pressure leads to deposition of a thick compacted fouling layer.

The advantages and disadvantages of in-line microfiltration and cross-flow filtration are compared in Table 7.2. In general, in-line filtration is preferred as a polishing operation for already clean solutions, for example, to sterilize water

Figure 7.17 Experiments showing the rate of fouling of $0.22\text{-}\mu\text{m}$ microfiltration membranes used to treat dilute biomass solutions. The membranes were operated at the fluxes shown, by increasing transmembrane pressure over time to maintain this flux as the membranes fouled [12]. Reprinted from *J. Membr. Sci.* **209**, B.D. Cho and A.G. Fane, Fouling Transients in Nominally Sub-critical Flux Operation of a Membrane Bioreactor, p. 391, Copyright 2002, with permission from Elsevier

Table 7.2 Comparison of advantages and disadvantages of in-line and cross-flow microfiltration

In-line microfiltration	Cross-flow microfiltration
Low capital cost	High capital cost
High operating costs—membrane must be replaced after each use and disposal can be a problem	Operating costs modest—membranes have extended lifetimes if regularly cleaned
Operation is simple—no moving parts	Operation is complex—filters require regular cleaning
Best suited to dilute (low solid content) solutions. Membrane replacement costs increase with particle concentrations in the feed solution	Best suited to high solid content solutions. Costs are relatively independent of feed solution particle concentrations
Representative applications: Sterile filtration Clarification/sterilization of beer and wine	Representative applications: Continuous culture/cell recycle Filtration of oilfield produced water

in the pharmaceutical and electronics industries. Cross-flow filtration is more expensive than in-line filtration in this type of application but, if the water has a high particle content, cross-flow filtration is preferred.

Applications

The microfiltration market differs significantly from that of other membrane separation processes in that membrane lifetimes are often measured in hours. In a few completely passive applications, such as treating sterile air vents, membranes may last several months; in general the market is dominated by single-use cartridges designed to filter a relatively small mass of particles from a solution. The volume of solution that can be treated by a microfiltration membrane is directly proportional to the particle level in the water. As a rough rule of thumb, the particle-holding capacity of a cartridge filter in a noncritical use is between 100 and 300 g/m² of membrane area. Thus, the volume of fluid that can be treated may be quite large if the microfilter is a final safety filter for an electronics plant ultrapure water system, but much smaller if treating contaminated surface water or a food processing stream. The approximate volume of various solutions that can be filtered by a 5- μ m filter before the filter is completely plugged is given in Table 7.3 [13].

Despite the limited volumes that can be treated before a filter must be replaced, microfiltration is economical because the cost of disposable cartridges is low. Currently, a 10-in.-long pleated cartridge costs between US\$10 and US\$20 and contains 0.3–0.5 m² of active membrane area. The low cost reflects the large numbers that are produced.

Table 7.3 Approximate volume of fluid that can be filtered by 1 m² of a 5- μ m membrane before fouling [13]

Solution	Volume filtered (m ³ /m ²)
Water from deep wells	1000
Solvents	500
Tap water	200
Wine	50
Pharmaceuticals for ampoules	50
20 % glucose solution	20
Vitamin solutions	10
Parenterals	10
Peanut oil	5
Fruit juice concentrate	2
Serum (7 % protein)	0.6

The primary market for the disposable cartridge is sterile filtration for the pharmaceutical industry and final point-of-use polishing of ultrapure water for the microelectronics industry. Both industries require very high-quality, particle-free water. The cost of microfiltration compared to the value of the products is small so these markets have driven the microfiltration industry for the past 15 years.

Sterile Filtration of Pharmaceuticals

Microfiltration is used widely in the pharmaceutical industry to produce injectable drug solutions. Regulating agencies require rigid adherence to standard preparation procedures to ensure a consistent, safe, sterile product. Microfiltration removes particles but, more importantly, all viable bacteria, so a 0.22- μ m-rated filter is usually used. Because the cost of validating membrane suppliers is substantial, users usually develop long-term relationships with individual suppliers.

A microfilter for this industry is considered sterile if it achieves a log reduction factor of better than 7. This means that if 10⁷ bacteria/cm² are placed on the filter, none appears in the filtrate. A direct relationship exists between the log reduction factor and the bubble point of a membrane.

Microfiltration cartridges produced for this market are often sterilized directly after manufacture and again just prior to use. Live steam, autoclaving at 120 °C, or ethylene oxide sterilization may be used, depending on the applications. A flow schematic of an ampoule-filling station (after material by Schleicher and Schuell) is shown in Figure 7.18.

In this process, feedwater is first treated by a deionization system consisting of reverse osmosis, followed by mixed bed ion exchange, and a final 5- μ m filtration step. The requirements of water for injection are a good deal less stringent

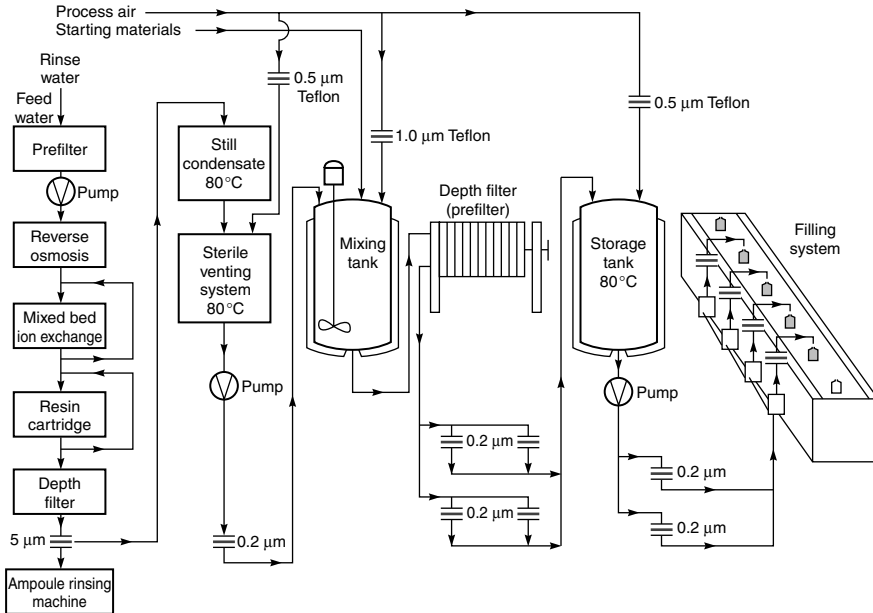

Figure 7.18 Flow diagram illustrating the use of microfiltration sterilization filters in a production line used to prepare ampoules of injectable drug solutions

than the requirements of ultrapure water for the electronics industry, so the water treatment system is relatively straightforward. The water is first sterilized with a 0.2- μm final filter before being mixed with the drug solution, then sent to a storage tank for the ampoule-filling station. Before use, the solution is filtered at least twice more with 0.2- μm filters to ensure sterility. Because pharmaceuticals are produced by a batch process, all filters are replaced at the end of each batch.

Sterilization of Wine and Beer

Cold sterilization of beer using microfiltration was introduced on a commercial scale in 1963. The process was not generally accepted at that time, but has recently become more common. Sterilization of beer and wine is much less stringent than pharmaceutical sterilization. The main objective is to remove yeast cells, which are quite large, so the product is clear and bright. Bacterial removal is also desirable; a 10^6 reduction in bacteria is equivalent to the best depth filters. The industry has found that 1- μm filters can remove essentially all the yeast as well as provide a 10^6 reduction in the common bacteria found in beer and wine. Because the cost structure of beer and wine production is very different from that

of pharmaceuticals, the filtration system typically involves one or more prefilters to extend the life of the final polishing filter.

Microfiltration in the Electronics Industry

Microfilters are used in the electronics industry, principally as final point-of-use filters for ultrapure water. The water is already very pure and almost completely particle- and salt-free, so the only potential problem is contamination in the piping from the central water treatment plant to the device fabrication area. Although fine filters with $0.1\ \mu\text{m}$ pore diameter or less may be used, lifetimes are relatively long.

The electronics industry also uses a variety of reactive gases and solvents which must be particle free. Teflon[®] microfilters are widely used to treat these materials.

Microfiltration for Drinking Water Treatment

Beginning in about 1990, the first microfiltration/ultrafiltration plants were installed to treat municipal surface water supplies [14,15]. The driver was implementation of an EPA surface water treatment rule requiring all utilities in the United

Figure 7.19 Photograph of a 25 million gal/day capillary hollow fiber module plant to produce potable water from a well, installed by Norit (X-Flow) in Keldgate, UK. Courtesy of Norit Membrane Technology BV

States to provide an LRV of 3 for *giardia* and an LRV of 4 for viruses. European regulators have adopted similar rules.

The plants installed have all been equipped with hollow fiber membrane modules. The feed water is generally fairly clean, so the modules are operated in a dead-end mode for 10–20 min and then backflushed with air or filtered water for 20–30 s. During backflushing, the modules are swept with water to remove the accumulated solids, after which the cycle is repeated. It is estimated that 40 000 water works in the United States are affected by the EPA ruling, so the potential market is very large. Many of these water works are small, but several large plants equipped with hundreds of modules have also been installed. A photograph of one such plant is shown in Figure 7.19. Similar plants are also being considered to prefilter and sterilize feed water for reverse osmosis desalination plants or for tertiary treatment and ultimate reuse of water from sewage treatment plants.

Conclusions and Future Directions

The main microfiltration market is for in-line disposable cartridge filters. These cartridges are sold into two growing modern industries—microelectronics and pharmaceuticals—so prospects for continued market growth of the industry are very good. In addition to these existing markets, significant potential markets exist for microfiltration in bacterial control of drinking water, tertiary treatment of sewage, and replacement of diatomaceous earth depth filters in the chemical processing and food industries. The particle load of all these waters is far higher than that presently treated by microfiltration and has required development of cross-flow filtration systems able to give filter lifetimes of months or even years. Such systems are now being installed in municipal water treatment plants. The units can be cleaned by backflushing and offer reliable performance. Municipal water treatment is likely to develop into a major future application of microfiltration technology.

8 GAS SEPARATION

Introduction and History

Gas separation has become a major industrial application of membrane technology only during the past 20 years, but the study of gas separation has a long history. Systematic studies began with Thomas Graham who, over a period of 20 years, measured the permeation rates of all the gases then known through every diaphragm available to him [1]. This was no small task because his experiments had to start with synthesis of the gas. Graham gave the first description of the solution-diffusion model, and his work on porous membranes led to Graham's law of diffusion. Through the remainder of the nineteenth and the early twentieth centuries, the ability of gases to permeate membranes selectively had no industrial or commercial use. The concept of the perfectly selective membrane was, however, used as a theoretical tool to develop physical and chemical theories, such as Maxwell's kinetic theory of gases.

From 1943 to 1945, Graham's law of diffusion was exploited for the first time, to separate $U^{235}F_6$ from $U^{238}F_6$ as part of the Manhattan project. Finely microporous metal membranes were used. The separation plant, constructed in Knoxville, Tennessee, represented the first large-scale use of gas separation membranes and remained the world's largest membrane separation plant for the next 40 years. However, this application was unique and so secret that it had essentially no impact on the long-term development of gas separation.

In the 1940s to 1950s, Barrer [2], van Amerongen [3], Stern [4], Meares [5] and others laid the foundation of the modern theories of gas permeation. The solution-diffusion model of gas permeation developed then is still the accepted model for gas transport through membranes. However, despite the availability of interesting polymer materials, membrane fabrication technology was not sufficiently advanced at that time to make useful gas separation membrane systems from these polymers.

The development of high-flux anisotropic membranes and large-surface-area membrane modules for reverse osmosis applications in the late 1960s and early 1970s provided the basis for modern membrane gas separation technology. The first company to establish a commercial presence was Monsanto, which

launched its hydrogen-separating Prism[®] membrane in 1980 [6]. Monsanto had the advantage of being a large chemical company with ample opportunities to test pilot- and demonstration-scale systems in its own plants before launching the product. The economics were compelling, especially for the separation of hydrogen from ammonia-plant purge-gas streams. Within a few years, Prism systems were installed in many such plants [7].

Monsanto's success encouraged other companies to advance their own membrane technologies. By the mid-1980s, Cynara, Separex and Grace Membrane Systems were producing membrane plants to remove carbon dioxide from methane in natural gas. This application, although hindered by low natural gas prices in the 1990s, has grown significantly over the years. At about the same time, Dow launched Generon[®], the first commercial membrane system for nitrogen separation from air. Initially, membrane-produced nitrogen was cost-competitive in only a few niche areas, but the development by Dow, Ube and Du Pont/Air Liquide of materials with improved selectivities has since made membrane separation much more competitive. This application of membranes has expanded very rapidly and is expected to capture more than one-half of the market for nitrogen separation systems within the next few years. To date, approximately 10 000 nitrogen systems

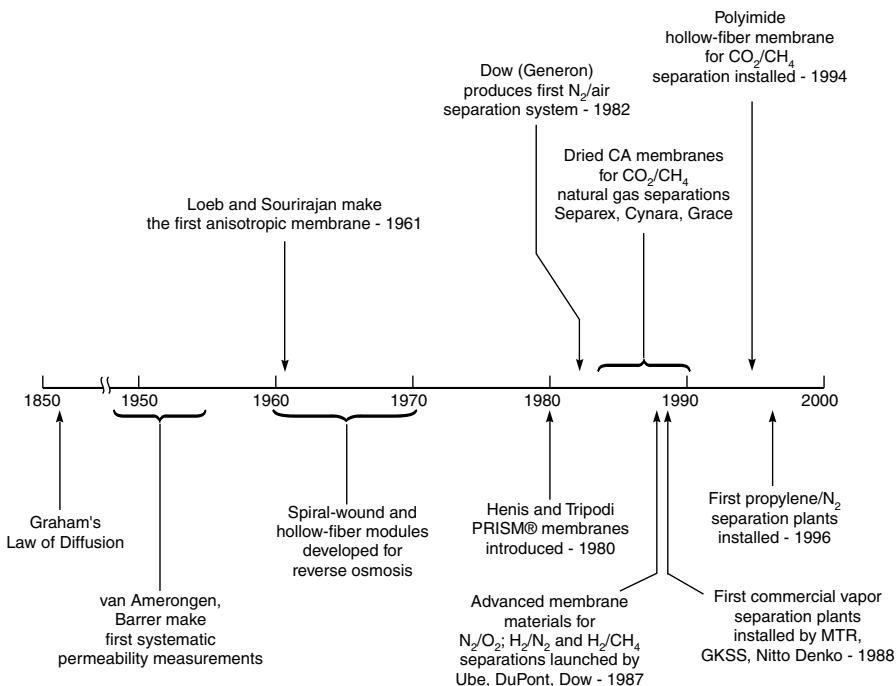

Figure 8.1 Milestones in the development of gas separation

have been installed worldwide. Gas separation membranes are also being used for a wide variety of other, smaller applications ranging from dehydration of air and natural gas to organic vapor removal from air and nitrogen streams. Application of the technology is expanding rapidly and further growth is likely to continue for the next 10 years or so. Figure 8.1 provides a summary of the development of gas separation technology.

Theoretical Background

Both porous and dense membranes can be used as selective gas separation barriers; Figure 8.2 illustrates the mechanism of gas permeation. Three types of porous membranes, differing in pore size, are shown. If the pores are relatively large—from 0.1 to 10 μm —gases permeate the membrane by convective flow, and no separation occurs. If the pores are smaller than 0.1 μm , then the pore diameter is the same size as or smaller than the mean free path of the gas molecules. Diffusion through such pores is governed by Knudsen diffusion, and the transport rate of any gas is inversely proportional to the square root of its molecular weight. This relationship is called Graham's law of diffusion. Finally, if the membrane pores are extremely small, of the order 5–20 \AA , then gases are separated by molecular sieving. Transport through this type of membrane is complex and includes both diffusion in the gas phase and diffusion of adsorbed species on the surface of the pores (surface diffusion). These very small-pore membranes have not been used on a large scale, but ceramic and ultramicroporous

Figure 8.2 Mechanisms for permeation of gases through porous and dense gas separation membranes

glass membranes with extraordinarily high selectivities for similar molecules have been prepared in the laboratory.

Although these microporous membranes are topics of considerable research interest, all current commercial gas separations are based on the dense polymer membrane shown in Figure 8.2. Separation through dense polymer films occurs by a solution-diffusion mechanism.

In Chapter 2 [Equation (2.59)], it was shown that gas transport through dense polymer membranes is governed by the expression

$$J_i = \frac{D_i K_i^G (p_{i_o} - p_{i_t})}{\ell} \quad (8.1)$$

where J_i is the flux of component i ($\text{g}/\text{cm}^2 \cdot \text{s}$), p_{i_o} and p_{i_t} are the partial pressure of the component i on either side of the membrane, ℓ is the membrane thickness, D_i is the permeate diffusion coefficient, and K_i^G is the Henry's law sorption coefficient ($\text{g}/\text{cm}^3 \cdot \text{pressure}$). In gas permeation it is much easier to measure the volume flux through the membrane than the mass flux and so Equation (8.1) is usually recast as

$$j_i = \frac{D_i K_i (p_{i_o} - p_{i_t})}{\ell} \quad (8.2)$$

where j_i is the volume (molar) flux expressed as $[\text{cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s}]$ of component i and K_i is a sorption coefficient with units $[\text{cm}^3(\text{STP})/\text{cm}^3 \text{ of polymer} \cdot \text{pressure}]$. The product $D_i K_i$ can be written as \mathcal{P}_i , which is called the membrane permeability, and is a measure of the membrane's ability to permeate gas.¹ A measure of the ability of a membrane to separate two gases, i and j , is the ratio of their permeabilities, α_{ij} , called the membrane selectivity

$$\alpha_{ij} = \frac{\mathcal{P}_i}{\mathcal{P}_j} \quad (8.3)$$

The relationship between polymer structure and membrane permeation was discussed in detail in Chapter 2 and is revisited only briefly here. Permeability can be expressed as the product $D_i K_i$ of two terms. The diffusion coefficient, D_i , reflects the mobility of the individual molecules in the membrane material; the gas sorption coefficient, K_i , reflects the number of molecules dissolved in the membrane material. Thus, Equation (8.3) can also be written as

$$\alpha_{ij} = \left[\frac{D_i}{D_j} \right] \left[\frac{K_i}{K_j} \right] \quad (8.4)$$

¹The permeability of gases through membranes is most commonly measured in Barrer, defined as $10^{-10} \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$ and named after R.M. Barrer, a pioneer in gas permeability measurements. The term $j_i/(p_{i_o} - p_{i_t})$, best called the pressure-normalized flux or permeance, is often measured in terms of gas permeation units (gpu), where 1 gpu is defined as $10^{-6} \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$. Occasional academic purists insist on writing permeability in terms of $\text{mol} \cdot \text{m}/\text{m}^2 \cdot \text{s} \cdot \text{Pa}$ (1 Barrer = $0.33 \times 10^{-15} \text{ mol} \cdot \text{m}/\text{m}^2 \cdot \text{s} \cdot \text{Pa}$), but fortunately this has not caught on.

The ratio D_i/D_j is the ratio of the diffusion coefficients of the two gases and can be viewed as the mobility selectivity, reflecting the different sizes of the two molecules. The ratio K_i/K_j is the ratio of the sorption coefficients of the two gases and can be viewed as the sorption or solubility selectivity, reflecting the relative condensabilities of the two gases. In all polymer materials, the diffusion coefficient decreases with increasing molecular size, because large molecules interact with more segments of the polymer chain than do small molecules. Hence, the mobility selectivity always favors the passage of small molecules over large

Figure 8.3 Diffusion coefficient as a function of molar volume for a variety of permeants in natural rubber and in poly(vinyl chloride), a glassy polymer. This type of plot was first drawn by Gruen [8], and has been used by many others since

ones. However, the magnitude of the mobility selectivity term depends greatly on whether the membrane material is above or below its glass transition temperature (T_g). If the material is below the glass transition temperature, the polymer chains are essentially fixed and do not rotate. The material is then called a glassy polymer and is tough and rigid. Above the glass transition temperature, the segments of the polymer chains have sufficient thermal energy to allow limited rotation around the chain backbone. This motion changes the mechanical properties of the polymer dramatically, and it becomes a rubber. The relative mobility of gases, as characterized by their diffusion coefficients, differs significantly in rubbers and glasses, as illustrated in Figure 8.3 [8]. Diffusion coefficients in glassy materials decrease much more rapidly with increasing permeate size than diffusion coefficients in rubbers. For example, the mobility selectivity of natural rubber for nitrogen over pentane is approximately 10. The mobility selectivity of poly(vinyl chloride), a rigid, glassy polymer, for nitrogen over pentane is more than 100 000.

The second factor affecting the overall membrane selectivity is the sorption or solubility selectivity. The sorption coefficient of gases and vapors, which is a measure of the energy required for the permeant to be sorbed by the polymer, increases with increasing condensability of the permeant. This dependence on condensability means that the sorption coefficient also increases with molecular diameter, because large molecules are normally more condensable than smaller ones. The gas sorption coefficient can, therefore, be plotted against boiling point or molar volume as shown in Figure 8.4 [9]. As the figure shows, sorption selectivity favors larger, more condensable molecules, such as hydrocarbon vapors, over permanent gases, such as oxygen and nitrogen. However, the difference between the sorption coefficients of permeants in rubbery and glassy polymers is far less marked than the difference in the diffusion coefficients.

It follows from the discussion above that the balance between the mobility selectivity term and the sorption selectivity term in Equation (8.4) [10] is different for glassy and rubbery polymers. This difference is illustrated by the data in Figure 8.5. In glassy polymers, the mobility term is usually dominant, permeability falls with increasing permeate size, and small molecules permeate preferentially. Therefore, when used to separate organic vapors from nitrogen, glassy membranes preferentially permeate nitrogen. In rubbery polymers, the sorption selectivity term is usually dominant, permeability increases with increasing permeate size, and larger molecules permeate preferentially. Therefore, when used to separate organic vapor from nitrogen, rubbery membranes preferentially permeate the organic vapor. The separation properties of polymer membranes for a number of the most important gas separation applications have been summarized by Robeson [11]. A review of structure/property relations has been given by Stern [12]. Properties of some representative and widely used membrane materials are summarized in Table 8.1.

Calculating the selectivity of a membrane using Equation (8.3) and using the permeabilities listed in Table 8.1 must be done with caution. Permeabilities in

Figure 8.4 Gas sorption coefficient as a function of molar volume for natural rubber membranes. Larger permeants are more condensable and have higher sorption coefficients [9]

Table 8.1 are measured with pure gases; the selectivity obtained from the ratio of pure gas permeabilities gives the ideal membrane selectivity, an intrinsic property of the membrane material. However, practical gas separation processes are performed with gas mixtures. If the gases in a mixture do not interact strongly with the membrane material, the pure gas intrinsic selectivity and the mixed

Figure 8.5 Permeability as a function of molar volume for a rubbery and a glassy polymer, illustrating the different balance between sorption and diffusion in these polymer types. The natural rubber membrane is highly permeable; permeability increases rapidly with increasing permeant size because sorption dominates. The glassy polyetherimide membrane is much less permeable; the permeability decreases with increasing permeant size because diffusion dominates [10]. Reprinted from R.D. Behling, K. Ohlrogge, K.-V. Peinemann and E. Kyburz, The Separation of Hydrocarbons from Waste Vapor Streams, in *Membrane Separations in Chemical Engineering*, A.E. Fouda, J.D. Hazlett, T. Matsuura and J. Johnson (eds), AIChE Symposium Series Number 272, Vol. 85, p. 68 (1989). Reproduced by permission of the American Institute of Chemical Engineers. Copyright © 1989 AIChE. All rights reserved

gas selectivity will be equal. This is usually the case for mixtures of oxygen and nitrogen, for example. In many other cases, such as a carbon dioxide and methane mixture, one of the components (carbon dioxide) is sufficiently sorbed by the membrane to affect the permeability of the other component (methane). The selectivity measured with a gas mixture may then be one-half or less of the selectivity calculated from pure gas measurements. Pure gas selectivities are much more commonly reported in the literature than gas mixture data because

Table 8.1 Permeabilities {Barrer [$10^{-10} \text{ cm}^3(\text{STP}) \cdot \text{cm}/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$]} measured with pure gases, at the temperatures given, of widely used polymers

they are easier to measure. Neglecting the difference between these two values, however, has led a number of workers to seriously overestimate the ability of a membrane to separate a target gas mixture. Figure 8.6 [13] shows some data for the separation of methane and carbon dioxide with cellulose acetate membranes. The calculated pure gas selectivity is very good, but in gas mixtures enough carbon dioxide dissolves in the membrane to increase the methane permeability far above the pure gas methane permeability value. As a result the selectivities measured with gas mixtures are much lower than those calculated from pure gas data.

Membrane Materials and Structure

Metal Membranes

Although almost all industrial gas separation processes use polymeric membranes, interest in metal membranes continues, mostly for the high-temperature membrane reactor applications discussed in Chapter 13 and for the preparation of pure hydrogen for fuel cells. For completeness, the background to these membranes is described briefly here. The study of gas permeation through metals began with Graham's observation of hydrogen permeation through palladium. Pure palladium absorbs 600 times its volume of hydrogen at room temperature and is measurably permeable to the gas. Hydrogen permeates a number of other metals including tantalum, niobium, vanadium, nickel, iron, copper, cobalt and platinum [14]. In most cases, the metal membrane must be operated at high temperatures (>300 °C) to obtain useful permeation rates and to prevent embrittlement and cracking of

Figure 8.6 The difference between selectivities calculated from pure gas measurements and selectivities measured with gas mixtures can be large. the metal by sorbed hydrogen. Poisoning of the membrane surface by oxidation or sulfur deposition from trace amounts of hydrogen sulfide also occurs. A breakthrough in metal permeation studies occurred in the 1960s when Hunter at Johnson Matthey discovered that palladium/silver alloy membranes showed no hydrogen embrittlement even when used to permeate hydrogen at room temperature [15]. Although most work on gas permeation through membranes has focused on hydrogen, oxygen-permeable metal membranes are also known; however, the permeabilities are low.

Hydrogen-permeable metal membranes are extraordinarily selective, being extremely permeable to hydrogen but essentially impermeable to all other gases. The gas transport mechanism is the key to this high selectivity. Hydrogen permeation through a metal membrane is believed to follow the multistep process illustrated in Figure 8.7 [16]. Hydrogen molecules from the feed gas are sorbed on the membrane surface, where they dissociate into hydrogen atoms. Each individual hydrogen atom loses its electron to the metal lattice and diffuses through the lattice as an ion. Hydrogen atoms emerging at the permeate side of the membrane reassociate to form hydrogen molecules, then desorb, completing the permeation

Figure 8.7 Mechanism of permeation of hydrogen through metal membranes

process. Only hydrogen is transported through the membrane by this mechanism; all other gases are excluded.

If the sorption and dissociation of hydrogen molecules is a rapid process, then the hydrogen atoms on the membrane surface are in equilibrium with the gas phase. The concentration, c , of hydrogen atoms on the metal surface is given by Sievert's law:

$$c = Kp^{1/2} \quad (8.5)$$

where K is Sievert's constant and p is the hydrogen pressure in the gas phase. At high temperatures ($>300\text{ }^\circ\text{C}$), the surface sorption and dissociation processes are fast, and the rate-controlling step is diffusion of atomic hydrogen through the metal lattice. This is supported by the data of Holleck and others, who have observed that the hydrogen flux through the metal membrane is proportional to the difference of the square roots of the hydrogen pressures on either side of the membrane. At lower temperatures, however, the sorption and dissociation of hydrogen on the membrane surface become the rate-controlling steps, and the permeation characteristics of the membrane deviate from Sievert's law predictions.

Palladium-alloy membranes were studied extensively during the 1950s and 1960s, and this work led to the installation by Union Carbide of a full-scale demonstration plant to separate hydrogen from a refinery off-gas stream containing methane, ethane, carbon monoxide and hydrogen sulfide [17]. The plant could produce 99.9% or better pure hydrogen in a single pass through the membrane. The plant operated with 25- μm -thick membranes, at a temperature of $370\text{ }^\circ\text{C}$ and a feed pressure of 450 psi. The high cost of the membranes and

the need to operate at high temperatures to obtain useful fluxes made the process uncompetitive with other hydrogen recovery technologies. In the 1970s and early 1980s, Johnson Matthey built a number of systems to produce on-site hydrogen by separation of hydrogen/carbon dioxide mixtures made by reforming methanol [18]. This was not a commercial success, but the company still produces small systems using palladium–silver alloy membranes to generate ultrapure hydrogen from 99.9% hydrogen for the electronics industry.

Recently, attempts have been made to reduce the cost of palladium metal membranes by preparing composite membranes. In these membranes a thin selective palladium layer is deposited onto a microporous ceramic, polymer or base metal layer [19–21]. The palladium layer is applied by electrolysis coating, vacuum sputtering or chemical vapor deposition. This work is still at the bench scale.

Polymeric Membranes

Most gas separation processes require that the selective membrane layer be extremely thin to achieve economical fluxes. Typical membrane thicknesses are less than 0.5 μm and often less than 0.1 μm . Early gas separation membranes [22] were adapted from the cellulose acetate membranes produced for reverse osmosis by the Loeb–Sourirajan phase separation process. These membranes are produced by precipitation in water; the water must be removed before the membranes can be used to separate gases. However, the capillary forces generated as the liquid evaporates cause collapse of the finely microporous substrate of the cellulose acetate membrane, destroying its usefulness. This problem has been overcome by a solvent exchange process in which the water is first exchanged for an alcohol, then for hexane. The surface tension forces generated as liquid hexane is evaporated are much reduced, and a dry membrane is produced. Membranes produced by this method have been widely used by Grace (now GMS, a division of Kvaerner) and Separex (now a division of UOP) to separate carbon dioxide from methane in natural gas.

Experience has shown that gas separation membranes are far more sensitive to minor defects, such as pinholes in the selective membrane layer, than membranes used in reverse osmosis or ultrafiltration. Even a single small membrane defect can dramatically decrease the selectivity of gas separation membranes, especially with relatively selective membranes such as those used to separate hydrogen from nitrogen. For example, a good polymeric hydrogen/nitrogen separating membrane has a selectivity of more than 100. A small defect that allows as little as 1% of the permeating gas to pass unseparated doubles the nitrogen flux and halves the membrane selectivity. The sensitivity of gas separation membranes to defects posed a serious problem to early developers. Generation of a few defects is very difficult to avoid during membrane preparation and module formation.

From 1978 to 1980, Henis and Tripodi [6,23], then at Monsanto, devised an ingenious solution to the membrane defect problem; their approach is illustrated in Figure 8.8. The Monsanto group made Loeb–Sourirajan hollow fiber membranes

Figure 8.8 The technique devised by Henis and Tripodi [23] to seal defects in their selective polysulfone Loeb–Sourirajan membrane

(principally from polysulfone), then coated the membranes with a thin layer of silicone rubber. Silicone rubber is extremely permeable compared to polysulfone but has a much lower selectivity; thus, the silicone rubber coating did not significantly change the selectivity or flux through the defect-free portions of the polysulfone membrane. However, the coating plugged membrane defects in the polysulfone membrane and eliminated convective flow through these defects. The silicone rubber layer also protected the membrane during handling. The development of silicone rubber-coated anisotropic membranes was a critical step in the production by Monsanto of the first successful gas separation membrane for hydrogen/nitrogen separations.

Another type of gas separation membrane is the multilayer composite structure shown in Figure 8.9. In this membrane, a finely microporous support membrane is overcoated with a thin layer of the selective polymer, which is a different material from the support. Additional layers of very permeable materials such as silicone rubber may also be applied to protect the selective layer and to seal any defects. In general it has been difficult to make composite membranes with

Figure 8.9 Two-layer composite membrane formed by coating a thin layer of a selective polymer on a microporous support that provides mechanical strength

glassy selective layers as thin and high-flux as good-quality Loeb–Sourirajan membranes. However, composites are the best way to form membranes from rubbery selective materials; the microporous support layer can be a tough glassy material to provide strength. Rubbery composite membranes of this type can withstand pressure differentials of 1500 psi or more.

Ceramic and Zeolite Membranes

During the last few years, ceramic- and zeolite-based membranes have begun to be used for a few commercial separations. These membranes are all multilayer composite structures formed by coating a thin selective ceramic or zeolite layer onto a microporous ceramic support. Ceramic membranes are prepared by the sol–gel technique described in Chapter 3; zeolite membranes are prepared by direct crystallization, in which the thin zeolite layer is crystallized at high pressure and temperature directly onto the microporous support [24,25].

Both Mitsui [26] and Sulzer [27] have commercialized these membranes for dehydration of alcohols by pervaporation or vapor/vapor permeation. The membranes are made in tubular form. Extraordinarily high selectivities have been reported for these membranes, and their ceramic nature allows operation at high temperatures, so fluxes are high. These advantages are, however, offset by the costs of the membrane modules, currently in excess of US\$3000/m² of membrane.

Mixed-matrix Membranes

The ceramic and zeolite membranes described above have been shown to have exceptional selectivities for a number of important separations. However, the membranes are not easy to make and consequently are prohibitively expensive for many separations. One solution to this problem is to prepare membranes from materials consisting of zeolite particles dispersed in a polymer matrix. These membranes are expected to combine the selectivity of zeolite membranes with the low cost and ease of manufacture of polymer membranes. Such membranes are called mixed-matrix membranes.

Mixed-matrix membranes have been a subject of research interest for more than 15 years [28–33]. The concept is illustrated in Figure 8.10. At relatively low loadings of zeolite particles, permeation occurs by a combination of diffusion through the polymer phase and diffusion through the permeable zeolite particles. The relative permeation rates through the two phases are determined by their permeabilities. At low loadings of zeolite, the effect of the permeable zeolite particles on permeation can be expressed mathematically by the expression shown below, first developed by Maxwell in the 1870s [34].

$$P = P_c \left[\frac{P_d + 2P_c - 2\Phi(P_c - P_d)}{P_d + 2P_c + \Phi(P_c - P_d)} \right] \quad (8.6)$$

Figure 8.10 Gas permeation through mixed-matrix membranes containing different amounts of dispersed zeolite particles

where P is the overall permeability of the mixed-matrix material, Φ is the volume fraction of the dispersed zeolite phase, P_c is the permeability of the continuous polymer phase, and P_d is the permeability of the dispersed zeolite phase.

At low loadings of dispersed zeolite, individual particles can be considered to be well separated. At higher loadings, some small islands of interconnected particles form; at even higher loadings, these islands grow and connect to form extended pathways. At loadings above a certain critical value, continuous channels form within the membrane, and almost all the zeolite particles are connected to the channels. This is called the percolation threshold. At this particle loading, the Maxwell equation is no longer used to calculate the membrane permeability. The percolation threshold is believed to be achieved at particle loadings of about 30 vol %.

Figure 8.11, adapted from a plot by Robeson *et al.* [35], shows a calculated plot of permeation of a model gas through zeolite-filled polymer membranes in which the zeolite phase is 1000 times more permeable than the polymer phase. At low zeolite particle loadings, the average particle is only in contact with one or two other particles, and a modest increase in average permeability occurs following the Maxwell model. At particle loadings of 25–30 vol % the situation is different—most particles touch two or more particles, and most of the permeating gas can diffuse through interconnected zeolite channels. The percolation threshold has been reached, and the Maxwell model no longer applies. Gas permeation is then best described as permeation through two interpenetrating, continuous phases. At very high zeolite loadings, the mixed-matrix membrane may be best described as a continuous zeolite phase containing dispersed particles of polymer. The Maxwell model may then again apply, with the continuous and the dispersed phases in Equation (8.6) reversed.

The figure also shows that the highly permeable zeolite only has a large effect on polymer permeability when the percolation threshold is reached. That is, useful

Figure 8.11 Change in membrane permeabilities for mixed-matrix membranes containing different volume fractions of zeolite. Adapted from Robeson *et al.* [35]

membranes must contain more than 30 vol % zeolite. This observation is borne out by the limited experimental data available.

Despite the great deal of recent research on mixed-matrix membranes, the results to date have been modest. Two general approaches have been used. The first, investigated by Koros [31–33] and Smolders [29], is to use the expected difference in the diffusion coefficients of gases in the zeolite particles. Koros, in particular, has focused on zeolites with small aperture sizes, for example, Zeolite 4A, with an effective aperture size of 3.8–4.0 Å, which has been used to separate oxygen (Lennard-Jones (LJ) diameter 3.47 Å) from nitrogen (LJ diameter 3.8 Å). The oxygen/nitrogen selectivity of the Zeolite 4A membrane has been calculated to be 37, with an oxygen permeability of 0.8 Barrer—an exceptional membrane. To maximize the effect of the zeolite in his mixed-matrix membrane, Koros used relatively low-permeability polymers, such as Matrimid[®] and other polyimides, or poly(vinyl acetate).

The second type of zeolite mixed-matrix membrane relies on relative sorption of different permeants to obtain an improved separation. For example, Smolders *et al.* [28] at the University of Twente, and Peinemann at GKSS, Geesthacht [30], showed that silicalite-silicone rubber mixed-matrix membranes had exceptional selectivities for the permeation of ethanol (kinetic diameter 4.5 Å) over water (kinetic diameter 2.6 Å). These zeolites separate by virtue of their higher sorption of ethanol compared to water on the hydrophobic silicalite surface. Differences in diffusion coefficients favor permeation of water, but this effect is overcome by the sorption effect. The net result is a more than seven-fold increase in the relative permeability of ethanol over water, compared to pure silicone rubber membranes. Because the aperture diameter of the silicalite particles is relatively large, permeabilities through the zeolite phase are also high, allowing rubbery, relatively high-permeability polymers to be used as the matrix phase.

Membrane Modules

Gas separation membranes are formed into spiral-wound or hollow fiber modules. Particulate matter, oil mist, and other potentially fouling materials can be completely and economically removed from gas streams by good-quality coalescing filters, so membrane fouling is generally more easily controlled in gas separation than with liquid separations. Therefore, the choice of module design is usually decided by cost and membrane flux. The hollow fiber membranes used in gas separation applications are often very fine, with lumen diameters of 50–200 μm. However, the pressure drop required on the lumen side of the membrane for these small-diameter fibers can become enough to seriously affect membrane performance. In the production of nitrogen from air, the membrane pressure-normalized fluxes are relatively low, from 1 to 2 gpu, and parasitic pressure drops are not a problem. However, in the separation of hydrogen from nitrogen or methane or carbon dioxide from natural gas, pressure-normalized fluxes are higher, and hollow fine fiber modules can develop excessive permeate-side pressure drops. The solution is to use capillary fibers or spiral-wound modules for this type of application. Nonetheless, these disadvantages of hollow fiber membranes may be partially offset by their lower cost per square meter of membrane. These factors are summarized for some important gas separation applications in Table 8.2.

Process Design

The three factors that determine the performance of a membrane gas separation system are illustrated in Figure 8.12. The role of membrane selectivity is obvious; not so obvious are the importance of the ratio of feed pressure (p_o) to permeate pressure (p_ℓ) across the membrane, usually called the pressure ratio, φ , and defined as

$$\varphi = \frac{p_o}{p_\ell} \quad (8.7)$$

Table 8.2 Module designs used for various gas separation applications

Application	Typical membrane material	Selectivity (α)	Average pressure-normalized flux [10^{-6} cm ³ (STP)/cm ² · s · cmHg]	Module design commonly used
O ₂ /N ₂	Polyimide	6–7	1–2	Hollow fiber
H ₂ /N ₂	Polysulfone	100	10–20	Hollow fiber
CO ₂ /CH ₄	Cellulose acetate	15–20	2–5	Spiral or hollow fiber
VOC/N ₂	Silicone rubber	10–30	100	Spiral
H ₂ O/Air	Polyimide	>200	5	Capillary —bore-side feed

and of the membrane stage-cut, θ , which is the fraction of the feed gas that permeates the membrane, defined as

$$\theta = \frac{\text{permeate flow}}{\text{feed flow}} \tag{8.8}$$

Pressure Ratio

The importance of pressure ratio in the separation of gas mixtures can be illustrated by considering the separation of a gas mixture with component concentrations of n_{i_o} and n_{j_o} at a feed pressure p_o . A flow of component i across the membrane can only occur if the partial pressure of i on the feed side of the membrane ($n_{i_o}p_o$) is greater than the partial pressure of i on the permeate side of the membrane ($n_{i_\ell}p_\ell$), that is,

$$n_{i_o}p_o > n_{i_\ell}p_\ell \tag{8.9}$$

It follows that the maximum separation achieved by the membrane can be expressed as

$$\frac{n_{i_\ell}}{n_{i_o}} \leq \frac{p_o}{p_\ell} \tag{8.10}$$

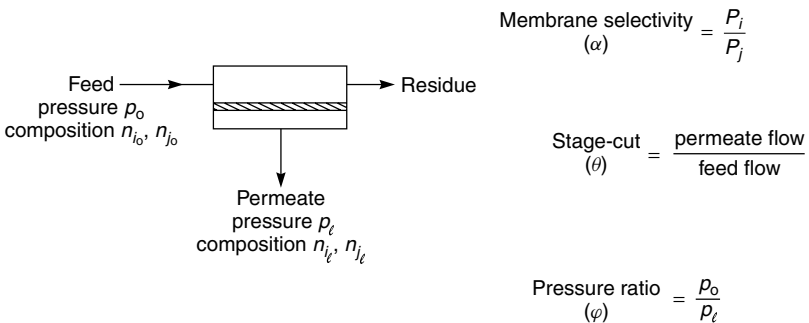

Figure 8.12 Parameters affecting the performance of membrane gas separation systems

That is, the separation achieved can never exceed the pressure ratio φ , no matter how selective the membrane:

$$\frac{n_{i\ell}}{n_{i_o}} \leq \varphi \quad (8.11)$$

The relationship between pressure ratio and membrane selectivity can be derived from the Fick's law expression for the fluxes of components i and j

$$j_i = \frac{\mathcal{P}_i(p_{i_o} - p_{i\ell})}{\ell} \quad (8.12)$$

and

$$j_j = \frac{\mathcal{P}_j(p_{j_o} - p_{j\ell})}{\ell} \quad (8.13)$$

The total gas pressures on the feed and permeate side are the sum of the partial pressures. For the feed side

$$p_o = p_{i_o} + p_{j_o} \quad (8.14)$$

and for the permeate side

$$p_\ell = p_{i\ell} + p_{j\ell} \quad (8.15)$$

The volume fractions of components i and j on the feed and permeate side are also related to partial pressures. For the feed side

$$n_{i_o} = \frac{p_{i_o}}{p_o} \quad n_{j_o} = \frac{p_{j_o}}{p_o} \quad (8.16)$$

and for the permeate side

$$n_{i\ell} = \frac{p_{i\ell}}{p_\ell} \quad n_{j\ell} = \frac{p_{j\ell}}{p_\ell} \quad (8.17)$$

while from mass balance considerations

$$\frac{j_i}{j_j} = \frac{n_{i\ell}}{n_{j\ell}} = \frac{n_{i\ell}}{1 - n_{i\ell}} = \frac{1 - n_{j\ell}}{n_{j\ell}} \quad (8.18)$$

Combining Equations (8.14–8.18) yields an expression linking the concentration of component i on the feed and permeate sides of the membrane

$$n_{i\ell} = \frac{\varphi}{2} \left[n_{i_o} + \frac{1}{\varphi} + \frac{1}{\alpha - 1} - \sqrt{\left(n_{i_o} + \frac{1}{\varphi} + \frac{1}{\alpha - 1} \right)^2 - \frac{4\alpha n_{i_o}}{(\alpha - 1)\varphi}} \right] \quad (8.19)$$

This somewhat complex expression breaks down into two limiting cases depending on the relative magnitudes of the pressure ratio and the membrane selectivity. First, if the membrane selectivity (α) is very much larger than the pressure ratio (φ), that is,

$$\alpha \gg \varphi \quad (8.20)$$

then Equation (8.20) becomes

$$n_{i_e} = n_{i_o} \varphi \quad (8.21)$$

This is called the pressure-ratio-limited region, in which the performance is determined only by the pressure ratio across the membrane and is independent of the membrane selectivity. If the membrane selectivity (α) is very much smaller than the pressure ratio (φ), that is,

$$\alpha \ll \varphi \quad (8.22)$$

then Equation (8.19) becomes

$$n_{i_e} = \frac{\alpha n_{i_o}}{1 - n_{i_o}(1 - \alpha)} \quad (8.23)$$

This is called the membrane-selectivity-limited region, in which the membrane performance is determined only by the membrane selectivity and is independent of the pressure ratio. There is, of course, an intermediate region between these two limiting cases, in which both the pressure ratio and the membrane selectivity affect the membrane system performance. These three regions are illustrated in Figure 8.13, in which the calculated permeate concentration (n_{i_e}) is plotted versus pressure ratio (φ) for a membrane with a selectivity of 30 [36]. At a pressure ratio of 1, feed pressure equal to the permeate pressure, no separation is achieved by the membrane. As the difference between the feed and permeate pressure increases,

Figure 8.13 Calculated permeate vapor concentration for a vapor-permeable membrane with a vapor/nitrogen selectivity of 30 as a function of pressure ratio. The feed vapor concentration is 1%. Below pressure ratios of about 10, separation is limited by the pressure ratio across the membrane. At pressure ratios above about 100, separation is limited by the membrane selectivity [36]

the concentration of the more permeable component in the permeate gas begins to increase, first according to Equation (8.21) and then, when the pressure ratio and membrane selectivity are comparable, according to Equation (8.19). At very high pressure ratios, that is, when the pressure ratio is four to five times higher than the membrane selectivity, the membrane enters the membrane-selectivity-controlled region. In this region the permeate concentration reaches the limiting value given by Equation (8.23).

The relationship between pressure ratio and selectivity is important because of the practical limitation to the pressure ratio achievable in gas separation systems. Compressing the feed stream to very high pressure or drawing a very hard vacuum on the permeate side of the membrane to achieve large pressure ratios both require large amounts of energy and expensive pumps. As a result, typical practical pressure ratios are in the range 5–20.

Because the attainable pressure ratio in most gas separation applications is limited, the benefit of very highly selective membranes is often less than might be expected. For example, as shown in Figure 8.14, if the pressure ratio is 20, then increasing the membrane selectivity from 10 to 20 will significantly improve system performance. However, a much smaller incremental improvement results from increasing the selectivity from 20 to 40. Increases in selectivity above 100 will produce negligible improvements. A selectivity of 100 is five times the pressure ratio of 20, placing the system in the pressure-ratio-limited region.

Figure 8.14 Calculated permeate vapor concentration as a function of selectivity. The feed vapor concentration is 1%; the pressure ratio is fixed at 20. Below a vapor/nitrogen selectivity of about 10, separation is limited by the low membrane selectivity; at selectivities above about 100, separation is limited by the low pressure ratio across the membrane [36]

stream containing 11.8 % of the permeable gas. However, the gas permeating the added membrane area only contains 83.0 % of the permeable component, so the average concentration of permeable component in the permeate stream is reduced from 93.1 to 88.1 %. If the fraction of the feed gas that permeates the membrane is increased to 75 % by adding even more membrane area, the concentration of the permeable component in the residue stream is reduced to only 0.04 %. However, the gas permeating the added membrane area only contains 23.8 % of the permeable component, *less than the original feed gas*. The average concentration of the permeable component in the feed gas is, therefore, reduced to 66.7 %. This means that one-half of the less permeable component has been lost to the permeate stream.

The calculations shown in Figure 8.15 illustrate the trade-off between recovery and purity. A single-stage membrane process can be designed for either maximum recovery or maximum purity, but not both. The calculations also show that membranes can produce very pure residue gas streams enriched in the less permeable component, although at low recoveries. However, the enrichment of the more permeable component in the permeate can never be more than the membrane selectivity, so a membrane with low selectivity produces an only slightly enriched permeate. This is why membranes with an oxygen/nitrogen selectivity of 4–6 can produce very pure nitrogen (>99.5 %) from air on the residue side of the membrane, but the same membranes cannot produce better than 50–60 % oxygen on the permeate side. If the more permeable component must be pure, very selective membranes are required or multistage or recycle membrane systems must be used.

Finally, the calculations in Figure 8.15 show that increasing the stage-cut to produce a pure residue stream requires a disproportionate increase in membrane area. As the feed gas is stripped of the more permeable component, the average permeation rate through the membrane falls. In the example shown, this means that permeating the first 25 % of the feed gas requires a relative membrane area of 1, permeating the next 25 % requires a membrane area increment of 1.8, and permeating the next 25 % requires an increment of 6.7.

Multistep and Multistage System Designs

Because the membrane selectivity and pressure ratio achievable in a commercial membrane system are limited, a one-stage membrane system may not provide the separation desired. The problem is illustrated in Figure 8.16. The target of the process is 90 % removal of a volatile organic compound (VOC), which is the permeable component, from the feed gas, which contains 1 vol % of this component. This calculation and those that immediately follow assume a feed gas mixture VOC and nitrogen. Rubbery membranes such as silicone rubber permeate the VOC preferentially because of its greater condensability and hence solubility in the membrane. In this calculation, the pressure ratio is fixed at 20

Figure 8.16 A one-stage vapor separation operation. The performance of this system was calculated from a crossflow model using a vapor/nitrogen selectivity of 20 and a pressure ratio of 20

by compressing the feed gas, and the permeate is maintained at atmospheric pressure. The membrane VOC/nitrogen selectivity is assumed to be 20.

Figure 8.16 shows that when 90 % of the VOC in the feed stream is removed, the permeate stream will contain approximately 4 % of the permeable component. In many cases, 90 % removal of VOC from the feed stream is insufficient to allow the residue gas to be discharged, and enrichment of the component in the permeate is insufficient also.

If the main problem is insufficient VOC removal from the feed stream, a two-step system as shown in Figure 8.17 can be used. In a two-step system, the residue stream from the first membrane unit is passed to a second unit, where the VOC concentration is reduced by a further factor of 10, from 0.1 to 0.01 %.

Because the concentration of VOC in the feed to the second membrane unit is low, the permeate stream is relatively dilute and is recirculated to the feed stream. A multistep design of this type can achieve almost complete removal of the permeable component from the feed stream to the membrane unit. However, greater removal of the permeable component is achieved at the expense of increases in membrane area and power consumption by the compressor. As a rule of thumb, the membrane area required to remove the last 9 % of a component from the feed equals the membrane area required to remove the first 90 %.

Sometimes, 90 % removal of the permeable component from the feed stream is acceptable for the discharge stream from the membrane unit, but a higher

Figure 8.17 A two-step system to achieve 99 % vapor removal from the feed stream. Selectivity, 20; pressure ratio, 20

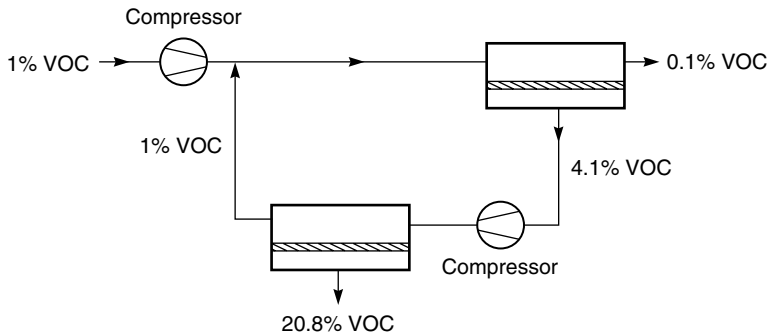

Figure 8.18 A two-stage system to produce a highly concentrated permeate stream. Selectivity, 20; pressure ratio, 20

concentration is needed to make the permeate gas usable. In this situation, a two-stage system of the type shown in Figure 8.18 is used. In a two-stage design, the permeate from the first membrane unit is recompressed and sent to a second membrane unit, where a further separation is performed. The final permeate is then twice enriched. In the most efficient two-stage design, the residue stream from the second stage is reduced to about the same concentration as the original feed gas, with which it is mixed. In the example shown in Figure 8.18, the permeate stream, concentrated a further five-fold, leaves the system at a concentration of 21%. Because the volume of gas treated by the second-stage membrane unit is much smaller than in the first stage, the membrane area of the second stage is relatively small. Thus, incorporation of a second stage only increases the overall membrane area and power requirements by approximately 15–20%.

Multistage/multistep combinations of two-step and two-stage processes can be designed but are seldom used in commercial systems—their complexity makes them uncompetitive with alternative separation technologies. More commonly some form of recycle design is used.

Recycle Designs

A simple recycle design, sometimes called a two-and-one-half-stage system, proposed by Wijmans [37] is shown in Figure 8.19. In this design, the permeate from the first membrane stage is recompressed and sent to a two-step second stage, where a portion of the gas permeates and is removed as enriched product. The remaining gas passes to another membrane stage, which brings the gas concentration close to the original feed value. The permeate from this stage is mixed with the first-stage permeate, forming a recycle loop. By controlling the relative size of the two second stages any desired concentration of the more permeable component can be achieved in the product. In the example shown, the permeable

Figure 8.19 Two-and-one-half-stage system: by forming a recycle loop around the second stage, a small, very concentrated product stream is created. Selectivity, 20; pressure ratio, 20 [37]

component is concentrated to 50% in the permeate. The increased performance is achieved at the expense of a slightly larger second-stage compressor and more membrane area. Normally, however, this design is preferable to a more complex three-stage system.

Figure 8.20 shows another type of recycle design in which a recycle loop increases the concentration of the permeable component to the point at which it can be removed by a second process, most commonly condensation [38]. The feed stream entering the recycle loop contains 1% of the permeable component as in Figures 8.16–8.19. After compression to 20 atm, the feed gas passes through a condenser at 30 °C, but the VOC content is still below the condensation concentration at this temperature. The membrane unit separates the gas into a VOC-depleted residue stream and a vapor-enriched permeate stream, which is recirculated to the front of the compressor. Because the bulk of the vapor is recirculated, the concentration of vapor in the loop increases rapidly until the pressurized gas entering the condenser exceeds the vapor dew point of 6.1%. At

Figure 8.20 Recycle system design using one membrane stage, preceded by a compressor and condenser: feed stream, 1% vapor in nitrogen; selectivity, 20; pressure ratio, 20

this point, the system is at steady state; the mass of VOC entering the recirculation loop is equal to the mass discharged in the residue stream plus the mass removed as liquid condensate.

Recycle designs of this type are limited to applications in which the components of the gas mixture, if sufficiently concentrated, can be separated from the gas by some other technique. With organic vapors, condensation is often possible; adsorption, chemical scrubbing or absorption can also be used. The process shown in Figure 8.20 is used to separate VOCs from nitrogen and air or to separate propane, butane, pentane and higher hydrocarbons from natural gas (methane).

Applications

The membrane gas separation industry is still growing and changing. Most of the large industrial gas companies now have membrane affiliates: Air Products (Permea), MG (Generon), Air Liquide (Medal) and Praxair (IMS). The affiliates focus mainly on producing membrane systems to separate nitrogen from air, but also produce some hydrogen separation systems. Another group of companies, UOP (Separex), Natco (Cynara), Kvaerner (GMS) and ABB Lummus Global (MTR), produces membrane systems for natural gas separations. A third group of smaller independents are focusing on the new applications, including vapor separation, air dehydration and oxygen enrichment. The final size and form of this industry are still unknown. The following section covers the major current applications. Overview articles on the main gas separation applications can be found in Paul and Yampol'skii [39], in Koros and Fleming [40] and elsewhere [41].

Hydrogen Separations

The first large-scale commercial application of membrane gas separation was the separation of hydrogen from nitrogen in ammonia purge gas streams. The process, launched in 1980 by Monsanto, was followed by a number of similar applications, such as hydrogen/methane separation in refinery off-gases and hydrogen/carbon monoxide adjustment in oxo-chemical synthesis plants [7]. Hydrogen is a small, noncondensable gas, which is highly permeable compared to all other gases. This is particularly true with the glassy polymers primarily used to make hydrogen-selective membranes; fluxes and selectivities of hydrogen through some of these materials are shown in Table 8.3. With fluxes and selectivities as high as these, it is easy to understand why hydrogen separation was the first gas separation process developed. Early hydrogen membrane gas separation plants used polysulfone or cellulose acetate membranes, but now a variety of specifically synthesized materials, such as polyimides (Ube, Praxair), polyaramide (Medal) or brominated polysulfone (Permea), are used.

Table 8.3 Hydrogen separation membranes

Membrane (developer)	Selectivity			Hydrogen pressure-normalized flux [10^{-6} cm ³ (STP)/cm ² · s · cmHg]
	H ₂ /CO	H ₂ /CH ₄	H ₂ /N ₂	
Polyaramide (Medal)	100	>200	>200	—
Polysulfone (Permea)	40	80	80	100
Cellulose acetate (Separex)	30–40	60–80	60–80	200
Polyimide (Ube)	50	100–200	100–200	80–200

	Stream Composition (%)			
	Membrane Feed ①	Membrane Vent ②	High-Pressure Permeate ③	Low-Pressure Permeate ④
Hydrogen	62	21	87.3	84.8
Nitrogen	21	44	7.1	8.4
Methane	11	23	36	4.3
Argon	6	13	2.0	2.5
Pressure (atm)	135	132	70	28
Flow (scfm)	2000	740	830	430

Figure 8.21 Simplified flow schematic of the PRISM[®] membrane system to recover hydrogen from an ammonia reactor purge stream. A two-step membrane system is used to reduce permeate compression costs

A typical membrane system flow scheme for recovery of hydrogen from an ammonia plant purge gas stream is shown in Figure 8.21. A photograph of such a system is shown in Figure 8.22. During the production of ammonia from nitrogen and hydrogen, argon enters the high-pressure ammonia reactor as an impurity with the nitrogen stream and methane enters the reactor as an impurity with the hydrogen. Ammonia produced in the reactor is removed by condensation, so the argon and methane impurities accumulate until they represent as much as 15% of the gas in the reactor. To control the concentration of these components, the reactor must be continuously purged. The hydrogen lost with this purge gas can represent 2–4% of the total hydrogen consumed. These plants are very large, so recovery of the hydrogen for recycle to the ammonia reactor is economically worthwhile.

In the process shown in Figure 8.21, a two-step membrane design is used to reduce the cost of recompressing the hydrogen permeate stream to the very high

Figure 8.22 Photograph of an Air Products and Chemicals, Inc. PRISM[®] membrane system installed at an ammonia plant. The modules are mounted vertically

pressures of ammonia reactors. In the first step, the feed gas is maintained at the reactor pressure of 135 atm, and the permeate is maintained at 70 atm, giving a pressure ratio of 1.9. The hydrogen concentration in the feed to this first step is about 45 %, high enough that even at this low pressure ratio the permeate contains about 90 % hydrogen. However, by the time the feed gas hydrogen concentration has fallen to 30 %, the hydrogen concentration in the permeate is no longer high enough for recycle to the reactor. This remaining hydrogen is recovered in a second membrane step operated at a lower permeate pressure

	Stream Composition		
	Untreated Purge ①	Recovered Hydrogen ②	Treated Purge ③
Hydrogen	82	96.5	34.8
Methane	12	2.6	43.3
Ethane	4.6	0.7	17.1
Propane	1.2	0.2	4.8
Pressure (psig)	1800	450	1450
Flow (MMscfd)	18.9	14.5	4.4

Figure 8.23 Hydrogen recovery from a hydrotreater used to lower the molecular weight of a refinery oil stream. Permea polysulfone membranes (PRISM®) are used [42]

of 28 atm and a pressure ratio of 4.7. The increased pressure ratio increases the hydrogen concentration in the permeate significantly. By dividing the process into two steps operating at different pressure ratios, maximum hydrogen recovery is achieved at minimum recompression costs.

A second major application of hydrogen-selective membranes is recovery of hydrogen from waste gases produced in various refinery operations [7,42,43]. A typical separation—treatment of the high-pressure purge gas from a hydrotreater—is shown in Figure 8.23. The hydrogen separation process is designed to recycle the hydrogen to the hydrotreater. As in the case of the ammonia plant, there is a trade-off between the concentration of hydrogen in the permeate and the permeate pressure and subsequent cost of recompression. In the example shown, a permeate of 96.5 % hydrogen is considered adequate at a pressure ratio of 3.9.

Another example of the use of highly hydrogen-selective membranes in the petrochemical industry is the separation of hydrogen from carbon monoxide/hydrogen mixtures to obtain the correct ratio of components for subsequent synthesis operations.

Oxygen/Nitrogen Separation

By far the largest gas separation process in current use is the production of nitrogen from air. The first membranes used for this process were based on poly(4-methyl-1-pentene) (TPX) and ethyl cellulose. These polymer materials have oxygen/nitrogen selectivities of 4; the economics of the process were marginal. The second-generation materials now used have selectivities of 6–7, providing very favorable economics, especially for small plants producing 5–500 scfm of nitrogen. In this range, membranes are the low-cost process, and most new small nitrogen plants use membrane systems.

Table 8.4 lists the permeabilities and selectivities of some of the materials that are used or have been used for this separation. There is a strong inverse relationship between flux and selectivity. Membranes with selectivities of 6–7 typically have 1 % of the permeability of membranes with selectivities of 2–3. This selectivity/permeability trade-off is very apparent in the plot of selectivity as a function of oxygen permeability shown in Figure 8.24, prepared by Robeson [11]. This plot shows data for a large number of membrane materials reported in the literature. A wide range of selectivity/permeability combinations are provided by different membrane materials; for gas separation applications only the most permeable polymers at a particular selectivity are of interest. The line linking these polymers is called the upper bound, beyond which no better material is currently known. The relative positions of the upper bound in 1991 and in 1980 show the progress that has been made in producing polymers specifically tailored for this separation. Development of better materials is a continuing research topic at the

Table 8.4 Permeabilities and selectivities of polymers of interest in air separation

Polymer	Oxygen permeability (Barrer)	Nitrogen permeability (Barrer)	Oxygen/nitrogen selectivity
Poly(1-trimethylsilyl-1-propyne) (PTMSP)	7600	5400	1.4
Teflon AF 2400	1300	760	1.7
Silicone rubber	600	280	2.2
Poly(4-methyl-1-pentene) (TPX)	30	7.1	4.2
Poly(phenylene oxide) (PPO)	16.8	3.8	4.4
Ethyl cellulose	11.2	3.3	3.4
6FDA-DAF (polyimide)	7.9	1.3	6.2
Polysulfone	1.1	0.18	6.2
Polyaramide	3.1	0.46	6.8
Tetrabromo <i>bis</i> polycarbonate	1.4	0.18	7.5

Figure 8.24 Oxygen/nitrogen selectivity as a function of oxygen permeability. This plot by Robeson [11] shows the wide range of combination of selectivity and permeability achieved by current materials. Reprinted from *J. Membr. Sci.* **62**, L.M. major gas separation companies and in some universities, so further but slower movement of the upper bound may be seen in the future.

High oxygen/nitrogen selectivity is required for an economical nitrogen production process. The effect of improved membrane selectivities on the efficiency of nitrogen production from air is illustrated in Figure 8.25. This figure shows the

Figure 8.25 Nitrogen recovery as a function of product nitrogen concentration for membranes with selectivities between 2 and 20

trade-off between the fraction of nitrogen in the feed gas recovered as nitrogen product gas as a function of the nitrogen concentration in the product gas. All oxygen-selective membranes, even membranes with an oxygen/nitrogen selectivity as low as 2, can produce better than 99% nitrogen, albeit at very low recoveries. The figure also shows the significant improvement in efficiency that results from an increase in oxygen/nitrogen selectivity from 2 to 20.

The first nitrogen production systems used membranes made from TPX with a selectivity of about 4. These membranes were incorporated in one-stage designs to produce 95% nitrogen used to render flammable-liquid storage tanks inert. As the membranes improved, more complex process designs, of the type shown in Figure 8.26, were used to produce purer gas containing >99% nitrogen. The

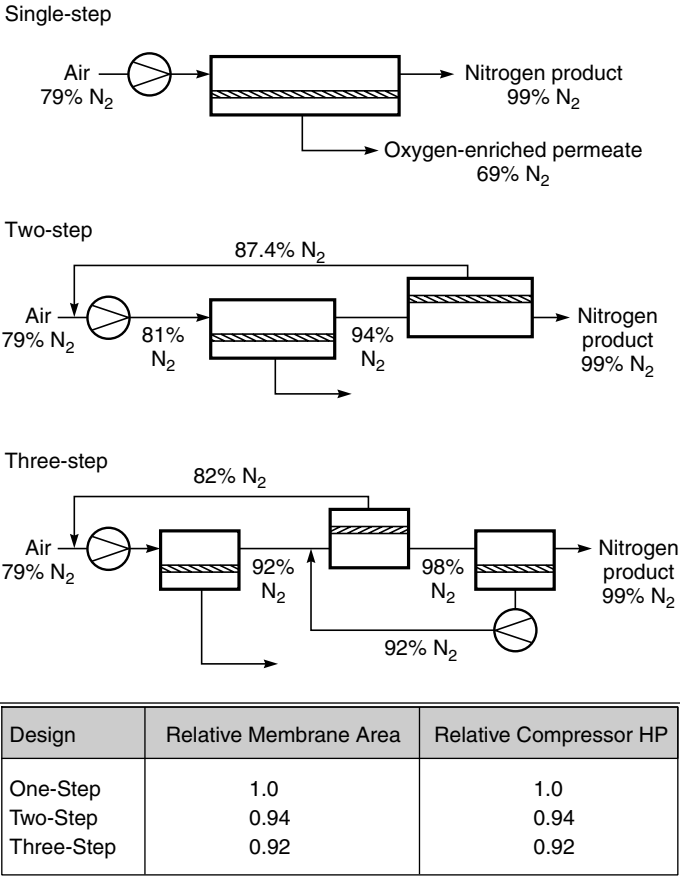

Figure 8.26 Single-, two- and three-step designs for nitrogen production from air

first improvement was the two-step process. As oxygen is removed from the air passing through the membrane modules, the concentration in the permeating gas falls. At some point the oxygen concentration in the permeate gas is less than the concentration in normal ambient feed air. Mixing this oxygen-depleted gas permeate with the incoming air then becomes worthwhile. The improvement will be most marked when the system is used to produce high-quality nitrogen containing less than 1 % oxygen. In the example shown in Figure 8.26, the second-step permeate gas contains 12.5 % oxygen, and recycling this gas to the incoming feed air reduces the membrane area and compressor load by about 6 %. This relatively small saving is worthwhile because it is achieved at essentially no cost by making a simple piping change to the system. In the two-step design, the 12.5 % oxygen permeate recycle stream is mixed with ambient air containing 21 % oxygen. A

more efficient design would be to combine the recycle and feed gas where the feed gas has approximately the same concentration. This is the objective of the three-step process shown in Figure 8.26. This design saves a further 2 % in membrane area and some compressor power, but now two compressors are needed. Three-step processes are, therefore, generally limited to large systems in which the energy and membrane area savings compensate for the extra complexity and higher maintenance cost of a second compressor. A discussion of factors affecting the design of nitrogen plants is given by Prasad *et al.* [44,45].

Membrane nitrogen production systems are now very competitive with alternative technologies. The competitive range of the various methods of obtaining nitrogen is shown in Figure 8.27. Very small nitrogen users generally purchase gas cylinders or delivered liquid nitrogen, but once consumption exceeds 5000 scfd of nitrogen, membranes become the low-cost process. This is particularly true if the required nitrogen purity is between 95 % and 99 % nitrogen. Membrane systems can still be used if high quality nitrogen (up to 99.9 %) is required, but the cost of the system increases significantly. Very large nitrogen users—above 10 MMscfd of gas—generally use pipeline gas or on-site cryogenic systems. Pressure swing adsorption (PSA) systems are also sometimes used in the 1–10 MMscfd range.

A membrane process to separate nitrogen from air inevitably produces oxygen-enriched air as a by-product. Sometimes this by-product gas, containing about 35 % oxygen, can be used beneficially, but usually it is vented. A market for oxygen or oxygen-enriched air exists, but because oxygen is produced as the permeate gas stream it is much more difficult to produce high-purity oxygen than

Figure 8.27 Approximate competitive range of current membrane nitrogen production systems. Many site-specific factors can affect the actual system selection

Figure 8.28 The maximum possible oxygen concentration in the permeate from a one-step membrane process with membranes of various selectivities (assumes zero stage-cut). Even the best current membrane materials, with a selectivity of 8, only produce 68 % oxygen in the permeate at an infinite pressure ratio

high-purity nitrogen with membrane systems. Figure 8.28 shows the maximum permeate oxygen concentration that can be produced by a one-step membrane process using membranes of various selectivities. Even at zero stage-cut and an infinite pressure ratio, the best currently available membrane, with an oxygen/nitrogen selectivity of 8, can only produce 68 % oxygen. At useful stage-cuts and achievable pressure ratios this concentration falls. These constraints limit membrane systems to the production of oxygen-enriched air in the 30–50 % oxygen range.

Oxygen-enriched air is used in the chemical industry, in refineries, and in various fermentation and biological digestion processes, but it must be produced very cheaply for these applications. The competitive technology is pure oxygen produced cryogenically then diluted with atmospheric air. The quantity of pure oxygen that must be blended with air to produce the desired oxygen enrichment determines the cost. This means that in membrane systems producing oxygen-enriched air, only the fraction of the oxygen above 21 % can be counted as a credit. This fraction is called the equivalent pure oxygen (EPO₂) basis.

A comparison of the cost of oxygen-enriched air produced by membranes and by cryogenic separation shows that current membranes are generally uncompetitive. The only exception is for very small users in isolated locations, where the

logistics of transporting liquid oxygen to the site increase the oxygen cost to US\$80–100/ton.

Development of better membranes for producing oxygen-enriched air has been, and continues to be, an area of research because of the potential application of the gas in combustion processes. When methane, oil, and other fuels are burned with air, a large amount of nitrogen passes as an inert diluent through the burners and is discarded as hot exhaust gas. If oxygen-enriched air were used, the energy lost with the hot exhaust gas would decrease considerably. Use of oxygen-enriched air also improves the efficiency of diesel engines [46]. The useful energy that can be extracted from the same amount of fuel increases significantly even if air is enriched only from 25 to 35% oxygen. But to make this process worthwhile, the fuel savings achieved must offset the cost of the oxygen-enriched air used. Calculations show that the process would be cost-effective for some applications at an EPO_2 cost as high as US\$60/ton and, for many applications, at an EPO_2 cost of US\$30–40/ton. Bhide and Stern [47] have published an interesting

Figure 8.29 Cost of oxygen-enriched air produced by membrane separation on an EPO_2 basis as a function of the oxygen permeability and oxygen/nitrogen selectivity of the membrane. The performance of today's best membranes is represented by the upper bound performance line from Robeson's plot (Figure 8.24) [35,47]. Reprinted from *J. Membr. Sci.* **62**, B.O. Bhide and S.A. Stern, A New Evaluation of Membrane Processes for the Oxygen-enrichment of Air, p. 87. Copyright 1991, with permission from Elsevier

analysis of this problem, the results of which are shown in Figure 8.29. The figure shows the cost of oxygen-enriched air produced by a membrane process for membranes of various permeabilities and selectivities. The assumptions were optimistic—low-cost membrane modules (US\$54/m²) and membranes with extremely thin selective separating layers (1000 Å). Also shown in Figure 8.29 is the portion of the upper-bound curve obtained from the permeability/selectivity trade-off plot shown in Figure 8.24. As the figure shows, a number of materials at the upper-bound limit, with oxygen/nitrogen selectivities of 3–4 and permeabilities of 50–500, are within striking distance of the US\$30–40/ton target. Production of these very high-performance membrane modules is at the outer limit of current technology but improvements in the technology could open up new, very large applications of membranes in the future.

Natural Gas Separations

US production of natural gas is about 20 trillion scf/year; total worldwide production is about 40 trillion scf/year. All of this gas requires some treatment, and approximately 20 % of the gas requires extensive treatment before it can be delivered to the pipeline. As a result, several billion dollars' worth of natural gas separation equipment is installed annually worldwide. The current membrane market share is about 2 %, essentially all for carbon dioxide removal. However, this fraction is expected to increase because applications of membranes to other separations in the natural gas processing industry are under development [48].

Raw natural gas varies substantially in composition from source to source. Methane is always the major component, typically 75–90 % of the total. Natural gas also contains significant amounts of ethane, some propane and butane, and 1–3 % of other higher hydrocarbons. In addition, the gas contains undesirable impurities: water, carbon dioxide, nitrogen and hydrogen sulfide. Although raw natural gas has a wide range of compositions, the composition of gas delivered to the pipeline is tightly controlled. Typical US natural gas specifications are shown in Table 8.5. The opportunity for membranes lies in the processing of gas to meet these specifications.

Table 8.5 Composition of natural gas required for delivery to the US national pipeline grid

Component	Specification
CO ₂	<2 %
H ₂ O	<120 ppm
H ₂ S	<4 ppm
C ₃₊	950–1050 Btu/scf
Content	Dew point, –20 °C
Total inerts (N ₂ , CO ₂ , He, etc.)	<4 %

Natural gas is usually produced from the well and transported to the gas processing plant at high pressure, in the range 500–1500 psi. To minimize recompression costs, the membrane process must remove impurities from the gas into the permeate stream, leaving the methane, ethane, and other hydrocarbons in the high-pressure residue gas. This requirement determines the type of membranes that can be used for this separation. Figure 8.30 is a graphical representation of the factors of molecular size and condensability that affect selection of membranes for natural gas separations.

As Figure 8.30 shows, water is small and condensable; therefore, it is easily separated from methane by both rubbery and glassy polymer membranes. Both rubbery and glassy membranes can also separate carbon dioxide and hydrogen sulfide from natural gas. However, in practice carbon dioxide is best separated by glassy membranes (utilizing size selectivity) [49,50], whereas hydrogen sulfide, which is larger and more condensable than carbon dioxide, is best separated by rubbery membranes (utilizing sorption selectivity) [51,52]. Nitrogen can be separated from methane by glassy membranes, but the difference in size is small, so the separations achieved are small. Finally, propane and other hydrocarbons, because of their condensability, are best separated from methane with rubbery sorption-selective membranes. Table 8.6 shows typical membrane materials and the selectivities that can be obtained with good-quality membranes.

Figure 8.30 The relative size and condensability (boiling point) of the principal components of natural gas. Glassy membranes generally separate by differences in size; rubbery membranes separate by differences in condensability

Table 8.6 Membrane materials and selectivities for separation of impurities from natural gas

Component to be permeated	Category of preferred polymer material	Typical polymer used	Typical selectivity over methane
CO ₂	Glass	Cellulose acetate, polyimide	10–20
H ₂ S	Rubber	Ether-amide block copolymer	20–40
N ₂	Glass	Polyimide, perfluoro polymers	2–3
H ₂ O	Rubber or glass	Many	>200
Butane	Rubber	Silicone rubber	7–10

Carbon Dioxide Separation

Removal of carbon dioxide is the only membrane-based natural gas separation process currently practiced on a large scale—more than 200 plants have been installed, some very large. Most were installed by Grace (now Kvaerner-GMS), Separex (UOP) and Cynara and all use cellulose acetate membranes in hollow fiber or spiral-wound module form. More recently, hollow fiber polyaramide (Medal) membranes have been introduced because of their higher selectivity.

The designs of two typical carbon dioxide removal plants are illustrated in Figure 8.31. One-stage plants, which are simple, contain no rotating equipment, and require minimal maintenance, are preferred for small gas flows. In such plants methane loss to the permeate is often 10–15%. If there is no fuel use for this gas, it must be flared, which represents a significant revenue loss. Nonetheless, for gas wells producing 1–2 MMscfd, one-stage membrane units with their low capital and operating costs may still be the optimum treatment method.

As the natural gas stream increases in size, the methane loss from a one-stage system becomes prohibitive. Often the permeate gas is recompressed and passed through a second membrane stage. This second stage reduces the methane loss to a few percent. However, the recompression cost is considerable, and the membrane system may no longer compete with amine absorption, the alternative technology. In general, membrane systems have proved to be most competitive for gas streams below 30 MMscfd containing high concentrations of carbon dioxide. Spillman [48] and McKee *et al.* [53] have reviewed the competitive position of membrane systems for this application. Currently the market for membrane carbon dioxide gas separation systems can be summarized as follows:

1. Very small systems (less than 5 MMscfd). At this flow rate, membrane units are very attractive. Often the permeate is flared or used as fuel, so the system is a simple bank of membrane modules.
2. Small systems (5–30 MMscfd). Two-stage membrane systems are used to reduce methane loss. In this gas flow range, amine and membrane systems

Figure 8.31 Flow scheme of one-stage and two-stage membrane separation plants to remove carbon dioxide from natural gas. Because the one-stage design has no moving parts, it is very competitive with other technologies especially if there is a use for the low-pressure permeate gas. Two-stage processes are more expensive because a large compressor is required to compress the permeate gas. However, the loss of methane with the fuel gas is much reduced

compete; the choice between the two technologies depends on site-specific factors.

3. Medium to large systems (greater than 30 MMscfd). In general, membrane systems are too expensive to compete head-to-head with amine plants. However, a number of large membrane systems have been installed on offshore platforms, at carbon dioxide flood operations, or where site-specific factors particularly favor membrane technology. As membranes improve, their market share is increasing.

In principle, the combination of membranes for bulk removal of the carbon dioxide with amine units as polishing systems offers a low-cost alternative to all-amine plants for many streams. However, this approach has not been generally used because the savings in capital cost are largely offset by the increased complexity of the plant, which now contains two separation processes. The one exception has been in carbon dioxide flood enhanced oil-recovery projects [49,54], in which carbon dioxide is injected into an oil formation to lower the viscosity of the oil. Water, oil and gas are removed from the formation; the carbon dioxide is separated from the gas produced and reinjected. In these projects,

Figure 8.32 A typical membrane/amine plant for the treatment of associated natural gas produced in carbon dioxide/enhanced oil projects. The membrane permeate gas is often used as a fuel for the amine absorption plant

the composition and volume of the gas changes significantly over the lifetime of the project. The modular nature of membrane units allows easy retrofitting to an existing amine plant, allowing the performance of the plant to be adjusted to meet the changing separation needs. Also, the capital cost of the separation system can be spread more evenly over the project lifetime. An example of a membrane/amine plant design is shown in Figure 8.32. In this design, the membrane unit removes two-thirds of the carbon dioxide, and the amine plant removes the remainder. The combined plant is usually significantly less expensive than an all-amine or all-membrane plant.

Dehydration

All natural gas must be dried before entering the national distribution pipeline to control corrosion of the pipeline and to prevent formation of solid hydrocarbon/water hydrates that can choke valves. Currently glycol dehydrators are widely used; approximately 50 000 units are in service in the United States. However, glycol dehydrators are not well suited for use on small gas streams or on offshore platforms, increasingly common sources of natural gas. In addition, these units coextract benzene, a known carcinogen and trace contaminant in natural gas, and release the benzene to the atmosphere. The Environmental Protection Agency (EPA) has announced its intention to require benzene emission control systems to be fitted to large glycol units.

Membrane processes offer an alternative approach to natural gas dehydration and are being developed by a number of companies. Membranes with intrinsic selectivities for water from methane of more than 500 are easily obtained, but because of concentration polarization effects, actual selectivities are typically about 200. Two possible process designs are shown in Figure 8.33. In the first

Figure 8.33 Dehydration of natural gas is easily performed by membranes but high cost may limit its scope to niche applications

design, a small one-stage system removes 90% of the water in the feed gas, producing a low-pressure permeate gas representing 5–6% of the initial gas flow. This gas contains the removed water. If the gas can be used as low-pressure fuel at the site, this design is economical and competitive with glycol dehydration. In the second design, the wet, low-pressure permeate gas is recompressed and cooled, so the water vapor condenses and is removed as liquid water. The natural gas that permeates the membrane is then recovered. However, if the permeate gas must be recompressed, as in the second design, the capital cost of the system approximately doubles, and membranes are then only competitive in special situations where glycol dehydration is not possible.

Dew Point Adjustment, C_{3+} Recovery

Natural gas usually contains varying amounts of ethane, propane, butane, and higher hydrocarbons. The gas is often close to its saturation point with respect to some of these hydrocarbons, which means liquids will condense from the gas at cold spots in the pipeline transmission system. To avoid the problems caused by condensation of liquids, the dew point of US natural gas is lowered to about -20°C before delivery to the pipeline by removing portions of the propane and butane and higher hydrocarbons. For safety reasons the Btu rating of the pipeline gas is also usually controlled within a narrow range, typically

950–1050 Btu per cubic foot. Because the Btu values of ethane, propane and pentane are higher than that of methane, natural gas that contains significant amounts of these hydrocarbons may have an excessive Btu value, requiring their removal. Of equal importance, these higher hydrocarbons are generally more valuable as recovered liquids than their fuel value in the gas. For all of these reasons almost all natural gas is treated to control the C_{3+} hydrocarbon content.

The current technology used to separate the higher hydrocarbons from natural gas streams is condensation, shown schematically in Figure 8.34. The natural gas stream is cooled by refrigeration or expansion to between -20°C and -40°C . The condensed liquids, which include the higher hydrocarbons and water, are separated from the gas streams and subjected to fractional distillation to recover the individual components. Because refrigeration is capital-intensive and uses large amounts of energy, there is considerable interest in alternative techniques, such as membrane gas separation.

A typical flow diagram of a membrane system for C_{3+} liquids recovery is also shown in Figure 8.34. The natural gas is fed to modules containing a higher-hydrocarbon-selective membrane, which removes the higher hydrocarbons as the permeate stream. This stream is recompressed and cooled by a cold-water exchanger to condense higher hydrocarbons. The non-condensed bleed

Current technology

Membrane system using C_{3+} hydrocarbon-selective membranes

Figure 8.34 Recovery of C_{3+} hydrocarbons from natural gas

stream from the condenser to the inlet will normally still contain more heavy hydrocarbons than the raw gas, so prior to returning the gas to the feed stream, the condenser bleed stream is passed through a second set of membrane modules. The permeate streams from the two sets of modules are combined, creating a recirculation loop around the condenser, which continuously concentrates the higher hydrocarbons [37].

The competitiveness of membrane systems in this application is very sensitive to the selectivity of the membranes for propane, butane and higher hydrocarbons over methane. If the membranes are very selective (propane/methane selectivity of 5–7, butane/methane selectivity of 10–15), the permeate stream from the main set of modules will be small and concentrated, minimizing the cost of the recompressor. Currently, silicone rubber membranes are being considered for this application, but other, more selective materials have been reported [55].

Vapor/Gas Separations

In the separation of vapor/gas mixtures, rubbery polymers, such as silicone rubber, can be used to permeate the more condensable vapor, or glassy polymers can be used to permeate the smaller gas. Although glassy, gas-permeable membranes have been proposed for a few applications, most installed plants use vapor-permeable membranes, often in conjunction with a second process such as condensation [36,38] or absorption [56]. The first plants, installed in the early 1990s, were used to recover vapors from gasoline terminal vent gases or chlorofluorocarbon (CFC) vapors from the vents of industrial refrigeration plants. More recently, membranes have begun to be used to recover hydrocarbons and processing solvents from petrochemical plant purge gas. Some of these streams are quite large and discharge vapors with a recovery value of US\$1–2 million/year.

One of the most successful petrochemical applications is treatment of resin degassing vent gas in polyolefin plants [57,58]. Olefin monomer, catalyst, solvents, and other co-reactants are fed at high pressure into the polymerization reactor. The polymer product (resin) is removed from the reactor and separated from excess monomer in a flash separation step. The recovered monomer is recycled to the reactor. Residual monomer is removed from the resin by stripping with nitrogen. The composition of this degassing vent stream varies greatly, but it usually contains 20–50 % of mixed hydrocarbon monomers in nitrogen. The monomer content represents about 1 % of the hydrocarbon feedstock entering the plant. This amount might seem small, but because polyolefin plants are large operations, the recovery value of the stream can be significant.

Several membrane designs can be used; two are shown in Figure 8.35 [59]. The two-step, two-stage system shown in Figure 8.35(a) achieves the target separation by linking several membrane units together, each unit performing a partial separation. The first unit removes a portion of the propylene from the feed gas to produce a concentrated permeate. The residue gas from this step is then sent to a

(a) Multi-stage membrane separation system design

(b) Hybrid compression-condenser-membrane Design

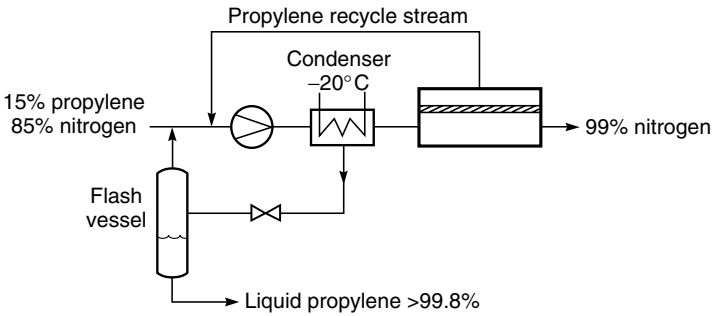

Figure 8.35 Vapor separation process designs able to achieve high vapor recovery and high-purity product streams

second membrane unit which produces a nitrogen gas stream containing less than 1% propylene. The permeate from this second step is only partially enriched in propylene, so it is mixed with the incoming feed gas.

To increase the propylene concentration in the permeate gas from the first step, a second-stage membrane unit is used. The permeate gas from the first stage is compressed and then passed through the second stage to produce a final permeate stream containing 95% propylene. The partially depleted second stage residue stream is recycled back to the feed. By linking together the three membrane separation units, the target recovery for both propylene and nitrogen can be achieved.

A number of multistep vapor separation systems of the type shown in Figure 8.35(a) have been installed. These systems have the advantage of operating at ambient temperatures and having as the main rotating equipment gas compressors with which petrochemical plant operators are very familiar.

However, if very good removal of the nitrogen from the recycle gas is required, the hybrid process combining condensation and membrane separation shown in Figure 8.35(b) is preferred. In this design, the compressed feed gas is sent to a condenser. On cooling the feed gas, a portion of the propylene content is removed as a condensed liquid. The remaining, uncondensed propylene is removed by the membrane separation system to produce a 99% nitrogen stream. The permeate gas is recycled to the incoming feed gas from the purge bin.

Because the gas sent to the membrane stage is cooled, the solubility of propylene in the membrane is enhanced, and the selectivity of the membrane unit is increased. The propylene condensate contains some dissolved nitrogen so the liquid is flashed at low pressure to remove this gas, producing a better than 99.5% pure hydrocarbon product. A photograph of a propylene/nitrogen vent gas treatment system is shown in Figure 8.36.

Vapor/Vapor Separations

A final group of separations likely to develop into a major application area for membranes is vapor/vapor separations, such as ethylene (bp -103.9°C) from

Figure 8.36 Photograph of a membrane unit used to recover nitrogen and propylene from a polypropylene plant vent gas

ethane (bp -88.9°C), propylene (bp -47.2°C) from propane (bp -42.8°C), and *n*-butane (bp -0.6°C) from isobutane (bp -10°C). These close-boiling mixtures are separated on a very large scale in the synthesis of ethylene and propylene, the two largest-volume organic chemical feedstocks, and in the synthesis of isobutane in refineries to produce high-octane gasoline. Because the mixtures are close-boiling, large towers and high reflux ratios are required to achieve good separations.

If membranes are to be used for these separations, highly selective materials must be developed. Several groups have measured the selectivities of polymeric membranes for ethylene/ethane and propylene/propane mixtures. Burns and Koros have reviewed these results [60]. The data should be treated with caution. Some authors report selectivities based on the ratio of the permeabilities of the pure gases; others use a hard vacuum or a sweep gas on the permeate side of the membrane. Both procedures produce unrealistically high selectivities. In an industrial plant, the feed gas will be at 100–150 psig and a temperature sufficient to maintain the gas in the vapor phase; the permeate gas will be at a pressure of 10–20 psig. Under these operating conditions, plasticization and loss of selectivity occur with even the most rigid polymer membranes, so selectivities are usually low. Because of these problems, this application might be one for which the benefits of ceramic or carbon fiber membranes can justify their high cost. Caro *et al.* have recently reviewed the ceramic membrane literature [24].

Dehydration of Air

The final application of gas separation membranes is dehydration of compressed air. The competitive processes are condensation or solid desiccants, both of which are established, low-cost technologies. Membranes with water/air selectivities of more than 500 are known, although actual selectivities obtained in membrane modules are less because of concentration polarization effects. Nonetheless, existing membranes are more than adequate for this separation. The problem inhibiting their application is the loss of compressed feed air through the membrane. Compressed air is typically supplied at about 7 atm (105 psi), so the pressure ratio across the membrane is about 7. Because air dehydration membranes have a selectivity of more than 200, these membranes are completely pressure-ratio-limited. Based on Equation (8.10), this means that the permeate gas cannot be more than seven times more concentrated than the feed. The result is that a significant fraction of the feed gas must permeate the membrane to carry away the permeate water vapor. Typically 15–20% of the pressurized feed gas permeates the membrane, which affects the productivity of the compressor significantly. Counterflow-sweep designs of the type discussed in Chapter 4 are widely used to reduce permeant loss. For this reason, membrane air dehydration systems have not found a wide market except where the reliability and simplicity of the membrane design compared to adsorbents or cooling are particularly attractive.

Conclusions and Future Directions

The application of membranes to gas separation problems has grown rapidly since the installation of the first industrial plants in the early 1980s. The current status of membrane gas separation processes is summarized in Table 8.7, in which the processes are divided into four groups. The first group consists of the established processes: nitrogen production from air, hydrogen recovery and air drying. These processes represent more than 80 % of the current gas separation membrane market. All have been used on a large commercial scale for 10 years, and dramatic improvements in membrane selectivity, flux and process designs have been made during that time. For example, today's hollow fine fiber nitrogen production module generates more than 10 times the amount of nitrogen, with better quality and at a lower energy consumption, than the modules produced in the early 1980s. However, the technology has now reached a point at which, barring a completely unexpected breakthrough, further changes in productivity are likely to be the result of a number of small incremental changes.

Developing processes are the second group of applications. These include carbon dioxide separation from natural gas, organic vapor separation from air and nitrogen, and recovery of light hydrocarbons from refinery and petrochemical plant purge gases. All of these processes are performed on a commercial scale, and in total several hundred plants have been installed. Significant expansion in these applications, driven by the development of better membranes and process designs, is occurring. For example, carbon dioxide removal from natural gas has been practiced using cellulose acetate membranes for more than 15 years. Introduction of more selective and higher-flux membranes has begun and, in time, is likely to make membrane processes much more competitive with amine absorption. The application of silicone rubber vapor separation membranes in petrochemical and refinery applications is currently growing.

The 'to be developed' membrane processes represent the future expansion of gas separation technology. Natural gas treatment processes, including dehydration, natural gas liquids (C_{3+} hydrocarbons) recovery, and hydrogen sulfide removal, are currently being studied at the field testing and early commercial stage by several companies. The market is very large, but the fraction that membranes will ultimately capture is unknown. The production of oxygen-enriched air is another large potential application for membranes. The market size depends completely on the properties of the membranes that can be produced. Improvements of a factor of two in flux at current oxygen/nitrogen selectivities would probably produce a limited membrane market; improvements by a factor of five to ten would make the use of oxygen-enriched air in natural gas combustion processes attractive. In this case the market could be very large indeed. The final application listed in Table 8.7 is the separation of organic vapor mixtures using membranes in competition, or perhaps in combination, with distillation.

Table 8.7 Status of membrane gas separation processes

Process	Application	Comments
Established processes		
Oxygen/nitrogen	Nitrogen from air	Processes are all well developed. Only incremental improvements in performance expected
Hydrogen/methane; hydrogen/nitrogen; hydrogen/carbon monoxide	Hydrogen recovery; ammonia plants and refineries	
Water/air	Drying compressed air	
Developing processes		
VOC/air	Air pollution control applications	Several applications being developed. Significant growth expected as the process becomes accepted
Light hydrocarbons from nitrogen or hydrogen	Reactor purge gas, petrochemical process streams, refinery waste gas	Application is expanding rapidly
Carbon dioxide/methane	Carbon dioxide from natural gas	Many plants installed but better membranes are required to change market economics significantly
To-be-developed processes		
C ₃₊ hydrocarbons/methane	NGL recovery from natural gas	Field trials and demonstration system tests under way. Potential market is large
Hydrogen sulfide, water/methane	Natural gas treatment	Niche applications, difficult for membranes to compete with existing technology
Oxygen/nitrogen	Oxygen enriched air	Requires better membranes to become commercial. Size of ultimate market will depend on properties of membranes developed. Could be very large
Organic vapor mixtures	Separation of organic mixtures in refineries and petrochemical plants	Requires better membranes and modules. Potential size of application is large

9 PERVAPORATION

Introduction and History

The pervaporation process to separate liquid mixtures is shown schematically in Figure 9.1. A feed liquid mixture contacts one side of a membrane; the permeate is removed as a vapor from the other side. Transport through the membrane is induced by the vapor pressure difference between the feed solution and the permeate vapor. This vapor pressure difference can be maintained in several ways. In the laboratory, a vacuum pump is usually used to draw a vacuum on the permeate side of the system. Industrially, the permeate vacuum is most economically generated by cooling the permeate vapor, causing it to condense; condensation spontaneously creates a partial vacuum.

The origins of pervaporation can be traced to the nineteenth century, but the word itself was coined by Kober in 1917 [1]. The process was first studied in a systematic fashion by Binning and co-workers at American Oil in the 1950s [2–5]. Binning was interested in applying the process to the separation of organic mixtures. Although this work was pursued at the laboratory and bench scales for a number of years and several patents were obtained, the process was not commercialized. Membrane technology at that time could not produce the high-performance membranes and modules required for a commercially competitive process. The process was picked up in the 1970s at Monsanto by Eli Perry and others. More than a dozen patents assigned to Monsanto issued from 1973 to 1980 cover a wide variety of pervaporation applications [6], but none of this work led to a commercial process. Academic research on pervaporation was also carried out by Aptel, Neel and others at the University of Toulouse [7,8]. By the 1980s, advances in membrane technology made it possible to prepare economically viable pervaporation systems.

Pervaporation systems are now commercially available for two applications. The first and most important is the removal of water from concentrated alcohol solutions. GFT, now owned by Sulzer, the leader in this field, installed the first pilot plant in 1982 [9]. The ethanol feed to the membrane contains about 10% water. The pervaporation process removes the water as the permeate, producing a residue of pure ethanol containing less than 1% water. All

Figure 9.1 In the pervaporation process, a liquid mixture contacts the membrane, which preferentially permeates one of the liquid components as a vapor. The vapor enriched in the more permeable component is cooled and condensed, spontaneously generating a vacuum that drives the process

the problems of azeotropic distillation are avoided. More than 100 plants have since been installed by Sulzer (GFT) and its licensees for this application [10]. The current largest plant was installed at Bethenville, France in 1988; this unit contains 2400 m² of membranes and processes 5000 kg/h of ethanol. The second commercial application of pervaporation is the removal of small amounts of volatile organic compounds (VOCs) from contaminated water. This technology was developed by Membrane Technology and Research [11–13]; the first commercial plant was sold in 1996.

Both of the current commercial pervaporation processes concentrate on the separation of VOCs from contaminated water. This separation is relatively easy, because organic solvents and water have very different polarities and exhibit distinct membrane permeation properties. No commercial pervaporation systems have yet been developed for the separation of organic/organic mixtures. However, current membrane technology makes pervaporation for these applications possible, and the process is being actively developed by a number of companies. The first pilot-plant results for an organic–organic application, the separation of methanol from methyl *tert*-butyl ether/isobutene mixtures, was reported by Separex in 1988 [14,15]. This is a particularly favorable application

Figure 9.2 Milestones in the development of pervaporation

because available cellulose acetate membranes achieve a good separation. More recently, Exxon, now ExxonMobil, started a pervaporation pilot plant for the separation of aromatic/aliphatic mixtures, a separation problem in refineries; polyimide/polyurethane block copolymer membranes were used [16,17]. A time line illustrating some of the key milestones in the development of pervaporation is shown in Figure 9.2.

Theoretical Background

In Chapter 2 it was shown that the flux of a component i through a pervaporation membrane can be expressed in terms of the partial vapor pressures on either side of the membrane, p_{i_o} and p_{i_ℓ} , by the equation

$$J_i = \frac{P_i^G}{\ell}(p_{i_o} - p_{i_\ell}) \tag{9.1}$$

where J_i is the flux, ℓ is the membrane thickness and P_i^G is the gas separation permeability coefficient. A similar equation can be written for component j . The separation achieved by a pervaporation membrane is proportional to the fluxes J_i and J_j through the membrane.

Equation (9.1) is the preferred method of describing membrane performance because it separates the two contributions to the membrane flux: the membrane contribution, P_i^G/ℓ and the driving force contribution, $(p_{i_o} - p_{i_e})$. Normalizing membrane performance to a membrane permeability allows results obtained under different operating conditions to be compared with the effect of the operating condition removed. To calculate the membrane permeabilities using Equation (9.1), it is necessary to know the partial vapor pressure of the components on both sides of the membrane. The partial pressures on the permeate side of the membrane, p_{i_e} and p_{j_e} , are easily obtained from the total permeate pressure and the permeate composition. However, the partial vapor pressures of components i and j in the feed liquid are less accessible. In the past, such data for common, simple mixtures would have to be found in published tables or calculated from an appropriate equation of state. Now, commercial computer process simulation programs calculate partial pressures automatically for even complex mixtures with reasonable reliability. This makes determination of the feed liquid partial pressures a trivial exercise.

Having said this, the bulk of the pervaporation literature continues to report membrane performance in terms of the total flux through the membrane and a separation factor, β_{pervap} , defined for a two-component fluid as the ratio of the two components on the permeate side of the membrane divided by the ratio of the two components on the feed side of the membrane. The term β_{pervap} can be written in several ways.

$$\beta_{\text{pervap}} = \frac{c_{i_e}/c_{j_e}}{c_{i_o}/c_{j_o}} = \frac{n_{i_e}/n_{j_e}}{n_{i_o}/n_{j_o}} = \frac{p_{i_e}/p_{j_e}}{p_{i_o}/p_{j_o}} \quad (9.2)$$

where c_i and c_j are the concentrations, n_i and n_j are the mole fractions, and p_i and p_j are the vapor pressures of the two components i and j .

The separation factor, β_{pervap} , contains contributions from the intrinsic permeation properties of the membrane, the composition and temperature of the feed liquid, and the permeate pressure of the membrane. The contributions of these factors are best understood if the pervaporation process is divided into two steps, as shown in Figure 9.3 [18]. The first step is evaporation of the feed liquid to form a saturated vapor in contact with the membrane; the second step is diffusion of this vapor through the membrane to the low-pressure permeate side. This two-step description is only a conceptual representation; in pervaporation no vapor phase actually contacts the membrane surface. Nonetheless, the representation of the process shown in Figure 9.3 is thermodynamically completely equivalent to the actual pervaporation process shown in Figure 9.1.

In the process illustrated in Figure 9.3, the first step is evaporation from the feed liquid to form a saturated vapor phase in equilibrium with the liquid. This evaporation step produces a separation because of the different volatilities of the components of the feed liquid. The separation can be defined as β_{evap} , the ratio of the component concentrations in the feed vapor to their concentrations in the

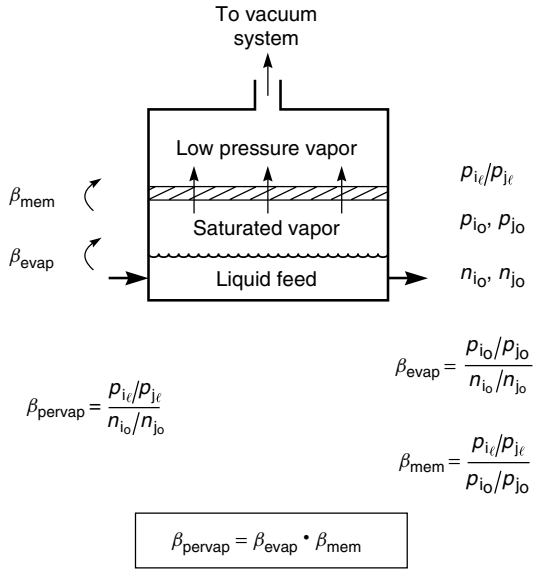

Figure 9.3 The pervaporation process shown in Figure 9.1 can be described by the thermodynamically equivalent process illustrated here. In this model the total pervaporation separation β_{pervap} is made up of an evaporation step followed by a membrane permeation step [18]

feed liquid:

$$\beta_{evap} = \frac{p_{i_o}/p_{j_o}}{n_{i_o}/n_{j_o}} \tag{9.3}$$

The second step in the process is permeation of components i and j through the membrane; this step is equivalent to conventional gas separation. The driving force for permeation is the difference in the vapor pressures of the components in the feed and permeate vapors. The separation achieved in this step, β_{mem} , can be defined as the ratio of the components in the permeate vapor to the ratio of the components in the feed vapor

$$\beta_{mem} = \frac{p_{i_e}/p_{j_e}}{p_{i_o}/p_{j_o}} \tag{9.4}$$

Equation (9.4) shows that the separation achieved in pervaporation is equal to the product of the separation achieved by evaporation of the liquid and the separation achieved by selective permeation through the membrane.¹

$$\beta_{pervap} = \beta_{evap} \cdot \beta_{mem} \tag{9.5}$$

¹Figure 9.3 illustrates the concept of permeation from a saturated vapor phase in equilibrium with the feed liquid as a tool to obtain Equation (9.5). A number of workers have experimentally compared vapor permeation and pervaporation separations and have sometimes shown that permeation from the

The first application of pervaporation was the removal of water from an azeotropic mixture of water and ethanol. By definition, the evaporative separation term β_{evap} for an azeotropic mixture is 1 because, at the azeotropic concentration, the vapor and the liquid phases have the same composition. Thus, the 200- to 500-fold separation achieved by pervaporation membranes in ethanol dehydration is due entirely to the selectivity of the membrane, which is much more permeable to water than to ethanol. This ability to achieve a large separation where distillation fails is why pervaporation is also being considered for the separation of aromatic/aliphatic mixtures in oil refinery applications. The evaporation separation term in these closely boiling mixtures is again close to 1, but a substantial separation is achieved due to the greater permeability of the membrane to the aromatic components.

The β_{pervap} term in Equation (9.2) and Equation (9.5) can be derived in terms of β_{evap} , membrane permeabilities, and membrane operating conditions using the standard solution-diffusion model from Chapter 2. The membrane fluxes can be written as

$$J_i = \frac{P_i^G (p_{i_o} - p_{i_e})}{\ell} \quad (9.6)$$

and

$$J_j = \frac{P_j^G (p_{j_o} - p_{j_e})}{\ell} \quad (9.7)$$

where J is the permeation flux through the membrane, P^G is the permeability coefficient of the vapors i and j , and ℓ is the thickness of the separating layer of the membrane. Dividing Equation (9.6) by Equation (9.7) gives

$$\frac{J_i}{J_j} = \frac{P_i^G (p_{i_o} - p_{i_e})}{P_j^G (p_{j_o} - p_{j_e})} \quad (9.8)$$

The fluxes J_i and J_j in Equation (9.8) are weight fluxes ($\text{g}/\text{cm}^2 \cdot \text{s}$); similarly the permeabilities P_i^G and P_j^G are weight-based ($\text{g} \cdot \text{cm}/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$). Equation (9.8) is more conveniently written in molar terms as

$$\frac{j_i}{j_j} = \frac{\mathcal{P}_i^G (p_{i_o} - p_{i_e})}{\mathcal{P}_j^G (p_{j_o} - p_{j_e})} \quad (9.9)$$

where j_i and j_j are molar fluxes with unit $\text{mols}/\text{cm}^2 \cdot \text{s}$ or $\text{cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s}$ and \mathcal{P}_i and \mathcal{P}_j are molar permeabilities with units $\text{mol} \cdot \text{cm}/\text{cm}^2 \cdot \text{s} \cdot \text{unit pressure}$

liquid is faster and less selective than permeation from the equilibrium vapor. This is an experimental artifact. In vapor permeation experiments the vapor in contact with the membrane is not completely saturated. This means that the activities of the feed components in vapor permeation experiments are less than their activity in pervaporation experiments. Because sorption by the membrane in this range is extremely sensitive to activity, the vapor permeation fluxes are lower than pervaporation fluxes. Kataoka *et al.* [19] have illustrated this point in a series of careful experiments.

or more conventionally $\text{cm}^3(\text{STP}) \cdot \text{cm}/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$. The ratio of the molar membrane permeability coefficients $\mathcal{P}_i^G/\mathcal{P}_j^G$ is the conventional gas membrane selectivity, α_{mem} [see Equation (8.3)].

The ratio of the molar fluxes is also the same as the ratio of the permeate partial pressures

$$\frac{j_i}{j_j} = \frac{p_{i\ell}}{p_{j\ell}} \quad (9.10)$$

Combining Equations (9.4), (9.5), (9.9) and (9.10) yields

$$\beta_{\text{pervap}} = \frac{\beta_{\text{evap}}\alpha_{\text{mem}}(p_{i_o} - p_{i\ell})}{(p_{j_o} - p_{j\ell})(p_{i_o}/p_{j_o})} \quad (9.11)$$

Equation (9.11) identifies the three factors that determine the performance of a pervaporation system. The first factor, β_{evap} , is the vapor–liquid equilibrium, determined mainly by the feed liquid composition and temperature; the second is the membrane selectivity, α_{mem} , an intrinsic permeability property of the membrane material; and the third includes the feed and permeate vapor pressures, reflecting the effect of operating parameters on membrane performance. This equation is, in fact, the pervaporation equivalent of Equation (8.19) that describes gas separation in Chapter 8.

As in gas separation, the separation achieved by pervaporation is determined both by the membrane selectivity and by the membrane pressure ratio. The interaction of these two factors is expressed in Equation (9.11). Also, as in gas separation, there are two limiting cases in which one of the two factors dominates the separation achieved. The first limiting case is when the membrane selectivity is very large compared to the vapor pressure ratio between the feed liquid and the permeate vapor:

$$\alpha_{\text{mem}} \gg \frac{p_o}{p_\ell} \quad (9.12)$$

This means that for a membrane with infinite selectivity for component i , the permeate vapor pressure of component i will equal the feed partial vapor pressure of i . That is,

$$p_{i\ell} = p_{i_o} \quad (9.13)$$

Equation (9.13) combined with Equation (9.4) gives

$$\beta_{\text{mem}} = \frac{p_{j_o}}{p_{j\ell}} \quad (9.14)$$

which, combined with Equation (9.5), leads to the limiting case

$$\beta_{\text{pervap}} = \beta_{\text{evap}} \cdot \frac{p_{j_o}}{p_{j\ell}} \quad \text{when } \alpha_{\text{mem}} \gg \frac{p_o}{p_\ell} \quad (9.15)$$

Similarly, in the case of a very large membrane selectivity in favor of component j

$$\beta_{\text{pervap}} = \beta_{\text{evap}} \frac{p_{i_o}}{p_{i_\ell}} \tag{9.16}$$

For the special case in which component i is the minor component in the feed liquid, p_{j_o} approaches p_o , p_{j_ℓ} approaches p_ℓ , and Equation (9.15) reverts to

$$\beta_{\text{pervap}} = \beta_{\text{evap}} \frac{p_o}{p_\ell} \tag{9.17}$$

where p_o/p_ℓ is the feed-to-permeate ratio of the total vapor pressures.

The second limiting case occurs when the vapor pressure ratio is very large compared to the membrane selectivity. This means that the permeate partial pressure is smaller than the feed partial vapor pressures, and p_{i_ℓ} and $p_{j_\ell} \rightarrow 0$. Equation (9.11) then becomes

$$\beta_{\text{pervap}} = \beta_{\text{evap}} \alpha_{\text{mem}} \text{ when } \alpha_{\text{mem}} \ll \frac{p_o}{p_\ell} \tag{9.18}$$

The relationship between the three separation factors, β_{pervap} , β_{evap} and β_{mem} , is illustrated in Figure 9.4. This type of plot was introduced by Shelden and Thompson [20] to illustrate the effect of permeate pressure on pervaporation separation

Figure 9.4 The effect of permeate pressure on the separation of ethanol/water mixtures with a poly(vinyl alcohol) membrane. The feed solution contains 20 wt% water and 80 wt% ethanol. The line drawn through the experimental data points is calculated from Equation (9.11)

and is a convenient method to represent the pervaporation process graphically. When the permeate pressure, $p_\ell = p_{i_\ell} + p_{j_\ell}$, approaches the feed vapor pressure, $p_o = p_{i_o} + p_{j_o}$, the vapor pressure ratio across the membrane shown on the right-hand axis of the figure approaches unity. The composition of the permeate vapor then approaches the composition obtained by simple evaporation of the feed liquid, shown by the point at which β_{pervap} equals β_{evap} . As the permeate pressure is decreased to below the feed vapor pressure, the vapor pressure ratio increases. The overall separation obtained, β_{pervap} , is then the product of the separation due to evaporation of the feed liquid, β_{evap} , and the separation due to permeation through the membrane, β_{mem} . The line labeled 'permeate' in Figure 9.4 can be calculated from Equation (9.11). Two limiting cases are also shown on the figure. The first limiting case, when the membrane selectivity α_{mem} is much larger than the pressure ratio p_o/p_ℓ , is calculated from Equation (9.15). The second limiting case, for the region in which the membrane selectivity is much smaller than the pressure ratio, is calculated from Equation (9.18). Figure 9.4 is the pervaporation equivalent of Figure 8.13 for gas separation discussed in Chapter 8.

The example shown in Figure 9.4 includes experimental data from GFT, which show the effect of permeate pressure on the pervaporation separation of an 80 wt% aqueous ethanol solution using a highly selective poly(vinyl alcohol) membrane. The line obtained from Equation (9.11) passes through all the data points when the water/ethanol membrane selectivity (α_{mem}) is assumed to be 250. Although this membrane is very selective, a good separation between the feed solution and the permeate vapor is only achieved at low permeate pressures when a high vapor pressure ratio exists across the membrane and the high intrinsic selectivity of the GFT membrane is utilized. For this reason, in practical applications of this membrane the feed solution is heated to about 120 °C (raising the feed vapor pressure to 2–4 atm), and the permeate vapor is condensed at –10 to –20 °C (to lower the vapor pressure of the permeate to about 1 cmHg). This combination achieves the vapor pressure ratio of more than 200 required for a good separation.

Membrane Materials and Modules

Membrane Materials

The selectivity (α_{mem}) of pervaporation membranes critically affects the overall separation obtained and depends on the membrane material. Therefore, membrane materials are tailored for particular separation problems. As with other solution-diffusion membranes, the permeability of a component is the product of the membrane sorption coefficient and the diffusion coefficient (mobility). The membrane selectivity term α_{mem} in Equation (9.11) can be written as

$$\alpha_{\text{mem}} = \frac{\mathcal{P}_i^G}{\mathcal{P}_j^G} = \left(\frac{D_i}{D_j} \right) \left(\frac{K_i}{K_j} \right) \quad (9.20)$$

(see Equation (8.3) in Chapter 8). This expression shows that membrane selectivity is the product of the mobility selectivity (D_i/D_j) of the membrane material, generally governed by the relative mobility of the permeants, and the solubility selectivity (K_i/K_j), generally governed by the chemistry of the membrane material. In gas permeation the total sorption of gases by the membrane material is usually low, often less than 1 wt%, so the membrane selectivity measured with gas mixtures is often close to the selectivity calculated from the ratio of the pure gas permeabilities. In pervaporation the membrane is in contact with the feed liquid, and typical sorptions are 2–20 wt%. Sorption of one of the components of the feed can then change the sorption and diffusion of the second component. As a rule of thumb, the total sorption of the feed liquid by the membrane material should be in the range 3–15 wt%. Below 3 wt% sorption, the membrane selectivity may be good, but the flux through the material will be too low. Above 15 wt% sorption, fluxes will be high, but the membrane selectivity will generally be low because the mobility selectivity will decrease as the material becomes more swollen and plasticized. The sorption selectivity will also tend towards unity.

By manipulating the chemistry of membrane materials, either sorption- or diffusion-selectivity-controlled membranes can be made. The range of results that can be obtained with different membranes with the same liquid mixture is illustrated in Figure 9.5 for the separation of acetone from water [21]. The figure shows the concentration of acetone in the permeate as a function of the concentration in the feed. The two membranes shown have dramatically different properties. The silicone rubber membrane, made from a hydrophobic rubbery material, preferentially sorbs acetone, the more hydrophobic organic compound. For rubbery materials the diffusion selectivity term, which would favor permeation of the smaller component (water), is small. Therefore, the silicone rubber membrane is sorption-selectivity-controlled and preferentially permeates acetone. In contrast, the poly(vinyl alcohol) membrane is made from a hydrophilic, rigid, crosslinked material. Because poly(vinyl alcohol) is hydrophilic, the sorption selectivity favors permeation of water, the more hydrophilic polar component. Also, because poly(vinyl alcohol) is glassy and crosslinked, the diffusion selectivity favoring the smaller water molecules over the larger acetone molecules is substantial [22]. As a result, poly(vinyl alcohol) membranes permeate water several hundred times faster than acetone.

In any membrane process, it is desirable for the minor components to permeate the membrane, so the acetone-selective silicone rubber membrane is best used to treat dilute acetone feed streams, concentrating most of the acetone in a small volume of permeate. The water-selective poly(vinyl alcohol) membrane is best used to treat concentrated acetone feed streams, concentrating most of the water in a small volume of permeate. Both membranes are more selective than distillation, which relies on the vapor–liquid equilibrium to achieve separation.

Figure 9.5 Pervaporation separation of acetone–water mixtures achieved with a water-selective membrane poly(vinyl alcohol) (PVA), and an acetone-selective membrane (silicone rubber) [21]. Reprinted from Hollein *et al.* [21], p. 1051 by courtesy of Marcel Dekker, Inc.

Most pervaporation membranes are composites formed by solution-coating the selective layer onto a microporous support. Some of the more commonly used membranes are listed in Table 9.1. For dehydration of organic solvents, such as ethanol, isopropanol and acetone, several excellent membrane materials are available. The technical and economic feasibility of these processes is controlled by membrane module and system engineering issues rather than by membrane flux and selectivity. Chemically crosslinked poly(vinyl alcohol), formed as a composite membrane by solution casting onto a polyacrylonitrile microporous support, was developed by GFT and has been used for a long time. The poly(vinyl alcohol) layer is crosslinked by heat or addition of crosslinking agents such as glutaraldehyde. This membrane has a water/alcohol selectivity (α_{mem}) of more than 200 [18] and can achieve extremely good separation of water from ethanol or isopropanol solutions. However, the membrane is swollen and even dissolved by hot acid or base solutions such as hot acetic acid or hot aniline. Membranes stable to such feed solutions can be prepared by plasma polymerization [23].

For separating VOCs from water, silicone rubber composite membranes are the state-of-the-art material. Silicone rubber is easy to fabricate, is mechanically and

Table 9.1 Widely used pervaporation membrane materials

Dehydration of organics	
Water/ethanol Water/isopropanol Water/glycol, etc.	Microporous polyacrylonitrile coated with a 5–20 μm layer of crosslinked poly(vinyl alcohol) is the most commonly used commercial material [10]. Chitosan [24] and polyelectrolyte membranes such as Nafion [25,26] have equivalent properties
VOC/water separation	
Toluene/water Trichloroethylene/water Methylene chloride/water	Membranes comprising silicone rubber coated onto polyimides, polyacrylonitrile or other microporous supports membranes are widely used [12,27]. Other rubbers such as ethylene-propylene terpolymers have been reported to have good properties also [28]. Polyamide-polyether block copolymers have also been used for pervaporation of some polar VOCs [29,30]
Organic/organic separation	
	The membrane used depends on the nature of the organics. Poly(vinyl alcohol) and cellulose acetate [14] have been used to separate alcohols from ethers. Polyurethane-polyimide block copolymers have been used for aromatic/aliphatic separations [17]

Table 9.2 Typical silicone rubber membrane module pervaporation separation factors (VOC removal from water)

chemically strong, and has good separation factors for many common organic compounds, as shown in Table 9.2. These representative data were obtained with industrial-scale modules under normal operating conditions. The performance of silicone membranes in laboratory test cells operated under ideal conditions is usually better.

A number of academic studies have produced rubbery hydrophobic membrane materials with far higher selectivities than silicone rubber [27]. For example,

Figure 9.6 Comparative separation factors for toluene and trichloroethylene from water with various rubbery membranes [28]. These experiments were performed with thick films in laboratory test cells. In practice, separation factors obtained with membrane modules are far less because of concentration polarization effects. Reprinted from Nijhuis *et al.* [28], p. 248 with permission of Bakish Materials Corporation, Englewood, NJ

Figure 9.6 shows the separation factors measured by Nijhuis *et al.* [28] for various membranes with dilute toluene and trichloroethylene solutions. The separation factor of silicone rubber is in the 4000–5000 range, but other materials have separation factors as high as 40 000. However, in practice, an increase in membrane separation factor beyond about 1000 provides very little additional benefit. Once a separation factor of this magnitude is obtained, other factors, such as ease of manufacture, mechanical strength, chemical stability, and control of concentration polarization become more important. This is why silicone rubber remains prevalent, even though polymers with higher selectivities are known.

Membranes with improved separation factors would be useful for hydrophilic VOCs such as ethanol, methanol and phenol, for which the separation factor of silicone rubber is in the range 5–10. As yet, no good replacement for silicone rubber has been developed. The most promising results to date have

been obtained with silicone rubber membranes containing dispersed zeolite particles [31]. Apparently, ethanol preferentially permeates the pores of the zeolite particles; membranes have been produced in the laboratory with ethanol/water selectivities of 40 or more. Membranes with these properties could be applied in fermentation processes and solvent recovery if they can be made on a large scale.

Polyamide-polyether block copolymers (Pebax[®], Elf Atochem, Inc., Philadelphia, PA) have been used successfully with polar organics such as phenol and aniline [32–34]. The separation factors obtained with these organics are greater than 100, far higher than the separation factors obtained with silicone rubber. The improved selectivity reflects the greater sorption selectivity obtained with the polar organic in the relatively polar polyamide-polyether membrane. On the other hand, toluene separation factors obtained with polyamide-polyether membranes are below those measured with silicone rubber.

For the separation of organic/organic mixtures, current membranes are only moderately selective, generally because the differences in sorption between different organic molecules are small, and many membrane materials swell excessively in organic solvent mixtures, especially at high temperatures. One approach is to use rigid backbone polymers to control swelling, for example, the Matrimid[®] polyimides developed by Grace [35]. However, the permeability of these materials is often very low. Another approach, used by Exxon [17], is to use block copolymers consisting of rigid polyimide segments that provide a strong network and softer segments formed from more flexible polymers through which permeant transport occurs. The permeation properties of the polymer were varied by tailoring the size and chemistry of the two blocks. Notwithstanding this work, development of more selective membranes is required for application of pervaporation to other important organic/organic separations, such as separation of aromatics from aliphatics, olefins from paraffins, and branched hydrocarbons.

Membrane Modules

Pervaporation applications often involve hot feed solutions containing organic solvents. Such solutions can degrade the seals and plastic components of membrane modules. As a result, the first-generation commercial pervaporation modules used a stainless steel plate-and-frame design. Recently attempts have been made to switch to lower-cost module designs. Texaco, Membrane Technology and Research (MTR) and Separex (UOP) have all used spiral-wound modules for pervaporation, and Zenon developed hollow fiber modules. One particular issue affecting pervaporation module design is that the permeate side of the membrane often operates at a vacuum of less than 100 torr. The pressure drop required to draw the permeate vapor to the permeate condenser may then be a significant fraction of the permeate pressure. Efficient pervaporation modules must have short, porous permeate channels to minimize this permeate pressure drop.

Process Design

Transport through pervaporation membranes is produced by maintaining a vapor pressure gradient across the membrane. As in gas separation, the flux through the membrane is proportional to the vapor pressure difference [Equation (9.1)], but the separation obtained is determined by the membrane selectivity and the pressure ratio [Equation (9.11)]. Figure 9.7 illustrates a number of ways to achieve the required vapor pressure gradient.

In the laboratory, the low vapor pressure required on the permeate side of the membrane is often produced with a vacuum pump, as shown in Figure 9.7(a). In a commercial-scale system, however, the vacuum pump requirement would be impossibly large. In the early days of pervaporation research, the calculated vacuum pump size was sometimes used as proof that pervaporation would never be commercially viable. An attractive alternative to a vacuum pump, illustrated in Figure 9.7(b), is to cool the permeate vapor to condense the liquid; condensation of the liquid spontaneously generates the permeate side vacuum. The feed solution may also be heated to increase the vapor pressure driving force. In this process, sometimes called thermo-pervaporation, the driving force is the difference in vapor pressure between the hot feed solution and the cold permeate liquid at the temperature of the condenser. This type of design is preferred for commercial operations, because the cost of providing the required cooling and heating is much less than the cost of a vacuum pump, and the process is operationally more reliable.

A third possibility, illustrated in Figure 9.7(c), is to sweep the permeate side of the membrane with a counter-current flow of carrier gas. In the example shown, the carrier gas is cooled to condense and recover the permeate vapor, and the gas is recirculated. This mode of operation has little to offer compared to temperature-gradient-driven pervaporation, because both require cooling water for the condenser. However, if the permeate has no value and can be discarded without condensation (for example, in the pervaporative dehydration of an organic solvent with an extremely water-selective membrane), this is the preferred mode of operation. In this case, the permeate would contain only water plus a trace of organic solvent and could be discharged or incinerated at low cost. No permeate refrigeration is required [36].

An alternative carrier-gas system uses a condensable gas, such as steam, as the carrier sweep fluid. One variant of this system is illustrated in Figure 9.7(d). Low-grade steam is often available at low cost, and, if the permeate is immiscible with the condensed carrier, water, it can be recovered by decantation. The condensed water will contain some dissolved organic and can be recycled to the evaporator and then to the permeate side of the module. This operating mode is limited to water-immiscible permeates and to feed streams for which contamination of the feed liquid by water vapor permeating from the sweep gas is not a problem. This idea has been discovered, rediscovered, and patented a number of times, but never used commercially [37,38]. If the permeate is soluble in the condensable

Figure 9.7 Schematics of potential pervaporation process configurations that have been suggested but not necessarily practiced

sweep generated, then the sweep gas is best obtained by evaporating a portion of the residue liquid as shown in Figure 9.7(e). The final pervaporation process, illustrated in Figure 9.7(f), is a system of particular interest for removing low concentrations of dissolved VOCs from water. The arrangement shown is used when the solubility of the permeating solvent in water is limited. In this case, the condensed permeate liquid separates into two phases: an organic phase, which can be treated for reuse, and an aqueous phase saturated with organic, which can be recycled to the feed stream for reprocessing.

In the process designs shown in Figures 9.1 and 9.7, the permeate vapor is condensed to yield a single liquid permeate condensate. A simple improvement

(a) Two-stage fractional condensation [40]

(b) Dephlegmator condensation [39]

Figure 9.8 The use of permeate vapor fractional condensation systems to improve the separation achieved in pervaporation of dilute ethanol solutions: (a) Two-stage fractional condensation [40] and (b) Dephlegmator condensation [39]

to the pervaporation process is to use fractional condensation of the permeate vapor to achieve an improved separation. Two process designs are shown in Figure 9.8. In Figure 9.8(a), the permeate vapor is condensed in two condensers in series. In the example shown, the recovery of ethanol from water, the first (higher temperature) condenser produces a first condensate containing about 5% ethanol that is recycled to the incoming feed. The second (lower temperature) condenser condenses the remaining vapor to produce an ethanol product stream containing about 50% ethanol. This design has not been widely used because the increase in product quality usually does not compensate for the increased complexity of the process.

The condensation system shown in Figure 9.8(b) uses a dephlegmator to achieve the separation required [39]. A dephlegmator in its simplest form is a vertical heat exchanger. Warm, low-pressure permeate vapor from the pervaporation unit enters the dephlegmator at the bottom. As the vapor rises up the column, some condenses on the cold tube wall. The resultant liquid flows downward within the feed passage countercurrent to the rising feed vapor. Mass transfer between the liquid and vapor enriches the liquid in the less volatile components as the more volatile components are revaporized. As a result, several theoretical stages of separation are achieved. The degree of separation achieved can be impressive. In the example shown, the 20 wt% ethanol permeate vapor is separated into 5 wt% bottoms, which is recycled to the pervaporation unit, and a 90–95 wt% overhead ethanol product stream.

Applications

The three current applications of pervaporation are dehydration of solvents, water purification, and organic/organic separations as an alternative to distillation. Currently dehydration of solvents, in particular ethanol and isopropanol, is the only process installed on a large scale. However, as the technology develops, the other applications are expected to grow. Separation of organic mixtures, in particular, could become a major application. Each of these applications is described separately below.

Solvent Dehydration

Several hundred plants have been installed for the dehydration of ethanol by pervaporation. This is a particularly favorable application for pervaporation because ethanol forms an azeotrope with water at 95% and a 99.5% pure product is needed. Because the azeotrope forms at 95% ethanol, simple distillation does not work. A comparison of the separation of ethanol and water obtained by various pervaporation membranes and the vapor–liquid equilibrium line that controls separation obtained by distillation is shown in Figure 9.9 [40]. The membranes

Figure 9.9 Comparison of separation of ethanol/water mixtures by distillation and by three pervaporation membranes: cellulose triacetate (CTA), an anionic polyelectrolyte membrane, and GFT’s poly(vinyl alcohol) (PVA) membrane [40]

all achieve a good separation, but the GFT poly(vinyl alcohol) membrane performance is the best. Most pervaporation dehydration systems installed to date have been equipped with this membrane, although Mitsui is producing zeolite tubular modules [41,42]. Because an ethanol/water azeotrope forms at 95 % ethanol, the concentration of ethanol from fermentation feeds to high degrees of purity requires rectification with a benzene entrainer, some sort of molecular-sieve drying process, or a liquid–liquid extraction process. All of these processes are expensive. However, the availability of extremely water-selective pervaporation membranes allows pervaporation systems to produce almost pure ethanol (>99.9 % ethanol from a 90 % ethanol feed). The permeate stream contains approximately 50 % ethanol and can be returned to the distillation column.

A flow scheme for an integrated distillation–pervaporation plant operating on a 5 % ethanol feed from a fermentation mash is shown in Figure 9.10. The distillation column produces an ethanol stream containing 80–90 % ethanol, which is fed to the pervaporation system. To maximize the vapor pressure difference and the pressure ratio across the membrane, the pervaporation module usually

Figure 9.10 Integrated distillation–pervaporation plant for ethanol recovery from fermentors

operates in the temperature range $105\text{--}130\text{ }^{\circ}\text{C}$ with a corresponding feed stream vapor pressure of 2–6 atm. Despite these harsh conditions, the membrane lifetime is good and manufacturers give qualified guarantees of up to 4 years.

Figure 9.10 shows a single-stage pervaporation unit. In practice, three to five pervaporation units are usually used in series, with additional heat supplied to the ethanol feed between each stage. This compensates for pervaporative cooling of the feed and maintains the feed temperature. The heat required is obtained by thermally integrating the pervaporation system with the condenser of the final distillation column. Therefore, most of the energy used in the process is low-grade heat. Generally, about 0.5 kg of steam is required for each kilogram of ethanol produced. The energy consumption of the pervaporation process is, therefore, about 500 Btu/L of product, less than 20% of the energy used in azeotropic distillation, which is typically about 3000 Btu/L.

Reliable capital and operating cost comparisons between pervaporation and distillation are not available. Pervaporation is less capital and energy intensive than distillation or adsorption processes for small plants treating less than 5000 L/h of feed solution. However, because of the modular nature of the process, the costs of pervaporation are not as sensitive to economies of scale as are the costs of distillation and adsorption processes. Distillation costs, on the other hand, scale at a rate proportional to 0.6–0.7 times the power consumption. Thus, distillation remains the most economical process for large plants. The cross-over point at which distillation becomes preferable to pervaporation from an energy and economic point of view currently appears to be 5000 L/h processing capacity. Bergdorf has made an analysis of the comparative costs of pervaporation, distillation and other processes [43].

Because most of the installed pervaporation alcohol dehydration plants are relatively small, in the 500–5000 L/h range, the membrane module cost is generally only 15–40 % of the total plant cost [44] even when relatively high-cost stainless steel plate-and-frame modules of the type originally developed by GFT are used. Cost savings could undoubtedly be achieved by using more economical spiral-wound or capillary fiber modules, but Sulzer (GFT) apparently does not regard these savings sufficient to cover the significant development costs involved in producing such modules able to operate at 100 °C with hot ethanol solutions. Photographs of the Sulzer (GFT) plate-and-frame module and of an ethanol dehydration system are shown in Figure 9.11 [44].

There is an increasing trend to replace liquid pervaporation with vapor permeation in some dehydration applications, particularly dehydration of ethanol and isopropanol. The main disadvantage of vapor permeation is that energy is used to evaporate the liquid, only a portion of which can be recovered when the vapor streams are ultimately recovered. On the other hand, by evaporating the liquid feed, any dissolved salts and solid contaminants are left in the evaporator, giving a purer product, important in the recovery of isopropanol, for example, in the electronics industry. More importantly, pervaporation requires the feed liquid to be repeatedly reheated to supply the latent heat of evaporation removed by the permeating vapor. The need for interstage reheating complicates the system design and leads to lower average fluxes, as the example calculations of Sander [45] show in Figure 9.12. In liquid pervaporation, the feed stream must be reheated five times as the water concentration drops from 6 to 1 % and the average temperature of the fluid is at about 95 °C. The vapor feed stream, however, requires no reheating and remains at about the initial feed temperature. High

Figure 9.11 Photograph of a 50-m² GFT plate-and-frame module and an ethanol dehydration system fitted with this type of module. The module is contained in the large vacuum chamber on the left-hand side of the pervaporation system [44]

Figure 9.12 Isothermal vapor permeation and multistage pervaporation with intermediate heating. GFT poly(vinyl alcohol) membranes [45]

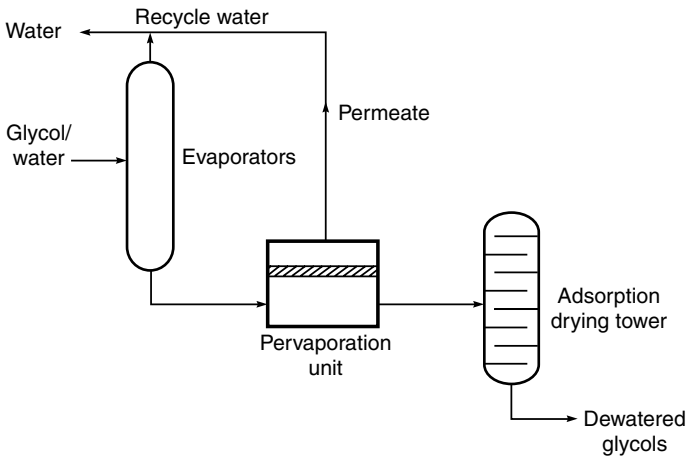

feed temperatures are needed to produce a high vapor pressure driving force to improve membrane separation performance and flux. The improvement in membrane flux achieved by increasing the average feed temperature as little as 5 or 10 °C is significant.

Most of the early solvent dehydration systems were installed for ethanol dehydration. More recently pervaporation has been applied to dehydration of other solvents, particularly isopropanol used as a cleaning solvent. Dehydration of other solvents, including glycols, acetone and methylene chloride, has been considered. Schematics of pervaporation processes for these separations are shown in Figure 9.13.

Dewatering of glycol is a difficult separation by distillation alone, so a hybrid process of the type shown in Figure 9.13(a) has been proposed. The product of the distillation step is approximately 90% glycol/10% water. This mixture is then sent to a pervaporation unit to remove most of the water as a dischargeable product. The glycol concentrate produced by the pervaporation unit contains 1–2 wt% water and can be sent to an optional adsorption dryer if further dehydration is required.

Figure 9.13(b) shows the use of pervaporation to dry a chlorinated solvent, in this case water-saturated ethylene dichloride containing 2000 ppm water. A poly(vinyl alcohol) dehydration membrane can easily produce a residue containing less than 10 ppm water and a permeate containing about 50 wt% water. On condensation the permeate vapor separates into two phases, a very small water

(a) Glycol/water separation process

(b) Dehydration of Ethylene Dichloride (EDC)

Figure 9.13 Other solvent dehydration processes under investigation

phase that can be discharged and an ethylene dichloride phase that can be recycled to the incoming feed.

A final interesting application of dehydration membranes is to shift the equilibrium of chemical reactions. For example, esterification reactions of the type

are usually performed in batch reactors, and the degree of conversion is limited by buildup of water in the reactor. By continuously removing the water, the equilibrium reaction can be forced to the right. In principle, almost complete conversion can be achieved. This process was first suggested by Jennings and

Binning in the 1960s [46]. A number of groups have since studied this type of process, and at least one commercial plant has been installed [47–49].

Separation of Dissolved Organics from Water

A number of applications exist for pervaporation to remove or recover VOCs from water. If the aqueous stream is very dilute, pollution control is the principal economic driving force. However, if the stream contains more than 1–2 % VOC, recovery for eventual reuse can enhance the process economics.

Several types of membrane have been used to separate VOCs from water and are discussed in the literature [11,28]. Usually the membranes are made from rubbery polymers such as silicone rubber, polybutadiene, natural rubber, and polyamide-polyether copolymers. Rubbery pervaporation membranes are remarkably effective at separating hydrophobic organic solutes from dilute aqueous solutions. The concentration of VOCs such as toluene or trichloroethylene (TCE) in the condensed permeate is typically more than 1000 times that in the feed solution. For example, a feed solution containing 100 ppm of such VOCs yields a permeate vapor containing 10–20 % VOC. This concentration is well above the saturation limit, so condensation produces a two-phase permeate. This permeate comprises an essentially pure condensed organic phase and an aqueous phase containing a small amount of VOC that can be recycled to the aqueous feed. The flow scheme for this process is shown in Figure 9.7(f). The separations achieved with moderately hydrophobic VOCs, such as ethyl acetate, methylene chloride and butanol, are still impressive, typically providing at least 100-fold enrichment in the permeate. However, the separation factors obtained with hydrophilic solvents, such as methanol, acetic acid and ethylene glycol, are usually modest, at 5 or below [8].

Some data showing measured pervaporation separation factors for dilute aqueous VOC solutions are shown in Figure 9.14, in which the total separation factor, β_{pervap} , is plotted against the theoretical evaporative separation factor, β_{evap} , obtained from the equation of state. Two sets of data, both obtained with silicone rubber membranes, are shown. One set was obtained with thick membranes in laboratory test cells under very well stirred conditions [33] that largely eliminate concentration polarization. The other set was obtained with high-flux membranes in spiral-wound modules [12]. The difference between the curves is due to the concentration polarization effects discussed in Chapter 4. With VOCs such as acetone, methyl ethyl ketone (MEK) and ethyl acetate, the difference between separation factors measured in the laboratory test cells and in spiral-wound modules is relatively small. The difference becomes very large for more hydrophobic VOCs with high separation factors. Concentration polarization effects reduce the separation factor for VOCs such as toluene or TCE 5- to 10-fold.

The data in Figure 9.14 also allow determination of the relative contributions of the evaporative separation term β_{evap} and the membrane selectivity term β_{mem}

Figure 9.14 Pervaporation separation factor, β_{pervap} , as a function of the VOC evaporation separation factor, β_{evap} . Data obtained with laboratory-scale spiral-wound modules containing a composite silicone rubber membrane and in laboratory cells with thick membranes

to the total separation achieved by pervaporation β_{pervap} [Equation (9.5)]. Earlier it was shown that membranes used to dehydrate ethanol achieved almost all of the total pervaporation separation as a result of a high membrane selectivity term, in the 100–500 range. With these membranes the evaporative separation term was usually close to 1. In the case of the separation of VOCs from water, the relative contribution of evaporation and membrane permeation to the separation is quite different. For example, MEK has a pervaporation separation factor of approximately 280. In this case, the evaporation contribution β_{evap} is 40; therefore, from Equation (9.5), the membrane contribution β_{mem} is 7. For more hydrophobic VOCs, the total separation factor increases, because the evaporative separation term is larger. For example, the separation factor β_{pervap} for toluene measured in cell experiments is an impressive 10 000, but most of the separation is due to the evaporation step β_{evap} , which is 8000. The membrane contribution β_{mem} is only 1.2, and the approximate selectivity of the membrane falls to 0.3 when concentration polarization effects are taken into account.

Concentration polarization plays a dominant role in the selection of membrane materials, operating conditions, and system design in the pervaporation of VOCs from water. Selection of the appropriate membrane thickness and permeate pressure is discussed in detail elsewhere [50]. In general, concentration polarization effects are not a major problem for VOCs with separation factors less than 100–200. With solutions containing such VOCs, very high feed velocities through

Figure 9.15 Once-through pervaporation system design. This design is most suitable for removal of VOCs with modest separation factors for which concentration polarization is not a problem

the membrane modules are not needed to control concentration polarization, so a once-through process design as illustrated in Figure 9.15 can be used. In the once-through design, the membrane modules are arranged in series, and the feed solution only passes through the modules once. The velocity of the solution in the modules is determined by the number of modules in series and the feed flow rate. With VOCs having modest separation factors, such a system can provide both adequate fluid velocities to control concentration polarization and sufficient residence time within the module to remove the required amount of VOC from the feed. With VOCs having large separation factors, such as toluene and TCE, it is difficult to balance the fluid velocity required to control concentration polarization with the residence time required to achieve the target VOC removal in a single pass.

For treating water containing VOCs with separation factors of more than 500, for which concentration polarization is a serious problem, feed-and-bleed systems similar to those described in the chapter on ultrafiltration can be used. For small feed volumes a batch process as illustrated in Figure 9.16 is more suitable. In a batch system, feed solution is accumulated in a surge tank. A portion of this solution is then transferred to the feed tank and circulated at high velocity through the pervaporation modules until the VOC concentration reaches the desired level. At this time, the treated water is removed from the feed tank, the tank is loaded with a new batch of untreated solution, and the cycle is repeated.

Applications for VOC-from-water pervaporation systems include treatment of contaminated wastewaters and process streams in the chemical industry, removal of small amounts of VOCs from contaminated groundwater, and the recovery of volatile flavor and aroma elements from streams produced in the processing of fruits and vegetables. A number of factors enter into the selection of pervaporation over a competing technology:

- *VOC type.* Pervaporation is best applied to recovery of VOCs with medium to high volatility, for which separation factors of 50 or more can be achieved.

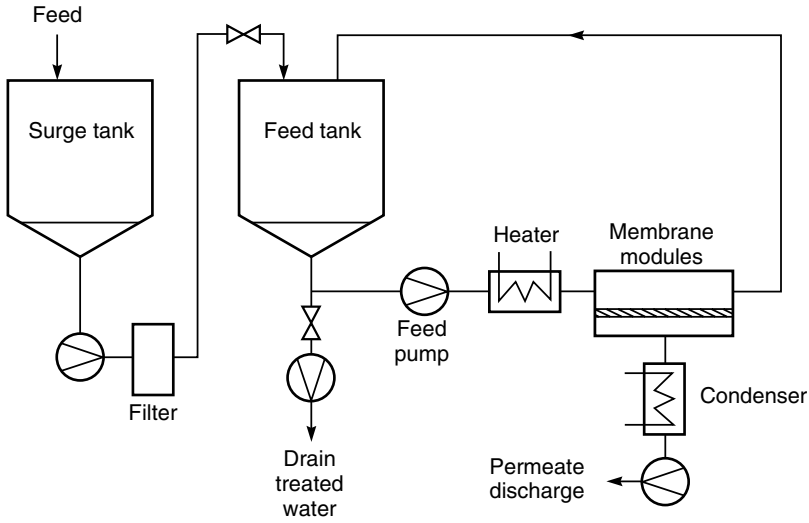

Figure 9.16 Flow diagram and typical performance for a 50-gal cyclic batch pervaporation system. The treatment time for the first 50-gal batch was set at 120 min because the unit was cold; thereafter, the cycle time was set at 90 min. The system achieved 99.8% removal of toluene from the feed water [13]

These VOCs are normally more hydrophobic than acetone and have a Henry's law coefficient of greater than about 2 atm/mol fraction.

- *VOC concentration.* In general, the optimum VOC concentration range for pervaporation is 200–50 000 ppm (5 wt%). In this range, the conventional technology is steam stripping. Generally streams containing more than 5 wt% organic are better treated by distillation or, if the organic has no recovery value, simply incinerated. If the water contains less than 100 ppm VOC, recovery of the VOC is not an objective, so a destructive technology such as UV oxidation is used, or the stream is treated by air stripping followed by carbon adsorption to remove the VOC from the effluent air stream.
- *Stream flow rate.* The costs of pervaporation, like other membrane processes, increase linearly with increasing system size, whereas processes such as steam stripping scale to the 0.6–0.7 power. This makes pervaporation most competitive for small- to medium-sized streams. For streams containing highly volatile VOCs with Henry's law coefficients greater than 100 atm/mol fraction, pervaporation will generally be limited to streams smaller than 100 gal/min. For moderately volatile VOCs (0.5–100 atm/mol fraction), pervaporation is preferred for streams smaller than 10–20 gal/min. Steam stripping is preferred for very large streams or for those containing VOCs with a poor pervaporation VOC/water separation factor.
- *VOC thermal stability.* Separation of VOCs from water by pervaporation generally requires heating the feed water to only 50–70 °C. This is significantly lower than the temperatures involved in distillation or steam stripping, a considerable advantage if the VOCs are valuable, thermally labile compounds. This feature is important in applications such as flavor and aroma recovery in the food industry.

Commercial development of pervaporation for VOC removal/recovery has been slower than many predicted; only a few plants have been installed. The first significant applications are likely to be in the food industry, processing aqueous condensate streams generated in the production of concentrated orange juice, tomato paste, apple juice and the like. These condensates contain a complex mixture of alcohols, esters and ketones that are the flavor elements of the juice. Steam distillation could be used to recover these elements, but the high temperatures involved would damage the product. Pervaporation recovers essentially all of these components, producing a concentrated, high-value oil without exposing the flavor elements to high temperatures [51,52]. Figure 9.17 shows gas chromatography (GC) traces of the feed and permeate streams produced by pervaporation of an orange juice evaporator condensate stream.

Another potential pervaporation application is removing small amounts of VOCs from industrial wastewaters, allowing the water to be discharged to the sewer and concentrating the VOCs in a small-volume stream that can be sent to a hazardous waste treater [13]. Without a treatment system such as pervaporation,

Figure 9.17 GC traces showing recovery of flavor and aroma components from orange juice evaporator condensate

the entire waste stream would have to be trucked off site. The avoided trucking cost can be considerable; a photograph of a batch pervaporation system installed for this purpose is shown in Figure 9.18.

Separation of Organic Mixtures

The third application area for pervaporation is the separation of organic/organic mixtures. The competitive technology is generally distillation, a well-established and familiar technology. However, a number of azeotropic and close-boiling organic mixtures cannot be efficiently separated by distillation; pervaporation can be used to separate these mixtures, often as a combination membrane-distillation process. Lipnizki *et al.* have recently reviewed the most important applications [53].

The degree of separation of a binary mixture is a function of the relative volatility of the components, the membrane selectivity, and the operating conditions. For azeotropic or close-boiling mixtures, the relative volatility is close to 1, so separation by simple distillation is not viable. However, if the membrane permeation selectivity is much greater than 1, a significant separation is possible using pervaporation. An example of such a separation is given in Figure 9.19, which shows a plot of the pervaporation separation of benzene/cyclohexane mixtures

Figure 9.18 Photograph of a 300–500 gal/day pervaporation system installed to treat wastewater contaminated with methylene chloride. This system has been operating at Applied Biosystems in Redwood City, California since 1995 [13]

using a 20- μm -thick crosslinked cellulose acetate-poly(styrene phosphate) blend membrane [54]. The vapor–liquid equilibrium for the mixture is also shown; the benzene/cyclohexane mixture forms an azeotrope at approximately 50 % benzene. A typical distillation stage could not separate a feed stream of this composition. However, pervaporation treatment of this mixture produces a vapor permeate containing more than 95 % benzene. This example illustrates the advantages of pervaporation over simple distillation for separating azeotropes and close-boiling mixtures.

It would be unusual for a pervaporation process to perform an entire organic/organic separation. Rather, pervaporation will be most efficient when combined with distillation in a hybrid process [55]. The two main applications of pervaporation–distillation hybrid processes are likely to be in breaking azeotropes and in removing a single-component, high-purity side stream from a multicomponent distillation separation. Figure 9.20 shows some potential pervaporation–distillation combinations. In Figure 9.20(a) pervaporation is combined with distillation to break an azeotrope that is concentrated in one component (>90 %). This approach is used in the production of high-purity ethanol. The ethanol/water azeotrope from the top of the distillation column is fed to a pervaporation unit where the water is removed as the permeate and returned to the column as a reflux.

Figure 9.19 Fraction of benzene in permeate as a function of feed mixture composition for pervaporation at the reflux temperature of a binary benzene/cyclohexane mixture. A 20- μm -thick crosslinked blend membrane of cellulose acetate and poly(styrene phosphate) was used [54]. Reprinted with permission from I. Cabasso, *Organic Liquid Mixtures Separation by Selective Polymer Membranes*, *Ind. Eng. Chem. Prod. Res. Dev.* **22**, 313. Copyright 1983 American Chemical Society

Figure 9.20(b) illustrates the use of pervaporation with two distillation columns to break a binary azeotrope such as benzene/cyclohexane. The feed is supplied at the azeotropic composition and is split into two streams by the pervaporation unit. The residue stream, rich in cyclohexane, is fed to a distillation column that produces a pure bottom product and an azeotropic top stream, which is recycled to the pervaporation unit. Similarly, the other distillation column treats the benzene-rich stream to produce a pure benzene product and an azeotropic mixture that is returned to the pervaporation unit.

Pervaporation can also be used to unload a distillation column, thereby reducing energy consumption and operating cost and increasing throughput. The example shown in Figure 9.20(c) is for the recovery of pure methanol by pervaporation of a side stream from a column separating a methanol/isobutene/methyl tertiary butyl ether (MTBE) feed mixture [14,15].

The principal problem hindering the development of commercial systems for organic/organic separations is the lack of membranes and modules able to withstand long-term exposure to organic compounds at the elevated temperatures required for pervaporation. Membrane and module stability problems are not

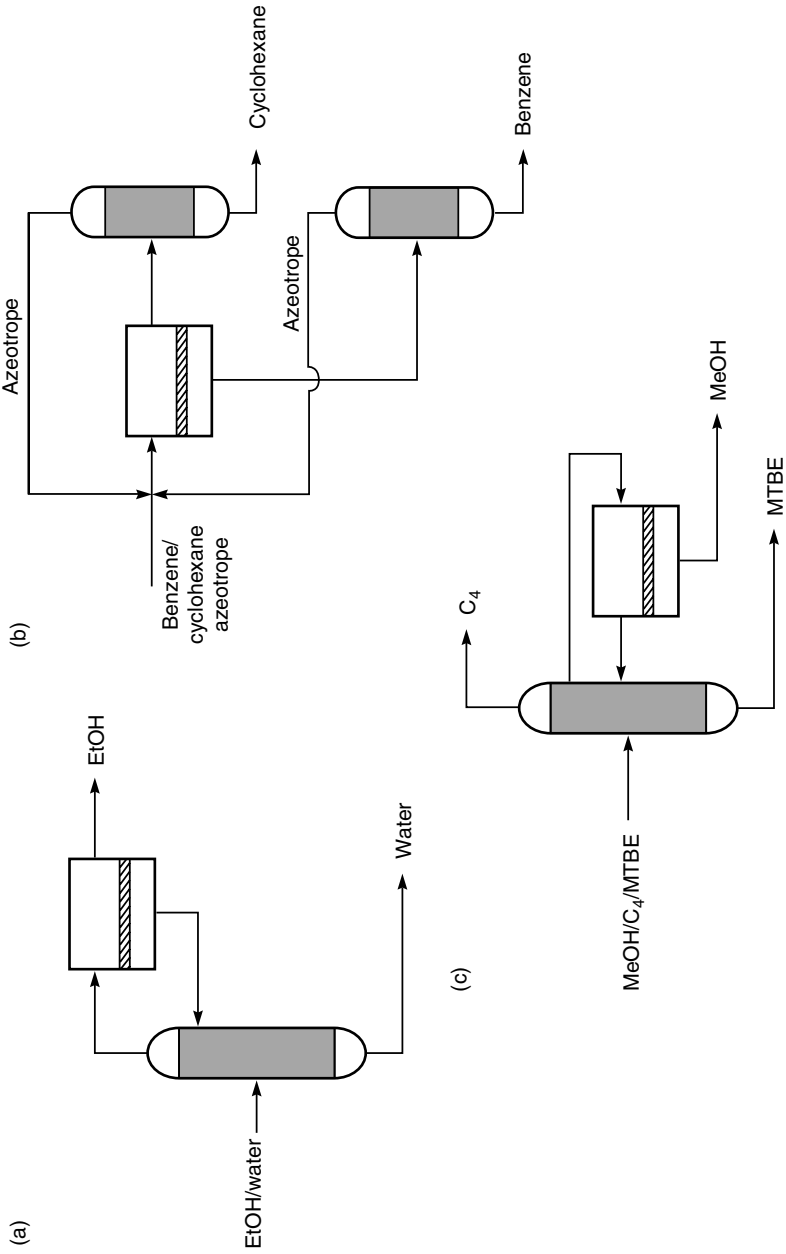

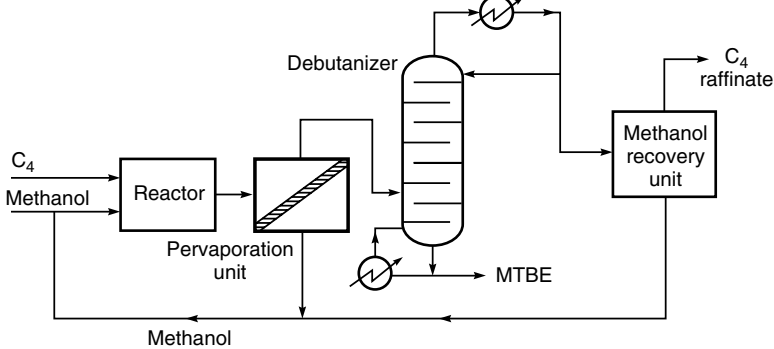

Figure 9.20 Potential configurations for pervaporation–distillation hybrid processes

MTBE Reaction Chemistry

insurmountable, however, as shown by the successful demonstration of a pervaporation process for the separation of methanol from an isobutene/MTBE mixture. This mixture is generated during the production of MTBE; the product from the reactor is an alcohol/ether/hydrocarbon mixture in which the alcohol/ether and the alcohol/hydrocarbon both form azeotropes. The product stream is treated by

pervaporation to yield a methanol-enriched permeate, which can be recycled to the etherification process. Two alternative ways of integrating the pervaporation process into a complete reaction scheme are illustrated in Figure 9.21.

The process shown in Figure 9.21 was first developed by Separex, using cellulose acetate membranes. The separation factor for methanol from MTBE is high (>1000) because the membrane material, cellulose acetate, is relatively glassy and hydrophilic. Thus, both the mobility selectivity term and the sorption term in Equation (9.5) significantly favor permeation of the smaller molecule, methanol, because methanol is more polar than MTBE or isobutene, the other feed components. These membranes are reported to work well for feed methanol concentrations up to 6%. Above this concentration, the membrane is plasticized, and selectivity is lost. More recently, Sulzer (GFT) has also studied this separation using their plasma-polymerized membrane [56].

Another application that has developed to the pilot scale is the separation of aromatic/aliphatic mixtures in refining crude oils into transportation fuels [16,17,57]. For hydrocarbons with approximately the same boiling point range, the permeability is generally in the order aromatics $>$ unsaturated hydrocarbons $>$ saturated hydrocarbons. For aliphatic hydrocarbons in approximately the same boiling point range, the order of permeabilities is straight chain $>$ cyclic chain $>$ branched chain. The goal in these processes is to perform a bulk separation of the hydrocarbon mixture by pervaporation; therefore, the membrane must be highly permeable and selective. The general approach [17,58] is to prepare segmented block copolymers consisting of hard segments not swollen by the hydrocarbon oil, to control the swelling of the soft segments through which the oil would permeate. Crosslinking was also used to control swelling of the membrane materials, polyester-polyimide and polyurea-polyurethane polymers.

Recently Sulzer, working with Grace Davison [35,59] and using polyimide, polysiloxane or polyurea urethane membranes, and ExxonMobil [60], using Nafion[®] or cellulose triacetate membranes, have described processes to separate sulfur compounds from various refinery streams.

Conclusions and Future Directions

During the 10 years after GFT installed the first commercial pervaporation plant in 1982, there was a surge of interest in all types of pervaporation. Much of this interest has now ebbed, and the number of companies involved in developing pervaporation has decreased considerably. The oil companies Texaco, British Petroleum and Exxon, all of which had large research groups working on pervaporation problems in the 1980s, with the exception mentioned above, seem to have abandoned this approach. The key problem seems to be economic. Pervaporation is a competitive technology on a small scale, but current membranes and modules are insufficiently selective and economical to compete with distillation, steam stripping, or solvent extraction in larger plants. As a result, most of the

systems sold are small, and the total value of new systems installed annually is probably less than US\$5 million/year. This market is likely to expand over the next few years, particularly if recovery of high-value aroma and flavor elements in food processing operations meets the developers' expectations.

10 ION EXCHANGE MEMBRANE PROCESSES— ELECTRODIALYSIS

Introduction and History

Ion exchange membranes are used in a number of separation processes, the most important of which is electrodialysis. In ion exchange membranes, charged groups are attached to the polymer backbone of the membrane material. These fixed charge groups partially or completely exclude ions of the same charge from the membrane. This means that an anionic membrane with fixed positive groups excludes positive ions but is freely permeable to negatively charged ions. Similarly a cationic membrane with fixed negative groups excludes negative ions but is freely permeable to positively charged ions, as illustrated in Figure 10.1.

In an electrodialysis system, anionic and cationic membranes are formed into a multicell arrangement built on the plate-and-frame principle to form up to 100 cell pairs in a stack. The cation and anion exchange membranes are arranged in an alternating pattern between the anode and cathode. Each set of anion and cation membranes forms a cell pair. Salt solution is pumped through the cells while an electrical potential is maintained across the electrodes. The positively charged cations in the solution migrate toward the cathode and the negatively charged anions migrate toward the anode. Cations easily pass through the negatively charged cation exchange membrane but are retained by the positively charged anion exchange membrane. Similarly, anions pass through the anion exchange membrane but are retained by the cation exchange membrane. The overall result of the process is that one cell of the pair becomes depleted of ions while the adjacent cell becomes enriched in ions. The process, which is widely used to remove dissolved ions from water, is illustrated in Figure 10.2.

Experiments with ion exchange membranes were described as early as 1890 by Ostwald [1]. Work by Donnan [2] a few years later led to development of the concept of membrane potential and the phenomenon of Donnan exclusion. These early charged membranes were made from natural materials or chemically

Figure 10.1 This cationic membrane with fixed carboxylic acid groups is permeable to cations such as sodium but is impermeable to anions such as chloride

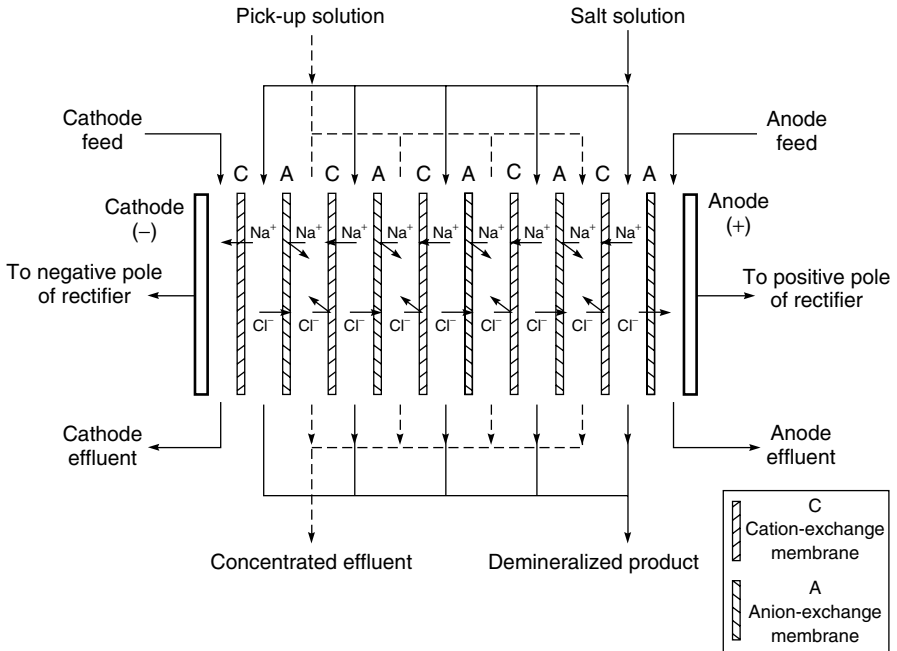

Figure 10.2 Schematic diagram of a plate-and-frame electrodiagnosis stack. Alternating cation- and anion-permeable membranes are arranged in a stack of up to 100 cell pairs

treated collodion membranes—their mechanical and chemical properties were very poor. Nonetheless, as early as 1939, Manegold and Kalauch [3] suggested the application of selective anionic and cationic exchange membranes to separate ions from water, and within another year Meyer and Strauss [4] described the concept of a multicell arrangement between a single pair of electrodes. The advances in polymer chemistry during and immediately after the Second World War led to the production of much better ion exchange membranes by Kressman [5], Murphy *et al.* [6] and Juda and McRae [7] at Ionics. With the development of these membranes, electro dialysis became a practical process. Ionics was the principal early developer and installed the first successful plant in 1952; by 1956 eight plants had been installed.

In the United States, electro dialysis was developed primarily for desalination of water, with Ionics being the industry leader. In Japan, Asahi Glass, Asahi Chemical (a different company), and Tokuyama Soda developed the process to concentrate seawater [8]. This application of electro dialysis is confined to Japan, which has no domestic salt sources. Electro dialysis membranes concentrate the salt in seawater to about 18–20% solids, after which the brine is further concentrated by evaporation and the salt recovered by crystallization.

All of the electro dialysis plants installed in the 1950s through the 1960s were operated unidirectionally, that is, the polarity of the two electrodes, and hence the position of the dilute and concentrated cells in the stack, were fixed. In this mode of operation, formation of scale on the membrane surface by precipitation of colloids and insoluble salts was often a severe problem. To prevent scale, pH adjustment and addition of antiscaling chemicals to the feed water was required, together with regular membrane cleaning using detergents and descaling chemicals. Nevertheless, scaling and membrane fouling remained major problems, affecting plant on-stream time and widespread acceptance of the process. In the early 1970s, a breakthrough in system design, known as electro dialysis polarity reversal, was made by Ionics [9]. In these systems the polarity of the DC power applied to the membrane electrodes is reversed two to four times per hour. When the electrode polarity is reversed, the desalted water and brine chambers are also reversed by automatic valves that control the flows in the stack. By switching cells and reversing current direction, freshly precipitated scale is flushed from the membrane before it can solidify. The direction of movement of colloidal particulates drawn to the membrane by the flow of current is also reversed, so colloids do not form a film on the membrane. Electro dialysis plants using the reverse polarity technique have been operating since 1970 and have proved more reliable than their fixed polarity predecessors.

Electro dialysis is now a mature technology, with Ionics remaining the worldwide industry leader except in Japan. Desalting of brackish water and the production of boiler feed water and industrial process water were the main applications until the 1990s, but electro dialysis has since lost market share due to stiff competition from improved reverse osmosis membranes. Beginning in the 1990s,

electrodeionization, a combination process using electrodialysis and ion exchange, began to be used to achieve very good salt removal in ultrapure water plants. This is now a major use of electrodialysis. Other important applications are control of ionic impurities from industrial effluent streams, water softening and desalting certain foods, particularly milk whey [10,11]. Over the last 20 years a number of other uses of ion exchange membranes have been found. Perhaps the most important is the development by Asahi, Dow and DuPont of perfluoro-based ion exchange membranes with exceptional chemical stability for membrane chlor-alkali cells [12]. More than 1 million square meters of these membranes have been installed. Ion exchange membranes are also finding an increasing market in electrolysis processes of all types. One application that has received a great deal of attention is the use of bipolar membranes to produce acids and alkalis by electrolysis of salts. Bipolar membranes are laminates of anionic and cationic membranes. The first practical bipolar membranes were developed by K.J. Liu and others at Allied Chemicals in about 1977 [13]; they were later employed in Allied's Aquatech acid/base production process [14]. A final, growing use of ion exchange membranes is in advanced fuel cells and battery systems in which the membranes regulate ion transport from various compartments in the cells [15]. A time line illustrating the major milestones in the development of ion exchange membranes is shown in Figure 10.3.

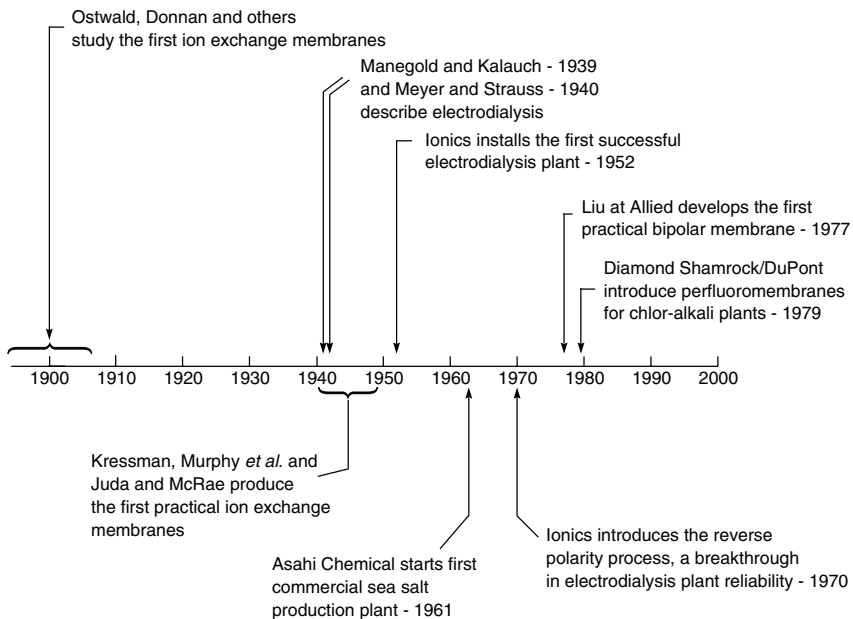

Figure 10.3 Milestones in the development of ion exchange membrane processes

Theoretical Background

Transport Through Ion Exchange Membranes

In electro dialysis and the other separation processes using ion exchange membranes, transport of components generally occurs under the driving forces of both concentration and electric potential (voltage) gradients. However, because the two types of ion present, anions and cations, move in opposite directions under an electric potential gradient, ion exchange membrane processes are often more easily treated in terms of the amount of charge transported than the amount of material transported. Consider, for example, a simple univalent–univalent electrolyte such as sodium chloride, which can be considered to be completely ionized in dilute solutions. The concentration of sodium cations is then c^+ , and the concentration of chloride anions is c^- . The velocity of the cations in an externally applied field of strength, E , is u (cm/s), and the velocity of the anions measured in the same direction is $-v$ (cm/s). Each cation carries the protonic charge $+e$ and each anion the electronic charge of $-e$, so the total amount of charge transported per second across a plane of 1 cm^2 area is

$$\frac{I}{F} = c^+(u)(+e) + c^-(-v)(-e) = ce(u + v) \quad (10.1)$$

where I is the current and F is the Faraday constant to convert transport of electric charge to a current flow in amps. This equation links the electric current with the transport of ions.

It has been found that the fractions of the current carried by the anions and cations do not necessarily have to be equal. The fraction of the total current carried by any particular ion is known as the transport number of that ion. Thus, the transport number for the cations is t^+ and the transport number for the anions is t^- . It follows that

$$t^+ + t^- = 1 \quad (10.2)$$

Combining Equations (10.1) and (10.2), the transport number of the cations in the univalent–univalent electrolyte described above is given as

$$t^+ = \frac{c^+ue}{ce(u + v)} = \frac{u}{u + v} \quad (10.3)$$

and similarly for the anion

$$t^- = \frac{v}{u + v} \quad (10.4)$$

Transport numbers for different ions, even in aqueous solutions, can vary over a wide range, reflecting the different sizes of the ions. Ions with the same charge as the fixed charge groups in an ion exchange membrane are excluded from the membrane and, therefore, carry a very small fraction of the current through the membrane. In these membranes the transport number of the excluded ions is

very small, normally between 0 and 0.05. Counter ions with a charge opposite to the fixed charged groups permeate the membrane freely and carry almost all of the current through the membrane. The transport numbers of these ions are between 0.95 and 1.0. This difference in transport number, a measure of relative permeability, allows separations to be achieved with ion exchange membranes.

Equation (10.1) shows that, as in other transport processes, the flux of the permeating component is the product of a mobility term (u or v) and a concentration term (c^+ or c^-). In ion exchange transport processes, most of the separation is achieved by manipulating the concentration terms. When the membrane carries fixed charges, the counter ions of the same charge will tend to be excluded from the membrane. As a result, the concentration of ions of the same charge is reduced, while the concentration of ions of opposite charge is elevated. This makes the membrane selective for ions of the opposite charge.

The ability of ion exchange membranes to discriminate between oppositely charged ions was put on a mathematical basis by Donnan in 1911 [2]. Figure 10.4 shows the distribution of ions between a salt solution and an ion exchange membrane containing fixed negative charges, R^- .

The equilibrium between the ions in the membrane (m) and the surrounding solution (s) can be expressed as

$$c^+_{(m)} \cdot c^-_{(m)} = kc^+_{(s)} \cdot c^-_{(s)} \quad (10.5)$$

where k is an equilibrium constant. Charge balance considerations lead to the expression

$$c^+_{(m)} = c^-_{(m)} + c_{R^-(m)} \quad (10.6)$$

Figure 10.4 An illustration of the distribution of ions between a cationic membrane with fixed negative ions and the surrounding salt solution

For a fully dissolved salt, such as sodium chloride, the total molar concentration of the salt $c_{(s)}$ is equal to the concentration of each of the ions, so

$$c_{(s)} = c^+_{(s)} = c^-_{(s)} \quad (10.7)$$

Combining these three equations and rearranging gives the expression

$$\frac{c^+_{(m)}}{c^-_{(m)}} = \frac{[c^-_{(m)} + c_{R^-}_{(m)}]^2}{k[c_{(s)}]^2} \quad (10.8)$$

Because the membrane is cationic (fixed negative charges), the concentration of negative counter-ions in the membrane will be small compared to the concentration of fixed charges, that is,

$$c_{R^-}_{(m)} \gg c^-_{(m)} \quad (10.9)$$

Figure 10.5 The sodium-to-chloride ion concentration ratio inside a negatively charged ion exchange membrane containing a concentration of fixed negative groups of 3 meq/g as a function of salt concentration. At salt concentrations in the surrounding solution of less than about 1 wt% sodium chloride (0.2 meq/g), chloride ions are almost completely excluded from the membrane

so it can be assumed that

$$c_{(m)}^{-} + c_{R-(m)}^{-} \approx c_{R-(m)}^{-} \quad (10.10)$$

Equation (10.8) can then be written

$$\frac{c_{(m)}^{+}}{c_{(m)}^{-}} = \frac{1}{k} \left(\frac{c_{R-(m)}^{-}}{c_{(s)}} \right)^2 \quad (10.11)$$

This expression shows that the ratio of sodium to chloride ions in the membrane ($c_{(m)}^{+}/c_{(m)}^{-}$) is proportional to the square of the ratio of the fixed charge groups in the membrane to the salt concentration in the surrounding solution ($c_{R-(m)}^{-}/c_{(s)}$). In the commonly used ion exchange membranes, the fixed ion concentration in the membrane is very high, typically at least 3–4 milliequivalents per gram (meq/g). Figure 10.5 shows a plot of the sodium-to-chloride concentration ratio in a cationic membrane calculated using Equation (10.11). The ion exchange membrane is assumed to have a fixed negative charge concentration of 3 meq/g. The plot shows that, at salt solution concentrations of less than 0.2 meq/g (~ 1 wt% sodium chloride), chloride ions are almost completely excluded from the ion exchange membrane. This means that in this concentration range the transport number for sodium is close to one and for chloride is close to zero. Only at high salt concentrations—above about 0.6 meq/g (3 wt% sodium chloride)—does the ratio of sodium to chloride ions in the membrane fall below 30, and the membrane becomes measurably permeable to chloride ions.

Chemistry of Ion Exchange Membranes

A wide variety of ion exchange membrane chemistries has been developed. Typically each electrodialysis system manufacturer produces its own membrane tailored for the specific applications and equipment used. An additional complication is that many of these developments are kept as trade secrets or are only described in the patent literature. Korngold [16] gives a description of ion exchange membrane manufacture.

Current ion exchange membranes contain a high concentration of fixed ionic groups, typically 3–4 meq/g or more. When placed in water, these ionic groups tend to absorb water; charge repulsion of the ionic groups can then cause the membrane to swell excessively. This is why most ion exchange membranes are highly crosslinked to limit swelling. However, high crosslinking densities make polymers brittle, so the membranes are usually stored and handled wet to allow absorbed water to plasticize the membrane. Most ion exchange membranes are

produced as homogenous films 50–200 μm thick. Typically the membrane is reinforced by casting onto a net or fabric to maintain the shape and to minimize swelling.

Ion exchange membranes fall into two broad categories: homogeneous and heterogeneous. In homogeneous membranes, the charged groups are uniformly distributed through the membrane matrix. These membranes swell relatively uniformly when exposed to water, the extent of swelling being controlled by their crosslinking density. In heterogeneous membranes, the ion exchange groups are contained in small domains distributed throughout an inert support matrix, which provides mechanical strength. Heterogeneous membranes can be made, for example, by dispersing finely ground ion exchange particles in a polymer support matrix. Because of the difference in the degree of swelling between the ion exchange portion and the inert portion of heterogeneous membranes, mechanical failure, leading to leaks at the boundary between the two domains, can be a problem.

Homogeneous Membranes

A number of early homogeneous membranes were made by simple condensation reactions of suitable monomers, such as phenol–formaldehyde condensation reactions of the type:

The mechanical stability and ion exchange capacity of these condensation resins were modest. A better approach is to prepare a suitable crosslinked base membrane, which can then be converted to a charged form in a subsequent reaction. Ionics is believed to use this type of membrane in many of their systems. In a typical preparation procedure, a 60:40 mixture of styrene and divinyl benzene is cast onto a fabric web, sandwiched between two plates and heated in an oven to form the membrane matrix. The membrane is then sulfonated with 98 % sulfuric acid or a concentrated sulfur trioxide solution. The degree of swelling in the final membrane is controlled by varying the divinyl benzene concentration in the initial mix to control crosslinking density. The degree of sulfonation can also be varied. The chemistry of the process is:

Anion exchange membranes can be made from the same crosslinked polystyrene membrane base by post-treatment with monochloromethyl ether and aluminum chloride to introduce chloromethyl groups into the benzene ring, followed by formation of quaternary amines with trimethyl amine:

A particularly important category of ion exchange polymers is the perfluoro-carbon type made by DuPont under the trade name Nafion[®] [17,18]. The base

polymer is made by polymerization of a sulfinol fluoride vinyl ether with tetrafluoroethylene. The copolymer formed is extruded as a film about 120 μm thick, after which the sulfinol fluoride groups are hydrolyzed to form sulfonic acid groups:

Asahi Chemical [8] and Tokuyama Soda [19] have developed similar chemistries in which the $\text{---CF}_2\text{SO}_2\text{F}$ groups are replaced by carboxylic acid groups. In these perfluoro polymers, the backbone is extremely hydrophobic whereas the charged acid groups are strongly polar. Because the polymers are not crosslinked, some phase separation into different domains takes place. The hydrophobic perfluoro-polymer domains provide a nonswelling matrix, ensuring the integrity of the membrane. The ionic hydrophilic domains absorb water and form as small clusters distributed throughout the perfluoro-polymer matrix. This configuration, illustrated in Figure 10.6, minimizes both the hydrophobic interaction of ions and water with the backbone and the electrostatic repulsion of close sulfonate groups. These perfluorocarbon membranes are completely inert to concentrated sodium hydroxide solutions and have been widely used in membrane electrochemical cells in the chlor-alkali industry.

Figure 10.6 Schematic of the cluster model used to describe the distribution of sulfonate groups in perfluorocarbon-type cation exchange membranes such as Nafion [18]

Heterogeneous Membranes

Heterogeneous membranes have been produced by a number of Japanese manufacturers. The simplest form has very finely powdered cation or anion exchange particles uniformly dispersed in polypropylene. A film of the material is then extruded to form the membrane. The mechanical properties of these membranes are often poor because of swelling of the relatively large—10–20 μm diameter—ion exchange particles. A much finer heterogeneous dispersion of ion exchange particles, and consequently a more stable membrane, can be made with a poly(vinyl chloride) (PVC) plastisol. A plastisol of approximately equal parts PVC, styrene monomer and crosslinking agent in a dioctyl phthalate plasticizing solvent is prepared. The mixture is then cast and polymerized as a film. The PVC and polystyrene polymers form an interconnected domain structure. The styrene groups are then sulfonated by treatment with concentrated sulfuric acid or sulfur trioxide to form a very finely dispersed but heterogeneous structure of sulfonated polystyrene in a PVC matrix, which provides toughness and strength.

Transport in Electrodialysis Membranes

Concentration Polarization and Limiting Current Density

Transport of ions in an electrodialysis cell, in which the salt solutions in the chambers formed between the ion exchange membranes are very well stirred, is shown in Figure 10.7. In this example, chloride ions migrating to the left easily

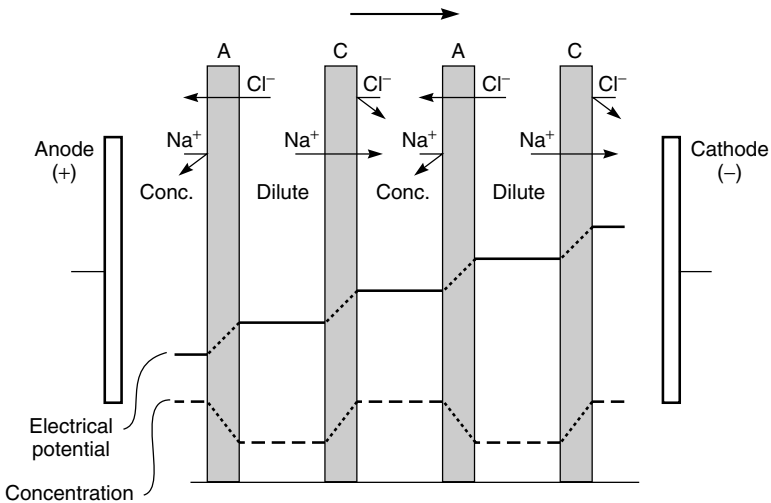

Figure 10.7 Schematic of the concentration and potential gradients in a well-stirred electrodialysis cell

permeate the anionic membranes containing fixed positive groups and are stopped by the cationic membranes containing fixed negative groups. Similarly, sodium ions migrating to the right permeate the cationic membranes but are stopped by the anionic membranes. The overall result is increased salt concentration in alternating compartments while the other compartments are simultaneously depleted of salt. The drawing shown implies that the voltage potential drop caused by the electrical resistance of the apparatus takes place entirely across the ion exchange membrane. This is the case for a very well-stirred cell, in which the solutions in the compartments are completely turbulent. In a well-stirred cell the flux of ions across the membranes and hence the productivity of the electro dialysis system can be increased without limit by increasing the current across the stack. In practice, however, the resistance of the membrane is often small in proportion to the resistance of the water-filled compartments, particularly in the dilute compartment where the concentration of ions carrying the current is low. In this compartment the formation of ion-depleted regions next to the membrane places an additional limit on the current and hence the flux of ions through the membranes. Ion transport through this ion-depleted aqueous boundary layer generally controls electro dialysis system performance.

Concentration polarization controls the performance of practical electro dialysis systems. Because ions selectively permeate the membrane, the concentration of some of the ions in the solution immediately adjacent to the membrane surface becomes significantly depleted compared to the bulk solution concentration. As the voltage across the stack is increased to increase the flux of ions through the membrane, the solution next to the membrane surface becomes increasingly depleted of the permeating ions. Depletion of the salt at the membrane surface means that an increasing fraction of the voltage drop is dissipated in transporting ions across the boundary layer rather than through the membrane. Therefore the energy consumption per unit of salt transported increases significantly. A point can be reached at which the ion concentration at the membrane surface is zero. This represents the maximum transport rate of ions through the boundary layer. The current through the membrane at this point is called the limiting current density, that is, current per unit area of membrane (mA/cm^2). Once the limiting current density is reached, any further increase in voltage difference across the membrane will not increase ion transport or current through the membrane. Normally the extra power is dissipated by side reactions, such as dissociation of the water in the cell into ions, and by other effects. Concentration polarization can be partially controlled by circulating the salt solutions at high flow rates through the cell chambers. But even when very turbulent flow is maintained in the cells, significant concentration polarization occurs.

The formation of concentration gradients caused by the flow of ions through a single cationic membrane is shown in Figure 10.8. As in the treatment of concentration polarization in other membrane processes, the resistance of the aqueous solution is modeled as a thin boundary layer of unstirred solution separating the

Figure 10.8 Schematic of the concentration gradients adjacent to a single cationic membrane in an electro dialysis stack. The effects of boundary layers that form on each side of the membrane on sodium ion concentrations are shown

membrane surface from the well-stirred bulk solution. In electro dialysis the thickness (δ) of this unstirred layer is generally 20–50 μm . Concentration gradients form in this layer because only one of the ionic species is transported through the membrane. This species is depleted in the boundary layer on the feed side and enriched in the boundary layer on the permeate side.

Figure 10.8 shows the concentration gradient of univalent sodium ions next to a cationic membrane. Exactly equivalent gradients of anions, such as chloride ions, form adjacent to the anionic membranes in the stack. The ion gradient formed on the left, dilute side of the membrane can be described by Fick's law. Thus the rate of diffusion of cations to the surface is given by:

$$J^+ = D^+ \frac{(c^+ - c_{(o)}^+)}{\delta} \quad (10.12)$$

where D^+ is the diffusion coefficient of the cation in water, c^+ is the bulk concentration of the cation in the solution, and $c_{(o)}^+$ is the concentration of the cation in the solution adjacent to the membrane surface (o).

The rate at which the cations approach the membrane by electrolyte transport is t^+I/F . It follows that the total flux of sodium ions to the membrane surface (J^+) is the sum of these two terms

$$J^+ = \frac{D^+(c^+ - c_{(o)}^+)}{\delta} + \frac{t^+I}{F} \quad (10.13)$$

Transport through the membrane is also the sum of two terms, one due to the voltage difference, the other due to the diffusion caused by the difference in ion concentrations on each side of the membrane. Thus, the ion flux through the membrane can be written

$$J^+ = \frac{t_{(m)}^+ I}{F} + \frac{P^+(c_{(o)}^+ - c_{(\ell)}^+)}{\ell} \quad (10.14)$$

where P^+ is the permeability of the sodium ions in a membrane of thickness ℓ . The quantity $P^+(c_{(o)}^+ - c_{(\ell)}^+)/\ell$ is much smaller than transport due to the voltage gradient, so Equations (10.13) and (10.14) can be combined and simplified to

$$\frac{D^+(c^+ - c_{(o)}^+)}{\delta} + \frac{t^+ I}{F} = \frac{t_{(m)}^+ I}{F} \quad (10.15)$$

For a selective cationic ion exchange membrane for which $t_{(m)}^+ \approx 1$, Equation (10.15) can be further simplified to

$$I = \frac{F}{1 - t^+} \cdot \frac{D^+}{\delta} (c^+ - c_{(o)}^+) \quad (10.16)$$

This important equation has a limiting value when the concentration of the ion at the membrane surface is zero ($c_{(o)}^+ \approx 0$). At this point the current reaches its maximum value; the limiting current is given by the equation

$$I_{\text{lim}} = \frac{D^+ F c^+}{\delta(1 - t^+)} \quad (10.17)$$

This limiting current, I_{lim} , is the maximum current that can be employed in an electro dialysis process. If the potential required to produce this current is exceeded, the extra current will be carried by other processes, first by transport of anions through the cationic membrane and, at higher potentials, by hydrogen and hydroxyl ions formed by dissociation of water. Both of these undesirable processes consume power without producing any separation. This decreases the current efficiency of the process, that is, the separation achieved per unit of power consumed. A more detailed discussion of the effect of the limiting current density on electro dialysis performance is given by Krol *et al.* [20].

The limiting current can be determined experimentally by plotting the electrical resistance across the membrane stack against the reciprocal electric current. This is called a Cowan–Brown plot after its original developers [21]; Figure 10.9 shows an example for a laboratory cell [22]. At a reciprocal current of 0.1/A, the resistance has a minimum value. When the limiting current is exceeded, the excess current is not used to transport ions. Instead the current causes water to dissociate into protons and hydroxyl ions. The pH of the solutions in the cell chambers then begins to change, reflecting this water splitting. This change in pH, also shown in Figure 10.9, can be used to determine the value of the

Figure 10.9 Cowan–Brown plots showing how the limiting current density can be determined by measuring the stack resistance or the pH of the dilute solution as a function of current [22]. Redrawn from R. Rautenbach and R. Albrecht, *Membrane Processes*, Copyright © 1989. This material is used by permission of John Wiley & Sons, Ltd

limiting current density. In industrial-scale electro dialysis systems, determining the limiting current is not so easy. In large membrane stacks the boundary layer thickness will vary from place to place across the membrane surface. The limiting current, where the boundary layer is relatively thick because of poor fluid flow distribution, will be lower than where the boundary layer is thinner. Thus, the measured limiting current may be only an approximate value. In practice, systems are operated at currents substantially below the limiting value.

The limiting current density for an electro dialysis system operated at the same feed solution flow rate is a function of the feed solution salt concentration, as shown in Equation (10.17). As the salt concentration in the solution increases, more ions are available to transport current in the boundary layer, so

Figure 10.10 Limiting current density and operating current density as a function of feed water salt concentration. The change in slope of the curves at about 3000 ppm salt reflects the change in the activity coefficient of the ions at high salt concentrations [23]

the limiting current density also increases. For this reason large electro dialysis systems with several electro dialysis stacks in series will operate with different current densities in each stack, reflecting the change in the feed water concentration as salt is removed. The normal range of limiting current densities and actual operating current densities used in an electro dialysis system is shown in Figure 10.10[23]. These values may change depending on the particular cell design employed.

Current Efficiency and Power Consumption

A key factor determining the overall efficiency of an electro dialysis process is the energy consumed to perform the separation. Energy consumption E in kilowatts, is linked to the current I through the stack and the resistance R of the stack by the expression

$$E = I^2 R \quad (10.18)$$

The theoretical electric current I_{theor} required to perform the separation is directly proportional to the number of charges transported across the ion exchange

membrane and is given by the expression

$$I_{\text{theor}} = z\Delta C F Q \quad (10.19)$$

where Q is the feed flow rate, ΔC is the difference in molar concentration between the feed and the dilute solutions, z is the valence of the salt and F is the Faraday constant. Thus the theoretical power consumption E_{theor} to achieve a given separation is given by substituting Equation (10.19) into Equation (10.18) to give:

$$E_{\text{theor}} = IRz\Delta C Q F \quad (10.20)$$

or

$$E_{\text{theor}} = Vz\Delta C Q F \quad (10.21)$$

where V is the theoretical voltage drop across the stack. In the absence of concentration polarization and any resistance losses in the membrane or solution compartments, the energy required to achieve a separation and a flow of ions out of the concentrated feed solution into the dilute solution for any cell pair is as shown in Figure 10.11.

Figure 10.11 Comparison of the theoretical energy consumption and the actual energy consumption of electrodesalination systems. Most of the difference results from concentration polarization effects [24]

The actual voltage drop and hence the energy consumed are higher than the theoretical value for two reasons [24]. First, as shown in Figure 10.8, the concentrations of ions in the solutions adjacent to the membrane surfaces are significantly lower than the bulk solution values. That is, the actual voltage drop used in Equation (10.21) is several times larger than the voltage drop in the absence of polarization. The result is to increase the actual energy consumption five to ten times above the theoretical minimum value. In commercial electro dialysis plants, concentration polarization is controlled by circulating the solutions through the stack at a high rate. Various feed spacer designs are used to maximize turbulence in the cells. Because electric power is used to power the feed and product solution circulation pumps, a trade-off exists between the power saved because of the increased efficiency of the electro dialysis stack and the power consumed by the pumps. In current electro dialysis systems, the circulation pumps consume approximately one-quarter to one-half of the total power. Even under these conditions concentration polarization is not fully controlled and actual energy consumption is substantially higher than the theoretical value.

Most inefficiencies in electro dialysis systems are related to the difficulty in controlling concentration polarization. The second cause is current utilization losses, arising from the following factors [10]:

1. Ion exchange membranes are not completely semipermeable; some leakage of co-ions of the same charge as the membrane can occur. This effect is generally negligible at low feed solution concentrations, but can be serious with concentrated solutions, such as the seawater treated in Japan.
2. Ions permeating the membrane carry solvating water molecules in their hydration shell. Also, osmotic transport of water from the dilute to the concentrated chambers can occur.
3. A portion of the electric current can be carried by the stack manifold, bypassing the membrane cell. Modern electro dialysis stack designs generally make losses due to this effect negligible.

System Design

An electro dialysis plant consists of several elements:

- a feed pretreatment system;
- the membrane stack;
- the power supply and process control unit;
- the solution pumping system.

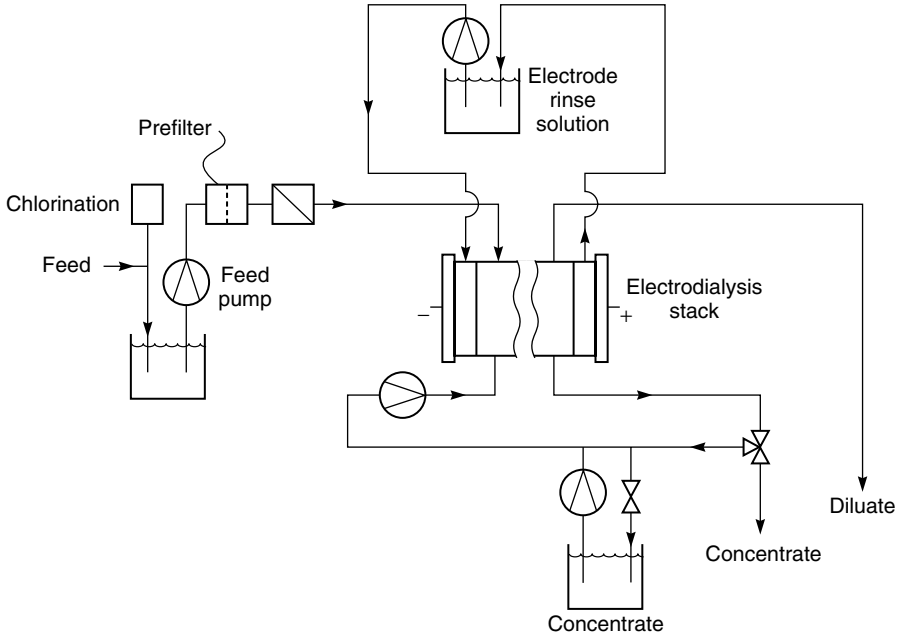

Figure 10.12 Flow diagram of a typical electrodiagnosis plant [10]

Many plants use a single electrodiagnosis stack, as shown in Figure 10.12. Manifolding may be used to allow the feed and brine solutions to pass through several cell pairs, but the entire procedure is performed in the single stack.

In large systems, using several electrodiagnosis stacks in series to perform the same overall separation is more efficient [25]. The current density of the first stack is higher than the current density of the last stack, which is operating on a more dilute feed solution. As in the single-stack system, the feed solution may pass through several cell pairs in each stack. Because concentration polarization becomes more important as the solution becomes more dilute, the solution velocity increases in the stacks processing the most dilute solution. The velocity is controlled by the number of cell pairs through which the solution passes in each stack. The number of cell pairs decreases from the first to the last stack; this is known as the taper of the system. The flow scheme of a three-stage design is shown in Figure 10.13.

Feed Pretreatment. The type and complexity of the feed pretreatment system depends on the content of the water to be treated. As in reverse osmosis, most feed water is sterilized by chlorination to prevent bacterial growth on the membrane.

Figure 10.13 Flow scheme of a three-stage electro dialysis plant [25]. Reprinted from A.N. Rogers, Design and Operation of Desalting Systems Based on Membrane Processes, in *Synthetic Membrane Processes*, G. Belfort (ed.), Academic Press, Copyright 1977, with permission from Elsevier

Scaling on the membrane surface by precipitation of sparingly soluble salts such as calcium sulfate is usually controlled by adding precipitation inhibitors such as sodium hexametaphosphate. The pH may also be adjusted to maintain salts in their soluble range. Large, charged organic molecules or colloids such as humic acid are particularly troublesome impurities, because they are drawn by their charge to the membrane surface but are too large to permeate. They then accumulate at the dilute solution side of the membrane and precipitate, causing an increase in membrane resistance. Filtration of the feed water may control these components, and operation in the polarity reversal mode is often effective.

Membrane Stack. After the pretreatment step, the feed water is pumped through the electro dialysis stack. This stack normally contains 100–200 membrane cell pairs each with a membrane area between 1 and 2 m². Plastic mesh spacers form the channels through which the feed and concentrate solutions flow. Most manufacturers use one of the spacer designs shown in Figure 10.14. In the tortuous path cell design of Figure 10.14(a), a solid spacer grid forms a long open channel through which the feed solution flows at relatively high velocity. The channel is not held open by netting, so the membranes must be thick and sturdy to prevent collapse of the channels. In the sheet flow design of Figure 10.14(b), the gap between the membrane leaves is maintained by a polyolefin mesh spacer. The spacer is made as thin as possible without producing an excessive pressure drop.

Two membranes and two gasket spacers form a single cell pair. Holes in the gasket spacers are aligned with holes in the membrane sheet to form the manifold

Figure 10.14 The two main types of feed solution flow distribution spacers used in electro dialysis [10]

channels through which the dilute and concentrated solutions are introduced into each cell. The end plate of the stack is a rigid plastic frame containing the electrode compartment. The entire arrangement is compressed together with bolts between the two end flow plates. The perimeter gaskets of the gasket spacers are tightly pressed into the membranes to form the cells. A large electro dialysis stack has several hundred meters of fluid seals around each cell. Early units often developed small leaks over time, causing unsightly salt deposits on the outside of the stacks. These problems have now been largely solved. In principle, an electro dialysis stack can be disassembled and the membranes cleaned or replaced on-site. In practice, this operation is performed infrequently and almost never in the field.

Power Supply and Process Control Unit. Electro dialysis systems use large amounts of direct current power; the rectifier required to convert AC to DC and to control the operation of the system represents a significant portion of a plant's capital cost. A typical voltage drop across a single cell pair is in the range 1–2 V and the normal current flow is 40 mA/cm². For a 200-cell-pair stack containing 1 m² of membrane, the total voltage is about 200–400 V and the current about

400 A per stack. This is a considerable amount of electric power, and care must be used to ensure safe operation.

Solution Pumping System. A surprisingly large fraction of the total power used in electro dialysis systems is consumed by the water pumps required to circulate feed and concentrate solutions through the stacks. This fraction increases as the average salt concentration of the feed decreases and can become dominant in electro dialysis of low-concentration solutions (less than 500 ppm salt). The pressure drop per stack varies from 15 to 30 psi for sheet flow cells to as much as 70–90 psi for tortuous path cells. Depending on the separation required, the fluid will be pumped through two to four cells in series, requiring interstage pumps for each stack.

Applications

Brackish Water Desalination

Brackish water desalination is the largest application of electro dialysis. The competitive technologies are ion exchange for very dilute saline solutions, below 500 ppm, and reverse osmosis for concentrations above 2000 ppm. In the 500–2000 ppm range electro dialysis is often the low-cost process. One advantage of electro dialysis applied to brackish water desalination is that a large fraction, typically 80–95 % of the brackish feed, is recovered as product water. However, these high recoveries mean that the concentrated brine stream produced is five to twenty times more concentrated than the feed. The degree of water recovery is limited by precipitation of insoluble salts in the brine.

Since the first plants were produced in the early 1950s, several thousand brackish water electro dialysis plants have been installed around the world. Modern plants are generally fully automated and require only periodic operator attention. This has encouraged production of many small trailer-mounted plants. However, a number of large plants with production rates of 10 million gal/day or more have also been installed.

The power consumption of an electro dialysis plant is directly proportional to the salt concentration of the feed water, varying from 4 kWh/1000 gal for 1000 ppm feed water to 10–15 kWh/1000 gal for 5000 ppm feed water. About one-quarter to one-third of this power is used to drive the feed water circulation pumps.

Salt Recovery from Seawater

The second major application of electro dialysis is the production of table salt by concentration of seawater [8]. This process is only practiced in Japan, which has no other domestic salt supply. The process is heavily subsidized by the

Figure 10.15 Flow scheme of the electro dialysis unit used in a seawater salt concentration plant [8]

government, and total production is approximately 1.2 million tons/year of salt. In total, these plants use more than 500 000 m² of membrane.

A flow scheme of one such seawater salt production plant is shown in Figure 10.15. A cogeneration unit produces the power required for the electro dialysis operation, which concentrates the salt in sea water to about 18–20 wt%. The waste stream from the power plant is then used to further concentrate the salt by evaporation.

Seawater contains relatively high concentrations of sulfate (SO₄²⁻), calcium (Ca²⁺), magnesium (Mg²⁺) and other multivalent ions that can precipitate in the concentrated salt compartments of the plant and cause severe scaling. This problem has been solved by applying a thin polyelectrolyte layer of opposite charge to the ion exchange membrane on the surface facing the seawater solution. A cross-section of a coated anionic membrane is shown in Figure 10.16.

Figure 10.16 Polyelectrolyte-coated ion exchange membranes used to separate multivalent and monovalent ions in seawater salt concentration plants [8]

Because the Donnan exclusion effect is much stronger for multivalent ions than for univalent ions, the polyelectrolyte layer rejects multivalent ions but allows the univalent ions to pass relatively unhindered.

Other Electrodialysis Separation Applications

The two water desalination applications described above represent the majority of the market for electrodialysis separation systems. A small application exists in softening water, and recently a market has grown in the food industry to desalt whey and to remove tannic acid from wine and citric acid from fruit juice. A number of other applications exist in wastewater treatment, particularly regeneration of waste acids used in metal pickling operations and removal of heavy metals from electroplating rinse waters [11]. These applications rely on the ability of electrodialysis membranes to separate electrolytes from nonelectrolytes and to separate multivalent from univalent ions.

The arrangement of membranes in these systems depends on the application. Figure 10.17(a) shows a stack comprising only cation exchange membranes to soften water, whereas Figure 10.17(b) shows an all-anion exchange membrane stack to deacidify juice [26]. In the water-softening application, the objective is to exchange divalent cations such as calcium and magnesium for sodium ions. In the juice deacidification process, the all-anion stack is used to exchange citrate ions for hydroxyl ions. These are both ion exchange processes, and the salt concentration of the feed solution remains unchanged.

Continuous Electrodeionization and Ultrapure Water

Electrodeionization systems were first suggested to remove small amounts of radioactive elements from contaminated waters [27], but the principal current application is the preparation of ultrapure water for the electronics and pharmaceutical industries [28]. The process is sometimes used as a polishing step after the water has been pretreated with a reverse osmosis unit.

In the production of ultrapure water for the electronics industry, salt concentrations must be reduced to the ppb range. This is a problem with conventional electrodialysis units because the low conductivity of very dilute feed water streams generally limits the process to producing water in the 10 ppm range. This limitation can be overcome by filling the dilute chambers of the electrodialysis stack with fine mixed-bed ion exchange beads as shown in Figure 10.18. The ions enter the chamber, partition into the ion exchange resin beads and are concentrated many times. As a result ion and current flow occur through the resin bed, and the resistance of the cell is much lower than for a normal cell operating on the same very dilute feed. An additional benefit is that, towards the bottom of the bed where the ion concentration is in the ppb range, a certain amount of water splitting occurs. This produces hydrogen and hydroxyl ions that also migrate to the membrane surface through the ion exchange beads. The presence of these ions maintains a high pH in the anion exchange beads and a low pH in the cation exchange beads. These extreme pHs enhance the ionization and removal of weakly ionized species such as carbon dioxide and silica that would otherwise be difficult to remove. Such modified electrodialysis systems can reduce most ionizable solutes to below ppb levels.

Bipolar Membranes

Bipolar membranes consist of an anionic and a cationic membrane laminated together [13]. When placed between two electrodes, as shown in Figure 10.19, the interface between the anionic and cationic membranes becomes depleted of ions. The only way a current can then be carried is by the water splitting reaction, which liberates hydrogen ions that migrate to the cathode and hydroxyl ions that

Figure 10.20 Schematic of a bipolar membrane process to split sodium chloride into sodium hydroxide and hydrochloric acid

migrate to the anode. The mechanism of water splitting in these membranes has been discussed in detail by Strathmann *et al.* [29]. The phenomenon can be utilized in an electro dialysis stack composed of a number of sets of three-chamber cells between two electrodes, as shown in Figure 10.20. Salt solution flows into the middle chamber; cations migrate to the chamber on the left and anions to the chamber on the right. Electrical neutrality is maintained in these chambers by hydroxyl and hydrogen ions provided by water splitting in the bipolar membranes that bound each set of three chambers [30].

Several other arrangements of bipolar membranes can achieve the same overall result, namely, dividing a neutral salt into the conjugate acid and base. The process is limited to the generation of relatively dilute acid and base solutions. Also, the product acid and base are contaminated with 2–4 % salt. Nevertheless the process is significantly more energy efficient than the conventional electrolysis process because no gases are involved. Total current efficiency is about 80 % and the system can often be integrated into the process generating the feed salt solution. A process utilizing bipolar membranes was first reported by Liu in 1977 [13]. Aquatech, originally a division of Allied Chemicals and now part of Graver Water, has pursued commercialization of the process for almost 20 years, but only a handful of plants have been installed. The principal problem appears to have been membrane instability, but these problems may now have been solved. Prospects for the process appear to be improving. A recent review of bipolar membrane technology has been produced by Kemperman [31].

Three other processes using ion exchange membranes (Donnan dialysis, diffusion dialysis and piezodialysis) are covered in Chapter 13.

Conclusions and Future Directions

Electrodialysis is by far the largest use of ion exchange membranes, principally to desalt brackish water or (in Japan) to produce concentrated brine. These two processes are both well established, and major technical innovations that will change the competitive position of the industry do not appear likely. Some new applications of electrodialysis exist in the treatment of industrial process streams, food processing and wastewater treatment systems but the total market is small. Long-term major applications for ion exchange membranes may be in the non-separation areas such as fuel cells, electrochemical reactions and production of acids and alkalis with bipolar membranes.

11 CARRIER FACILITATED TRANSPORT

Introduction and History

Carrier facilitated transport membranes incorporate a reactive carrier in the membrane. The carrier reacts with and helps to transport one of the components of the feed across the membrane. Much of the work on carrier facilitated transport has employed liquid membranes containing a dissolved carrier agent held by capillary action in the pores of a microporous film.

The types of transport that can occur in a liquid membrane are illustrated in Figure 11.1. Passive diffusion down a concentration gradient is the most familiar—this process is usually relatively slow and nonselective. In facilitated transport, the liquid membrane phase contains a carrier agent that chemically combines with the permeant to be transported. In the example shown, the carrier is hemoglobin, which transports oxygen. On the upstream side of the membrane, hemoglobin reacts with oxygen to form oxyhemoglobin, which then diffuses to the downstream membrane interface. There, the reaction is reversed: oxygen is liberated to the permeate gas and hemoglobin is re-formed. The hemoglobin then diffuses back to the feed side of the membrane to pick up more oxygen. In this way, hemoglobin acts as a shuttle to selectively transport oxygen through the membrane. Other gases that do not react with hemoglobin, such as nitrogen, are left behind.

Coupled transport resembles facilitated transport in that a carrier agent is incorporated in the membrane. However, in coupled transport, the carrier agent couples the flow of two species. Because of this coupling, one of the species can be moved against its concentration gradient, provided the concentration gradient of the second coupled species is sufficiently large. In the example shown in Figure 11.1, the carrier is an oxime that forms an organic-soluble complex with copper ions. The reaction is reversed by hydrogen ions. On the feed side of the membrane two oxime carrier molecules pick up a copper ion, liberating two hydrogen ions to the feed solution. The copper–oxime complex then diffuses to the downstream membrane interface, where the reaction is reversed because of

Figure 11.1 Schematic examples of passive diffusion, facilitated transport and coupled transport. The facilitated transport example shows permeation of oxygen across a membrane using hemoglobin as the carrier agent. The coupled transport example shows permeation of copper and hydrogen ions across a membrane using a reactive oxime as the carrier agent

the higher concentration of hydrogen ions in the permeate solution. The copper ion is liberated to the permeate solution, and two hydrogen ions are picked up. The re-formed oxime molecules diffuse back to the feed side of the membrane. Because carrier facilitated transport has so often involved liquid membranes, the process is sometimes called liquid membrane transport, but this is a misnomer, because solid membranes containing carriers dispersed or dissolved in the polymer matrix are being used increasingly.

Coupled transport was the first carrier facilitated process developed, originating in early biological experiments involving natural carriers contained in cell walls. As early as 1890, Pfeffer postulated that the transport in these membranes involved carriers. Perhaps the first coupled transport experiment was performed by Osterhout, who studied the transport of ammonia across algae cell walls [1]. A biological explanation of the coupled transport mechanism in liquid membranes is shown in Figure 11.2 [2].

Figure 11.2 Gliozzi's biological model of coupled transport [2]

By the 1950s, the carrier concept was well established, and workers began to develop synthetic analogs of the natural systems. For example, in the mid-1960s, Shean and Sollner [3] studied a number of coupled transport systems using inverted U-tube membranes. At the same time, Bloch and Vofsi published the first of several papers in which coupled transport was applied to hydrometallurgical separations, namely the separation of uranium using phosphate ester carriers [4–6]. Because phosphate esters also plasticize poly(vinyl chloride) (PVC), Bloch and Vofsi prepared immobilized liquid films by dissolving the esters in a PVC matrix. The PVC/ester film, containing 60 wt% ester, was cast onto a paper support. Bloch and others actively pursued this work until the early 1970s. At that time, interest in this approach lagged, apparently because the fluxes obtained did not make the process competitive with conventional separation techniques.

Following the work of Bloch and Vofsi, other methods of producing immobilized liquid films were introduced. In one approach, the liquid carrier phase was held by capillarity within the pores of a microporous substrate, as shown in Figure 11.3(a). This approach was first used by Miyauchi [7] and by Largman and Sifniades and others [8,9]. The principal objective of this early work was to recover copper, uranium and other metals from hydrometallurgical solutions. Despite considerable effort on the laboratory scale, the first pilot plant was not installed until 1983 [10]. The main problem was instability of the liquid carrier phase held in the microporous membrane support.

Figure 11.3 Methods of forming liquid membranes

Another type of immobilized liquid carrier is the emulsion or ‘bubble’ membrane. This technique employs a surfactant-stabilized emulsion as shown in Figure 11.3(b). The organic carrier phase forms the wall of an emulsion droplet separating the aqueous feed from the aqueous product solution. Metal ions are concentrated in the interior of the droplets. When sufficient metal has been extracted, the emulsion droplets are separated from the feed, and the emulsion is broken to liberate a concentrated product solution and an organic carrier phase. The carrier phase is decanted from the product solution and recycled to make more emulsion droplets. One technical problem is the stability of the liquid membrane. Ideally, the emulsion membrane would be completely stable during the extraction step to prevent the two aqueous phases mixing, but would be completely broken and easily separated in the stripping step. Achieving this level of control over emulsion stability has proved difficult. The technique of emulsion membranes was invented and popularized by Li and his co-workers at Exxon, starting in the late 1960s and continuing for more than 20 years [11–14]. The first use of these membranes was as passive devices to extract phenol from water. In 1971–1973 Cussler used this technique with carriers to selectively transport metal ions [15,16]. The Exxon group’s work led to the installation of a pilot plant in 1979 [17]. The process is still not commercial, although a number of pilot plants have been installed, principally on hydrometallurgical feed streams [18].

More recently the use of membrane contactors to solve the stability problem of liquid membranes has been proposed [19–21]. The concept is illustrated in Figure 11.4. Two membrane contactors are used, one to separate the organic carrier phase from the feed and the other to separate the organic carrier phase from the permeate. In the first contactor metal ions in the feed solution diffuse across the microporous membrane and react with the carrier, liberating hydrogen counter ions. The organic carrier solution is then pumped from the first to the second membrane contactor, where the reaction is reversed. The metal ions are

Figure 11.4 Use of two contactors in a liquid membrane process

liberated to the permeate solution, and hydrogen ions are picked up. The reformed carrier solution is then pumped back to the first membrane contactor. Sirkar [19,20] has used this system to separate metal ions. A similar process was developed to the large demonstration plant scale by Davis *et al.* at British Petroleum for the separation of ethylene/ethane mixtures, using a silver nitrate solution as the carrier phase [21].

Carrier facilitated transport processes often achieve spectacular separations between closely related species because of the selectivity of the carriers. However, no coupled transport process has advanced to the commercial stage despite a steady stream of papers in the academic literature. The instability of the membranes is a major technical hurdle, but another issue has been the marginal improvements in economics offered by coupled transport processes over conventional technology such as solvent extraction or ion exchange. Major breakthroughs in performance are required to make coupled transport technology commercially competitive.

Facilitated transport membranes are also a long way from the commercial stage and are plagued by many difficult technical problems. However, the economic rationale for developing facilitated transport membranes is at least clear. Practical facilitated transport membranes, able to separate gas mixtures for which polymeric membranes have limited selectivity, would be adopted. Target applications meeting this criterion are the separation of oxygen and nitrogen and the separation of paraffin/olefin mixtures. The selectivities of current polymeric membranes are modest in both of these separations. Scholander [22] reported the first work on facilitated transport in 1960—he studied the transport of oxygen through aqueous hemoglobin solutions. In the late 1960s through the early 1980s a great

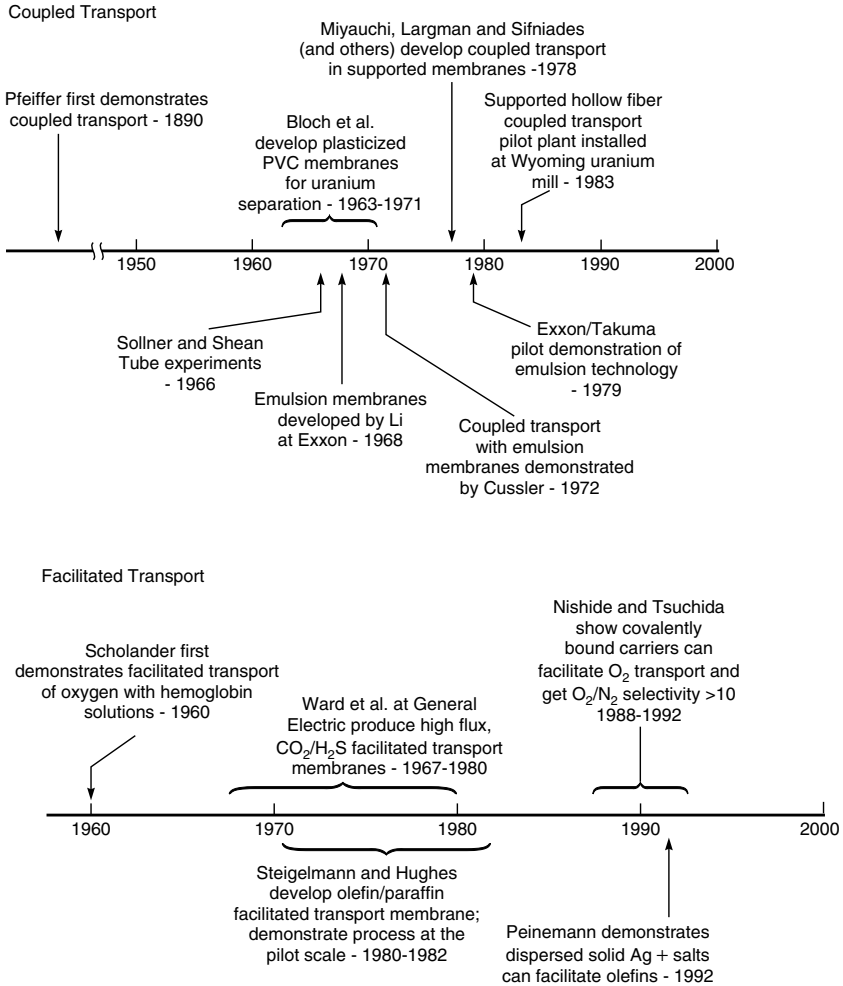

Figure 11.5 Milestones in the development of carrier facilitated transport

deal of work was performed by Ward and others at General Electric [23–26] and Steigelmann and Hughes [27] at Standard Oil. Ward's work focused on carbon dioxide and hydrogen sulfide separation, and some remarkable selectivities were obtained. However, the problems of membrane stability and scale-up were never solved. This group eventually switched to the development of passive polymeric gas separation membranes. Steigelmann and Hughes at Standard Oil concentrated most of their efforts on propylene/propane and ethylene/ethane separation, using concentrated silver salt solutions as carriers. Propylene/propane selectivities of several hundred were obtained, and the process was developed to

the pilot plant stage. The principal problem was instability of the silver–olefin complex, which led to a decline in membrane flux and stability over 10–20 days. Although the membrane could be regenerated periodically, this was impractical in an industrial plant.

Following the development of good quality polymeric gas separation membranes in the early 1980s, industrial interest in facilitated transport waned. However, in the last few years, a number of workers have shown that facilitated transport membranes can be made by dispersing or complexing the carrier into a solid polymeric film. Such membranes are more stable than immobilized liquid film membranes, and formation of these membranes into thin, high-flux membranes by conventional techniques should be possible. Nishide, Tsuchida and others in Japan, working with immobilized oxygen carriers [28–30] and Peinemann in Germany [31] and Ho [32] and Pinnau [33] in the US, working with silver salts for olefin separation, have reported promising results. Apparently, the carrier mechanism in these membranes involves the permeant gas molecule hopping from active site to active site.

A milestone chart showing the historical development of carrier facilitated transport membranes is given in Figure 11.5. Because of the differences between coupled and facilitated transport applications these processes are described separately. Reviews of carrier facilitated transport have been given by Ho *et al.* [18], Cussler, Noble and Way [34–37,39], Laciak [38] and Figoli *et al.* [40].

Coupled Transport

Background

Carrier facilitated transport involves a combination of chemical reaction and diffusion. One way to model the process is to calculate the equilibrium between the various species in the membrane phase and to link them by the appropriate rate expressions to the species in adjacent feed and permeate solutions. An expression for the concentration gradient of each species across the membrane is then calculated and can be solved to give the membrane flux in terms of the diffusion coefficients, the distribution coefficients, and the rate constants for all the species involved in the process [41,42]. Unfortunately, the resulting expressions are too complex to be widely used.

An alternative approach is to make the simplification that the rate of chemical reaction is fast compared to the rate of diffusion; that is, the membrane diffusion is rate controlling. This approximation is a good one for most coupled transport processes and can be easily verified by showing that flux is inversely proportional to membrane thickness. If interfacial reaction rates were rate controlling, the flux would be constant and independent of membrane thickness. Making the assumption that chemical equilibrium is reached at the membrane interfaces allows the coupled transport process to be modeled easily [9]. The process is

Figure 11.6 An illustration of the carrier agent concentration gradients that form in coupled transport membranes

shown schematically in Figure 11.6, in which the reaction of the carrier (RH) with the metal (M^{n+}) and hydrogen ion (H^+) is given as

This reaction is characterized by an equilibrium constant

$$K = \frac{[MR_n][H]^n}{[RH]^n[M]} \quad (11.2)$$

where the terms in square brackets represent the molar concentrations of the particular chemical species. The equilibrium equation can be written for the organic phase or the aqueous phase. As in earlier chapters the subscripts o and ℓ represent the position of the feed and permeate interfaces of the membrane. Thus

the term $[\text{MR}_n]_o$ represents the molar concentration of component MR in the aqueous solution at the feed/membrane interface. The subscript m is used to represent the membrane phase. Thus, the term $[\text{MR}_n]_{o(m)}$ is the molar concentration of component MR_n in the membrane at the feed interface (point o).

Only $[\text{MR}_n]$ and $[\text{RH}]$ are measurable in the organic phase, where $[\text{H}]$ and $[\text{M}]$ are negligibly small. Similarly, only $[\text{H}]$ and $[\text{M}]$ are measurable in the aqueous phase, where $[\text{MR}_n]$ and $[\text{RH}]$ are negligibly small. Equation (11.2) can, therefore, be written for the feed solution interface as

$$K' = \frac{[\text{MR}_n]_{o(m)}[\text{H}]_o^n}{[\text{RH}]_{o(m)}^n[\text{M}]_o} = \frac{k_m}{k_a} \cdot K \quad (11.3)$$

where k_m and k_a are the partition coefficients of M and H between the aqueous and organic phases. This form of Equation (11.2) is preferred because all the quantities are easily accessible experimentally. For example, $[\text{MR}_n]_{o(m)}/[\text{M}]_o$ is easily recognizable as the distribution coefficient of metal between the organic and aqueous phases.

The same equilibrium applies at the permeate-solution interface, and Equation (11.3) can be recast to

$$K' = \frac{[\text{MR}_n]_{\ell(m)}[\text{H}]_{\ell}^n}{[\text{RH}]_{\ell(m)}^n[\text{M}]_{\ell}} \quad (11.4)$$

Consider now the situation when a counter ion concentration gradient that exactly balances the metal ion concentration gradient is established, so no flux of either ion across the membrane occurs. Under this condition, $[\text{MR}_n]_{o(m)} = [\text{MR}_n]_{\ell(m)}$ and $[\text{RH}]_{o(m)}^n = [\text{RH}]_{\ell(m)}^n$, producing the expression

$$\frac{[\text{M}]_o}{[\text{M}]_{\ell}} = \left(\frac{[\text{H}]_o}{[\text{H}]_{\ell}} \right)^n \quad (11.5)$$

Thus, the maximum concentration factor of metal ion that can be established across the membrane varies with the counter ion (hydrogen ion) concentration ratio (in the same direction) raised to the n th power.

This development, of course, says nothing about the metal ion flux across the membrane under non-equilibrium conditions; this is described by Fick's law. At steady state, the flux j_{MR_n} , in $\text{mol}/\text{cm}^2 \cdot \text{s}$, of metal complex MR_n across the liquid membrane is given by

$$j_{\text{MR}_n} = \frac{D_{\text{MR}_n}([\text{MR}_n]_{o(m)} - [\text{MR}_n]_{\ell(m)})}{\ell} \quad (11.6)$$

where D_{MR_n} is the mean diffusion coefficient of the complex in the membrane of thickness ℓ . To put Equation (11.6) into a more useful form, the terms in $[\text{MR}_n]$ are eliminated by introduction of Equation (11.3). This results in a complex

expression involving the desired quantities [M] and [H], but also involving [RH]. However, mass balance provides the following relationship

$$n[\text{MR}_n]_{(m)} + [\text{RH}]_{(m)} = [\text{R}]_{(m)\text{tot}} \quad (11.7)$$

where $[\text{R}]_{(m)\text{tot}}$ is the total concentration of R in the membrane.

Substitution of Equations (11.3) and (11.4) into (11.6) gives an expression for the metal ion flux in terms of only constants and the concentrations of metal and counter ion in the aqueous solutions on the two sides of the membrane [9]. The solution is simple only for $n = 1$, in which case

$$j_{\text{MR}_n} = \frac{D_{\text{MR}_n} [\text{R}]_{(m)\text{tot}}}{\ell} \left[\left(\frac{1}{[\text{H}]_o / [\text{M}]_o K' + 1} \right) - \left(\frac{1}{[\text{H}]_\ell / [\text{M}]_\ell K' + 1} \right) \right] \quad (11.8)$$

This equation shows the coupling effect between the metal ion [M] and the hydrogen ion [H] because both appear in the concentration term of the Fick's law expression linked by the equilibrium reaction constant K' . Thus, there will be a positive 'uphill' flux of metal ion from the downstream to the upstream solution (that is, in the direction $\ell \rightarrow o$) as long as

$$\frac{[\text{M}]_o}{[\text{H}]_o} > \frac{[\text{M}]_\ell}{[\text{H}]_\ell} \quad (11.9)$$

When the inequality is opposite, the metal ion flux is in the conventional or 'downhill' direction. The maximum concentration factor, that is, the point at which metal ion flux ceases, can be determined in terms of the hydrogen ion concentration in the two aqueous phases

$$\frac{[\text{M}]_o}{[\text{M}]_\ell} = \frac{[\text{H}]_o}{[\text{H}]_\ell} \quad (11.10)$$

This expression is identical to Equation (11.5) for the case of a monovalent metal ion.

Characteristics of Coupled Transport Membranes

Concentration Effects

Equations (11.1)–(11.10) provide a basis for rationalizing the principal features of coupled transport membranes. It follows from Equation (11.8) that coupled transport membranes can move metal ions from a dilute to a concentrated solution against the metal ion concentration gradient, provided the gradient in the second coupled ion concentration is sufficient. A typical experimental result demonstrating this unique feature of coupled transport is shown in Figure 11.7. The process is counter-transport of copper driven by hydrogen ions, as described in Equation (11.1). In this particular experiment, a pH difference of 1.5 units is

Figure 11.7 Demonstration of coupled transport. In a two-compartment cell, copper flows from the dilute (feed) solution into the concentrated (product) solution, driven by a gradient in hydrogen ion concentration [9]. Membrane, microporous Celgard 2400/LIX 64N; feed, pH 2.5; product, pH 1.0

maintained across the membrane. The initial product solution copper concentration is higher than the feed solution concentration. Nonetheless, copper diffuses against its concentration gradient from the feed to the product side of the membrane. The ratio of the counter hydrogen ions between the solutions on either side of the membrane is about 32 to 1 which, according to the appropriate form of Equation (11.5), should give a copper concentration ratio of

$$\frac{[Cu^{2+}]_l}{[Cu^{2+}]_o} = \left(\frac{[H^+]_l}{[H^+]_o} \right)^2 = (32)^2 \approx 1000 \tag{11.11}$$

In the experiment shown in Figure 11.7, this means that the feed solution copper concentration should drop to just a few ppm, and this is the case.

A more convenient method of measuring the copper concentration factor is to maintain the product solution at some high copper concentration and to allow the feed solution copper concentration to reach a measurable steady-state value.

Figure 11.8 Experiments to demonstrate the maximum achievable concentration factor. Membrane, microporous Celgard 2400/LIX 64N; feed, pH 2.5, copper ion concentration, 0 or 100 ppm; product, pH 1.0, 9.3 wt% copper [9]. The concentration in the feed solution moves to a plateau value of 40 ppm at which the copper concentration gradient across the membrane is balanced by the hydrogen ion gradient in the other direction

Figure 11.8 shows the feed copper concentration in such an experiment, in which the steady-state feed solution concentration was about 40 ppm. The feed solution was allowed to approach steady state from both directions, that is, with initial copper concentrations higher and lower than the predicted value for the given pH gradient. As Figure 11.8 shows, regardless of the starting point, the copper concentration factors measured by this method are in reasonable agreement with the predictions of Equation (11.11).

Feed and Product Metal Ion Concentration Effects

A second characteristic of coupled transport membranes is that the membrane flux usually increases with increasing metal concentration in the feed solution, but is usually independent of the metal concentration in the product solution. This behavior follows from the flux Equations (11.6) and (11.8). In typical coupled

transport experiments, the concentration of the driving ion (H^+) in the product solution is very high. For example, in coupled transport of copper, the driving ions are hydrogen ions, and 100 g/L sulfuric acid is often used as the product solution. As a result, on the product side of the membrane the carrier is in the protonated form, the term $[MR_n]_{\ell(m)}$ is very small compared to $[MR_n]_{o(m)}$, and Equation (11.8) reduces to

$$j_{MR_n} = \frac{D_{MR_n}[R]_{(m)tot}}{\ell} \cdot \frac{1}{[H]_o/[M]_o K' + 1} \quad (11.12)$$

The permeate solution metal ion concentration, $[M]_{\ell}$, does not appear in the flux equation, which means that the membrane metal ion flux is independent of the concentration of metal on the permeate side. However, the flux does depend on the concentration of metal ions, $[M]_o$, on the feed solution side. At low values of $[M]_o$, the flux will increase linearly with $[M]_o$, but at higher concentrations the flux reaches a plateau value as the term $[H]_o/[M]_o K'$ becomes small compared to 1. At this point all of the available carrier molecules are complexed and no further increase in transport rate across the membrane is possible. The form of this dependence is illustrated for the feed and product solution metal ion concentrations in Figure 11.9.

pH and Metal Ion Effects

It follows from flux Equation (11.12) that the concentration of the counter hydrogen ion and the equilibrium coefficient K' for a particular metal ion will affect the metal ion flux. The effect of these factors can best be understood by looking at curves of metal ion extraction versus pH. Examples are shown in Figure 11.10 for copper and other metals using the carrier LIX 64N [43]. The counter ion

Figure 11.9 Effect of metal concentration in the feed and product solution on flux. Membrane, microporous Celgard 2400/30% Kelex 100 in Kermac 470B; feed, pH 2.5; product, 100 g/L H_2SO_4 [9]

Figure 11.10 Metal extraction curves for four metal ions by LIX 64N. The aqueous phase initially contained 1000 ppm metal as the sulfate salt [43]

is hydrogen and the metal ions are extracted by reactions of the type shown in Equation (11.1).

The pH at which metal ions are extracted depends on the distribution coefficient for the particular metal and complexing agent. As a result, the pH at which the metal ions are extracted varies, as shown by the results in Figure 11.10. This behavior allows one metal to be separated from another. For example, consider the separation of copper and iron with LIX 64N. As Figure 11.10 shows, LIX 64N extracts copper at pH 1.5–2.0, but iron is not extracted until above pH 2.5. The separations obtained when 0.2% solutions of copper and iron are tested with a LIX 64N membrane at various pHs are shown in Figure 11.11. The copper flux is approximately 100 times higher than the iron flux at a feed pH of 2.5.

Carrier Agent

In the examples given in Figures 11.9–11.11 to illustrate coupled transport, the two oxime carriers used for copper were LIX 64N and Kelex 100, which have the structures:

Figure 11.11 Copper and iron fluxes as a function of feed pH [9]. Membrane, Celgard 2400/LIX 64N; feed, 0.2% metal; product, pH 1.0

However, a large number of complexing agents of all kinds with chemistries designed for specific metal ions have been reported in the literature. The tertiary amine Alamine 336 is widely used to transport anions such as $\text{UO}_2(\text{SO}_4)^{4-}$ and $\text{Cr}_2\text{O}_7^{2-}$ [44–46]. The macrocyclic crown ether family has also been used to transport alkali and rare earth metals [47,48]:

Coupled Transport Membranes

Supported Liquid Membranes

In supported liquid membranes, a microporous support impregnated with the liquid complexing agent separates the feed and product solutions. In coupled

transport, the fluid on both sides of the membrane must be circulated to avoid concentration polarization, which is much more significant on the feed side than on the permeate side. In the laboratory, concentration polarization is easily avoided by using flat sheet membranes in a simple permeation cell with stirred solutions on both sides of the membrane. On a larger scale, hollow-fiber systems with the feed solution circulated down the bore of the fibers have been the most common form of membrane.

Large-scale processes require many modules to remove most of the metal from a continuous feed stream. In general, a multistage system operating in a feed-and-bleed mode is the most efficient design; a schematic representation of a three-stage system is shown in Figure 11.12 [49]. A fixed feed volume circulates through each module at a high rate to control concentration polarization; this flow is indicated by the solid lines in the figure. Feed solution is continuously introduced into the circulating volume of the first stage and is bled off at the

Figure 11.12 Schematic of a three-stage feed-and-bleed hollow fiber coupled transport concentrator [49]

Figure 11.13 The effect of replenishing a hollow fiber coupled transport module with fresh complexing agent. Membrane, polysulfone, hollow fiber/Kelex 100; feed, 0.2% copper, pH 2.5; product, 2% copper, 100 g/L H_2SO_4 [49]

same rate. The bleed from the first stage constitutes the feed for the second, and the bleed from the second stage constitutes the feed for the third. In operation, the concentration of metal in the feed solution decreases as it flows from stage 1 to stage 3, with the final raffinate concentration depending on the feed-and-bleed flow rate. The product solution flows in series through the stages. The advantage of this multistage design over a single-stage system is that only the final stage operates on feed solution depleted of metal.

Liquid membranes supported by hollow fibers are relatively easy to make and operate, and the membrane fluxes can be high. However, membrane stability is a problem. The variation in coupled transport flux during long-term tests is illustrated in Figure 11.13 [49]. The detailed mechanism for this flux instability is not completely established but appears to be related to loss of the organic complexing agent phase from the support membrane [49–51]. Although membrane fluxes could be restored to their original values by reloading the membrane with fresh complexing agent for copper-coupled transport, this is not practical in a commercial system.

Emulsion Liquid Membranes

A form of liquid membrane that received a great deal of attention in the 1970s and 1980s was the bubble or emulsion membrane, first developed by Li at Exxon [11–13]. Figure 11.14 is a schematic illustration of an emulsion liquid membrane process, which comprises four main operations. First, fresh product solution is emulsified in the liquid organic membrane phase. This water/oil emulsion then enters a large mixer vessel, where it is again emulsified to form a water/oil/water emulsion. Metal ions in the feed solution permeate by coupled

Figure 11.14 Flow diagram of a liquid emulsion membrane process

transport through the walls of the emulsion to the product solution. The mixture then passes to a settler tank where the oil droplets separate the metal-depleted raffinate solution. A single mixer/settler step is shown in Figure 11.14, but in practice a series of mixer/settlers may be used to extract the metal completely. The emulsion concentrate then passes to a de-emulsifier where the organic and concentrated product solutions are separated. The regenerated organic solution is recycled to the first emulsifier.

The optimum operating conditions for this type of process vary a great deal. The first water/oil emulsion is typically an approximately 50/50 mixture, which is then mixed with the aqueous feed solution phase at a ratio of 1 part emulsion phase to 5–20 parts feed solution phase. Typical extraction curves for copper using LIX 64N are shown in Figure 11.15. The extraction rate generally follows a first order expression [52]. The slope of the curve in Figure 11.15 is proportional to the loading of complexing agent in the organic phase and the rate of agitation in the mixer vessel.

Figure 11.15 also illustrates one of the problems of emulsion membrane systems, namely, degradation of the emulsion on prolonged contact with the feed solution and high-speed mixing of the product and feed solutions. Prolonged stirring of the emulsion with the feed solution causes the copper concentration to rise as some of the emulsion droplets break. Careful tailoring of the stirring rate and surfactant composition is required to minimize premature emulsion breakdown [52,53].

Although emulsion degradation must be avoided in the mixer and settler tanks, complete and rapid breakdown is required in the de-emulsifier in which the

Figure 11.15 Copper extraction by a liquid emulsion membrane process [52]. Feed, 200 ml, pH 2.0, 300 ppm Cu^{2+} ; membrane, 15 mL LIX 64N in kerosene, 3% Span 80; stripping solution, 15 mL H_2SO_4 . Schügerl, Copper Extraction by Means of a Liquid Surfactant Membrane Process, p. 19, Copyright 1980, with permission from Elsevier

product solution is separated from the organic complexing agent. Currently, electrostatic coalescers seem to be the best method of breaking these emulsions. Even then, some of the organic phase is lost with the feed raffinate.

Applications

The best application of coupled transport is removal and recovery of metals from large, dilute feed solutions such as contaminated ground water or dilute hydrometallurgical process streams. Treatment of such streams by chemical precipitation, conventional solvent extraction with liquid ion exchange reagents, or extraction with ion exchange resins is often uneconomical. The ability of coupled transport to treat large-volume, dilute streams with relatively small amounts of the expensive carrier agent is an advantage.

An application that has received a good deal of attention is the recovery of copper from dilute hydrometallurgical process streams. Such streams are produced by extraction of low-grade copper ores with dilute sulfuric acid. Typically, the leach stream contains 500–5000 ppm copper and various amounts of other metal ions, principally iron. Currently, copper is removed from these streams by precipitation with iron or by solvent extraction. A scheme for recovering the copper by coupled transport is shown in Figure 11.16. The dilute copper solution from the dump forms the feed solution; concentrated sulfuric acid from the electrowinning operation forms the product solution. Copper from the feed solution permeates the membrane, producing a raffinate solution containing 50–100 ppm copper,

Figure 11.16 Schematic of copper recovery by coupled transport from dump leach streams. The concentrated copper solution produced by coupled transport separation of the dump leach liquid is sent to an electrolysis cell where copper sulfate is electrolyzed to copper metal and sulfuric acid

which is returned to the dump. The product solution, which contains 2–5% copper, is sent to the electrowinning tankhouse. Many papers have described this application of coupled transport with supported [9,49] and emulsion [13,52] membranes. Membrane stability was a problem and, although the economics appeared promising, the advantage was insufficient to encourage adoption of this new process.

Facilitated Transport

Background

The transport equations used for facilitated transport parallel those derived for coupled transport [27]. The major difference is that only one species is transported across the membrane by the carrier. The carrier-species equilibrium in the membrane is

where R is the carrier, A is the permeant transported by the carrier and RA is the permeant-carrier complex. Examples of reactions used in facilitated transport processes are shown in Table 11.1.

Table 11.1 Facilitated transport carrier reactions

CO ₂	$\text{CO}_2 + \text{H}_2\text{O} + \text{Na}_2\text{CO}_3 \rightleftharpoons 2\text{NaHCO}_3$
O ₂	$\text{O}_2 + \text{CoSchiff's base} \rightleftharpoons \text{CoSchiff's base}(\text{O}_2)$
SO ₂	$\text{SO}_2 + \text{H}_2\text{O} + \text{Na}_2\text{SO}_3 \rightleftharpoons 2\text{NaHSO}_3$
H ₂ S	$\text{H}_2\text{S} + \text{Na}_2\text{CO}_3 \rightleftharpoons \text{NaHS} + \text{NaHCO}_3$
CO	$\text{CO} + \text{CuCl}_2 \rightleftharpoons \text{CuCl}_2(\text{CO})$
C ₂ H ₄	$\text{C}_2\text{H}_4 + \text{AgNO}_3 \rightleftharpoons \text{AgNO}_3(\text{C}_2\text{H}_4)$

As with coupled transport, two assumptions are made to simplify the treatment: first, that the rate of chemical reaction is fast compared to the rate of diffusion across the membrane, and second, that the amount of material transported by carrier facilitated transport is much larger than that transported by normal passive diffusion, which is ignored. The facilitated transport process can then be represented schematically as shown in Figure 11.17.

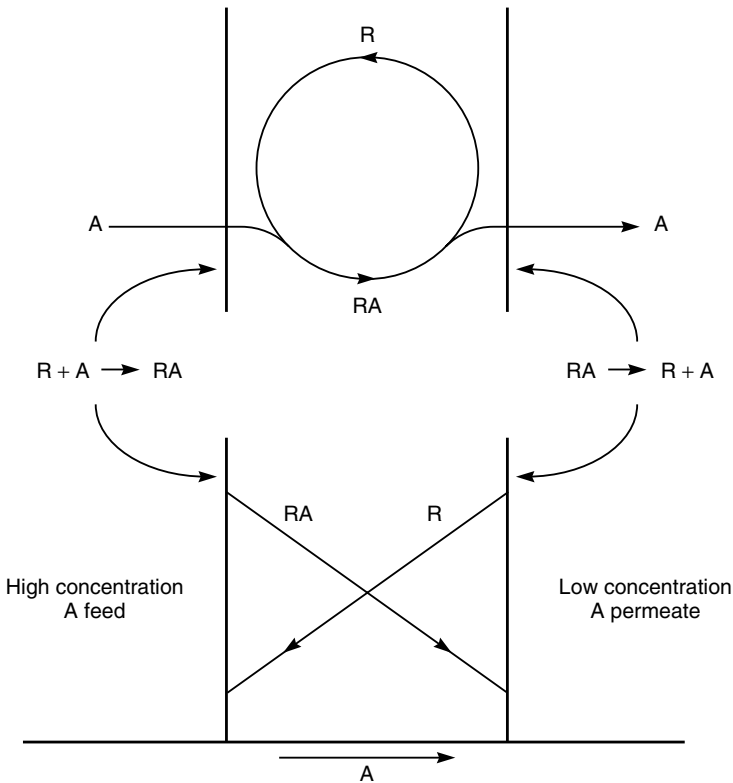

Figure 11.17 Illustration of the facilitated transport process

The carrier–permeate reaction within the membrane is described by the equilibrium constant

$$K = \frac{[\text{RA}]_{(m)}}{[\text{R}]_{(m)}[\text{A}]_{(m)}} \quad (11.14)$$

The concentration of permeant, $[\text{A}]_{(m)}$, within the membrane phase can be linked to the concentration (pressure) of permeant A in the adjacent gas phase, $[\text{A}]$, by the Henry's law expression

$$[\text{A}]_{(m)} = k[\text{A}] \quad (11.15)$$

Hence Equation (11.14) can be written

$$\frac{[\text{RA}]_{(m)}}{[\text{R}]_{(m)}[\text{A}]} = K \cdot k = K' \quad (11.16)$$

The components $[\text{R}]_{(m)}$ and $[\text{RA}]_{(m)}$ can be linked by a simple mass balance expression to the total concentration of carrier $[\text{R}]_{(m)\text{tot}}$ within the membrane phase, so Equation (11.16) can be rearranged to

$$[\text{RA}]_{(m)} = \frac{[\text{R}]_{(m)\text{tot}}}{1 + 1/[\text{A}]K'} \quad (11.17)$$

Equation (11.17) shows the fraction of the carrier that reacts to form a carrier complex. At very large values of the term $[\text{A}]K'$, all the carrier is complexed, and $[\text{RA}]_{(m)} \rightarrow [\text{R}]_{(m)\text{tot}}$. At low values, $[\text{A}]K' \rightarrow 0$, none of the carrier is complexed ($[\text{RA}]_{(m)} \rightarrow 0$). Equation (11.17) allows the concentration of the carrier–permeate complex at each side of the membrane to be calculated in terms of the equilibrium constant between the carrier and the permeant, and the concentration (pressure) of the permeant in the adjacent feed and permeant fluids. This allows transport through the membrane to be calculated using Fick's law. The flux, j_{RA} , of RA through the membrane is given by

$$j_{\text{RA}} = \frac{D_{\text{RA}}([\text{RA}]_{o(m)} - [\text{RA}]_{\ell(m)})}{\ell} \quad (11.18)$$

Substituting Equation (11.17) into Equation (11.18) yields

$$j_{\text{RA}} = \frac{D_{\text{RA}}[\text{R}]_{(m)\text{tot}}}{\ell} \left[\frac{1}{1 + 1/[\text{A}]_o K'} - \frac{1}{1 + 1/[\text{A}]_{\ell} K'} \right] \quad (11.19)$$

To illustrate the dependence of the membrane flux on the equilibrium constant K' and the pressure gradient across the membrane, the flux, j_{RA} , when the permeant pressure is close to zero, that is, $[\text{A}]_{\ell} \approx 0$, can be written as

$$j_{\text{RA}} = \frac{D_{\text{RA}}[\text{R}]_{(m)\text{tot}}}{\ell} \left(\frac{1}{1 + 1/[\text{A}]_o K'} \right) \quad (11.20)$$

Figure 11.18 Flux through a facilitated transport membrane calculated using Equation (11.20) ($[A]_l \approx 0$ and $D_{RA}[R]_{(m)tot}/\ell \approx 1$)

This expression is plotted in Figure 11.18 as flux as a function of feed pressure for different values of the equilibrium constant, K' . In this example, at an equilibrium constant K' of 0.01 atm^{-1} , very little of carrier R reacts with permeant A even at a feed pressure of 10 atm, so the flux is low. As the equilibrium constant increases, the fraction of carrier reacting with permeant at the feed side of the membrane increases, so the flux increases. This result would suggest that, to achieve the maximum flux, a carrier with the highest possible equilibrium constant should be used. For example, the calculations shown in Figure 11.18 indicate a carrier with an equilibrium constant of 10 atm^{-1} or more.

The calculations shown in Figure 11.18 assume that a hard vacuum is maintained on the permeate side of the membrane. The operating and capital costs of vacuum and compression equipment prohibit these conditions in practical systems. More realistically, a carrier facilitated process would be operated either with a compressed gas feed and atmospheric pressure on the permeate side of the membrane, or with an ambient-pressure feed gas and a vacuum of about 0.1 atm on the permeate side. By substitution of specific values for the feed and permeate pressures into Equation (11.19), the optimum values of the equilibrium constant can be calculated. A plot illustrating this calculation for compression and vacuum operation is shown in Figure 11.19.

Under the assumptions of this calculation, the optimum equilibrium constant is 0.3 atm^{-1} for compression operation (feed pressure, 10 atm; permeate pressure,

Figure 11.19 Illustration of the effect of feed and permeate pressure on the optimum carrier equilibrium constant. $D_{RA}[R]_{(m)tot}/\ell \approx 1$; vacuum operation, feed pressure 1 atm, permeate pressure 0.1 atm; compression operation, feed pressure 10 atm, permeate pressure 1 atm

1 atm) and 3 atm⁻¹ for vacuum operation (feed pressure, 1 atm; permeate pressure, 0.1 atm). The results show that rather precise control of the equilibrium constant is required to achieve a useful facilitated transport process. In this example calculation, although carriers with equilibrium constants less than 0.3 atm⁻¹ or greater than 3 atm⁻¹ can transport the permeant across the membrane, obtaining the maximum flux for the process would require operation at feed and permeate pressures likely to make the process uneconomical.

Process Designs

Until quite recently, most of the facilitated transport results reported in the literature were obtained with supported liquid membranes held by capillarity in microporous films. The instability of these membranes has inhibited commercial application of the process. Three factors contribute to this instability and the consequent loss of membrane performance over time:

1. Evaporation of the solvent used to prepare the liquid membrane, leading to membrane failure.

2. Expulsion of liquid held by capillarity within the microporous membrane pores. The membrane must always be operated well below the average bubble point of the membrane, because liquid expulsion from even a few larger-than-average pores can cause unacceptable leakage of gas.
3. Degradation of the carrier agent by the permeant gas or by minor components such as water, carbon dioxide or hydrogen sulfide in the feed gas.

Significant progress has been made in alleviating the first two physical causes of membrane instability. The magnitude of the long-term chemical stability problem depends on the process. It is a major issue for carriers used to transport oxygen and olefins, but for carriers used to transport carbon dioxide, chemical stability is a lesser problem.

Several techniques can minimize the pressure difference across supported liquid membranes to improve membrane stability. In the laboratory, flow of an inert sweep gas such as helium on the permeate side can be used to maintain low partial pressure of the permeating component, while the hydrostatic pressure is about equal to that of the feed. A variation on this approach proposed by Ward is to use a condensable sweep gas such as steam. The permeate-steam mixture is cooled and condensed, separating the permeate gas from the condensed water, which is then sent to a boiler to regenerate the steam [25,26]. A simplified flow scheme of this process is shown in Figure 11.20(a). An alternative approach is to sweep the permeate side of the membrane with an absorbent liquid in which the permeate gas dissolves. Hughes *et al.* [27], for example, used liquid hexane to sweep the permeate side of their propylene/propane separating membrane, as illustrated in Figure 11.20(b). The hexane/propylene mixture leaving the membrane permeator is sent to a small distillation column to recover the hexane liquid and a concentrated propylene gas stream.

Both techniques shown in Figure 11.20 increase the complexity of the separation process significantly, and neither has advanced to a commercial process. The focus of much of the recent work on facilitated transport has been to produce membranes that are inherently stable and can be used in conventional gas separation systems. Laciak has recently reviewed this work [38].

One approach used with ionic carriers is to impregnate ion exchange membranes with the carrier feed solution. Ion exchange sites in the membrane are ion-paired to the facilitated transport carrier [54–56]. The membrane is swollen with a solvent, usually water but sometimes glycerol, so that the carrier ions have some mobility. These membranes are, in effect, swollen polymeric gels, so the problem of carrier fluid displacement from the membrane pores if the bubble pressure is exceeded does not occur. Evaporation of the solvent remains a problem, and addition of solvent vapor to the feed gas is generally required.

Another method of solving the solvent evaporation problem was devised by Pez, Laciak and others [38,57–60] at Air Products, using carriers in the form

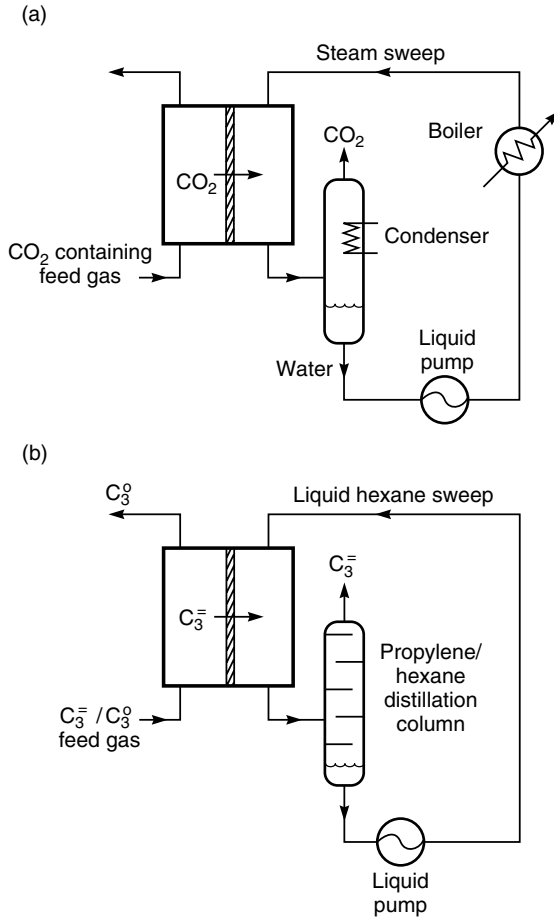

Figure 11.20 Flow schematics of (a) a steam sweep configuration used in the facilitated transport of carbon dioxide [25,26] and (b) a liquid hexane sweep used in the transport of propylene [27]

of organic salts that become liquids (molten salts) at ambient temperatures. Examples of such salts are:

- triethyl ammonium chlorocuprate $(C_2H_5)_3 \cdot NHCuCl_2$, a carrier for carbon monoxide;
- tetrahexyl ammonium benzoate $(C_6H_{13})_4 \cdot N^+C_6H_5CO_2^-$, a carrier for carbon dioxide;
- tetrahexyl ammonium fluoride tetrahydrate $(C_6H_{13})_4 \cdot NF \cdot 4H_2O$, a carrier for carbon dioxide.

Under the membrane test conditions, these carrier salts are liquids with essentially no vapor pressure, so the solvent evaporation problem is eliminated.

Yet another approach to stabilizing facilitated transport membranes is to form multilayer structures in which the supported liquid-selective membrane is encapsulated between thin layers of very permeable but nonselective dense polymer layers. The coating layers must be very permeable to avoid reducing the gas flux through the membrane; materials such as silicone rubber or poly(trimethylsiloxane) are usually used [26].

Despite many years of effort, none of these methods of stabilizing liquid membranes has had real success. For this reason, a number of workers are trying to develop solid carrier facilitated membranes. Two approaches are being tried. One is to covalently link the carrier complex to the matrix polymer. So far the improvement in selectivity obtained by this approach has been modest. This may be due to the difficulty of obtaining high loadings of the carrier in the polymer matrix. The second approach, which has been more successful, is to produce facilitated transport membranes in which the polymer matrix acts as a partial solvent for the carrier. For example, poly(ethylene oxide) or ethylene oxide copolymers can dissolve covalent salts such as silver tetrafluoroborate (AgBF_4), a facilitated transport carrier for olefins [31–33,61–63]. Significant facilitation of some gases has been achieved with these membranes.

Examples of the best results obtained are shown in Figure 11.21 [33,61]. The composite membranes with which these data were obtained were formed by casting a solution of 80 wt% silver tetrafluoroborate in a propylene oxide copolymer matrix onto a microporous support. When subjected to a 40-day test with a gas

Figure 11.21 Long-term performance of a composite solid polymer electrolyte membrane consisting of 80 wt% AgBF_4 dissolved in a propylene oxide copolymer matrix. Feed gas, 70 vol% ethylene/30 vol% ethane at 50 psig; permeate pressure, atmospheric [33,61]

Figure 11.22 Mixed-gas ethylene/ethane selectivity of a solid polymer electrolyte membrane as a function of AgBF_4 concentration in the polyamide-polyether matrix [62]

mixture of 70 vol% ethylene/30 vol% ethane, the membrane produced a permeate containing 98.7–99.4% ethylene over the entire test period. Conventional wisdom suggests that these immobilized carriers would lose their facilitation ability, but this does not appear to be the case. The exact transport mechanism is not clear but appears to involve the permeable gas molecules moving between fixed sites through the polymer [28–30,34]. These solid matrix membranes often show clear evidence of a percolation threshold. At low carrier loadings, little or no facilitation is observed until, at a certain critical loading, facilitation occurs, and thereafter increases rapidly [62,64]. Some results illustrating this effect are shown in Figure 11.22. At loadings below 70 wt% AgBF_4 , essentially no facilitation is seen; at loadings greater than this threshold value, facilitation occurs. It is believed that the percolation threshold level is the point at which carrier sites are close enough that the permeating complex molecule can hop from carrier site to carrier site through the membrane.

Applications

Over the last 30 years a variety of facilitated transport carriers have been studied for a number of important separation problems, reviewed briefly below.

Carbon Dioxide/Hydrogen Sulfide Separation

From the late 1960s to the early 1980s, Ward and others at General Electric studied facilitated transport membranes, particularly for separation of the acid gases carbon dioxide and hydrogen sulfide from methane and hydrogen [23–26].

This work was finally abandoned after the development of selective polymeric membranes in the 1980s.

Although many carriers are available for carbon dioxide and hydrogen sulfide transport, one of the most studied chemistries uses aqueous carbonate/bicarbonate solutions. Four principal reactions occur in the film

Equations (11.21) and (11.22) are measurably slow reactions; Reactions (11.23) and (11.24) are essentially instantaneous. All four reactions determine the equilibrium concentrations, but the process can be illustrated in simple form by Figure 11.23 [25].

At the feed side of the membrane, carbon dioxide dissolves in the aqueous carbonate/bicarbonate solution and reacts with water and carbonate ions according to Equations (11.21) and (11.23).

Ward III, Progress on the Selective Removal of H_2S from Gasified Coal Using an Immobilized Liquid Membrane, *Ind. Eng. Chem., Prod. Res. Dev.* **16**, 370. Copyright 1977, American Chemical Society and American Pharmaceutical Association

At the permeate side of the membrane the reaction is reversed, and bicarbonate ions form carbon dioxide, water, and carbonate ions.

Coupled transport of hydrogen sulfide through the same carbonate/bicarbonate membrane is shown in Figure 11.24 [26]. The overall reaction is simple

but, again, a number of reactions occur simultaneously to establish the equilibrium concentrations.

Because some of the reactions involved in establishing equilibrium at the membrane surface are slow compared to diffusion, the calculated concentration gradients formed in the liquid membrane do not have a simple form. The equations for partial reaction rate control have been derived by Ward and Robb [23].

The transport rates of carbon dioxide and hydrogen sulfide through these carbonate membranes can be significantly increased by adding catalysts to increase the rates of the slow reactions of Equations (11.21) and (11.22). A variety of materials can be used, but the anions of the weak acids such as arsenite, selenite and hypochlorite have been found to be the most effective. Small concentrations of these components increase permeation rates three- to five-fold.

Membranes selective to carbon dioxide and hydrogen sulfide have been considered for removal of these gases from natural gas and various synthetic gas streams. Again, the main problem has been instability of available supported liquid membranes under the typical pressure gradients of several hundred psi. Because the membranes are generally more permeable to hydrogen sulfide than to carbon dioxide, their use to selectively remove hydrogen sulfide from streams contaminated with both gases has also been studied.

Olefin Separation

Concurrently with the work on carbon dioxide and hydrogen sulfide at General Electric, Steigelmann and Hughes [27] and others at Standard Oil were developing facilitated transport membranes for olefin separations. The principal target was the separation of ethylene/ethane and propylene/propane mixtures. Both separations are performed on a massive scale by distillation, but the relative volatilities of the olefins and paraffins are so small that large columns with up to 200 trays are required. In the facilitated transport process, concentrated aqueous silver salt solutions, held in microporous cellulose acetate flat sheets or hollow fibers, were used as the carrier.

Silver ions react readily with olefins, forming a silver–olefin complex according to the reaction:

Hughes and Steigelmann used silver nitrate solutions mainly because of the low cost and relatively good stability compared to other silver salts. Silver tetrafluoroborate (AgBF_4) has been used by others. The absorption isotherm obtained with a 4 M silver nitrate solution equilibrated with ethylene is shown in Figure 11.25 [26].

The propylene isotherm is reported to be very similar. Based on these data, silver salt membranes are best used with pressurized ethylene feed streams; pressures of 3–6 atm are generally used. The Standard Oil work was continued for a number of years and was taken to the pilot-plant stage using hollow fiber

Figure 11.25 Solubility of ethylene in a 4 M silver nitrate solution [26]. Reprinted with permission from S.L. Matson, C.S. Herrick and W.J. Figure 11.26 Performance of a 37 m² hollow fiber silver-nitrate-impregnated facilitated transport membrane for the separation of propylene/propane mixtures. The feed pressure was 5–13 atm; the permeate was a hexane liquid sweep stream. The vertical dotted lines show when the membrane was regenerated with fresh silver nitrate solution [27]. Reprinted with permission from R.D. Hughes, J.A. Mahoney and E.F. Steigelmann, Olefin Separation by Facilitated Transport Membranes, in *Recent Developments in Separation Science*, N.N. Li and J.M. Calo (eds) (1986). Copyright CRC Press, Boca Raton, FL

modules containing almost 40 m² membrane area. Some typical data are shown in Figure 11.26 [27]. In these experiments, the feed pressure was maintained at 5–13 atm with liquid hexane circulated on the permeate side of the fibers. In laboratory tests propylene/propane selectivities of more than 100 were obtained routinely; in the large pilot system the initial selectivity was not quite as high but was still very good. Unfortunately, the selectivity and flux deteriorated over a period of a few weeks, partly due to loss of water from the fibers, which could not be prevented even when the feed gas was humidified. Periodic regeneration by pumping fresh silver nitrate solution through the fibers partially restored their properties. However, this technique is not practical in an industrial plant. These instability problems caused Standard Oil to halt the program, which remains the largest facilitated transport trial to date.

The best hope for olefin/paraffin facilitated membrane separations seems to be the solid polymer electrolyte membranes discussed earlier, the results of which are shown in Figures 11.21 and 11.22. If stable membranes with these properties can be produced on an industrial scale, significant applications could develop in treating gases from steam crackers that manufacture ethylene and from polyolefin plants.

Oxygen/Nitrogen Separations

The first demonstration of facilitated transport of oxygen was performed by Scholander [22] using thin films of cellulose acetate impregnated with aqueous hemoglobin solutions. Later Bassett and Schultz [65] demonstrated the process with cobalt dihistidine, a synthetic carrier. The enhancements obtained in these

Figure 11.27 Examples of cobalt-based facilitated transport oxygen carriers [66]

Figure 11.28 The oxygen/nitrogen selectivity plotted against oxygen permeability for polymeric membranes [68] and Co(3-MeOsaltmen)-based facilitated transport membranes [66]

experiments were low, but Johnson and others [66,67] demonstrated very large enhancements using a series of cobalt-based metal chelate carriers. The chemical structures of two typical cobalt Schiff's-base carriers of the type used in this study and in most later work are shown in Figure 11.27. All of these compounds have a central cobalt (II) ion with four coordinating atoms in a planar array. The oxygen molecule coordinates with the cobalt ion from one side of the plane while another coordinating atom, usually a nitrogen group, acts as an electron-donating axial base. In compound I, referred to as Co(3-MeOsaltmen), the coordinating base is usually an imidazole or pyridine group, which must be present for oxygen complexation to occur. In compound II, referred to as Co(SalPr), the coordinating base group is provided by a donor nitrogen atom that is part of the structure.

(a) An oxygen carrier chemically bonded to the polymer backbone

(b) An oxygen carrier chemically bonded to the polymer backbone through a donor base

Figure 11.29 Methods of forming bound oxygen carriers

Using carriers of this type, high degrees of facilitation can be achieved. Some data from Johnson's work plotted on the Robeson plot [68] for the polymeric oxygen/nitrogen separating materials described in Chapter 8 are shown in Figure 11.28. This figure shows the promise of facilitated transport membranes and why, even after many failures, interest in this topic has not waned. If stable, thin membranes with these permeabilities and selectivities could be made, major reductions in the cost of membrane-produced oxygen and nitrogen—the second and third largest volume industrial chemicals—would result.

One promising approach to facilitated transport pioneered by Nishide and co-workers at Wasada University is to chemically bind the oxygen carrier to the polymer backbone, which is then used to form a dense polymer film containing no solvent [28]. In some examples, the carrier species is covalently bonded to the polymer matrix as shown in Figure 11.29(a). In other cases, the polymer matrix contains base liquids which complex with the carrier molecule through the base group as shown in Figure 11.29(b). Because these films contain no liquid solvent, they are inherently more stable than liquid membranes and also could be formed into thin films of the selective material in composite membrane form. So far the selectivities and fluxes of these membranes have been moderate.

Conclusions and Future Directions

Carrier facilitated transport membranes have been the subject of serious study for more than 30 years, but no commercial process has resulted. These membranes are a popular topic with academic researchers, because spectacular separations can be achieved with simple laboratory equipment. Unfortunately, converting these laboratory results into practical processes requires the solution of a number of intractable technological problems.

Coupled transport with supported and emulsion liquid membranes has made very little real progress towards commercialization in the last 15 years. In addition, it is now apparent that only a few important separation problems exist for which coupled transport offers clear technical and economic advantages over conventional technology. Unless some completely unexpected breakthrough occurs, it is difficult to imagine that coupled transport will be used on a significant commercial scale within the next 10–20 years. The future prospects for coupled transport are, therefore, dim.

The prospects for facilitated transport membranes for gas separation are better because these membranes offer clear potential economic and technical advantages for a number of important separation problems. Nevertheless, the technical problems that must be solved to develop these membranes to an industrial scale are daunting. Industrial processes require high-performance membranes able to operate reliably without replacement for at least one and preferably several years. No current facilitated transport membrane approaches this target, although some of the solid polymer electrolyte and bound-carrier membranes show promise.

Development of industrial-scale facilitated transport membranes and systems requires access to membrane technology not generally available in universities, and a commitment to a long-term development program that few companies are willing to undertake.

12 MEDICAL APPLICATIONS OF MEMBRANES

Introduction

In this chapter, the use of membranes in medical devices is reviewed briefly. In terms of total membrane area produced, medical applications are at least equivalent to all industrial membrane applications combined. In terms of dollar value of the products, the market is far larger. In spite of this, little communication between these two membrane areas has occurred over the years. Medical and industrial membrane developers each have their own journals, societies and meetings, and rarely look over the fence to see what the other is doing. This book cannot reverse 50 years of history, but every industrial membrane technologist should at least be aware of the main features of medical applications of membranes. Therefore, in this chapter, the three most important applications—hemodialysis (the artificial kidney), blood oxygenation (the artificial lung) and controlled release pharmaceuticals—are briefly reviewed.

Hemodialysis

The kidney is a key component of the body's waste disposal and acid–base regulation mechanisms. Each year approximately one person in ten thousand suffers irreversible kidney failure. Before 1960, this condition was universally fatal [1] but now a number of treatment methods can maintain these patients. Of these, hemodialysis is by far the most important, and approximately 800 000 patients worldwide benefit from the process. Each patient is dialyzed approximately three times per week with a dialyzer containing about 1 m² of membrane area. Economies of scale allow these devices to be produced for about US\$15 each; the devices are generally discarded after one or two uses. As a result the market for dialyzers alone is about US\$1.3 billion [2,3].

The operation of the human kidney simulated by hemodialyzers is illustrated in Figure 12.1. The process begins in the glomerulus, a network of tiny capillaries surrounding spaces called Bowman's capsules. Blood flowing through these

Figure 12.1 Schematic of a single nephron, the functional unit of the kidney. Microsolute are filtered from blood cells in Bowman's capsules. As the filtrate passes towards the collection tubule most of the microsolute and water are reabsorbed by a type of facilitated transport process. The fluid finally entering the collecting tubule contains the nitrogenous wastes from the body and is excreted as urine. There are about 1 million nephrons in the normal kidney [1]

capillaries is at a higher pressure than the fluid in Bowman's capsules, and the walls of the capillaries are finely microporous. As a result, water, salts and other microsolute in the blood are ultrafiltered into the capsule while blood cells stay behind. Each Bowman's capsule is connected by a relatively long, thin duct to the collecting tubule, ultimately forming urine, which is sent via the urethra to the bladder. The average kidney has approximately 1 million tubules and many Bowman's capsules are connected to each tubule. As the fluid that permeates

into Bowman's capsules from the blood travels down the collection duct to the central tubule, more than 99 % of the water and almost all of the salts, sugars and proteins are reabsorbed into the blood by a process similar to facilitated transport. The remaining concentrated fluid ultimately forms urine and is rich in urea and creatinine. This is the principal method by which these nitrogen-containing metabolites are discharged from the body. The acid–base balance of the body is also controlled by the bicarbonate level of urine, and many drugs and toxins are excreted from the body this way.

The first successful hemodialyzer was constructed by Kolf and Berk in The Netherlands in 1945 [4,5]. Kolf's device used dialysis to remove urea and other waste products directly from blood. A flat cellophane (cellulose) tube formed the dialysis membrane; the tube was wound around a rotating drum immersed in a bath of saline. As blood was pumped through the tube, urea and other low molecular weight metabolites diffused across the membrane to the dialysate down a concentration gradient. The cellophane tubing did not allow diffusion of larger components in the blood such as proteins or blood cells. By maintaining the salt, potassium and calcium levels in the dialysate solution at the same levels as in the blood, loss of these components from the blood was prevented.

Kolf's early devices were used for patients who had suffered acute kidney failure as a result of trauma or poisoning and needed dialysis only a few times. Such emergency treatment was the main application of hemodialysis until the early 1960s, because patients suffering from chronic kidney disease require dialysis two to three times per week for several years, which was not practical with these early devices. However, application of hemodialysis to this class of patient was made possible by improvements in the dialyzer design in the 1960s. The development of a plastic shunt that could be permanently fitted to the patient to allow easy access to their blood supply was also important. This shunt, developed by Scribner *et al.* [6], allowed dialysis without the need for surgery to connect the patient's blood vessels to the dialysis machine for each treatment.

Kolf's first tubular dialyzer, shown in Figure 12.2, required several liters of blood to prime the system, a major operational problem. In the 1950s, tubular dialyzers were replaced with coil (spiral) devices, also developed by Kolf and coworkers. This coil system was the basis for the first disposable dialyzer produced commercially in the early 1960s. The blood volume required to prime the device was still excessive, however, and during the 1960s the plate-and-frame and hollow fiber devices shown in Figure 12.3 were developed. In the US in 1975, about 65 % of all dialyzers were coil, 20 % hollow fiber systems and 15 % plate-and-frame. Within 10 years the coil dialyzer had essentially disappeared, and the market was divided two-thirds hollow fibers and one-third plate-and-frame. By 1996, hollow fiber dialyzers had more than 95 % of the market.

Hollow fiber dialyzers typically contain 1–2 m² of membrane in the form of fibers 0.1–0.2 mm in diameter. A typical dialyzer module may contain several thousand fibers housed in a 2-in.-diameter tube, 1–2 ft long. Approximately

Figure 12.2 Schematic of an early tubular hemodialyzer based on the design of Kolf's original device. The device required several liters of blood to fill the tubing and minor surgery to connect to the patient. Nonetheless, it saved the lives of patients suffering from acute kidney failure [1]

Figure 12.3 Schematic of hollow fiber and plate-and-frame dialyzers

100 million hemodialysis procedures are performed annually worldwide. Because hollow fiber dialyzers are produced in such large numbers, prices are very low. Today a 1–2 m² hollow fiber dialyzer sells for about US\$15, which is well below the module costs of any other membrane technology. These low costs have been achieved by the use of high speed machines able to spin several hundred fibers simultaneously around the clock. The entire spinning, cutting, module potting and testing process is automated.

In a hollow fiber dialyzer the blood flows down the bore of the fiber, providing good fluid flow hydrodynamics. An advantage of the hollow fiber design is that only 60–100 mL of blood is required to fill the dialyzer. At the end of a dialysis procedure hollow fiber dialyzers can also be easily drained, flushed with sterilizing agent, and reused. Dialyzer reuse is widely practiced, in part for economic reasons, but also because the biocompatibility of the membrane appears to improve after exposure to blood.

The regenerated cellulose membranes used in Kolf's first dialyzer are still in use in some dialyzers. Cellulose membranes are isotropic hydrogels generally about 10 μm thick and, although very water swollen, they have a high wet strength. The hydraulic permeability of cellulose is relatively low, and the membrane has a molecular weight cut-off of about 2000 dalton. The permeability of cellulose hydrogel membranes compared to the calculated permeability of an aqueous film of equal thickness is shown in Figure 12.4.

Although cellulose has been used successfully in hemodialyzers for many years, there is some concern about the ability of the free hydroxyl groups on the

Figure 12.4 Solute permeability relative to the permeability of a film of water for various solutes in a regenerated cellulose membrane (Cuprophane 150). This type of membrane is still widely used in hemodialysis devices

Figure 12.5 Clearance, a measure of membrane permeability, as a function of molecular weight for hemodialyzers and the normal kidney [7]

membrane surface to activate the blood clotting process. When cellulose-based dialyzers are reused, the membrane's blood compatibility improves because a coating of protein has formed on the membrane surface. Recently, synthetic polymers have begun to replace cellulose. These membrane materials are substituted cellulose derivatives, specifically cellulose acetate or polymers such as polyacrylonitrile, polysulfone, polycarbonate, polyamide and poly(methyl methacrylate). These synthetic fiber membranes are generally microporous with a finely microporous skin layer on the inside, blood-contacting surface of the fiber. The hydraulic permeability of these fibers is up to 10 times that of cellulose membranes, and they can be tailored to achieve a range of molecular weight cut-offs using different preparation procedures. The blood compatibility of the synthetic polymer membranes is good, and these membranes are likely to largely replace unsubstituted cellulose membranes over the next few years.

One attractive feature of some of the new synthetic polymer membranes is their ability to remove some of the middle molecular weight metabolites in blood. This improvement in performance is illustrated by Figure 12.5. Cellulose membranes efficiently remove the major metabolites, urea and creatinine, from blood, but metabolites with molecular weights between 1000 and 10 000 are removed poorly. Patients on long-term dialysis are believed to accumulate these metabolites, which are associated with a number of health issues. The new synthetic polymer membranes appear to simulate the function of the normal kidney more closely.

Blood Oxygenators

Blood oxygenators are used during surgery when the patient's lungs cannot function normally. Pioneering work on these devices was carried out in the 1930s

and 1940s by J.H. Gibbon [8,9], leading to the first successful open heart surgery on a human patient in 1953. Gibbon's heart-lung machine used a small tower filled with stainless steel screens to contact blood with counter-flowing oxygen. Direct oxygenation of the blood was used in all such devices until the early 1980s. Screen oxygenators of the type devised by Gibbon were first replaced with a disk oxygenator, which consisted of 20–100 rotating disks in a closed cylinder containing 1–2 L of blood. Later, bubble oxygenators were developed, in which blood was oxygenated in a packed plastic tower through which blood flowed. Because these direct-contact oxygenators required rather large volumes of blood to prime the device and, more importantly, damaged some of the blood components, they were used in only a few thousand operations per year in the 1980s. The introduction of indirect-contact membrane oxygenators resulted in significantly less blood damage and lower blood priming volumes. The devices were rapidly accepted, and the total number of procedures performed following their introduction expanded rapidly. The first membrane oxygenators were introduced in 1980, and by 1985 represented more than half of the oxygenators in use. This percentage had risen to 70% by 1990; now, only membrane oxygenators are used. Over the same period, the number of procedures using blood oxygenators has risen to approximately 1 million per year worldwide. Each device costs around US\$500–600, so the total annual market is about US\$500 million.

The function of a membrane blood oxygenator is shown schematically in Figure 12.6. In the human lung, the total exchange membrane area between

Figure 12.6 Flow schematic of a membrane blood oxygenator

the blood capillaries and the air drawn in and out is about 80 m^2 . The human lung membrane is estimated to be about $1 \text{ }\mu\text{m}$ thick, and the total exchange capacity of the lung is far larger than is normally required. This allows people with impaired lung capacity to lead relatively normal lives. A successful heart–lung machine must deliver about $250 \text{ cm}^3(\text{STP})/\text{min}$ oxygen and remove about $200 \text{ cm}^3(\text{STP})/\text{min}$ carbon dioxide [10]. Because of the limited solubility of these gases in the blood, relatively large blood flows through the device are required, typically $2\text{--}4 \text{ L}/\text{min}$, which is approximately 10 times the blood flow through a kidney dialyzer. The first membrane oxygenators used silicone rubber membranes, but now microporous polyolefin fibers are used. To maintain good mass transfer with minimal pressure drop through the device, blood is generally circulated on the outside of the fibers.

Controlled Drug Delivery

In controlled drug delivery systems a membrane is used to moderate the rate of delivery of drug to the body. In some devices the membrane controls permeation of the drug from a reservoir to achieve the drug delivery rate required. Other devices use the osmotic pressure produced by diffusion of water across a membrane to power miniature pumps. In yet other devices the drug is impregnated into the membrane material, which then slowly dissolves or degrades in the body. Drug delivery is then controlled by a combination of diffusion and biodegradation.

The objective of all of these devices is to deliver a drug to the body at a rate predetermined by the design of the device and independent of the changing environment of the body. In conventional medications, only the total mass of drug delivered to a patient is controlled. In controlled drug delivery, both the mass and the rate at which the drug is delivered can be controlled, providing three important therapeutic benefits:

1. The drug is metered to the body slowly over a long period; therefore, the problem of overdosing and underdosing associated with conventional periodic medication is avoided.
2. The drug is given locally, ideally to the affected organ directly, rather than systemically as an injection or tablet. Localized delivery results in high concentrations of the drug at the site of action, but low concentrations and hence fewer side effects elsewhere.
3. As a consequence of metered, localized drug delivery, controlled release devices generally equal or improve the therapeutic effects of conventional medications, while using a fraction of the drug. Thus, the problems of drug-related side effects are correspondingly lower.

The concept of controlled delivery is not limited to drugs. Similar principles are used to control the delivery of agrochemicals, fertilizers and pesticides, for example, and in many household products. However, most of the technology development in the past 30 years has focused on drug delivery; only this aspect of the topic is covered here.

The origins of controlled release drug delivery can be traced to the 1950s. Rose and Nelson [11], for example, described the first miniature osmotic pump in 1955. A key early publication was the paper of Folkman and Long [12] in 1964 describing the use of silicone rubber membranes to control the release of anesthetics and cardiovascular drugs. Concurrent discoveries in the field of hormone regulation of female fertility quickly led to the development of controlled release systems to release steroids for contraception [13–15]. The founding of Alza Corporation by Alex Zaffaroni in the late 1960s gave the entire technology a decisive thrust. Alza was dedicated to developing novel controlled release drug delivery systems [16]. The products developed by Alza during the subsequent 25 years stimulated the entire pharmaceutical industry. The first pharmaceutical product in which the drug registration document specified both the total amount of drug in the device and the delivery rate was an Alza product, the Ocusert[®], launched in 1974. This device, shown in Figure 12.7, consisted of a three-layer laminate with the drug sandwiched between two rate-controlling polymer membranes. The device is an ellipse about 1 mm thick and 1 cm in diameter. The device is placed in a cul de sac of the eye where it delivers the drug (pilocarpine) at a constant rate for 7 days, after which it is removed and replaced. The Ocusert was a technical tour de force, although only a limited marketing success. Alza later developed a number of more widely used products, including multilayer transdermal patches designed to deliver drugs through the skin [17]. The drugs include scopolamine (for motion sickness), nitroglycerine (for angina), estradiol (for hormone replacement), and nicotine (for control of smoking addiction). Many imitators have followed Alza's success, and more than 20 transdermal products delivering a variety of drugs are now available.

Membrane Diffusion-controlled Systems

In membrane diffusion-controlled systems, a drug is released from a device by permeation from its interior reservoir to the surrounding medium. The rate of diffusion of the drug through the membrane governs its rate of release. The reservoir device illustrated in Figure 12.8 is the simplest diffusion-controlled system. An inert membrane encloses the drug to be released; the drug diffuses through the membrane at a finite, controllable rate. If the concentration (or thermodynamic activity) of the material in equilibrium with the inner surface of the enclosing membrane is constant then the concentration gradient, the driving force for

Figure 12.7 The Ocusert pilocarpine system is a thin multilayer membrane device. The central sandwich consists of a core containing the drug pilocarpine. The device is placed in the eye, where it releases the drug at a continuous rate for 7 days. Devices with release rates of 20 or 40 $\mu\text{g/h}$ are used. Controlled release of the drug eliminates the over- and under-dosing observed with conventional eyedrop formulations, which must be delivered every 4–6 h to maintain therapeutic levels of the drug in the eye tissue [18]

Figure 12.8 Reservoir device

diffusional release of the drug, is constant. This occurs when the inner reservoir contains a saturated solution of the material, providing a constant release rate for as long as excess solid is maintained in the solution. This is called zero-order release. If, however, the active drug within the device is initially present as

an unsaturated solution, its concentration falls as it is released. The release rate declines exponentially, producing a first-order release profile.

For a device containing a saturated solution of drug, and excess solid drug, Fick's law

$$J = -DK \frac{dc_s}{dx} \tag{12.1}$$

can be restated for a slab or sandwich geometry as

$$\frac{dM_t}{dt} = \frac{AJ}{l} = \frac{ADKc_s}{l} \tag{12.2}$$

where M_t is the mass of drug released at any time t , and hence dM_t/dt is the steady-state release rate at time t ; A is the total surface area of the device (edge effects being ignored); c_s is the saturation solubility of the drug in the reservoir layer; and J is the membrane-limiting flux.

The Ocusert system illustrated in Figure 12.7 is one example of a diffusion-controlled reservoir device. Another is the steroid-releasing intrauterine device (IUD) shown in Figure 12.9. Inert IUDs of various shapes were widely used for

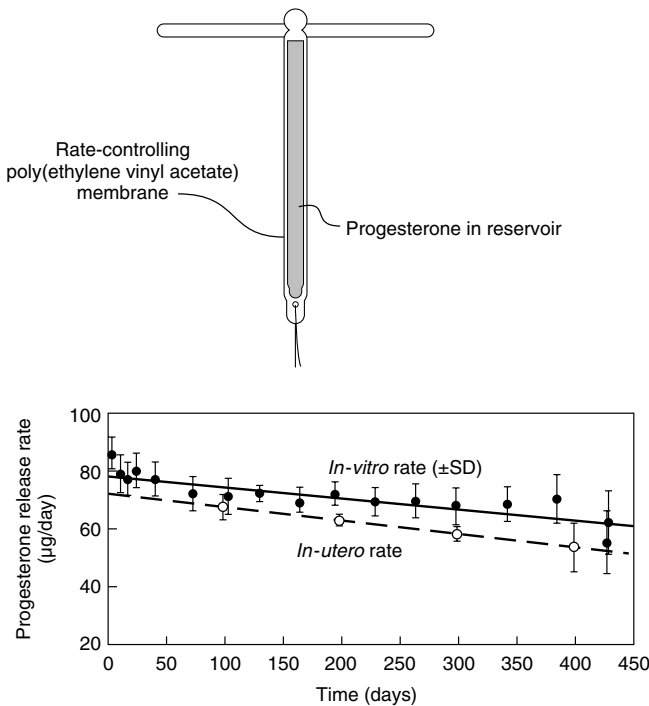

Figure 12.9 Progestasert® intrauterine device (IUD) designed to deliver progesterone for contraception at 65 µg/day for 1 year [19]

birth control in the 1950s and 1960s. The contraceptive effect of these IUDs was based on physical irritation of the uterus. Thus, the devices resulting in the lowest pregnancy rate were often associated with unacceptable levels of pain and bleeding, whereas more comfortable devices were associated with unacceptably high pregnancy rates. Researchers tried a large number of different IUD shapes in an attempt to produce a device that combined a low pregnancy rate with minimal pain and bleeding, but without real success.

Steroid-releasing IUDs, in which the contraceptive effect of the device comes largely from the steroid, offer a solution to the discomfort caused by inert IUDs. Such devices can use IUDs with a low pain and bleeding level as a platform for the steroid-releasing system. Scommegna *et al.* performed the first clinical trials to test this concept [15]. The commercial embodiment of these ideas is shown in Figure 12.9, together with the drug release rate curve [19]. Inspection of this curve shows an initial high drug release during the first 30–40 days, representing drug that has migrated into the polymer during storage of the device and which is released as an initial burst. Thereafter, the device maintains an almost constant drug release rate until it is exhausted at about 400 days. Later versions of this device contained enough drug to last 2 years or more.

The second common category of diffusion-controlled devices is the monolithic system, in which the agent to be released is dispersed uniformly throughout the rate-controlling polymer medium, as shown in Figure 12.10. The release profile is then determined by the loading of dispersed agent, the nature of the components, and the geometry of the device. Thin spots, pinholes, and other similar defects, which can be problems with reservoir systems, do not substantially alter the release rate from monolithic devices. This, together with the ease with which dispersions can be compounded (by milling and extruding, for example), results in low production costs. These advantages often outweigh the less desirable feature of the declining release rate with time characteristic of these systems.

There are two principal types of monolithic device. If the active agent is dissolved in the polymer medium, the device is called a *monolithic solution*. Examples of this type of device are pesticide-containing cat and dog collars to control ticks and fleas. Such devices are often used when the active agent is a liquid; some polymers [for example, poly(vinyl chloride)] can easily sorb up to 20% or more of these liquids. However, if the solubility of the active agent in the

Figure 12.10 Monolithic device

polymer medium is more limited, then only a portion of the agent is dissolved and the remainder is dispersed as small particles throughout the polymer. A device of this type is called a *monolithic dispersion*.

The kinetics of release from a monolithic solution system have been derived for a number of geometries by Crank [20]. For a slab geometry, the release kinetics can be expressed by either of two series, both given here for completeness

$$\frac{M_t}{M_0} = 1 - \sum_{n=0}^{\infty} \frac{8 \exp[-D(2n + 1)^2 \pi^2 t / l^2]}{(2n + 1)^2 \pi^2} \tag{12.3}$$

or

$$\frac{M_t}{M_0} = 4 \left(\frac{Dt}{l^2} \right)^{1/2} \left[\pi^{-1/2} + \sum_{n=0}^{\infty} (-1)^n \operatorname{ierfc} \left(\frac{nl}{2\sqrt{Dt}} \right) \right] \tag{12.4}$$

where M_0 is the total amount of drug sorbed, M_t is the amount desorbed at time t and l is the thickness of the device.

Fortunately, these complex expressions reduce to two approximations, reliable to better than 1%, valid for different parts of the desorption curve. The early time approximation, which holds for the initial portion of the curve, derived from Equation (12.4), is

$$\frac{M_t}{M_0} = 4 \left(\frac{Dt}{\pi l^2} \right)^{1/2} \text{ for } 0 \leq \frac{M_t}{M_0} \leq 0.6 \tag{12.5}$$

The late time approximation, which holds for the final portion of the desorption curve, derived from Equation (12.3), is

$$\frac{M_t}{M_0} = 1 - \frac{8}{\pi^2} \exp \left(\frac{-\pi^2 Dt}{l^2} \right) \text{ for } 0.4 \leq \frac{M_t}{M_0} \leq 1.0 \tag{12.6}$$

These approximations are plotted in Figure 12.11, which illustrates their different regions of validity.

In general, the rate of release at any particular time is of more interest than the accumulated total release. This rate is easily obtained by differentiating Equations (12.5) and (12.6) to give

$$\frac{dM_t}{dt} = 2M_0 \left(\frac{D}{\pi l^2 t} \right)^{1/2} \tag{12.7}$$

for the early time approximation and

$$\frac{dM_t}{dt} = \frac{8DM_0}{l^2} \exp \left(\frac{-\pi^2 Dt}{l^2} \right) \tag{12.8}$$

for the late time approximation. These two approximations are plotted against time in Figure 12.12. Again, for simplicity, M_0 and D/l^2 have been set at unity.

Figure 12.11 The fraction of drug desorbed from a slab as a function of time using the early time and late time approximations. The solid line shows the portion of the curve over which the approximations are valid ($D/l^2 = 1$) [21]

Figure 12.12 The release rate of drug initially dissolved in a slab as a function of time, using the early time and late time approximations. The solid line shows the portion of the curve over which the approximations are valid ($D/l^2 = 1$)

The release rate falls off in proportion to $t^{-1/2}$ until 60% of the agent has been desorbed; thereafter, it decays exponentially.

The expressions (12.5)–(12.8) are also convenient ways of measuring diffusion coefficients in polymers. A permeant is contacted with a film of material of known geometry until equilibrium is reached. The film is then removed from the permeant solution, washed free of contaminants, and the rate of release of the permeant is measured. From the release curves, the diffusion coefficient and permeant sorption can be obtained.

A monolithic dispersion system consists of a dispersion of solid active drug in a rate-limiting polymer matrix. As with monolithic solution systems, the release rate varies with the geometry of the device; it also varies with drug loading. The starting point for release of drug from these systems can be described by a simple model due to Higuchi [22] and is shown schematically in Figure 12.13.

Higuchi's model assumes that solid drug in the surface layer of the device dissolves in the polymer matrix and diffuses from the device first. When the surface layer becomes exhausted of drug, the next layer begins to be depleted. Thus, the interface between the region containing dispersed drug and the region containing only dissolved drug moves into the interior as a front. The validity of Higuchi's model has been demonstrated experimentally numerous times by comparing the predicted release rate calculated from the model with the actual release rate. In addition, the movement of a dissolving front can be monitored directly by sectioning and examining monolithic devices that have been releasing agent for various lengths of time [23]. The proof of Higuchi is straightforward

Figure 12.13 Schematic representation of a cross-section through a polymer matrix initially containing dispersed solid drug. The interface between the region containing dispersed drug and the region containing only dissolved drug has moved a distance x from the surface [22]

and leads to the equation

$$\begin{aligned} M_t &= A[DKtc_s(2c_0 - c_s)]^{1/2} \\ &\simeq A(2DKtc_s c_0)^{1/2} \quad \text{for } c_0 \gg c_s \end{aligned} \quad (12.9)$$

The release rate at any time is then given by

$$\begin{aligned} \frac{dM_t}{dt} &= \frac{A}{2} \left[\frac{DKc_2}{t} (2c_0 - c_s) \right]^{1/2} \\ &\simeq \frac{A}{2} \left(\frac{2DKc_s c_0}{t} \right)^{1/2} \quad \text{for } c_0 \gg c_s \end{aligned} \quad (12.10)$$

The Higuchi model is an approximate solution in that it assumes a ‘pseudosteady state’, in which the concentration profile from the dispersed drug front to the outer surface is linear. Paul and McSpadden [24] have shown that the correct expression can be written as:

$$M_t = A[2DKtc_s(c_0 - Kc_s)]^{1/2} \quad (12.11)$$

which is almost identical to Equation (12.9), and reduces to it when $c_0 \gg c_s$. Clearly the release rate is proportional to the square root of the loading; thus, it can be easily varied by incorporating more or less agent. Furthermore, although the release rate is by no means constant, the range of variation is narrower than would be the case if the agent were merely dissolved, rather than dispersed, in the matrix. An example of the release rate of the drug from an ethylene-vinyl acetate slab containing dispersed antibiotic chloramphenicol is shown in Figure 12.14. The drug release rate decreases in proportion to the square root of time in accordance with Equation (12.10).

Biodegradable Systems

The diffusion-controlled devices outlined so far are permanent, in that the membrane or matrix of the device remains implanted after its delivery role is completed. In some applications, particularly in the medical field, this is undesirable; such applications require a device that degrades during or subsequent to its delivery role.

Many polymer-based devices that slowly biodegrade when implanted in the body have been developed; the most important are based on polylactic acid, polyglycolic acid and their copolymers. In principle, the release of an active agent can be programmed by dispersing the material within such polymers, with erosion of the polymer effecting release of the agent [25,26]. One class of biodegradable polymers is *surface eroding*; the surface area of such polymers decreases with time as the conventionally cylindrical- or spherical-shaped device erodes. This

Figure 12.14 Release of the antibiotic drug chloramphenicol dispersed in a matrix of poly(ethylene-vinyl acetate). The solid line is calculated from Equation (12.10) [21]

results in a decreasing release rate unless the geometry of the device is appropriately manipulated or the device is designed to contain a higher concentration of the agent in the interior than in the surface layers. In a more common class of biodegradable polymer, the initial period of degradation occurs very slowly, after which the degradation rate increases rapidly. The bulk of the polymer then erodes over a comparatively short period. In the initial period of exposure to the body, the polymer chains are being cleaved but the molecular weight is still high, so the polymer's mechanical properties are not seriously affected. As chain cleavage continues, a point is reached at which the polymer fragments become swollen or soluble in water. At this point the polymer begins to dissolve. This type of polymer can be used to make reservoir or monolithic diffusion-controlled systems that degrade after their delivery role is over. A final category of polymer has the active agent covalently attached by a labile bond to the backbone of a matrix polymer. When placed at the site of action the labile bonds slowly degrade, releasing the active agent and forming a soluble polymer. The methods by which these concepts can be formulated into actual practical systems are illustrated in Figure 12.15.

Osmotic Systems

Osmotic effects are often a problem in diffusion-controlled systems because imbibition of water swells the device or dilutes the drug. However, several devices

(a) Degradation-controlled Monolithic System

(b) Diffusion-controlled Monolithic System

(c) Diffusion-controlled Reservoir System

(d) Erovable Polyagent System

Figure 12.15 Methods of using biodegradable polymers in controlled release implantable devices to release the active agent, A

have been developed that actually use osmotic effects to control the release of drugs. These devices, called osmotic pumps, use the osmotic pressure developed by diffusion of water across a semipermeable membrane into a salt solution to push a solution of the active agent from the device. Osmotic pumps of various designs are applied widely in the pharmaceutical area, particularly in oral tablet formulations [27].

The forerunner of modern osmotic devices was the Rose–Nelson pump. Rose and Nelson were two Australian physiologists interested in the delivery of drugs to the gut of sheep and cattle [11]. Their pump, illustrated in Figure 12.16,

Figure 12.16 Principle of the three-chamber Rose–Nelson osmotic pump first described in 1955 [11]

consists of three chambers: a drug chamber, a salt chamber containing excess solid salt and a water chamber. The salt and water chambers are separated by a rigid semipermeable membrane. The difference in osmotic pressure across the membrane moves water from the water chamber into the salt chamber. The volume of the salt chamber increases because of this water flow, which distends the latex diaphragm separating the salt and drug chambers, thereby pumping drug out of the device.

The pumping rate of the Rose–Nelson pump is given by the equation

$$\frac{dM_t}{dt} = \frac{dV}{dt}c \tag{12.12}$$

where dM_t/dt is the drug release rate, dV/dt is the volume flow of water into the salt chamber and c is the concentration of drug in the drug chamber. The osmotic water flow across a membrane is given by the equation

$$\frac{dV}{dt} = \frac{A\theta\Delta\pi}{l} \tag{12.13}$$

where dV/dt is a water flow across the membrane of area A , thickness l , and osmotic permeability θ ($\text{cm}^3 \cdot \text{cm}/\text{cm}^2 \cdot \text{h} \cdot \text{atm}$), and $\Delta\pi$ is the osmotic pressure difference between the solutions on either side of the membrane. This equation is only strictly true for completely selective membranes—that is, membranes permeable to water but completely impermeable to the osmotic agent. However, this is a good approximation for most membranes. Substituting Equation (12.13) for the flux across the membrane gives

$$\frac{dM_t}{dt} = \frac{A\theta\Delta\pi c}{l} \quad (12.14)$$

The osmotic pressure of the saturated salt solution is high, on the order of tens of atmospheres, and the small pressure required to pump the suspension of active agent is insignificant in comparison. Therefore, the rate of water permeation across the semipermeable membrane remains constant as long as sufficient solid salt is present in the salt chamber to maintain a saturated solution and hence a constant osmotic pressure driving force.

The Higuchi–Leeper pump designs represent the first of a series of simplifications of the Rose–Nelson pump made by Alza Corporation beginning in the early 1970s. An example of one of these designs [28] is shown in Figure 12.17. The

Figure 12.17 The Higuchi–Leeper osmotic pump design [28]. This device has no water chamber and can be stored in a sealed foil pouch indefinitely. However, once removed from the pouch and placed in an aqueous environment, for example, by an animal swallowing the device, the pumping action begins. The active agent is pumped at a constant rate according to Equation (12.14)

Higuchi–Leeper pump has no water chamber; the device is activated by water imbibed from the surrounding environment. This means that the drug-laden pump can be prepared and then stored for weeks or months prior to use. The pump is only activated when it is swallowed or implanted in the body. Higuchi–Leeper pumps contain a rigid housing, and the semipermeable membrane is supported on a perforated frame. This type of pump usually has a salt chamber containing a fluid solution with excess solid salt. The target application of this device was the delivery of antibiotics and growth hormones to animals because repeated delivery of oral medications to animals is difficult. The problem is solved by these devices, which are designed to be swallowed by the animal and then to reside in the rumen, delivering a full course of medication over a period of days to weeks.

In the early 1970s, Higuchi and Theeuwes developed another, even simpler variant of the Rose–Nelson pump [29,30]. One such device is illustrated in Figure 12.18. As with the Higuchi–Leeper pump, water to activate the osmotic action of the pump comes from the surrounding environment. The Higuchi–Theeuwes device, however, has no rigid housing—the membrane acts as the outer casing of the pump. This membrane is quite sturdy and is strong enough to withstand the pumping pressure developed inside the device. The device is loaded with the desired drug prior to use. When the device is placed in an aqueous environment, release of the drug follows a time course set by the salt used in the salt chamber and the permeability of the outer membrane casing.

The principal application of these small osmotic pumps has been as implantable controlled release delivery systems in experimental studies on the effect of continuous administration of drugs. The devices are made with volumes of 0.2–2 mL. Figure 12.18 shows one such device being implanted in a laboratory rat. The delivery pattern obtained with the device is constant and independent of the site of implantation, as shown by the data in Figure 12.19.

The development that made osmotic delivery a major method of achieving controlled drug release was the invention of the elementary osmotic pump by Theeuwes in 1974 [31]. The concept behind this invention is illustrated in Figure 12.20. The device is a further simplification of the Higuchi–Theeuwes pump, and eliminates the separate salt chamber by using the drug itself as the osmotic agent. The device is formed by compressing a drug having a suitable osmotic pressure into a tablet using a tableting machine. The tablet is then coated with a semipermeable membrane, usually cellulose acetate, and a small hole is drilled through the membrane coating. When the tablet is placed in an aqueous environment, the osmotic pressure of the soluble drug inside the tablet draws water through the semipermeable coating, forming a saturated aqueous solution inside the device. The membrane does not expand, so the increase in volume caused by the imbibition of water raises the hydrostatic pressure inside the tablet slightly. This pressure is relieved by a flow of saturated drug solution out of the device through the small orifice. Thus, the tablet acts as a small pump, in which water is drawn osmotically into the tablet through the membrane wall and then

Figure 12.18 The Higuchi–Theeuwes osmotic pump has been widely used in drug delivery tests in laboratory animals. The device is small enough to be implanted under the skin of a rat and delivers up to 1000 μL of drug solution over a 3- to 4-day period [29,30]

leaves as a saturated drug solution through the orifice. This process continues at a constant rate until all the solid drug inside the tablet has been dissolved and only a solution-filled shell remains. This residual dissolved drug continues to be delivered, but at a declining rate, until the osmotic pressures inside and outside the tablet are equal. The driving force that draws water into the device is the difference in osmotic pressure between the outside environment and a saturated

drug solution. Therefore, the osmotic pressure of the dissolved drug solution has to be relatively high to overcome the osmotic pressure of the body, but for drugs with solubilities greater than 5–10 wt% these devices function very well. Later variations on the simple osmotic tablet design have been made to overcome the solubility limitation. The elementary osmotic pump was developed by Alza under the name OROS[®], and is commercially available for a number of drugs.

The four types of osmotic pump described above are interesting examples of how true innovation is sometimes achieved by leaving things out. The first osmotic pump produced by Rose and Nelson contained six critical components, had a volume of 80 cm³, and was little more than a research tool. In the early 1980s, Felix Theeuwes and others progressively simplified and refined the concept, leading in the end to the elementary osmotic pump, a device that looks almost trivially simple. It has been described as a tablet with a hole, but is, in fact, a truly elegant invention having a volume of less than 1 cm³, containing only two components, achieving almost constant drug delivery, and allowing manufacture on an enormous scale at minimal cost. Figure 12.21 shows examples of the four main types of osmotic pumps taken from the patent drawings. The pumps are drawn to scale to illustrate the progression that occurred as the design was simplified.

13 OTHER MEMBRANE PROCESSES

Introduction

Any book must leave something out, and this one has left out a good deal; it does not cover membranes used in packaging materials, sensors, ion-selective electrodes, fuel cells, battery separators, electrophoresis and thermal diffusion. In this final chapter, five processes that come under the general title of 'other' are covered briefly.

Dialysis

Dialysis was the first membrane process to be used on an industrial scale, with the development of the Cerini dialyzer in Italy [1]. The production of rayon from cellulose expanded rapidly in the 1930s, resulting in a need for technology to recover sodium hydroxide from the large volumes of hemicellulose-sodium hydroxide by-product solutions. The hemicellulose was of little value, but the 17–18 wt% sodium hydroxide, if separated, could be reused directly in the process. Hemicellulose has a much higher molecular weight than sodium hydroxide, so parchmented woven fabric or impregnated cotton cloth made an adequate dialysis membrane. The Cerini dialyzer, illustrated in Figure 13.1, consisted of a large tank containing 50 membrane bags. Feed liquid passed through the tank while the dialysate solution passed countercurrently through each bag in parallel. The product dialysate solution typically contained 7.5–9.5% sodium hydroxide and was essentially free of hemicellulose. About 90% of the sodium hydroxide in the original feed solution was recovered. The economics of the process were very good, and the Cerini dialyzer was widely adopted. Later, improved membranes and improved dialyzer designs, mostly of the plate-and-frame type, were produced. A description of these early industrial dialyzers is given in Tuwiner's book [2].

Dialysis was also used in the laboratory in the 1950s and 1960s, mainly to purify biological solutions or to fractionate macromolecules. A drawing of the

Figure 13.1 Elevation, plan drawing and flow scheme of the Cerini dialyzer, the first successful industrial dialyzer used to recover sodium hydroxide from waste streams resulting from the production of rayon [2]

laboratory dialyzer used by Craig and described in a series of papers in the 1960s is shown in Figure 13.2 [3,4]. Until ultrafiltration membranes became available in the late 1960s, this device was the only way to separate many large-volume biological solutions.

Now the major application of dialysis is the artificial kidney and, as described in Chapter 12, more than 100 million of these devices are used annually. Apart from this one important application, dialysis has essentially been abandoned as a separation technique, because it relies on diffusion, which is inherently unselective and slow, to achieve a separation. Thus, most potential dialysis separations are better handled by ultrafiltration or electro dialysis, in both of which an outside force and more selective membranes provide better, faster separations. The only three exceptions—Donnan dialysis, diffusion dialysis and piezodialysis—are described in the following sections.

Figure 13.2 Schematic drawing of laboratory dialyzer developed by Craig [4] to separate low-molecular-weight impurities from biological solutions. This was the best method of performing this separation until ultrafiltration membranes became available in the late 1960s. The feed solution was circulated through the inside of the membrane tube; solvent solution was circulated on the outside. Boundary layer formation was overcome by rotating the outer shell with a small motor

Donnan Dialysis and Diffusion Dialysis

One dialysis process for which the membrane does have sufficient selectivity to achieve useful separations is Donnan dialysis. If salt solutions are separated by a membrane permeable only to ions of one charge, such as a cation exchange membrane containing fixed negatively charged groups, then distribution of two different cations M^+ and N^+ across the membrane can be expressed by the Donnan expression

$$\frac{[M]_o}{[M]_l} = \frac{[N]_o}{[N]_l} \tag{13.1}$$

where $[M]_o$ and $[N]_o$ are the concentrations of the two ions in the feed solution, and $[M]_l$ and $[N]_l$ are the concentrations of the two ions in the product solution. The derivation of the expression is given in Chapter 10. This equation has the same form as Equation (11.10) derived for coupled transport in Chapter 11, in which a cation-permeable, anion-impermeable membrane separates the two solutions. The difference between coupled transport and Donnan dialysis lies in how the membrane performs the separation.

Donnan dialysis was first described as a separation technique in 1967 by Wallace [5,6], who was interested in concentrating small amounts of radioactive metal ions. He used cation exchange membranes to treat a large volume of nearly neutral feed solution containing small amounts of metal salts such as uranyl nitrate $\text{UO}_2(\text{NO}_3)_2$. A small volume of 2 M nitric acid was used as the receiving solution. Because the membrane contained fixed negative charges, negative ions from the surrounding solutions were essentially excluded from the membrane, and only hydrogen ions (H^+) and uranyl ions (UO_2^{++}) could permeate the membrane. The very large difference in hydrogen ion concentration across the membrane meant that a large driving force was generated for hydrogen ions to diffuse to the dilute feed solution. To maintain electrical neutrality, an equal number of uranyl ions had to diffuse to the receiving solution. Wallace's apparatus and the results of one of his experiments are shown in Figure 13.3. In this experiment, 98 % of the

Figure 13.3 Illustration of a Donnan dialysis experiment to separate and concentrate uranyl nitrate, $\text{UO}_2(\text{NO}_3)_2$, after Wallace [5]

uranyl ions were stripped from the feed solution and concentrated 28-fold in the product nitric acid strip solution.

Like coupled transport, Donnan dialysis can concentrate metal ions many fold. The process is usually driven by an appropriate pH gradient. Because the membranes are normal cation or anion exchange membranes, the stability problems that plague the liquid membranes used in coupled transport are avoided. On the other hand, coupled transport uses carriers selective for one particular ion, excluding others. This property allows coupled transport membranes to selectively transport one particular ion across the membrane, both concentrating and separating the target ion from similar ions in the feed solution. Donnan dialysis membranes are essentially nonselective—all ions of the same charge in the feed solution are transported to the product solution at about the same rate.

Donnan dialysis can be made more selective if a complexing agent specific to one of the ions being transported across the membrane is added to the strip solution. For example, Huang *et al.* [7] used cation exchange membranes driven by sodium ions to transport copper and nickel ions across the membrane. Addition of complexing agents specific for nickel ions, such as oxalic acid or glycine, to the strip solution increased the selectivity of the membrane for nickel over copper dramatically. By removing nickel ions from the receiving solution, the complexing agent maintained a high driving force for nickel transport even when the copper ion concentration had reached equilibrium.

Although Donnan dialysis membranes can perform interesting separations, these membranes are a solution to few industrially important applications. Consequently, Donnan dialysis remains a solution in search of a problem.

A related dialysis process, diffusion dialysis, has found an application, mostly to recover acids from spent metal pickling agents such as sulfuric acid, hydrochloric acid or nitric–hydrofluoric acids [8]. These pickling chemicals remove scale from metal parts and become contaminated over time with iron, chromium, copper, nickel, zinc and other heavy metals. Acid recovery by electro-dialysis is possible but diffusion-dialysis—a completely passive process—is often preferred because of its simplicity. The process utilizes the difference in permeability of hydrogen ions and multivalent metal ions through anion exchange membranes. A flow schematic is shown in Figure 13.4. The feed solution, containing heavy metal salts and acid, flows countercurrent to water, from which it is separated by an anion exchange membrane. The membrane, which is freely permeable to anions, also preferentially permeates hydrogen ions over heavy-metal cations. As a result, the acids in the feed solution, sulfuric acid in the example of Figure 13.4, are removed from the spent liquor and metal ions remain behind. Recovery of 70–80% acid, contaminated with only a few percent of the metal ions, is possible.

Figure 13.4 Schematic of a diffusion dialysis process to separate acids from heavy metal/acid mixtures

Charge Mosaic Membranes and Piezodialysis

Donnan dialysis, described in the previous section, is a type of ion exchange process. Ions of the same charge are redistributed across the membrane, but no net flow of salt from one side of the membrane to the other occurs. This is because ion exchange membranes are quite impermeable to salts. Although counter-ions to the fixed charge groups in the membrane can easily permeate the membrane, ions with the same charge as the fixed charge groups are excluded and do not permeate. Sollner [9] proposed that, if ion exchange membranes consisting of separated small domains of anionic and cationic membranes could be made, they would be permeable to both anions and cations. These membranes are now called charge mosaic membranes; the concept is illustrated in Figure 13.5. Cations permeate the cationic membrane domain; anions permeate the anionic domain.

Charge mosaic membranes can preferentially permeate salts from water. This is because the principle of electroneutrality requires that the counter-ion concentration inside the ion exchange regions be at least as great as the fixed charge density. Because the fixed charge density of ion exchange membranes is typically greater than 1 M, dilute counter-ions present in the feed solution are concentrated 10- to 100-fold in the membrane phase. The large concentration gradient that forms in the membrane leads to high ion permeabilities. Water and neutral solutes are not concentrated in the membrane and permeate at low rates. When used as dialysis membranes, therefore, these charged mosaic membranes are permeable to salts but relatively impermeable to non-ionized solutes.

Figure 13.5 Charge mosaic membranes, consisting of finely dispersed domains containing fixed negatively and fixed positively charged groups, are salt permeable [15]

For charge mosaic membranes to work most efficiently, the cationic and anionic domains in the membrane must be close together to minimize charge separation effects [10–12]. The first charge mosaic membranes were made by distributing very small ion exchange beads in an impermeable support matrix of silicone rubber [13,14]. A second approach, used by Platt and Schindler [15], was to use the mutual incompatibility of most polymers that occurs when a solution containing a mixture of two different polymers is evaporated. Figure 13.6 shows a photomicrograph of a film cast from poly(styrene-*co*-butadiene) and poly(2-vinyl pyridine-*co*-butadiene). The *co*-butadiene fraction makes these two polymers mutually soluble in tetrahydrofuran but, on evaporation of the solvent, a two-phase-domain structure extending completely through the membrane layer forms. Once formed, the poly(2-vinyl pyridine-*co*-butadiene) portion of the membrane is quaternarized to form fixed positive groups, and the poly(styrene-*co*-butadiene) portion of the membrane is sulfonated to form fixed negative groups.

Miyaki and Fujimoto and co-workers [16,17] have obtained an even finer distribution of fixed charge groups by casting films from multicomponent block copolymers such as poly(isoprene-*b*-styrene-*b*-butadiene-*b*-(4-vinyl benzyl)dimethylamine-*b*-isoprene). These films show a very regular domain structure with a 200–500 Å spacing. After casting the polymer film, the (4-vinyl benzyl) dimethylamine blocks were quaternarized with methyl iodide vapor, and the styrene blocks were sulfonated with chlorosulfuric acid.

Figure 13.6 Film cast from a 1:2 mixture of poly(styrene-*co*-butadiene) and poly(2-vinyl pyridine-*co*-butadiene) with about 15 mol% butadiene content (10 wt% solution of the copolymers in tetrahydrofuran). Dark areas, poly(styrene-*co*-butadiene); light areas, poly(2-vinyl pyridine-*co*-butadiene) [15]. Courtesy of Dr A. Schindler

Table 13.1 Solute flux measured in well-stirred dialysis cells at 25 °C using 0.1 M feed solutions [17]. Reprinted with permission from K. Hirahara, S.-I. Takahashi, M. Iwata, T. Fujimoto and Y. Miyaki, Artificial Membranes from Multiblock Copolymers (5), *Ind. Eng. Chem. Prod. Res. Dev.* **305**, 25. Copyright 1986, American Chemical Society and American Pharmaceutical Association

Solute	Flux (10^{-8} mol/cm ² · s)
Sodium chloride	7.5
Potassium chloride	9
Hydrochloric acid	18
Sodium hydroxide	10
Glucose	0.08
Sucrose	0.04

Using the block copolymer membranes described above, significant selectivities for electrolytes over non-electrolytes have been observed. Some data reported by Hirahara *et al.* [17] are shown in Table 13.1. The ionizable electrolytes were 100 times more permeable than non-ionized solutes such as glucose and sucrose, suggesting a number of potential applications in which deionization of mixed solutions is desirable. The permeabilities of salts in these membranes are also

orders of magnitude higher than values measured for normal ion exchange membranes. In principle then, these membranes can be used in deionization processes, for example, to remove salts from sucrose solutions in the sugar industry.

A second potential application is pressure-driven desalination. When a pressure difference is applied across the membrane, the concentrated ionic groups in the ion exchange domains are swept through the membrane, producing a salt-enriched permeate on the low-pressure side. This process, usually called piezodialysis, has a number of conceptual advantages over the alternative, conventional reverse osmosis, because the minor component (salt), not the major component (water), permeates the membrane.

Piezodialysis has been the subject of sporadic research for a number of years but so far has met with little success. It was originally hoped that the flow of water and salt through charge mosaic membranes would be strongly coupled. If this were the case, the 100-fold enrichment of ions within the charged regions of the membrane would provide substantial enrichment of salt in the permeate solution. In practice, the enrichment obtained is relatively small, and the salt fluxes are low even at high pressures. The salt enrichment also decreases substantially as the salt concentration in the feed increases, limiting the potential applications of the process to desalination of low concentration solutions. Some results of piezodialysis experiments with block copolymer membranes and a potassium chloride solution are shown in Figure 13.7.

Figure 13.7 Piezodialysis of 0.02 M potassium chloride solution with block copolymer charge mosaic membranes [14]. Enrichment is calculated using the expression:

$$\text{enrichment} = 100 \left(\frac{\text{concentration permeate}}{\text{concentration feed}} - 1 \right)$$

Membrane Contactors and Membrane Distillation

In the membrane processes discussed elsewhere in this book, the membrane acts as a selective barrier, allowing relatively free passage of one component while retaining another. In membrane contactors, the membrane functions as an interface between two phases but does not control the rate of passage of permeants across the membrane. The use of a membrane as a contactor in a process to deoxygenate water is shown in Figure 13.8. Typically the membrane is a microporous hollow fiber that separates oxygen-containing water from a nitrogen sweep gas. Dissolved oxygen in the water diffuses to the nitrogen sweep gas. Even though the dissolved oxygen concentration in the water is very low, its equilibrium concentration in the gas phase in contact with the water is several thousand times higher. This means that oxygen permeation through the membrane down the concentration gradient to the nitrogen sweep gas is high. The function of the membrane in this application is to provide a high surface area for contact between the water and the nitrogen sweep gas. The relative permeabilities of oxygen and water vapor through the membrane are not a factor; exactly the same separation could be achieved by running the water and nitrogen countercurrent to each other in a packed tower. However, as shown later, membrane contactors can offer useful advantages over packed towers.

Membrane contactors are typically shell-and-tube devices containing microporous capillary hollow fiber membranes. The membrane pores are sufficiently small that capillary forces prevent direct mixing of the phases on either side of the membrane. The membrane contactor shown in Figure 13.8 separates a liquid and a gas phase: this is a liquid/gas contactor [18]. Membrane contactors

Figure 13.8 Application of a membrane contactor to remove dissolved oxygen from water

can also be used to separate two immiscible liquids (liquid/liquid contactors) or two miscible liquids (usually called membrane distillation). Contactors can also be used to selectively absorb one component from a gas mixture into a liquid (gas/liquid contactors). The various types of membrane contactors that have been used are illustrated in Figure 13.9.

Contactors have a number of advantages compared to simple liquid/gas absorber/strippers or liquid/liquid extractors. Perhaps the most important advantage is high surface area per volume. The contact area of membrane contactors compared to traditional contactor columns is shown in Table 13.2. Membrane contactors provide 10-fold higher contactor areas than equivalent-sized towers. This makes membrane

Figure 13.9 Examples of membrane contactors and their applications

Table 13.2 The specific surface areas of different contactors [20]

Contactor	Surface area per volume (cm ² /cm ³)
Free dispersion columns	0.03–0.3
Packed/trayed columns	0.3–3
Mechanically agitated columns	2–5
Membranes	10–50

contactors small and light, sometimes an important advantage. Blood oxygenators were not widely used for open heart surgery until the membrane blood oxygenator was developed, reducing the volume of blood required to operate the device to a manageable level. Similarly, the principal motivation to develop membrane contactors for offshore dehydration and carbon dioxide removal from natural gas is the reduction in weight and footprint possible. Kvaerner have shown that membrane contactors for this service have one-fourth of the footprint and one-tenth of the weight of conventional absorber/strippers [19].

A second advantage of membrane contactors is the physical separation of the counter-flowing phases by the membrane. The membrane area between the two phases is independent of their relative flow rates, so large flow ratio differences can be used without producing channeling or flooding or poor phase contact, and maximum advantage can be taken of the ability of counter-flow to separate and concentrate the components crossing the membrane. Small volumes of high cost extractants can be used to treat large volumes of low value feed. Separation of the two phases also eliminates entrainment of one phase by the other, as well as foaming. Finally, unlike traditional contactors, fluids of equal density can be used for the two phases.

The main disadvantages of contactors are related to the nature of the membrane interface. The membrane acts as an additional barrier to transport between the two phases that can slow the rate of separation. Over time, the membranes can foul, reducing the permeation rate further, or develop leaks, allowing direct mixing of the two phases. Finally, the polymeric membranes are necessarily thin (to maximize their permeation rate) and consequently cannot withstand large pressure differences across the membrane or exposure to harsh solvents and chemicals. In many industrial settings, this lack of robustness prohibits the use of membrane contactors.

Despite these caveats, the use of membrane contactors is growing rapidly. Positive reviews are given by Reed *et al.* [20], Qi and Cussler [21], Gabelman and Hwang [22] and Prasad and Sirkar [23].

Table 13.3 shows the dimensions of a series of industrial hollow fiber contactors produced by Hoechst Celanese under the trade name Liqui-Cel[®]. The

Table 13.3 Details of Liqui-Cel[®] hollow fiber membrane contactor modules

Module dimensions		Number of fibers ($\times 1000$)	Membrane area (m^2)	Area/unit volume (cm^2/cm^3)
Diameter (cm)	Length (cm)			
8	28	8	1.4	29
10	71	45	19	36
25	71	300	130	39

contact area per unit volume (cm^2/cm^3) is between 25 and 40. This high surface-to-volume ratio is achieved by making the fluid space between the membranes small—in the case of Liqui-Cel devices, between 200 and 400 μm . This means that the fluids passed through these devices must be particulate-free to avoid rapid plugging with retained particulates.

Applications of Membrane Contactors

Gas Exchange Contactors

Delivery or removal of gases from liquids is currently the largest commercial application of membrane contactors. One example is blood oxygenators, described in Chapter 12. Industrial applications of similar devices include deoxygenation of ultrapure water for the electronics industry or boiler feed water [24] and the adjustment of carbonation levels in beverages. [25] The performance of an industrial-scale oxygen removal system is shown in Figure 13.10. This unit consists of a 10-in.-diameter, rather short, capillary device containing about 135 m^2 of contactor area. The aqueous phase is circulated on the outer, shell-side of the fibers to avoid the excessive pressure required to circulate fluid at a high velocity down the fiber bore. The major resistance to mass transfer is in the liquid boundary on the outside of the fiber, so a baffled hollow fiber membrane module design [26] is used to cause radial flow of the fluid across the membrane from a central fluid distribution tube. Nitrogen sweep gas flows down the inside of the fibers. This design produces good turbulent mixing in the contactor at moderate pressure drops.

Figure 13.10 Oxygen removal from water with a 10-in.-diameter membrane contactor (135 m^2 membrane area) [24]

In Europe, the TNO [27] and Kvaerner [19] are both developing contactors to remove water and carbon dioxide from natural gas. Glycol or amines are used as the absorbent fluid. The goal is to reduce the size and weight of the unit to allow use on offshore platforms, so oftentimes only the absorber, the largest piece of equipment in a traditional absorber/stripper, is replaced with a membrane contactor. Kvaerner has taken this technology to the demonstration phase and commercial units are expected to be introduced soon.

Another type of gas exchange process, developed to the pilot plant stage, is separation of gaseous olefin/paraffin mixtures by absorption of the olefin into silver nitrate solution. This process is related to the separation of olefin/paraffin mixtures by facilitated transport membranes described in Chapter 11. A membrane contactor provides a gas-liquid interface for gas absorption to take place; a flow schematic of the process is shown in Figure 13.11 [28,29]. The olefin/paraffin gas mixture is circulated on the outside of a hollow fiber membrane contactor, while a 1–5 M silver nitrate solution is circulated countercurrently down the fiber bores. Hydrophilic hollow fiber membranes, which are wetted by the aqueous silver nitrate solution, are used.

The olefin fraction of the feed gas crosses the membrane and reacts reversibly with silver ions to form a soluble silver-olefin complex

The olefin-laden silver solution is then pumped to a flash tank, where the pressure is lowered and the temperature raised sufficiently to reverse the complexation reaction and liberate pure ethylene. The regenerated silver nitrate solution is returned to the contactor. In this process, the high cost of the silver nitrate carrier

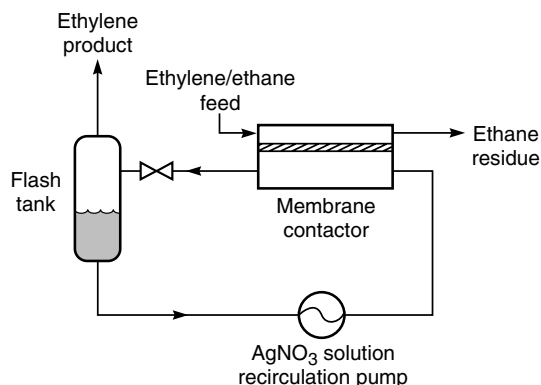

Figure 13.11 Flow schematic of the membrane contactor process developed by British Petroleum to separate ethylene/ethane mixtures by absorption into silver nitrate solution [28,29]

must be balanced against the cost of the membrane contactor. If the silver solution is circulated through the contactor at a very high rate, high fluxes are obtained, but the silver utilization calculated from the silver ion amount complexed in the contactor is low compared to the maximum possible complexation achievable under the condition of the test.

Absorption of olefin from olefin/paraffin mixtures has been scaled up to the pilot plant scale, and a number of successful trials were performed in the early 1990s. Separation factors of 200 or more were obtained, producing 99.7% pure ethylene. However, slow degradation of the silver nitrate solution is a problem, and a portion of the recirculating degraded silver nitrate solution must be bled off and replaced with fresh solution continuously. Boundary layer problems on the liquid side of the membrane are also a serious issue in these devices [21].

To reduce the relatively large volume of silver nitrate solution held in the flash tank portion of the plant shown in Figure 13.11, Bessarabov *et al.* [30] have proposed using two membrane contactors in series, as shown in Figure 13.12. One contactor functions as an absorber, the other as a stripper. The first contactor removes ethylene from the pressurized feed gas into cold silver nitrate solution. The solution is then warmed and pumped to the second contactor where ethylene is desorbed from the silver nitrate solution into a low-pressure product ethylene gas stream. The regenerated silver nitrate solution is cooled and returned to the first contactor.

Bessarabov's devices use composite membranes consisting of a thin silicone rubber polymer layer coated onto a microporous poly(vinylidene fluoride) support layer. These membranes have high fluxes and minimal selectivities for the hydrocarbon gases, but the dense silicone layer provides a more positive barrier to bleed-through of liquid than do capillary effects with simple microporous membranes.

Figure 13.12 Flow schematic of process using two membrane contactors for the separation of ethylene/ethane mixtures proposed by Bessarabov *et al.* [30]

Liquid/Liquid Membrane Contactors (Membrane Distillation)

The most important example of liquid/liquid membrane contactors is membrane distillation, shown schematically in Figure 13.13. In this process, a warm, salt-containing solution is maintained on one side of the membrane and a cool pure distillate on the other. The hydrophobic microporous membrane is not wetted by either solution and forms a vapor gap between the two solutions. Because the solutions are at different temperatures, their vapor pressures are different; as a result, water vapor flows across the membrane. The water vapor flux is proportional to the vapor pressure difference between the warm feed and the cold permeate. Because of the exponential rise in vapor pressure with temperature, the flux increases dramatically as the temperature difference across the membrane is increased. Dissolved salts in the feed solution decrease the vapor pressure driving force, but this effect is small unless the salt concentration is very high. Some typical results illustrating the dependence of flux on the temperature and vapor pressure difference across a membrane are shown in Figure 13.14.

Figure 13.13 A schematic illustration of the membrane distillation process showing temperature and water vapor pressure gradients that drive the process

Figure 13.14 Water flux across a microporous membrane as a function of temperature and vapor pressure difference (distillate temperature, 18–38 °C; feed solution temperature, 50–90 °C). Taken from the data of Schneider *et al.* [31]

Membrane distillation offers a number of advantages over alternative pressure-driven processes such as reverse osmosis. Because the process is driven by temperature gradients, low-grade waste heat can be used and expensive high-pressure pumps are not required. Membrane fluxes are comparable to reverse osmosis fluxes, so membrane areas are not excessive. Finally, the process is still effective with slightly reduced fluxes even for very concentrated solutions. This is an advantage over reverse osmosis, in which the feed solution osmotic pressure places a practical limit on the concentration of a salt in the feed solution to be processed.

The principal application proposed for the technique is the separation of water from salt solutions. In the 1980s Enka, a division of Akzo, developed membrane distillation to the commercial scale using microporous polypropylene capillary membrane modules. The design and performance of their process are shown in Figure 13.15 [31]. The condensed distillate produced is almost salt free, whereas the salt concentration on the warm brine side of the membrane increases from 0.05 % to more than 20 %. At very high salt concentrations the flux across the membrane decreases slightly. Essentially all the power to drive the process is provided as low-grade heat. Despite the technical success of the device, a significant market did not develop. For large applications such as seawater desalination,

Figure 13.15 Flow scheme and performance data for a membrane distillation process for the production of water from salt solutions [31]. Feed salt solution is heated to 100 °C and passed counter-current to cool distillate that enters at 42 °C. The distillate product is almost salt-free as shown by its low conductivity. The distillate flux is almost constant up to salt concentrations as high as 20 % NaCl. Reprinted from *J. Membr. Sci.* **39**, K. Schneider, W. Hölz, R. Wollbeck and S. Ripperger, *Membranes and Modules for Transmembrane Distillation*, p. 25. Copyright 1988, with permission from Elsevier

for which the potential energy savings were significant, the capillary membrane contactor modules were too expensive compared to low-cost, reliable reverse osmosis modules. For smaller applications on chemical process streams, the energy savings were not important, so cost and reliability compared to simple evaporation were an issue. Currently there are no commercial producers of membrane distillation systems, although the process is still the subject of academic interest [32,33].

Membrane Reactors

By the early 1980s membrane technology had developed to the point at which a number of industrial groups began to consider using membranes to control the products of chemical reactions. Two properties of membranes are used; the first is the membrane as a contactor, as illustrated in Figure 13.16(a). The membrane separates the reaction medium in one chamber from a second chamber containing a catalyst, enzymes or a cell culture. This type of application has a long history in fermentation processes involving so-called bioreactors [34]. More recently, membrane reactors are being developed for conventional chemical

Figure 13.16 Examples of the three types of membrane reactor

separations [35]. As the reaction medium flows through the first chamber, membrane reactants diffuse through the membrane, react in the second chamber, and then diffuse back out to be collected as a product stream. The membrane provides a large exchange area between the catalytic material and the reaction medium but performs no separation function. In the example shown, the reactant is pectin, a high molecular weight polysaccharide present in citrus juice that causes an undesirable haze in the juice. Degradation of the pectin to galacturonic acid by the enzyme pectinase eliminates the haze [36].

The second type of membrane reactor, illustrated in Figure 13.16(b), uses the separative properties of a membrane. In this example, the membrane shifts the equilibrium of a chemical reaction by selectively removing one of the components of the reaction. The example illustrated is the important dehydrogenation reaction converting *n*-butane to butadiene and hydrogen

Removing hydrogen from the reaction chamber by permeation through the membrane causes the chemical equilibrium to shift to the right, and the conversion of butane to butadiene increases [37].

A third type of membrane reactor combines the functions of contactor and separator. An example of this combination membrane reactor is shown in Figure 13.16(c), in which the membrane is a multilayer composite. The layer facing the organic feed stream is an immobilized organic liquid membrane; the layer facing the aqueous product solution contains an enzyme catalyst for the de-esterification reaction

Organic-soluble ester is brought to the reactor with the organic feed solution and freely permeates the immobilized organic liquid membrane to reach the catalyst enzyme. The ester is then hydrolyzed. The alcohol and acid products of hydrolysis are much more polar than the ester and, as such, are water soluble but relatively organic insoluble. These products diffuse to the aqueous permeate solution. The membrane both provides an active site for the reaction and separates the products of reaction from the feed [38].

In the membrane reactor shown in Figure 13.16(c), the chemical reaction and the separation step use the same membrane. However, in some processes it is desirable to separate reaction and separation into two distinct operations. If the net result of the process is to change the products of the chemical reaction, the process is still classified under the broad heading of membrane reactor. Two examples in which chemical reaction and separation are physically separated are shown in Figure 13.17. Figure 13.17(a) shows the use of a pervaporation membrane to shift the equilibrium of the de-esterification reaction [39,40]. A portion of the organic solution in the esterification reactor is continuously circulated past the

(a) Removal of the water of reaction from batch esterification processes to drive the reaction to completion

(b) Removal of hydrogen in the dehydrogenation of *n*-butane

Figure 13.17 Examples of membrane reactors used to change the products of chemical reaction in which the membrane separation step is physically separated from the chemical reaction step

surface of a water-permeable membrane. Water produced in the esterification reaction is removed through the membrane. By removing the water, the reaction can be driven to completion.

Figure 13.17(b) shows the use of a hydrogen-permeable membrane to shift the equilibrium of the *n*-butane dehydrogenation reaction. The catalytic reactor is divided into steps, and the hydrogen-permeable membrane placed between each step. Because the hydrogen is removed from the reactor in two discrete steps, some inefficiency results, but separating the membrane separation step from the catalytic reactor allows the gas to be cooled before being sent to the membrane separator. Polymeric membranes can then be used for the gas separation operation [37]. Such membranes can remove hydrogen very efficiently from

the butane–butadiene/hydrogen mixture but cannot be used at the 400–500 °C operating temperature of the catalytic reactor.

Applications of Membrane Reactors

Membrane reactors are being considered for many processes, and some are already being used on an industrial scale. A detailed description of this work is beyond the scope of this book; the three main application categories are described briefly below.

Cell Culture and Fermentation Processes

The traditional, and still the most common, fermentation process involves the addition of microbial cell cultures to the reaction medium in a batch reactor. This type of batch process is inherently slow, and microbial cells are lost with each batch of product. Recently there has been a great deal of interest in developing continuous fermentation processes using membrane bioreactors [34,41,42]. Much of this work has concentrated on fermentation of ethanol or acetone/butanol from low-grade food processing waste such as cheese whey, using a recycle membrane reactor design as shown in Figure 13.18. The principal advantages of the reactor are its continuous operation, the high cell densities that are maintained, and the lack of build-up of reaction products that inhibit the reaction.

Another type of microbiological reactor is the hollow fiber membrane bioreactor shown in Figure 13.19. In this device, the microbial cells are trapped on

Figure 13.18 Continuous recycle fermentor membrane reactor. An ultrafiltration module removes the liquid products of fermentation as a clean product. This system is being developed for production of ethanol, acetone and butanol by fermentation of food processing waste streams

Figure 13.19 A hollow fiber membrane reactor. Nutrients (S) diffuse to the microbial cells on the shell side of the reactor and undergo reaction to form products (P) such as monoclonal antibodies [31]. Reprinted from *J. Membr. Sci.* **39**, K. Schneider, W. Hölz, R. Wollbeck and S. Ripperger, *Membranes and Modules for Transmembrane Distillation*, p. 38. Copyright 1988, with permission from Elsevier

the shell side of a capillary hollow fiber module. The feed solution, containing substrate and the products of microbial reaction, is circulated down the bore of the fibers [43,44]. This device has proved particularly useful in producing protein antibodies by genetically engineered mammalian cells. By manipulating the molecular weight cut-off of the fiber, the flux of molecules of different molecular weights across the filter can be controlled. Very high cell densities can be achieved in these hollow fiber cartridges, which have been used to produce monoclonal antibodies.

Light Hydrocarbon Gas-phase Catalytic Reactions

Several important refinery and chemical feedstock reactions appear to be good candidates for membrane reactor systems; some such reactions are listed in Table 13.4. Because of the high temperatures involved, developing the appropriate

Table 13.4 Petrochemical reactions being considered as applications for membrane reactors

Figure 13.20 Methylcyclohexane conversion to toluene as a function of reactor temperature in a membrane and a nonmembrane reactor [45]. Reprinted with permission from J.K. Ali and D.W.T. Rippin, Comparing Mono and Bimetallic Noble Metal Catalysts in a Catalytic Membrane Reactor for Methyl-cyclohexane Dehydrogenation, *Ind. Eng. Chem. Res.* **34**, 722. Copyright 1995, American Chemical Society and American Pharmaceutical Association

selective membranes is difficult, and this type of membrane reactor has not moved beyond the laboratory stage.

The first four reactions listed in Table 13.4 are dehydrogenation reactions in which one of the reaction products is hydrogen. By removing hydrogen, the reaction equilibrium can be driven to completion, increasing the degree of conversion of the dehydrogenated product significantly. An example of the improvement in conversion that is possible is shown in Figure 13.20 [45]. In this figure, the fractional conversion of methylcyclohexane to toluene in a simple tube reactor is compared to that in a reactor with hydrogen-permeable, palladium-silver-alloy walls. Without the membrane, the degree of conversion is limited to the equilibrium value of the reaction. By removing the hydrogen, higher degrees of conversion can be achieved. Figure 13.20 also illustrates the problem that has inhibited widespread use of membrane reactors—the high temperature of the reactions. The reactions listed in Table 13.4 are all normally performed at 300–500 °C. These temperatures are far above the normal operating range of

polymeric membranes, so hydrogen-permeable metal membranes, microporous carbon membranes, or ceramic membranes must be used. A review of membranes used in this application is given by Hsieh [46]. Currently metal or ceramic membranes are too expensive and too unreliable to be used in a commercial process. Rezac *et al.* [37,47] have tried to circumvent the problem by using reactors in series and cooling the gas between the reactor stages to the point that a high-temperature, polyimide-based polymer can be used to remove the hydrogen. Improved conversions are obtained by this process, and in the target dehydrogenation reaction studied, dehydrogenation of butane to butene and butadiene, good conversions can be obtained at relatively low reactor temperatures. Low-temperature reactor operations have a number of process benefits, so this approach may be developed further.

Another membrane application that could become a business is the use of ion-conducting membranes in membrane reactors. In the past 3 years, more than 70 US patents have appeared on this topic, as well as many papers. The overall concept is to use ceramic membranes that conduct oxygen or hydrogen ions at high temperatures. Materials that can conduct both ions and electrons are called mixed-conducting matrices. Several important early papers describing these materials were published by Teraoka *et al.* in the 1980s [48,49]. Various complex metal oxide compositions, including some better known for their properties as superconductors, have mixed-conducting properties; recent efforts in the field focus on these materials. Examples are perovskites having the structure $\text{La}_x\text{A}_{1-x}\text{Co}_y\text{Fe}_{1-y}\text{O}_{3-z}$, where A is barium, strontium, or calcium; x and y are 0–1; and the value of z makes the overall material charge neutral. Passage of oxygen ions and electrons is related to the defect structure of these materials; at temperatures of 800–1000 °C, disks of these materials have shown extraordinary permeabilities to oxygen. Similar mixed-oxide membranes can also conduct protons [50].

Two large consortia, one headed by Air Products [51] and the other by Praxair/BP [52], are developing the membranes. At the appropriate high operating temperatures, the membranes are perfectly selective for oxygen over nitrogen, and oxygen permeabilities of 10 000 Barrer can be obtained. This means that, if the membrane thickness can be reduced to 1 μm , pressure-normalized fluxes of $10\,000 \times 10^6 \text{ cm}^3(\text{STP})/\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}$ are possible. On this basis, for a plant to produce 1 MMscfh of oxygen, about 4000 m^2 of membrane tube area will be required—a large, but not inconceivably large, membrane area.

The most practical application, and the principal driving force behind the development of these membranes, is membrane reactor processes, such as the production of synthesis gas (syngas) by partial oxidation of methane or the oligomerization of methane to produce ethylene. Both processes are illustrated in Figure 13.21. In syngas production, oxygen ions diffusing through the membrane react with methane to form carbon monoxide and hydrogen. This gas can then be used without further separation to form methanol or other petrochemicals.

Figure 13.21 Use of ion-conducting ceramic membranes in a membrane reactor to produce (a) syngas ($CO + H_2$) and (b) ethylene

In ethylene production, methane is catalytically reacted to produce ethylene and hydrogen. The hydrogen permeates the membrane and then reacts with the oxygen in air to produce water. This second reaction produces the energy necessary to heat the process. Many large natural gas fields are not currently exploited because they are too far from the end-users. If this technology were developed, it would allow these fields to be developed, and so change the basis of the chemical and refining industries.

The membrane areas needed in these plants are not huge, but the technical challenges are substantial. Defect-free, anisotropic composite ceramic membranes that are 1–5 μm thick, able to operate continuously at 800–1000 $^\circ\text{C}$, nonpoisoning, nonfouling and low-cost are required—not impossible, but difficult. Conceptual designs of the type of reactor required are beginning to appear.

The magnitude of the engineering task involved is indicated by the assumptions for the calculations [53]: a sealed vessel, containing 1000 1-in. diameter tubes, each 31 ft long, coated inside with perovskite membrane, in which the tubes are 1.5 in. apart, with a lower preheated section of 6 ft, a central reaction section of 18 ft, and an upper cooling section of 7 ft. The construction of such a vessel is neither simple nor cheap.

Chiral Drug Separation

Many drugs are produced as racemic mixtures of two mirror-image isomers. Often only one of these enantiomers has a beneficial pharmaceutical effect and the second enantiomer is much less active or, even worse, produces toxic side effects. For this reason many drugs must be resolved into their component enantiomers before being used. A number of techniques are available, but most are complex and costly. Resolution of racemic mixtures using stereoselective enzymatic reactions in a membrane bioreactor was pioneered by Sepracor and has been applied on an industrial scale for a number of important drugs [54,55]. Several ingenious process schemes have been proposed, one of which is illustrated in Figure 13.22.

The process shown in Figure 13.22 uses the stereospecific, enzymatically catalyzed hydrolysis of the ethyl ester of naproxen to the free acid to perform a chiral separation:

The lipase enzyme stereospecifically hydrolyzes the (+) isomer of naproxen ester. The enzyme is immobilized in the wall of an inside-skinned hollow fiber membrane. The racemic *d* and *l* naproxen ester mixture, dissolved in methyl isobutyl ketone, is introduced on the shell side of the fiber and an aqueous buffer solution is circulated through the fiber lumen. The lipase enzyme hydrolyzes the *d* form of naproxen ester, forming ethanol and naproxen *d*. Naproxen *d* is a carboxylic acid soluble in aqueous buffer but insoluble in methyl isobutyl ketone. Consequently naproxen *d* is removed from the reactor with the buffer solution. The naproxen *l* ester remains in the methyl isobutyl ketone solution. This technique achieves an essentially complete separation of the *d* and *l* forms. In a clever final step

Figure 13.22 Application of a membrane bioreactor to separate chiral drug mixtures

the naproxen *l* ester is racemized to a *d* and *l* racemic mixture and recirculated to the membrane reactor. In this way all of the original mixture is eventually converted to the pure, pharmaceutically active *d* form. This technology has been applied to the chiral resolution of a number of drugs. A full-scale plant for the chiral separation of diltiazem intermediates, developed by Tanabe/Sepracor engineers, contains 1440 m² of hollow fiber membrane and produces 75 tons/year of resolved diltiazem intermediate [54].

Conclusions and Future Directions

Of the processes described in this chapter, membrane contactors and membrane reactors have the greatest potential to develop into large-scale commercial processes. Both technologies are already used on a small scale in niche applications, and both are being developed for much larger and more important processes. Membrane contactors are currently most widely used to deaerate liquids, but the

best long-term application may be in the natural gas industry to replace amine absorber-strippers to remove carbon dioxide and hydrogen sulfide. Similarly, membrane reactors are currently used only in a few specialized biotech applications. However, long-term, this type of device will be used in the petrochemical industry, with very different membranes, for dehydrogenation processes or the partial oxidation of methane. Such applications could be much more important, but the development of suitable membranes poses a number of very challenging technical problems.

APPENDIX

Table A1 Constants

Mathematical

$$e = 2.71828 \dots$$

$$\ln 10 = 2.30259 \dots$$

$$\pi = 3.14159 \dots$$

Gas law constant, R

$$1.987 \text{ cal/g-mol} \cdot \text{K}$$

$$82.05 \text{ cm}^3 \cdot \text{atm/g-mol} \cdot \text{K}$$

$$8.314 \times 10^7 \text{ g} \cdot \text{cm}^2/\text{s}^2 \cdot \text{g-mol} \cdot \text{K}$$

$$8.314 \times 10^3 \text{ kg} \cdot \text{m}^2/\text{s}^2 \cdot \text{kg-mol} \cdot \text{K}$$

Standard acceleration of gravity

$$980.665 \text{ cm/s}^2$$

$$32.1740 \text{ ft/s}^2$$

Avogadro's number

$$6.023 \times 10^{23} \text{ molecules/g-mol}$$

Faraday's constant, \mathcal{F}

$$9.652 \times 10^4 \text{ abs-coulombs/g-equivalent}$$

STP (standard temperature and pressure)

$$273.15 \text{ K and } 1 \text{ atm pressure}$$

Volume of 1 mol of ideal gas at STP = 22.41 L

Table A2 Conversion factors for weight and volume

Given a quantity in these units	Multiply by	To convert quantity to these units
Pounds	453.59	Grams
Kilograms	2.2046	Pounds
Ton, short (US)	2000	Pounds

Table A14 Mean free path of gases (25 °C)

Gas	λ (Å)
Argon	1017
Hydrogen	1775
Helium	2809
Nitrogen	947
Neon	2005
Oxygen	1039
UF ₆	279

Table A15 Estimated diameter of common gas molecules

Gas molecule	Kinetic diameter (Å)	Lennard–Jones diameter (Å)
Helium	2.60	2.55
Neon	2.75	2.82
Hydrogen	2.89	2.83
Nitrous oxide	3.17	3.49
Carbon dioxide	3.30	3.94
Acetylene	3.30	4.03
Argon	3.40	3.54
Oxygen	3.46	3.47
Nitrogen	3.64	3.80
Carbon monoxide	3.76	3.69
Methane	3.80	3.76
Ethylene	3.90	4.16
Propane	4.30	5.12
Propylene	4.50	4.68

Gas diameters can be determined as kinetic diameter based on molecular sieve measurements or estimated as Lennard–Jones diameters based on viscosity measurements. The absolute magnitude of the estimated diameters is not important, but the ratio of diameters can give a good estimate of the relative diffusion coefficients of different gas pairs [see Equation (8.4)]. On this basis the kinetic diameters do a better job of predicting the relative diffusion coefficients of carbon dioxide/methane (always greater than 1 and often as high as 5–10 in glassy polymers). However, the Lennard–Jones diameter does a better job of predicting the relative diffusion coefficients of propylene/propane (always greater than 1 and often as high as 5 in glassy polymers).

Table A16 Experimental diffusion coefficient of water in organic liquids at 20–25 °C at infinite dilution

Liquid	Temperature (°C)	Viscosity	cm ² /s × 10 ⁵
Methanol	20	—	2.2
Ethanol	25	1.15	1.2
1-Propanol	20	—	0.5

Toluene	0.071
<i>n</i> -Octane	0.051

Source: Selected values from *International Critical Tables*, W.P. Boynton and W.H. Brattain.

Table A19 Interdiffusion of vapors into air, carbon dioxide or hydrogen

Gas/vapor	Diffusion coefficient (cm ² /s)		
	Air	CO ₂	H ₂
Oxygen	0.18	0.14	0.70
Water	0.22	0.14	0.75
Ethyl acetate	0.072	0.049	0.27
<i>n</i> -Propyl alcohol	0.085	0.058	0.32
Propyl butyrate	0.053	0.036	0.21

INDEX

- anisotropic membranes 5, 96–126
artificial kidney (see hemodialyzer)
artificial lung (see blood oxygenators)
- backflushing 252–254, 292–295
Barrer, R.M. 301, 304
batch systems 258–260, 380–381
bioreactors 512–513
blood oxygenators 470–472
Bondi method 56–57
brackish water desalination 223–224
Brownian diffusion 72–73
bubble point 282–286
- Cadotte, John 191–192
capillary condensation 77–80
carbon dioxide separation 302, 340–342, 452–454
carbon membranes 77–80, 132
carrier facilitated transport 425–463
 coupled transport applications 443–444
 coupled transport characteristics 434–439
 emulsion liquid membranes 428–429, 441–443
 facilitated transport applications 452–459
 facilitated transport process design 448–452
 facilitated transport theory 444–448
 Giozzi's biological model 427
 liquid membranes 132, 426–429
 supported liquid membranes 427–428, 439–441
ceramic membranes 6, 129–132, 314–317
co-flow 185–186
- composite membranes (solution coated) 119–122, 313–314
concentration polarization 161–190
 boundary layer model 164–172, 241–251
 in electro dialysis 404–409
 in gases 178–181
 in liquids 176–178
 in pervaporation 177–178, 278–279
 in ultrafiltration 177, 241–251
 gel layer model 241–251
 Peclet number 171–175
 Peclet number measurement 172–175
 Wilson plot 174
continuous systems 260–262
controlled drug delivery 472–489
 biodegradable systems 480–482
 diffusion-controlled systems 473–480
 osmotic systems 481–489
 Rose-Nelson osmotic pump 482–483
 Theeuwes elementary osmotic pump 485–489
counter-flow 182–188
cross-flow 182–188
- Darcy's law 16
depth filter 69–72, 74, 277–279
dialysis 27–30, 491–493
 Cerini dialyzer 491–492
 charge mosaic membranes 496–499
 theory 27–30
 diffusion dialysis 493–496
 Donnan dialysis 493–496
 Piezodialysis 496–499
diffusion coefficients 50–58
 diffusion of gases in polymers 49, 53–54, 305–306
 diffusion in liquid 51–53

- Donnan equation 397–400, 493
 Donnan dialysis 493–496
 dual sorption model 63–66
 dynamically formed membranes 125
- electrodialysis 393–423
 bipolar membranes 418–421
 brackish water desalination 415
 coupled transport theory 431–434
 Cowan-Brown plot 407–408
 Donnan exclusion 397–400, 493
 applications 415–421
 current efficiency 409–411
 system design 411–415
 theory 397–400
 transport mechanism 404–409
 ion exchange membranes 400–402
 limiting current density 404–409
 Nafion membranes 402–403
 salt from seawater 415–417
 ultrapure water 225–226, 418–420
 emulsion liquid membranes 428–429, 443–444
 expanded film membranes 94–96
- feed-and-bleed design 260–262, 270–271, 440
 Ferry model 69–71
 Ferry-Renkin equation 71
 Fick's law 16
 Flory-Huggins theory 61–63
 flux paradox 249
 free volume 56–58, 80
- gas permeabilities 38–39, 308–309, 329, 332
 gas separation 301–353
 Robeson plot 331–332, 338, 457
 gas separation applications
 carbon dioxide/hydrogen sulfide 340–342, 452–454
 dehydration of air 342–343
 status 349–350
 hydrogen separation 327–330
 natural gas dehydration 342–343
 natural gas dew point adjustment 343–345
 natural gas separations 338–345
 olefin separations 347–348, 451–452, 455–456
 oxygen/nitrogen 331–338, 457–459
 vapor/gas 325–327, 345–347
 gas solubility 48–50, 58–66, 305–307
 in liquids 59–61
 in polymers 48–50, 58–66, 305–307
 Gibbon, J.H. 471
 glass (microporous) membranes 76–79, 132
 glass transition temperature 53–58, 305–306
 Graham's Law of Diffusion 75, 302–303
 Graham, Thomas 74, 302
- hemodialyzer 465–470
 Henry's law 42, 304
 history of membrane technology 1–3
 carrier facilitated transport 425–431
 electrodialysis 393–396
 gas separation 301–303
 microfiltration 275–278
 pervaporation 355–357
 reverse osmosis 191–193
 ultrafiltration 237–238
 hollow-fiber membranes 133–139
 melt spinning 133–134
 membrane recipes 137
 solvent spinning 133–139
 hollow-fiber modules (see membrane modules)
 hyperfiltration 209–211, 229–231
- inertial capture 72–74
 interfacial polymerization membranes 116–119, 201–204
 ion-conducting membranes 516–517
 isotropic membranes 4–5, 190–196
 dense membranes 5, 90–92
 microporous membranes 4–5, 92–96
- Knudsen diffusion 74–76, 303
 Kolf kidney 467–468
- liquid membranes (see carrier facilitated transport)
 Loeb-Sourirajan membranes 96–109, 312–313
 membrane formation theory 102–109
 membrane recipes 102
 lube oil separation 229–231

- Manhattan project 74, 301
- melt extruded film 91–92
- membrane cleaning 220–221, 251–523
- membrane concentration gradients 22–26
- membrane contactors 429, 500–508
 - gas exchange 503–505
 - membrane distillation 501, 506–508
- membrane defects 126–128, 312–313
- membrane distillation 501, 506–508
- membrane fouling 215–220, 241–243, 292–295
- membrane modules 139–154
 - hollow fiber 143–150, 253–254
 - plate-and-frame 139–141, 151–154, 256–257, 287, 368, 375, 413–414, 467–468
 - spiral-wound 141–143, 151–154, 213–215
 - tubular 140, 151–154, 256, 292
 - vibrating 150–151
- membrane preparation 89–139
 - anisotropic membranes 96–128
 - carbon membranes 77–80, 132
 - ceramic membranes 129–132
 - expanded film membranes 94–96
 - formation by absorption of water vapor 114–116
 - formation by solvent evaporation 112–114
 - formation by thermal gelation 109–112
 - glass (microporous) membranes 76–79, 132
 - ion exchange membranes 400–404
 - Loeb-Sourirajan membranes 96–109, 312–313
 - melt extruded film 91–92
 - metal membranes 6, 128
 - Nafion membranes 402–403
 - nucleation track membranes 73, 92–94
 - slip cast ceramic membranes 129
 - sol gel ceramic membranes 129–132
 - solution cast membranes 90–91
- membrane porosity 66–68
- membrane pressure gradients 21–26

- pervaporation (*continued*)
 organic/organic mixtures 383–388
 organics from water 378–383
 solvent dehydration 372–378
 theory 39–44, 357–362
 phase diagrams 105–109
 phase separation membranes 97–116
 piezodialysis 496–499
 plasma polymerization membranes
 122–125
 plate-and-frame modules (see membrane
 modules)
 Poiseuille flow 74–76, 303
 poly(1-trimethylsilyl-1-propyne) [PTMSP]
 57–58, 80–82
 pore flow membranes 66–82
 pore flow model 16–18, 69–72
 pressure ratio 317–321
- recycle designs 325–327, 345–347
 rejection coefficient 33, 71
 reverse osmosis 191–235
 applications 221–231
 brackish water desalination 223–224
 cellulosic membranes 197–200
 furfuryl alcohol membranes 204–206
 hyperfiltration 209–211, 229–231
 interfacial composite 201–204
 Jiddah plant 191, 203
 membrane cleaning 220–221
 membrane fouling 215–220
 membrane selectivity 206, 212–213
 membranes 196–212
 modules 213–215
 municipal water treatment 298–299
 nanofiltration membrane 82–83,
 208–210, 229
 noncellulosic membranes 200–201
 PEC-1000 membrane 204–205, 206
 Pretreatment 215–220
 Scale 216–217
 seawater desalination 224–225
 silt density index 217–219
 theory 30–36, 193–196
 ultrapure water 225–226
 wastewater treatment 226–229
- salt permeability constant 33, 193–194
 screen filter 69–72, 277–279
 seawater desalination 205–206,
 224–225
 slip cast ceramic membranes 129–132
 sol gel ceramic membranes 129–132
 solution cast membranes 90–91
 solution-diffusion model 18–48
 solvent dewaxing 229–231
 sorption coefficients in polymers 58–66
 spiral-wound modules (see membrane
 modules)
 stage-cut 318, 322–323
 Stokes-Einstein equation 51–52
 surface diffusion 74–80, 303
 sweep 182–188, 348, 369–371,
 449–450
- template leaching 96
 track etch membranes (see nucleation
 track)
 transdermal patch 13–14, 473
 tubular membranes (see membrane
 modules)
- ultrafiltration 237–274
 cheese production 265–267
 electrocoat paint 264–265
 fruit juice 267–268
 gel layer model 241–251
 membrane characterization 72,
 238–241
 membrane cleaning 251–253
 membrane fouling 241–243
 membrane modules 255–258
 membranes 3, 253–255
 oil-water emulsions 268–269
 PVA recovery 270–271
 system design 258–262
 ultrapure water 418–420
- vibrating modules 150–151
- water permeability constant 32
 water purification 298–299
