Other areas where in-cylinder flows impact engine operation include misfire and cycle-to-cycle variability (CCV), post-combustion mixing (important for completion of the final oxidation of CO and particulate matter as well as reduction of NO_x formation), heat transfer, and mixing of crevice hydrocarbons with hot bulk gases during the expansion stroke. An excellent recent example of the importance of these flows to engine design is provided by Yamakawa *et al.* (2011), who describe their efforts to control mean flow structures, turbulence and burn duration, heat transfer, and engine knock in a direct-injection SI engine through modification of piston geometry and manipulation of the flow structure by the injected fuel sprays.

As indicated by the quote opening this chapter, both the authors have been heavily influenced by the ideas of John Lumley, who has been a stalwart of both the fluid mechanics and the automotive engineering communities. In keeping with the spirit of his book *Engines: An Introduction*, our primary objective in this chapter is to

provide the automotive engineer with a basic physical understanding of the underlying flow processes that occur in engines. We follow this with a description of the various flow structures and turbulence generation mechanisms observed in engines, and the parameters that the engine designer can vary to modify or control these structures and mechanisms. Our hope is that physical understanding, coupled with practical examples of the embodiment and control of flow structures, will give designers the fundamental insight and ideas they need to accomplish their goals. With this insight to guide them, the predictive modeling tools described in Zero- and One-Dimensional Methodologies and Tools and Multidimensional Simulation can then be effectively and efficiently employed. Our additional objective, however, is to provide the fluid mechanics community a synopsis of how basic turbulent flow structures are manifested in engines, and the gaps in our understanding of these structures, with the objective of guiding their work to improve the understanding and tools needed by the engine design community.

2 GENERAL CONCEPTS

2.1 Tumble and swirl and their generation

Engine induction port and valve geometries are carefully designed to produce large-scale organized motions known as *tumble* and *swirl* (Figure 1). Tumble, which is also called *barrel swirl*, is a rotational motion with an axis that is perpendicular to the cylinder axis and to the diametral plane bisecting the intake ports of a four-valve engine. Tumble motion, with an axis parallel to the bisecting plane, is usually referred to as *cross-tumble*; for our purposes, there will be little need to distinguish between the two. Swirl is defined as expected intuitively: rotational motion with an axis aligned with the cylinder axis. This terminology is a convenient way to define globally the three components of fluid rotation in an engine. If both swirl and tumble are present, the flow is often described as a tumble flow which is spinning about the cylinder axis or as a swirling flow with an axis that is tilted with respect to and that precesses about the cylinder axis. Although tumble and swirl are useful and widely used concepts, the detailed, instantaneous flow structure and its associated physics cannot generally be described by such simple motions or their superposition, as will be seen in subsequent text.

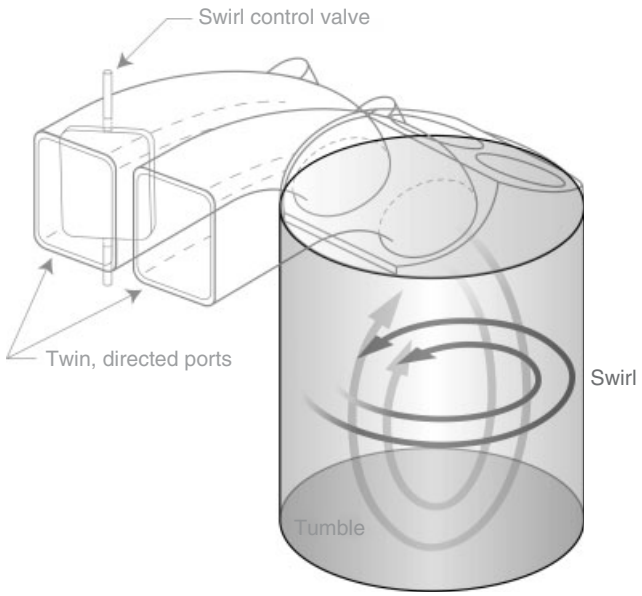

Figure 1. Definition of swirl and tumble, and illustration of the twin ports and optional swirl control valve typically employed in modern SI engines.

Engine designers are concerned with generating and quantifying the amount of in-cylinder swirl or tumble because momentum and energy stored in these rotational motions provides a means by which both mean flow structures and turbulence can be manipulated or generated later in the cycle, when these motions are needed to assist in the fuel–air mixture preparation process, the main combustion process, or the late-cycle, post-combustion oxidation processes. Inducing and manipulating internal aerodynamics to best aid these processes is the art of combustion system design, although very little has been written to explicitly describe how this is accomplished. However, many examples of flow manipulation are based on one common theme: the angular momentum stored within the tumble or swirl structures is manipulated to either force the breakdown of these structures, thereby releasing their energy into turbulence, or to drive the generation of new structures that can effectively transport fuel or combustion products within the cylinder or that can generate turbulence where it is needed locally. This manipulation is accomplished through either changes in geometry that occur with piston motion or through the action of an external stimulus—such as the fuel injection process.

The strength of the swirl and tumble motions are estimated from data acquired at several valve lifts on a steady-state "flow bench" (e.g., Xu, 2001). Through weighting the angular momentum of the tumble or swirl components of the steady flow by the mass flow rate through the valve at each lift, an estimate of the average angular momentum per unit mass inducted into the cylinder can be obtained (e.g., Heywood, 1988). The angular velocity ω_s or ω_t of the solid-body rotating flow with the same average angular

momentum is used to define swirl and tumble ratios

$$R_s = \frac{\omega_s}{2\pi N}$$

and

$$R_t = \frac{\omega_t}{2\pi N} \quad (1)$$

N represents the rotational speed of the crankshaft and the subscripts s and t denote swirl and tumble, respectively. Typical values of tumble ratios in engines designed for tumble are in the range of 1–2, while typical swirl ratios in engines designed for swirl range from 1 to 5. Generally, as will be discussed further in subsequent text, tumble is associated with SI engine technologies (although gasoline direct-injection engines can employ significant swirl), and swirl is associated with CI engine technologies (although large ~2 L per cylinder displacement CI engines often use very little swirl). In-cylinder measurements of the swirl velocity field generally show remarkably close agreement between the measured angular momentum and that estimated from flow bench measurements (Reuss *et al*., 1995; Petersen and Miles, 2011).

Tumble is also generated naturally in loop-scavenged, two-stroke engines—although two-stroke designers are often concerned primarily with scavenging efficiency and short-circuiting of fresh charge rather than flow manipulation and turbulence generation later in the cycle. Examples of measured tumble structures and engine design to enhance these structures can be found in the work of Fansler and Drake (2009) and of Tsui and Cheng (2007).

Notice that the swirl or tumble ratios discussed earlier are defined in terms of engine speed, but speed is not referenced when we speak of an engine as having a swirl ratio of 2, for example. The reason for this has already been alluded to in the introduction: the turbulent flow velocities in engines scale very closely with engine speed provided the effects of wave dynamics in the manifolds are not too strong. In research engines that have been specifically designed to minimize the effects of manifold dynamics (Margary, Nino, and Vafidis, 1990; Miles *et al*., 2004), detailed in-cylinder velocity measurements—when normalized by the mean piston speed $\overline{V}_p = 2SN$—are independent of engine speed. Here, S denotes the engine stroke. This scaling of the flow structure with piston speed applies to both the mean flow velocities as well as the statistics of the turbulent velocity fluctuations. A more thorough discussion and review of studies of engine speed scaling has been provided by Miles (2009).

Ports are generally classified as directed or helical, as shown in Figure 2. Classic work investigating the flows created by these ports in engines with a single intake valve includes that of Monaghan and Pettifer (1981), Tindal, Williams, and Aldoory (1982), and Brandstätter, Johns, and Wigley (1985). In four-valve engines, the outflows from the two intake ports interact, and the details of the in-cylinder flow structure depend strongly on the specific port geometry being investigated. However, four-valve engines designed for tumble usually have a similar port layout, which is sketched in Figure 1. The induction-generated flow in engines with this geometry has been characterized both experimentally and computationally and is described in detail in subsequent text. The nearly identical geometry of the twin, directed intake ports typically provides very low swirl. By installing a throttle plate (often called a *swirl control valve*) in one port, however, significant levels of flow swirl can be achieved. Tumble can also be controlled using throttle plates (tumble flaps) in the intake ports that direct the port flow toward the upper portion of the intake valve, where it enters the cylinder along the roof of the combustion chamber (e.g., Wurms *et al*., 2011). This can also be accomplished by designing the port to induce flow separation at the bottom of the port, just before the valve, thereby decreasing the flow through the lower portion of the intake valves. In engines with near-vertical intake ports, the flow velocities are highest near the lower portion of the valves, and a counter-rotating, "reverse-tumble" motion can be generated (e.g., Kume *et al*., 1996).

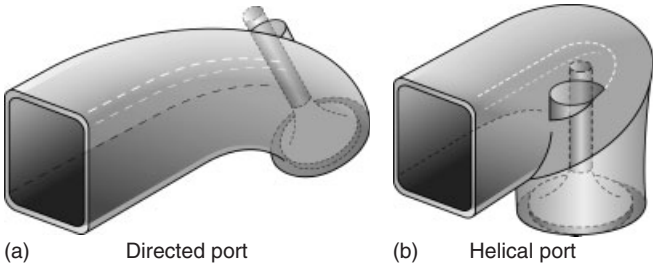

Figure 2. (a,b) Typical port geometries. Directed ports are employed in both SI and CI engines, while helical ports are typically found on CI engines.

In contrast, the two ports designed to generate swirl in modern four-valve engines are often very different. A common design employed in diesel engines incorporates one directed port, positioned such that the net linear momentum leaving the valve is oriented tangential to the cylinder wall and generates significant levels of swirl. The second port is often of helical design, with a lower level of swirl generation. Helical ports typically have higher discharge coefficients, and this port is often called the *fill* port. CI (diesel) engines are frequently found to require a higher swirl ratio at low speed and load for best performance. Under these conditions, the consequences of increased flow restriction are relatively unimportant, and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a swirl control valve is often placed in the fill port. By throttling the fill port, a higher average level of angular momentum is introduced into the cylinder, raising the swirl ratio. At high speeds and loads, both ports are open. Typical swirl ratios achieved with both ports open are in the range of 1–3, and in the range of 3–5 with the fill port throttled. As expected, these ports will also generate some in-cylinder tumble, which may contribute to the considerable tilt in the swirl axis that has been measured in typical diesel engines (Petersen, 2010).

While engine designers are generally concerned with only a single, global swirl ratio or tumble ratio, this is only because there is a lack of knowledge as to the true, detailed impact of in-cylinder flows on the combustion process. Often, the performance and emissions of an engine can vary dramatically at the same swirl ratio, depending on the particular geometry of the ports. A clear example of this can be found in the work of Krieger *et al*. (1997), in which the smoke emissions from an automotive diesel engine are found to differ significantly, at the same swirl ratio, when the engine is fitted with heads having different port geometries. In some instances, it is not only the level of smoke emissions that differs, but an opposite trend in smoke emissions is observed as swirl is varied. The impact of swirl on combustion and emissions can clearly not be correlated by the single, global parameter R_s. To develop and optimize engine combustion chambers, it is thus very important to consider the local, spatio-temporal properties of the turbulent, in-cylinder flows (ideally within each cycle).

2.2 Cycle-to-cycle variations and turbulent flow decomposition

A key challenge facing engine development engineers is the understanding, modeling, and control of cycle-to-cycle variation (CCV) in engine performance, which can contribute to unevenness in the running of the engine, excessive engine noise and emissions, and potentially damaging engine knock. The consequences of CCV are particularly important for direct-injection SI engines with stratified combustion.

Cyclic variability is caused by large-scale variations in flow structures that affect the gas motion and composition throughout the cylinder, although we are especially concerned with changes in the vicinity of the spark plug and at the time of ignition (Ozdor, Dulger, and Sher, 1994) that influence the early flame kernel development in SI engines. These large-scale variations are viewed as distinct from random fluctuations due to turbulent flow motions. Indeed, obtaining a high level of turbulent kinetic energy (TKE) near top dead center (TDC), carried predominantly by a range of energetic eddies of size $\sim l$, is the primary goal of the engine designer who seeks to minimize the duration of the combustion process. While these turbulent fluctuations are essential for combustion and flame propagation, they coexist with the generally lower frequency, larger scale coherent structures in the in-cylinder flow that contribute to CCV.

Turbulence is defined by fluctuations about an average velocity:

$$U_i(\mathbf{x},\theta,n) = \widetilde{U}_i(\mathbf{x},\theta,n) + u_i(\mathbf{x},\theta,n) \qquad (2)$$

U_i is the ith component of the velocity at the location $\mathbf{x}$, crank-angle or phase θ, and during the cycle number n. The definition of $\widetilde{U}_i$ (and hence u_i) is a matter of considerable debate. The simpler definition is the phase average $\widetilde{U}_i(\mathbf{x},\theta,n) = \langle U_i\rangle(\mathbf{x},\theta) = (1/N)\sum_{n=1}^{N} U_i(\mathbf{x},\theta,n)$ computed, at the phase θ, from a large number (N) of independent cycles. Such a definition obviously lumps together all of the fluctuations from the mean, including coherent fluctuations associated with CCV, into the TKE and its associated integral length scale l. This definition is adopted in all Reynolds-averaged Navier–Stokes (RANS) modeling approaches, wherein Equation 2 is substituted into the conservation equations for mass and momentum to derive equations that govern the evolution of the mean flow field as well as the turbulence. RANS-based approaches to turbulence modeling or data analysis are very efficient and useful tools to study engine flow fields. However, this approach is not appropriate for modeling, understanding, and ultimately controlling cyclic variability.

To separate random contributions from turbulence to u_i from the coherent contributions associated with CCV, moving averages in the time or in the spatial domain, or equivalently high pass filtering, have been proposed: see, for example, Fansler and French (1988) and Marc *et al*. (1997). More sophisticated time–frequency approaches, such as wavelet transforms (Sullivan, Ancimer, and Wallace, 1999; Söderberg, Johansson, and Lindoff, 1998) have also been explored. Such approaches are valid only if there is a distinct temporal (frequency) or spatial scale separation between the random and coherent motions (Lumley, 1999) at each phase. A careful analysis, however, shows that such a scale separation is not observed and that "*high pass filtering of velocity data in order to extract turbulence intensity estimates based on time scale discrimination is subject to arbitrary selection of filtering criteria*" (Enotiadis, Vafidis, and Whitelaw, 1990). Moreover, removal of large-scale, anisotropic turbulent motions by inappropriate filtering will significantly impact the ability of the remaining "turbulence" to transport mass and momentum. Finally, it is important to remark that these approaches are not statistically equivalent to crank-angle

averaging. Although various modeling approaches are dealt with in detail in Multidimensional Simulation, it is relevant to note here that while large-eddy simulation (LES) techniques (Haworth, 1999; Vermorel *et al*., 2009) are based on spatial filtering, the filtering occurs on much smaller length scales that contain little energy and are approximately isotropic. Temporal filtering has also been recently proposed—see Gatski, Rumsey, and Manceau (2007) for a recent review.

A promising alternative approach to the problem of separating random turbulent fluctuations from cyclic variability associated with coherent structures is to extract these structures directly from the measured or computed velocity fields. Identification of large-scale coherent structures can also help isolate the distinct physical processes that are influencing flow development. Specific tools have been developed to accomplish this (Bonnet *et al*., 1998; Bonnet and Delville, 2001), including proper orthogonal decomposition (POD) (Lumley, 1967), a technique that expresses the spatial structure of the flow in terms of the set of orthogonal basis functions (modes) that capture the highest fraction of the flow kinetic energy using the fewest modes. POD has been applied to engine flows to identify flow structures in the valve jet region (Kapitsa *et al*., 2010) and in the central region of a tumbling flow (Maurel, Borée, and Lumley, 2001; Borée, Maurel, and Bazile, 2002). However, POD filtering, which involves projection of the velocity field on a limited number of modes at a given phase, can provide no clear definition of the structures contributing to CCV. As with the spatial or temporal filtering discussed earlier, this is because no clear threshold separating turbulence from the large-scale motions associated with CCV can be objectively defined.

Nevertheless, POD can be employed to define "families" of cycles according to their structure near TDC and more refined statistics can be computed, with $\widetilde{U}_i$ being computed within each family of cycles. Contributions to u_i from differences in $\widetilde{U}_i$ among the different families—that is, contributions from cycle-to-cycle differences in coherent structures—can then be readily computed. This technique was applied to tumble breakdown measured by particle image velocimetry (PIV) in a pent-roof chamber during the second half of the compression phase (Voisine *et al*., 2011). POD also shows promise for constructing reduced-order models built on a phase-invariant POD basis (Fogleman *et al*., 2004).

Additional techniques built to educe the spatial coherence of flows have also been recently applied in engines. When focusing on an unsteady saddle point (e.g., propagation of a jet, fluid ejection away from a solid boundary), Lagrangian finite time techniques (Haller, 2002; Shadden, Dabiri, and Marsden, 2006) can be successfully applied to engine flows (Voisine *et al*., 2011) or even used to define a local triple decomposition based on the location of separation (Ruiz *et al*., 2010). Such advanced approaches are believed to be very useful to the engine community in order to analyze CCV. However, the route to any quantitative and objective definition of CCV is still long, if indeed such a goal is possible in a cylinder that gathers flow regions of different and complex physics, promoting energy exchange at a wide range of scales.

3 FUNDAMENTAL PROPERTIES OF IN-CYLINDER FLOWS

In-cylinder flows are compressed, rotating, and turbulent. This section provides useful estimates of the order of magnitude of various flow quantities and physical insights associated with these three fundamental keywords. A note concerning near-wall turbulence is provided at the end of this section.

3.1 One-dimensional compression

The thermodynamic state of the gas varies significantly during the compression and expansion phases. These variations are, however, imposed by the varying boundary conditions and not by the flow itself. Indeed, except for the flow through valves (not considered in detail here), the Mach number of in-cylinder flows is always very low—the speed of sound is much larger than the flow velocity—see Mansour and Lundgren (1990) and Leblanc and Le Penven (1999). In-cylinder flows are therefore called *compressed flows* where the density varies in time in a deterministic way but not in space. During the compression and expansion phases, the mass balance then easily shows that the flow divergence is nonzero with $\nabla \cdot \mathbf{U} = -\dot{\rho}/\rho$, where $\dot{\rho}$ is the rate of variation of the density. The mean and fluctuating velocity components then satisfy $\nabla \cdot \langle \mathbf{U} \rangle = -\dot{\rho}/\rho$ and $\nabla \cdot \mathbf{u} = 0$. The fluctuating motion is therefore solenoidal for a deterministic variation of the density.

In the case of one-dimensional (1D) compression of a uniform-density, initially quiescent fluid (Gosman, Johns, and Watkins, 1980), the solution to the continuity equation yields a linear variation in the axial velocity $U(z) = V_p(z/z_p)$. Here, z is the axial distance from the cylinder head and z_p denotes the piston position. This expression is commonly used to initialize multidimensional simulations of engine flows when the induction stroke is not simulated. In the general case, the mean velocity field can be uniquely decomposed (Batchelor, 1967) as the sum of a deterministic velocity field induced by the known dilatation rate, in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the given cylinder geometry, and a solenoidal part. This property and the simplified expression $U(z) = V_p(z/z_p)$ was used by Cosadia *et al*. (2006) to analyze spatial properties of a swirling flow during compression.

Recognizing that the cylinder volume V is proportional to z_p, the given expression for $U(z)$ can be differentiated to obtain $\nabla \cdot \mathbf{U} \cong (1/V)(\mathrm{d}V/\mathrm{d}t)$. This expression is generally valid in engine flows, even those that are not 1D, provided we are considering locations outside the thermal boundary layers and provided mass loss rates due to blow-by and global heat transfer rates are small. The divergence can also be estimated directly from the measured cylinder pressure P as

$$\nabla \cdot \mathbf{U} \cong -\frac{1}{P^{1/\gamma}} \frac{\mathrm{d}P^{1/\gamma}}{\mathrm{d}t} \tag{3}$$

In this case, the estimate is expected to be accurate even if mass loss and heat transfer rates are large, provided local density gradients are small and an accurate, local value of the specific heat ratio γ is available.

As will be seen in subsequent text, a significant source (or sink) of turbulence in engines is associated with bulk compression. Likewise, the heating or cooling rates of the in-cylinder gases—which impact ignition, combustion, and emission formation processes—are affected by $\nabla \cdot \mathbf{U}$. Accordingly, the magnitude and timing of $\nabla \cdot \mathbf{U}$, and its dependency on basic engine design parameters, particularly compression ratio, are of interest. Figure 3 shows how $\nabla \cdot \mathbf{U}$ varies with engine crank angle. Note also that the magnitude of $\nabla \cdot \mathbf{U}$ typically peaks near 30° before or after TDC, and that the location of this maximum approaches TDC more closely as compression ratio is increased. The ratio of the crankshaft throw ($S/2$) to the connecting rod length can also impact $\nabla \cdot \mathbf{U}$, but its effect is minor.

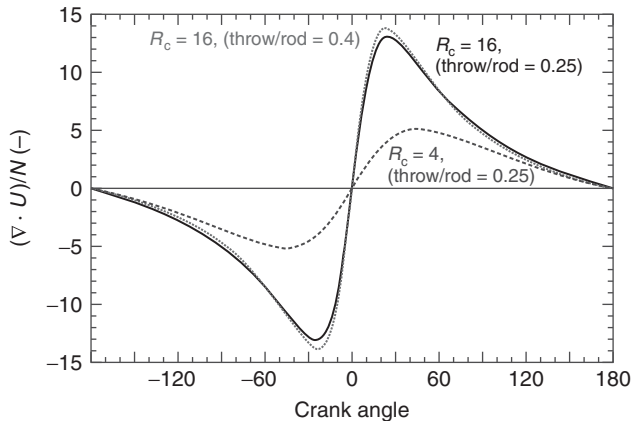

Figure 3. The impact of compression ratio and connecting rod length on the velocity field divergence normalized by the engine rotational rate.

3.2 Large-scale rotation

Engine flows are confined rotating flows, characterized by the swirl ratio or tumble ratio introduced earlier. We introduce here a few simple concepts in order to provide some insights into the physics of these flows. The equations governing the mean radial and azimuthal momentum of a fluid element in a spatially uniform density flow are, respectively,

$$\frac{D\langle U_r \rangle}{Dt} - \frac{\langle U_\theta^2 \rangle}{r} = -\frac{1}{\rho}\frac{\partial \langle p \rangle}{\partial r} + [\text{Reynolds stress terms}] \tag{4}$$

and

$$\frac{D(r\langle U_\theta \rangle)}{Dt} = -\frac{1}{\rho}\frac{\partial \langle p \rangle}{\partial \theta} + [\text{Reynolds stress terms}] \tag{5}$$

These equations are written in cylindrical coordinates. U_r is the radial velocity component, while U_θ is the azimuthal velocity component. Viscous terms can be neglected because the turbulent Reynolds number is large. The mean radial momentum equation (Equation 4) simply states that the acceleration responsible for a departure of a fluid element from a circular streamline is due to a competition between the fictitious centrifugal force and the radial pressure gradient. In engine flows, which are often nearly axisymmetric, the interpretation of the azimuthal momentum equation (Equation 5) is particularly simple: the mean angular momentum $r\langle U_\theta \rangle$ of the fluid element is conserved when the action of turbulent stresses can be neglected.

Conservation of angular momentum is also a very important concept if one wants to understand the evolution of rotational flows submitted to compression. Kelvin's circulation theorem (Batchelor, 1967) can be employed to show that in a flow field where the density is spatially uniform, the vorticity (twice the rotation rate) of a vortex with initial vorticity ω_0, length ℓ_0, and density ρ_0, after being stretched or compressed to a final length ℓ_f and density ρ_f, will be given by

$$\omega_f = \omega_0 \left(\frac{\ell_f}{\ell_0}\right)\left(\frac{\rho_f}{\rho_0}\right) \tag{6}$$

For a large-scale tumble vortex, the length of the vortex does not change during compression; hence, its rotation rate should increase as the vortex is compressed until it eventually breaks up because of the confinement in the reduced combustion chamber volume or internal instability. On the contrary, in a swirling flow, the axial compression of the swirl motion does not impact the rotation rate, as the change in the density is counteracted by the change in the vortex length.

3.3 Turbulence: basic properties and production

To illustrate the various sources of turbulence and the physics governing its evolution, in this section we briefly review the fundamental physical principles underlying turbulent flows, discuss the RANS equations governing the evolution of the turbulence, and estimate the order of magnitude of the various terms in the equations. These ideas and equations are very important in order to understand the role of in-cylinder coherent flows, dominant sources of turbulence, and modeling issues further discussed in the chapter devoted to multidimensional modeling (see Multidimensional Simulation). Additional introductory material describing the fundamentals of turbulent flow is provided by Tennekes and Lumley (1972).

Although the specific details of the turbulent flow structure are as varied as the number of possible flow geometries that could exist, the turbulence itself has a remarkably similar structure in each case. Turbulence consists of random, 3D vortices that exist over a broad range of scales. The turbulence energy is extracted from the mean flow by large-scale turbulent vortices of size $\sim l$, which efficiently interact with the velocity gradients in the mean flow. The TKE k is defined by $k = \langle u_i u_i \rangle / 2$[2] with $u_i(\mathbf{x}, \theta, n) = U_i(\mathbf{x}, \theta, n) - \langle U_i \rangle(\mathbf{x}, \theta)$, and a characteristic velocity scale can be defined as $u = \sqrt{2k/3}$. For a large turbulent Reynolds number, $\mathrm{Re}_l = ul/\nu$, the viscous forces on these eddies are small, and very little dissipation of the turbulence energy occurs at scales of size l. Instead, energy is passed from the larger, most energetic scales to the smaller scales through a cascade process, wherein each successively smaller scale draws its energy from larger, but comparable size, scales that are able to interact efficiently. Viscous dissipation occurs predominantly at the smallest scales, which are approximately bounded by the Kolmogorov scale η, at which $\mathrm{Re}_\eta = u_\eta \eta / \nu = 1$. The relationships between the Kolmogorov length scale η, velocity scale u_η, and time scale τ_η and the corresponding large scales are:

$$\frac{\eta}{l} \sim \mathrm{Re}_l^{-3/4}, \quad \frac{u_\eta}{u} \sim \mathrm{Re}_l^{-1/4}, \quad \frac{\tau_\eta u}{l} \sim \mathrm{Re}_l^{-1/2} \tag{7}$$

In a statistically stationary flow, the energy cascade process described reaches a steady state, and the turbulence is said to be in equilibrium. If the flow is nonstationary, and the turbulence is being perturbed (by compression or by changing mean flow structure) on a time scale not significantly greater than l/u, then a steady energy cascade does not have time to develop.

As described, two key features of any turbulent flow are (i) that it receives kinetic energy from the mean motion and (ii) that it is strongly dissipative. The RANS equation governing the local turbulent energy balance reads:

$$\frac{\partial k}{\partial t} + \langle U_j \rangle \frac{\partial k}{\partial x_j} = \mathcal{P} + T - \varepsilon \tag{8}$$

Here, $\varepsilon = 2\nu \langle s_{ij} s_{ij} \rangle$ is the dissipation rate of k per unit mass and $s_{ij} = 1/2(\partial u_i/\partial x_j + \partial u_j/\partial x_i)$ is the fluctuating deformation rate tensor. The smallest scales have the smallest characteristic time scale ($1/s_{ij}$), and hence the largest deformation rate. T is often called *turbulent transport* because, neglecting the average power of the fluctuating pressure and the viscous stresses in the fluctuating motion (Tennekes and Lumley, 1972), the dominant effect of this term is the average transport of the fluctuating kinetic energy by the turbulence itself. The mathematical form of this term will not be useful here, but we note that it strongly contributes to the homogeneity of the turbulence in the chamber. $\mathcal{P}$ is the production term, responsible for kinetic energy exchanges with the mean flow, and reads (δ_{ij} is the Kronecker delta symbol):

$$\begin{aligned} \mathcal{P} &= -\langle u_i u_j \rangle \frac{\partial \langle U_i \rangle}{\partial x_j} = -\left(\langle u_i u_j \rangle - \frac{2k}{3} \delta_{ij} \right) \frac{\partial \langle U_i \rangle}{\partial x_j} \\ &\quad - \frac{2k}{3} (\nabla \cdot \langle \mathbf{U} \rangle) = \mathcal{P}_\mathrm{f} + \mathcal{P}_\mathrm{comp} \end{aligned} \tag{9}$$

Notice that we have written Equation 9 to emphasize that the production of turbulent energy can be viewed as having two distinct components. The first, $\mathcal{P}_\mathrm{f}$, is highly dependent on the flow structure, as indicated by its dependence on the mean velocity gradient tensor and the anisotropic part of the turbulent stress tensor. The second, $\mathcal{P}_\mathrm{comp}$, is dependent only on scalar quantities: the existing TKE k and the rate of compression.

Considering first that turbulence is sharply suppressed during the expansion stroke and that very little turbulence is generated during the exhaust stroke, the TKE at the end of the compression phase is determined primarily by the intake and the compression phases. During the intake stroke, $\mathcal{P}_\mathrm{comp}$ is zero because the flow is essentially divergence-free (low Mach number). Turbulence is then mainly produced in the high mean shear regions of the inlet jets and by their impingement on the solid surfaces (responsible for turbulent boundary layer formation and secondary flow separation). At the end of the intake phase, the role of the intake jets, of course, vanishes, but the turbulence continues to interact with large-scale mean flow structures generated during intake. During the compression (resp. expansion) phase, the second term $\mathcal{P}_\mathrm{comp}$ provides a positive (resp. negative) contribution to k.

3.4 Turbulence: estimation and evolution of turbulence energy, length, and time scales

Engine turbulence is fascinating and inherently complex. Despite this complexity, a great deal of understanding regarding the magnitude of the turbulence scales, how they relate to various engine parameters, their effectiveness in promoting mixing processes, and how the turbulence evolves throughout the cycle can be derived from simple order-of-magnitude estimates. We begin with the following general observations regarding the evolution of turbulent engine flows:

1. They are confined in a complex geometry that is strongly varying in time (say, by one order of magnitude for a typical compression ratio of $r \approx 10$). For order-of-magnitude estimation purposes, we will consider the characteristic length scale (l) of the most energetic eddies to scale with the most confined direction. Hence, $l \approx \alpha b$ at BDC and $l \approx \alpha h$ as the piston approaches TDC. Here, b is the cylinder bore and h the clearance height. A reasonable choice for α is $\alpha \approx 1/6$ (Lumley, 1999).
2. The time available for flow evolution is constrained by the engine rotation rate (N). Indeed, any portion of the cycle between two crank angles is proportional to $\tau_e = S/\overline{V}_p = 1/2N$, where S is the piston stroke and $\overline{V}_p = 2SN$ is the mean piston speed. Note that $\langle|\nabla \cdot \mathbf{U}|\rangle \cong \langle|(1/V)(\mathrm{d}V/\mathrm{d}t)|\rangle \cong (1/\tau_e)$.
3. The thermodynamic state of the gas varies significantly during the compression and expansion phases. Hence, the Reynolds number can vary significantly because of large changes in density and viscosity, even if changes in the flow velocities are small.

Beginning with the intake phase, we now estimate the order of magnitude of the various turbulence quantities introduced earlier. The order of magnitude of the turbulent velocity scale u ($\sim k^{1/2}$) can be obtained at mid-intake by assuming the flux of kinetic energy of the mean flow through the valves to be entirely converted to turbulence energy. Such a global estimation (Lumley, 1999) provides an estimate of $u \approx 10\overline{V}_p$ that approximately agrees with experimental values (Heywood, 1988) and will be retained here. We also adopt the following typical values of $\overline{V}_p \approx 5\,\mathrm{m/s}$, $l \approx 10$ mm and $\nu \approx 10^{-5}\,\mathrm{m^2/s}$, giving $R_l = 50{,}000$. Several observations can be made with these values:

- First, the turbulent Reynolds number $R_l = ul/\nu$ is large and scales linearly with the engine rotation rate. Consequently, the smallest, dissipative scales of the turbulent flow, bounded by the Kolmogorov scale (η), are very small. With the numerical values provided, $\eta \approx 3\ \mu\mathrm{m}$ and is characterized by a molecular diffusion time of roughly $\eta^2/\nu \sim 1\,\mu\mathrm{s}$. This is approximately two orders of magnitude smaller than the time required by the turbulence to mix l-sized inhomogeneities down to the smallest scales ($\approx l/u$).
- Second, such intense turbulence will transport any quantity very efficiently throughout the cylinder. Indeed, from a simple eddy viscosity hypothesis $\delta^2 = \nu_T \Delta t$, where δ is the distance covered by turbulent diffusion $\nu_T = ul$ during the time Δt, it is straightforward to show that with $u \approx 10\overline{V}_p$, $l \approx b/6$, and $b \approx S$, turbulent transport over a distance equal to the radius $\delta = b/2$ of the cylinder requires a time $\Delta t = 0.15S/\overline{V}_p$—corresponding to only 15% of the piston stroke.
- Third, of utmost importance although it has been neglected so far, the turbulence field is responsible for an intense dissipation rate ε. A classical experimental fact (Tennekes and Lumley, 1972; Pope, 2000) is that the amount of fluctuating kinetic energy ($\approx u^2$) and the time needed to dissipate it ($\approx l/u$) are governed by the energy-containing scales. This implies $\varepsilon \approx u^2/\tau_1 \approx u^3/l$, a relationship that is embedded in all classical RANS models. This relationship is only valid, however, if the turbulent energy cascade is in equilibrium and if no other physical phenomena perturb the turbulent energy cascade at a comparable rate. We will come back to this point in what follows. Comparing the decay time scale τ_1 with the engine period leads to $N\tau_1 = 1/120 \ll 1$ (with $u \approx 10\overline{V}_p$, $l \approx b/6$, and $b \approx S$). This means that turbulence has plenty of time to decay during the intake phase. Experimental data indicate that usually $u \approx \overline{V}_p$ at BDC, which means that 99% of the TKE generated during intake has been dissipated [compare ${\overline{V}_p}^2$ to $(10\overline{V}_p)^2$!].

From a global point of view, the objective of engine engineers when inducing large-scale, phase-averaged motions such as swirl or tumble is to store the kinetic energy of the intake flow into large-scale coherent motions that are less dissipative than the turbulent field. Tumble, in particular, is designed to give back this kinetic energy—through the production term $\mathcal{P}$ in Equation 8—in the second half of the compression stroke. It is interesting to compare the order of magnitude of the mean flow kinetic energy E stored in a coherent motion of radius $\approx b/2$, length $\approx b$, rotating in solid-body rotation at $\omega = R_s\omega_e$ (R_s is the swirl ratio but the tumble ratio could be adopted also and $\omega_e = 2\pi N$) to the estimate $E_{tot} = Mu^2/2$ (M is the total mass, $u \approx 10\overline{V}_p$) obtained by Lumley (1999) for the total energy flux into the cylinder. With $E \approx Mb^2\omega^2/16$, one gets $E/E_{tot} \approx 0.01{R_t}^2$. About 5% of the total kinetic energy is therefore stored in

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

large-scale motions at BDC for the usual tumble or swirl ratios. This is significant when compared with the results obtained regarding the dissipation of TKE.

The intake valves close shortly after BDC and the in-cylinder flow is then compressed. The further development of the flow through TDC is influenced by the in-cylinder flow properties at valve closure. By dividing the turbulent energy equation by k, we see that the competing factors determining the relative rate of variation of k when following a mean fluid particle are

$$\frac{1}{k}\frac{Dk}{Dt} = \frac{\mathcal{P}_f}{k} + \frac{\mathcal{P}_{comp}}{k} + \frac{T}{k} - \frac{\varepsilon}{k} \tag{10}$$

The first term on the right-hand side ($\mathcal{P}_f/k$) is the rate of production of turbulence energy from the organized in-cylinder motion (tumble, swirl, squish). This term will be considered in detail in the next section. The second term is very specific to the engine context and can be written $\mathcal{P}_{comp}/k = -2/3(\nabla \cdot \mathbf{U})$. A compression time scale can be defined as $\tau_c = -(\nabla \cdot \mathbf{U})^{-1} = (\rho/\dot{\rho})$. Adopting from Figure 3 a typical value during the second half of the compression stroke of $-(\nabla \cdot \mathbf{U})/N = 6$, we obtain $\tau_c \approx 1/3(S/\overline{V}_p)$. Comparing the time scale of compression $\mathcal{P}_{comp}/k$ to the decay rate due to dissipation $\varepsilon/k \approx u/l = 1/\tau_t$ (with $u \approx \overline{V}_p$ and $l \approx b/6$), one obtains $\mathcal{P}_{comp}/\varepsilon = 2/3(\tau_t/\tau_c) \approx 1/3$.

This estimate has important consequences. It shows first that compression (or expansion) has a non-negligible contribution to the TKE balance. Furthermore, $\tau_t/\tau_c \approx 1/2$ means that the compression time scale is on the order of the turbulence time scale. This implies that compressed turbulence in an engine is neither quasi-steady (that would require $\tau_t/\tau_c \ll 1$) nor rapidly distorted (valid if $\tau_t/\tau_c \gg 1$). Therefore, the hypothesis of spectral equilibrium—assumed by nearly all current RANS models—is not strictly applicable (Schiestel, 1987; Lumley, 1990). Equally, simplified linear computations such as rapid distortion theory (RDT)—see, for example, Pope (2000) and references therein—cannot be pursued. To the authors' knowledge, a time-dependent scaling, valid for isotropic compression of an initially isotropic and homogeneous turbulence of very large Reynolds number, is the only strict theoretical frame proposed so far that allows a rational modification of the model equation for ε in RANS models (Cambon, Mao, and Jeandel, 1992). Although modeling is not the focus of this contribution, let us stress that LES techniques solve the equations of motion directly for all compression-affected scales, where $\tau_t \approx \tau_c$, and limit the modeling to the filtered scales where $\tau_t \ll \tau_c$.

Beyond this time scale comparison, one should of course have in mind that compression in an engine is unidirectional. Computation of the compression-induced production of each component of the Reynolds stress tensor for an initially homogeneous and isotropic turbulence shows that strictly 1D compression only "feeds" directly the component aligned with the piston motion. This is a direct consequence of Equation 6, which we considered in the discussion of large-scale structures. For smaller, turbulent structures as well, the length of a vortex aligned with the compression axis is shortened in proportion to the amount of compression, while it is unchanged if it is perpendicular to the compression axis. The angular velocity is therefore conserved for the former and enhanced for the latter, contributing to the anisotropy of the normal stresses and associated length scales. This effect is strongly opposed by the intercomponent energy exchange by the pressure-strain-rate correlations that try to equilibrate the energy in the three components.

We end this section by describing typical orders of magnitude of the state of the turbulent field near TDC. One difficulty, which we have ignored till now, arises when we try to define the length scale. Even in isotropic turbulence, there are two different length scales that can be defined on the basis of spatial velocity correlations. For incompressible, isotropic turbulence, the longitudinal scale, based on the correlation of velocities parallel to the separation vector, is demonstrated to be twice the magnitude of the lateral scale based on the correlation of the velocities perpendicular to the separation vector. Data obtained in near-isotropic grid turbulence (Comte-Bellot and Corrsin, 1971) indicate that the relation $\varepsilon \sim u^3/l$ is most closely satisfied when l is chosen to be approximately equal to the longitudinal scale.

During intake and early compression we have adopted Lumley's (1999) suggestion that $l \approx 1/6$ of the limiting dimension. Near TDC, experimental evidence in both model compression machines (Borée, Maurel, and Bazile, 2002) and engines (see the review in Miles, 2009) suggests that a larger estimate may be more appropriate. In a cylindrical combustion chamber, the limiting dimension (the clearance height) h is $h \approx S/(r-1)$. Here, we adopt $l \approx h/2$ as an estimate of the near-TDC length scale. Assuming that production due to organized motions and compression have been able to maintain $u \approx \overline{V}_p$, one sees that the TKE dissipates very quickly with $N\tau_t \approx 1/4(r-1) \ll 1$. For a compression ratio of 10, we expect the turbulence energy to be dissipated with a time scale characterized by just 10° of crankshaft rotation.

Even if the turbulence energy could be maintained near TDC, it is important to keep in mind that the turbulent transport due to near-TDC turbulence is much less efficient because scales are smaller and the available time for combustion is short. Assuming an available time

of $\Delta t = S/10\overline{V}_p$, the distance $\delta \approx \sqrt{u\,l\,\Delta t}$ covered by turbulent transport during one-tenth of the piston stroke ($\Delta\theta = 18$ CAD) is just $\delta/b \approx 1/\sqrt{20(r-1)} \approx 0.07 \ll 1$. In contrast, large-scale, coherent motions can be expected to have a much more significant impact on bulk transport and subsequent combustion processes.

These estimates have addressed only the large-scale turbulent motions near TDC. Near TDC, $\nu \approx 4 \times 10^{-5}$ m/s^2 and with $u \approx \overline{V}_p \approx 5$ m/s and $h/2 \approx 5$ mm, then $\mathrm{Re}_l \approx 6000$. Using Equation 7, we obtain for the Kolmogorov scales: $\eta \approx 7\,\mu$m, $u_\eta \approx 0.6$ m/s, and $\tau_\eta \approx 12\,\mu$s. To put these numbers into perspective, the thermal thickness of a flame at a pressure of 30 bar is roughly 30 μm, corresponding to a chemical reaction time scale of $\sim$50 μs. Turbulent and chemical time scales thus overlap. Large scales of turbulence can be expected to transport reacting fluid (flames) without influencing the progression of chemical reaction, while the smaller scales will interact with and alter the progress of combustion. More complete discussions of the interaction between turbulence and chemistry can be found elsewhere, for example, Abraham, Williams, and Bracco (1985).

Finally, we close with the observation that this discussion is derived from studies of the evolution of in-cylinder flows in which the turbulent flow structure is generated by the intake process. Modern, direct-injection SI and CI engines present an additional level of complexity, in that the fuel injection event results in significant turbulence generation and modification of flow structures at times closely coupled to the combustion event. Recent results describing the impact of fuel injection on the in-cylinder flows will be described in greater detail in subsequent text. Here, we limit our remarks to noting that, similar to the intake-generated turbulence, the dissipation of turbulence generated by the fuel injection event will be very rapid. Modern SI fuel injection systems generate fuel jet velocities exceeding 100 m/s, while high pressure diesel injection systems can generate velocities of $\sim$500 m/s. Assuming a length scale of $\sim$1 mm, and a turbulent velocity scale of 30% of the jet centerline velocity, the turbulent time scale characterizing the decay of this turbulence is on the order of tens of microseconds or a fraction of a degree of crankshaft rotation. It will clearly be advantageous to employ the fuel injection process to generate or alter mean flow structures such that turbulence generation continues after the fuel injection event has ended.

3.5 Turbulence: boundary layer structure

Understanding and modeling the physics of near-wall flows is very important because of their role in convective heat and momentum transfer. Here, we briefly review the structure of turbulent boundary layers and sketch their salient properties through an order-of-magnitude analysis similar to that given earlier.

In a near-wall flow, the total shear stress, driven by the turbulent flow, is the sum of a Reynolds stress—dominant away from the wall—and a viscous stress. At the wall, the no-slip boundary condition dictates that all the Reynolds stresses are zero, and the wall shear stress is entirely due to the viscous contribution. Appropriate "friction velocity" and "viscous length" scales are thus defined, with the physical understanding that viscous diffusion of momentum has to adapt itself to the total stress τ_p imposed by turbulence. They read:

$$u_\tau = \sqrt{\frac{\tau_p}{\rho}}$$

and

$$\delta_\nu = \frac{\nu}{u_\tau} \tag{11}$$

The classical description of a turbulent boundary layer results from a two-scale problem (Tennekes and Lumley, 1972; Pope, 2000). The viscous length $\delta_\nu = \nu/u_\tau$ has to be compared with an external scale δ—thickness of a boundary layer, half height of a channel—with $\delta/\delta_\nu = \delta u_\tau/\nu = \mathrm{Re}_\tau$. Re_τ is the friction Reynolds number and is much larger than one. The distance from the wall can be naturally measured in terms of the viscous length $y^+ \equiv y/\delta_\nu$, and the local mean velocity is likewise represented in terms of $u^+ \equiv <U>/u_\tau$. Viscous diffusion of momentum dominates near the wall ($y^+ < 5$) and the mean velocity profile is linear with $u^+ = y^+$, as shown in Figure 4. At larger values in terms of y^+ ($y^+ \gtrsim 30$), but small enough values in terms of y/δ ($y/\delta < 0.3$), the velocity profile is logarithmic because the dependence on ν (or δ_ν) and δ vanishes. Beyond $y/\delta \approx 0.3$, the mean velocity profile is no longer universal and becomes flow specific.

In what follows, we examine if typical boundary layers in engine cylinders can be considered to possess this universal structure, despite the highly transient nature of the flow. To estimate the relevant viscous scales, we will use $u_\tau \approx \langle U_\theta \rangle/30$, an estimate expected to be valid over a wide range of Reynolds numbers (Lumley, 1999). Computing $\langle U_\theta \rangle$ for solid body rotation at a radius $r = b/2$, one obtains $\langle U_\theta \rangle \approx (\pi R_s/2)\,\overline{V}_p$ and $u_\tau \approx (R_s/20)\,\overline{V}_p$.

Our first remark is that the near-wall viscous length scale δ_ν is very small. Comparing δ_ν with the cylinder bore, one obtains $\delta_\nu/b \approx (20/R_s)1/\mathrm{Re}$, where the Reynolds number $Re = b\overline{V}_p/\nu$ is very large. Typically, for $R_s = 2$, $\overline{V}_p \approx 5$ m/s, $b = 80$ mm, and $\nu \approx 10^{-5}$ m^2/s, $\delta_\nu/b \approx 2.5 \times 10^{-4} \ll 1$. The thickness of the viscous

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

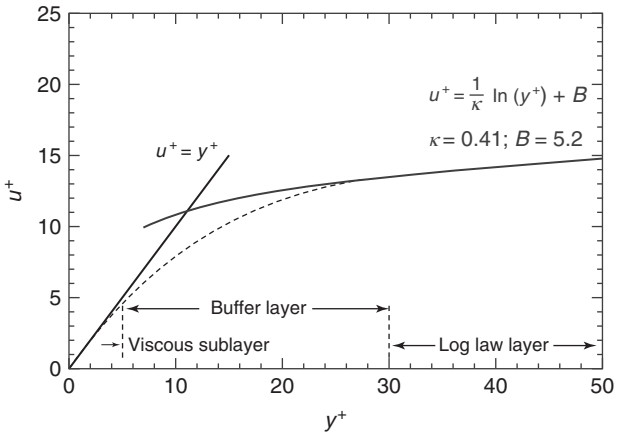

Figure 4. The structure of a turbulent boundary layer.

sublayer is consequently ∼0.1 mm, and a very fine near-wall grid resolution is required if the near-wall boundary layer is to be resolved by a computational model. It is also easy to show that the viscous time scale $\tau_\nu = {\delta_\nu}^2/\nu$ is much smaller than the swirl, tumble, or even compression time scale. This means that viscous diffusion dominates momentum transfer in the viscous sublayer (as expected) and that the local momentum balance is quasi-steady in this very thin layer.

We now move further away from the wall to, say, $y_1 = b/100$ (≈1 mm)—consistent with a typical engine computational grid resolution. In viscous lengths, this corresponds to ${y_1}^+ = 40$ for the numerical values chosen earlier. We, therefore, consider that this location is within the "log-law" region shown in Figure 4. Note that this value of ${y_1}^+$ increases linearly with $\overline{V}_\mathrm{p}$. For canonical near-wall turbulent flows, the expected universal logarithmic velocity profile in this region plus the fact that production and dissipation are in equilibrium can be used to build "wall functions," which constitute a mixed boundary condition specifying the mean velocity $\langle U \rangle$ and the shear stress τ_p at y_1. The great simplification and savings provided by such wall functions is very attractive. Therefore, they are used in most commercial computational fluid dynamics (CFD) codes. However, engines provide many flow conditions—, for example, unsteadiness, separated and impinging flow, regions with strong pressure gradients, compressibility—in which their physical basis and particular implementation may not be well founded.

A simple order of magnitude analysis can again help us here. From Tennekes and Lumley (1972), we learn that a good approximation of the turbulence time scale in a log-law region is $\tau_1 = \kappa y_1/u_\tau$, where the Von Karman constant $\kappa = 0.41$ and y_1 is held fixed at $b/100$. This near-wall timescale can then be compared with the turnover time scale $(1/\omega)$ of the swirl (or tumble) and to the bulk turbulence time scale $\tau_\mathrm{t} \approx l/u \approx b/6\overline{V}_\mathrm{p}$. The first comparison leads to $\omega\tau_1 \approx 0.25$; it is interesting to note in this straightforward computation that this ratio is of order one independent of the specific engine parameters because the dependencies on swirl ratio, engine rotation rate, and geometry cancel out. The second comparison leads to $\tau_1/\tau_\mathrm{t} = 0.5/R_\mathrm{s}$. If a log-law region is supposed to exist, we thus find that the turbulence time scale τ_1 in this region is of the same order of magnitude as the large-scale flow and bulk turbulence (and therefore of the compression time scale). Consequently, we expect near-wall turbulence to be significantly modified by bulk turbulence (having much larger length scales but comparable time scales). Bulk compression will also affect near-wall turbulence in a nonisotropic manner and any evolution of the large-scale rotating flow that occurs over its own turnover time scale—such as tumble breakdown—will lead to unsteady behavior in the near-wall region. Moreover, even steady swirling flows have been noted to cause significant departures from log-law behavior (Jakirlic, Hanjalic, and Tropea, 2002). These observations mean that neither the usual CFD RANS simulations using "wall functions," nor the more sophisticated LES simulations relying on wall functions are well adapted to engine conditions. Experimental data bases are needed on which to test and build models (e.g., Alharbi and Sick, 2010) but are very challenging to obtain.

4 IN-CYLINDER MACRO FLOWS

In this section we describe the generic mean flow structures that are observed in engines, as well as how they can be manipulated by the engine designer. Through this admittedly incomplete description, we hope to provide the reader with the background needed to foster new ideas of flow manipulation. We describe not only the flow structures observed in the cylinder but also available analytical solutions that describe certain simple flow features. Such descriptions are useful even in the age of multidimensional modeling, as they provide the engine designer with useful information on the order of magnitude of various flow features, as well as their approximate phasing within the engine cycle.

4.1 Tumbling flow

The need to induce a tumbling motion in a cylinder has been introduced in Section 2, and in Section 3 it was shown that such a structure can store a significant amount of kinetic

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

energy. Our goal in this section is to give more insights about the structure of the flow and its CCV during the intake and early compression phase. The important tumble breakdown phase will then be discussed and we will end with a note concerning spray–tumble interactions.

4.1.1 Intake flow: the impinging intake jet

Flow structure early in the intake stroke, say before 90 CAD, is generally not discussed in detail in the literature. The confinement is very high and the valve jets impact on the piston. Using horizontal PIV planes a few millimeters away from a flat piston surface, and analyzing the flow topology as proposed by Depardon *et al*. (2006), Voisine (2010) showed that the jet–piston interaction is very strong and results in complex patterns that exhibit noticeable CCV. A system of two mean ringlike vortices generated beneath the intake valves is detected by Dannemann *et al*. (2010), and constitutes the major flow structure at this time. However, in a study involving tumble control using moving flaps located inside the intake port, Keromnes *et al*. (2010) show that a mean tumbling flow can be induced as early as 90 CAD when the flaps are positioned to maximize the tumble. Finally, in a numerical study, Hasse, Sohm, and Durst (2010) identify key flow patterns responsible for cyclic variations in modern engines. These patterns include "*the flow separation at machined edges in the intake port, the separation at the inlet valve as well as the jet deflection at the moving piston*." CCV arising from the combination of these key flow patterns is expected to be amplified during early intake, thereby influencing the rest of the cycle.

Beyond 90 CAD, a tumbling jet structure develops along the wall of the cylinder, opposite to the intake valves, and impinges on the moving piston. The jet is deflected by the piston, spreads along the flat surface and interacts with the curved cylinder wall—generating an up-wash flow along the cylinder walls. Velocities measured in a horizontal plane located at mid-height show that the up-wash flows are recirculated and merge with the descending valve jets. A schematic of the mean flow structure at BDC is proposed in Figure 5 (Voisine *et al*., 2011). The sketch of Figure 5b demonstrates that the true structure of the flow is 3D, and that flow patterns measured in all planes are intimately coupled. Concentrating only on the description of a "tumble center," particularly if measurements are only taken in a symmetry plane, is an oversimplification and can be misleading. Figure 5b also emphasizes the fact that nonsymmetrical jet–piston interactions will significantly impact the formation of the so-called tumble vortex.

Several flow regions are marked in Figure 5a and were used by Voisine *et al*. (2011) to study the CCV of the flow structure. The results are believed to be of general value:

(i) The location of region A (the "tumble center") is strongly correlated with the momentum flux of the descending valve jets. The global sensitivity of the 3D structure at BDC to the development and merging of the valve jets is thus very clear.

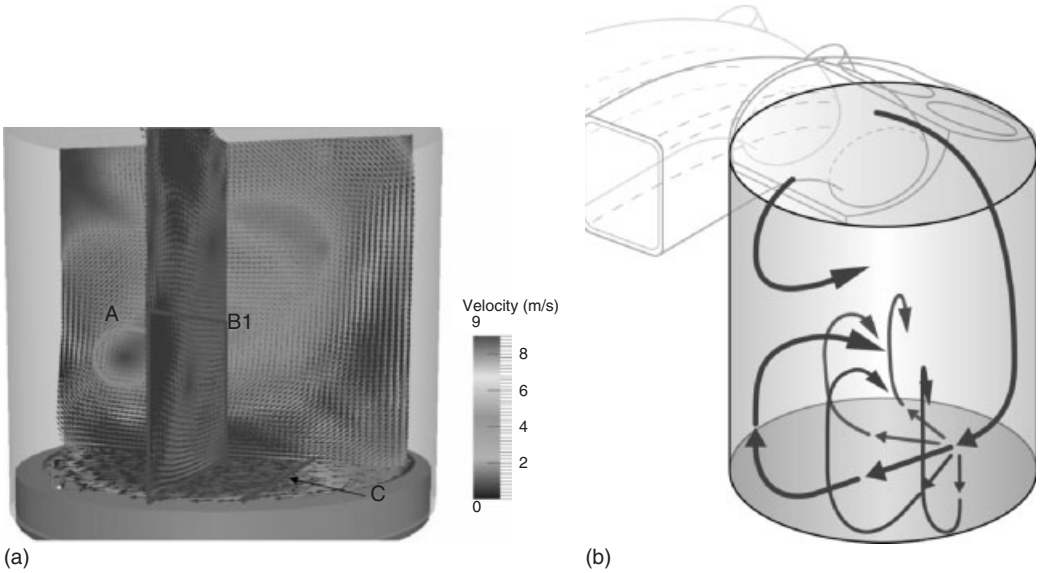

Figure 5. (a) Superposition of orthogonal, two-component PIV planes inside the cylinder at BDC (Reproduced from *Experiments in Fluids*, 2011, p. 1393–1407, Spatio-temporal structure and cycle to cycle variations of an in-cylinder tumbling flow, Voisine *et al*. With kind permission of Springer Science+Business Media); (b) sketch of the three-dimensional mean flow at BDC. (Color Figures are available in the electronic version.)

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(ii) The circulation computed from the velocity along contour B1 in the transverse plane is of the order of $\overline{V}_p b$, and is comparable to the circulation of the main tumble structure in the symmetry plane. The coefficient of variation of the fluctuating circulation along B1 is high (about 30%) and fluctuations in circulation on both sides of the symmetry plane are uncorrelated. This means that the large-scale CCV associated with jet–piston interactions is significant, but that it induces no large-scale flow symmetry or antisymmetry relative to the engine symmetry plane.

(iii) RMS variations of about 15% in the integrated momentum flux across line C (line C is located in a horizontal plane 2 mm above the piston surface) show that there are large, coherent fluctuations of the momentum flux.

Each of these observations is the consequence of significant variation in the development, strength, and spatial extent of the valve jet and of the valve jet–piston interactions. Such high levels of fluctuations in integral quantities like circulation are significant and show that CCVs have a direct effect on the global 3D, recirculating flow structure at BDC.

4.1.2 Early compression phase

The early compression phase is characterized by the closure of the intake valves and a less intense jet–piston interaction. The tumbling structure becomes organized and its structure is influenced by the earlier cycle-to-cycle variations in the properties of the tumbling jet. The 3D representation of Figure 6b displays the footprint of the mean 3D motion in horizontal planes 2 mm above the piston top and in the upper region of the cylinder—locations shown by the horizontal lines in Figure 6a. We see that the flow along the piston top diverges away from the jet impact region, rolls up not only in the symmetry plane but also along the cylinder wall, recombines in the central region of the upper region of the cylinder, and impacts the piston in a down-wash motion—the downward motion is apparent when the velocity field in the vertical plane is considered in comparison with the approximate piston-induced velocity $U(z) = V_p(z/z_p)$. Consequently, the mean tumbling motion is not at all symmetric with respect to a "cross-tumble" plane. Moreover, we see that the two "vortical structures" detected in the upper horizontal plane are the signature of this 3D flow structure evolution and not the signature of the vortex breakdown.

A classical way of reasoning, adopted in the previous sections, is to consider the tumble as a simple transverse vortex. As explained in the context of Equation 6, if the length of this vortex does not change during compression, its rotation rate should increase as the compression stroke proceeds. While this spin-up process occurs, angular momentum is approximately conserved, but rotational kinetic energy is not. Conserving mass and assuming a circular vortex cross-section, we find that the ratio of the final-to-initial rotational moment of inertia of

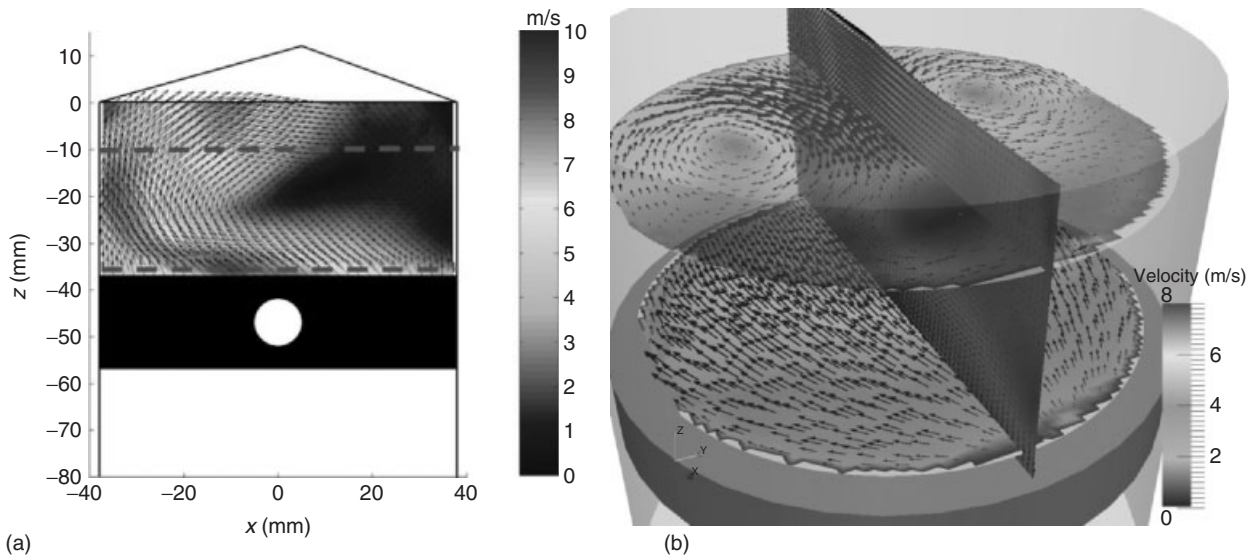

Figure 6. (a) Phase-averaged mean velocity field at $\theta = 270$ CAD, (b) superposition of 2D PIV planes inside the cylinder at half compression stroke. The vertical planes in Figure 6a and b are at the same location. the vortex I_f/I_0 is inversely proportional to the vorticity ratio, and hence the rotational kinetic energy $I\omega^2$ increases as ρ_f/ρ_0. A tumble vortex is thus not only a structure that allows the storage of mean flow momentum and energy but it also theoretically allows us to increase the mean flow energy during compression, making a greater amount of energy available to generate turbulence near TDC. The source of this energy is work done by the piston. Qualitatively, we expect the rate of energy transfer to the vortex to be similar to $-\nabla \cdot \mathbf{U}$, and hence the increase in kinetic energy should be strongly affected by compression ratio. The available data only partially support this expectation: at low compression ratio (~4) the mean kinetic energy associated with the tumble motion decreases throughout the compression process (Borée, Maurel, and Bazile, 2002), although a 30% increase is seen at higher compression ratio (Müller, Arndt, and Dreizler, 2011). In the latter case, however, the mean flow kinetic energy peaks at approximately 65° before TDC—well before the peak in $\nabla \cdot \mathbf{U}$. To our understanding, these results are not unexpected: as shown, the real mean flow structure is far more complex and is geometry dependent. Moreover, in each geometry, flow separations, for example, at the corners formed by the cylinder wall and head or piston surfaces, lead to shear flow regions and significant transfer of mean kinetic energy to turbulence.

Characterization of the single-cycle properties of the tumbling jet structure has led to significant progress in increasing our understanding of cycle-to-cycle, large-scale fluctuations of the tumbling motion. Lagrangian techniques for identifying coherent flow structures (Shadden, Dabiri, and Marsden, 2006) have been used to detect the unsteady flow separation away from the cylinder wall (left hand side, $x \approx -5$ mm in Figure 6a) induced by the roll up of the tumbling motion. In the symmetry plane, the vertical location of the jet front—which approximates the separation location—is accurately detected between BDC and 220 CAD and exhibits a very strong cycle-to-cycle variation. For the combustion chamber considered in Voisine *et al*. (2011), the RMS variation in the position of the jet front is approximately 10% of the piston stroke and is strongly correlated with the value of the instantaneous tumble ratio in the chamber. These Lagrangian techniques are believed to be promising ways to explore the in-cycle spatial and temporal coherence of engine flows and to link this coherence with the integral properties relevant for engine development (such as tumble ratio) and their cycle-to-cycle variations.

Finally, we close this section with a brief discussion on the potential for reduction of cycle-to-cycle variations in the tumbling motion. In the tumble control study referenced earlier, by calculating the spatial correlation coefficients for the two velocity components in the symmetry plane at 270 CAD, Keromnes *et al*. (2010) show very clearly that CCVs are considerably reduced when the tumble control flaps are positioned to maximize tumble. In particular, variability in the longitudinal (horizontal) velocity component correlation coefficient is reduced to less than 50% of its value without a flap. Moreover, a distinct tumble structure in the symmetry plane is observed later in the compression stroke than when the tumble is lower—behavior that will likely impact near-TDC turbulence levels, as discussed in subsequent text. More work is needed to determine the mechanisms by which this reduction in CCV and increase in stability of the tumble vortex occurs.

4.1.3 The breakdown phase

Near the end of the compression phase, a transfer of kinetic energy from the large-scale tumbling motion to small-scale turbulence occurs. Even if, as stated earlier, the 3D structure of tumble is geometry dependent, a literature survey of phase-averaged statistics (Arcoumanis, Hu, and Whitelaw, 1990; Hill and Zhang, 1994; Borée, Maurel, and Bazile, 2002; Müller *et al*., 2010; Voisine *et al*., 2011) shows that the transfer of energy from the mean flow to turbulence always occurs beyond $\theta \approx 300$ CAD. Moreover, in very different geometries—square-piston research compression chambers or cylindrical chambers—a semi-log plot of the CA evolution of the mean flow kinetic energy shows that the energy decay is exponential beyond $\theta \approx 300$ CAD and is characterized by the turnover time scale of the large-scale motion. The confined large-scale flow is thus believed to be intrinsically unstable near the end of the compression.

Many fundamental studies have addressed the problem of 3D instability of large 2D vortices in unbounded domains or in bounded geometries with free slip boundaries—see, for example, Lundgren and Mansour (1996). Likewise, a direct numerical simulation of a compressed Taylor vortex has been performed by Le Roy and Le Penven (1997). Lumley (2001) also points out the role of this instability in engine-related flows. The instability of the compressed tumble-vortex may be due to the elliptical nature of the 2D vortex streamlines. The plane strain associated with ellipticity is responsible for an amplification of perturbations carried by the rotating flow. A typical effect is the production of small-scale fluctuations directly from a smooth initial state. An evaluation of the time scale characterizing the growth of the elliptical instability in a model compression chamber was obtained by Borée *et al*. (1999) using the work of Lundgren and Mansour (1996). It shows that there is ample time for this instability to develop, and it is therefore a good candidate for causing tumble breakdown. It is, however, very important to note that the theoretical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

studies always assume a free-slip boundary. In a real engine, near-wall flow separation has a strong impact on the topology of the flow in the chamber and the transfer of kinetic energy to turbulence. The route to turbulence in the compression chamber beyond 300 CAD might therefore be driven by the confined, naturally unstable, elliptical vortex core interacting both with the walls and with the resulting separated regions.

It is important to understand that the measured increase of TKE due to tumble breakdown is due to a combination of the transfer of energy to small scale turbulence and to large scale cycle-to-cycle variability. To clarify and separate the contributions from these two sources, Voisine *et al*. (2011) analyzed high speed PIV measurements in the pent-roof region during the second part of the compression phase. Distinct families of cycles were identified according to the spatial structure of the velocity field in the symmetry plane near TDC. More precisely, a globally coherent tumbling flow structure was still detected for some cycles near TDC, while other cycles experienced a loss of large-scale coherence. The conditional probabilities associated with these families were then used in order to compute conditional statistics. Phase invariant POD (Fogleman *et al*., 2004; Fogleman, 2005) was used as a rigorous and objective statistical approach to classify and quantify the single-cycle structures. The main conclusions of this analysis are as follows:

(i) In a statistical sense, flows having the largest kinetic energy in the symmetry plane before the breakdown phase are likely to transfer this kinetic energy to smaller scale turbulent fluctuations during the breakdown phase. This indicates that cyclic variability in tumble flow formation will impact near-TDC turbulence levels on a cycle-by-cycle basis.

(ii) The increase in the fluctuating kinetic energy is the largest for cycles that experience a loss of large-scale coherence, whereas no maximum is detected for cycles keeping their coherence. In conjunction with the previous conclusion, this suggests that both large-scale coherent flow structure variations and differences in small-scale turbulence occur on a cycle-to-cycle basis.

(iii) Conditional statistics can be used to decompose the phase-averaged Reynolds stresses into contributions from families of cycles with similar single-cycle coherent structures and contributions from the turbulence. In the experiments of Voisine *et al*. (2011), approximately 30% of the fluctuating kinetic energy is due to cycle-to-cycle coherent structure variations near TDC. Moreover, in the symmetry plane within the pent-roof chamber, this large-scale cyclic variability is mostly due to strong variations in the longitudinal component of velocity. Such variability, especially along the chamber head near the spark location, is expected to strongly influence the ignition process.

4.1.4 Spray–tumble interaction

A short note is made here to emphasize the fact that engine designers may employ the fuel injection process in order to influence and control in-cylinder flows. Supposing that the momentum flux of the liquid fuel spray is efficiently transferred to the gas motion (this is only partially true and depends on spray characteristics), an order of magnitude analysis indeed shows that the flux of angular momentum due to the spray can significantly perturb the tumble vortex for a typical tumble ratio. Yamakawa *et al*. (2011) specifically attempt to tailor the injection process to strengthen the tumble vortex. A similar strategy is described by Hyundai (Han *et al*., 2011). If not properly designed, however, injection–vortex interactions can interfere with vortex breakdown, even when the momentum introduced by fuel injection reinforces the tumble motion. Indeed, measurements made in a research engine (Moreau *et al*., 2004), designed to be dominated by a single tumble vortex, have shown that injection of a single jet can promote breakdown of the vortex structure and lead to turbulence energies three to four times lower at TDC than are seen in the undisrupted vortex because dissipation of TKE has more time to act. Simulation results also suggest that, even when fuel injection occurs during the intake stroke, spray-flow interactions can significantly impact the tumble development and lead to substantial differences in flow turbulence throughout much of the compression stroke (Chen *et al*., 2011).

4.2 Swirling and squish flows

Swirling flows have traditionally been most closely associated with CI engine technologies; accordingly, most of the examples given here have been drawn from the CI engine literature. However, as noted in Section 2, direct-injection SI engines are now often employing significant levels of swirl. An important feature of swirl-supported SI combustion systems is that they are generally less susceptible to CCVs (Zhao, Lai, and Harrington, 1999)—undoubtedly due in part to the fact that the swirl structure does not break down during compression.

So-called squish flows, created when the piston closely approaches a stationary combustion surface, were more important in older engines with L- or wedge-shaped combustion chambers. While modern pent-roof SI engines

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

may generate squish flows over a limited area, squish flows are more dominant in bowl-in-piston CI engine designs. Moreover, the impact of squish flows on turbulence generation is greatly enhanced when they are coupled with flow swirl. Hence, we treat them both in this section.

4.2.1 *One-dimensional analytical representation of a swirl vortex*

In parallel with the simple analytical representation of the axial velocity distribution, there is a simple representation for the radial profile of the swirl velocity, first noted in the context of engine flows by Johnston *et al*. (1979), which arises from a direct solution of the momentum equations. When U_θ is the only nonzero velocity component, the flow is axially and azimuthally uniform, and thermodynamic properties are uniform, the radial velocity profile and its decay rate can be expressed as

$$U_\theta(r,t) = \frac{(2\pi N R_s)\alpha B}{2J_2(\alpha)} \cdot J_1\left(\alpha\frac{2r}{B}\right) \cdot \exp\left(-\frac{4\alpha^2}{B^2}\nu t\right) \tag{12}$$

In Equation 12, B represents the cylinder bore diameter, ν is the viscosity, and α is a nondimensional parameter. J_1 and J_2 are Bessel functions of the first and second kind, respectively. If the no-slip condition at the cylinder wall is enforced, a value of $\alpha = 3.83$ is obtained, which provides an unrealistic shape for the radial profile; selecting $\alpha = 0$ results in a linear profile (solid body rotation). Velocity profiles for various representative values of α are shown in Figure 7.

This simple solution is of importance as it allows the tangential velocity profile to be initialized for multi-dimensional simulations by specifying only the engine speed, swirl ratio, and a value of α. In conjunction with $U(z) = V_p(z/z_p)$ (a convention that is inconsistent with the derivation of Equation 12), it is employed by several commercial CFD codes. A value of $\alpha = 3.11$ is often recommended (Amsden, O'Rourke, and Butler, 1989); however, a value of $\alpha = 2.2$ generally provides a better match to in-cylinder measurements (Petersen and Miles, 2011). These measurements have been made at ~50° before top center, in engines with various port geometries. Hence, well into the compression stroke, the value of $\alpha = 2.2$ can be assumed to have some generality.

If an appropriate turbulent viscosity were known, the decay rate of the swirl could be estimated from Equation 12. However, a more accurate estimate can likely be obtained from empirical formulae for the skin friction at the wall, and calculating the resulting torque acting on the cylinder contents. Employing the correlations in Heywood (1988), we find that it will take approximately one engine revolution to halve the angular velocity of the flow. Evidently, swirl is a very stable flow structure that is well able to survive the compression process.

4.2.2 *Cylindrical compression of a swirling flow*

As discussed earlier, in a swirling flow the axial compression of the swirl motion does not impact the rotation rate, as the change in the density is counteracted by the change in the vortex length. However, when the vortex is compressed into a reduced diameter combustion bowl, as illustrated in the simplified schematic shown in Figure 8, we expect an increase in rotation rate and in rotational kinetic energy. For a hypothetical bore-to-bowl diameter ratio of two, the volume occupied by the vortex is reduced by a factor of 4, providing a proportional increase in density. Hence, Equation 6 predicts a fourfold increase in rotational rate ω. The rotational kinetic energy $I\omega^2$ will also increase by a factor of 4, reflecting the reduction in the rotational moment of inertia which also occurs.

Measurements (Arcoumanis, Hadjiapostolou, and Whitelaw, 1991) indicate that in a typical, bowl-in-piston automotive diesel engine geometry, approximately 60% of the rotational angular momentum is conserved as the swirl vortex is compressed into the bowl. With a bore-bowl diameter ratio of 2, the rotational kinetic energy in the bowl is thus increased by 40–50%. Similar to the spin-up of a tumble vortex during compression, the source of this energy is piston work.

4.2.3 Magnitude and phasing of the squish flow

To gain an appreciation for the strength of the squish flow, and how it varies with changing piston position and combustion chamber geometry, it is useful to examine the analytical expression derived by Fitzgeorge and Allison (1962) for a cylindrical bowl-in-piston geometry[3]

$$\frac{U_{sq}}{V_p} = \frac{D}{4z}\left[\left(\frac{B}{D}\right)^2 - 1\right]\frac{4V_{bowl}}{4V_{bowl} + \pi B^2 z} \qquad (13)$$

Equation 13 for the squish velocity, U_{sq}, assumes an axially and azimuthally uniform squish velocity through the surface defined by the bowl rim radius $D/2$ and the clearance height z. B is defined as in Figure 8, V_p represents the instantaneous piston speed, and V_{bowl} represents the volume of the piston bowl. The variation in squish velocity, normalized by the mean piston speed, is shown in Figure 9. Similar to the velocity field divergence shown in Figure 3, the peak magnitude of the squish flow occurs quite near to TDC, and turbulence generated by this jet will tend to peak at this time. As will be seen in subsequent text, both the mean flow structures and the turbulence generated by the squish flow are highly dependent on the swirl level.

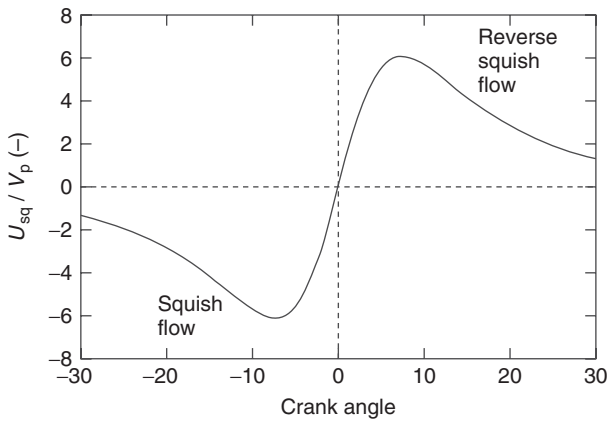

Figure 9. The variation in squish flow strength for a typical bowl-in-piston geometry.

4.2.4 Squish–swirl interaction

During the process of compressing the swirling flow into the bowl, different flow structures within the bowl are generated because of the rearrangement of the in-cylinder angular momentum by the "squish" flow (Gosman, 1986; El Tahry, 1982). The process is illustrated in Figure 10, where we consider the application of conservation of angular momentum to an individual fluid element. As the element is displaced inwardly, its tangential velocity increases in accordance with Equation 5. Owing to the increased tangential velocity, the centrifugal forces acting on the fluid element are increased. Eventually, as the fluid moves inward, the radial momentum imparted by the squish flow, in addition to the radial pressure force, is overcome by increased centrifugal forces and further inward motion is impeded.

Because the squish flow is dominated by the changing combustion chamber geometry, the radial momentum imparted to fluid elements during the squish process is independent of the flow swirl level. In contrast, the centrifugal forces acting on a fluid element will increase approximately quadratically with the flow swirl ratio. The inward penetration of the squish flow, therefore, is strongly influenced by the swirl, with the greatest penetration occurring at the lowest swirl levels. The consequence of this changing balance between squish-imparted momentum and centrifugal forces is shown in Figure 11. For low levels of flow swirl ($R_s \sim 0$), the squish flow penetrates to nearly the cylinder centerline before it turns down into the bowl, as required by symmetry constraints. As the flow swirl is increased, the inward penetration is reduced and the flow turns down into the bowl at larger r, when the increasing centrifugal forces have overcome the initial radial momentum imparted by the squish process. For high swirl levels, the centrifugal forces are sufficiently great that the squish flow turns down into the bowl as soon as the combustion chamber geometry permits. Note that the direction of rotation of the vortex structure that dominates

the bowl at $R_s \sim 0$ and at $R_s \sim 2.5$ has been reversed in Figure 11.

4.2.5 Spray–swirl interaction

In-cylinder measurements coupled with multidimensional simulations (Miles, 2009 and references therein) have shown that the engine designer can influence the development of mean flow structures in a bowl-in-piston combustion chamber by altering the in-cylinder spatial distribution of angular momentum through the fuel injection process. Changes in the spatial distribution of angular momentum drive the formation of flow structures by the same mechanism as the squish–swirl interaction discussed—by balancing the momentum added to the flow by injection against the changing centrifugal forces on a fluid element as it is displaced radially. The redistribution of angular momentum is principally accomplished through two mechanisms: first, the fuel jets entrain nearly quiescent, low angular momentum fluid from the central portion of the cylinder and deposit it near the bowl periphery. Second, the fuel jets are a large source of linear momentum. Deflection of the fuel jets and their accompanying, entrained fluid by the walls of the combustion chamber results in energetic rotating flow structures in the vertical (r–z) plane. Both displacement by the low-momentum fluid transported from the center of the cylinder to the bowl periphery and convection by the rotating vertical plane structures generally act to transport high angular momentum fluid inward in a manner similar to the inward transport of high momentum fluid by the squish flow.

As depicted in Figure 12, by varying the injection pressure P_{inj} or the swirl ratio, the balance between linear momentum added by the fuel jets and the angular momentum associated with the commingled air can be changed. At low swirl ratios, depicted in the upper row of the figure, the deflected momentum of the fuel jet creates a single, clockwise-rotating structure. This structure transports high angular momentum fluid from near the bowl rim down into the bowl, where it is conveyed inward to the central bowl protrusion. Although the tangential velocity of this fluid increases as it moves inward, the centrifugal forces are sufficiently small that they do not strongly alter the vortex structure: the angular momentum is transported much like a passive scalar. As the swirl ratio is increased, larger centrifugal forces associated with the higher angular momentum compel the inwardly displaced fluid to return to the outer regions of the bowl after it turns upward from the bottom of the bowl. As a result, the clockwise-rotating vortex becomes progressively smaller and is centered lower and at larger radii within the bowl, and a complementary counter-rotating vortex forms in the upper central region of the combustion chamber. The relative sizes of these vortical structures can also be impacted by injection pressure: increasing injection pressure increases the momentum in the fuel-induced vortex structure, thereby allowing greater inward and upward displacement of a fluid element before the vortex momentum is overcome by centrifugal forces. Hence, the size of the lower vortex increases.

Generalizing, it is apparent that the geometry of the piston bowl lip, where the linear momentum of the fuel jet is deflected, will also impact the relative size of these vortices. Likewise, an increase in load can be expected to have an effect similar to an increase in injection pressure, as a greater amount of linear momentum is injected with the fuel. Finally, an increase in engine speed will have an effect on the structure of the flow similar to that of an increase in swirl ratio. This latter observation may help explain the

With kind permission of Springer Science+Business Media.)

need for increased swirl ratio to obtain optimum low speed performance in many diesel engines.

Three additional observations related to the spray–swirl interaction are relevant. First, when high angular momentum fluid is transported inward the angular momentum of the fluid is conserved, but not the kinetic energy—which is theoretically expected to increase. Conceptually, the kinetic energy of the spray is employed to perform work on the fluid in transporting it inward. Thus, the spray–swirl interaction provides a mechanism by which the energy of the injection event can be stored within the mean, rotational energy of the fluid for later release as TKE. Second, the process of rearranging the in-cylinder angular momentum can lead to negative radial gradients in angular momentum; an example is shown by the dashed ellipsoid in the upper-right portion of Figure 12. Such flow patterns are inherently unstable—any radial perturbation of the position of a fluid element will be amplified (e.g., Bradshaw, 1973; Tritton, 1977). Consequently, the flow can be expected to very rapidly and efficiently produce turbulence, as will be discussed further in subsequent text. Third, at the interface between the two vortical structures, there are sharp gradients in the swirl velocity, as well as significant flow deformation in the vertical (r–z) plane. These attributes are likewise expected to result in high levels of turbulence production.

4.2.6 *Toroidal vortex structures*

A final example of strongly rotating flows in engines is the toroidal vortex, or vortex ring, which is a very

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

stable flow structure that can be produced in a variety of ways; the essential requirement for its production is that linear momentum should be imparted to a fluid in an axisymmetric manner (Batchelor, 1967). This structure is a very common feature of engine flows, in large part due to the axisymmetric geometry of cylinders and piston bowls and the approximately cylindrical geometry of valves and ports. One of the striking characteristics of a vortex ring is its persistence and stability. An example is shown in Figure 13a, which depicts a vortex ring formed at the piston bowl mouth by hot oxidation products leaving the bowl. It forms by 25° after TDC, and clearly persists until at least 50–55° after TC. The vortex forms a flow barrier separating and impeding mixing between fluid leaving the bowl and the remaining charge within the squish volume, causing the expanding squish volume to be filled from the top of the cylinder. Images of soot luminosity further suggest that this vortex may directly impact the mixing and further oxidation of soot in the squish volume of diesel engines.

Additional examples of toroidal vortices are also shown in Figure 13. The "roll-up" vortex (b), formed as the rising piston scrapes stagnant boundary layer fluid off the cylinder wall during the exhaust stroke, can grow to a diameter of approximately 15% of the bore. It is thought to contain a sizable fraction of the exhaust hydrocarbons emitted from SI engines. Unburned hydrocarbons have also been observed in a similar corner vortex in the upper portion of the cylinder in an optically accessible engine with a large ring-land crevice (c). CFD simulations, however, indicate that this vortex will be much less pronounced in engines with smaller crevice volumes. Finally, very distinct ring-vortex structures are predicted to form behind the intake valve face during induction (d). The experimental detection of these structures has been noted in the discussion of the intake jet flows in SI engines.

Notice that these ring-vortex structures can have rotation rates that significantly exceed the rotation rates of typical swirl or tumble structures. For example, ring vortices at the mouth of the piston bowl rotating at over 10 times the crankshaft speed have been measured in light-duty engines. As will be shown in the next section, rotation of this magnitude will clearly impact the structure of the turbulence.

4.2.7 *The impact of swirl on turbulence: theoretical considerations*

The effects of rotation on turbulence are very profound and complex (Sagaut and Cambon, 2008; Mathieu and Scott, 2000). Although analysis in a rotating coordinate system shows that for homogeneous turbulence, the equation governing the local TKE balance (Equation 8) is unchanged, rotation can still impact the turbulence energy through changes in both the production $\mathcal{P}$ and the dissipation ε. The production is impacted through the Reynolds stresses, while the dissipation is impacted by the tendency of rotation to inhibit the transfer of energy in the turbulent energy cascade, thereby reducing the dissipation rate.

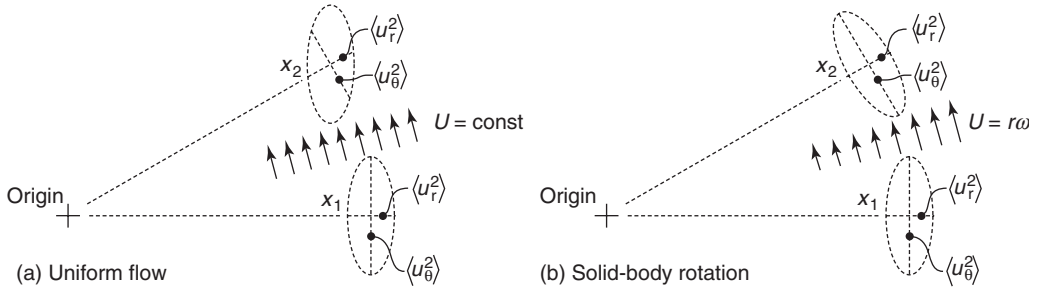

Figure 14. Examples of the impact of basis vector rotation on the individual components of the turbulent stress tensor. In (a) the production is zero and the stresses vary solely because of basis vector rotation. In (b) the effects of basis vector rotation and production cancel to leave the r–θ components of the stress tensor unchanged.

Here we pursue a simplified analysis of the production term, employing a cylindrical coordinate system within a stationary (inertial) reference frame. Before proceeding with the analysis, it will be useful to review briefly how the various Reynolds stress components vary as a result of mean flow convection in a cylindrical coordinate system. Consider first a steady, 2D flow in which the turbulence is transported from location $\mathbf{x}_1$ to location $\mathbf{x}_2$ by a uniform mean velocity field. We represent the turbulent stress tensor as an elliptical object shown on the left-hand side of Figure 14, where the minor axis of the ellipse at location $\mathbf{x}_1$ represents the magnitude of the radial stress $\langle u_r^2 \rangle$ and the major axis represents the tangential stress $\langle u_\theta^2 \rangle$. Because the velocity gradients are zero, the production of the individual Reynolds stresses is zero. Nevertheless, when expressed in cylindrical coordinates, the magnitude of both the normal stresses and the shear stress has clearly changed from location $\mathbf{x}_1$ to $\mathbf{x}_2$—an artifact of the changing orientation of the coordinate system basis vectors. Next, consider the right-hand-side of Figure 14, which depicts turbulence in equilibrium in a cylindrical coordinate system, where the mean flow is solid-body like and the radial and tangential stresses are unchanging. In this case, the production of $\langle u_r^2 \rangle$ and $\langle u_\theta^2 \rangle$ is nonzero, but the production-like terms that arise as a result of coordinate system rotation exactly cancel the production of the individual stress components such that the stresses at $\mathbf{x}_1$ and $\mathbf{x}_2$ are equal. These two examples clearly illustrate that both the true stress production and the production-like terms associated with the changing basis vector orientation must be considered jointly when we examine the variation in the turbulent stresses in an r–θ coordinate system. Note, however, that the terms arising from the changing basis vectors do not contribute to the production of TKE, they simply redistribute it among the various components.

As we will see in subsequent text, in swirling flows a dominant source of turbulence is often associated with production associated with r–θ plane velocity gradients, which are dominated by radial gradients in the tangential velocity component (the swirl velocity). Under these conditions, the production of k is

$$\mathcal{P}_f = -\langle u_r u_\theta \rangle r \frac{\partial}{\partial r}\left(\frac{\langle U_\theta \rangle}{r}\right) \tag{14}$$

Production of k can be further separated into terms that feed energy into the tangential and the radial fluctuations, and combined with the terms arising from coordinate system rotation, to yield

$$\mathcal{P}_{f,\theta} = -\langle u_r u_\theta \rangle \frac{\partial \langle U_\theta \rangle}{\partial r} - \langle u_r u_\theta \rangle \frac{\langle U_\theta \rangle}{r} = -\langle u_r u_\theta \rangle \frac{1}{r}\frac{\partial (r\langle U_\theta \rangle)}{\partial r} \tag{15}$$

and

$$\mathcal{P}_{f,r} = \langle u_r u_\theta \rangle \frac{\langle U_\theta \rangle}{r} + \langle u_r u_\theta \rangle \frac{\langle U_\theta \rangle}{r} = \langle u_r u_\theta \rangle \frac{2\langle U_\theta \rangle}{r} \tag{16}$$

For most engine flows, $\partial(\langle U_\theta \rangle / r)/\partial r < 0$, and a positive production of turbulence energy requires that $\langle u_r u_\theta \rangle$ be positive. Lumley (1999) argues that, provided the radial gradient in the mean flow angular momentum is positive, $\langle u_r u_\theta \rangle$ will be negative—indicating that swirl will suppress turbulence. The reasoning supporting this argument is that a positive radial excursion of a fluid particle, during which angular momentum is conserved, will lead to a local deficit in angular momentum at the new radius and hence, on average, a negative u_θ. This physical reasoning finds support in the RANS equation governing the evolution of $\langle u_r u_\theta \rangle$, which under the same assumptions leading to Equation 14 and accounting for changing basis vector orientation, shows that the production of $\langle u_r u_\theta \rangle$ is

$$\mathcal{P}_{r\theta} = -\langle u_r^2 \rangle \frac{1}{r}\frac{\partial (r\langle U_\theta \rangle)}{\partial r} + \langle u_\theta^2 \rangle \frac{2\langle U_\theta \rangle}{r} \tag{17}$$

Lumley's reasoning is embodied in the first term, where we recognize $\partial(r\langle U_\theta \rangle)/\partial r$ as the angular momentum gradient. However, the production of negative $\langle u_r u_\theta \rangle$ indicated

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

by the first term is counterbalanced by the second term, which is always positive. The form of the second term, by comparison with Equation 4, suggests that it is associated with centrifugal forces. Indeed, a positive fluctuation in u_θ would be expected to lead to a positive fluctuation in u_r, due to the increased centrifugal forces acting on a fluid element—as has been argued previously by Holloway and Tavoularis (1992). Equation 17 further shows that if the mean swirl velocity profile is solid body like, and the normal stresses are equal, then both terms are of equal magnitude. There is thus no compelling reason to expect $\langle u_r u_\theta \rangle < 0$. In fact, if $U_\theta \propto r^n$ and the normal stresses are equal, we expect from Equation 17 that $\langle u_r u_\theta \rangle > 0$ for $n < 1$, which is typical of local swirl velocity profiles seen in engines. If perchance $n > 1$, then $\partial(\langle U_\theta \rangle / r)/\partial r > 0$, and $\mathcal{P}$ is again positive. As we will see in subsequent text, direct measurements of $\langle u_r u_\theta \rangle$ in an automotive diesel show that it is often positive. Accordingly, swirl might more typically be expected to augment turbulence, a conclusion consistent with many of the measurements reported in the literature (Hill and Zhang, 1994).

Finally, note from Equation 17 that when the angular momentum gradient is negative, we expect $\langle u_r u_\theta \rangle$ to be positive and large, as both terms reinforce each other. Likewise, $\partial(\langle U_\theta \rangle / r)/\partial r$ will be large and negative, and Equation 14 therefore indicates that turbulent energy production will be large and positive. As we have seen earlier, negative angular momentum gradients can be readily produced in engine flows through interaction of the fuel injection process with the rotating motions.

The potential for the mean flow rotation to affect the turbulence by inhibiting the transfer of energy in the turbulent energy cascade can be evaluated by computing a nondimensional number, the Rossby number Ro, which compares the turbulence time scale to a rotation time scale ($1/2\omega$). With $l \approx b/6$, $u \approx \overline{V}_p$, and $b \approx S$, one gets: $\mathrm{Ro} = \frac{(1/2\omega)}{(l/u)} = \frac{u}{2\omega l} = \frac{3}{\pi R_s}$ or $\frac{3}{\pi R_t}$. For a swirl or tumble ratio of order 2, we therefore obtain $\mathrm{Ro} \approx 1/2$. Direct numerical simulations, reviewed by Sagaut and Cambon (2008), indicate that when $\mathrm{Ro} \lesssim 1$ rotation can significantly impact the structure of the turbulence. Consequently, modeling approaches that account for the impact of rotation (see e.g., Bardina, Ferziger, and Rogallo, 1985 for a RANS-based example) should be considered.

4.2.8 *The impact of swirl on turbulence: measurements*

The majority of the measurements made in swirling flows have been obtained in swirl-supported CI engine geometries, and the spatial and temporal properties of turbulence in these engines have been reviewed recently by Miles (2009). Here, we provide only a brief summary of the most important features and processes. Because swirling flows and flows driven by the rapidly changing combustion chamber geometry of bowl-in-piston engines are less susceptible to CCVs, in this section we treat measured velocity fluctuations as predominantly associated with turbulence. There are three principal observations supporting this practice. First, the results of frequency analysis of velocity measurements made in a typical firing automotive diesel engine (Miles *et al*., 2002) show that small-scale, high frequency flow fluctuations follow proportionally the evolution of the total flow fluctuations. Second, as will be seen in subsequent text, the evolution, anisotropy, and production of the measured fluctuations are remarkably consistent with the behavior that is predicted by the RANS equations governing the evolution of the turbulence energy and the individual component stresses. Third, the measured turbulent stresses compare very well with the predictions of models derived in canonical, ergodic flows (Miles, RempelEwert, and Reitz, 2009).

At low swirl ratios ($R_s \lesssim 1.5$), the turbulence is approximately homogeneous in the latter portion of the compression stroke, and remains homogeneous throughout the remainder of compression and early expansion. This is a direct consequence of the dominance of $\mathcal{P}_{comp}$, which depends on the existing turbulence energy and the rate of compression—both of which are spatially homogeneous. Measurements and simulations (Miles *et al*., 2004) show that near the end of compression (25° to 5° bTDC), turbulence production associated with r–θ plane production (Equations 14–16) and production associated with axial gradients in the swirl velocity become more important but do not significantly impact the spatial homogeneity. Surprisingly, the turbulence production by shear at the edges of the squish flow jets (i.e., production associated with $\langle u_r u_z \rangle \partial \langle U_r \rangle / \partial z$) is predicted to be small.

As the swirl ratio is increased ($R_s \sim 2.5$), significant inhomogeneity in the turbulence energy develops, with the highest levels near the piston bowl lip (Figure 15). Measurement and/or simulation of the various production terms near the lip shows that while $\mathcal{P}_{comp}$ continues to dominate before $\sim -25°$, r–θ plane production is a significant source of turbulence just before TDC. Note that the rate of change of TKE correlates closely with the measured r–θ plane net production rate. At this time, the turbulence in the near lip region is highly anisotropic, with the tangential fluctuations exceeding the radial fluctuations. Similar peaks in turbulence and anisotropy near the bowl lip have been reported in other studies (e.g., Fansler and French, 1987; Auriemma *et al*., 1998). The observed anisotropy is fully consistent with the behavior expected from Equations 15–17. Inward transport and "spin up" of high angular

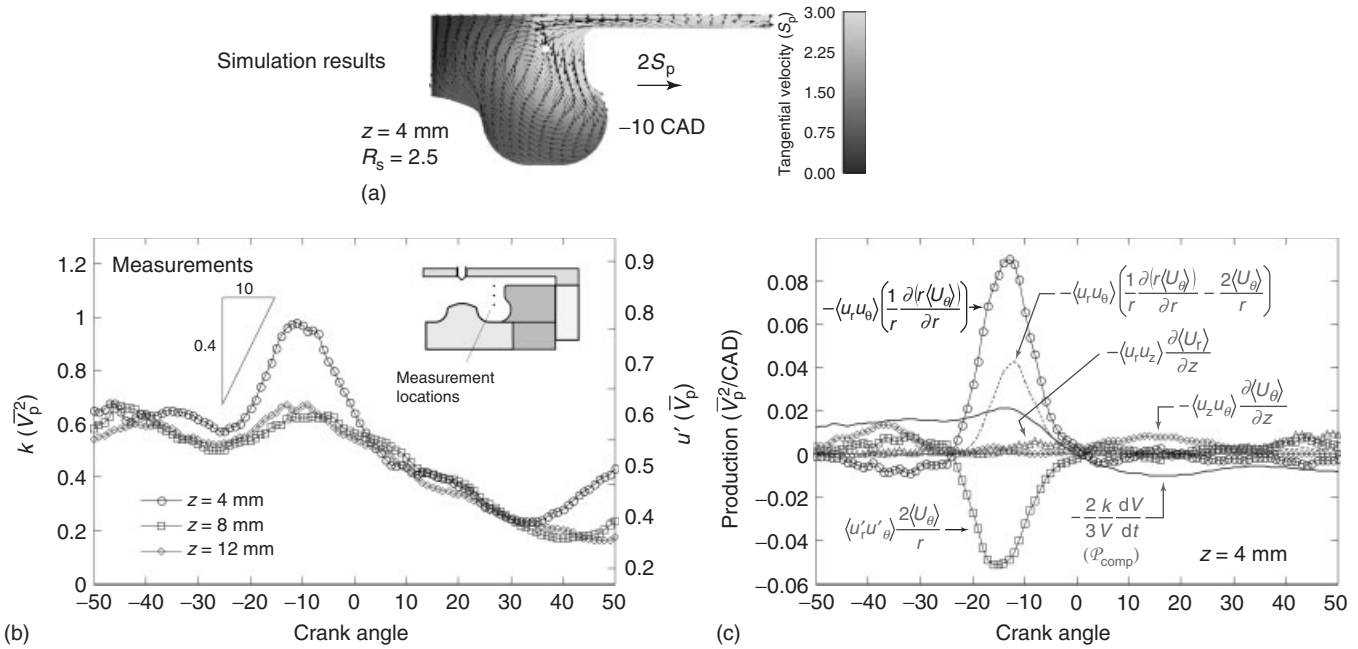

Figure 15. (a) Simulation results depicting the spatial distribution of the swirl velocity and the vertical plane flow structure; (b) the measured evolution of the turbulent kinetic energy; (c) turbulence production terms near the bowl lip ($z = 4$ mm, the upper measurement location designated in "(b)". $\mathcal{P}_{comp}$ and the r–θ plane production terms are estimated directly from the measurements; the eddy viscosity hypothesis is used to estimate $\langle u_z u_\theta \rangle$ from the measured $\partial\langle U_\theta \rangle/\partial z$, and $-\langle u_r u_z \rangle \partial\langle U_r \rangle/\partial z$ is obtained from simulations.

momentum fluid from the squish volume creates a large positive angular momentum gradient near the bowl lip. The angular momentum gradients force $\langle u_r u_\theta \rangle$ to become negative, leading to significant positive production of the tangential velocity fluctuations. In contrast, the component of the r–θ plane production that feeds the radial fluctuations is negative.

As with the results at the lower swirl ratio, turbulence production *directly* associated with the squish flow ($\langle u_r u_z \rangle \partial\langle U_r \rangle/\partial z$) is predicted to be small. However, the squish flow *indirectly* impacts the production of turbulence through its redistribution of angular momentum, leading to high rates of turbulence production associated with r–θ plane velocity gradients and with $\partial\langle U_\theta \rangle/\partial z$.

With further increases in swirl ratio (to $R_s \sim 3.5$), turbulence levels and anisotropy near the bowl lip continue to increase. However, near-TDC increases in turbulence are also observed lower in the bowl, where the radial fluctuations increase rapidly and eventually exceed the tangential fluctuations. These fluctuations are again being produced by r–θ plane flow deformation, but in this case angular momentum gradients are small, $\langle u_r u_\theta \rangle$ is positive (cf. Equation 17), and the production of radial component fluctuations is positive while the production of tangential component fluctuations is negative (cf. Equations 15 and 16).

To close this subsection, we mention a curious but potentially important phenomenon that has been measured in both SI research engines with a "pancake" combustion chamber at TDC (e.g., Reuss *et al.*, 1995) and in CI engine configurations above the piston top during compression (Figure 16). With moderate-to-high swirl ratios ($R_s \gtrsim 2.5$), fluctuating velocities are observed to decrease strongly at intermediate radii, before again increasing as the high shear regions near the wall are approached. As discussed earlier, there is no clear reason to expect negative turbulence production in these flows and further work is needed to ascertain the cause of this behavior. However, considering that swirl is now a common feature in direct-injection SI engines, and that flame speeds and burn times are strongly dependent on the fluctuating velocity, understanding and correctly modeling this behavior is clearly important.

4.2.9 *Turbulence generation through spray–swirl interactions*

In the discussion of Figure 12, we have illustrated the ability of the fuel injection process to impact the angular momentum distributions within the combustion chamber, and in the previous section have shown that the inward transport of angular momentum by the squish flow can lead to significant turbulence production. It is reasonable

DOI: 10.1002/9781118354179.auto119
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

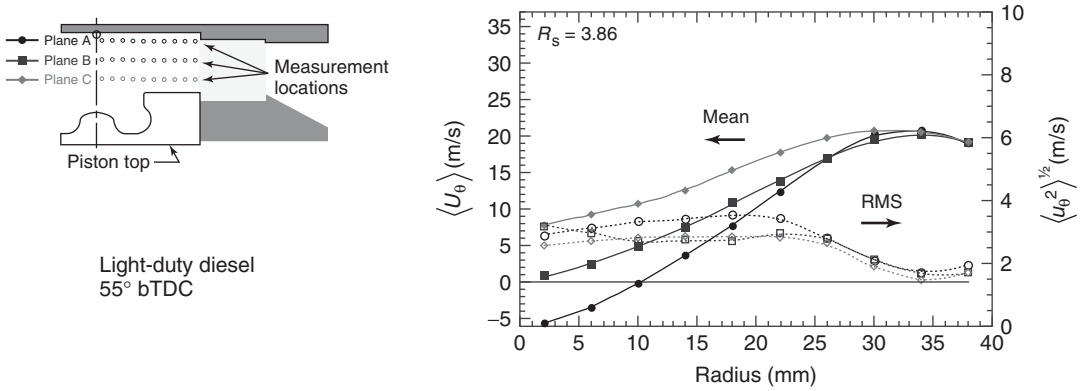

Figure 16. Radial profiles of the mean and RMS tangential velocities, demonstrating the attenuation of the fluctuations as the radius increases.

to expect, therefore, that the fuel injection process can be fruitfully employed to create mean flow structures that will generate additional turbulence. To isolate the impact of the spray on the turbulence field, the studies described in this section were performed in an engine operating with an N_2 intake charge. Consequently, complicating factors associated with cyclic variability in the ignition and combustion process, or in turbulence generation associated with combustion-induced density variations are avoided.

One mechanism by which turbulence can be generated efficiently is by formation of negative radial gradients in mean flow angular momentum, as was discussed in connection with Figure 12. Figure 17 shows experimental estimates of turbulence energy derived from two-component laser velocimetry measurements made with the engine operating at a simulated idle condition. As the measurement location approaches regions where simulations indicate that a negative angular momentum gradient is expected, the turbulence energy increases by an order of magnitude.

To further illustrate the impact of r–θ plane turbulence production, and angular momentum gradients in particular, the left-hand column of Figure 18 shows the evolution of the normal stresses and the components of the r–θ plane production given by Equations 15 and 16 ($\mathcal{P}_{f,\theta}$ and $\mathcal{P}_{f,r}$). The production terms were calculated from measurements of $\langle u_r u_\theta \rangle$ and of r–θ plane velocity gradients within the piston bowl of an engine operating with a typical swirl ratio of $R_s = 2.5$. These measurements are shown in the right-hand column of Figure 18. Our first observation is that in contrast to the production rates shown in Figure 15, during the period of maximum turbulence production, both the production of $\langle u_r^2 \rangle$ and of $\langle u_\theta^2 \rangle$ are positive. As required by Equations 15 and 16, this is due to the formation of a negative angular momentum gradient at this time, which can be seen in both the measured temporal profiles and the simulated velocity field shown in the right-hand column of Figure 18. A second observation is that the radial fluctuations are increased more than the tangential

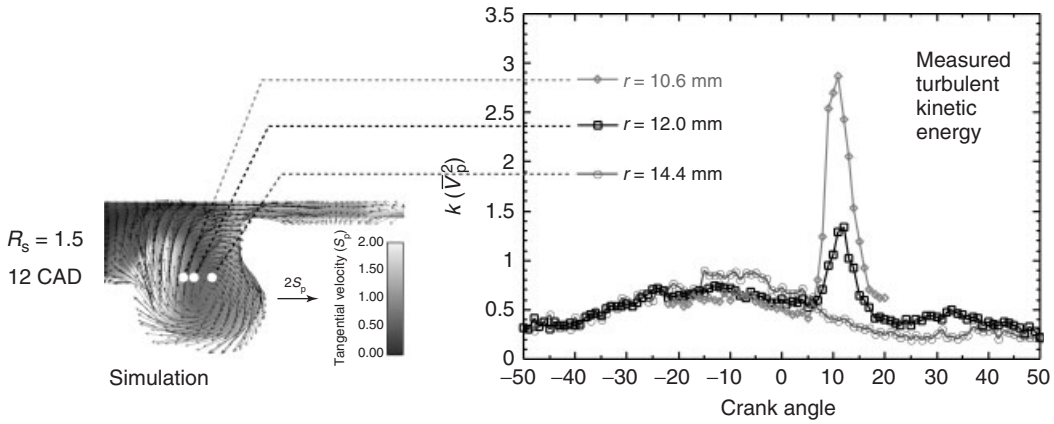

Figure 17. Variation in measured turbulent kinetic energy as the measurement location approaches regions with negative radial gradients in the mean flow angular momentum.

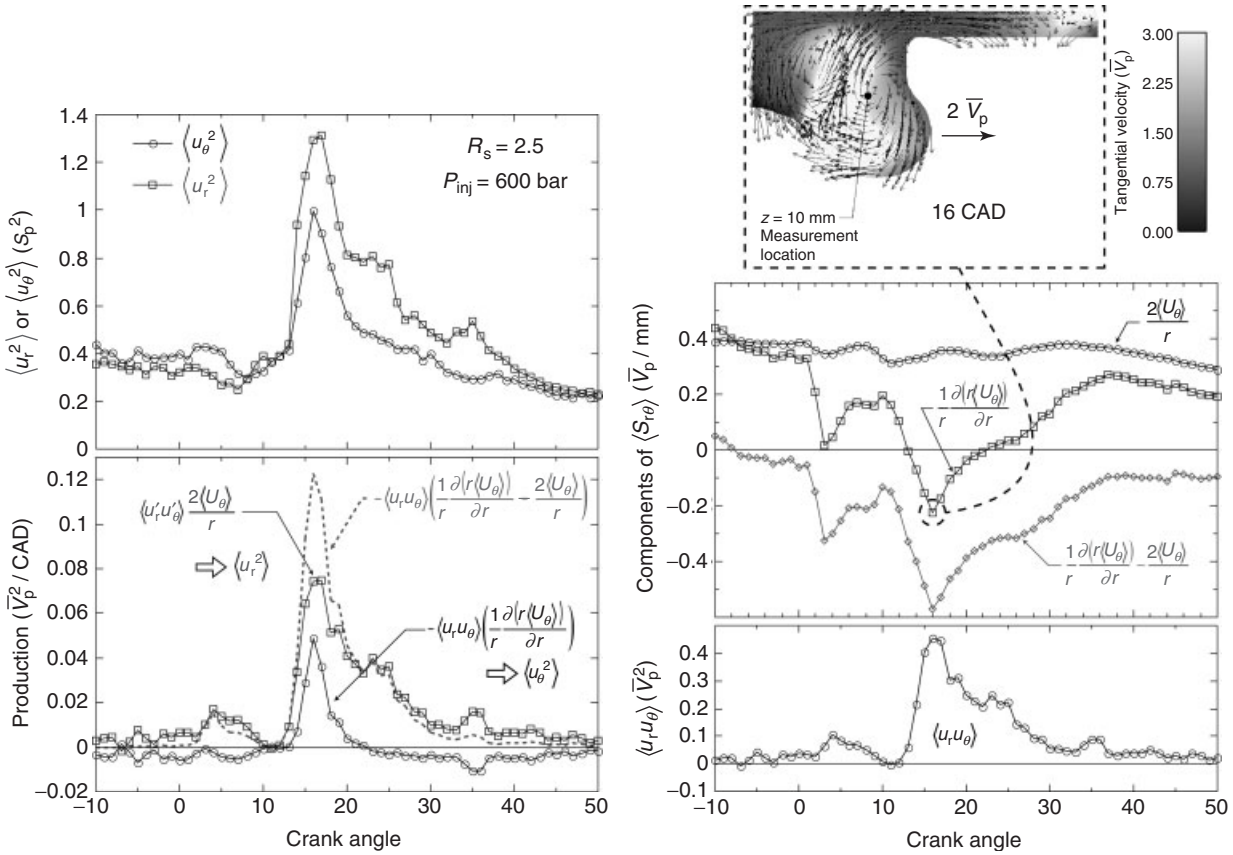

Figure 18. Variation in measured turbulent stresses and in the measured production terms and r–θ plane deformation rates at $R_s = 2.5$.

fluctuations, and remain elevated longer, in accordance with the measured difference in the production terms. Lastly, we also observe that $\langle u_r u_\theta \rangle$ shows a sharp, positive peak, while the angular momentum gradient is negative, as expected from Equation 17.

Although the correlation between the turbulent stresses and the turbulence production shown in Figure 18 is very good, we stress that the instantaneous, local value of the stresses will also be influenced by factors other than the r–θ plane production, especially in these highly inhomogeneous flows. Consider, for example, that the peak rate-of-change of turbulence energy that can be deduced from Figure 18 is ~ 0.4–$0.5\overline{V}_p^2/^\circ$CA, while the peak production is only 25% of this value. Moreover, the peak rate-of-change in energy is phased slightly earlier than the peak in production. The measurements indicate, however, that steep radial gradients in turbulence production are present, and that the r–θ plane production at a location just 1 mm inward from that shown in Figure 18 is over twice as great. In addition, unmeasured production terms, mean flow convection, and turbulent transport (cf. Equation 8) will also impact the overall turbulent energy, whereas redistributive terms associated with the fluctuating pressure–strain-rate correlation will further influence the relative magnitude of the individual normal stresses.

No direct measurements exist to illustrate the mechanisms of turbulence production associated with r–z and z–θ flow deformation. However, simulation results indicate that significant sources of turbulence production, exceeding $0.1\overline{V}_p^2/^\circ$CA, are found near the interface between the two vertical plane vortices illustrated in Figure 12. These sources are associated with both r–z plane deformation and with strong axial gradients in the swirl velocity, and are especially pronounced at higher swirl ratios. Examples are depicted in Figure 19, which also identifies sources of r–θ plane deformation, including those discussed earlier. As is discussed further in Diesel and Diesel LTC Combustion, the interfacial region between these two vortices can often correspond closely with the interface between partially oxidized fuel and additional air, and turbulence generated in this region can therefore directly impact fuel–air mixing rates and subsequent combustion.

We close this section by noting that in addition to employing the fuel injection event to enhance turbulence

generation and mixing through the portion of the production that depends on flow structure $\mathcal{P}_f$, the fuel injection event can also be timed to take advantage of $\mathcal{P}_{comp}$. Although the intense turbulence generated by the fuel injection event will normally dissipate rapidly, compression can amplify this turbulence and extend the time over which it will impact fuel–air mixing. A simple calculation applying Equation 8 to homogeneous turbulence, considering $\mathcal{P}_{comp}$ to be the only source of production and modeling ε as proportional to $k^{3/2}$, indicates that "injecting" turbulence into the engine roughly 30–40°CA before TDC will maximize the turbulence energy when integrated over the 30°CA following the injection event.

4.2.10 The impact of combustion on turbulence

The general topic of the impact of turbulence on SI combustion is covered in Fundamental Combustion Modes, and the impact of increased early- and late-cycle mixing processes on CI combustion is addressed in Diesel and Diesel LTC Combustion. Accordingly, we do not discuss combustion-flow interactions in detail here. Nevertheless, given the large influence that the fuel injection event has on the generation of turbulence without combustion, it is relevant to briefly examine if these processes continue to operate with combustion. Figure 20 compares, for a variety of injection pressures and swirl ratios, the evolution in TKE measured with fuel injection only (right-hand side) against the energy measured with fuel injection and combustion (left-hand side). The most striking observation is that the form of the temporal evolution and the trends observed as both injection pressure and swirl ratio are varied are very similar for both cases—although with combustion the increase in energy is larger. A second feature worth noting is that the combustion event, dominated by a rapid premixed burn near 5° after TDC, results in only a small increase in the fluctuating energy which rapidly decays.[4] Apart from this small increase, combustion and heat release, which adds sensible energy but not momentum to the flow, does not appear to fundamentally alter the main turbulence generation processes.

With combustion, however, additional turbulence production mechanisms are present, but these that have not yet been discussed—in particular buoyant production associated with density inhomogeneities embedded in the swirl-induced radial pressure gradient. An order-of-magnitude analysis (Miles *et al.*, 2002) indicates that buoyant production may be at least as large as production associated with r–θ plane flow deformation. Apart from turbulence production, buoyancy can also play a role in generating temperature or composition stratification in engines. Lumley (1999) shows that buoyant forces can be expected to transport hot combustion products from the cylinder periphery to the cylinder center in approximately 1/5 of the time required for a piston stroke, and that even without combustion swirl can be effective in promoting fuel stratification because of the higher density of the fuel-containing mixture.

The discussion of turbulence generation in swirling flows relates particularly to light-duty diesel engines operating at light load. However, profiles of swirl velocity measured in heavy-duty engines with swirl-supported combustion systems operating at medium and high loads also show evidence of strong production of turbulence by r–θ plane flow deformation. Dembinski and Ångström (2012) measure a marked decrease in angular velocity within the piston bowl, from peak values approaching 20 times the crankshaft velocity near the bowl centerline to levels of twice the crankshaft velocity at the bowl periphery. Although the mechanism by which these angular velocity gradients are created has not been clarified, it is almost certainly associated with the inward transport of high angular momentum fluid due to displacement by the charge entrained into the fuel jets and with volume expansion due to combustion at the bowl periphery.

5 SUMMARY AND CONCLUDING REMARKS

We end this chapter by restating the main properties of in-cylinder flows: they are compressed, rotating, and turbulent. It is our hope that we have provided the background needed to understand some of the basic mechanisms by which these three fundamental properties can be influenced by the engine designer, and that we have provided the engine research community with some guidance as to fruitful areas for future work.

If the flow energy created during the intake process is to be employed to promote mixing and combustion near TDC, it must be stored in large-scale, mean flow structures such as tumble and swirl. Bulk flow compression, which is often considered only in the context of changing the thermodynamic state of the in-cylinder charge, can then act to modify these flow structures. Compression provides a mechanism by which piston motion augments the mean flow kinetic energy stored in tumbling flow structures, deforms and ultimately causes the breakdown of these structures into small-scale turbulence, and then further amplifies the turbulence thus created. Consequently, compression ratio—the selection of which is usually guided primarily by idealized efficiency, knock, ignition delay, and cold-start considerations—also has a significant impact on flow processes, impacting the magnitude and the phasing at which piston motion augments the flow energy. Changes in turbulence energy can go on to impact both burning rates and heat transfer rates, which also affect engine efficiency. Considerable progress has been made in understanding the detailed mechanisms by which these processes occur, but substantial further work needs to be done to understand the topology of desirable flow structures, how to most efficiently form these structures, how to reduce the cycle-to-cycle variability in the formation and breakdown processes, how to phase the breakdown to obtain the most benefit to the ensuing combustion, and how to best take advantage of the interaction of these structures with the fuel sprays in direct-injection engines.

Mean flow swirl has also been shown to impact turbulence generation near TDC, even though bulk compression does not directly impact the energy or stability of the mean flow. In the case of swirl, secondary flow processes such as squish flows or spray-driven flows redistribute angular momentum within the cylinder. It is this redistribution that creates significant departures from solid-body-like velocity profiles, with subsequent high flow deformation and turbulence generation. In some cases, unstable angular momentum distributions that break down rapidly into turbulence are formed. Bulk compression can then act to amplify the turbulence generated. Similar to the tumble

flow formation and breakdown, there has been significant progress made in understanding how swirl and squish–swirl or spray–swirl interactions can impact flow turbulence, but much more remains to be done to identify how these processes can best be optimized and adapted as engine speed and load vary.

Finally, it should be clear from the complexity of typical SI and CI induction, compression, and turbulence generation processes that optimization of in-cylinder flow processes—considering flow losses, cyclic variability, turbulence levels, heat transfer, and the ensuing combustion and emissions formation processes—is a daunting task that will be unlikely to be accomplished with "cut-and-try" approaches. Providing the engine designer with a physical understanding of the important flow processes, a task we have tried to accomplish in this chapter, is an important part of achieving this optimization. However, another essential task will be to provide the designer with tools that can be used to accurately test his ideas through truly predictive simulation. Hence, we encourage the continued development of models needed for both RANS-based simulations and LES—such as the wall functions described earlier. We further see need for acquisition of detailed planar or full-field, spatially and temporally resolved experimental data and the development of specific quantitative analysis tools associated with comprehensive physical filters that will support the development of the models and understanding needed to accomplish this goal.

ACKNOWLEDGMENTS

The authors acknowledge the contributions of the research group of Professor Rolf D. Reitz at the University of Wisconsin (Madison), who provided all of the simulation results represented in the figures in this chapter. We are also grateful to Dr. Rémi Manceau of CNRS—University of Poitiers, who kindly reviewed the sections related to production of turbulence in swirling flows and offered helpful suggestions on how it might be clarified. The first author acknowledges his long-term collaboration with Renault SA and the contributions of several PhD students (Y. Cao, I. Cossadia, S. Maurel, and M. Voisine). Support for the second author was provided by the United States Department of Energy (Office of Vehicle Technologies) and by General Motors Corporation (agreement FI083070326). This work was performed at the Combustion Research Facility of Sandia National Laboratories in Livermore, California. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

ENDNOTES

1. Full affiliation of Prof. J. Borée: Institut Pprime, UPR-3346 CNRS, ISAE-ENSMA, Université de Poitiers, Futuroscope Chasseneuil, France.
2. We adopt the usual convention that a repeated index indicates summation over all velocity components.
3. Heywood (1988) provides expressions for the squish velocity in wedge-chamber geometries.
4. Frequency analysis indicates that the combustion event generates small-scale, high frequency fluctuations that likely correspond to true turbulence, not simply cycle-to-cycle fluctuations associated with variations in the phasing or location of the combustion.

1 INTRODUCTION

Diesel engine combustion is an enormously complex process. To design and optimize diesel combustion systems, it is necessary to consider thermodynamic processes and their efficiency, fuel spray and atomization processes, multicomponent fuel vaporization processes under potentially supercritical conditions, complex turbulent flow and fuel–air mixing processes, oxidation kinetics of mixtures of large hydrocarbon fuels, pollutant formation and control, as well as heat transfer and radiation processes. The fuel introduction, mixing with ambient charge, ignition, combustion, and pollutant reduction processes must also be completed within a very short time period, while the piston is close to top-dead-center (TDC). In automotive engines, which operate at higher rotational speeds than heavy-duty truck engines, this time can be very short—on the order of 1×10^{-3} s. Beyond these considerations associated with fluid dynamics and the thermal sciences, the combustion system design process cannot be divorced from additional concerns related to materials, manufacturing, durability, and packaging. Finally, if diesel engines are to gain widespread market penetration worldwide, combustion system design must also aim to meet consumer expectations related to cost and refinement (noise, vibration, etc.).

The complexity of the diesel combustion process is compensated for by the higher thermal efficiency that can be achieved with diesel engines. Because diesel engine load control is achieved by regulating the amount of fuel injected, rather than by throttling the charge inducted, diesel engines have considerably lower pumping losses than conventional spark ignition engines. Moreover, with fuel injection near TDC, compression ratios (r_c) are not limited by fuel preignition. High engine r_c that improve thermodynamic efficiency can therefore be employed. The diesel engine combustion process also typically takes place under fuel-lean conditions, which keeps both global average temperatures and concentrations of CO_2 and H_2O in the product gases low—resulting in post-combustion gases characterized by a higher specific heat ratio than is found under stoichiometric combustion conditions. The higher specific heat ratio allows a greater amount of work to be extracted during expansion. Finally, for conventional diesel combustion, the introduction of the fuel into the cylinder near TDC prevents fuel from reaching engine crevices, and the combustion efficiencies are usually very high—typically >98%. These factors translate into a notable efficiency advantage when diesel engines are

ISBN: 978-0-470-97402-5

compared with conventional (port-injected) spark ignition engines. A review of US Environmental Protection Agency (EPA) vehicle fuel efficiency ratings, for the same vehicle equipped with either a diesel or a gasoline engine, indicates that a diesel engine will typically provide a 30–40% improvement in fuel consumption estimated for a combined city/highway test cycle. Similar reductions in CO_2 emissions over a European drive cycle have been reported (Tanaka, 2011).

Because of their efficiency advantage, the potential reward for optimizing diesel engines and increasing their market penetration is large. The US Energy Information Agency (2013) estimates that by 2015, world energy usage by the transportation sector will be 1.1×10^{20} J, corresponding to the energy content of over 50 million barrels of oil per day. Of this, roughly 60% will be consumed by the light-duty sector. Every 1% improvement in the energy efficiency of the light-duty sector, achieved through either optimization of engines or increased diesel engine market penetration, thus corresponds to an energy savings equivalent to approximately 300,000 barrels of oil per day.

Diesel engines used in the light-duty sector through the 1980s were dominated by indirect injection (IDI) or "pre-chamber" designs. In these engines, the fuel is injected into a smaller chamber appended to the main combustion chamber, where it mixes with fresh charge and ignites. After ignition, the burning, fuel-rich mixture is expelled from the pre-chamber into the cylinder, where it rapidly mixes with the rest of the charge. IDI designs are characterized by lower noise and less demanding fuel injection equipment (FIE) requirements. However, throttling and heat transfer losses incurred as the charge is expelled into the main chamber, and higher heat transfer losses in general due to the large combustion chamber surface area, result in a significant loss in efficiency. Hence, virtually all modern engines designed for automotive applications employ direct injection (DI). In this chapter, we restrict our attention to DI combustion systems and refer the reader to Heywood (1988) for a more detailed discussion of IDI diesel combustion.

In the space available here, we cannot hope to summarize the full complexity of diesel combustion processes, and our objective is more modest. First, we will provide an overview of recent trends in diesel engine designs and a summary of the dominant engineering considerations that have factored into the choice of the design parameters. These considerations—which encompass the practical design knowledge that has been accumulated in over a century of building and operating these engines—involve balancing multiple trade-offs as the engineer selects such basic design parameters as bore-to-stroke ratio, r_c, and combustion chamber shape. Second, we provide a brief description of the science behind the diesel engine mixture formation, combustion, and pollutant formation and destruction processes. Lastly, we attempt to link engineering practice with the fundamental science, thereby providing diesel combustion system engineers with a sound foundation on which to base their design and optimization efforts.

2 MODERN TRENDS IN ENGINE DESIGN

The two most notable trends in diesel engines developed over the last decade have been a steady decrease in r_c and an increase in the maximum injection pressure. In a majority of these engines, the decrease in r_c has been driven by a desire to increase the power density, without requiring a large increase in the maximum cylinder pressure rating. Increased power density is enabled by higher injection pressure, which also aids in reducing soot emissions. The steady increase in power density can be clearly seen in the power density of engines released during the last decade, shown in Figure 1. However, there are a number of new engines, designated by the filled markers, which fall outside the general trend. These engines have maintained power densities (and peak torque, or maximum brake mean effective pressure (BMEP)) consistent with levels seen in older engines, although several feature r_c as low as 14.

The lower power density of these engines reflects a basic difference in design philosophy. For the higher power density engines, the engine designers have sought both improved performance and improved brake specific fuel

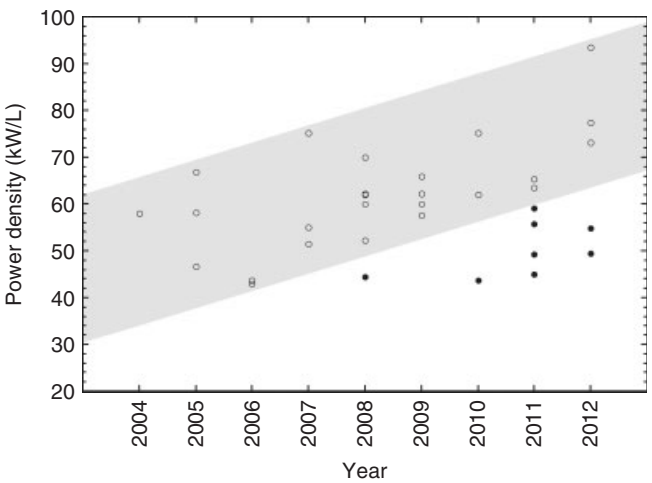

Figure 1. Sampling of power density ratings of light-duty diesel engines released in the last decade.

consumption (BSFC) by reducing engine displacement. The engine can therefore spend more time operating at more efficient, higher load points, but performance is not compromised due to the high peak power capability. The high peak power density comes with increased cost, however, for improved FIE and boosting technologies. Moreover, if the engine is aggressively downsized, after-treatment costs can also increase. In contrast, lowering the r_c without increasing power density can enable improved BSFC through friction reduction and lower cost due to decreased component and after-treatment system costs. Note that the pursuit of lower engine costs does not necessarily imply poor performance. In developing the Mazda Skyactiv-D engine (Terazawa *et al*., 2011), Mazda's stated objectives in selecting a low r_c were decreased peak firing pressure and lower engine-out emissions through improved premixing. Nevertheless, this engine provides an impressive 59 kW/L and a peak BMEP of over 25 bar, while meeting Euro 6 NO_x emissions regulations without after-treatment. More will be said regarding the trade-offs incurred in engine design in what follows.

Trends in future engine design will also be impacted by technology advances and rising fuel costs. Owing to the introduction of stop–start systems, low load engine performance has become less important, while emissions released shortly after starting are of even greater consequence. The potential future introduction of mild hybridization can be expected to result in a further de-emphasizing of low load operation when considering design choices. Likewise, advances in after-treatment technology may drive different design choices by altering the trade-offs between various pollutants. Engine designs can be expected to change to accommodate these technology advances, which are addressed in greater detail in (Trends—Compression Ignition). However, the fundamental physics behind the selection of many design parameters, and behind the combustion and pollutant formation processes, can be expected to remain unchanged.

3 PRACTICAL COMBUSTION SYSTEM DESIGN

Some practical aspects of diesel combustion systems will be discussed here in order to provide a more concrete basis for subsequent topics. We will point out the typical features of diesel combustion systems and highlight the various factors that must be considered when making design choices regarding variables such as displacement, r_c, bore-to-stroke ratio, and combustion chamber geometry.

3.1 Topology and operating characteristics of light- and heavy-duty engines

Modern DI diesel combustion systems consist of a multi-hole fuel injector mounted in the cylinder head and a cavity in the piston where the main part of combustion takes place. The injector nozzle is normally placed on the cylinder centerline and the fuel jets emanating from it are directed radially into the cavity. A central injector location allows an axisymmetric fuel injection and combustion chamber geometry to be utilized, which facilitates full utilization of the trapped charge.

One reason for placing the cavity in the piston is that it allows a flat cylinder head surface. This increases the mechanical strength, which is favorable for withstanding the high peak cylinder pressures prevalent at high loads. Another reason is that the cavity plays an important role in generating a gas motion that supports the combustion process. The combustion chamber has a number of characteristic features that are described schematically in Figure 2. The area outside the cavity above the piston top is referred to as the *squish region*. Inside the cavity—often called the *bowl* there is a central protuberance or "pip" below the nozzle. If the top of the bowl has a smaller diameter than the maximum bowl diameter (i.e., if it has a "lip"), it is called a *re-entrant combustion chamber*. If there is no lip, it is called an *open combustion chamber*. The re-entrant chamber is the dominating one in light-duty engines, but

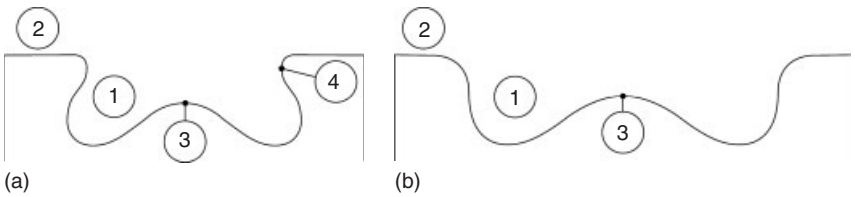

Figure 2. Schematic sections through the pistons in re-entrant (a) and open (b) combustion chambers: (1) bowl, (2) squish volume, (3) pip, and (4) lip. The open combustion chamber is drawn larger to indicate that it is predominantly used in heavy-duty engines, whereas the re-entrant chamber dominates in light-duty engines. Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

both types may be encountered in both light- and heavy-duty engines.

The re-entrant combustion system was invented in Switzerland by Hippolyt Saurer. His patent from 1934 describes a combustion system that is still surprisingly representative of most modern diesel engines, with an axisymmetric, re-entrant combustion chamber, a centrally mounted DI nozzle, and a gas motion typical of modern engines (Saurer, 1934). Saurer's combustion system is depicted in Figure 3.

Light-duty systems, which are optimized for the low-to-medium loads that characterize urban driving, typically employ relatively short fuel injections, which result in a major part of the heat release often taking place after the end of injection. The turbulence generated during injection is located in the direct vicinity of the spray and decays rapidly after the end of injection. For this reason, the spray cannot deliver all the kinetic energy needed to drive the mixing, and combustion system features promoting enhanced late-cycle mixing and oxidation play a more central role in light-duty systems. This is why such engines tend to be used in combination with a rotating gas motion—swirl—and with re-entrant combustion system geometries.

Toward the end of the compression stroke, the swirling air mass in the cylinder is pushed into the bowl. As the bowl has a smaller diameter than the cylinder, this results in an amplification of the rotational velocity due to the conservation of angular momentum, which aids the mixing process both during and after the end of injection. In the process of compressing the swirling charge into the bowl, large velocity gradients are also created, generating higher levels of turbulence. Both the amplification of the rotational velocity and turbulence generation are greater in re-entrant bowl geometries than in open geometries. Later, as the piston begins to descend, the lip of a re-entrant bowl geometry helps keep the swirling flow within the bowl. Turbulence generation from swirl will be discussed in greater detail in Section 4.5.

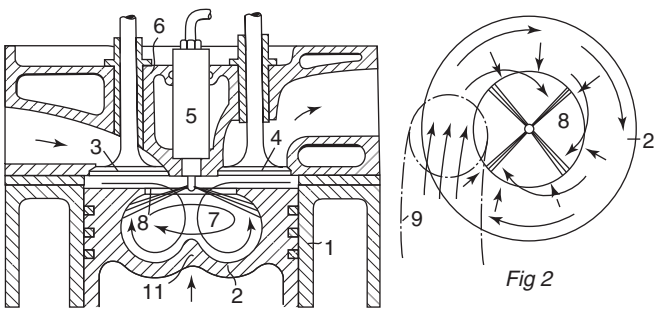

Figure 3. An image from Saurer's patent from 1934, describing the principles of the re-entrant combustion system. (Reproduced from Saurer (1934).)

In contrast to the lower load duty cycles characteristic of light-duty engines, heavy-duty diesel engines tend to be operated at high loads where the long injection durations produce a combustion process that is largely spray-driven. Developers of heavy-duty combustion systems thus tend to focus on spray formation and the quasi-steady phase of combustion, which puts different demands on the combustion systems. Heavy-duty combustion systems frequently employ open combustion chambers. This is partly because the absence of a lip makes the piston more robust to the high thermal loads that are typical for these engines. Another reason is that such systems are often quiescent, that is, there is no organized gas motion (swirl) in the cylinder, thus avoiding the need for a lip. Quiescent systems ideally do not have energy losses associated with setting up the swirl motion. This often gives them a higher volumetric efficiency and hence increased power density, but it also increases the demands on the fuel injection system, which may require higher fuel pressures and smaller nozzle holes (Beer, 1994). Another advantage of quiescent combustion systems is minimized heat transfer losses, as swirl enhances heat transfer to the combustion chamber walls by increasing the turbulence.

During the typical high load conditions in a heavy-duty combustion system, the quasi-steady jet phase is often assumed to play a dominant role in combustion. The conceptual image of the jet depicted in Figure 11 of the next section and the concurrent reasoning about the flame lift-off length are thereby useful models to guide the combustion system design. Although late-cycle oxidation plays a role also in these systems, the long injection process produces intense turbulence during an extended part of the cycle. The guiding principle in these combustion systems is that the sprays should do as much of the mixing work as possible.

In addition to the typical light-duty and heavy-duty combustion systems introduced above, so-called narrow-angle direct injection (NADI) combustion systems have also been introduced (Cursente *et al*., 2008b; Walter and Gatellier, 2002). Although these combustion systems have important advantages for low load, highly premixed operating conditions, they may have difficulty meeting full-load performance targets (Hardy *et al*., 2004). Because these systems have not yet been incorporated in production vehicle designs, we do not describe them in detail here, but refer the reader to the above references.

3.2 Global combustion system parameters

The highest level parameters impacting combustion system design—engine displacement, number of cylinders, and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

power or torque density—will be determined by the power, torque, and packaging requirements needed for the specific vehicle application. These top-level parameters will subsequently influence the choice of additional parameters such as engine geometric compression ratio r_c and bore-to-stroke ratio (B/S).

3.2.1 Displacement

An attractive strategy to improve fuel consumption is to "downsize" the engine, selecting a lower displacement. As mentioned above, this strategy allows the engine to spend more time operating at higher loads, where friction and heat transfer losses are a smaller fraction of the total fuel energy released. To meet peak torque or peak power requirements, however, the peak power and/or torque density must be increased. Although high power or torque density is always desirable, the benefit must be weighed against additional expense related to the block and head structure, boosting requirements, after-treatment systems, and FIE.

Some manufacturers have adopted a very different approach to improve efficiency. Kanda *et al*. (2004) argue that by increasing displacement, lower boost levels, lower injection pressures, and lower swirl ratios can be employed, such that friction and heat transfer losses are reduced and improved fuel economy can be obtained at the same emissions levels. With the larger displacement, the gearing can then be adjusted while maintaining similar vehicle performance levels, leading to a further reduction in fuel consumption. Mazda engineers (Sakono *et al*., 2011; Terazawa *et al*., 2011) follow similar logic but, moreover, argue that due to the nonlinear relationship between torque and NO_x emissions, this engine "upsizing" strategy is also an effective means of NO_x control.

3.2.2 Compression ratio r_c

Increasing the r_c increases the theoretical efficiency of the engine. For an ideal limited-pressure cycle, which encompasses both constant volume and constant pressure cycles, the engine efficiency increases with increasing compression (or expansion) ratio, as indicated in Figure 4. The advantages of a high geometric expansion ratio may not always be achieved, however. Limits on the peak cylinder pressure or control of NO_x emissions may require retardation of the combustion event (Inagaki *et al*., 2011; Yamada *et al*., 2011), resulting in a lower effective expansion ratio. Likewise, a high specific heat ratio γ will increase engine efficiency by increasing the pressure drop that occurs for a given expansion ratio. Because H_2O and CO_2 have higher heat capacities than diatomic molecules such as O_2 and N_2, and hence, lower γ, charge dilution with air is preferred over charge dilution with exhaust gas recirculation (EGR) if maximum efficiency is desired.

There are several additional factors that also prevent achievement of the full advantages of high r_c. Higher r_c results in both higher compression pressures and, for a given amount of heat release, a larger pressure rise due to combustion. In turn, higher cylinder pressures increase ring and journal bearing friction. The surface area-to-volume ratio near TDC (Figure 5) also increases as r_c increases, resulting in higher heat losses to the piston and head surfaces. Finally, air utilization becomes more difficult with higher r_c. It is common to evaluate the potential for full air utilization using the so-called k-factor, defined as the ratio of the volume inside the bowl to the total volume at TDC; see, for example, Fasolo *et al*. (2005). A high k-factor is considered to be beneficial for the air utilization. This is because air outside the bowl, for example in the squish

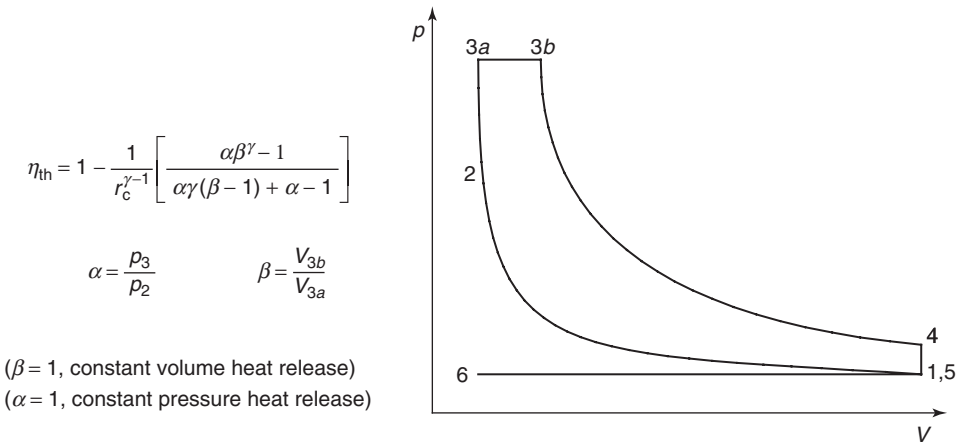

Figure 4. Thermal efficiency of a limited-pressure cycle. (Adapted with permission from J. Heywood, Internal Combustion Engine Fundamentals (Heywood, 1988) © The McGraw-Hill Companies, Inc.)

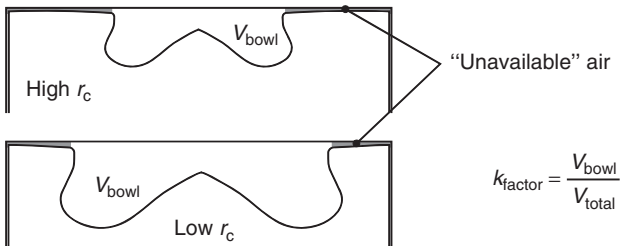

Figure 5. Illustration of the impact of compression ratio on surface area-to-volume ratio and on the *k*-factor.

volume, is assumed to be unavailable for the combustion process and for the oxidation of soot. As shown in Figure 5, for a fixed engine displacement, the volume at TDC is reduced as r_c increases, resulting in a reduced *k*-factor, more difficult air utilization, and consequently lower maximum torque leading to reduced power density and reduced full-load efficiency. Overall, reasonable variations in r_c are expected to have limited impact on efficiency (Heywood, 1988; Inagaki *et al*., 2011; Middlemiss, 1978).

As mentioned in Section 2, lowering r_c allows greater specific power at a given peak firing pressure. This is one of the main reasons for the current trend of decreasing r_c in diesel engines. Another reason to decrease r_c is to lower engine-out emissions by lowering compression temperatures, which lowers peak combustion temperatures (and hence, NO_x formation) and increases ignition delay, thereby enabling more fuel–air premixing which mitigates soot formation. With a typical intake temperature, lowering r_c from 17 : 1 to 14 : 1 will decrease the near-TDC compression temperature, and hence the peak combustion temperature, by approximately 50 K.

The choice of a lower r_c is supported by several additional considerations:

- Owing to the lower expansion, exhaust gas temperatures are generally higher. Higher exhaust gas temperature allows for more energy extraction by the turbocharger, and higher boost levels can be achieved at low speed, improving the maximum low speed torque characteristics (Catania *et al*., 2009; Fasolo *et al*., 2005).
- Diesel oxidation catalysts (DOCs) operate more efficiently with higher exhaust gas temperatures, and despite problems with low load engine-out HC and carbon monoxide (CO) emissions, post-DOC HC and CO levels can be reduced (Cipolla *et al*., 2007). Faster catalyst light-off might also be expected.
- A lower r_c results in slower cooling during expansion, providing more time for oxidation of soot and other products of partial combustion (Inagaki *et al*., 2011; Van den Huevel *et al*., 2006).
- A low r_c, with an attendant large bowl volume, allows the removal of piston top valve pockets with a smaller deterioration in *k*-factor.
- Lastly, at low load, low r_c engines may be able to meet soot emission targets with lower injection pressures, resulting in improved brake specific fuel consumption (Catania *et al*., 2009).

Lowering the r_c can have drawbacks, however:

- The low compression temperatures lead to long ignition delays and low combustion temperatures that can result in high engine-out HC and soot emissions, as mentioned above. These are especially problematic during the first few minutes of operation, before DOC light-off.
- Long ignition delays may also increase combustion noise. Combustion stability suffers as well, and large, robust pilot injection strategies must be adopted to recover acceptable noise and stability levels (Cursente, Pacaud, and Gatellier, 2008a; Terazawa *et al*., 2011). Larger pilots injected early into low density gases can over-penetrate, however, causing problems with oil dilution and cylinder wear.
- Despite the expected greater premixing, low speed, mid-load soot emissions can suffer (Catania *et al*., 2009).
- Low r_c engines exhibit lower BMEP at high speeds, when the maximum torque is limited by exhaust gas temperature.
- Finally, the lower r_c limit is set by demands on startability at low ambient temperatures. In light-duty engines, the limit steadily decreases as new glow plug technology becomes available.

In the end, selection of r_c is driven less by efficiency and fuel consumption concerns and more by a compromise among the desired power density, emission characteristics, and startability.

3.2.3 *Bore-to-stroke ratio (B/S)*

Bore-to-stroke ratio is another high level combustion system parameter that, like r_c, impacts the combustion system design. Diesel engines are almost always "under-square" or "long stroke". Of the engines represented in Figure 1, the average *B*/*S* is ~0.91. One reason that *B*/*S* usually falls below unity is that it affects the height and length of the engine, which are usually limited by vehicle constraints. Even differences of a couple of centimeters may be critical for packaging an engine into a vehicle. There are several additional reasons, however, that impact efficiency and combustion system design directly:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- Friction is the most frequently cited factor that is influenced by the bore-to-stroke ratio. Piston ring friction is thought to scale with S/B^2, which—for a fixed engine displacement—scales as $(B/S)^{-4/3}$ (Heywood, 1988). Likewise, viscous piston friction can be shown to scale with $(B/S)^{-2/3}$. Overall, it is reasonable to anticipate that piston assembly friction scales inversely with B/S, and short-stroke engines are characterized by lower friction.
- Piston speed is reduced with large B/S, thereby allowing greater engine rotational speeds and potential for higher peak power.
- With large B/S, a larger area is available for the inlet valves, allowing higher intake air mass flow rates and thus higher engine power or torque density.
- A larger bore also allows a wider bowl, which could be advantageous at high engine speeds (Fasolo *et al*., 2005) and reduces the risk of liquid fuel wetting the bowl wall. This is mainly a problem during cold conditions when vaporization is impeded (Chartier *et al*., 2009a). Large B/S may be well-suited to low r_c designs due to the larger fuel jet penetration that occurs when the ambient density is low.

There are also disadvantages to having a large B/S:

- With smaller bores, the bowl aspect ratio (depth-to-diameter ratio) more closely approaches 1, as shown in Figure 6. The surface area-to-volume ratio is thus reduced near TDC—even if near bottom-dead-center (BDC), the surface area-to-volume ratio is larger. A smaller B/S is thus expected to result in reduced near-TDC heat losses, although total heat transfer losses may actually increase (Flowers, Martinez-Frias, and Cleeves, 2010). The expected reduction in near-TDC heat loss due to reduced surface area-to-volume ratio will be lessened, however, by somewhat higher convective heat transfer coefficients at smaller B/S.
- Figure 6 also shows that with a smaller B/S, the k-factor is increased, suggesting more efficient air utilization.
- Empirically, turbulent velocity fluctuations are known to scale with mean piston speed, which at fixed displacement scales as $(B/S)^{-2/3}$. Thus, with larger B/S, turbulent fluctuations are reduced, and turbulent mixing times are expected to increase—leading to slower combustion rates. This factor can be quite significant in SI engines (Filipi and Assanis, 2000; Siewert, 1978). Although the impact of B/S on the duration of diesel mixing-controlled combustion has not been explored explicitly, engine speed has been shown to exert a major influence on combustion rates in diesel engines (Timoney, 1987), pointing to the importance of turbulence generated by piston motion.

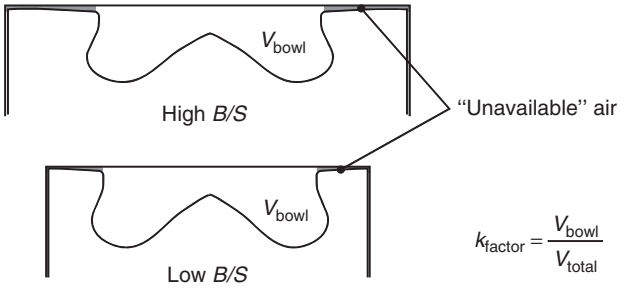

Figure 6. Illustration of the impact of bore-to-stroke ratio (at fixed r_c) on surface area-to-volume ratio and on the k-factor.

A very broad summary assessment of the impact of B/S on combustion system design is that a small B/S is favored for higher engine efficiency, whereas larger B/S favors power density (National Research Council, 2011).

3.3 Combustion chamber geometry

The combustion chamber geometry plays a crucial role in generating the gas motion that supports the combustion process. A successful design provides conditions for a favorable interaction among the sprays, the combustion chamber surfaces, and the swirling gas flow. Geometry also plays an important role in setting up a flow pattern that aids the late-cycle oxidation. Typically, soot emissions are found to be more strongly impacted by combustion chamber geometry than NO_x emissions or fuel consumption, although improvements in all three quantities can be achieved with well-optimized geometries (Andersson *et al*., 2009). In this context, it should be noted that the complex influence of geometry on transport and mixing phenomena in the combustion chamber makes the practical relevance of the k-factor somewhat doubtful. While indicating how large a portion of the air that is available resides within the bowl, two well-optimized bowls with exactly the same k-factor may produce very different soot emissions at exactly the same operating condition (Andersson *et al*., 2009).

Owing to the complexity of the interactions among chamber geometry, sprays, and flows, it is difficult to state general design rules that apply across a range of swirl-based combustion systems. This is reflected in the wide variety of re-entrant designs present on the market. Nevertheless, we attempt to summarize the important considerations in this section.

3.3.1 Axisymmetry

Axisymmetry of the combustion chamber is strongly desirable to promote air utilization, and is a major consideration

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(along with power density) driving the adoption of four-valve designs (Horrocks, 2010). The presence of valve pockets in the piston top adversely impacts combustion chamber symmetry, although the *k*-factor is improved. Increased symmetry can benefit part-load emissions as well as full-load performance (Fasolo *et al*., 2005), and consequently many new engine designs feature vertical valves and no-valve pockets in the piston top (Abe *et al*., 2004; Bauder *et al*., 2005; Dworschak *et al*., 2009; Langen *et al*., 2010; Steinparzer *et al*., 2007; Van den Huevel *et al*., 2006). As noted above, in four-valve designs, the injector is typically mounted along the cylinder centerline to promote axisymmetry, and the piston bowl is likewise centered in the cylinder. While non-axisymmetric bowls (e.g., square) may have advantages and have been released in production engines (Kihara, Mikami, and Kinbara, 1983), such designs have not been widely adopted.

3.3.2 Piston bowl diameter

The maximum diameter of typical piston bowls is typically greater than ~60% of the bore diameter, and roughly three to four times the maximum bowl depth. Computational studies indicate that bowl diameter is the dominant geometry variable impacting combustion system performance (Genzale, Reitz, and Wickman, 2007). Like many geometry variables, there is no single value that proves optimal at all engine operating conditions. Full-load operation is usually found to benefit from a wide bowl design, whereas narrower bowls are preferred at lower load (Cursente, Pacaud, and Gatellier, 2008a; Ge *et al*., 2010; Lisbona, Olmo, and Rindone, 2000).

A trend that seems to be general is that re-entrant combustion chambers tend to become wider and shallower with each generation, (e.g., Matsui *et al*., 2008; Bauder *et al*., 2005; Crabb *et al*., 2013). This development is dictated by both mechanical demands and combustion considerations. As the specific power and peak combustion pressure increases, the maximum pressure difference between the combustion chamber and the volume below the top piston ring increases, resulting in larger deformation of the piston top during combustion. Considering that there is an oil gallery between the combustion chamber and the piston ring pack, this is one of the weaker regions of the piston. Using a shallower piston bowl makes the top of the piston more robust to deformation, and to maintain r_c, the bowl must be made wider.

There are multiple ways in which a wider bowl diameter impacts the combustion process, most of them positive:

- Wider bowls provide a longer free spray length to reduce the risk of wall wetting (Hadler *et al*., 2007) and over-penetration of fuel vapor. Higher power requires higher fuel flow rates through the nozzle. This translates into larger orifices and longer liquid penetration lengths, especially at cold ambient conditions.
- Increased injection pressures are also employed to support higher power densities, resulting in more rapid penetration of the sprays. Wider bowls are thus thought to more closely match combustion chamber shape to higher injection pressures (Chi *et al*., 2008; Lee *et al*., 2009; Lee *et al*., 2012).
- Wider bowls complement low r_c designs, due to the increased spray penetration associated with lower ambient density (Cipolla *et al*., 2007).
- Wider bowls improve the *k*-factor (improve air utilization) and reduce the heat load on the piston due to a more favorable surface-to-volume ratio (Crabb *et al*., 2013).
- Large diameter bowls are more tolerant to advanced injection timing and help prevent oil dilution (Cipolla *et al*., 2007).
- Wider bowls tend to increase the tolerance of the combustion system to variations in spray targeting (Fasolo *et al*., 2005).
- The soot-NO_x trade-off may suffer at part load with wide bowls (Fasolo *et al*., 2005).
- Low load HC and CO emissions may increase in low r_c engines when wide bowls are employed (Cursente, Pacaud, and Gatellier, 2008a).

3.3.3 Piston bowl re-entrancy

Most light-duty combustion systems feature re-entrant bowls. As noted above, re-entrancy promotes the amplification of the swirl velocity as the charge is compressed into the bowl. It also impacts the strength of the flow from the squish volume into the bowl, as described by Zolver, Griard, and Henriot (1997), and is thus expected to increase turbulence levels and mixing rates within the bowl. Moreover, a re-entrant bowl shape preserves the kinetic energy of the fuel sprays after they impact the bowl wall, redirecting them toward the cylinder center and preventing stagnation of rich mixture near the bottom of the bowl (Terazawa *et al*., 2011). Re-entrancy further retains the swirling flow within the bowl, impeding the spread of burning fluid into the squish volume (Zhang *et al*., 1995).

Experimental investigations confirm that re-entrant bowl geometries increase mixing rates, allowing greater timing retardation before fuel consumption or soot emissions suffer excessively (Ikegami *et al*., 1990a; Kidoguchi, Yang, and Miwa, 1999; Middlemiss, 1978; Saito *et al*., 1986). Although the increased mixing rates may result in higher NO_x, the greater retardability compensates. A greater EGR

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

tolerance is also to be expected from re-entrant combustion systems. Re-entrancy is moreover reported to be advantageous even in large-bore, quiescent combustion systems when highly premixed operation is desired (Cao *et al*., 2009).

Despite these advantages, there appears to be a trend toward lower levels of re-entrancy as existing engines are modified and updated (Hadler *et al*., 2007; Lee *et al*., 2012). Part of this trend is related to combustion performance. Lower values of re-entrancy are reported to promote robustness to spray targeting variations associated with dispersion in spray angle and injector protrusion (Diwakar and Singh, 2009; Fasolo *et al*., 2005). Likewise, re-entrant bowls have higher rim temperatures and can shorten ignition delay (Saito *et al*., 1986)—impeding the premixing of fuel. This disadvantage is expected to be less relevant in contemporary engines where ignition delays are deliberately shortened by means of pilot injections (in order to reduce combustion noise) but may become important in low temperature combustion (LTC) modes, which are based on premixing during an extended ignition delay. Reduced re-entrancy also responds to the higher mechanical and thermal loads in today's downsized diesel engines. Either a decreased degree of re-entrancy or remelting of parts of the piston top during manufacturing (see, e.g., Eidenböck *et al*., 2012) is needed to ensure piston robustness and durability.

3.3.4 *Piston bowl lip shape*

The various features defining the piston bowl lip shape are shown in Figure 7. It is generally believed that a small radius at the upper lip of the piston is beneficial for soot emissions as well as increasing the combustion system EGR tolerance (e.g., Steinparzer *et al*., 2007)—benefits that may be related to turbulence generation by the reverse squish flow during expansion. The smallest radius that can be practically incorporated, however, is often limited by piston durability issues.

The lower lip shape has been found to impact both smoke and fuel consumption (Middlemiss, 1978). Computational studies indicate that both the angle with which the spray impacts the bowl wall and the bowl radius of curvature near the lip affect the distribution of fuel within the chamber and the strength of the flow structures within the bowl (Diwakar and Singh, 2009). Experiments have likewise shown that the lower lip shape affects the jet spreading rate deep in the bowl (Montajir *et al*., 2001); smooth transitions are preferred to create a large spray volume indicative of increased entrainment. However, the apparent enhancement in spray volume does not translate into improved moderate-load smoke emissions. Lastly, a large outer bowl (torus) radius, resulting in a small lip height, has been reported to improve the soot/NO_x trade-off characteristics at both part and full load (Zhu *et al*., 2004).

3.3.5 *"Stepped-lip" bowl geometries*

In contrast to the typical bowl lip geometry discussed above, engines recently designed for both light- and heavy-duty applications often have "stepped" or chamfered bowl lips, as shown in Figure 8. These steps are also sometimes referred to as *soot-in-oil rims* (Dreisbach *et al*., 2007).

One objective of stepped-lip bowls is to split the fuel spray, directing a portion of it upward toward the head and the remainder downward into the bowl. By redirecting the radial momentum of the upper portion toward the head, the penetration of the jet into the squish volume is impeded. An obvious result is that less soot is generated near the cylinder walls, where it could find its way into the engine oil. A second benefit is that heat loss to the cylinder liner is reduced, and a third benefit is expected for cold-starting—the glow plug can be located near the head of the spray plumes, where it is less susceptible to variability in the rotational alignment of the fuel sprays (Styron *et al*., 2011). In addition to reduced heat loss to the liner, stepped-lip bowls also favor reduced heat losses to the piston surfaces, due to the improved surface area-to-volume ratio.

Another objective of stepped-lip designs is to enhance air utilization—thereby reducing particulate matter (PM) emissions (Yoo *et al*., 2013). The use of multiple injection strategies is expected to help in maximizing the air utilization. By targeting the upper portion of the bowl with

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

an initial injection and the lower portion with a second injection, mixing of the second injection with O_2-depleted charge is avoided and soot and CO emissions are reduced (Dolak, Shi, and Reitz, 2010). The success of these multiple injection strategies will clearly require the impact of injection pressure, engine speed, and injection timing on spray targeting to be carefully considered. Enhanced air utilization is also reputed to improve the EGR tolerance of the combustion system. Reports of increased robustness of stepped-lip designs to parameter variations, including swirl and spray angle (Styron *et al*., 2011), are likely related to improved air utilization.

3.3.6 *Top clearance or "squish" height*

The top clearance between the uppermost surface of the piston and the head surface is typically set to roughly 0.6–0.8 mm. From the previous discussion, it is clear that this height should be kept as small as possible in order to promote full air utilization (a high *k*-factor). Indeed, both soot emissions (Ikegami *et al*., 1990b) and low load HC/CO emissions (Aronsson *et al*., 2009) have been found to benefit from a small squish height. However, too small a squish height can place severe demands on manufacturing tolerances, even when multiple head gasket thicknesses are available to compensate. Fuel consumption has also been shown to be minimized with a squish height between 0.6 and 0.8 mm, possibly due to increased heat losses when too small a squish height is employed (Ikegami *et al*., 1990b). It should be noted that, for a given r_c, changes in the squish height must be compensated by changes to the bowl volume. It is thereby difficult to separate the effects of the squish height from those of the combustion chamber geometry.

3.3.7 *Bowl pip geometry*

Like the lower bowl lip and outer bowl shape, one purpose of the central pip in the piston bowl is to help redirect the fuel jets and avoid stagnation of fuel-rich mixtures in the central region of the bowl. The bowl center is a region where flow velocities and mixing rates are low, making optimal mixture formation difficult (Bauder and Stock, 1990; Middlemiss, 1978)—accordingly, it is thought to be advantageous to fill this area with metal, thereby allowing for increased charge mass along the bowl periphery. This simple consideration is likely at least partly responsible for the observations of increased mixing rates in bowl designs with central pips (Middlemiss, 1978), resulting in less deterioration of fuel consumption and smoke as injection is retarded. However, a central pip is also thought to increase turbulence levels within the bowl (Béard, Mokaddem, and Baritaud, 1998; Kidoguchi, Sanda, and Miwa, 2003), which will also enhance mixing rates.

There are a variety of common bowl pip shapes that have been released in production engines, some of which are illustrated in Figure 9. Computational studies focusing on pip and lower bowl shape find a clear, load-dependent impact of pip shape on emissions and performance, but no profile gives universally better behavior at all loads or for all performance metrics (Juttu *et al*., 2009). The simple W-shaped or conical pip design has been featured in numerous engines and has a high expected reliability (Fasolo *et al*., 2005). So-called step-cone pips displace a greater amount of charge from the bowl center, thereby favoring larger bowl diameters. Bowls with this pip geometry promote better full-load air utilization and tolerate more advanced part-load injection timings without excessive oil dilution (Cipolla *et al*., 2007). However, too high a pip may interfere with air entrainment into the spray (Wickman, Senecal, and Reitz, 2001).

The more complex shapes on the right-hand side of Figure 9 were designed with the stated objective of influencing the bulk flow structures within the bowl late in the combustion process. In the Volvo design (Andersson *et al*., 2009), the designers sought to create a system of two counter-rotating toroidal vortices that serve to transport fuel and oxidant to a common interface (stagnation plane),

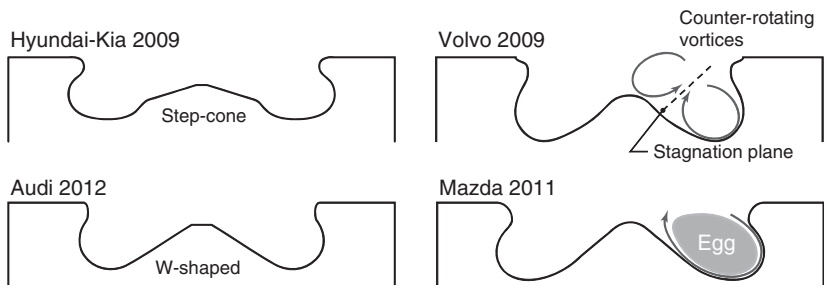

Figure 9. A sample of the variety of central pip shapes found in production engines.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where local turbulence generation rates are high. Enhancing the late-cycle mixing via this dual-vortex system led to reduced soot emissions and reduced combustion duration, thus leading to improved fuel economy. This concept has also been employed in off-highway engines (Crosse, 2010), enabling them to meet off-highway particulate emissions regulations without after-treatment.

In the Mazda design, the focus was on reduction of NO_x (Shimo, Kataoka, and Fujimoto, 2004; Terazawa *et al*., 2011). In this concept, the outer "egg-shaped" vortex transports hot combustion products to the cylinder center where they mix rapidly with cooler surrounding charge, thereby quenching thermal NO_x production. The thermal efficiency is also increased due to a shortening of the combustion duration (Shimo, Kataoka, and Fujimoto, 2004). Toyota has also recognized the importance of the outer vortex on promoting soot oxidation (Hotta *et al*., 2002a).

3.4 Matching piston geometry to flow and fuel injection parameters

The features of the combustion chamber geometry described above are not independent of the flow in the cylinder or of the geometry of the FIE and the maximum available injection pressure. Like the features of the combustion chamber geometry discussed above, it is difficult to state general design rules for matching the geometry to flow and injector characteristics. Consequently, we again endeavor only to summarize the most important considerations.

3.4.1 Swirl level

One purpose of flow swirl, as indicated by the preceding discussion, is to support the development of large-scale flow structures that disperse the burning fuel throughout the bowl. Another is to generate small-scale turbulence that completes molecular level fuel–air mixing on sufficiently short time-scales. As noted above, swirl is particularly important in light-duty engines, where a major part of the heat release often takes place after the turbulence directly generated by the fuel injection event has already decayed. The increased mixing rates associated with flow swirl can result in both lower soot emissions and improved fuel consumption due to shortened combustion duration; see for example, Steinparzer *et al*. (2007).

Employing flow swirl also has disadvantages. First, ports designed to generate swirl typically have greater flow losses and the ensuing reduction in volumetric efficiency results in a loss in power density. Recent engine designs are making greater use of chamfers in the cylinder head, however, which help increase the swirl generated at low valve lifts and reduce interference between the flows from the two intake ports (Bauder, Fröhlich, and Rossi, 2010; Chi *et al*., 2008; Eidenböck *et al*., 2012; Lee *et al*., 2009; Van den Huevel *et al*., 2006). Consequently, flow losses are becoming less severe. Second, flow swirl will increase heat losses, which can adversely affect fuel economy despite the more rapid combustion. The increased heat loss also impacts cold-start behavior. Third, excessive swirl can reduce the penetration of the fuel jets and impede air utilization. Near-nozzle entrainment is not expected to be impacted by swirl due to the low local tangential velocities and high injection velocities (Andersson, 2010). However, excessive swirl has been shown to impede penetration at part load (Sahoo, Petersen, and Miles, 2012), and has been shown to significantly deflect the fuel sprays even at high load (Hotta *et al*., 2002b). Despite these disadvantages, the benefits of swirl are such that, to the authors' knowledge, no modern automotive-scale DI engines have been introduced that do not employ some level of flow swirl.

Swirl can be quantified by a variety of metrics (e.g., Stone and Ladommatos, 1992). The most common is the swirl ratio $R_s = \omega_s/2\pi N$. This is the ratio of the angular velocity ω_s of the solid-body rotating flow with the same average angular momentum to the angular velocity of the crankshaft. N represents the rotational speed of the engine. Light-duty engines are typically designed to operate with either a fixed swirl ratio of between roughly 2 and 2.5 or are fitted with a swirl control valve that restricts one port and allows the flow swirl to vary in the range from approximately 1 to 4. The lower swirl is achieved when both ports are fully open and is appropriate for high engine speeds and loads. At lower speeds and loads, when flow restrictions are less important, the higher swirl levels are used to promote soot oxidation (Chi *et al*., 2008; Cursente, Pacaud, and Gatellier, 2008a). However, high swirl at low loads and high EGR rates can also increase HC and CO emissions (Cursente, Pacaud, and Gatellier, 2008a).

The optimal swirl level is generally found to depend on the number of nozzle holes and is usually lower for a greater number of holes (Akihama *et al*., 2008; Fasolo *et al*., 2005; Kurtz and Styron, 2012; Van den Huevel *et al*., 2006). With a sufficient number of holes, the full-load soot is not overly sensitive to swirl, and it may be possible to use a single swirl level optimized under part-load conditions without a large adverse impact on full-load behavior (Van den Huevel *et al*., 2006). A second parameter that impacts the optimum swirl level is bowl diameter. As the swirling flow is compressed into the piston bowl, its rotational speed is amplified, and combustion systems have been thought to optimize at "bowl" swirl ratios near 5. Larger bowls can be found to require higher swirl levels, because the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

swirl amplification is less (e.g., Hadler *et al*., 2007). This traditional thinking may not be applicable to low r_c designs, in which part-load soot emissions are mitigated primarily through increased fuel–air premixing rather than increased late-cycle oxidation. In this case, low swirl and large bowl diameters can be jointly employed to reduce heat losses and improve both cold-start behavior and fuel consumption (Inagaki *et al*., 2011).

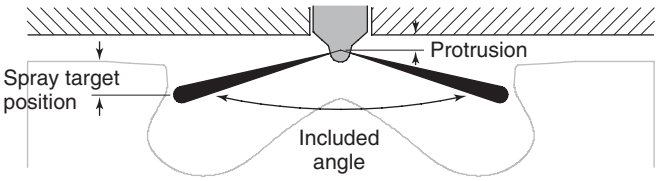

Figure 10. Definitions of variables impacting the interaction of the sprays with the piston.

3.4.2 Fuel injection parameters

Matching the desired power density, the piston bowl geometry, and the swirl level to the characteristics of the fuel injection system is a critical aspect of diesel combustion system design. At the most basic level, the fuel injector flow capability and the maximum injection pressure must be selected to provide sufficient fuel to meet the rated power requirements. The full-load fuel delivery must take place within a 30–35° window, which at rated speed is only about 1 ms in duration. The lowest flow nozzle that meets the full-load requirements is usually selected, as lower flow nozzles generally result in an improved soot/NO_x trade-off (e.g., Fasolo *et al*., 2005). The fuel injector flow rating is determined by the number of nozzle holes, their diameter, and the nozzle hole discharge coefficient. Thus, a small nozzle hole size requires a larger number of holes in order to meet rated power targets. Modern, conical nozzles with rounded nozzle hole inlets exhibit discharge coefficients of ~0.85. The injector needle opening and closing characteristics are also important. Hydraulically actuated injector designs with control chambers close to the nozzle tip and designs that are directly driven by piezoelectric actuators can significantly increase the amount of fuel delivered for the same overall injection duration.

Once the nozzle flow rating is determined, the nozzle hole diameter and number of holes must be fixed, as well as the parameters affecting how the spray interacts with the piston. As noted above, the optimal number of holes is coupled to the swirl ratio. Although a greater number of holes generally optimizes at a lower swirl level, the optimum achieved may be higher for too many or too few holes, or have less robustness to swirl variation (Fasolo *et al*., 2005; Kurtz and Styron, 2012; Van den Huevel *et al*., 2006). The optimal number of holes also depends on the specific engine operating condition and r_c (Cursente, Pacaud, and Gatellier, 2008a; Inagaki *et al*., 2011) as well as the metric used to define the optimum. In general, the higher swirl needed when too few holes are used will adversely affect part-load fuel consumption, whereas with too many nozzle holes, the soot and fuel consumption at higher loads deteriorates. In recent years, there has been a general trend toward an increased number of nozzles holes; 7–8 is now typical for new engine designs.

The spray interaction with the piston is affected by the spray target position, which is set by the injector nozzle tip protrusion and the included spray angle or umbrella angle (Figure 10). Like the optimal nozzle hole size and number, the optimal spray targeting will depend on numerous other combustion system parameters (bowl geometry, swirl ratio, etc.) as well as the engine operating condition. However, a few generalizations can be made.

At higher loads, the choice of spray targeting is mainly concerned with minimizing soot emissions. As described earlier, the shape of the bowl lip in conjunction with targeting location must enforce an appropriate fuel split between the squish volume and the bowl and create sufficiently strong flow structures to avoid stagnation of fuel-rich mixture near the bowl walls or floor. As the load is increased, the optimal targeting that satisfies these conditions moves lower in the bowl (Andersson *et al*., 2009). Targeting lower in the bowl also reduces light-load HC and CO emissions (Andersson *et al*., 2009; Aronsson *et al*., 2009; Cipolla *et al*., 2007), indicating that over-lean mixture formed from fuel injected directly into the squish volume is an important source of these emissions. Spray targeting has also been found to impact secondary liquid atomization by the piston and to have potential for enhancing cold-start behavior (Lippert *et al*., 2000).

Many investigations of spray targeting vary primarily the included angle of the spray, which is cited in modeling studies of heavy-duty engines as the dominant nozzle geometry-related factor impacting NO_x, soot, and fuel consumption (Genzale, Reitz, and Wickman, 2007). In light-duty engines, however, the included angle has been found to be of little importance at mid-to-high loads, provided the same spray targeting position is maintained (Andersson *et al*., 2009). Generally, with typical re-entrant bowls and widely varying spray targeting position, wide included angles are found to give improved part-load soot emissions (Cipolla *et al*., 2007; Siewert, 2007). The impact of nozzle tip protrusion is not typically addressed directly. Here, we note only that increased protrusion will tend to increase the nozzle tip temperature, which is known to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

increase deposit formations within the nozzle (Tang *et al*., 2009).

4 FUNDAMENTALS

This section treats more fundamental aspects of the spray and mixture formation processes, the ignition and heat release processes, and flow processes that drive the design choices discussed above. We will focus on the processes occurring while the intake and exhaust ports are closed. Since the swirling gas motion in the cylinder is of central importance to the combustion process, the intake ports are sometimes considered to be an important part of the combustion system. Port flows and in-cylinder flows are described separately in (Gas Exchange - Breathing and Air Management and In-Cylinder Flow), respectively, and will not be treated here. Peripheral systems for supercharging and cooling the intake air and EGR also have important effects on combustion. These external systems are likewise not treated here, but are covered in (Gas Exchange - Breathing and Air Management, Intake Boosting and Engine Thermal Management).

4.1 The anatomy of a burning diesel jet

It is useful to begin with a description of the history of a fuel element that travels through a burning diesel jet. Figure 11 reproduces Dec's (1997) well-accepted picture of quasi-steady diesel combustion, applicable at moderate-to-high loads in large-bore diesel engines where combustion chamber wall and in-cylinder flow interactions are relatively minor. The picture shows the development of a single diesel fuel jet, which is injected into the cylinder at high pressure. The injection event occurs near TDC, when the ambient, undiluted charge density is $\sim$20 kg/m^3 and the temperature $\sim$1000 K.

On entering the cylinder, the fuel jet atomizes and rapidly entrains the hot ambient charge. Liquid fuel extends downstream to a location where the energy of the entrained charge is sufficient to vaporize the fuel, giving rise to a characteristic "liquid length" (Siebers, 2008). Beyond the liquid length, the vaporized fuel–air mixture continues to entrain hot gases, and eventually undergoes a putative premixed combustion process, generating a large amount of soot precursors and surface growth species—poly-aromatic hydrocarbons (PAHs) and C_2H_2—in the hot products of the fuel-rich combustion. These soot precursors go on to form soot particles. Meanwhile, a diffusion flame has surrounded the hot products and extends upstream to a location denoted the flame "lift-off" length.

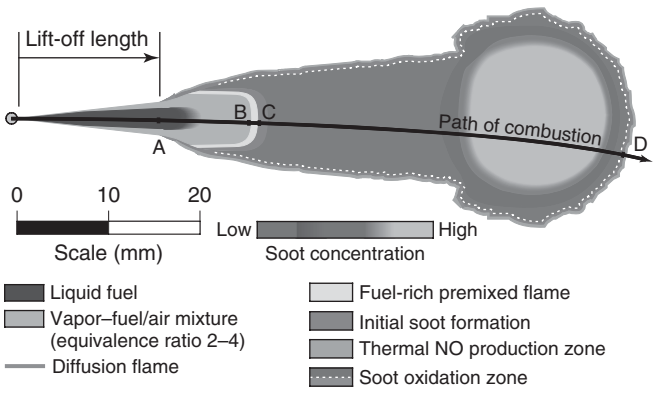

Figure 11. Dec's (1997) quasi-steady model of heavy-duty diesel combustion. The fuel element trajectory shown is correlated to the "path" of combustion in a $\phi-T$ parameter space in Figure 19 below. (From Dec (1997). Copyright © 1997 SAE International. Reprinted with permission.)

The lift-off length is extremely important, as it determines the spatial extent over which the fuel jet is able to entrain fresh charge. The magnitude of the lift-off length is thereby a limiting factor for the equivalence ratio of the mixture that undergoes premixed combustion, and hence, the propensity for soot formation (Siebers, 2008). Beyond the lift-off length, O_2 entrained into the jet is consumed within the diffusion flame, and the hot gases entrained and mixed with the fuel vapor and rich combustion products consist of the products of combustion formed in the diffusion flame. Accordingly, the temperature of the mixture increases, and the mixture fraction decreases, but concentrations of oxygen and key species such as OH are low. Soot formation processes proceed, and although concurrent oxidation of the soot precursors and soot formed also takes place, the oxidation rates are slow as compared to those that occur within the diffusion flame. Pickett *et al*. (2006) provide more information on the soot formation and oxidation processes in the downstream regions of the jet. Owing to the low oxygen concentrations in the downstream regions, NO_x formation likewise takes place predominantly at the diffusion flame, where high temperatures and oxygen concentrations coexist.

4.2 Air entrainment and mixing in diesel fuel jets

Given the central role of the rich premixed reaction zone for the formation of soot, there are in principle two ways to decrease the soot formation in quasi-steady jets. The first, as suggested above, is to increase the lift-off length to provide a longer distance for air entrainment. The second

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is to enhance the air entrainment upstream of the lift-off position.

The following description of the air entrainment follows the analysis of Naber and Siebers (1996), who used an idealized model jet. The jet is assumed to be isothermal and incompressible, to have no velocity slip between the injected fuel and the ambient air, and to have a constant spreading angle, α. It is also assumed to have radially uniform velocity and fuel concentration profiles. Although this is a highly idealized model of a real jet, the analysis focuses on the essential underlying physics of the spray: the conservation of mass and momentum. As a consequence, the fundamental factors limiting the air entrainment process are exposed.

The idealized model jet is depicted in Figure 12. Fuel enters through the orifice on the left and is assumed not to vaporize. As the fuel droplets reach the rightmost boundary of the control volume (dashed line), a certain amount of air has been entrained (white arrows). The mass flow of fuel at the orifice is given by

$$\dot{m}_f = \rho_f A(0) U(0) \tag{1}$$

where ρ_f is the fuel density, $A(0)$ is the effective orifice area, and $U(0)$ is the injection velocity. The air mass flow rate at x, the rightmost boundary of the control volume, is given by

$$\dot{m}_a = \rho_a A(x) U(x) \tag{2}$$

where ρ_a is the ambient air density, $A(x)$ is the jet cross-sectional area, and $U(x)$ is the jet velocity at x. The downstream location, x, is assumed to be large enough that the area occupied by the fuel droplets is negligible compared to $A(x)$.

The fuel mass flow over the control volume boundary at x is the same as the mass flow at the orifice, but the entrained air slows the jet down. The jet velocity at x is given by the conservation of momentum,

$$\rho_f A(0) U(0)^2 = [\rho_f A(0) U(0) + \rho_a A(x) U(x)] U(x) \tag{3}$$

where the left-hand side is the momentum flux at the orifice and the right-hand side is the momentum flux at x. This can be solved for $U(x)$ and inserted into Equation 2. An expression for the fuel-to-air mass flow ratio at x is obtained by dividing Equation 1 by Equation 2. With some algebraic manipulation, this analysis gives a powerful scaling relationship for the mean equivalence ratio in the jet cross section,

$$\overline{\phi} = \frac{2 f_s}{\sqrt{1 + 16\widetilde{x}^2} - 1} \tag{4}$$

where f_s is the stoichiometric air-to-fuel mass ratio for the fuel and ambient air composition. The coordinate $\widetilde{x}$ is a nondimensional axial distance from the orifice,

$$\widetilde{x} = \frac{x}{x^+} \tag{5}$$

where x is the physical distance from the orifice and x^+ is a characteristic length scale,

$$x^+ = \frac{d_f \sqrt{\frac{\rho_f}{\rho_a}}}{\tan(\alpha/2)} \tag{6}$$

In Equation 6, d_f is the effective nozzle diameter (adjusted for cavitating flow) and $\alpha/2$ is half the spreading angle of the model jet, as defined in Figure 12. Although Equation 4 was developed for a non-vaporizing spray, it also applies to vaporizing sprays. Naber and Siebers found that the differences in penetration speed and spreading angle between vaporizing and non-vaporizing sprays were small. As the jet deceleration depends on the air entrainment—through the conservation of momentum—this indicates very similar air entrainment in the two cases.

A number of interesting conclusions can be drawn from Equations 4 through 6. The most obvious one is perhaps that $\overline{\phi}$ decreases with increasing distance from the nozzle, that is, more air is entrained over a longer distance. Equation 6 also implies that:

- Air entrainment increases strongly with decreasing orifice diameter.
- Air entrainment has a weaker dependence on the density ratio between fuel and ambient gas than on orifice diameter.
- The spatial structure of the jet has no explicit dependence on injection pressure. This indicates that air

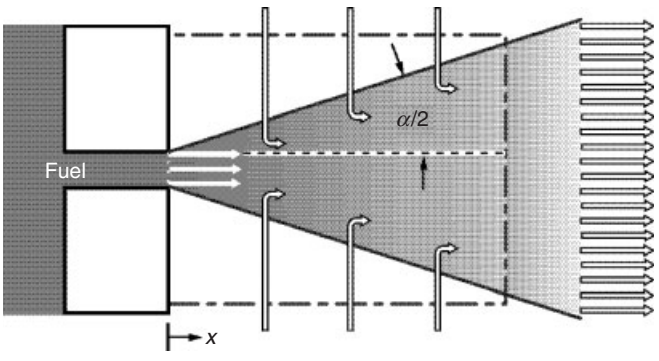

Figure 12. Idealized model jet. (Adopted from Naber and Siebers (1996). Copyright © 1996 SAE International. Reprinted with permission.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

entrainment increases in direct proportion to the increase in fueling rate that occurs with increasing injection pressure.

The spreading angle α mainly depends on orifice flow effects, such as cavitation, and on the density ratio between fuel and ambient gas (Siebers, 1999). A larger jet spreading angle reflects more air entrainment, as more air is present inside a wider cone.

In summary, the nozzle hole diameter and the ambient gas density are the main factors affecting the air entrained per unit of fuel, and thus the variation of the average fuel–air equivalence ratio as function of distance from the nozzle.

As previously discussed, the flame lift-off length is an important variable for soot formation as it limits the amount of air entrained into the jet upstream of the premixed reaction zone. A longer lift-off length allows air entrainment over a longer distance. Numerous investigations of the lift-off length have been made in optical engines and spray chambers. A comprehensive experimental database shows that the lift-off length increases as the injector orifice diameter or the injection pressure increases. More specifically, it scales with the square root of the pressure drop over the nozzle, that is, the lift-off length has a linear relationship with the injection velocity U. Furthermore, the lift-off length decreases when:

- The ambient temperature increases.
- The ambient density increases.
- The ambient oxygen concentration increases.

On single, quasi-steady jets under quiescent diesel conditions, the lift-off length, H, scales with these parameters according to

$$H \propto T_a^{-3,74} \rho_a^{-0,85} d^{0,34} U Z_{st}^{-1} \quad (7)$$

where T_a is the temperature of the ambient gas, ρ_a is the ambient density, d is the nozzle orifice diameter, and U is the injection velocity. Z_{st} is the stoichiometric mixture fraction, that is, the ratio of the fuel mass to the total mass of fuel and ambient gas in a stoichiometric mixture. The practical implications of this relationship will be discussed further in Section 5.2 below. These dependencies have been empirically established in a constant volume combustion vessel (e.g., Pickett, Siebers, and Idicheria, 2005), but a fundamental understanding of the underlying mechanisms is still missing. Further research is also needed to clarify the effects of fuel parameters on the lift-off length, such as the cetane number defined below. In an engine, the interaction among adjacent jets on multi-hole injectors (Chartier *et al*., 2013), the influence of the piston bowl, and in-cylinder flow effects such as swirl (Neal and Rothamer, 2012) may also become important.

4.3 Ignition behavior

Ignition delay is an important quantity as it determines the amount of premixing that the fuel undergoes before combustion. This impacts combustion noise, formation of soot, and the oxidation of hydrocarbons and CO formed in lean mixtures. Ignition delay is determined by both physical and chemical processes. After the fuel is injected into the cylinder, it must vaporize and mix with the hot ambient gases before the chemical processes can commence. Several variables impact this initial atomization, vaporization and mixing process, including injector geometry, injection pressure, ambient gas density, and temperature, and the physical properties of the fuel. Once the fuel–air mixture is "prepared," the chemical ignition process commences. Considerable progress has been made in the last two decades in understanding the chemistry of ignition of the various compounds found in typical diesel fuels and in developing detailed chemical kinetic mechanisms to simulate the ignition process. Additional details can be found in (Fundamental Chemical Kinetics). For the purposes of this background, we will focus only on the impact of two major variables on ignition delay: the fuel–air equivalence ratio and the temperature of the prepared mixture.

Although ignition delay is not a property of the fuel alone, fuels possess an inherent ignition quality, which is traditionally described by the fuel cetane number. Cetane numbers are measured in a standardized test employing a variable r_c test engine following ASTM Method D613 (ASTM International, 2008a). Owing to the expense of running the original cetane number test, many fuels are now characterized using a derived cetane number, following ASTM method D6890 (ASTM International, 2008b). High cetane numbers imply high ignition quality, or short ignition delay. The current European Union fuel specification EN 590 requires a minimum fuel cetane number of 51. In North America, the minimum cetane number is 40, although typical cetane numbers average 45–50. Japanese regulations specify cetane numbers >45. In general, fuels rich in normal alkanes have higher cetane numbers, and cetane number increases with the length of a normal alkane. Branched, iso-alkane compounds have lower cetane number, and the cetane number decreases with the number of branches. Naphthenes and aromatic compounds have the lowest cetane numbers.

Figure 13 depicts the variation of ignition delay with temperature computed from simulations of the ignition of a

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

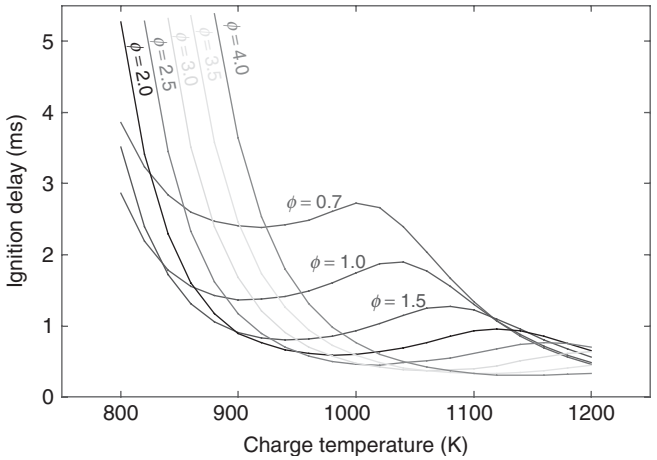

Figure 13. Temperature and equivalence ratio dependency of the ignition delay of n-C_7H_{16}. The ambient composition is 12.7% O_2 and 87.3% N_2.

homogeneous mixture of n-C_7H_{16} at a constant pressure of 50 bar, for a variety of different mixture equivalence ratios. The initial temperature was determined for each ambient temperature and equivalence ratio by assuming an adiabatic fuel vaporization and mixing process. The ignition delay is defined as the time from the start of the simulation until the peak rate of temperature rise associated with the high temperature, OH-driven heat release.

There are several important observations that can be made from Figure 13:

- At lower temperatures, the rapid rise in ignition delay, which is particularly pronounced for mixtures with $\phi > 1$, corresponds to an exponential dependency of ignition delay on T^{-1}. As will be seen below, lowering the charge compression temperature is a powerful method for increasing ignition delay and charge premixing.
- At temperatures typical of conventional diesel combustion in high r_c engines (~1000 K), richer mixtures are expected to ignite first, with very little difference in ignition delay times for ϕ between 2 and 4.
- At temperatures characteristic of low r_c diesel engines (~850 K), near-stoichiometric mixtures are expected to be the first to ignite. These mixtures will reach a high flame temperature, and on subsequent compression by combustion of the remaining mixture, will likely be the hottest regions in the cylinder and the regions where NO_x formation is greatest.
- At intermediate temperatures, the ignition delay is not as sensitive to T, due to the "negative temperature coefficient" or NTC behavior of typical diesel fuels. In this range, decreased temperature can actually lead to reduced ignition delay. The practical consequence of this behavior is that compression temperatures must be reduced below approximately 950 K before decreases in T become particularly effective in increasing ignition delay.

4.4 Heat release in diesel engines

The combustion process in engines is monitored by the rate of heat release as determined from the cylinder pressure trace, following the procedures described in (Pressure and Heat Release Analysis). Traditional heat release curves from diesel engines are divided into three phases. These are delimited by vertical lines in Figure 14, which show the rate of heat release at 50% load in a heavy-duty diesel engine operated with a single injection.

The first phase is the premixed burn and is typically considered to begin when the heat release rate turns positive. Combustible mixture that has been prepared in the cylinder between the start of injection and this point burns in a premixed volumetric reaction zone at a high combustion rate, determined by the rate of the chemical reactions. This produces a steep increase in the cylinder pressure, which is the origin of the characteristic clattering diesel sound. In high r_c engines, the premixed reactions take place in fuel-rich zones, characterized by equivalence ratios ranging from approximately 2 to 4, in the leading portion of the developing diesel jet (Dec, 1997). When a large portion of this mixture has been consumed, the heat release rate temporarily drops, indicating the end of the phase.

The period from the end of the premixed burn until the end of fuel injection is the main mixing-controlled burn

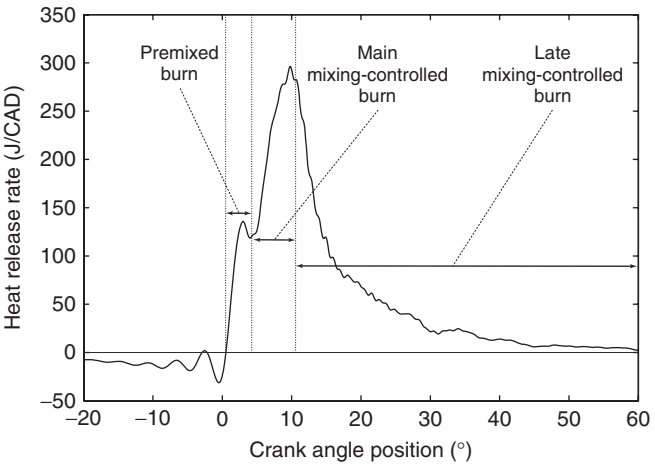

Figure 14. Rate of heat release from a 13-L heavy-duty diesel engine operated at 50% load.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

period. During this phase, combustion occurs in a quasi-steady jet as described in Figure 11. A turbulent diffusion flame has formed around the jet where combustion products from the rich, premixed reactions are consumed. The rate of heat release rate is limited by the rate of mixing between air and these products, which is driven by the spray-induced turbulence. In reality, as described in the context of Figure 11, premixed and mixing-controlled combustion occur simultaneously in different parts of the jet, making the division into these different periods less exact than Figure 14 implies. The curve merely indicates which type of combustion is dominating at different times. The end of injection is not explicitly indicated in Figure 14, but can often be seen as peak or a sudden change in the slope of the heat release rate.

After the end of injection, remaining fuel or combustion intermediates burn in a diffusion flame. This latter period is called the *late mixing-controlled burn*. The main difference from the preceding period is that the spray no longer drives the mixing. As the spray turbulence dissipates, the heat release rate drops rapidly and then gradually tails off to zero. Owing to the expanding motion of the piston, the mixture cools down, which may lead to poor combustion efficiency if the late-cycle mixing is too low.

The period between needle opening and the start of the premixed burn is referred to as the *ignition delay period*, described in the previous section. It is not indicated in Figure 14 as it is not an actual part of the heat release. During this period, the injected fuel is atomized into fine droplets, heated, and vaporized by mixing with hot air until a combustible mixture is formed. As the heat needed for vaporization is absorbed from the in-cylinder gas, it is seen as a negative rate of heat release in the diagram before the start of the premixed burn.

It is common to see a more prominent premixed burn in textbook heat release curves (e.g., Heywood, 1988). Typical injection pressures have increased steadily over the years and have accelerated the mixing and shortened the ignition delay in modern engines. As a result, diesel engines today only display a small portion of premixed heat release. The reason why a 50% load case was chosen for Figure 14 is that at 100% load, the injection pressure has increased enough to render the premixed peak all but invisible. At full load, which is a more representative operating condition for heavy-duty engines, the heat release is dominated by an extended main mixing-controlled phase and the subsequent late mixing-controlled phase.

Typical heat release curves change as engine technology advances. Today, light-duty diesel engines use several injections during the same cycle. This makes it more difficult to divide the heat release into the different modes of combustion outlined above, but it is still instructive to show

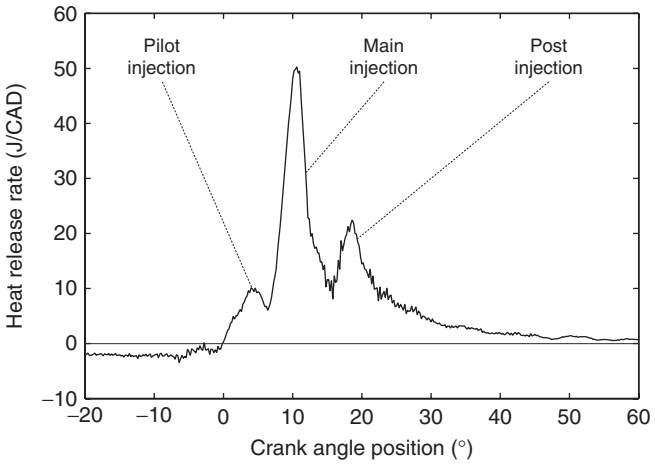

Figure 15. Typical rate of heat release from a light-duty diesel engine operated at 20% load (4 ar IMEP).

how advanced injection strategies affect the combustion heat release. Figure 15 shows a heat release rate from a light-duty engine operated at 20% load, which is a typical urban driving condition. The main heat release peak is preceded by a peak associated with an earlier pilot injection and succeeded by another from a later post injection.

The pilot injection is a small quantity of fuel injected before the main injection. Its primary purpose, described in greater detail below, is to decrease the ignition delay of the main injection—thereby decreasing combustion noise and light-load HC and CO emissions. A post injection is a small amount of fuel injected after the main injection, during the tail of the late mixing-controlled burn. The purpose is to improve the conditions for soot oxidation, by increasing either the turbulent mixing rate or the temperature, and the result is decreased PM emissions. Notice that with a post injection, the mixing-controlled tail of the heat release curve is delayed, and efficiency is expected to decrease. Paradoxically, this is not generally the case, as will be discussed further below.

4.5 In-cylinder flow processes

In-cylinder flow processes are covered in detail in (In-Cylinder Flow), and we review only the essentials here. There are conventionally two types of organized flow motion in diesel engines. As previously mentioned, swirl is the organized rotating motion about the cylinder axis, set up by the intake ports. The second type is squish, which will be introduced shortly. Flow swirl can significantly affect both the initial mixture preparation process and the late-cycle oxidation processes, and the optimum level is dependent on both. A third type of flow motion, tumble, is an organized

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

rotating motion with an axis perpendicular to the cylinder axis. While tumble is of great importance in spark ignition engines, it does not appear to improve diesel combustion and will not be considered further here.

Rotating flow structures such as swirl are impacted by compression. For a flow swirling about the cylinder axis, axial compression will have little effect on the angular velocity of the swirl, as the moment of inertia of the rotating flow is not appreciably affected. However, when the flow is compressed radially into the piston bowl, the moment of inertia decreases by approximately the square of the bowl-to-bore diameter ratio, and the rotational velocity must increase accordingly to conserve angular momentum. Measurements indicate that the resulting "bowl" swirl ratio is approximately 60% of the theoretical value computed from the reduction in the moment of inertia (Arcoumanis, Hadjiapostolou, and Whitelaw, 1991). This process results in an increase in the rotational kinetic energy of the flow—work is performed on the flow as it is compressed into the bowl. With a typical B/S ratio of 0.9, a bowl-to-bore diameter ratio of 0.6, and a swirl ratio at intake valve closing of 2.5, the maximum swirl velocity U_θ in the bowl will be roughly seven times the mean piston speed $\overline{V}_p$.

The second organized flow structure is the "squish" flow, formed as fluid is forced out of the squish volume by the rising piston motion (Figure 16). For typical engine geometries, the squish flow (and the reverse squish flow that occurs during expansion) peaks within 10° of TDC and reaches a magnitude closely comparable to the peak swirl velocity—roughly five to six times the mean piston speed.

The squish flow and the flow swirl interact. As a fluid element is displaced inward, conservation of angular momentum dictates that the tangential velocity U_θ increases to keep the angular momentum—the product rU_θ—constant. With sufficient swirl, the increasing centrifugal force acting on the fluid element as it moves inward overcomes the competing influence of the radial pressure gradient $\partial p/\partial r$, and strongly opposes the inward movement. Thus, with low swirl, the squish flow penetrates inward to near the cylinder centerline, whereas with high swirl, the inward penetration of the squish flow is impeded and the squish flow instead descends into the bowl. As a consequence, the rotational structure formed in the vertical r–z plane rotates in the opposite direction as in the low swirl case, as shown on the right-hand side of Figure 16.

The displacement of angular momentum by strong radial flows, which subsequently drives the development of vertical plane flow structures, is an essential feature of swirling flows in diesel engines. The strong, vertical plane flow structures formed by the interaction of the fuel sprays with the lower bowl lip and bowl wall can also displace high angular momentum fluid from near the bowl lip inward, which then attempts to return to the cylinder periphery due to the increased centrifugal forces. This process is illustrated in Figure 17, depicting how the vertical plane vortices shown previously in Figure 9 are formed. Like the squish–swirl interaction, the development of these vortices arises from a balance between the radial momentum imparted by the fuel sprays and the centrifugal forces imparted by the flow swirl.

There are several important consequences of the displacement of high angular momentum fluid inward and the formation of vertical plane vortical structures:

- Like the squish–swirl interaction discussed above, work is done on the high angular momentum fluid and its rotational kinetic energy increases as it is displaced inward by the spray-generated flow structures. This additional rotational energy is provided by the translational kinetic energy of the fuel sprays. Thus, this process allows a fraction of the kinetic energy of the fuel injection event to be stored in the rotating mean flow for later release

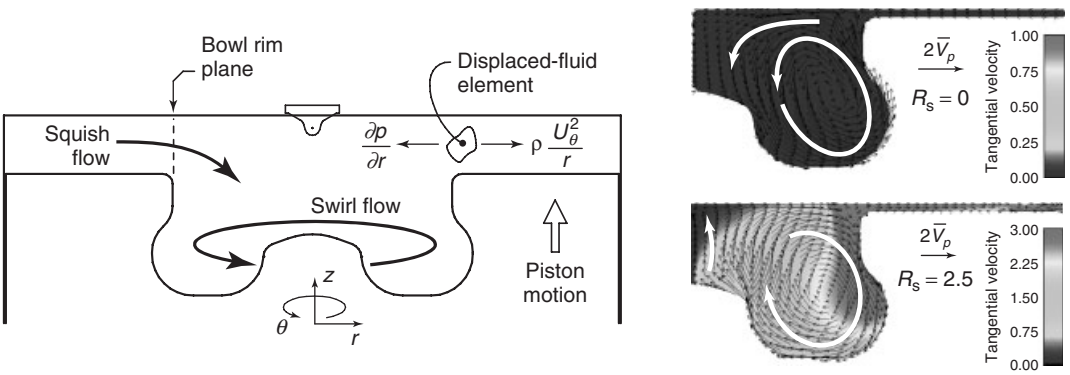

Figure 16. Illustration of the dominant in-cylinder flows and the mechanism by which they interact—conservation of angular and radial momentum.

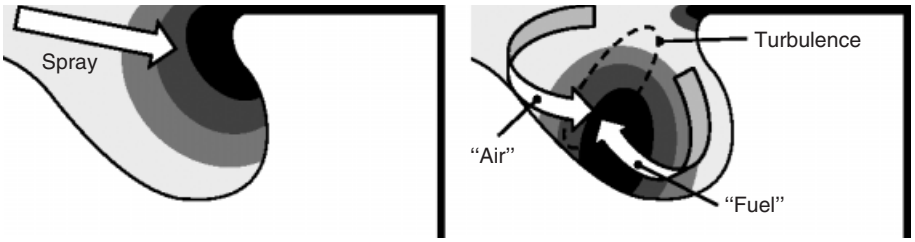

Figure 17. The fluid redistribution in the bowl due to injection. Half the bowl region is depicted from the cylinder centerline to the cylinder wall. The black regions correspond to gas with high tangential velocity. The lighter gray the color, the lower the tangential velocity of the gas. The left and right pictures correspond to the situations before and after injection, respectively. (Reproduced from Andersson (2010). © Wiley-VCH Verlag GmbH & Co. KGaA.)

into turbulence. Re-entrant bowl geometries promote this process. Simple estimates based on conservation of angular momentum (Miles, Rempelewert, and Reitz, 2003) suggest that displacing 25% of the combustion chamber mass from the outer bowl periphery to the bowl center can increase the rotational kinetic energy of the mean flow by over 50%.

- The displacement of high angular momentum fluid inward can result in formation of negative radial gradients of angular momentum. Such flows are inherently unstable (Tritton, 1977) and will result in a rapid breakdown into turbulence. Even when negative radial gradients in angular momentum are not formed, any departure in U_θ from a solid-body-like distribution will result in internal fluid deformation and turbulence production.
- When a dual-vortex structure is formed, a turbulent stagnation plane results (Figure 9), where there is large flow deformation due to radial and axial gradients in U_θ and due to r–z plane gradients in U_r and U_z. This region of high flow deformation is expected to result in considerable turbulence production.

The latter two bullets represent the mechanism by which the kinetic energy stored in the rotational flow is released as turbulence.

The practical importance of these vertical flow structures lies in the fact that they can also provide for bulk transport of unburned fuel or partially oxidized products to the same stagnation plane where turbulence generation and mixing rates are high (Andersson *et al*., 2009; Crosse, 2010; Miles, 2008). The predicted formation of these structures has been shown to correspond to a distinct increase in the measured rate of heat release (Miles *et al*., 2005), and to also correlate closely with combustion system designs providing low soot emissions (Andersson *et al*., 2009; Crosse, 2010).

The balance between radial momentum provided by the fuel injection event and centrifugal forces associated with flow swirl will be impacted by injection pressure, nozzle hole size, targeting on the bowl rim, the shape of the lower bowl lip, outer wall and pip, as well as the swirl ratio. These variables can all be expected to impact the formation of the dual-vortex structure. Excessive radial momentum (higher loads, higher injection pressures) might be expected to result in too large a lower, outer vortex, reducing the size of the upper vortex and its ability to transport O_2 to the stagnation plane (Andersson *et al*., 2009). Conversely, too high a swirl ratio can result in a small outer vortex that traps the partial oxidation products within the bowl (Kook *et al*., 2006).

Several of the practical design considerations cited above are consistent with this momentum balance and suggest a working hypothesis that late-cycle oxidation, perhaps more so than initial mixture preparation, is the process impacted most by flow swirl:

- Since flow velocities scale linearly with engine speed, at high engine speeds, one would expect a lower swirl ratio to be optimal, for the same injected fuel quantity and injection pressure.
- With a large bowl diameter, the increase in swirl as the flow is compressed into the bowl is less, and higher swirl ratios at intake valve closure (IVC) may be required to maintain a proper balance. On the other hand, the jet velocity will decrease at larger radii, which may reduce the need to increase swirl.
- A greater number of nozzle holes will reduce the mass and radial momentum in each fuel spray, and a lower swirl ratio will be required to achieve a balance.

A few additional observations should be made, which are relevant to the below discussion of multiple injection strategies. First, a poorly designed pilot injection can displace the high angular momentum fluid from the region near the bowl lip, such that the fluid entrained and transported inward by the main injection does not possess

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the necessary high tangential velocity needed to create the desired vertical plane vortical structures. Pilot injections may thus increase soot through reducing premixing by reducing the ignition delay *and* by impeding the formation of flow structures that promote late-cycle oxidation. Second, a post injection—intended to increase late-cycle mixing rates—could potentially disrupt beneficial flow structures and ultimately prove harmful.

Lastly, heavy-duty combustion systems are also often swirl supported. We reiterate that in these systems, a guiding principle is to ensure that the sprays do as much of the mixing work as possible. Nevertheless, swirl is often used to reduce soot emissions. Very little is known regarding the impact of swirl and how its interaction with the fuel sprays can impact flow structures in heavy-duty engines. However, recent measurements (Dembinski and Angstrom, 2012) show that similar mechanisms to those observed in light-duty engines are operative. The fuel injection and combustion process displace high angular momentum fluid inward, leading to significantly enhanced angular velocities in the center regions of the cylinder, undoubtedly promoting enhanced turbulence production and mixing.

4.6 Combustion process details related to emissions

If the main advantage of the diesel engine is its efficiency, its main drawback has traditionally been its emissions of oxides of nitrogen, collectively known as NO_x, and PM. Owing to ever-stricter emission legislations, NO_x and PM emissions have decreased steadily over the years. In Europe, the Euro 6 standard for light-duty vehicles brings an almost complete convergence of diesel and gasoline emissions of NO_x and PM by 2014 (Regulation (EC), 2007), whereas in the United States, there is already no distinction between the allowable emissions from gasoline and diesel engines.

Diesel PM consists of a solid part, soluble organic material, and sulfuric acid. The solid part consists of carbonaceous material (soot) originating from the combustion process, ash compounds from lubrication oil additives and particles generated by engine wear, and sulfates. The soot particles dominate (Majewski, 2002) and this is the only part of PM that will be treated in this chapter. Diesel PM is connected with respiratory and cardiovascular diseases (Peng *et al*., 2009). As soot particles are efficient light absorbers, they have been identified as major short-lived climate forcers and may also affect the climate by acting as condensation nuclei for cloud formation (UNEP/WMO, 2011).

Chemically, soot formation is very complex. It involves decomposition and oxidation of fuel, formation and growth of PAHs, coagulation and growth of these into primary particles, followed by aggregation into larger agglomerates, as well as growth on the particle surfaces. The soot formation rate is strongly dependent on temperature and the local mixture equivalence ratio. Generally, ϕ must exceed a value of roughly two for significant soot formation to occur. Soot particles are also oxidized during combustion. This process requires temperatures above 1300 K and takes place at the particle surfaces. Hydroxyl radicals (OH) and O_2 are generally considered to be the most important oxidizing species (Tree and Svensson, 2007).

NO_x emissions can arise through a number of mechanisms, but when using fuels that do not contain nitrogen, oxidation of atmospheric nitrogen by the so-called thermal mechanism is the major source. More specifically, this mechanism is responsible for NO formation, and the remaining part of NO_x (NO_2) is subsequently formed from the NO (Miller and Bowman, 1989); —see (NO_x Formation and Models) for further details. The thermal mechanism is characterized by a strong temperature dependence and relatively slow reaction rates. On timescales typical of engines, significant amounts of NO_x are generally not produced at temperatures below 1800 K (Heywood, 1988). Thermal NO_x is formed in stoichiometric or slightly lean mixtures. In the atmosphere, NO_x contributes to the formation of photochemical smog—a common problem in large cities that is associated with respiratory irritation.

The classic dilemma of diesel combustion is the trade-off between soot and NO_x, meaning that decreasing one of these emissions usually results in the other increasing. This is often explained by these emissions having different temperature dependencies; elevated temperatures promote both NO_x formation and soot oxidation (see, e.g., Heywood, 1988). Figure 18 shows results from a computational fluid dynamics (CFD) simulation of a typical light-duty diesel combustion cycle. It illustrates that soot and NO_x concentrations typically develop in quite different ways as function of time. The NO_x curve is dominated by a steep increase in the early parts of the cycle. This is because mixture that burns early is characterized by high temperatures and has time to form NO_x via the relatively slow thermal mechanism. When expansion cools the in-cylinder gas, the chemistry freezes and the NO_x levels in the exhaust gases thereby tend to be substantially higher than the equilibrium concentration at the ambient conditions (Heywood, 1988). The boot at the beginning of the NO_x curve is due to the pilot injection. Looking at the soot curve, on the other hand, we see a steep increase in the beginning of the cycle and a slower, but large, decrease during the expansion stroke. This is because soot is first formed in fuel-rich zones under high temperature conditions, and later oxidized in near-stoichiometric zones.

Soot emissions are thereby dictated by two competing processes of comparable magnitude, whereas trends in NO_x emissions largely can be understood in terms of formation only. As a result, the trade-off between soot and NO_x in a given combustion system can often be improved as these emissions are formed through different mechanisms in different regions of the combustion chamber.

Apart from NO_x and PM, tailpipe emission standards include unburned hydrocarbons (UHCs) and CO, resulting from incomplete oxidation of the fuel. These emissions have traditionally been less challenging for diesel engines than for gasoline engines. Today, tightening NO_x requirements call for decreasing the combustion temperature, for example, by using EGR, and this tends to increase UHC and CO at low loads. UHCs mainly arise from four sources: rich zones, where the oxygen deficit impedes the oxidation process; zones too lean for complete oxidation; cold zones, for example, near walls; and unburned fuel from the sac volume of the injector. CO mainly becomes problematic when the final combustion stages have not been completed before the bulk temperature drops below approximately 1500 K during the expansion stroke. The oxidation step from CO to CO_2 then cannot be completed (Heywood, 1988).

5 OVERVIEW OF THE COMBUSTION PROCESS

In this section, we build on the fundamentals presented above to describe the mixture formation, combustion, and emissions processes that occur during diesel combustion. We subsequently link this picture back to the practical design information presented in Section 3, showing how the design and operating parameter choices impact the overall combustion process.

5.1 Conventional, quasi-steady diesel combustion

The progress of diesel combustion is dictated by the relative rates of two inter-related physical processes: turbulent fuel–air mixing and the kinetics of the fuel oxidation. A useful, albeit qualitative, tool for illustrating the process is a map (Kamimoto and Bae, 1988) illustrating zones of soot and NO_x formation as a function of fuel–air equivalence ratio ϕ and mixture temperature T. An example of such a map, based on the calculations of Kitamura *et al.* (2002), is shown in Figure 19. Also shown on the left-hand side of the map is a dashed gray line that depicts the mixture temperature achieved when the fuel vaporizes and mixes adiabatically with ambient air at 1000 K. Finally, toward the central portion of the map, a solid gray line is shown, which indicates the locus of maximum flame temperatures achieved within 1 ms of ignition. For near-stoichiometric and richer mixtures, the maximum temperature can considerably exceed the adiabatic flame temperature before endothermic reactions lower the final temperature to its equilibrium value.

We will be concerned with the "path" that a fuel element traces through the ϕ–T space as combustion progresses. This mixing process can be naturally characterized by

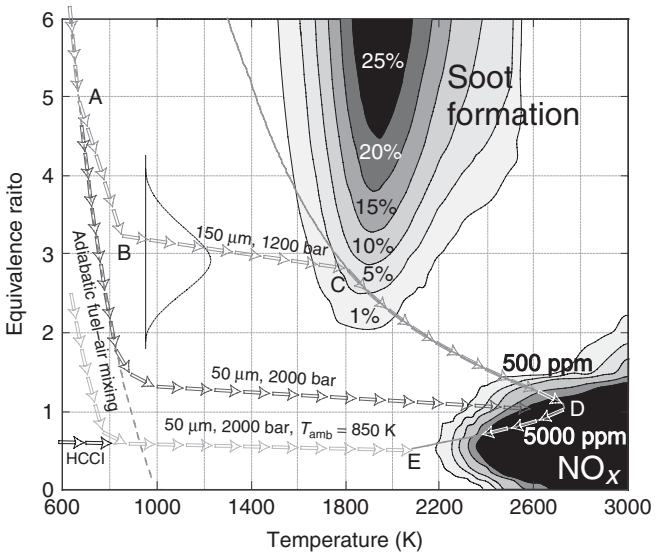

Figure 19. Regions of soot and NO_x formation computed by Kitamura *et al.* (2002) for n-C_7H_{16} at a pressure of 60 bar and a residence time of 2 ms. Potential paths of diesel combustion in an undiluted (21% O_2) ambient charge are also shown.

the mixture fraction Z, which physically represents the fraction of the mixture mass that originated from the fuel. In the absence of combustion, Z can be related to the equivalence ratio by $Z = \phi/(\phi + f_s)$; where f_s is the stoichiometric charge-fuel mass ratio introduced in Equation 4. After the start of combustion, the relationship between ϕ and Z changes, and depends on the progress of the combustion event and on the specific definition employed for ϕ. In this chapter, we will follow common practice in the diesel engine community and refer to the mixture state by the equivalence ratio that would exist in the absence of combustion, such that Z can be readily obtained from the above relationship.

A connection between the progress of combustion in the $\phi-T$ space of Figure 19 and the physical coordinates of space and time is most readily achieved by considering Figure 19 in conjunction with the conceptual model of Dec and coworkers depicted in Figure 11 (Dec, 1997; Flynn *et al*., 1999) and with the mixing rate estimates provided by Siebers and coworkers (Naber and Siebers, 1996; Siebers, 2008). In what follows, we discuss the "path" that a fuel element traces through the $\phi-T$ space (shown by the gray arrows in Figure 19) as the combustion process progresses. Similar descriptions, some of which address changes in the location of the soot and NO_x formation zones as combustion parameters are varied, have been provided by others (Denbratt, 2010; Golovitchev *et al*., 2007; Pickett *et al*., 2006). In general, the path is dictated by the relative magnitudes of the time-scale characterizing the rate of fuel–air mixing experienced by a fuel element and the time-scale characterizing the rate of heat release (temperature increase) due to combustion. Information on the relative magnitude of these time-scales can be obtained from the cross sectionally averaged mixing-rate model by Naber and Siebers (1996) and combustion time-scales predicted using detailed chemical kinetic mechanisms.

Initial fuel–air mixing time-scales are very short. For conventional diesel operating conditions, a "typical" fuel element reaches the lift-off length (point "A" in Figures 11 and 19) in less than 100 μs, at which point the cross-sectional average jet equivalence ratio may be ~4–5 and the temperature ~700 K. The fuel jet subsequently begins to entrain hot combustion products, and the temperature rise per unit of entrained mass can be expected to be roughly double that of a non-combusting jet. With the increased rate of temperature rise, the path of the fuel element departs from the adiabatic mixing line and reaches a threshold temperature of approximately 850 K at an equivalence ratio somewhat greater than 3 (point "B"). For temperatures above 850 K, the chemical heat release rate becomes significant, and the maximum flame temperature is reached in less than 100 μs (point "C"). Fuel–air mixing rates have dropped considerably by this time, and the equivalence ratio is expected to decrease by only about ~0.5 over this period if mixing rates are comparable to a non-combusting jet. Entrainment and mixing are generally impeded by heat release in burning jets, however, and the change in ϕ can be expected to be somewhat smaller. The essential point to recognize is that over the portion of the path from "B" to "C", the time-scales characterizing combustion are considerably smaller than the mixing time-scales, leading to the substantial departure of the path from the adiabatic mixing trajectory.

It is important to recognize that various fuel elements will be subject to stochastic variations in the rates they mix with ambient air or combustion products, and their ignition chemistry will also be impacted by mixing with and diffusion of radicals from mixture that is more advanced in the ignition process. Consequently, at ignition (~850 K), there will be a range of equivalence ratios in the downstream region of the jet, that have been measured to be in the range of 2–4 (Dec, 1997). This distribution is represented by the Gaussian curve sketched in Figure 19. As discussed in Section 4.3, with ambient temperatures of ~1000 K, the ignition delay times for mixtures with equivalence ratios between 2 and 4 are expected to be quite similar.

After the rich premixed combustion, fuel elements continue to mix with additional products of stoichiometric combustion from the diffusion flame, during which time the temperature increases and "ϕ" decreases ("C" to "D"). During this "mixing-limited" period, the process is represented by a path that is similar to the locus of maximum flame temperatures, as is indicated in Figure 19. More rigorous estimates of the temperatures (Pickett *et al*., 2006) experienced by a typical fuel element during this period indicate that temperatures would likely exceed the maximum flame temperature, as the products of combustion from the diffusion flame have not had sufficient time to undergo the relatively slow endothermic reactions that take place when they mix with the products of the rich premixed burn. The process is thus not truly limited by mixing rates, but is also impacted by finite-rate chemistry; higher temperatures are expected when mixing rates are high during this period.

An aspect of the combustion process that is missing from Figure 19 is the cooling of the in-cylinder gases that occurs during expansion, which will predominantly impact the mixing-limited portion of the combustion process. Expansion cooling will lower the maximum flame temperatures reached, and thus reduce both soot and NO_x formation. However, soot oxidation rates will also be impacted, and it is essential that the mixing process be completed before cylinder volume expansion slows chemical reaction rates excessively. The opposing effects of volume expansion, as

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

well as other combustion system parameters, on the relative rates of soot oxidation and NO_x formation give rise to the well-known soot-NO_x trade-off. Because the decay time of the turbulence created by the fuel jets is ~10 μs (a fraction of a crank angle degree), the turbulent mixing rates fall rapidly after the end of injection (EOI)—and completing the path from "C" and "D" with sufficient rapidity to avoid quenching of oxidation reactions by expansion can be challenging. Maintaining high "late-cycle" mixing rates, as discussed in Section 4.5, is essential.

At $\phi = 1$ (point "D"), the fuel oxidation is complete, but thermal NO_x production is near its peak due to the simultaneous presence of high temperatures and high oxygen concentrations. Because NO_x production persists even beyond $\phi < 1$, it is advantageous to maintain high mixing rates after combustion is complete. High rates of post-combustion mixing will cool the hot combustion products and will help reduce NO_x emissions. As discussed above, commercial combustion systems have been designed to accomplish this purpose.

5.2 Impact of design parameters

With this background, the impact of several combustion system design parameters on the combustion process can be clarified. To be able to do so more quantitatively, we will first discuss how the air entrainment scales with important parameters.

5.2.1 *Injection pressure*

As explained in Sections 4.1 and 4.2, the spatial structure of a non-combusting jet is not changed by changes in the injection pressure P_{inj}, as the air entrainment rate changes in proportion to the changes in the fueling rate. However, with increasing P_{inj}, the time-of-flight for a fuel element to reach a given axial location is shorter due to the higher injection velocity. While the physical mechanisms that determine the lift-off length are not yet well-understood, if the lift-off length is dominated by flame propagation processes, then higher jet velocities can be expected to "blow" the flame downstream. Conversely, if the lift-off length is determined by autoignition processes, then the decreased time-of-flight of a fuel element will likewise result in an increased lift-off length. In either case, leaner mixtures undergo premixed combustion and fewer soot precursors are formed. Beyond lift-off and ignition, increased mixing rates will reduce residence times in the soot forming regions, although temperatures may be higher. Overall, increased injection pressure is an effective method of reducing soot formation and subsequent emissions.

5.2.2 *Nozzle hole diameter*

Reducing nozzle hole diameter d_f is also an effective method of reducing the equivalence ratio at the lift-off length and hence soot formation. With smaller diameter holes, the spatial structure of the jet is significantly altered, such that lean mixtures are formed more quickly, at spatial locations closer to the nozzle. Although there is a concurrent shortening of the lift-off length—which, according to Equation 7, scales as $d_f^{0.34}$ (Pickett, Siebers, and Idicheria, 2005)—the more rapid mixing dominates. In addition to formation of leaner mixtures before the lift-off length, reduced nozzle hole size, like increased injection pressure, also impacts soot formation by decreasing the residence time in the soot/precursor formation regions (Pickett *et al*., 2006). With small enough nozzle holes, or a combination of small nozzle holes and increased injection pressure, it is possible to avoid soot formation entirely—even at relatively high ambient temperatures (Chartier *et al*., 2009b; Pickett and Siebers, 2004). The path indicated in Figure 19 by the dashed blue arrows is representative of what might be expected with a nozzle hole size of 50 μm and an injection pressure of 2000 bar. Measurements made under a variety of ambient temperatures, densities, and nozzle sizes confirm the expectation that soot formation will be eliminated under these conditions (Pickett and Siebers, 2004), although NO_x formation is expected to be high.

5.2.3 *Ambient density*

Both the fuel–air mixing rate and the lift-off length are impacted by changes in ambient density, which can be effected by varying intake pressure or r_c. Like smaller nozzle diameters, increased ambient density causes more rapid mixing and alters the spatial structure of the spray—leaner mixtures are formed when the ambient density is higher. Increasing the ambient density also shortens the lift-off length, which scales as $\rho_{amb}^{-0.85}$ (Equation 7). In this case, the impact of lift-off length dominates, and increased ambient density results in richer mixtures at the lift-off length and increased soot formation (Pickett and Siebers, 2004).

5.2.4 *Ambient temperature*

Ambient temperature has a much larger effect on the equivalence ratio at the lift-off length than ambient density, and is a powerful lever that can be used to impact the degree of premixing. For the conditions of Figure 19, a reduction in r_c from 20 : 1 to 16 : 1 would reduce the near-TDC temperature by approximately 75 K, leading to a reduction in ϕ at the lift-off length from ~5 to ~3.5.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Such a change would clearly have a significant impact on the intersection of the path of the combustion process with the soot formation region. Similar benefits can be expected through reduction of intake temperature.

Pickett and Siebers (2004) have shown that, using a combination of small nozzle diameters and reduced intake temperature, lean premixed combustion yielding near-zero soot and low NO_x can be achieved even at 21% O_2—as shown by the green arrows in Figure 19. A similar path can be achieved using very early injection, such that the fuel and air become fully premixed, although not necessarily homogeneous, at low temperature. The "typical" combustion path in this case enters from the lower left of Figure 19, and is labeled "homogeneous charge compression ignition (HCCI)." More information on HCCI combustion systems can be found in (Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot).

5.2.5 *Swirl*

Flow swirl can be expected to influence both the initial and the late-cycle mixing processes. An increase in flow swirl has been shown to generally increase the lift-off length, resulting in leaner mixtures and lower soot formation as indicated by reduced soot luminosity (Neal and Rothamer, 2012). The effectiveness of flow swirl in enhancing late-cycle mixing rates has been discussed above in the context of Figures 9 and 17. Like an increase in injection pressure, enhanced late-cycle mixing rates will reduce the residence time in soot forming regions along the path from "C" and "D" in Figure 19, thus likely reducing formation as well as increasing the rate of soot oxidation.

5.2.6 *Fuel properties*

As might be expected, fuel ignition quality, or cetane number, impacts lift-off length—shorter lift-off lengths are to be expected with low ignition delay fuels (Pickett, Siebers, and Idicheria, 2005). Fuel density also impacts mixing rates, although less strongly than ambient density. Lighter fuels form leaner mixtures close to the nozzle. The impact of fuel density on lift-off length has not been studied carefully, although there is no evidence to indicate that it will have a large effect.

5.2.7 *Effect of EGR*

Charge dilution with EGR (recirculated exhaust gas) also has a significant impact on both the fuel–air mixing process and the combustion kinetics. EGR is the foundation of in-cylinder NO_x control, although it is generally associated with an increase in soot emissions. We begin examining the impact of EGR by considering the path in the ϕ–T plane in a quasi-steady mode of combustion such as is shown in Figure 11. For near-full-load conditions, engines operate at a fuel/air equivalence ratio of about 0.7, and an EGR rate of 25% results in an intake $[O_2]$ of about 17%.

Because the diluted charge has a higher heat capacity for a given mass of O_2, during the initial adiabatic mixing process, the temperature is higher at a fixed ϕ. In addition, due to the additional diluent mass, longer mixing times are required to achieve a fixed ϕ. Both of these factors would seem to favor richer mixtures at the lift-off length. However, the lift-off length increases with the addition of EGR, such that ϕ at the lift-off length is very nearly the same as in the undiluted charge. Likewise, the relative rates of mixing processes and oxidation processes are expected to be similar for both ambient O_2 concentrations throughout the premixed burn—both rates are slowed by the presence of EGR. In the end, the path followed through the ϕ–T plane is likely to differ significantly only during the mixing-limited portion, represented by the solid gray line in Figure 19. Since dilution lowers the adiabatic flame temperature, this line will be displaced to the left.

On the basis of the lower temperature path followed with dilution, we might expect dilution to reduce both soot and NO_x formation. This expectation turns out to be only partially true. NO_x formation is certainly reduced, but while increased dilution slows soot formation rates, it increases the residence time in the soot forming regions by slowing the rate at which O_2 needed for soot oxidation is entrained. Moreover, the soot formation regions are shifted toward lower ϕ and T with charge dilution. This shift can be significant. For example, with no dilution, the production of pyrene (an important soot precursor) is 0.1% of the fuel mass with a ϕ of ~1.8 and a T of ~1850 K, whereas these limits move to ~1.3 and ~1700 K, respectively, when $[O_2]$ is reduced to 10% using EGR (Pickett *et al*., 2006). At moderate EGR rates ($[O_2] \gtrsim 15\%$), the net result is increased soot formation (Idicheria and Pickett, 2005). Only for the high EGR rates and/or the lower ambient temperatures employed for low temperature combustion strategies are both soot and NO_x formation reduced simultaneously.

5.3 Light-load operation

While the quasi-steady phase is short or nonexistent at the lower loads typical of light-duty engine operation, the spray physics and chemistry governing the formation of emissions are the same. This means that parameters that control the air entrainment into the fuel jets will affect the formation of soot and NO_x at light loads in roughly the same way as they do under quasi-steady conditions. Higher injection pressure,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

smaller nozzle holes, higher ambient density, and increased swirl all tend to increase fuel–air mixing rates, decreasing the soot formation in light-duty engines. Similarly, lowered ambient temperature slows the chemical rates, allowing still further premixing. While premixing can reduce both soot and NO_x formation, problems can arise with HC and CO emissions stemming from lean mixtures as well as with increasing combustion-generated noise. These problems are primarily addressed using multiple injection strategies, as described below.

A typical light-load heat release rate has an extended tail after the main heat release, well after the end of injection. This is the slow, mixing-controlled burn of combustion products formed earlier in the cycle, for example, soot and partial oxidation products—primarily CO. As previously mentioned, the main challenge at light loads is to maintain sufficient mixing rates after the end of injection to promote oxidation of these products. The advantages of enhanced late-cycle mixing are twofold. First, if the tail of the heat release is shifted toward TDC, the thermodynamic efficiency will increase as it allows for a greater effective expansion ratio. Second, the emissions will decrease as enhanced oxidation permits less partially oxidized products to survive into the exhaust port. Enhancing the late-cycle mixing rate is therefore an important method for reducing both soot emissions and fuel consumption at light loads.

A different approach to suppressing both soot and NO_x is to use so-called LTC (Low Temperature Combustion). This method is enabled by adopting low engine r_c and by the use of large portions of cooled EGR. These measures result in very extensive premixing by substantially extending the ignition delay. Another effect of the EGR dilution and lower compression temperature is that the peak combustion temperature is decreased, slowing both the soot and NO_x formation chemistry. LTC concepts using diesel-like fuel are usually restricted to light-load operation. This is due to the high level of dilution limiting the available air and thereby the attainable load, as well as the in-cylinder temperatures increasing with load and thereby shortening the ignition delays. Although LTC greatly reduces soot and NO_x emissions, CO and HC emissions are typically very high—as is combustion noise. LTC using diesel fuel will be described in greater detail in a separate section below.

6 MULTIPLE INJECTION STRATEGIES

Multiple injection strategies can have a number of variants, as depicted in Figure 20. One or more pilot injections of a small quantity of fuel can be employed before the main injection. When these pilot injections occur some tens of crank degrees before the main injection, they are often called *far pilots*, whereas "close" pilots—sometimes called *preinjections*—typically occur within a few crank degrees of the start of the main injection. A combination of both "close" and "far" pilots may also be used. At idle, there may be no "main" injection, just a sequence of small pilot injections. As a consequence of these numerous variants, the literature describing pilot injections is vast and confusing. Here, we provide only a brief introduction by considering just a single pilot injection.

Post injections similarly are described in a number of ways. A post injection (sometimes called an *after injection*) that is closely coupled to the main injection event is generally employed to reduce smoke emissions, as explained earlier. Post injection events can also be used with the primary purpose of controlling exhaust gas temperature or HC/CO content to support exhaust gas after-treatment devices. These latter injection events occur later in the cycle and do not significantly impact the main combustion event. Likewise, the main injection may be split into multiple components, with the objective of controlling combustion noise as well as soot. Below, we restrict our attention to close-coupled post injections, containing approximately 20% or less of the total fuel mass injected.

6.1 Pilot injections

The pilot injection, introduced in Section 4.4, is used to decrease the ignition delay of the main injection. Although

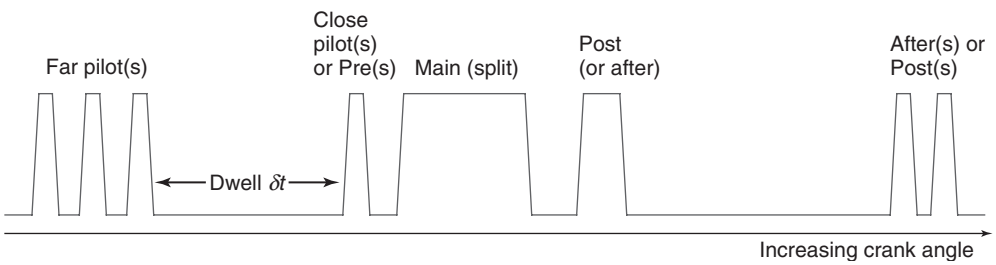

Figure 20. Definition of various injection events.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the details of the impact of the pilot injection on the main charge ignition process are not yet well-understood, modeling studies suggest that the initiation of the combustion is fundamentally changed from an autoignition process to a process resembling flame propagation, and that the nature of this change allows ignition and combustion in regions of the spray with high temperature and concentration gradients that could not otherwise support ignition (Hasse and Peters, 2005). The main impact of the reduced ignition delay is to decrease the amount of fuel–air premixing, and hence, the pressure rise rate and the acoustic noise generated during the main combustion. The pilot injection does not contribute much mechanical work and may even decrease the efficiency of the engine. Its main advantage is found in increased driving comfort, which is an important customer demand.

A second benefit of a reduced ignition delay is a reduction in overmixing of the main injection, which leads to light-load or cold-start HC and CO emissions. However, from the above discussion of the combustion process, it should be clear that increased soot emissions will also be expected when fuel–air premixing is reduced—an outcome that is almost universally observed. Pilot injections can also impact BSFC and NO_x emissions, as discussed below.

In addition to impacting ignition delay, pilot injections are useful for preventing excessive liquid penetration. With early injections, liquid fuel can impact the cylinder liner, resulting in excessive liner wear and oil dilution by the fuel (Dronniou *et al*., 2005; Oinuma *et al*., 2005). By employing multiple, short injections, liquid penetration can be reduced (Pickett, Kook, and Williams, 2009). Even when liquid impingement does not occur, however, limiting the penetration of the vapor phase may be advantageous. Reduced penetration and greater mixture stratification, due to the use of multiple short injections, are likely responsible for reduced HC emissions observed when piezo injectors are applied to low r_c engines (Tomishima *et al*., 2008).

Generally, ignition delay is shortened as the timing of a pilot injection approaches the main injection event or as the heat released from the pilot injection is increased (Badami, Millo, and D'amato, 2001; Carlucci, Ficarella, and Laforgia, 2003; Carlucci, Ficarella, and Laforgia, 2005; Park, Kook, and Bae, 2004). Consequently, light-load HC and CO typically decrease (Hotta *et al*., 2005; Kastner *et al*., 2006). With far pilots, over-penetration of the pilot fuel due to the low in-cylinder density and long mixing times can result in overly lean mixture, resulting in higher HC and CO emissions. Conversely, when the dwell time between the pilot and the main injection is too short, disruption of the pilot ignition process by the main injection event may cause overmixing of the pilot fuel, again increasing HC and CO. Consequently, a minimum HC and CO emissions is observed when the dwell between the pilot and main injection is $\sim 10^\circ$ (Kastner *et al*., 2006). It is unfortunate, then, that the increase in soot emissions is typically greatest with intermediate pilot-main dwell times, between roughly 5 and 20° (Badami, Millo, and D'amato, 2001; Hasse and Peters, 2005; Hotta *et al*., 2005; Kastner *et al*., 2006; Park, Kook, and Bae, 2004; Ricaud and Lavoisier, 2002). Soot emissions can be reduced again, however, with increased rail pressure (Ehleskog, Ochoterena, and Andersson, 2007; Ricaud and Lavoisier, 2002).

The impact of pilot-main dwell on NO_x depends on operating conditions and on the timing of the main injection, and reported results are also influenced by the specific optimization strategy employed or trade-off emphasized. Typically, however, a close-coupled pilot injection is associated with higher NO_x emissions (Hotta *et al*., 2005; Kastner *et al*., 2006), even above levels observed with a single injection (Chen, 2000; Hotta *et al*., 2005). Smaller pilots result in lower NO_x, but can increase BSFC and noise (Badami, Millo, and D'amato, 2001; Hotta *et al*., 2005). As the pilot injection is advanced, NO_x is generally reduced (Badami, Millo, and D'amato, 2001; Hotta *et al*., 2005), albeit at the potential expense of increased UHC, CO, or soot.

The physics responsible for the variation in NO_x emissions is not clearly understood, but the behavior is consistent with the expected effects of combustion phasing. When the timing of the main injection is fixed, the increase in ignition delay as the pilot is advanced retards the main combustion due to the increased ignition delay, which can be expected to reduce NO_x. Moreover, compared to the case with no pilot, combustion is advanced—which produces more NO_x as there is a greater period of time available for NO_x production before cylinder volume expansion reduces the temperature. Advancing combustion will also typically improve BSFC, and a BSFC/NO_x trade-off is observed. Well-optimized pilot injection strategies have been observed to improve the BSFC/NO_x trade-off (e.g., Ishida *et al*., 1994; Kastner *et al*., 2008).

6.2 Post injections

The mechanism by which post injections affect soot emissions is still not clearly understood, and it is not always true that post injections are beneficial. In a recent review article, O'Connor and Musculus (2013) present a compilation of data showing that under many circumstances, post injections can lead to up to an order of magnitude increase in soot emissions. Moreover, the impact of a post injection on soot cannot be considered in isolation—its impact on BSFC and NO_x, CO, and HC emissions must also be considered.

Nevertheless, it is generally accepted that with an appropriate post injection mass and timing, significant reductions

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in soot can be achieved without a significant adverse impact on fuel economy and other emissions—particularly at low-to-moderate speeds and loads (e.g., Ricaud and Lavoisier, 2002). Modest post injections of a few milligrams that occur within a few °CA of the main injection are usually found to be most effective (e.g., Vanegas *et al*., 2008; Yun *et al*., 2008; Barro *et al*., 2012; Beatrice *et al*., 2003), although they may increase NO_x (Beatrice *et al*., 2003; Badami *et al*., 2003) and adjustments in EGR rate may be required to simultaneously improve NO_x, BSFC, and soot (Hotta *et al*., 2005). Post injections that are too late or too large can increase BSFC, HC, and CO emissions (Chen, 2000; Badami *et al*., 2003); and post injections that are too close to the main have been reported to increase soot emissions (Badami *et al*., 2003; Yun *et al*., 2008).

Several mechanisms have been proposed to explain how a post injection can affect soot emissions, which have been summarized by O'Connor and Musculus (2013):

(1) The post injection enhances mixing rates which can reduce soot formation—by redistributing the fuel from the main injections into smaller and fewer fuel-rich zones—and late-cycle oxidation—by enhancing the rate at which soot laden mixture mixes with fresh O_2. Recall, however, that the possibility exists for a post injection to disrupt flow structures that are beneficial to late-cycle mixing. Such unintended consequences may be partially responsible for reports of increased soot when post injections are used.
(2) Local temperatures are increased as a post injection burns, which increase the kinetic rates of oxidation, may also be capable of reducing soot emissions. The effect of increased temperatures is very difficult to separate from the effects of increased mixing rates, which will also serve to raise the local temperature. Moreover, as discussed in the context of Figure 19, increasing the mixing rate of fuel-rich mixture with embedded soot can raise the temperature due to finite-rate chemistry effects.
(3) Variations in the overall fuel–air equivalence ratio distribution formed when post injections are used may also impact soot formation processes. Owing to a reduction in the mass injected in the main injection, leaner mixtures and reduced soot formation are expected. In this view, fuel from the post injection is thought to form less fuel-rich mixture, and hence form less soot, than if it had been injected along with the main injection.

Lastly, in the discussion of Figure 15, we noted that with a post injection, the mixing-controlled tail of the heat release curve is delayed, and efficiency is expected to decrease. This seems to contradict the studies cited above that report an improvement in both BSFC and soot when post injections are employed. In practice, however, the efficiency is often limited by NO_x constraints, which may call for a later than optimal phasing of combustion. Transferring part of the fuel from the main injection to the post injection decreases the NO_x formation associated with combustion of the main injection. The somewhat counterintuitive result is that the main injection can be advanced, simultaneously increasing the efficiency and decreasing PM for a given NO_x target level. Alternatively expressed, the post injection improves the NO_x-PM trade-off at a given efficiency level.

7 LOW TEMPERATURE DIESEL COMBUSTION PROCESSES

Diesel LTC processes employ extensive dilution of the combustible charge to keep peak combustion temperatures low and minimize NO_x formation. This is accomplished with either extensive premixing to lean equivalence ratios or through use of EGR. LTC systems also seek to minimize soot formation through increased premixing, although not necessarily to fuel-lean conditions.

With very early injection, all of the fuel can be premixed to fuel-lean conditions before the start of heat release. In this case, the phasing of the combustion process is determined by the kinetics of the ignition process—it is decoupled from the timing of the injection event. Early injection can present problems associated with fuel impingement on the cylinder walls, and special fuel injection hardware and atypical diesel combustion chamber geometries are often employed to alleviate these problems. Examples of diesel combustion systems that employ very early-injection strategies have been reviewed by Dec (2003).

Our focus is on low temperature combustion systems that use more conventional diesel engine hardware and that allow some degree of control of the combustion phasing through selection of the fuel injection timing. Generally, this restricts the injection timing to within about 30° of TDC. Within this restriction, we can further subdivide LTC systems into early- and late-injection strategies. Early-injection strategies attempt to achieve a large degree of premixing by injecting into the cool cylinder gases at ~30° before TDC. Extensive charge dilution with EGR is used to delay ignition and to control the maximum pressure rise rate (combustion noise). In contrast, late-injection strategies typically inject fuel near or shortly after TDC. EGR rates are generally lower, and due to the higher near-TDC temperatures and densities, as well as the decreased dilution, the ignition process commences more quickly than with early-injection strategies. However, the slowing of the ignition kinetics by cooling due to volume expansion allows

increased premixing before high temperatures characteristic of soot and NO_x formation are achieved, and also moderates the pressure rise rate. For this reason, late-injection systems have been called *modulated kinetics (MK)* combustion systems by their initial developers (Kimura *et al*., 2001; Kimura *et al*., 1999). Modern, low NO_x engine calibrations often employ injection timings and EGR rates that are similar to late-injection LTC strategies. Both strategies are currently useful over only limited speed and load ranges; accordingly, the description provided below is typical of the combustion process under the light engine loads characteristic of the lower half of the loads experienced in an urban drive cycle.

The significant impact of injection timing, and the coupling between the chemistry of oxidation and the engine compression and expansion processes, is illustrated in Figure 21 for a moderately lean mixture with $\phi = 0.7$. Although at first glance, the evolution of the combustion process appears to be considerably different for early- and late-injection strategies, there are substantial similarities.

At low temperatures, the various stages that occur in the ignition and oxidation processes become distinct, and are separated in time by several crank degrees. The first stage of ignition, occurring at temperatures near 850 K, occurs after about 0.5 ms in the early-injection case. With late injection, ignition is advanced due to the higher temperatures and densities at the time of injection. These early reactions produce important combustion intermediates (H_2CO, H_2O_2, and CO among others) that drive the later stages of heat release. After the first stage of ignition, the heat release rate decreases and the temperature rises more slowly. With early injection, the rate of temperature rise gradually increases until at ~1000 K a second, rapid period of heat release occurs. At this time, the remaining UHCs and combustion intermediates are partially oxidized to form CO. The onset of this second, higher temperature period of heat release is considered to be the main ignition event. As temperatures and the OH radical pool rise, the CO is quickly oxidized and NO_x formation increases. Notice that even after completion of combustion, NO_x formation continues due to the high temperature, as was discussed in Section 5.1.

With late injection, the sequence of events is the same, but occurs at very different rates. After the first-stage ignition, the local gas temperature actually decreases slightly due to the expanding cylinder volume. However, beyond about 0.8 ms, the heat release rate begins to increase monotonically. The decreasing rate of temperature rise observed near 1 ms is thus due to the increasing importance of volume expansion, which largely counterbalances the heat release beyond 0.9 ms. Later, beyond 2 ms, the heat release becomes more dominant, the temperature rises more rapidly, and CO formation increases—as seen

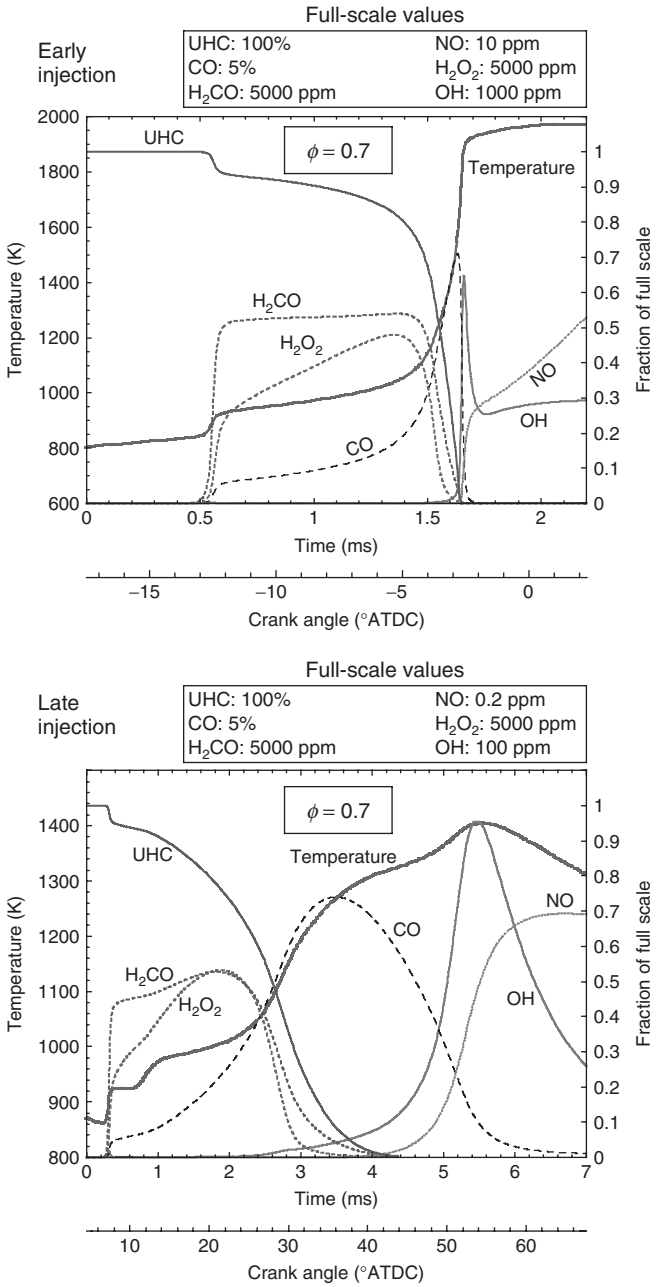

Figure 21. Comparison of the oxidation process for early- and late-injection LTC strategies. The temperatures and species concentrations were simulated using a detailed kinetic mechanism (Lawrence Livermore National Laboratory, 2013) for *n*-heptane mixed with a 12.7% O_2 ambient charge. The pressure was constrained to follow a measured cylinder pressure trace typical of each combustion strategy. (Adapted from Musculus, Miles, and Pickett (2013). © Elsevier.)

also with early injection. Nevertheless, volume expansion significantly delayed the main ignition and slowed the heat release rate and associated pressure rise rate appreciably. The final stages of combustion are also slowed, and the CO oxidation rate, which is highly dependent on the OH concentration, is significantly lower. The low OH concentrations present with late injection will also likely slow the oxidation of soot.

With this understanding of the temporal progress of combustion, the spatial structure of the reacting jet under LTC conditions, which is illustrated in Figure 22, can be more easily understood. Despite the differences in the temporal evolution seen in Figure 21, the spatial structure of the jet does not differ greatly between early- and late-injection strategies, and only a single picture is required. For typical, light-load LTC operation, the duration of the fuel injection process is less than the ignition delay, and a quasi-steady period does not exist. Accordingly, rather than showing a "path" followed by a fuel element through a steady jet, we show the progress of the transient combustion at several times during the combustion event.

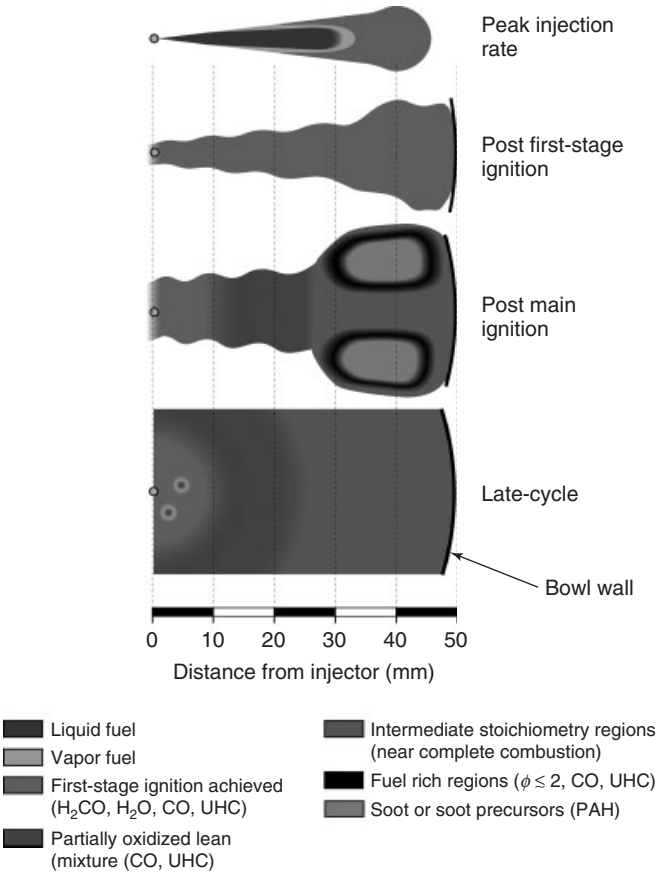

Figure 22. Heavy-duty low temperature diesel combustion at light load. (Adapted from Musculus, Miles, and Pickett (2013). © Elsevier.)

As with conventional diesel combustion, the process starts with the initial penetration of liquid fuel into the gases. For early-injection LTC, the fuel jet penetrates faster and further into the lower temperature, less dense ambient gases, and the maximum liquid penetration observed (~30 mm or more) is somewhat longer than for conventional or late-injection timings. Beyond this "liquid length," the vapor phase fuel continues to penetrate downstream, and if sufficient time has elapsed, undergoes first-stage ignition reactions. These initial reactions are observed to occur nearly simultaneously throughout the fuel vapor, in both rich and lean regions.

As the end of injection approaches, a second important process occurs. The decreasing injection rate creates a mass flux deficit near the injector, and conservation of mass dictates that ambient gas entrainment must therefore increase. The increased entrainment further reinforces the mass flux deficit and drives yet more entrainment (Musculus and Kattke, 2009). This increased entrainment near the end of injection process helps vaporize the remaining liquid and leads to the rapid formation of very lean fuel–air mixtures near the injector, which soon undergo first-stage ignition. Although this process also occurs under conventional diesel combustion, the flame surrounding the jet rapidly propagates toward the injector at the end of injection and prevents the formation of over-lean mixture.

After the first stage of ignition, the temporal evolution of the combustion process depends very strongly on the local equivalence ratio, the degree of dilution, and the injection timing. If the mixture is overly lean ($\phi \lesssim 0.2$–0.7, depending on injection timing and EGR rate), the combustion process is unable to progress beyond the first stage of ignition. Consequently, as shown in Figure 22, UHC, CO, and combustion intermediates persist in the very lean mixture near the injector. For somewhat richer mixtures, combustion progresses further and the UHCs and combustion intermediates are partially oxidized to form CO. However, if the temperature achieved is not sufficiently high, the CO cannot be fully oxidized in the available time before cylinder temperatures drop excessively due to expansion.

Still richer mixtures, characterized by intermediate equivalence ratios near unity, achieve high enough temperatures to enable the second, rapid period of heat release that results in nearly complete combustion. However, if $\phi > 1$, there is insufficient O_2 available to fully oxidize the CO. These intermediate stoichiometry regions are found in the downstream regions of the jet, as shown in Figure 22. Lastly, for sufficiently fuel-rich mixtures, typically found in recirculation zones near the head of the jet or in regions where

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

adjacent jets interact, soot precursors and soot are formed in the period following the high temperature heat release.

As the expansion stroke proceeds, fuel-rich regions mix with leaner regions and the embedded CO, UHC, and soot are oxidized. Lean regions may also mix with hot products of richer combustion, partially oxidizing the remaining products of first-stage ignition. Because the global, in-cylinder equivalence ratios are generally quite lean, however, this is far less probable than the leaning of fuel-rich regions through additional mixing, and extensive regions of UHC, CO, and other partial combustion products remain in the central regions of the cylinder. Fuel droplets that dribble from the injector late in the cycle are also observed near the cylinder center, and likely contribute to engine-out UHC and CO emissions. Additional details are provided by Musculus, Miles, and Pickett (2013) and the references therein.

For light-duty diesel engines, the combustion proceeds in a very similar manner, although the interaction of the fuel jets with the combustion chamber walls adds additional complications, and leads to differences in the way the combustion process unfolds that depend on the injection timing. Consequently, a separate illustration is provided for early- and for late-injection strategies relevant for light-duty engines in Figure 23. The uppermost row of images in Figure 23 illustrates the interaction of the fuel spray with the piston bowl at a time approaching the end of injection, when increased entrainment is acting to rapidly vaporize the remaining liquid fuel. With early injection, the liquid fuel typically impacts the bowl lip and spreads into both the squish volume and the bowl. In contrast, with late injection, the maximum liquid length is ~20 mm, and significant liquid impingement does not occur.

The delay until the first-stage ignition reactions occur depends on the in-cylinder conditions and fuel type. In the second row of images in Figure 23, we choose to illustrate a case in which the first-stage ignition reactions do not occur until after the end of injection. At this time, most of the liquid has been vaporized, although in the early-injection case, there is evidence of liquid films on the piston top. Large fuel droplets frequently observed near the piston rim may be formed as the flow out of the squish volume shears off liquid from these films.

Shortly after much of the fuel jet achieves second-stage (main) ignition, over-lean mixture containing UHC, CO, and other partial oxidation products remains near the injector, as seen previously in Figure 22. With early injection, the region of over-lean mixture is larger and reaches to the bowl wall. Hence, separate regions of intermediate stoichiometry are seen—one in the squish volume and a second deep in the bowl. Soot is observed forming in rich mixtures near the head of the jet in the bowl, whereas additional over-lean mixture is seen near the tip of and between the jets in the squish volume. Although fuel-rich mixture is measured within the squish volume at the start of second-stage heat release (Petersen, Miles, and Sahoo, 2012), equivalence ratios are sufficiently low that significant soot or PAH is not formed.

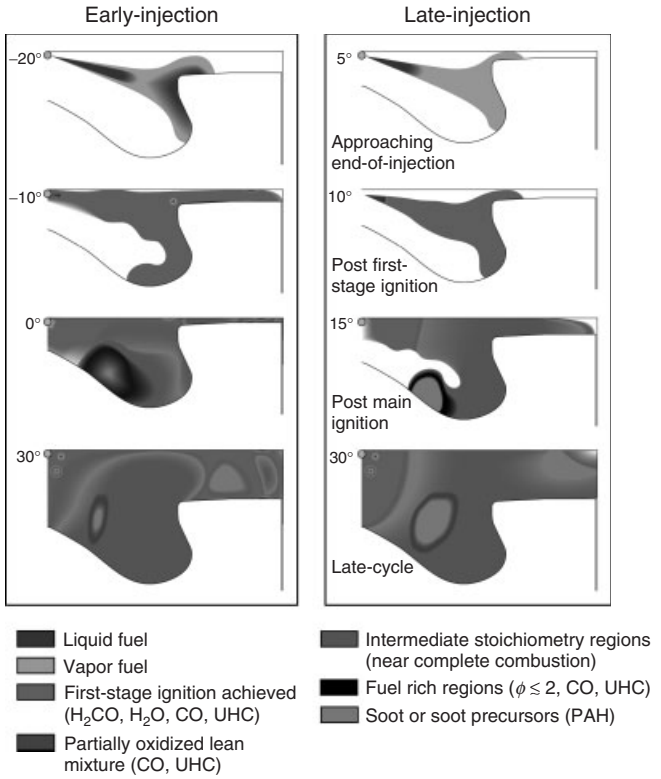

Figure 23. Illustrations of light-duty LTC progress. Separate illustrations are provided for early- and late-injection combustion systems due to differences in the way the fuel jet interacts with the combustion chamber surfaces. (Adapted from Musculus, Miles, and Pickett (2013). © Elsevier.)

With late injection, over-lean mixture is confined closer to the cylinder center, and near complete combustion occurs throughout much of the fuel jet. Owing to the retarded timing, more fuel enters the bowl, and richer mixtures leading to more soot formation than seen in the early-injection case are observed. Although the fuel jets do not initially penetrate far into the squish volume, they are displaced outward as the products of the intermediate stoichiometry combustion from near the bowl lip are drawn in by the reverse squish flow. Mixtures formed within the squish volume are too lean to support soot formation, and over-lean mixture is again observed near the tip of and between the jets (Miles, Petersen, and Sahoo, 2012).

Unlike the late-injection case, the mixture that is drawn into the squish volume with early injection consists largely

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto120
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the first-stage ignition products from the over-lean, upstream regions of the fuel jets. Thus, UHC and CO observed within the squish volume late in expansion stem from both upstream as well as downstream regions of the jet; with late injection, only downstream regions are likely to contribute to emissions within the squish volume. In both cases, like the heavy-duty case, over-lean mixture is also found in the central region of the cylinder, where fuel drops are likewise observed. A discussion of the combustion paths through the ϕ–T map for early- and late-injection combustion systems is provided by (Kook *et al*., 2005).

7.1 Influence of equivalence ratio and combustion temperature

From the temporal progress and physical structure of LTC combustion discussed above, it is apparent that while LTC strategies can significantly reduce NO_x and soot emissions, low temperatures and over-lean mixtures can lead to significant UHC and CO emissions. Figure 24 presents the yield of UHC and CO predicted for the same constant temperature and pressure conditions as the soot and NO_x regions which have been previously presented in Figure 19. Although we expect that emissions of UHC and CO will also depend on the dilution rate and the fuel injection timing, the contours shown in Figure 24 provide a good qualitative indicator of the equivalence ratio and combustion temperature ranges that are likely to lead to UHC and CO emissions.

Figure 24 shows that the yield of UHC is high for all ϕ when the temperature is low. For temperatures below ~750 K, fuel breakdown occurs so slowly that little or no CO is formed. Hydrocarbons trapped in combustion chamber crevices suffer this fate. UHC remains high as the temperature increases from 750 to about 1000 K, although partial oxidation forms substantial amounts of CO. This region of the ϕ–T map represents over-lean mixtures formed at the edges and tail of the fuel jets, or richer mixtures formed as hydrocarbons out-gas from crevices or leak from the injector late in the cycle when the cylinder temperatures have dropped. At temperatures above about 1000 K, and for $\phi \lesssim 2$, the UHC is rapidly consumed and CO rises. Recall that this is the temperature at which the rapid, second-stage ignition processes begin—as was seen previously in Figure 21. For lean to moderately rich mixtures ($\phi \lesssim 1.3$), if the temperature exceeds 1200–1300 K, the partial oxidation of hydrocarbons to CO is sufficiently rapid and UHC yield is very low, even for the rich mixtures. CO oxidation is slower however, and temperatures above 1450–1500 K are required to fully oxidize CO (Sjöberg and Dec, 2005).

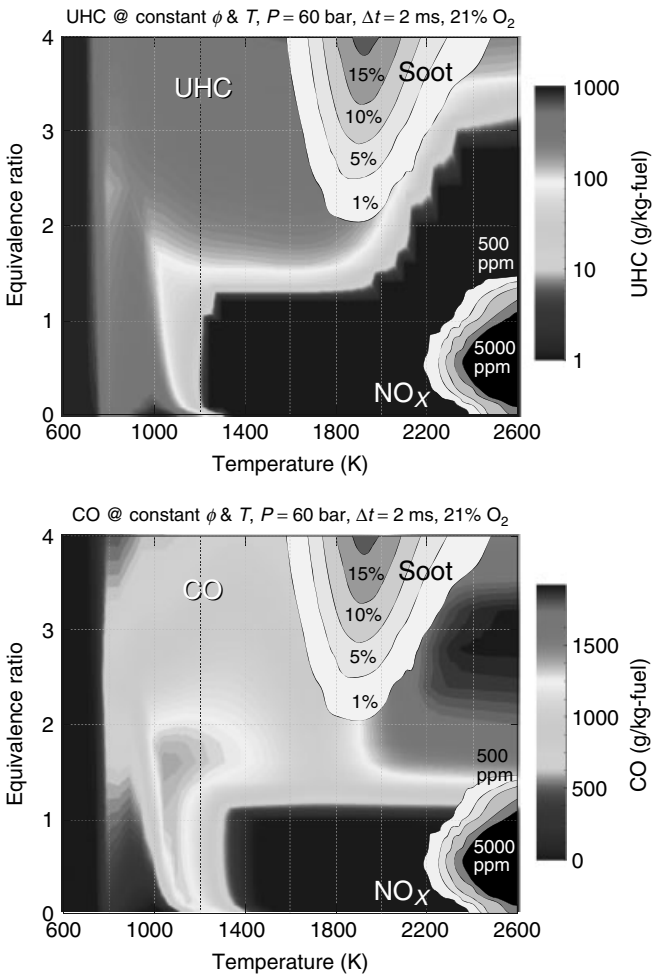

Figure 24. Yield of UHC and CO at constant ϕ, T, and P predicted using a detailed n-heptane kinetic mechanism (Lawrence Livermore national Laboratory, 2013).

The low UHC observed for mixtures with $\phi \lesssim 1.3$ invites comment. At these equivalence ratios, the remaining partial oxidation products are primarily H_2 and CO. Only at equivalence ratios greater than about 1.3 is there significant UHC in the product gases—and then combustion simulations indicate that the UHC is restricted primarily to three species: CH_4, C_2H_4, and C_2H_2. It is not until the equivalence ratio approaches 2 that significant quantities of PAH are formed, in agreement with the soot formation predictions. CO, of course, is present for all $\phi > 1$. Consequently, when adequate bulk-gas mixing is not achieved in the cylinder, CO emissions are likely to be impacted more severely by over-rich mixture than UHC emissions. Additional information regarding CO and UHC emissions is provided in (UHC and CO Formation and Models).

In summarizing this section, we reiterate that low temperature combustion strategies using diesel-like fuels are

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

currently only applicable at light loads. Because soot and NO_x are more problematic at high loads, and HC and CO are of lesser concern due to the higher average cylinder equivalence ratios and temperatures, there is great interest in extending LTC strategies to higher loads. Moreover, there is a natural synergy between LTC strategies and the use of pilot injections, which alleviate excessive combustion noise and UHC and CO emissions through a shortening of the main ignition delay. Although shortening the ignition delay will reduce the premixing characteristic of LTC strategies, high EGR rates and the maintenance of high mixing rates late in the cycle can mitigate the tendency toward increased soot production (Kitamura and Ito, 2010). Considerable work remains to be done in this area.

8 SUMMARY

In this chapter, we have attempted to review the practical design considerations impacting diesel combustion systems and to link them with a fundamental description of the various physical and chemical processes that take place in diesel engines. In the past two decades, significant advances in our fundamental understanding have allowed us to better understand how design and operating parameter choices such as combustion chamber geometry, fuel injection nozzle geometry, fuel injection pressure, and in-cylinder flows impact engine performance and emissions. This understanding has two main benefits. First, it provides combustion system designers with a mental picture to guide their thinking as they attempt to solve problems or optimize certain aspects of the combustion process. Second, it supports the development of more accurate simulation tools that can be used to iteratively optimize engines when human engineering judgment and intuition is insufficient.

The development of accurate simulation tools is particularly important. As we believe has been made clear in this chapter, the multiple interactions between design variables and chemical and physical processes makes the achievement of an optimal design a formidable task. Moreover, the basic design cannot be divorced from the calibration process—that is, the selection of specific settings for the swirl ratio, injection pressure, EGR rate, intake pressure and temperature, injection schedule, and so on, that is employed at each speed, load, and unique set of ambient conditions. An example of this interaction is the design of a bowl geometry to enhance late-cycle mixing. Such a design is clearly dependent on fuel injection parameters that vary from one operating condition to the next, such as injection pressure, injection timing, and the use of pilot and post injections. Ultimately, an optimal design will be a compromise based on a wide range of anticipated operating conditions.

Although significant progress has been made, it is apparent that for many aspects of the design process, both our understanding and the accuracy or speed of current simulation tools is not yet sufficient. Nevertheless, the substantial advantages that diesel engines offer with regard to efficiency, and their certain widespread use for decades to come, provide strong motivation to continue this task.

ACKNOWLEDGMENTS

This work was performed at the Department of Energy Sciences of Lund University in Lund, Sweden, and at the Combustion Research Facility, Sandia National Laboratories in Livermore, California, with support provided by the Swedish Energy Agency, the United States Department of Energy (Office of Vehicle Technologies), and by General Motors Corporation (agreement # FI083070326). Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000. Pressure and Heat Release Analysis

Jaal B. Ghandhi
University of Wisconsin-Madison, Madison, WI, USA

1 INTRODUCTION

The pressure in the cylinder of an internal combustion engine determines the net work transfer to the crankshaft and is, thus, the critical parameter that defines an engine's overall performance. The cylinder pressure, however, is affected by several processes including changes in cylinder volume, heat transfer to the combustion chamber surfaces, mass loss from the combustion chamber due to blowby, mass addition due to fuel injection, and the chemical processes occurring within the gases of combustion chamber. It is this latter quantity that represents the combustion performance of the engine and the thermodynamic analysis used to isolate it is referred to as *heat release analysis*.

The application of thermodynamic principles to the cylinder contents requires a set of simplifying assumptions that will have a strong bearing on the calculated quantities. It is, therefore, important to always keep these assumptions, and their validity, in mind while assessing the results. For example, for diesel engine combustion, where large property gradients are known to exist, the contents of the cylinder are often assumed to be uniform and in thermodynamic equilibrium to allow a tractable analysis. The discrepancies between the model assumptions and reality are important, but very difficult to quantitatively put bounds on. The individual must, therefore, use appropriate caution in their interpretation of the results, especially when comparisons are being made in absolute terms across different engine platforms. One goal of this chapter is to expose and highlight the model assumptions to prepare end users for the proper interpretation of the results.

This chapter is structured based on the fundamental assumption of how the combustion chamber gases are treated in the thermodynamic analysis. Multizone models, where the chamber contents are segregated into (typically two) zones, are discussed first. These models identify the burning rate as the rate at which mass is transferred from the reactant zone to the product zone. Single-zone models that treat the cylinder contents as homogeneous in composition and temperature and are easier to apply than multizone models are discussed second. Finally, approximate methods are discussed. The multi- and single-zone approaches attempt to use a rigorous thermodynamic treatment of the gas properties and, within their assumptions, are quantitative. The approximate methods rely on polytropic fits to the data and are thus not considered to provide absolute quantities.

The topic of heat release calculation has received extensive discussion in the past literature, for example, Krieger and Borman (1966), Gatowski *et al*. (1984), and Foster (1985). This work builds on that knowledge, but does not attempt to comprehensively review it.

2 MULTIZONE MODELS

In principle, the combustion chamber gases can be assigned to N zones of uniform composition and temperature, with each zone considered to be in thermodynamic equilibrium. In practice, the utility of this physical model is that it approximates the spark-ignition engine well, where the flame separates the burned gas at high temperature with equilibrium products from the unburned gas at the reactant composition. Thus, the discussion herein is restricted to a two-zone model comprised of burned and unburned zones, identified by subscripts b and u, respectively.

The First Law applied separately to each zone, with a rate of mass transfer between the two zones that represents the rate of conversion of reactants to products, is given by

$$\frac{\mathrm{d}(m_\mathrm{b}u_\mathrm{b})}{\mathrm{d}t} = \dot{Q}_\mathrm{w,b} - p\frac{\mathrm{d}V_\mathrm{b}}{\mathrm{d}t} + h_\mathrm{b}\frac{\mathrm{d}m_\mathrm{b}}{\mathrm{d}t} \tag{1}$$

$$\frac{\mathrm{d}(m_\mathrm{u}u_\mathrm{u})}{\mathrm{d}t} = \dot{Q}_\mathrm{w,u} - p\frac{\mathrm{d}V_\mathrm{u}}{\mathrm{d}t} + h_\mathrm{b}\frac{\mathrm{d}m_\mathrm{u}}{\mathrm{d}t} \tag{2}$$

where m is the mass, u is the internal energy, $\dot{Q}_\mathrm{w}$ is the wall heat transfer to the system, p is the cylinder pressure, V is the volume, and we have used the fact that the flame is occurring at constant pressure so that $h_\mathrm{u} = h_\mathrm{b}$, where h is the specific enthalpy. Equations 1 and 2 are written in terms of temporal derivatives but can be converted to crank angle-based derivatives using the rotational speed of the engine. The solution of Equations 1 and 2 for the mass burning rate is subjected to constraints on the total volume and mass

$$V_\mathrm{u} + V_\mathrm{b} = V \tag{3}$$

$$m_\mathrm{u} + m_\mathrm{b} = m \tag{4}$$

where the unsubscripted quantities represent the total cylinder conditions. It should be noted that in the development of Equations 1 and 2 it has been assumed that there is no heat transfer between the burned and unburned zones and that there is no mass loss to crevice volumes. The former assumption is justified by the treatment of the flame, but the latter assumption is necessitated because of the difficulty of assigning a proportion to each zone.

By measuring the cylinder pressure and knowing the kinematic relationship for total cylinder volume, the solution of Equations 1–4 is possible provided that thermodynamic property data are available for u and h and that a valid correlation for the heat transfer rate is available.

It is important to note that there is no identified "heat release" in this analysis. In fact, the heat release comes about by the chemical conversion of reactants to products. Thus, the internal energy and enthalpy must be represented as their absolute values, that is, the internal energy of species i is $u_i = \Delta u^\circ_{\mathrm{f},i} + u^\mathrm{s}_i$ where $\Delta u^\circ_\mathrm{f}$ is the internal energy of formation and $u^\mathrm{s} = \int c_v \mathrm{d}T$ is the sensible internal energy with constant-volume specific heat c_v and temperature T. The heat release comes about due to the conversion of chemical to sensible energy. The evaluation of the thermodynamic properties also requires an equation of state for the determination of the temperature. The ideal gas equation of state is used, and its applicability will be assessed later.

Each zone is considered to be in thermodynamic equilibrium. For the unburned zone, the composition is frozen at the reactant state, but the internal energy changes with the changes in temperature (consistent with the ideal gas assumption) and $\frac{\mathrm{d}u_\mathrm{u}}{\mathrm{d}T} = \frac{\mathrm{d}u^\mathrm{s}_\mathrm{u}}{\mathrm{d}T} = c_\mathrm{v,u}$. The burned gas composition, however, varies with time; the composition follows a shifting equilibrium. The equilibrium state is affected by both temperature and pressure, and, therefore, $u = u(p, T)$ in spite of the fact that the gas is considered an ideal gas. Further, the changes in composition affect the total amount of chemical energy, so $\frac{\mathrm{d}u_\mathrm{b}}{\mathrm{d}T} \neq \frac{\mathrm{d}u^\mathrm{s}_\mathrm{b}}{\mathrm{d}T}$ and $\frac{\mathrm{d}u^\mathrm{s}_\mathrm{b}}{\mathrm{d}T} \neq c_\mathrm{v,b}$ as both neglect the change in composition and the former neglects the change in chemical energy.

An assessment of the validity of the ideal gas assumption and the necessity of accounting for the shifting equilibrium of the product composition is shown in Figure 1, which shows a pressure–temperature map with contours of the compressibility factor Z (solid) and $\alpha \equiv \frac{\mathrm{d}h_\mathrm{b}}{\mathrm{d}T}/c_\mathrm{p;b}$ (dashed)—the meaning of α is discussed later and $c_\mathrm{p,b}$ is the burned gas constant-pressure specific heat. The data points superimposed on the plot arise from a two-zone model prediction of the unburned (open symbols) and burned (filled symbols) states for a low load (squares) and high load, pressure-charged (circles) condition. The compressibility factor was calculated for a mixture of ideal stoichiometric combustion products (CO_2, H_2O, N_2) using the Peng–Robinson equation of state (Klein and Nellis, 2012). It can be seen in Figure 1 that, as expected, the compressibility factor deviates from unity the most at low temperatures and elevated pressures. As can be seen from the two limiting engine cases, the largest deviation from ideal gas behavior is $Z = 1.03$, and, therefore, the use of the ideal gas equation of state for this global analysis is justified.

The parameter α describes the importance of the shifting equilibrium composition. The numerator was calculated by finding the equilibrium composition and the corresponding absolute enthalpy at a grid of temperature and pressure, then numerically calculating the derivative with respect to temperature at fixed pressure; the denominator was directly evaluated as $\sum y_i c_{\mathrm{p},i}$. For $\alpha > 1$, the shifting composition

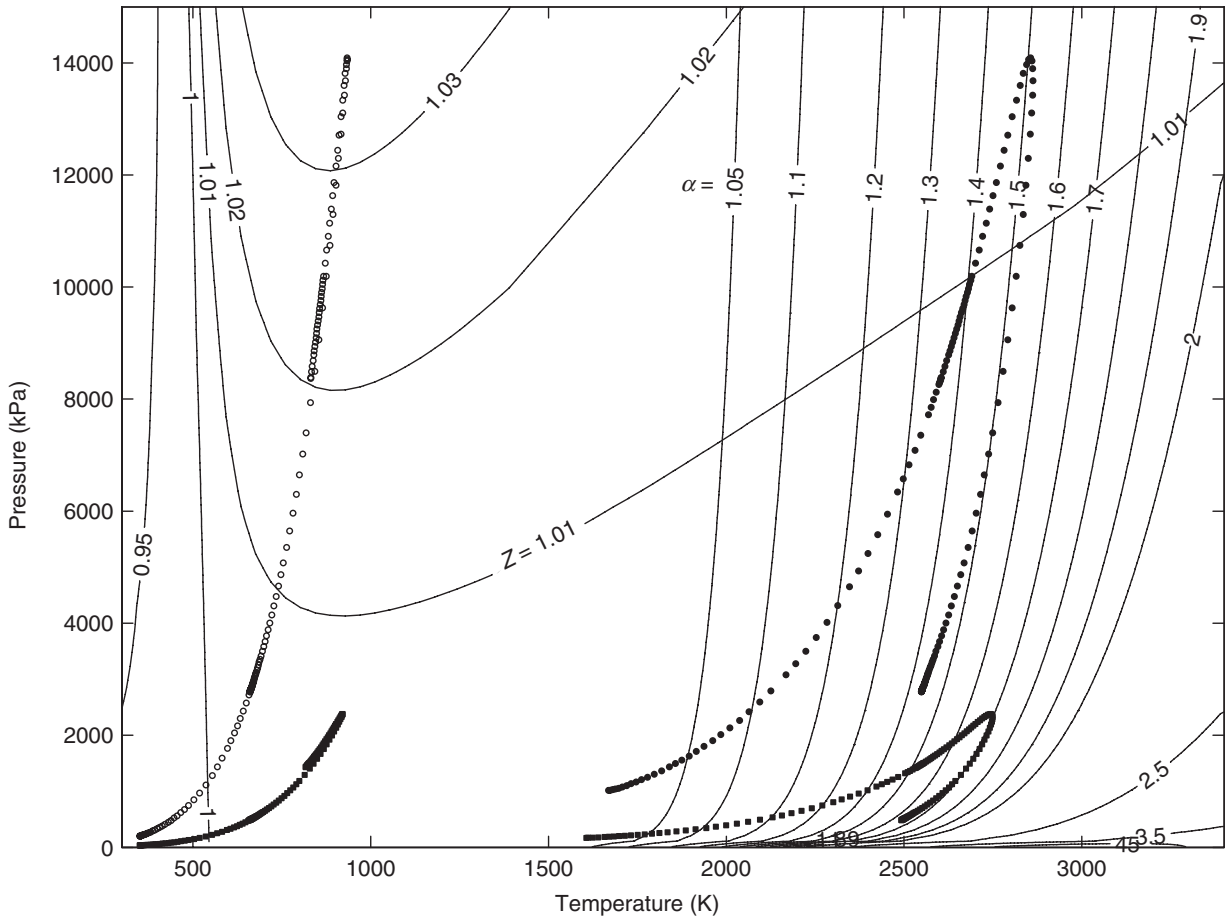

Figure 1. A comparison of the compressibility factor Z (solid) and the quantity α (dashed—see text for definition) as a function of pressure and temperature. Calculations are for a stoichiometric isooctane–air mixture. The data symbols show unburned (open) and burned (filled) states for a low load, stoichiometric condition (squares), and a high load, rich condition (circles).

of the system is significant and materially affects the relationship between enthalpy and temperature, that is, the ideal caloric gas assumption that $h = h(T)$ is insufficient. It can be seen in Figure 1 that for temperatures greater than $\sim$1800 K the magnitude of the iso-α contours are significantly larger than one. Further, the contours are seen to have significant positive curvature, which is an indication of the importance of pressure on the shifting equilibrium and highlights the need to include the pressure dependence in the thermodynamic property calculations. Finally, it can be seen that the burned engine states shown on the figure fall in the regions of $1 \leq \alpha \leq 1.7$, and thus, it is necessary to include the effect of the shifting equilibrium in the calculation of $\frac{\mathrm{d}u_\mathrm{b}}{\mathrm{d}T}$.

On the basis of this information, the necessary equations required to close the problem are the statement of the ideal gas law for the burned and unburned zones and the property relations. The ideal gas equations in differential form for the burned and unburned zones are

$$V_\mathrm{b}\frac{\mathrm{d}p}{\mathrm{d}t} + p\frac{\mathrm{d}V_\mathrm{b}}{\mathrm{d}t} - m_\mathrm{b}R_\mathrm{b}\frac{\mathrm{d}T_\mathrm{b}}{\mathrm{d}t} + \frac{m_\mathrm{b}R_\mathrm{b}T_\mathrm{b}}{W_\mathrm{b}}\frac{\mathrm{d}W_\mathrm{b}}{\mathrm{d}t} - R_\mathrm{b}T_\mathrm{b}\frac{\mathrm{d}m_\mathrm{b}}{\mathrm{d}t} = 0 \qquad (5)$$

$$V_\mathrm{u}\frac{\mathrm{d}p}{\mathrm{d}t} + p\frac{\mathrm{d}V_\mathrm{u}}{\mathrm{d}t} - m_\mathrm{u}R_\mathrm{u}\frac{\mathrm{d}T_\mathrm{u}}{\mathrm{d}t} + \frac{m_\mathrm{u}R_\mathrm{u}T_\mathrm{u}}{W_\mathrm{u}}\frac{\mathrm{d}W_\mathrm{u}}{\mathrm{d}t} - R_\mathrm{u}T_\mathrm{u}\frac{\mathrm{d}m_\mathrm{u}}{\mathrm{d}t} = 0 \qquad (6)$$

where W is the molar mass and R is the specific gas constant ($R \equiv R_\mathrm{u}/W$). It is important to note that the molar mass can change significantly between the reactants and products (discussed more fully later). As previously stated, the effect of pressure shifts the composition and thus $W = W(p,T)$, which gives

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto122
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$\frac{dW_b}{dt} = \frac{\partial W_b}{\partial T_b}\frac{dT_b}{dt} + \frac{\partial W_b}{\partial p}\frac{dp}{dt} \quad (7)$$

$$\frac{dW_u}{dt} = \frac{\partial W_u}{\partial T_u}\frac{dT_u}{dt} + \frac{\partial W_u}{\partial p}\frac{dp}{dt} \quad (8)$$

where the last equation is trivial for the present example as the composition of the unburned zone is fixed. Collectively, Equations 1–8, along with the measured pressure and volume, provide the relations necessary to calculate the temporal history of mass, temperature, volume, and molar mass of the burned and unburned zones.

The solution of these differential-algebraic equations can be achieved using existing software packages, and property data are available from detailed kinetic mechanisms (see Fundamental Chemical Kinetics). The result of the calculation procedure is the mass burning rate, $\dot{m}_b$, where the over dot represents the time rate of change, which can differ from an energy conversion rate. In the remainder of this chapter, three test cases will be followed. The test cases were computed using a two-zone model with a prescribed mass burning rate given by a Wiebe function (see Zero- and One-Dimensional Methodologies and Tools). Synthetic model data were used because they allow all of the parameters to be known to full precision as compared to using engine data directly for which there are experimental uncertainties in all of the parameters. The three test cases are shown in Table 1 and represent (1) a light-load spark-ignition condition; (2) a high load, heavily boosted spark-ignition condition; and (3) a light-load, lean, low temperature combustion condition. Cases 1 and 2 were shown in Figure 1.

Figure 2 shows a comparison between the mass burning rate and the energy conversion rate as a function of crank angle for all three cases. The mass burning rate is given by $\frac{dy_m}{d\theta} = \frac{\dot{m}_b}{m}$. The energy conversion rate is defined as the rate of change of chemical internal energy, $u^c \equiv \sum y_i \Delta u^\circ_{f,i}$, normalized by the total energy released

$$\frac{dy_c}{d\theta} = -\frac{1}{y_f \eta_c \mathrm{LHV}}\frac{du^c}{d\theta} \quad (9)$$

where y_f is the fuel mass fraction in the reactant mixture, η_c is the combustion efficiency and LHV is the fuel's lower heating value, and the negative sign is needed because a reduction in the chemical internal energy results in an increase in the sensible internal energy, which would be considered as a positive energy conversion rate. Appendix A describes the calculation of η_c and LHV. The mass burning curves shown in Figure 2 were the input to the model calculations.

Table 1. Test cases computed using a two-zone model.

Case	Φ	IMEP (bar)	P_{max} (bar)
1	1.0	2.4	13.2
2	1.2	25.8	141.2
3	0.3	2.4	21.9

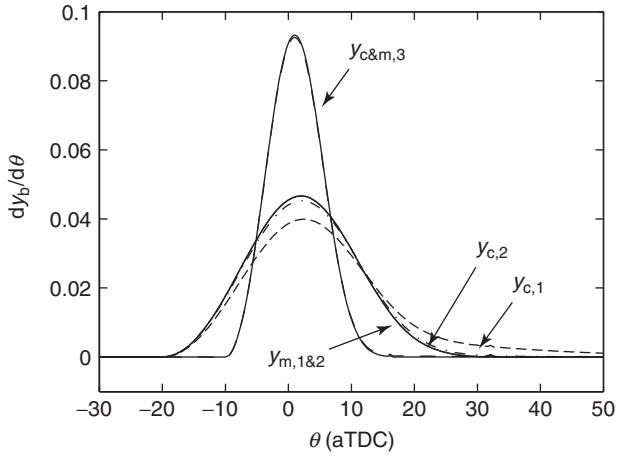

Figure 2. A comparison of the normalized mass (subscript m, and solid) and energy conversion rate (subscript c, and dashed) for the three test cases.

It can be seen in Figure 2 that there is a difference in $\dot{y}_m$ and $\dot{y}_c$, and that the difference is largest for case 1. The discrepancy between the mass burning rate and the energy conversion rate is due to dissociation of the combustion products. Intermediate carbon- and hydrogen-containing species typically have less negative heats of formation than CO_2 and H_2O, causing the chemical energy release rate to be reduced for conditions of high dissociation. As demonstrated in Figure 1, the light-load stoichiometric condition (case 1) has burned gas conditions that have high temperature and relatively low pressure, which promotes dissociation and puts the burned gas states at high levels of α. For the high load condition, the high pressure reduces the effects of dissociation, and the mass burning and energy conversion rates are very close. The lean, low temperature combustion light-load condition has negligible dissociation because of the low peak temperatures, and the mass burning and energy conversion rates are nearly identical.

3 SINGLE-ZONE MODELS

The implementation of a single-zone thermodynamic model is based on six major assumptions, which are enumerated in the text later as (A1–A6). The most significant assumption is that (A1) the cylinder contents are uniform in temperature and composition. This assumption is invalid for virtually all engine combustion regimes during the combustion event,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto122
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

that is, at the time of interest. For homogeneous-charge spark-ignition engines, the chamber is more aptly described as having two zones of different composition and temperature; for direct-injection compression-ignition engines, the mixture varies substantially in composition (containing various fractions of air, fuel, and combustion products) and temperature. In both cases, the mass-average composition and temperature, which are available to describe the single-zone's thermodynamic state, are not necessarily realized anywhere in the chamber except before and after combustion. This complicates the assignment of thermodynamic properties to the mixture.

There are two methods of implementing a single-zone model. The first, and most widespread, method assumes that the combustion event can be modeled as a heat addition to the system across the system boundary, which is defined to enclose the cylinder contents. This rate of heat addition is assumed to be the rate of conversion of chemical to sensible internal energy, see Equation 9. Heat transfer from the surroundings to the system can (and should) be accounted for separately. The second implementation method assumes that mass (fuel) is added to the system and that the in-cylinder mixture represents the equilibrium thermodynamic state of the air–fuel mixture. The rate of mass addition then represents the combustion rate. There are significant differences in these treatments. First, as was seen in Figure 2, there is a difference between a mass burning rate and an energy conversion rate. Second, because the former treatment does not use the changing chemical composition of the mixture to assess the mixture's internal energy (it is done through the heat addition term), the *sensible* internal energy should be used, whereas the latter treatment, which does account for the chemical energy in the fuel mass added, uses the *absolute* internal energy.

The First Law for an open system defined by the piston crown and combustion chamber walls can be written as

$$u\frac{\mathrm{d}m}{\mathrm{d}t} + m\frac{\mathrm{d}u}{\mathrm{d}t} = \dot{Q}_{\mathrm{w}} - p\frac{\mathrm{d}V}{\mathrm{d}t} + \dot{m}_{\mathrm{crev}}h_{\mathrm{crev}} + \dot{m}_{\mathrm{f}}h_{\mathrm{f}} \qquad (10)$$

where all thermodynamic properties are their absolute values and provision has been made for mass addition (considered positive) to the system from the crevice (e.g., piston ring crevices), $\dot{m}_{\mathrm{crev}}$, and via the addition of fuel, $\dot{m}_{\mathrm{f}}$, to the system. The value of h_{crev} depends on the direction of the flow, taking its value based on where it flowed from. The heat addition method described earlier is developed by (A2) neglecting the fuel addition term, writing the internal energy explicitly in terms of the chemical and sensible parts, $u = u^{\mathrm{c}} + u^{\mathrm{s}}$, (A3) neglecting the chemical enthalpy of the crevice flow, (A4) neglecting the chemical internal energy of the system mass derivative term, and defining the chemical heat addition, $\dot{Q}_{\mathrm{ch}}$, as

$$\dot{Q}_{\mathrm{ch}} \equiv -m\frac{\mathrm{d}u^{\mathrm{c}}}{\mathrm{d}t} \qquad (11)$$

similar to Equation 9. This gives an explicit relation for chemical heat addition

$$\dot{Q}_{\mathrm{ch}} = m\frac{\mathrm{d}u^{\mathrm{s}}}{\mathrm{d}t} + p\frac{\mathrm{d}V}{\mathrm{d}t} + (u^{\mathrm{s}} - h^{\mathrm{s}}_{\mathrm{crev}})\dot{m}_{\mathrm{crev}} - \dot{Q}_{\mathrm{w}} \qquad (12)$$

The mass addition method requires the assumption that $\dot{m}_{\mathrm{crev}} = 0$ because the composition of the mixture varies with time so it would be difficult to know the crevice composition. Using an overall mass balance, $\frac{\mathrm{d}m}{\mathrm{d}t} = \dot{m}_{\mathrm{f}}$, one finds the following expression for the mass addition rate

$$(u - h_{\mathrm{f}})\ \frac{\mathrm{d}m}{\mathrm{d}t} = \dot{Q}_{\mathrm{w}} - p\frac{\mathrm{d}V}{\mathrm{d}t} - m\ \frac{\mathrm{d}u}{\mathrm{d}t} \qquad (13)$$

The major challenge for the heat addition method is defining the gas properties. The composition of the mixture is known to change with time, but this composition is undefined, so assessing the sensible internal energy and its rate of change by conventional means is not strictly possible. The major challenge of the mass addition method is that the composition of the mixture is assumed to change as a function of the fuel mass addition, which may be a suitable physical description of diesel combustion but does not describe spark-ignition combustion well.

The one added complication that arises in the mass addition method is that the mixture state is changing because of pressure, temperature, and equivalence ratio (as fuel mass is added to the system). As such, all thermodynamic properties are a function of three properties, and the temporal derivatives of a property, such as Equation 7, need to include this equivalence ratio, Φ, effect. The mass addition method is not extensively used and will not be discussed further.

The standard development of the heat addition method involves the additional assumptions: (A5) the sensible internal energy is a function of temperature only so $\frac{\mathrm{d}u^{\mathrm{s}}}{\mathrm{d}t} = c_{\mathrm{v}}\frac{\mathrm{d}T}{\mathrm{d}t}$; and (A6) the mixture has a constant molecular weight, which enables the ideal gas equation of state, for example, Equation 5, to be simplified to find $\frac{\mathrm{d}T}{\mathrm{d}t}$ in terms of known or measured values. Using these assumptions and the specific heat ratio $\gamma \equiv \frac{c_{\mathrm{p}}}{c_{\mathrm{v}}}$, one gets

$$\dot{Q}_{\mathrm{ch}} = \frac{\gamma}{\gamma - 1}p\frac{\mathrm{d}V}{\mathrm{d}t} + \frac{1}{\gamma - 1}V\frac{\mathrm{d}p}{\mathrm{d}t} + (u^{\mathrm{s}} - h^{\mathrm{s}}_{\mathrm{crev}})\dot{m}_{\mathrm{crev}} - \dot{Q}_{\mathrm{w}} \qquad (14)$$

where the mixture composition is still undefined. The assumption (A6) also allows a direct estimate of the gas temperature as $T = pV\,/\,(mR)$.

As stated earlier, appropriately defining the mixture's properties is difficult. Figure 3a compares the specific heat ratio, γ, calculated for pure air, stoichiometric isooctane–air reactants, and the equilibrium products of stoichiometric isooctane–air combustion. The product γ values were calculated using both the absolute mixture internal energy, $\widetilde{c}_{v,1} = \frac{\partial u}{\partial T}|_p$, and the mixture sensible internal energy $\widetilde{c}_{v,2} = \frac{\partial u^s}{\partial T}|_p$; both values of $\widetilde{c}_v$ differ from $\sum y_i c_{v,i}$ because of the shifting equilibrium composition. From the data of Figure 3a, it can be seen that there is a significant difference between pure air, the reactant mixture, and the product mixture. The product γ is seen to vary substantially depending on the method of calculation. Using the absolute internal energy, one sees a significant decrease in γ above 1500 K, and the value of γ in this temperature range is strongly pressure dependent, consistent with the curvature of the iso-α contours in Figure 1. Using the sensible internal energy, one finds that the product mixture γ is nearly constant for temperatures greater than 1500 K and nearly independent of pressure. It should be noted that the curves shown in Figure 3a for the absolute internal energy method closely resemble those of Gatowski *et al*. (1984), from which they developed the often cited correlation

$$\gamma = \ 1.392 - 8.13 \times 10^{-5} T \tag{15}$$

where the temperature is in Kelvin. The γ in Equation 14 is, however, based on the changes in sensible internal energy, and the behavior of the sensible internal energy is significantly different—instead of continuing to decrease with temperature it plateaus for temperatures in excess of 1500 K—and is nearly independent of pressure, which satisfies assumption (A5).

Chun and Heywood (1987) suggested that a three-part representation for γ should be used. Up to combustion, the reactant mixture value, consistent with Figure 3a, should be used; during combustion, a constant value should be used; and after combustion, the product mixture value should be used. They arrived at this result by back-calculating γ from a single-zone model applied to results acquired from a two-zone model. They argue that during the combustion event the change in internal energy is dominated by the change in composition from reactants to products, that is, the chemical change, and was, therefore, independent of temperature. The end of combustion period was not clearly defined. These results highlight a fundamental problem with the heat addition method. At the time of peak temperature, unless Equation 12 can be satisfied with $\frac{du^s}{dt} = 0$, the mixture specific heat will be infinite. It is interesting to note that the γ results based on the sensible internal energy in Figure 3a show a similar trend of a nearly constant γ value for the combustion products at combustion-like conditions. A simple correlation for γ can be found from data like Figure 3a with a second fit performed to account for the equivalence ratio, Φ, in the range $0.3 < \Phi < 1.2$, as

$$\gamma = \max \begin{cases} \gamma_0 + \gamma_1 T \text{ [K]} \\ \gamma_{HT} \end{cases} \tag{16}$$

where $\gamma_0 = 1.426 - 0.0459\Phi$, $\gamma_1 = 10^{-5} \times (1.02\Phi^2 - 3:30\Phi - 9.44)$, and $\gamma_{HT} = 0.0386\Phi^2 - 0.0838\Phi + 1.33$. The temperature-dependent part of Equation 16 corresponds to the reactant mixture, and the constant part corresponds to the plateau region of the products (with a slight 0.03 offset to better match heat release data). A simple justification for this correlation for γ is that the mixture will likely contain zones of reactants at modest temperature and products at high temperature at the time of combustion.

Figure 3b shows the change in the molar mass between reactants and products of an isooctane–air mixture as a function of the equivalence ratio. It can be seen that there is a significant difference between the two values, with the difference being nearly 10% at stoichiometric, with a small effect of pressure. These differences will minimally affect the results of the heat release calculation—through the γ correlation—but it will affect the mass-average temperature calculated from the ideal gas relation by a proportional amount. The more subtle effect comes through (A6), where the molar mass changes have been neglected in the application of the ideal gas equation.

Wall heat transfer in the engine environment is difficult to model accurately because it varies significantly across the chamber surface and is difficult to measure. The convective heat transfer coefficient, in an analogy to turbulent pipe flows, is usually written as a Nusselt–Reynolds number relation of the form

$$\frac{hL}{k} = a\left(\frac{\rho UL}{\mu}\right)^b \tag{17}$$

where h is the convection coefficient, L is a representative length scale, k is the thermal conductivity, U is a representative velocity, μ is the dynamic viscosity, and a, b are constants. The choice of the characteristic length and velocity scales, in addition to the two constants, differentiate the correlations found in the literature (Borman and Nishiwaki, 1987; Heywood, 1988).

A major issue in the heat transfer model is that the absolute magnitude predicted by correlations such as Equation 17 is not well captured. This has a direct bearing on the estimated heat release rate and can be ameliorated by invoking an overall energy balance. The integrated heat

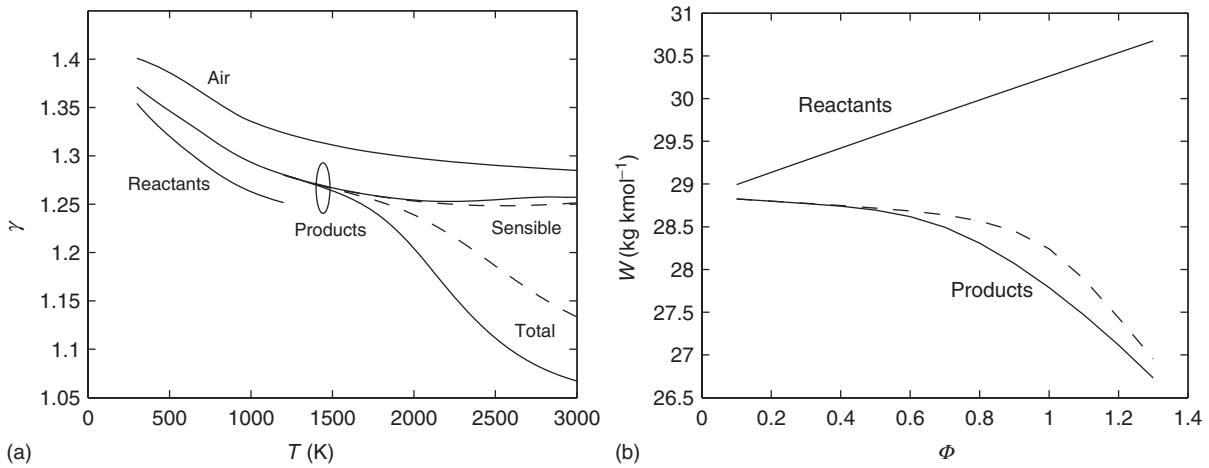

Figure 3. (a) Comparison of specific heat ratio for air, stoichiometric reactants, and the equilibrium products of stoichiometric combustion found from the sensible and total internal energy changes with temperature at 1 atm (solid) and 100 atm (dashed). (b) The molecular weight of reactants and products at the equilibrium flame temperature for 1 atm (solid) and 100 atm (dashed). All calculations performed with isooctane as the fuel.

release is made to equal the total fuel energy, $\int \dot{Q}_{ch} = \eta_c m_f \text{LHV}$, by scaling the wall heat transfer term with a multiplicative constant. The scaling constant that satisfies this condition can be found by iteration or analytically by performing term-wise integration of the parts of Equation 14.

4 APPROXIMATE METHODS

Before the advent of modern computers, several investigators had developed methods of estimating the cumulative burn fraction using the fact that engine pressure data show a polytropic behavior when plotted on logarithmic pressure–volume axes. These methods are described more fully by Amann (1985) and Brunt and Emtage (1997) and are briefly summarized here. All of these methods rely on using a polytropic exponent that is derived from fitting the pressure–volume data, and no direct effort is made to relate the quantities to fundamental thermodynamic properties. Thus, these methods should be considered approximate and used appropriately, for example, for relative comparisons between operating conditions in the same or similar engines.

Assuming a constant-volume combustion process, and neglecting crevice and heat transfer effects, it can be seen from Equation 14 that the heat release rate is proportional to the pressure rise rate. Integrating to an intermediate time, and normalizing to the integral overall time, one finds that the cumulative burn fraction, y_1, where the subscript 1 refers to the first approximate method, is found as

$$y_1 = \frac{p - p_i}{p_f - p_i} \tag{18}$$

where p_i and p_f are the pressures at the start and the end of combustion, respectively. Because the combustion event does not occur at a fixed volume, the pressure terms need to be corrected to their top dead center (TDC) equivalent values using the polytropic assumption $p_{TDC} V_{TDC}^n = pV^n$, where n is the polytropic exponent. Making this adjustment, one finds

$$y_1 = \frac{pV^n - p_i V_i^n}{p_f V_f^n - p_i V_i^n} \tag{19}$$

This approach was originally developed by Marvin (1927). The end of combustion is difficult to define accurately, but Brunt and Emtage (1997) suggest using 10 crank angles past the point that had the maximum value of $pV^{1.15}$.

Rassweiler and Withrow (1938) developed an approximate method of estimating heat release based initially on their high speed flame images, but extended it to an arbitrary case where only pressure data were measured. The burned mass at a given crank angle is compared to that at exhaust valve opening to determine the burned mass fraction. This is combined algebraically with a similar relation based on the unburned gas to find

$$y_2 = \frac{p^{1/n} V - p_i^{1/n} V_i}{p_f^{1/n} V_f - p_i^{1/n} V_i} \tag{20}$$

5 COMPARISON OF CALCULATION METHODS

The three test cases that were generated from a two-zone model (Table 1) were postprocessed to determine the heat release rate using both the single-zone (denoted First Law) and approximate methods, and the results are shown in Figure 4. The single-zone method was calculated using Equation 16 for the determination of γ, the Woschni correlation (Borman and Nishiwaki, 1987 and Heywood, 1988) for the heat transfer rate, and the heat transfer rate was scaled to enforce an overall energy balance as described earlier. Figure 4 also includes the known mass (m_{act}) and energy (q_{act}) conversion rates. The formulation of the single-zone and approximate methods are more consistent with the energy conversion rate and that will serve as the basis of comparison.

In all three cases, which span a wide range of operating conditions, there is a reasonable agreement between the calculated heat release rate and the known values. There are, however, some differences. For cases 1 and 2, the single-zone method shows the best agreement and is nearly indistinguishable from the actual energy conversion rate curve. For case 3, however, the single-zone method slightly overshoots the real case. The overshoot is corrected at the end of the calculation by the normalization and this effect could be minimized by shortening the calculation window, but this would require *a priori* knowledge of the combustion event.

The approximate methods, although not rigorous treatments, provide results that are relatively close to the single-zone analysis. The largest discrepancy is seen for case 1 where there is a significant amount of dissociation. For this case, the approximate methods are closer to the mass

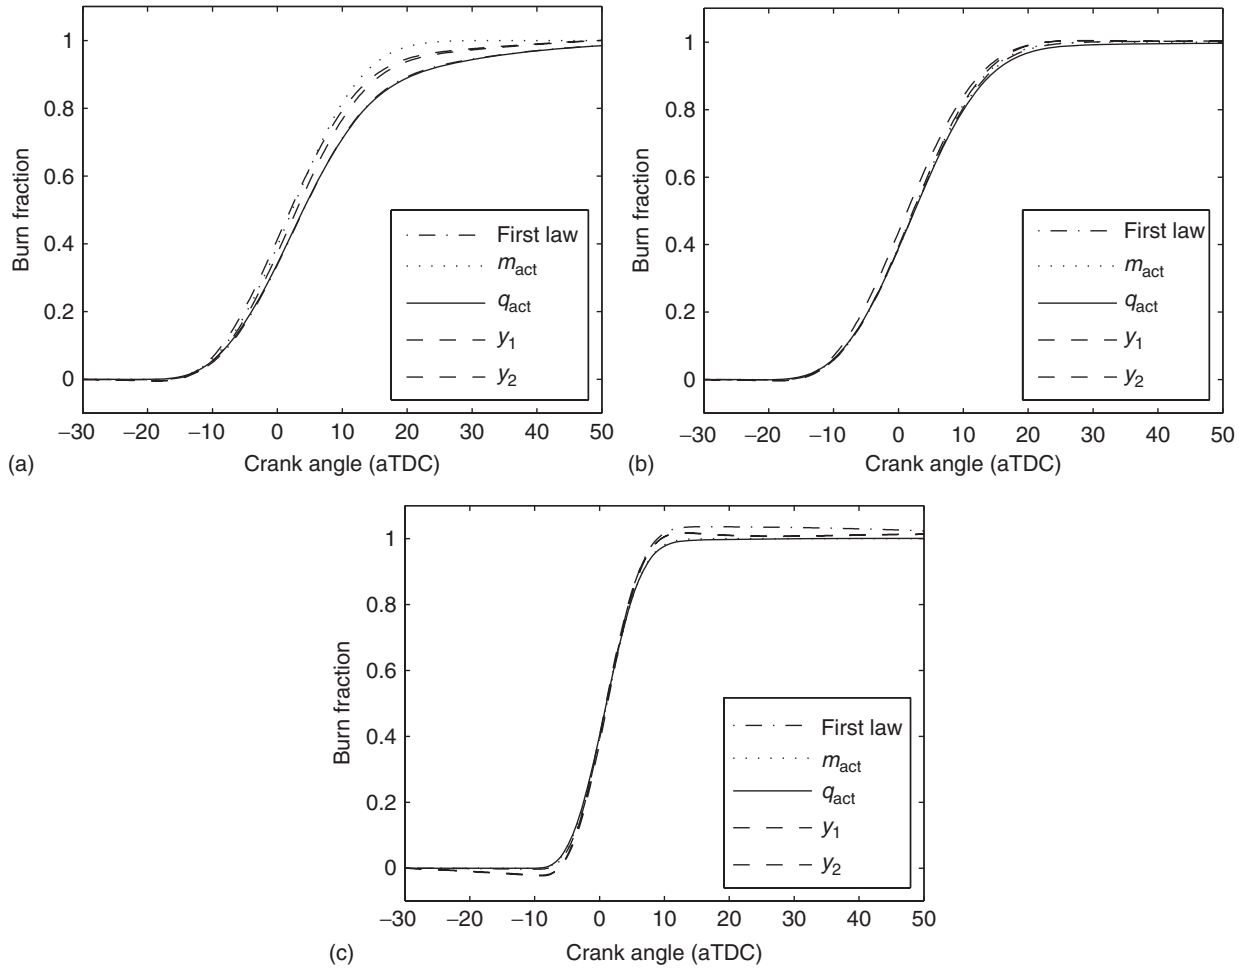

Figure 4. Comparison of actual (mass- and energy-based) and calculated cumulative burn fractions for (a) case 1, (b) case 2, and (c) case 3. The First Law curves were calculated using the heat addition method, and the two approximate cases shown correspond to the numbers given in the text.

Table 2. Comparison of the accuracy of the single-zone and approximate methods for the calculation of CA_{10}, CA_{50}, and CA_{90}.

	First Law			y_1			y_2		
Case	CA_{10}	CA_{50}	CA_{90}	CA_{10}	CA_{50}	CA_{90}	CA_{10}	CA_{50}	CA_{90}
1	0.23	0.05	− 0.42	− 0.18	− 1.02	− 5.08	− 0.90	− 1.98	− 6.02
2	0.16	− 0.02	− 0.45	0.11	− 0.21	− 1.10	− 0.60	− 1.11	− 1.70
3	0.30	0.04	− 0.61	0.62	0.18	− 0.44	0.46	− 0.06	− 0.60

The value given corresponds to the difference between the calculated value and that derived from the energy release rate from the two-zone model.

conversion rate than the energy conversion rate, but this is considered to be a coincidence rather than a result. The other significant deviation of the approximate methods is for case 3 where both y_1 and y_2 are seen to go negative before the start of combustion. This is a result of a deviation from polytropic behavior because of either heat transfer effects or temperature effects on γ.

Heat release results are often represented by the crank angle at which the cumulative heat release reaches a specified fraction, for example, CA_{50} corresponds to the crank angle at 50% of the cumulative heat release. Table 2 quantitatively compares the accuracy of the CA_{10}, CA_{50}, and CA_{90} values obtained using the single-zone and both approximate methods. The results are presented in terms of the difference between the calculated value and the value directly calculated from the known energy conversion rate, that is, $\Delta\theta = CA_x - CA_{x,\text{known}}$. It can be seen from Table 2 that, for the cases tested, the single-zone model returns values of CA_{10}, CA_{50}, and CA_{90} that are within ± 0.5 crank angles of the actual result. For cases 2 and 3, the approximate methods give reasonable results, within ± 1.5 crank angles, but it can be seen that the errors are largest for CA_{90}. The approximate methods applied to case 1 show the worst performance, especially for CA_{90} where a difference of ~6 crank angles is observed.

5.1 Data collection effects

It is well known that the accuracy of the pressure data has a direct impact on the calculation of heat release and that acquiring accurate cylinder pressure data requires care (Randolph, 1990). Pressure data are typically acquired using piezoelectric transducers that measure the dynamic pressure very accurately, but the dynamic pressure needs to be pegged to an absolute reference pressure once per cycle to obtain thermodynamic pressure, and this pegging pressure value has limited accuracy. The pressure data also need to be referenced to the TDC position of the crankshaft in order to be able to use the kinematic relationship for volume, and there can be an inaccuracy in the location of TDC determined with a rotary encoder. In addition, there can be inaccuracy in knowing the clearance volume (compression ratio) and the trapped mass of fuel and air; the latter are problematic in multicylinder engines where the cylinder-to-cylinder distribution may be imbalanced. For the present calculations, the total trapped mass will be adjusted at a constant equivalence ratio.

The effects of the aforementioned parameters on CA_{10}, CA_{50}, and CA_{90}, obtained using the single-zone method applied to case 1, are shown in Figure 5. The results are presented as the difference relative to the known energy conversion rate equivalent, $\Delta\theta$. Figure 5a shows the effect of an inaccuracy of the pegging pressure on $\Delta\theta$. It can be seen that CA_{10} and CA_{50} are relatively unaffected by an offset in the pegging pressure, but CA_{90} is strongly affected with the calculated CA_{90} retarding as the offset in pegging pressure increases. The effect of the encoder phasing is shown in Figure 5b. There is a noticeable effect on both CA_{10} and CA_{50}, but the two values track in the same direction, that is, they retard with an increase in phasing offset. The CA_{90} value is again more sensitive than both CA_{10} and CA_{50}, and for phasing errors, it moves in an opposite direction from the CA_{90} value, causing even more significant errors in the CA_{10-90}, which is often used as a measure of combustion duration.

The effect of inaccuracies in the TDC volume and trapped mass is presented in Figure 5c and d as a function of the ratio of the assigned value to the actual value. The effect of the TDC volume (or compression ratio) is significant for CA_{10} and CA_{50} and quite strong for CA_{90}. For all three parameters, the direction of the shift is consistent, that is, everything phases in the same direction. The effect of the trapped mass ratio is weak on CA_{10} and CA_{50} but is moderate on CA_{90}, although of lower magnitude than the other parameters investigated.

In order to extend these results to the other operating cases and to the approximate calculation methods, the results have been recast in terms of a required accuracy of the measurement in order to obtain ± 0.5 crank angle precision of CA_{10}, CA_{50}, or CA_{90} independent of the offset shown in Table 2. The accuracy was found by dividing 0.5 crank angles by the slope of the respective CA_x curve at the nominal location (an offset of zero or a ratio of

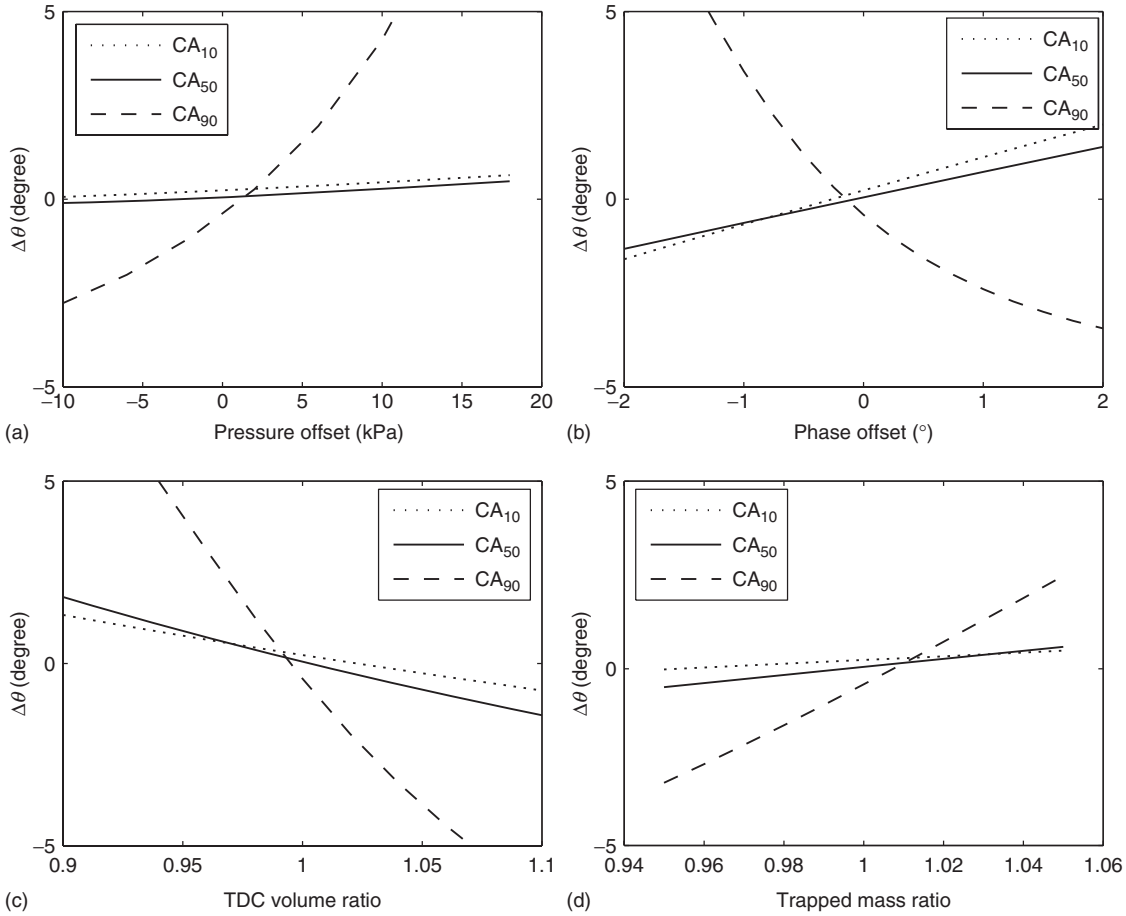

Figure 5. The effect on CA_{10}, CA_{50}, and CA_{90} from incorrect (a) pressure pegging, (b) TDC timing, (c) clearance volume measurement, and (d) trapped mass assignment. All data are for case 1 and were calculated using the single-zone method.

unity). Using this approach, large numbers indicate that low accuracy is required and that the results are very insensitive to a parameter, conversely, small values indicate a high level of sensitivity and the need for high data fidelity. The results for the single-zone and both approximate methods are shown in Table 3.

Table 3 contains a lot of data, and only the general trends will be discussed. For all calculation methods, the throttled,

light-load operating condition (case 1) required the highest accuracy. In addition, the highest accuracy was required to correctly calculate CA_{90}, consistent with the results seen in Figure 5. The two approximate methods gave very similar results. The approximate methods are only sensitive to changes in the polytropic coefficient, which is determined by a power-law fit to the pressure-volume data, and thus are not affected by the trapped mass. The approximate methods are very sensitive to the pegging pressure, requiring on the order of 1 kPa accuracy to correctly estimate CA_{50}, and significantly better to accurately measure CA_{90}. In contrast, the single-zone model is nearly an order of magnitude less sensitive to the pegging pressure. The effect of encoder phasing inaccuracy is comparable for the single-zone and approximate methods, and 0.5 crank angle accuracy provides sufficient results for the range of conditions tested. The trapped mass estimation is relatively unimportant for CA_{10} and CA_{50}, but it does produce a significant effect on CA_{90} for the single-zone method. The effect of the clearance volume is more important for the single-zone model, with ~1% accuracy required to correctly calculate CA_{90}.

In addition to the effects described earlier, another major issue with respect to utilizing either the single- or two-zone methods is the ability to accurately measure the pressure derivative. The accurate determination of the pressure derivative is a function of the frequency content of the pressure signal, the presence of random noise, biases imposed by the data acquisition hardware, and the numerical method used for evaluating the derivative from the measured pressure data. These issues become more demanding when single-cycle analysis of the data is performed and the smoothing effect of ensemble averaging multiple cycles is removed.

Differentiating experimental data amplifies noise, thus, data are often numerically smoothed before differentiation. This can, however, bias the results if rapid pressure transients associated with the heat release event are present. A wide array of data smoothing techniques has been used ranging from simple nearest-neighbor or running averages to more complicated methods. The preferred method is to use a rigorous filter with a well-defined cutoff frequency and roll-off because the cutoff frequency can be tuned to avoid specific fixed frequencies (discussed later) and the effect of the filtering on the gradient can be quantified.

The rapid expansion of a local pocket of gas in a closed chamber can excite pressure oscillations that are associated with the allowable standing wave modes of the enclosure. This occurs when the end gas of a spark-ignition engine autoignites (knock), but it can occur in compression-ignited engines as well. These oscillations occur during the energy release period and affect the pressure derivative calculation. Because this is a resonance phenomenon, the oscillation frequencies are fixed and can be reasonably estimated based on the resonance characteristics of a cylindrical chamber. Therefore, it is possible to design a *time-domain* filter that can alleviate the pressure oscillations from the measured data. Another issue that can arise with high rates of pressure rise (due to either the combustion or chamber resonances) is the excitation of the natural frequency of the pressure transducer, which is typically ~100 kHz. If the data collection rate is significantly higher, this can be filtered out; with sample rates lower than the natural frequency, which are typical for crank-angle-based collection systems, it is possible that the high natural frequency can alias the measured signal. It is recommended to use an analog anti-aliasing filter ahead of the data acquisition system to avoid this possibility. The effects of random noise are normally eliminated by the filtering, and it is typical to have data quality that will enable single-cycle analysis of the heat release.

5.2 Single-zone assumption effects

Directly assessing each of the single-zone method assumptions, that is, (A1)–(A6), is difficult without detailed information from all points within the combustion chamber. Using the two-zone model data for the evaluation of the heat release calculations, assumptions (A2–A4) were automatically satisfied. The assumption that the mixture sensible internal energy is a function of temperature only, assumption (A5), was justified, in part, by the lack of pressure dependence seen for the sensible energy-derived γ in Figure 3. However, this assumes that the single-zone composition is that of the products. In reality, the composition is (in a loose sense) defined by the choice of γ. Figure 6a shows the effect that the correlation used for γ in Equation 14 has on the cumulative energy release for case 2. It can be seen that the use of Equation 16 gives a good match between the calculated and known heat release rates (as seen previously). Further, the choice of $\gamma = 1.28$, which is slightly higher than the high temperature plateau seen in Figure 3a, also gives a good match to the known heat release rate. The fixed value of $\gamma = 1.28$ also gave acceptable results for case 1 but resulted in a significant overshoot for case 3. This occurred because this value of γ is too low for the very lean mixture and low temperatures of case 3. The linear relation of Gatowski *et al*. (1984) (Equation 15) gives results that are significantly different than the actual value; a similar result was found for case 1. This result underscores the sensitivity of the calculation procedure to the choice of γ, but from

the larger perspective, it shows the importance of how one ascribes thermodynamic properties to a single-zone mixture that is in reality not homogeneous in temperature or composition.

Figure 6b shows the effect that the choice of the heat transfer correlation in the single-zone model has on the cumulative energy release; recall that an overall energy balance is used to find a multiplicative constant. Four cumulative energy release curves are shown in Figure 6b: the known value from the two-zone model, the results from the Woschni and Anand correlations, and the result achieved using the known heat loss rate from the two-zone model directly in the heat release calculation. It can be seen that there is very little sensitivity of the cumulative energy release to the heat transfer correlation used. It is interesting to note that the multiplier on the heat transfer varied from 0.5 to 1.7 over these conditions.

6 SUMMARY

The essential elements of the calculation of the heat release rate from experimentally derived cylinder pressure data were discussed. The fundamental equations for a two-zone thermodynamic calculation were developed, and it was shown that the ideal gas equation of state was sufficient, but the shifting equilibrium composition of the gas required that the enthalpy and internal energy be written as functions of both temperature and pressure. A two-zone model (with a prescribed mass conversion rate) was used to generate test data against which a single-zone and two approximate heat release calculation methods were tested. The energy conversion rate for the two-zone model result was shown to be different from the mass conversion rate because of the dissociation of the product species. This effect was most pronounced for high temperature, low pressure conditions as are found in throttled spark-ignition engines; at higher loads or under dilute conditions, there was not a significant effect of dissociation.

The single-zone model for heat release calculations was developed based on modeling the heat release as either a fuel mass addition or an external heat addition; the former method was not explored in detail because of the widespread use of the latter method. The heat addition method does not consider the chemical energy of the gas mixture, thus the sensible internal energy should be used. It was shown that the product-mixture-specific heat ratio calculated based on the sensible internal energy was nearly constant for temperatures in excess of 1500 K and was nearly independent of pressure. A two-part equation for γ that considers the mixture equivalence ratio was presented. The assignment of thermodynamic properties to the (assumed) homogeneous mixture that represents the cylinder contents, which is solely manifested in the specific heat ratio, was seen to have a significant effect on the heat release calculation. The correlation chosen for the wall heat transfer, however, did not strongly affect the heat release rate when an overall energy balance was used to ensure that the integrated heat release matched the known fuel energy converted. The multiplier of the heat transfer term required to close the energy balance differed significantly from unity and highlights the difficulties associated with accurately calculating heat transfer in engines. Using the proposed equation for γ and enforcing an overall energy balance, a good correspondence was seen between the calculated heat release rate and the known energy conversion rate.

The approximate methods were found to provide a reasonable estimate of the cumulate heat release for conditions where there was minimal dissociation. The agreement was worse for the light-load condition, especially at high cumulative burn fractions. The major drawback of the approximate methods is that they do not quantitatively estimate energy, that is, the cumulative burn fraction will always asymptote to unity. Therefore, on a cycle-by-cycle basis, it is not possible to assess the mass of fuel burned, which can be done using the single-zone model when the heat transfer is well modeled.

Both the single-zone and approximate methods are sensitive to the quality of the pressure data. The effects of incorrect pressure pegging, TDC determination, clearance volume, and trapped mass were investigated. The approximate methods were not sensitive to the trapped mass but required high accuracy of the pegging pressure in order to correctly predict CA_{50} and CA_{90}. All methods required ~0.5 crank angle accuracy of the shaft encoder.

APPENDIX A—COMBUSTION EFFICIENCY CALCULATION

The combustion efficiency is calculated as the ratio of the isothermal, constant pressure heat rejection from a given fuel–air mixture to that from a stoichiometric mixture with ideal products, that is, CO_2, H_2O, and N_2. From a simple First Law balance, the heat rejection per mass of fuel is given by

$$\frac{\dot{Q}}{y_f \dot{m}} = \frac{1}{y_f} \sum_{\text{prod}} y_i \Delta h^\circ_{f,i} - \Delta h^\circ_{f,f} \qquad \text{(A1)}$$

and in the case of ideal products, this gives the lower heating value of the fuel, that is, $\text{LHV} = \dot{Q}_{id}/(y_{f,id}\dot{m})$, where the id identifier is for the ideal case. The combustion efficiency is then found as

$$\eta_c = \frac{\frac{1}{y_f}\sum_{\text{prod}} y_i \Delta h^\circ_{f,i} - \Delta h^\circ_{f,f}}{\frac{1}{y_{f,id}}\sum_{\text{prod}} y_{i,id} \Delta h^\circ_{f,i} - \Delta h^\circ_{f,f}} \qquad \text{(A2)}$$

Zero- and One-Dimensional Methodologies and Tools

Jerald A. Caton
Texas A&M University, College Station, TX, USA

1 INTRODUCTION

Zero- and quasi-one-dimensional engine cycle simulations are well-established tools for modern engine development. These cycle simulations are mainly based on the first law of thermodynamics, and often are called *thermodynamic simulations*. They have evolved over the years from elementary cycle analyses to fairly complex, thorough descriptions of engine processes and fluid properties. Today, a number of commercial codes are available, which are based on these methodologies. This chapter will provide descriptions of these simulations, and some example results to illustrate the type of information that may be obtained from the simulations.

The goal of these simulations is to mathematically simulate the significant engine processes, provide detailed time-resolved information, and predict overall engine performance. The significant engine processes include cylinder heat transfer, combustion, flows, friction, and related items. Benefits of these types of simulations are multiple, which include: (i) they help guide and interpret experimental work, (ii) they are an efficient way to complete extensive parametric studies, (iii) they provide opportunities for optimization, (iv) they may be the only technique to study certain variables, (v) they provide an educational opportunity to better understand engine processes, and (vi) they may contribute to the development of advanced on-board engine controllers.

The evolution of these simulations has been a result of improved computing capabilities, and increased understanding of the individual engine processes and the fluid properties. The first thermodynamic simulations were introduced in the 1960s. A signal work by Patterson and van Wylen (1964) is a good example of these early simulations. Some of the simplifications of this earlier work included idealized flow processes and adiabatic assumptions for some of the processes. Nevertheless, this work was a pioneering effort and an early version of current simulations. Interestingly, they included second-law calculations that were a dozen or more years ahead of any such similar work.

Engine cycle simulation development continued through the 1960s and 1970s, and by the end of the 1970s, these simulations had reached a fairly mature level. Examples of these simulations at the end of the 1970s have been described by Mattavi and Amann (1980) and Blumberg, Lavoie, and Tabaczynski (1979).

An important feature of these simulations is the treatment of the intake and exhaust flows. For cases where the flow dynamics are of less concern, quasi-steady flow and plenum assumptions for the intake and exhaust manifolds are often acceptable. For those cases where the flow dynamics are important, one-dimensional unsteady gas flow equations may be used. This latter feature is necessary where intake and exhaust piping arrangements must be evaluated. More on this topic may be found in Gas–Breathing and Air Management.

In the mid-1980s, commercial codes began to appear. Examples today include GT Power (Gamma Technologies, Inc.), Wave (Ricardo, Inc.), Boost (AVL, GmbH), and Virtual 4-Stroke (Optimum Power Technologies, Inc.). For the most part, these simulations share the same basic principles that are described in this chapter. Of course, each code has unique features and capabilities that go beyond the basics. They are generally user friendly, but often the algorithms and methodologies are based on assumptions and approximations that are not clearly understood by the user. The information in this chapter is at least partly aimed at helping to improve this understanding.

1.1 Zero- and quasi-one-dimensional cycle simulations

Zero-dimensional cycle simulations are based on a global energy analysis of the cylinder contents (Foster, 1985). From this, time-varying global cylinder pressures and gas temperatures are obtained. Often, multiple zones may be designated to capture some of the spatial differences: but, this is still a zero-dimensional result. These multiple zones, for thermodynamic simulations, have no dimensionality (i.e., these zones are not related to specific locations). This type of simulation requires an input of information on the burning rate. This is often supplied as a mass fraction of fuel burned as a function of the crank angle. This input would need to include the duration of combustion. Since often these items are not known, the zero-dimensional cycle simulation is not generally predictive. In addition, these simulations do not include any dependence on the detail cylinder geometry.

Alternatively, the quasi-one-dimensional cycle simulations are based on attempts to predict the burning rates from more basic inputs such as turbulence, swirl, fuel chemistry, and any fuel jet characteristics or other fuel mixing processes. Some model of the geometry of the flame propagation or fuel jet development is needed as part of the description. Ideally, the start of combustion, the combustion duration, and the instantaneous combustion rate would be predicted. These items would then be used by the cycle simulation along with the other features described for the zero-dimensional simulations. These types of simulations include at least some dependence on the cylinder geometry. Although cycle simulations based on the quasi-dimensional features may be more predictive, often the inputs (turbulence, chemical kinetics, flame speeds) are not well known.

1.2 Multidimensional cycle simulations

For completeness, multidimensional cycle simulations are briefly mentioned next. These types of simulations, often called *computational fluid dynamic* (*CFD*) *models*, are described more fully in Multidimensional Simulation. In principle, these simulations solve the complete governing equations in all dimensions. These simulations require fine grids and small time steps. The inputs are detailed and include all geometry, turbulence, chemistry, and boundary-layer processes. These simulations are computer-intensive and often require hours or days of runtime. In addition, these multidimensional cycle simulations must resolve the complex interactions between the turbulence, combustion, heat transfer, and other key processes. Most of these interactions are still not fully understood. Nevertheless, great progress has been made over the past several decades and these simulations are being used more and more.

2 SPARK-IGNITION ENGINE SIMULATIONS

This section will describe the features of a specific example of a thermodynamic simulation for spark-ignition (SI) engines. Other simulations will possess similar features. We will then present example results, and highlight the strengths and weaknesses of such simulations. Some of the features (e.g., piston motion, heat transfer, flows, and friction) described for SI engines are equally applicable to compression-ignition (CI) engines.

2.1 Description of the thermodynamic simulation

This simulation (Caton, 2001, 2003, 2005, 2006; Shyani and Caton, 2009) is largely based on thermodynamic formulations, and is a complete representation of the four-stroke cycle including the intake, compression, combustion, expansion, and exhaust processes. Many submodels, assumptions, and approximations are integrated into the final simulation. The following describes some of these items for the simulation used here. Other simulations may employ slightly different assumptions and approximations.

The thermodynamic system is the cylinder contents (Figure 1). For portions of the cycle where the cylinder mixture is homogeneous, one zone is used for the thermodynamic system. During combustion, three zones (Caton, 2001, 2003) are used to better capture the high temperatures of combustion. For the purpose of this simulation, the engine is operating at steady state. The thermodynamic properties (including pressure and temperature) vary only with time (crank angle) and are spatially uniform in each zone. The intake and exhaust flow rates are determined from quasi-steady one-dimensional flow equations, and the intake and exhaust manifolds are infinite plenums containing gases

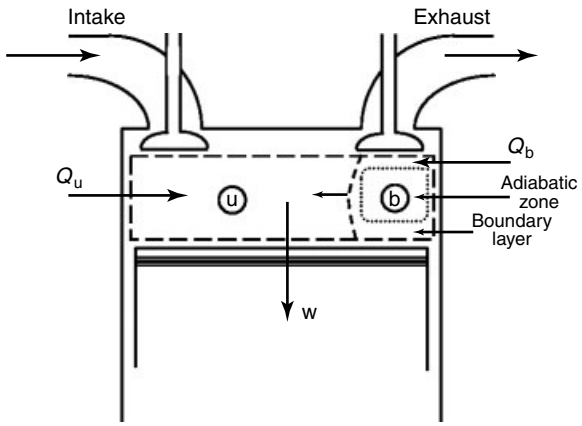

Figure 1. Schematic of the thermodynamic system.

at constant temperature and pressure. These assumptions result in the neglect of any "wave" dynamics in the inlet and exhaust systems.

Although no experimental data are cited in this chapter, previous work (e.g., Mattavi and Amann, 1980; Blumberg, Lavoie, and Tabaczynski, 1979) has demonstrated the success of these types of simulations on a global basis for duplicating experimental results.

2.1.1 *Energy equations*

As a result of thermodynamic analysis, the governing differential equations are obtained for the gas temperatures, cylinder pressure, volumes, and masses. The instantaneous cylinder conditions (temperatures, pressure, volumes, masses, and thermodynamic properties) as a function of crank angle are obtained by the simultaneous numerical integration of the various differential equations.

For the single-zone cases, the following is the appropriate relation:

$$\frac{\mathrm{d}(mu)}{\mathrm{d}\theta} = \dot{Q} - p\dot{V} + \dot{m}_{\mathrm{in}}h_{\mathrm{in}} - \dot{m}_{\mathrm{out}}h_{\mathrm{out}} \qquad (1)$$

where m is the cylinder mass, u is the specific internal energy, θ is the crank angle, $\dot{Q}$ is the rate of heat transfer, p is the cylinder pressure, $\dot{V}$ is the rate of cylinder volume change, $\dot{m}_{\mathrm{in}}$ is the mass flow rate into the cylinder, h_{in} is the specific enthalpy of the inlet mixture, $\dot{m}_{\mathrm{out}}$ is the mass flow rate out of the cylinder, and h_{out} is the specific enthalpy of the exiting mixture. In conjunction with other relations (such as for the thermodynamic properties, heat transfer, and burn rate (Olikara and Borman, 1975; Woschni, 1968; Wiebe, 1970; Heywood *et al.*, 1979; Heywood, 1988; Watts and Heywood, 1980; Sherman and Blumberg, 1977; Sandoval and Heywood, 2003), Equation 1 may be used to find explicit relations for the derivatives of the overall average cylinder gas temperature and cylinder pressure.

The intake and exhaust processes are based on equations for one-dimensional quasi-steady flow that are corrected by an empirical discharge coefficient (see Gas–Breathing and Air Management for related details). The intake and exhaust manifolds are assumed to be at constant pressures. The instantaneous valve lift is approximated with a sinusoidal shape based on valve timings and the maximum valve lift. This approximation has been used for cases where the exact valve lift profile is not known (Sherman and Blumberg, 1977).

For the combustion process, multiple zones are used (Figure 1). First, the formulation is developed for two zones: an unburned zone (u) and a burned zone (b). The burned zone entrains mass from the unburned zone as the flame front proceeds. The next step is to divide the burned zone into the boundary layer and adiabatic core zones. Initially, the boundary layer has zero mass, and the adiabatic core is equal to the burned mass. The boundary layer increases in mass by entraining mass from the adiabatic core. The rate of mass entrainment of the boundary layer is dictated by the mass and energy conservation relations for the adiabatic core and boundary layer zones with a specified temperature definition. In other words, to satisfy the energy and mass conservation relations, a specific boundary layer mass is required. All the burned gas heat transfer is assigned to the boundary layer.

The engine friction includes mechanical friction and pumping friction. Mechanical friction, in turn, includes the rubbing friction (such as from the crank, pistons, and valve train) and the work associated with the auxiliaries (such as oil and water pump, and alternator). Algorithms for each of these items were published by Sandoval and Heywood (2003), and these are used here exactly as presented.

To complete the required input information, the boundary conditions for the inlet (temperature and pressure) and for the exhaust (pressure) are specified. To begin a particular engine cycle calculation, several parameters are not known. The initial amount of exhaust gases left in the cylinder from the previous engine cycle (residual), as well as the initial cylinder gas temperature and pressure, must be assumed. The complete calculation is repeated until the final values agree (within a specified tolerance) with the initial values. Depending on the initial values and the specified tolerance, this procedure usually finds convergence within about three complete cycles.

2.1.2 *Exergy parameters*

In addition to the first law of thermodynamics, the second law provides further insight about engine operation. The

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto123
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

second law of thermodynamics is a rich and powerful statement of related physical observations and has a wide range of implications with respect to engineering design and operation of thermal systems. For example, the second law can be used to determine the direction of processes, to establish the conditions of equilibrium, to specify the maximum possible performance of thermal systems, and to identify those aspects of processes that are detrimental to the overall performance. Related to the analysis based on the second law of thermodynamics is the concept of exergy (or available energy). Exergy, a thermodynamic property of a system and its surroundings, is a measure of the maximum useful work that a given system may attain as the system is allowed to reversibly transition to a thermodynamic state that is in equilibrium with its environment. One key aspect of exergy is the fact that a portion of a given amount of energy is "available" to produce useful work while the remaining portion of the original energy is "unavailable" for producing useful work.

The exergy of the fuel and the cylinder gases is described by a number of parameters. For completeness, these parameters are briefly discussed next. Full details are available elsewhere (Caton, 2003, 2005, 2006; Shyani and Caton, 2009). Once the thermodynamic properties are known for a given set of conditions, the determination of exergy is fairly straightforward. In this development, the kinetic and potential energies are neglected (and can be shown to be negligible). At all times, for each zone

$$b = (u - u_o) - [-p_o(v - v_o)] - T_o(s - s_o) \qquad (2)$$

where b is the specific exergy (or exergy for closed systems); u, v, and s are the specific internal energy, the specific volume, and the specific entropy, respectively; u_o, v_o, and s_o are the specific internal energy, specific volume, and specific entropy for the restricted dead state, respectively, and p_o and T_o are the pressure and temperature of the dead state, respectively. The dead state is defined as the conditions of the environment at a temperature of T_o and a pressure of p_o.

For the flow periods (open system), the flow exergy (or exergy for flows) b_f is given by

$$b_f = (h - h_o) - T_o(s - s_o) \qquad (3)$$

where h is the specific enthalpy, h_o and s_o are the specific enthalpy and specific entropy of the restricted dead state, respectively, and s is the specific entropy of the flowing matter. For flows out of the system, the flowing matter is the cylinder contents, and for flows into the system, the flowing matter must be specified.

Exergy is not a conserved property, and hence may be destroyed by irreversibilities such as heat transfer through a finite temperature difference, combustion, friction, or mixing processes. Between any end states, therefore, the change in the exergy may be related to the relevant processes:

$$\Delta B = B_{end} - B_{start}$$
$$\Delta B = B_{in} - B_{out} + B_Q - B_W - B_{dest} \qquad (4)$$

where ΔB is the change of the total system exergy for a process, B_{end} is the total exergy at the end of the period, B_{start} is the total exergy at the start of the period, B_{in} is the total exergy transferred into the system accompanying flow into the system, B_{out} is the exergy transferred out of the system accompanying flow out of the system, B_Q is the exergy transferred accompanying the heat transfer, B_W is the exergy transfer due to work, and B_{dest} is the exergy that is destroyed by irreversible processes. This relation may be used to ascertain the destruction of exergy by solving Equation 4 to find B_{dest}. That is,

$$B_{dest} = B_{start} - B_{end} + B_{in} - B_{out} + B_Q - B_W \qquad (5)$$

$$B_W = W - W_{surr} \qquad (6)$$

where the work done against the surroundings is given by

$$W_{surr} = p_o(V_{end} - V_{start}) \qquad (7)$$

For heat transfer, the exergy that is transferred out of the system is equal to the "available" portion of the heat transfer:

$$B_Q = \int \left(1 - \frac{T_o}{T}\right) \delta Q \qquad (8)$$

where B_Q is the available portion of the heat transfer, and δQ is the differential heat that is transferred at a system (boundary) temperature T. The exergy that transfers into the system (B_{in}) and out of the system (B_{out}) due to flows is given as follows:

$$B_i = \int (\dot{m}_i b_{f,i}) dt \qquad (9)$$

$$B_{fuel} = -(\Delta G)_{T_o, p_o} \qquad (10)$$

where $b_{f,i}$ is the specific flow exergy, and the subscript "i" refers to each individual flow [for this study, intake (in) or exhaust (out)].

For determining the engine efficiency, and for completing the energy and exergy balances, values are needed for the

energy and exergy of the fuel. For the fuel, the lower heating value (LHV) evaluated for a constant pressure process is used. By definition, the fuel exergy (B_{fuel}) is given by the Gibbs free energy (Equation 10).

2.1.3 Example results

2.1.3.1 Engine specifications and operating conditions. The results provided next are for an automotive, 5.7-L V-8 engine with a bore and stroke of 101.6 and 88.4 mm, respectively. Table 1 lists the engine specifications. The combustion model used is based on the Wiebe function, which has been found to be representative of engine combustion (Wiebe, 1970). The Wiebe combustion parameters used here were recommended by Heywood (1988): $m = 2.0$ and $a = 5.0$.

A base-case operating condition has been selected for most of the following results. This condition is a part-load condition that is near the frequent operating conditions for many light-duty driving cycles, and includes an engine speed of 1400 rpm and an engine load specified by a brake mean effective pressure (BMEP) of 325 kPa. Table 2 lists examples of the values of other parameters (and "how obtained") that were needed in this work. The inlet pressure was determined for obtaining a BMEP of 325 kPa, and the combustion start was selected to maximize the brake torque (MBT). This section provides some examples of the results from the engine thermodynamic simulation, and these results include detailed time-resolved results and the overall performance results.

DOI: 10.1002/9781118354179.auto123
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is nearly symmetrical about top dead center (TDC) (0° crank angle) with a maximum pressure of about 720 kPa. The firing pressure has a maximum of 1863 kPa at 17.5° after top dead center (aTDC). The one-zone (average of all zones) cylinder gas temperature increases rapidly during the combustion period and reaches a maximum of 2341 K at 29.2° aTDC.

Figure 3 shows the average overall (one-zone) gas temperature (T_{avg}) from Figure 2, and the temperatures associated with the zones defined after combustion begins as functions of crank angle for the base-case conditions. The latter zones include the unburned zone (T_u), the burned zone (T_b), adiabatic core (T_a), and the boundary layer (T_{bl}) zones. The adiabatic core and the boundary layer combine to form the burned zone. At the bottom of the figure is the unburned zone temperature, which remains below about 870 K. The burned zone gas temperature is the energy-averaged temperature of the boundary layer and adiabatic zones. The adiabatic zone has the highest temperatures, and for this case a maximum of about 2600 K is attained. The slightly higher adiabatic zone temperature compared to the burned zone temperature is particularly important for nitric oxide concentration predictions, which are highly temperature dependent (see NO_x Formation and Models). After combustion, the burned-zone temperature and the average temperature are the same. At any crank angle, the average (one-zone) temperature represents the energy-averaged temperature for all zones.

Figure 4 shows the mass flow rates as functions of crank angle (where 0° crank was defined in Figures 2 and 3) for both the intake (solid curve) and exhaust (dashed curve) flows for the base-case conditions. The positive flow rates are the flow rates in the natural directions: the intake flow is positive into the cylinder and the exhaust flow is positive out of the cylinder. The "blow-down" after the exhaust valve opens (EVO) attains a maximum flow of about 42.6 g/s, and then the exhaust flow decreases. The displacement phase of the exhaust flow, which is caused largely by the piston motion, results in a maximum of about 17 g/s at a crank angle of 300°. The flow is back into the cylinder during the valve overlap period—the time between the intake valve open (IVO) and the exhaust valve close (EVC) times. The intake flow begins the flow into the intake manifold during the valve overlap period. The flow reverses shortly after the EVCs. The first matter into the cylinder is the matter that previously flowed into the intake manifold. Once that matter has returned, then the fresh air and fuel vapor mixture flows into the cylinder. The intake flow attains a maximum flow rate of 32 g/s and then decreases. At the end of the IVO period, the flow reverses back into the manifold for a short period.

Figure 5 shows the average one-zone gas temperature as a function of the specific entropy for the base-case conditions. Specific crank angle "times" are denoted in the figure so that the complete process is shown from intake valve close, through compression, combustion, expansion, exhaust, intake, and back to intake valve close. The temperature increases at nearly constant entropy during the compression process, and then the temperature and entropy increase during the combustion process. The increase of entropy during the combustion process is indicative of the highly irreversible combustion process. Once combustion ends, the temperature decreases rapidly and the entropy decreases slightly during the expansion process. Once the "blow-down" portion of the exhaust period ends, the temperature decreases less rapidly and the entropy decreases a little more rapidly. Once fresh charge starts entering the cylinder, the temperature and entropy continue to decrease until they attain their values at intake valve close.

Although the entropy results are not needed for routine engine performance evaluations, these results are required for determining the exergy values. As described earlier, computing exergy requires a knowledge of entropy. The exergy results are provided later.

2.1.3.3 Engine performance results. Once the cylinder pressure is known as a *function of cylinder volume*, the engine performance may be obtained. The area within the pressure–volume diagram is proportional to the engine work output. From the work output, all the other engine performance and efficiency parameters may be determined using standard relationships (Heywood, 1988).

Table 3 lists results from the simulation for the base condition. The net indicated and brake thermal efficiencies were 30.6% and 25.3%, respectively. The associated net indicated and brake specific fuel consumption values were 264.8 and 320.7 g/kWh, respectively. The energy distribution indicates that about 28.5% and 40.2% of the fuel energy was assigned to heat transfer and exhaust gas energy, respectively. Additional results are listed that serve to illustrate the type of detail that is possible from these simulations. These additional results include peak cylinder pressures and temperatures, average exhaust gas temperatures, average overall fuel and airflow rates, and the residual fraction. Other such results are described below.

Table 4 is a summary of the energy and exergy values for the base case. These values are given both as a percentage of the fuel energy and exergy value, and as the actual value. The fuel energy is divided among work, friction,

Table 4. Summary of energy and exergy values for base case.

Item	Energy		Exergy	
	Value (kJ)	Percent (%)	Value (kJ)	Percent (%)
Brake work	0.2326	25.28	0.2328	24.66
Friction	0.0491	5.34	0.0492	5.21
Net indicated work	0.2817	30.62	0.2820	29.87
Heat loss	0.2626	28.51	0.2165	22.93
Net flowout	0.3703	40.20	0.2284	24.20
Destruction (comb.)	n/a	n/a	0.1979	20.97
Destruction (intake)	n/a	n/a	0.0128	1.36
Fuel not used	0.0062	0.67	0.0064	0.68
Total	0.9213	100.0	0.9440	100.0

heat transfer, exhaust, and unburned fuel. The fuel exergy is divided among the same items plus destruction during the combustion processes and intake mixing processes. Further comments on these distributions are provided next.

Figure 6 shows a "pie" chart of the energy (a) and exergy (b) distributions for the base-case conditions. The top half of the charts contains the energy and exergy inputs, and the bottom half of the charts contains the outputs. Inputs are from the fuel and the pumping work. The energy and exergy inputs are the fuel energy (or exergy) and the pumping work. The energy outputs are the gross indicated work, heat transfer, net exhaust gas energy, and unburned fuel. The gross indicated work consists of the brake work, mechanical friction, and pumping work. For this operating condition, significant energy is associated with the heat transfer and exhaust gas flow.

The right side of Figure 6 shows the exergy distribution. The exergy inputs are similar to the energy inputs. For the exergy outputs, since the work is exergy, the work values are the same as for the energy chart. The heat transfer and exhaust exergy are smaller portions (compared to the energy portions) since not all of the energy is equivalent to exergy. The new item for the exergy distribution is the destruction terms and especially the destruction during the combustion process, which for this case is about 21% of the fuel exergy.

The next three figures show results for engine performance as functions of operating and design variables. Figure 7 shows percentage of the fuel energy distributed among the various energy output items as functions of the engine load. Engine load is expressed in terms of BMEP. Brake work increases as load increases from idle to peak load. As plotted, the brake work percentage is actually equivalent to the brake thermal efficiency since these items are based on the fuel input energy (LHV). The relative heat transfer decreases as load increases (note that the actual heat transfer is increasing but at a slower rate than the fueling rate increase). Finally, the exhaust gas energy percentage increases as the engine load increases. These results confirm the notion that operating the engine closer to full load improves brake efficiency because of lower relative losses.

As examples of using a thermodynamic cycle simulation to study engine design variables, the following results examine changes in compression ratio (Figure 8) and exhaust gas recirculation (EGR) levels (Figure 9). Figure 8 shows the relative energy (percentage of fuel input energy) as functions of compression ratio for the base-case conditions (Caton, 2007). The brake work increases rapidly as the compression ratio increases to about 10, and then the increases are much more modest as the compression ratio increases to 20. The friction work increases slightly with increases of compression ratio primarily because of the

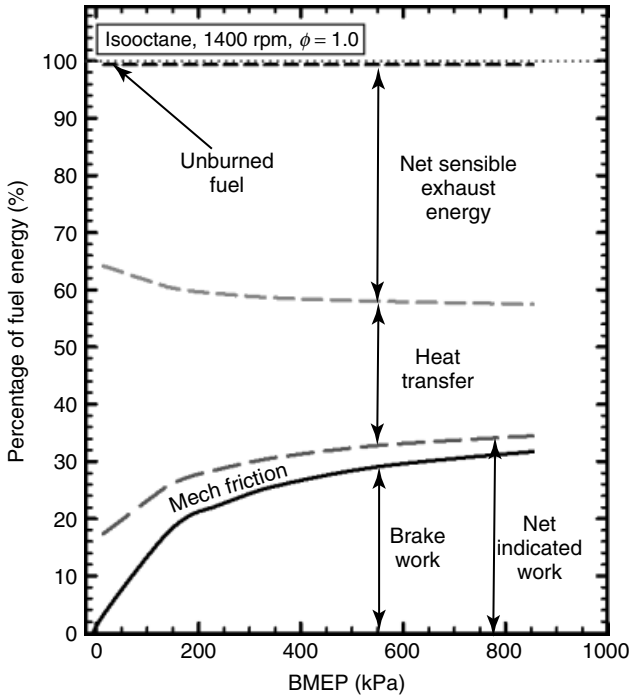

Figure 7. The percentage of the fuel energy for each item for 1400 rpm as a function of load for the base-case conditions.

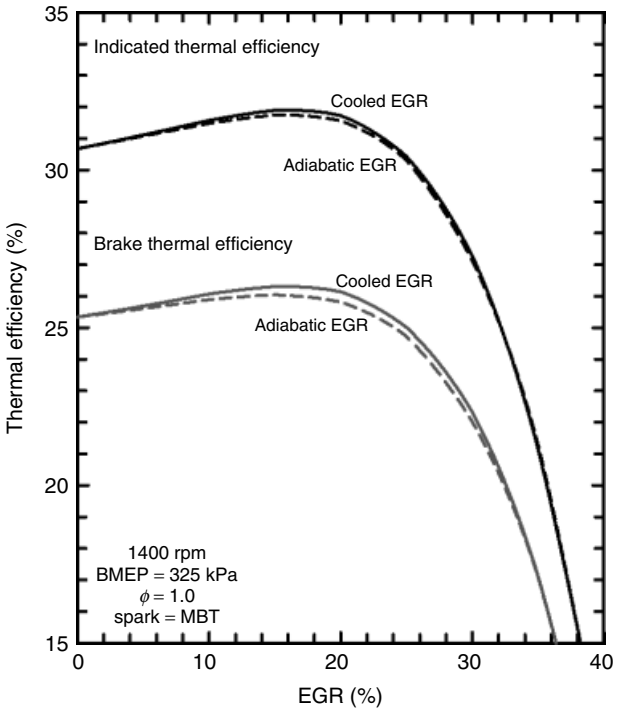

Figure 9. The net indicated and brake thermal efficiencies as functions of EGR for the base-case conditions.

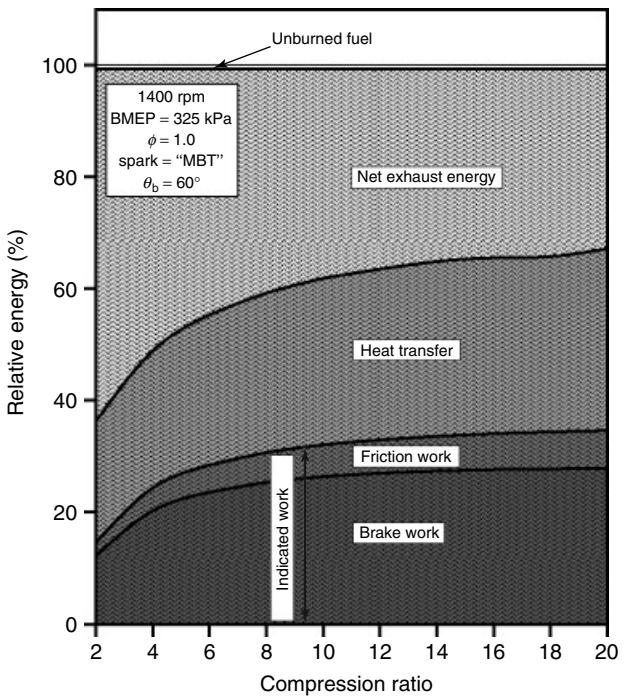

Figure 8. The percentage of the fuel energy for each item for 1400 rpm as a function of compression ratio for the base-case conditions.

higher cylinder pressures. The accuracy of the friction model plays a role in the exact details of this trade-off. The relative heat transfer increases as the compression ratio increases because of higher peak temperatures (even though temperatures during the expansion stroke are lower), higher pressures, and lower fuel consumption (higher efficiencies). Finally, the exhaust gas energy percentage decreases since work and heat transfer increase.

Figure 9 shows the net indicated and brake thermal efficiencies as functions of EGR level for both a cooled and an adiabatic EGR system (Shyani and Caton, 2009). An actual EGR system would be expected to have performance that is in between those of the cooled and adiabatic EGR systems. The efficiencies increase as EGR increases up to an EGR level of about 16%. For higher EGR levels, the efficiencies rapidly decrease because of increasing misfires and eventually incomplete combustion. The increase of the efficiencies for the 0–16% EGR range is largely due to decreasing heat transfer, lower temperatures, and favorable thermodynamics (largely the ratio of specific heats, or "gamma").

2.1.3.4 Low temperature combustion engines. A current example of the utility of these thermodynamic simulations is the assessment of the thermodynamics of low temperature combustion (LTC) engines. Examples of LTC engines are diesel LTC engines (discussed in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto123
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Diesel and Diesel LTC Combustion) and homogeneous charge, compression ignition (HCCI) engines (discussed in Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot). These engines have been shown to not only possess low emissions but also have significantly increased thermal efficiencies for some operating conditions. These new combustion modes involve various combinations of stratification, lean mixtures, high levels of EGR, high compression ratios, multiple injections, variable valve timings, two fuels, and other such features. A thermodynamic simulation has been used (Caton, 2010) to determine the fundamental thermodynamic reasons for the increases of the thermal efficiencies and to quantify these effects. Results were compared with similar experimental studies (Kokjohn *et al*., 2009), and these comparisons provided confidence that the dominant thermodynamic processes were captured correctly.

By systematically considering a number of the above features in a step-by-step manner, the impact of each feature was quantified. Five specific features were examined: the compression ratio increased from 8 to 20; the burn duration shortened from 60 to 30°CA; the equivalence ratio decreased from 1.0 to 0.7; the EGR level increased from 0% to 50%; and the cylinder wall temperature increased from 450 to 550 K. Each of these changes increased the thermal efficiencies. The greatest increases were obtained from the compression ratio increase, the leaner operation, and the increase in the EGR level. The brake thermal efficiency increased from 32.7% to 41.6% for a 900-kPa BMEP, 2000-rpm operation. Similar improvements were noted for a lower load case.

The thermodynamic simulation provided the following insights concerning the reasons for these improvements. The low temperatures due to the dilute charge were responsible for lower heat losses and higher ratios of the specific heats (gamma). The higher gammas resulted in more effective conversion of the thermal energy into work. The dilute charge operation, however, required higher inlet pressures to produce the 900 BMEP and this resulted in more friction that mitigated some of the thermodynamic gains noted for the net indicated thermal efficiency. Complete details of this study are available elsewhere (Caton, 2010).

2.1.3.5 Overexpanded engine designs. A final example of how these engine cycle simulations may be used is in evaluating engine concepts. An overexpanded engine design is one such concept. (This concept should not be confused with the "Miller cycle" concept that uses valve timing to modify the effective compression ratio relative to the expansion ratio.) The advantages of a longer expansion stroke compared to the compression stroke have been recognized from the very beginning of engine development. The overall cycle for these designs is often called an *Atkinson cycle*. The potential benefits of these overexpanded designs are frequently illustrated with simple air-standard cycle evaluations, but these analyses are too simple and miss some of the important features. The following results show how thermodynamic engine cycle simulations can be used to evaluate such a concept on a quantified basis. Complete details of this study are provided elsewhere (Caton, 2007).

The basic idea was to modify the conventional engine kinematics so as to allow a greater expansion stroke compared to the compression stroke. The engine performance parameters (such as BMEP) are based on the standard engine configuration using the compression stroke to determine the displaced volume. A wide range of compression and expansion ratios have been assumed. These may be outside practical ranges, but the intention was to illustrate the major trends more completely. A multiplier factor for the expansion stroke relative to the compression stroke was defined. For example, if an expansion ratio of 15 is desired and the compression ratio is 10, then the expansion stroke must be increased by a factor of 1.5 relative to the compression stroke.

For the part-load computations, the BMEP was held constant (=325 kPa). So, as the brake efficiency increased, the inlet pressure reduced. For each compression ratio case, as the expansion ratio increased, the thermal efficiency first increased, reached a maximum, and then decreased. The decrease of the efficiency after the maximum value was due to increased heat losses, increased friction, and ineffective exhaust processes (due to the reduced cylinder pressure at the time of exhaust valve opening). The expansion ratio for the highest efficiency appears to be equal to about the compression ratio plus 3. The use of this expansion ratio provides a modest thermal efficiency increase of about 1% absolute (e.g., from 24% to 25%).

For the wide-open throttle (WOT) computations, the inlet pressure remained at 95 kPa and the BMEP (load) was not constant. For WOT, the higher expansion ratios provided significant gains. For example, for a compression ratio of 10, expansion ratios of 10 (conventional engine) and 30 provided brake thermal efficiencies of about 34% and 43%, respectively. Although the net thermodynamic gains are significant, large expansion ratios (such as 30) may not be practical in most applications. Also, for many applications, WOT is not a frequent operating condition and the expense and complexity of an overexpanded engine design may not be justified.

In summary, the use of an overexpanded engine design is most effective for increasing an engine's efficiency at WOT conditions. For these cases, a large expansion ratio is needed to achieve the maximum efficiencies, and these large

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto123
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

expansion ratios may not be practical for most applications. Further, the efficiency gains are mitigated for part-load operation because of increased pumping losses associated with the constant load requirement. For all load conditions, the maximum efficiency was found for a specific expansion ratio for each compression ratio. Additional complexity and friction are further reasons why the overexpanded engine design is not more attractive than conventional designs.

3 COMPRESSION-IGNITION (DIESEL) ENGINE SIMULATIONS

This section will briefly describe the use of thermodynamic simulations for CI (diesel) engines. As mentioned above, much of the formulation is similar to that of the SI engine; the main difference is that the conventional diesel engine possesses a highly stratified combustion process that results in highly nonuniform temperatures and equivalence ratios. This may lead to significant problems with respect to considerations of ignition, combustion, heat transfer, and emissions. On the other hand, with good submodels, the overall performance predicted will still be consistent with the thermodynamics.

Historically, CI engines were the first to be modeled using these thermodynamic simulations (e.g., Heywood, 1988). The most important difference from the SI simulations is in the treatment of the heat release. This has been accomplished with empirical models that attempt to capture the various stages of combustion such as premixed and diffusion. More modern approaches have used models of the fuel jet.

3.1 Single-zone models

Single-zone models assume that the cylinder contents are uniform and may be represented by the average property values. Much like with the SI engine, the heat release may be prescribed. Because of the longer duration and different characteristics of the combustion process for the CI engine, alternative models are often used. For example, Watson, Pilley, and Marzouk (1980) described an algebraic function that incorporated two stages: a rapid premixed phase, followed by a slower mixing controlled burning phase. Many such models exist in the literature. The disadvantage is that these types of empirical models may not be correct for different operating conditions or for different engines.

3.2 Fuel-jet-based models

Fuel-jet-based models are attempts to describe the combustion process in a more fundamental way while still retaining the simplicity of the overall one-zone thermodynamics. In this case, the progress of the fuel spray is modeled by allowing "packets" to form as a function of time and for different "locations" in the fuel spray. For this simple simulation, the different "locations" are conceptual and cannot be related to actual spatial coordinates. However, this approach does allow different packets to have different equivalence ratios, different temperatures, and so forth. The total heat release is obtained by summing the heat release from the individual packets. Although this approach appears to be more realistic, items such as the entrainment into each packet is still somewhat arbitrary. Ultimately, these types of models are only as good as the experimental verification, much like the single-zone models described first.

The usefulness of these phenomenological models relies heavily on accurate information and knowledge of the fuel spray, fuel/air mixing, autoignition, and reaction. Development of advanced laser-based diagnostics has provided an abundance of new information and important knowledge concerning the reacting diesel fuel jet development (Espey *et al*., 1994; Dec and Espey, 1992). Dec (1997) proposed a conceptual model by combining these results, and provided a detailed understanding of the temporal and spatial evolution of a reacting diesel fuel jet. This new model has significant differences from old descriptions, and offers completely new insight and a clear picture of how diesel combustion proceeds.

This relatively newer conceptual model has promoted the development of newer and more advanced phenomenological models. Maiboom *et al*. (2009) developed a new phenomenological combustion model based on Dec's conceptual model. They were able to predict relatively accurate heat release rate and provide some important local information. This work did not include chemistry and thus was not able to calculate LTC conditions. In addition, the prediction of pollutant emissions was also not included. Asay (2003) and Ebrahimi, Bazargan, and Jazayeri (2007) created five-zone diesel cycle simulation models with the knowledge of the internal structure of direct-injection diesel fuel jets as well as empirical correlations predicting jet development. This model included all the basic features of diesel combustion. In particular, they extended the chemical equilibrium model to include 21 species, which allowed the program to be valid for equivalence ratios up to at least 8.0 (λ of 0.125). The downside of this model was the lack of some important submodels such as the lift-off length, the gas entrainment after combustion (incomplete combustion products oxidation), and the allocation of heat transfer. The lack of this information resulted in some inaccuracy of local thermodynamic properties as well as the heat release rate.

4 SUMMARY

This chapter has focused on the uses and limitations of zero- and quasi-one-dimensional thermodynamic engine cycle simulations with respect to understanding and development of engines. After a general description of the key items that comprise such a simulation, basic time-resolved cylinder pressures and temperatures and overall engine performance parameters were presented for a part-load operating condition. The temperature as a function of entropy, as well as the distribution of energy and exergy for the base case, was shown. Other example results included the percentage of the fuel energy as functions of load (BMEP) and compression ratio, and the thermal efficiencies as functions of the EGR level. The use of these simulations for LTC engines was briefly described. The use of these simulations to evaluate engine concepts was illustrated by examining an overexpanded engine concept. Finally, the application to CI engines was briefly described.

ACKNOWLEDGMENTS

Multidimensional Simulation

Rolf D. Reitz and Christopher J. Rutland

University of Wisconsin-Madison, Madison, WI, USA

1 INTRODUCTION

The combustion process in IC engines is characterized by complex multiphase, turbulent reacting flows. In addition, IC engine combustion spans multiple regimes that cover premixed flame propagation, mixing-controlled burning, and chemical-kinetics-controlled processes (Haworth, 2005). Modeling IC engines requires that these physical and chemical processes be described using mathematical models and accurate numerical schemes, as reviewed by Reitz and Sun (2009). The goal is that model predictions can be used to reduce the need for expensive laboratory engine testing and for efficient engine design optimization. The integration of engine modeling with optimization methods has been described by Shi, Ge, and Reitz (2011).

Zero-dimensional (0D) IC engine models based on thermodynamic cycle analysis were introduced in the mid-1900s, and are still useful for interpreting measured engine data (e.g., Zero- and One-Dimensional Methodologies and Tools, Herold *et al*., 2011). These models use simple mathematical formulae such as the Wiebe function (Wiebe, 1956, 1962; Ghojel, 2010) to specify the fuel burning rate. 0D engine heat transfer models are also based on empirical models, such as that of Woschni (1967). However, these empirical models have been shown to require extensive tuning, especially when applied to new engine concepts such as low temperature combustion (LTC) (e.g., Caton, 2011).

Multidimensional computational fluid dynamics (CFD) modeling promises to reduce the amount of model calibration effort required in engine simulation. Instead of describing engine processes empirically, partial differential conservation equations are solved on a finite difference numerical mesh that represents the time-varying engine geometry and the evolution of the combustion process. Submodels are still required to describe processes that occur on time and length scales too small to be resolved in the simulations, but these models have more "universality," as they refer to "microscale" processes that are common to general flows. For example, even though wall boundary layers may be too thin to be resolved in a practical engine CFD mesh, adequate wall heat transfer predictions can be obtained using "law-of-the-wall" submodels that use local information about the mean flow in computational cells at the combustion chamber walls. These submodels are often derived from experiments conducted in more controlled environments than engines, such as in steady pipe flow.

1.1 Multidimensional modeling

The use of multidimensional CFD for engine modeling began to displace simpler 0D models as computers became more and more powerful starting in the 1980s. However, engine CFD modeling was still not generally applied for engine design, as computer capacity was limited and engine submodels were still under development. Instead, in that era, 0D engine modeling was supplemented by

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

ISBN: 978-0-470-97402-5

phenomenological models to extend the predictive capability of models. These phenomenological models include the quasi-steady spray models of Hiroyasu, Kadota, and Arai (1978), and the soot and NO formation models of Hiroyasu and Kodota (1976), which are still widely used today for rapid trend analysis. Engine phenomenological models for engine applications are reviewed by Lakshminarayanan and Aghav (2010).

A significant step in the progress of multidimensional modeling was the release in the 1980s of engine CFD codes by the Los Alamos National Laboratory, eventually culminating in the widely used open-source KIVA codes (Amsden *et al*., 1985; Amsden, O'Rourke, and Butler, 1989; Amsden, 1993, 1997). This was accompanied by the release of several commercial engine codes, such as Computational Dynamics' Star-CD, AVL's FIRE and Ricardo's VECTIS code. These codes included the capability to represent moving meshes for the piston and valves, and they provided submodels to handle turbulent compressible flows with spray and droplet evaporation, and with fuel combustion chemistry. In a 1995 review, Reitz and Rutland (1995) concluded that multidimensional CFD modeling was able to match experimental engine pressure traces and heat release rates over wide ranges of conditions, and that good quantitative agreements in nitric oxide (NO*x*) and soot emissions were also attainable. Relatively simple combustion chemistry models, such as those based on the Shell Ignition model (Halstead, Kirsh, and Quinn, 1977), were integrated in these CFD codes to describe the combustion process (e.g., Kong, Han, and Reitz, 1995). However, the inclusion of more and more detailed and realistic fuel chemistry models was made possible by the early 2000s with further increases in computer power (e.g., Kong *et al*., 2001). Significant advances have since been made in spray submodel development, as reviewed by Shi, Ge, and Reitz (2011). These improvements include the development of more accurate atomization, secondary drop breakup, collision and coalescence, vaporization and spray-wall impingement models (see also Fuel Introduction: Fuel Introduction). In addition, significant effort has been placed on the development of models that provide reasonably grid-size and time-step independent predictions (e.g., Abani and Reitz, 2010).

Although today's multidimensional engine modeling codes still have quantitative uncertainties, it should be recognized that often the input to codes is itself uncertain, and this can greatly affect predictions (e.g., Yi *et al*., 2000). For example, injector nozzle-hole diameters can have a dramatic effect on pollutant emission predictions. However, typically, only nominal nozzle-hole sizes are specified, and these diameters can even change during engine use because of erosion and cavitation effects. In addition, owing to the hostile engine environment, validation experiments are difficult to perform, and measurement accuracy is affected by compromises that are required in setting up experiments that provide access to the combustion process or real engine phenomena such as cycle-by-cycle variability. In spite of these difficulties, it is now widely recognized that engine CFD model simulations can offer significant advantages to supplement experimental measurements in the engine development process by providing detailed in-cylinder information, which is normally not available or is inaccessible in experiments. Other advantages over engine experiments include lower cost, the ability to explore wider ranges of parameter variation, and the ability to separate and monitor individual physical and chemical processes. In addition, when coupled with optimization tools, previously unimagined engine concepts can be discovered using multidimensional modeling.

Shi, Ge, and Reitz (2011) provide examples that demonstrate that current multidimensional CFD tools are mature enough to guide the development of more efficient and cleaner internal combustion engines. For example, modeling has been applied to study new LTC concepts, such as homogeneous charge compression ignition (HCCI), premixed charge compression ignition (PCCI), and reactivity-controlled compression ignition (RCCI), that offer the promise of dramatically improved engine efficiencies. Optimized dual-fuel RCCI operation (port injection of gasoline together with optimized in-cylinder multiple diesel fuel injections) was discovered using CFD modeling by Kokjohn *et al*. (2011a). The computer simulations predicted high efficiency, low emission operation with excellent combustion phasing control at high and low engine loads without excessive rates of pressure rise. Subsequent engine experiments confirmed the model predictions, and demonstrated that US EPA 2010 NO*x* and soot emissions mandates can be met in-cylinder without after-treatment, while achieving up to 57% gross indicated thermal efficiency. The model and experiment comparisons for RCCI are presented in more detail in Section 3.2.1.

1.1.1 Governing equations

The basic governing equations for the multiphase flows in IC engines are the continuity (mass conservation), momentum (Navier–Stokes equations), energy, turbulence equations (normally the k–ε equations), and equations of state (ideal gas law). The gas mixture consists of multiple species, and the continuity equation for species k is

$$\frac{\partial(\rho Y_k)}{\partial t} + \frac{\partial(\rho Y_k U_j)}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\rho D \frac{\partial Y_k}{\partial x_j}\right) + \dot{\omega}_k + \dot{\rho}_k^{\mathrm{s}} \quad (1)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where Y_k is the mass fraction of species k, ρ the total mass density of the mixture, and U is the fluid velocity, t is time and x_j ($j = 1, 2, 3$) are Cartesian space coordinates. D is the single turbulent diffusion coefficient with the assumption of Fick's law diffusion. $\dot{\omega}_k$ and ${\rho_k}^{\mathrm{s}}$ are source terms due to chemical reaction and spray evaporation/condensation, respectively. Summing Equation 1 over all species yields the continuity equation for the gas phase:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho U_j)}{\partial x_j} = \dot{\rho}^{\mathrm{s}} \tag{2}$$

where ρ^{s} is the sum of all species spray evaporation/condensation terms.

The momentum equations for the gas-phase are

$$\frac{\partial (\rho U_i)}{\partial t} + \frac{\partial (\rho U_i U_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j} + F_i^{\mathrm{s}} + F_i^{b} \tag{3}$$

where p is the pressure and τ is the viscous stress tensor:

$$\tau_{ij} = \mu \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} - \frac{2}{3} \frac{\partial U_{\mathrm{k}}}{\partial x_{\mathrm{k}}} \delta_{ij} \right) \tag{4}$$

where δ is the Kronecker delta, and ${F_i}^{\mathrm{s}}$ is a source term due to spray drop drag forces. ${F_i}^{\mathrm{b}}$ is the gravitation body force equal to ρg.

The energy conservation equation can be expressed in terms of sensible energy, e, which is the specific internal energy exclusive of chemical energy, as

$$\frac{\partial (\rho e)}{\partial t} + \frac{\partial (\rho e U_j)}{\partial x_j} = -p \frac{\partial U_j}{\partial x_j} + \frac{\partial J_j}{\partial x_j} + \dot{Q}^{\mathrm{s}} + \dot{Q}^{\mathrm{c}} \tag{5}$$

The heat flux vector $\mathbf{J}$ is the sum of contributions due to heat conduction and enthalpy diffusion:

$$J_j = -K \frac{\partial T}{\partial x_j} - \rho D \sum_{k=1}^{N_{\mathrm{s}}} h_k \frac{\partial Y_k}{\partial x_j} \tag{6}$$

$\dot{Q}^{\mathrm{s}}$ and $\dot{Q}^{\mathrm{c}}$ are source terms due to spray and chemical reaction, respectively, and N_{s} is the total number of species. Assuming an ideal gas, the state equation is used to relate pressure and density:

$$p = \rho R T \sum_{k=1}^{N_{\mathrm{s}}} \frac{Y_k}{W_k} \tag{7}$$

where W_k is the molecular mass of the kth species.

1.1.2 Solution methods

Eulerian–Eulerian or Eulerian–Lagrangian (i.e., Discrete Droplet/Particle) methods have been proposed for solving the governing equations. However, the Eulerian–Lagrangian approach is used in most engine CFD simulations. In this approach, the gas phase is treated as continuous and the Eulerian formulation is used to solve the gas-phase equations. As described in Fuel Introduction, the liquid phase is treated as consisting of discrete particles described using the Lagrangian approach, in which liquid droplets are represented as assemblages of particles using the discrete particle method (Dukowicz, 1980). The Lagrangian description avoids numerical diffusion and allows individual attributes, such as particle size, velocity, position, and so on, to be statistically assigned to each particle. Mass, momentum, and heat transfer between the gas and liquid phases is accounted for using the spray source terms in Equations 1–3, and 5.

Finite volume, finite difference, and finite element methods that use a finite-difference mesh or grid to subdivide the computational region into a number of small cells are used to approximate the continuum partial differential equations of the gas phase. Most engine CFD codes employ the finite volume method because of its inherently conservative nature. The finite volume method applies the integral form of the governing equations, involving surface integrals (fluxes) and volume integrals (sources and sinks) to preserve the local conservation properties of the differential equations. The equations are discretized in both space and time. Usually, implicit differencing schemes are used to permit large numerical timesteps.

Mesh generation can be a tedious process in engine simulations owing to the complex, time-varying geometry of an engine. However, commercial software packages are available to aid in the process. In general, it is believed that body-fitted meshes, whose computational cells faithfully follow the combustion chamber surfaces, yield more accurate results near walls. But this can lead to distorted cells in the interior of the domain, with a corresponding reduction in accuracy, as numerical truncation errors increase on distorted meshes. Several commercial codes use Cartesian meshes whose wall cells require "clipping" or "trimming" in order to match wall boundaries. In this case, truncation error accuracy loss can be reduced by using local mesh refinement, but with corresponding increases in the computer time needed to solve the CFD equations on the resulting fine meshes.

As noted earlier, submodels are still required to describe the spray and combustion source terms in the governing conservation equations as they incorporate processes that occur on time and length scales too small to be resolved

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on the numerical mesh. Thus, numerous engine-related numerical models have been developed to describe the turbulent flow, injection, spray, fuel/air mixing, ignition, combustion, pollutant formation, heat transfer, and other processes in engines. The fuel injection and spray-related models are described in Fuel Introduction, while this section focuses on turbulence, combustion, pollutant formation, and other models.

2 TURBULENCE MODELS

The governing equations given earlier describe flows in IC engines completely. However, this would require enormous computing resources and the practical use of these equations require averaging. This averaging is viewed as ensemble or cycle averaging for Reynolds-averaged Navier–Stokes (RANS) approaches and local spatial averaging for large eddy simulations (LES). The averaging process is applied to velocities, pressure, temperature, and species concentrations so that they are replaced by decompositions into mean and fluctuating components. For illustration, the velocity vector is replaced by

$$U_i = \overline{u}_i + u_i' \tag{8}$$

where the overbar represents the averaged velocity and the prime indicates the fluctuating component. For engine flows, the averaging is commonly thought of as a density-weighted averaging (Poinsot and Veynante, 2005). When this decomposition of the velocity and other quantities is substituted into Equation 3 and the averaging process is applied to the equation, additional terms occur because of nonlinearities. The most important terms that occur are the Reynolds stresses and they arise from the second term on the left-hand side of Equation 3. The Reynolds stresses are the average (or correlation) between fluctuating velocity components and can be represented by a turbulent stress term:

$$\tau_{ij}^T = -\overline{\rho}\overline{u_i' u_j'} \tag{9}$$

Then, the momentum equation, Equation 3, can be rewritten as

$$\frac{\partial(\overline{\rho u_i})}{\partial t} + \frac{\partial(\overline{\rho u_i u_j})}{\partial x_j} = -\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial \overline{\tau}_{ij}}{\partial x_j} + \frac{\partial \tau_{ij}^T}{\partial x_j} + \overline{F}_i^{\mathrm{s}} + \overline{F}_i^{\mathrm{b}} \tag{10}$$

To solve this equation, a turbulence model for the Reynolds stresses is required. Additional modifications can occur because of nonlinearities in the F terms of Equation 3 as well as nonlinearities in the energy and species equations. All of these nonlinearities result in additional terms in the equations and they all require modeling. The modeling of the Reynolds stresses in Equation 9 forms the basis of most of these other models, so it is examined in detail.

2.1 Reynolds-averaged Navier–Stokes (RANS) models

RANS models are the most prevalent turbulence models in engine simulations. RANS models, specifically the k–ε model and its variants, have been used in engine simulations since CFD was first applied to the engine field. k is the turbulent kinetic energy and ε is its dissipation rate. With these two quantities, the Reynolds stresses are modeled by

$$\tau_{ij}^T = -\mu_{\mathrm{T}}\left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i}\right) \tag{11}$$

where μ_{T} is the turbulent viscosity and is modeled by

$$\mu_{\mathrm{T}} = \overline{\rho} C_\mu \frac{k^2}{\varepsilon} \tag{12}$$

The constant, C_μ, typically has a value of 0.09. An improved k–ε model, which is based on the renormalized group (RNG) theory, was first proposed by Yakhot and Orszag (1986). The k equation in the RNG version is the same as in the standard k–ε model, but the ε equation is based on a more rigorous mathematical derivation, instead of using empirical constants. The RNG k–ε equations are written as

$$\frac{\partial \rho k}{\partial t} + \nabla\cdot(\rho \mathbf{u} k) = -\frac{2}{3}\rho k \nabla\cdot\mathbf{u} + \tau : \nabla\mathbf{u} + \nabla\cdot[\alpha_k \mu \nabla k] - \rho\varepsilon + \dot{W}^{\mathrm{s}} \tag{13a}$$

$$\frac{\partial \rho \varepsilon}{\partial t} + \nabla\cdot(\rho \mathbf{u} \varepsilon) = -\left(\frac{2}{3}C_1 - C_3 + \frac{2}{3}C_\mu C_\eta \frac{k}{\varepsilon}\nabla\cdot\mathbf{u}\right) \times \rho\varepsilon\nabla\cdot\mathbf{u} + \nabla\cdot[\alpha_\varepsilon \mu \nabla\varepsilon] + \frac{\varepsilon}{k}[(C_1 - C_\eta)\tau : \nabla\mathbf{u} - C_2\rho\varepsilon + C_{\mathrm{s}}\dot{W}^{\mathrm{s}}] \tag{13b}$$

where τ is the stress tensor and μ is the dynamic viscosity, and α's and C's are model constants.

The standard k–ε model includes a source term $\left(-\left(\frac{2}{3}C_1 - C_3\right)\rho\varepsilon\nabla\cdot\mathbf{u}\right)$ in the ε equation to account for length scale changes with velocity dilation, and spray-induced source terms, $\dot{W}^{\mathrm{s}}$. Han and Reitz (1995) modified the constant C_3 in the RNG k–ε model to take

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the compressibility effect into account. In their modified RNG k–ε model,

$$C_3 = \frac{-1 + 2C_1 - 3m(n-1) + (-1)^{\delta}\sqrt{6}C_{\mu}C_{\eta}\eta}{3}$$

where η is a ratio of turbulence and mean flow time scales, and m and n are related gas properties while C_{μ} and C_{η} are constants. Other details of the modified RNG k–ε turbulence model are given by Han and Reitz (1995) who applied the model to engine simulations. It was shown that the model could predict more realistic large-scale flame structures compared with the standard k–ε model. These structures influence in-cylinder temperature predictions and the modified model was able to quantitatively improve NOx emission predictions (Kong, Han, and Reitz, 1995).

2.2 Large eddy simulation (LES) models

The engine fuel preparation and combustion processes are controlled by the details of turbulent fluid motions. Although the simpler k–ε turbulence models are still widely used in industry, they have limited ability to resolve the detailed flow structures that are responsible for mixing and combustion in engines. LES is a numerical technique for simulating turbulent flows, first introduced by Smagorinsky (1963), that addresses this shortcoming. Kolmogorov's theory of self-similarity implies that the large eddies of a turbulent flow are dependent on the device geometry, while smaller eddies are self-similar and have a universal character (Kolmogorov, 1991). Therefore, the basic idea of LES is to solve only for large-scale eddies explicitly (i.e., those that can be resolved on the computational mesh), and to model the more universal small-scale (sub-grid scale, SGS) eddies on large meshes through the use of an SGS model. In contrast, in RANS, all fluctuations about the ensemble mean are modeled.

Therefore, LES has advantages over RANS in terms of predicting the instantaneous large-scale flow characteristics. This means LES is able to simulate important aspects of engine flows that RANS is not able to capture. For example, one of the more important applications of LES is to simulate cyclic variability (Vermorel *et al*., 2009). Another important use of LES is to simulate design sensitivities such as variations in port design (Thobois, Lauvergne, and Poinsot, 2007) and fuel injection characteristics (Giannadakis *et al*., 2009). Because LES captures large-scale flow features, it can also be more accurate than RANS simulations (Richard *et al*., 2007). However, LES is usually more computationally intensive than RANS and often requires the simulation of multiple, consecutive combustion cycles, increasing the computational cost even more (Vermorel *et al*., 2007).

Background information on LES modeling can be found in Pope (2000) for general information and in Rutland (2011) for LES in engine simulations. LES modeling assumes a different decomposition than RANS for Equation 8. In LES, the overbar represents a local spatial average. This can also be viewed as a local filtering of the velocity field that leaves the large eddies and removes the high frequency or sub-grid velocities. Then, $\overline{u_i}$ represents the large eddies and u'_i represents the sub-grid velocities. When this type of averaging is used in the momentum equations, Equation 3, the nonlinear term results in sub-grid stresses:

$$\tau_{ij}^{\mathrm{SGS}} = -\overline{\rho}(\overline{u_i u_j} - \overline{u}_i \overline{u}_j) \tag{14}$$

This replaces the Reynolds stresses τ_{ij}^{T} in Equation 10 and requires modeling. There are many types of LES models available, but the Smagorinsky model is common.

$$\tau_{ij}^{\mathrm{SGS}} = -\mu_{\mathrm{SGS}}\left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right) \tag{15}$$

where μ_{SGS} is the sub-grid scale turbulent viscosity and is modeled by

$$\mu_{\mathrm{SGS}} = \overline{\rho}(C_{\mathrm{s}}\Delta)^2|\overline{S}| \tag{16}$$

In this expression C_{s} is the Smagorinsky constant, typically $\sim$0.17. The length scale, Δ, is related to the filter width and is commonly related to the local cell size. The inverse time scale, $|\overline{S}|$, is the magnitude of the strain rate tensor formed using the local filtered velocities. There are several improvements to the Smagorinsky model. For example, there is the dynamic Smagorinsky model, which uses the dynamic procedure of Germano *et al*. (1991) to find the constant, C_{s}, locally as a function of the solution. There is also the one-equation viscosity model (Deardorff, 1980), which includes a transport equation for the sub-grid kinetic energy, k_{SGS}, that is similar to the turbulent kinetic energy Equation 13a and uses this to model the sub-grid viscosity as

$$\mu_{\mathrm{SGS}} = \overline{\rho}C_{\mu k}\Delta k_{\mathrm{SGS}}^{1/2} \tag{17}$$

where the constant, $C_{\mu k}$, is typically given values in the range 0.05–0.1. Additional advancements in LES models make use of technologies that are only available in LES and not in RANS. These include scale similarity concepts (Meneveau and Katz, 2000), Taylor series models (Clark, Ferziger, and Reynolds, 1979), Lagrangian models (Meneveau, Lund, and Cabot, 1996), and nonviscosity models (Rutland, 2011).

3 PHYSICAL AND CHEMICAL SUBMODELS

As mentioned, submodels are required to describe physical and chemical processes that occur on time and length scales too small to be resolved in a practical engine CFD mesh. The following sections review current models that are used to describe ignition, flame propagation and volumetric combustion, and the formation of pollutants. In addition, heat transfer, wall-film, and crevice flow models are briefly discussed. Details of practical spray and droplet submodels are described in Fuel Introduction.

3.1 Ignition and combustion submodels

Combustion models are needed to represent the chemical source terms, $\dot{\omega}_k$, in Equation 1 and $\dot{Q}^c$ in Equation 5. Combustion models have been developed to simulate a wide variety of combustion phenomena in both spark-ignited (SI) and compression-ignited (CI) engines, including spark and autoignition, laminar and turbulent combustion, premixed, non-premixed and stratified-charge combustion, kinetics and mixing-controlled combustion, and flame propagation combustion. For SI engines, the main task of combustion modeling is to describe the spark ignition, flame kernel growth, and flame propagation processes. For CI engines, combustion modeling also involves two steps: low temperature chemistry, which leads to autoignition, and subsequent high temperature reactions that contribute most of the heat release. Advanced LTC strategies combine the premixed charge strategy of the SI engine with the compression ignition of the diesel, as described, for example, by Lu, Han, and Huang (2011).

3.1.1 Ignition models

In SI engines, the flame is initiated by the electrical discharge of the spark plug. As typical length and time scales in engine CFD models are much larger than those of the developing flame kernels during the spark ignition processes, it is not feasible to resolve ignition details in engine CFD calculations. Thus, a phenomenological description is often used in engine simulations. Spark ignition can be simply simulated by adding energy to the ignition cells empirically over the spark duration.

Other models that account for different levels of physics are available, such as the discrete particle ignition kernel (DPIK) model introduced by Fan *et al.* (1999) and later improved by Tan and Reitz (2003). In the original DPIK model, the flame kernel was assumed to be spherical during the spark period and marked by particles. The particles initially move as prescribed by the local laminar flame speed and spark discharge velocities, and then transition to the turbulent burning velocity as the kernel size becomes comparable to turbulent eddy size scales. Precise tracking of the growth of the ignition kernel is thus possible without the need for a very fine mesh near the spark plug. This modeling approach has recently been extended by Dahms *et al.* (2011) to allow the particles to be convected by the local CFD-predicted flow field, thus removing the constraint of a spherical growing spark flame kernel.

Autoignition must be considered to model knock phenomena in SI engines (e.g., conventional gasoline and GDI) and compression ignition in CI engines (e.g., conventional diesel and LTC). The autoignition process is controlled by the chemical properties of the fuel and oxidizer. Relatively simple models that use correlations for ignition delay times are available. More accurate results are found with the use of reduced chemistry models, or with more detailed chemical kinetics mechanisms. Early engine CFD studies used the multistep "Shell" ignition model (Halstead, Kirsh, and Quinn, 1977), which was developed to predict the autoignition of hydrocarbon (HC) fuels. The premise of the Shell model is that degenerate branching plays an important role in determining the cool flame and two-stage ignition phenomena that are observed during the autoignition of realistic fuels. The model assumes that the ignition process can be described with five generic species and eight generic reactions, which represent the initiation, propagation, branching, and termination steps. To model diesel combustion, the Shell model is used only for the low temperature chemistry. After ignition (i.e., when the local gas temperature is greater than $\sim 1000\,K$), combustion models are used simulate the subsequent second-stage high temperature combustion (e.g., Kong and Reitz, 1993). As described next, in recent studies the ignition process is modeled by integrating it into the combustion model using detailed or reduced chemistry mechanisms that have been validated against shock tube or flow reactor data.

3.1.2 Flame propagation models

As engine combustion occurs in a turbulent flow field, combustion models are often based on RANS and LES turbulence timescales. However, turbulent flames, such as those in SI engines, are thought to comprise interacting laminar flame sheets, and under typical engine pressures and temperatures the laminar flame thickness is less than $50\,\mu m$, while typical CFD mesh sizes are about $1\,mm$. Thus, it is not possible to resolve turbulent flame structures and their detailed evolution in practical engine simulations. Instead, combustion models attempt to describe the overall combustion characteristics, such as the turbulent

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

flame propagation velocity and the conversion rate of reactants to products of combustion. The concepts of mixture fraction (Z) or reaction progress (c) are introduced in many combustion models. The mixture fraction quantifies the local mass fractions that originate from the reactant fuel (see Solving Combustion Chemistry in Engine Simulations—for detailed development of mixture fraction). This is useful in the analysis and modeling of non-premixed reacting systems. For premixed combustion systems, a reaction progress variable is often used. The progress variable increases from zero in the unburned reactants to unity in the burned products. The calculation of the progress variable can be associated with the mass fraction of a specific species (e.g., combustion products) or the temperature.

Flamelet and probability density function (PDF) models belong in the category of mixing-controlled combustion models. However, for spatially homogeneous fuel–air mixtures where flame propagation is not dominant, it is reasonable to assume that turbulence plays a lesser role in the combustion process. This is the case under engine operating conditions with low Damköhler numbers (slow chemistry timescales), for example, in LTC of premixed lean mixtures, such as in HCCI engines where chemical kinetics effects dominate. (However, it should be noted that turbulent fuel–air mixing is usually the agency by which the homogeneous fuel–air mixture is established in the engine.) In this case, it is often assumed that combustion occurs volumetrically in each computational cell, as in a "well-stirred reactor," and to account for the complex reaction pathways, detailed or reduced reaction chemistry mechanisms are used.

The simplest combustion model assumes a one-step global reaction (i.e., single timescale) for conversion of reactants to products based, for example, on a temperature-dependent Arrhenius model. This model neglects the effects of complex reaction paths and turbulence on the mean chemical reaction rate, and thus is generally only applicable over a narrow range of operating conditions. In turbulent mixing-controlled combustion models, it is assumed that the burn rate of the mixture is determined by the turbulent mixing rate, instead of by the chemical rate. This applies, for example, in diffusion combustion in conventional diesel engines, where turbulent mixing occurs relatively slowly compared to chemical reactions (high Damköhler number). In this case, it is reasonable to expect that turbulent transport of species and enthalpy to the reaction zone is the controlling factor. Spalding's (1971) eddy breakup (EBU) model was one of the first mixing-controlled models. Here, the burned and unburned gases are assumed to be located in different eddies, and the mean chemical conversion rate is controlled by the eddy's dissipation rate and by fluctuations of the fuel mass fraction or progress variable. In the EBU model, the reaction rate is expressed as

$$\dot{\tilde{\omega}}_{\mathrm{F}} = C_{\mathrm{EBU}} \frac{\overline{\rho}(\widetilde{Y_{\mathrm{F}}''^2})^{1/2}}{\tau_t}$$

where $\widetilde{Y_{\mathrm{F}}''^2}$ is the fluctuation of the fuel mass fraction and C_{EBU} is a model constant. When the k–ε turbulence model or its variants are used, the EBU time is $\tau_t \propto k/\varepsilon$.

For non-premixed turbulent combustion, Magnussen and Hjertager (1976) modified the EBU model such that the combustion rate is limited by the deficient species (fuel, oxidizer, or product depending on whether the mixture is lean or rich or the progress of reaction), and the fuel burn rate is

$$\dot{\tilde{\omega}}_{\mathrm{F}} = \frac{A\overline{\rho}\min\left(\widetilde{Y_{\mathrm{F}}}, \frac{\widetilde{Y_{\mathrm{F}}}}{r}, B\frac{\widetilde{Y_{\mathrm{P}}}}{1+r}\right)}{\tau_t}$$

where A and B are model constants, r is the stoichiometric oxidizer/fuel ratio, and Y_{F} and Y_{P} are the fuel and product mass fractions.

Other hybrid EBU/Arrhenius models have also been proposed. For example, Reitz and Bracco (1983) proposed a laminar and turbulent characteristic timescale combustion (CTC) model, which was applied to engine combustion by Abraham, Bracco, and Reitz (1985). The model uses the k–ε model for turbulent transport and assumes that the characteristic timescale (τ_{c}) at which all the chemical species approach their equilibrium (indicated by * in the equation), is the sum of a turbulence characteristic time (τ_{t}) and a laminar or chemical characteristic time (τ_{l}) of Arrhenius form. The rate change of the concentration of species i is given as (Kong, Han, and Reitz, 1995)

$$\frac{\mathrm{d}Y_i}{\mathrm{d}t} = -\frac{Y_i - Y_i^*}{\tau_{\mathrm{c}}} \tag{18}$$

The CTC model has been used successfully to model both premixed (Abraham, Bracco, and Reitz, 1985) and non-premixed (Kong, Han, and Reitz, 1995) turbulent combustion.

Flamelet models have also been developed for both premixed and non-premixed combustion regimes. For premixed combustion with flame propagation, the models are based on tracking a flame-front interface defined either by a combustion progress variable, c, or by a nonreacting scalar, G, which divides the flow into burned and unburned portions (Peters, 2000). In the Bray–Moss–Libby (BML) model (Bray and Libby, 1994) and the coherent flame model (CFM) (Marble and Broadwell, 1977), the progress variable is viewed either as a normalized temperature or as a normalized product mass fraction. These models assume

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a single-step reaction from unburned reactants to burned products and an infinitely thin flame structure. In the BML model, a PDF of the progress variable is assumed to be a two-delta function distribution and the progress variable is tracked by solving a transport equation.

For premixed combustion with flame propagation, such as stoichiometric combustion in conventional SI engines, the premise of flamelet models is that the principal effect of turbulence on combustion is to increase the effective flame surface area, as described by Haworth (2005). The overall burn rate is assumed to be the product of the fuel burn rate per unit flame area and the active flame area per unit volume, and the local mean fuel burning rate is expressed as

$$\tilde{\dot{\omega}}_{\mathrm{F}} = \rho_{\mathrm{u}} \widetilde{Y_{\mathrm{FR}}} S_{\mathrm{L}} \Sigma$$

where ρ_{u} is the unburned gas density, $\widetilde{Y_{\mathrm{FR}}}$ the fuel mass fraction, S_{L} the local laminar flame speed, and Σ the flame surface density (flame surface area per unit volume). The laminar flame speed can be computed or stored in tables as a function of pressure, temperature, equivalence ratio, and strain rate. The flame surface density can be specified as an algebraic model, such as suggested by Bray and Libby (1994). A more complete approach is to solve a transport equation, as in the CFM. For example, Trouve and Poinsot (1994) proposed a formulation based on DNS data. Flamelet models decouple the chemical kinetics and turbulence, while maintaining local coupling between chemical kinetics and molecular transport (Haworth, 2005). Boudier *et al*. (1992) validated a CFM model by comparing simulation results with in-cylinder flame-front contours in an experimental SI engine.

Recently, flamelet models have been proposed for flame propagation in premixed combustion systems based on a level set method (Sethian, 1999), which tracks interfaces. With application to combustion, Williams (1985) suggested a transport equation of a nonreactive scalar, $G(x, t)$, for laminar flame propagation known as the *G-equation method*. In the G-equation method, flame propagation is driven by the bulk fluid velocity, u, of the unburned mixture ahead of the flame front, and the laminar flame speed S_{L} normal to the flame, n. The rate of change of flame position, x_{f}, that is, the flame propagation velocity is

$$\frac{\mathrm{d}x_{\mathrm{f}}}{\mathrm{d}t} = u + nS_{\mathrm{L}}$$

and the flame front is defined by the $G(x, t) = G_0$ iso-surface with G_0 normally set equal to zero. The domain is divided into an unburned region where $G < G_0$ and a burned region where $G > G_0$. The normal vector $\mathbf{n}$ is defined as

$$\mathbf{n} = -\frac{\nabla G}{|\nabla G|} = -\frac{\nabla G}{[(\nabla G)^2]^{1/2}}$$

and the transport equation for G is derived by differentiating $G(x, t) = G_0$ with respect to t, as

$$\rho\left(\frac{\partial G}{\partial t} + \boldsymbol{u} \cdot \nabla G\right) = (\rho S_{\mathrm{L}})|\nabla G|$$

Peters (2000) extended the G-equation to model turbulent flames as

$$\rho\frac{\partial G}{\partial t} + \rho \boldsymbol{u} \cdot \nabla G = (\rho S_{\mathrm{L}}^0)|\nabla G| - \underbrace{(\rho D_{\mathrm{L}})\kappa|\nabla G|}_{\text{Flame curvature}} - \underbrace{(\rho L)S|\nabla G|}_{\text{strain rate}} \quad (19)$$

In this case, the turbulent flame front is regarded as an ensemble of local laminar flamelets with considerations of flame stretch effects on the flame speed. The turbulent G-equation concept has been successfully applied to combustion simulations for SI engines by Dekena and Peters (1999), Tan and Reitz (2003), (2004), and Liang and Reitz (2006). Tan and Reitz (2004) showed that the G-equation model can also be applied to non-premixed combustion because, in this case, the only change is that $S_{\mathrm{L}} = 0$. This extension also forms the basis of their so-called GAMUT (G equation for all mixtures a universal turbulent) combustion model.

For non-premixed (or partially premixed) combustion, such as turbulent diffusion combustion in conventional CI engines, a representative interactive flamelet (RIF) model has been proposed (see Solving Combustion Chemistry in Engine Simulations for more details). The model is based on the assumption that the smallest turbulent time and length scales are much larger than the chemical ones, and that there exists locally undisturbed flame sheets where the chemical reaction occurs and that the turbulent eddies do not enter the reaction zone (Pitsch, Barths, and Peters, 1996). The composition, mass fraction of each species is assumed to be only dependent on the mixture fraction, Z. Therefore, only the transport equations of the mean and variance of the mixture fraction ($\widetilde{Z}, \widetilde{Z''^2}$) are solved, instead of having to solve the transport equations of each species, and the composition, Y_{i}, as a function of Z is given by laminar flamelet calculations that use detailed fuel chemistry. The flamelet equation for each species is given as

$$\frac{\partial Y_i}{\partial t} = \frac{\chi}{2}\left(\frac{\partial^2 Y_i}{\partial Z^2}\right) + \frac{\dot{\omega}_i W_i}{\rho} \quad (20)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where χ is the scalar dissipation rate. The scalar dissipation rate accounts for strain effects as

$$\chi = 2D\left(\frac{\partial Z}{\partial x}\right)^2$$

In this equation, the diffusivity D is taken as the turbulent diffusivity and thus both turbulent (first term on right hand side) and chemistry (second term) timescales appear in the flamelet Equation 20, similar to the CTC model, Equation 18. However, a single "representative" turbulence timescale is used for the entire computational domain in the RIF model, which limits its accuracy, as discussed by Singh, Reitz, and Musculus (2006). Variations of the RIF model that attempt to remove this restriction by introducing more than one "representative" flamelet in the simulation have been introduced.

To account for the effects of turbulent fluctuation, a presumed PDF can be used for Z. The PDF is usually assumed to be a beta PDF, which has two varying parameters determined from the mean and variance of Z ($\widetilde{Z}, \widetilde{Z''^2}$), and the mean composition is computed by integrating Z from 0 to 1 with the presumed PDF, $P(Z, \widetilde{Z}, \widetilde{Z''^2})$ as

$$\widetilde{Y}_i(\overrightarrow{x}) = \int_0^1 P(Z, \widetilde{Z}, \widetilde{Z''^2}) Y_i(Z) \mathrm{d}Z$$

In the original RIF model, the entire domain was represented by one flamelet (Pitsch, Barths, and Peters, 1996). Hence, the scalar dissipation rate at stoichiometric mixture χ_{st} is defined as the domain-averaged value rather than being spatially resolved. However, in improved flamelet models, the composition Y_{i} is computed as a function of both Z and χ, and a global value for the scalar dissipation rate is not assumed, but is computed using the local properties of each computational cell. Advanced flamelet models also consider fluctuations of the dissipation rate, which are usually modeled using a log-normal PDF. The integration for the mean composition then becomes:

$$\widetilde{Y}_i(\overrightarrow{x}) = \int_0^\infty \int_0^1 P(Z) P(\chi) Y_i(Z, \chi) \mathrm{d}Z \, \mathrm{d}\chi$$

To apply flamelet models to spray combustion, the effects of liquid vaporization on small-scale turbulent mixing and turbulent combustion should also be considered, such as in the model proposed by Demoulin and Borghi (2000).

PDF models can be used for both premixed and nonpremixed turbulent combustion modeling. Other turbulent combustion models determine the PDF by solving a transport equation, instead of specifying a presumed PDF. In these models, joint velocity-composition PDF transport equations for velocity and reactive scalars are solved, usually by using the Lagrangian Monte Carlo particle-based methods (Pope, 1985). The gas-phase flow is represented by a large number of particles, where each particle contains information about its position, velocity, temperature, composition, and so on, which evolve with time. This treatment is similar to the Lagrangian method used for spray modeling (see Fuel Introduction).

3.1.3 *Volumetric combustion models*

As mentioned, under premixed conditions it is often justified to ignore turbulence–chemistry interactions and to assume volumetric heat release in each computational cell. In this case, a chemical kinetics mechanism is provided and integrated directly into the combustion source terms in the energy and species conservation Equations 1 and 5. This usually involves solving a stiff system of ordinary differential equations (ODEs) that govern the rate of change of the chemical species involved in the reactions. The L reversible reactions in a general chemistry mechanism with N species can be expressed as

$$\sum_{j=1}^{N} \nu'_{ji} X_j \Longleftrightarrow \sum_{j=1}^{N} \nu''_{ji} X_j, \quad \text{for} \quad i = 1, 2, \ldots, L$$

where ν'_{ji} and ν''_{ji} are the stoichiometric coefficients for the reactants and products, respectively, X_j is the chemical symbol, and the system of ODEs, which expresses the net production rate of each species, is

$$\dot{\omega}_j = \sum_{i=1}^{L} (\nu''_{ji} - \nu'_{ji}) \left(k_{\mathrm{f}i} \prod_{j=1}^{N} [X_j]^{\nu'_{ji}} - k_{\mathrm{r}i} \prod_{j=1}^{N} [X_j]^{\nu''_{ji}} \right), \quad \text{for} \quad j = 1, 2, \ldots, N \qquad (21)$$

where $k_{\mathrm{f}i}$ and $k_{\mathrm{r}i}$ are the elementary forward and reverse rate coefficients for the ith reaction, usually expressed in Arrhenius form. The CHEMKIN code (Kee, Rupley, and Miller, 1991) is widely used to solve chemical kinetics problems, and can be integrated into CFD codes (e.g., in KIVA-CHEMKIN by Kong *et al.* (2001).

Various chemical mechanisms have been developed to describe the oxidation of different fuels. Gasoline and diesel fuels are multicomponent fuels and mechanisms are still not available for all of the component fuel species. To simplify the problem, iso-octane and *n*-heptane are often used as surrogates in reduced chemistry models because they have similar chemical characteristics as those of gasoline and diesel, respectively. However, the physical properties of the original multicomponent fuels (e.g., vapor pressure, density, surface tension, etc.) should still be used in modeling

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

nonchemical processes, such as the fuel spray vaporization, as described by Anand *et al*. (2011).

It should be noted that when chemical kinetics is directly integrated into CFD, the effects of turbulence on combustion are still considered at the resolved grid scale. However, each computational cell is treated as a "well-stirred" reactor undergoing volumetric heat release. Therefore, SGS turbulence–chemistry interactions are not considered. As stated earlier, each model has its own applicable range. However, it follows that as numerical grid sizes are reduced, more of the combustion process becomes resolved. Indeed, the direct integration of chemistry approach has been shown to be effective in modeling HCCI combustion (Kong *et al*., 2001) as well as conventional diesel diffusion combustion (Kong, Sun, and Reitz, 2007). Flamelet models such as the G-equation GAMUT model of Tan and Reitz (2004) and Singh, Reitz, and Musculus (2006) are available for cases where SGS turbulence–chemistry interactions might be important.

3.1.4 "Knock" models

Liang *et al*. (2007) modeled knock in spark-ignition engines using the G-equation flame propagation model combined with detailed chemical kinetics. Spark ignition was modeled with the DPIK ignition model, and the turbulent flame propagation was described by the G-equation. A 22-species, 42-reaction iso-octane (iC_8H_{18}) mechanism was adopted to model the autoignition process of the gasoline/air/residual-gas mixture ahead of the flame front, as depicted in Figure 1. In the simulations, the local pressure was monitored at numerous locations within the cylinder to obtain

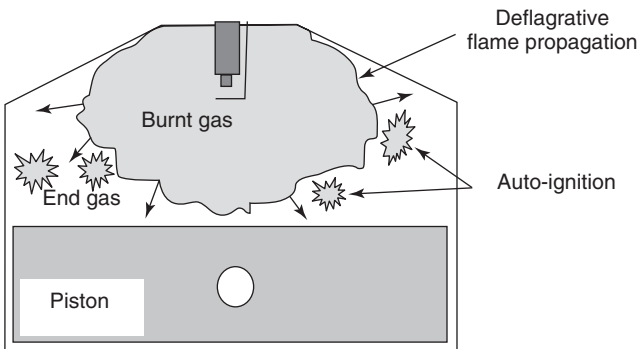

Figure 1. Schematic diagram of combustion modeling in SI engines. The DPIK particle model is used to model spark kernel growth, the G-equation is used to model turbulent flame propagation and a reduced chemistry mechanism is used for autoignition or knock modeling. (Reprinted with permission Copyright © 2007 SAE International (Liang *et al*., 2007).)

pressure fluctuation information that signaled the onset of knocking combustion or autoignition, as shown in Figure 2. The computed local pressure traces shown in Figure 3 were processed using a digital fourth-order Butterworth band-pass filter, and the maximum peak-to-peak value PP_{max} of the filtered data was used to quantify the knock intensity.

For quantitative comparison of knock intensities under different operating conditions, a knock index KI was defined as the average of the local PP_{max} values at N different locations, that is,

$$KI = \frac{1}{N}\sum_{n=1}^{N} PP_{max,n}$$

The corresponding flame front and temperature evolutions of the -25° after top dead center (ATDC) spark timing case are shown in the left column of Figure 4. In this case, end-gas autoignition does not occur until 25° after spark (or TDC). However, within a further 5°CA almost all the end gas is autoignited simultaneously at around TDC, giving a violent knock. In contrast, in the -10° ATDC case (right column of Figure 4), a considerable amount of end gas is autoignited ahead of the flame front by 20° after spark (much earlier than the 25° ATDC case). However, the autoignited mixture propagates along with the turbulent flame front (indicated by the solid black line), and no explosive autoignition is observed throughout the flame propagation process. Therefore, only a light knock is caused.

When including detailed fuel chemistry mechanisms in CFD codes, the computational time can become prohibitive owing to the large number of chemical species and reactions in Equation 21. Therefore, significant research has been focused on developing methods to save computer time while maintaining acceptable accuracy. For example, much effort has been placed on developing methods to reduce

detailed fuel chemistry mechanisms to skeletal mechanisms that eliminate species and reactions that are not crucial and still capture the major combustion characteristics of interest. In addition, reactions can be combined to remove unimportant intermediate species and reactions. In this case, the reaction rate constants of the remaining reactions usually need adjustment to account for the changes (e.g., Patel, Kong, and Reitz, 2004; Ra and Reitz, 2008). A detailed mechanism may contain several hundred species and several thousand reactions, and it can take months to finish a single cycle in engine simulations with realistic engine geometries. In contrast, a skeletal mechanism with tens of species and reactions only requires days or even hours of run time, which makes its application in engine simulations feasible. Other approaches, such as storage/retrieval-based schemes (Pope, 1997) and on-the-fly mechanism reduction during the computation, have also been used to speed up calculations (e.g., Shi, Ge, and Reitz, 2011; Puduppakkam *et al*., 2011).

3.1.5 Turbulence–chemistry interactions

Combustion regimes that range from locally premixed to partially premixed and non-premixed, with and without turbulence–chemistry interactions, can occur simultaneously in an engine. Thus, "universal" combustion models that can describe all types of combustion phenomena simultaneously are of interest. Hybrid models (e.g., Zellat *et al*., 2003; Tan and Reitz, 2004) that combine the models described have been described. Singh, Reitz, and Musculus (2006) assessed the CTC, RIF, and well-stirred or volumetric reaction (CHEMKIN) models for modeling diesel combustion in a heavy-duty (HD) DI diesel engine in different operating modes ranging from conventional high temperature diesel diffusion combustion regimes to so-called LTC regimes. The volumetric heat release model showed superior performance in predicting the LTC behavior and soot emissions as compared to the other two methods.

Kokjohn and Reitz (2011b) compared the performance of the G-equation flame propagation and volumetric heat release models as applied to diesel sprays, and found that turbulence–chemistry interaction effects were only noticeable at the flame lift-off location, the most upstream location of the OH mass fraction contours (surrounding the jets) shown in Figure 5. This work addressed the question of whether the flame lift-off length is governed by autoignition or flame propagation, and demonstrated that both the volumetric heat release and G-equation models described provide accurate lift-off predictions, whether or not flame propagation is considered in the model, as long as the lift-off length is defined as the distance from the tip of the injector to that axial location where significant OH radical formation is seen. As seen in Figure 5, both simulations and the experiments show a thin band of OH surrounding the spray plume, which indicates the presence of a diffusion flame at the periphery of the jet.

3.2 Pollutant emission models

A major goal of engine CFD modeling is to predict pollutant emissions. Of most concern are NO*x* and particulate matter (PM) or soot. The mechanisms of NO*x* production at high temperatures are well known and the extended Zel'dovich mechanism is the most commonly used to describe NO formation (see NO_x Formation and Models and Heywood,

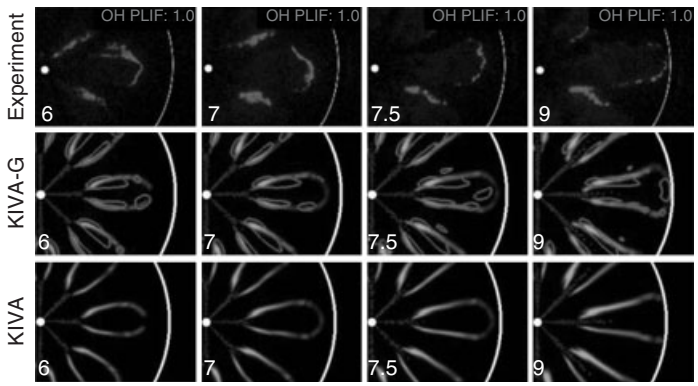

Figure 5. Comparison of measured OH PLIF (top row) and computed OH mass fractions (bottom two rows) for a high temperature, short ignition delay condition from 6 to 9° before TDC. Modeling with (KIVA-G) and without (KIVA) considering flame propagation. Dot indicates injector nozzle location. OH contours surround the jets, predicted $G = 0$ flame surface shown as islands, and spheres in simulation images show location of spray droplets. Flame lift-off is at the most upstream contour location.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

1988):

$$\begin{aligned} O + N_2 &\Longleftrightarrow NO + N \quad (a) \\ N + O_2 &\Longleftrightarrow NO + O \quad (b) \\ N + OH &\Longleftrightarrow NO + H \quad (c) \end{aligned} \tag{22}$$

A factor of 1.533 (the ratio of the molecular weight of NO_2 to NO) is introduced to convert NO to NO*x*, and the steady-state assumption for *N* atoms is usually made. The Zel'dovich mechanism only accounts for the thermal NO. A number of other NO*x* mechanisms are also important under different engine operating conditions, such as the N_2O—intermediate mechanism, which plays an important role in NO production in fuel-lean LTC, and the Fenimore or prompt NO mechanism, which is important in fuel-rich combustion. When a detailed fuel chemistry kinetics mechanism is used for the combustion calculations, a NO mechanism can be integrated into the fuel mechanism to better predict NO*x* emissions. In this case, NO*x* is given as the sum of NO and NO_2. For example, a detailed NO mechanism has been developed and included in the GRI (Gas Research Institute) mechanism (see NO_x Formation and Models and Bowman *et al*., 1997) for methane by the GRI. Sun (2007) reduced the GRI NO mechanism significantly (containing an additional 22 species and 101 reactions, in addition to the fuel chemistry mechanism) and showed that a reduced mechanism, which contains only 4 additional species and 12 reactions, adequately reproduces results obtained with the original GRI NO mechanism in engine simulations.

Soot production involves complicated physical and chemical processes: particle nucleation, surface growth, surface oxidation, and particle coagulation, and so on. (see Particulate Formation and Models). As the mechanism of soot production is still not completely understood, developing an accurate soot model is a subject of much current research. Although soot models with detailed descriptions of the physical and chemical processes leading from the fuel molecules to soot particles have been developed (e.g., Particulate Formation and Models and Kitamura *et al*., 2002, use of such models in engine applications is still not feasible, because solving the soot related gas-phase chemistry itself takes significant computer time. Therefore, empirical soot models are still widely used in multidimensional engine simulations. For example, the Hiroyasu, Kadota, and Arai (1983) two-step soot model considers soot formation and soot oxidation as two competing processes, where:

$$\frac{dM_s}{dt} = \frac{dM_{sf}}{dt} - \frac{dM_{so}}{dt}$$

and M_{sf}, M_{so}, and M_s are the formed, oxidized, and net soot mass in each computational cell at time, *t*. In this model, soot formation is assumed to be proportional to the concentration of fuel vapor and the oxidation step describes the destruction of soot particles by oxygen. Patterson *et al*. (1994) replaced the original Hiroyasu soot oxidation formulation with the Nagle and Strickland-Constable oxidation model (Nagle and Strickland-Constable, 1962) and achieved more realistic predictions. In their model, carbon oxidation occurs by two mechanisms whose rates depend on surface chemistry involving more reactive and less reactive sites. Kong, Sun, and Reitz (2007) pointed out that the concentration of fuel vapor can no longer be associated with soot formation when detailed fuel chemistry is used, as the fuel decomposes to smaller intermediate HC molecules very quickly once the low temperature reactions occur. They suggested use of acetylene (C_2H_2) as the inception species for the soot formation.

Although adequate results can be obtained using the relatively simple two-step soot model, its model constants require some tuning, as described by Wang, Reitz, and Yao (2012). Thus, more detailed models are of interest. Fusco, Knox-Kelecy, and Foster (1994) proposed an eight-step phenomenological soot model in which eight global reactions describe the fuel pyrolysis, particle inception, surface growth, coagulation, and oxidation. Tao *et al*. (2005) improved this model by generating soot precursor species from acetylene, rather than directly from fuel molecules. They also added an additional OH-related oxidation step into the eight-step soot model. This modeling approach has been extended by Vishwanathan and Reitz (2010) to include a reduced kinetics model for PAH species up to pyrene (four-ring aromatic), which serves as the soot precursor species. This model has been found to be able to successfully reproduce soot formation trends in diesel sprays and engines with reduced need for model constant tuning.

3.2.1 *Application to optimization of RCCI combustion*

To illustrate application of the above-mentioned combustion and emission models, the dual-fuel RCCI results of Kokjohn *et al*. (2011a) are reviewed in Figures 6 and 7. RCCI combustion uses in-cylinder blending of two fuels with differing autoignition characteristics to control premixed charge combustion. In Kokjohn *et al*.'s study, gasoline was delivered using a port-fuel injector and diesel fuel was delivered using a common rail-direct injector using multiple injections in a 2.4 L single-cylinder HD diesel engine operating at 1300 rev/min. The injections' timings and durations were selected using CFD modeling combined with the genetic algorithm optimization tools

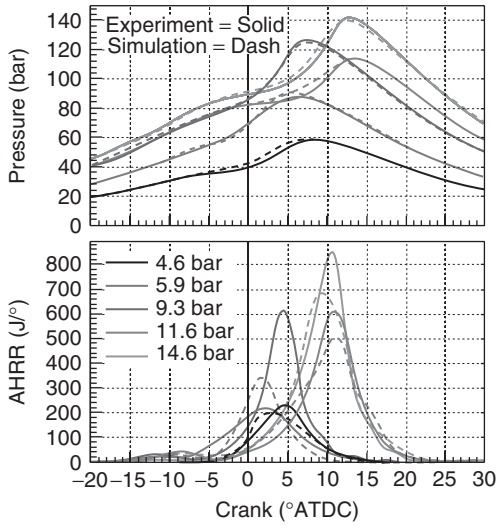

Figure 6. Comparison of measured and predicted dual-fuel RCCI cylinder pressure and apparent heat release rate (AHRR) over the load range from 4.6 to 14.6 bar IMEP. The experimental traces are shown in solid lines and the simulation results are the dashed curves. (Reproduced with permission from Kokjohn *et al.*, 2011a. © SAGE Publications Ltd.)

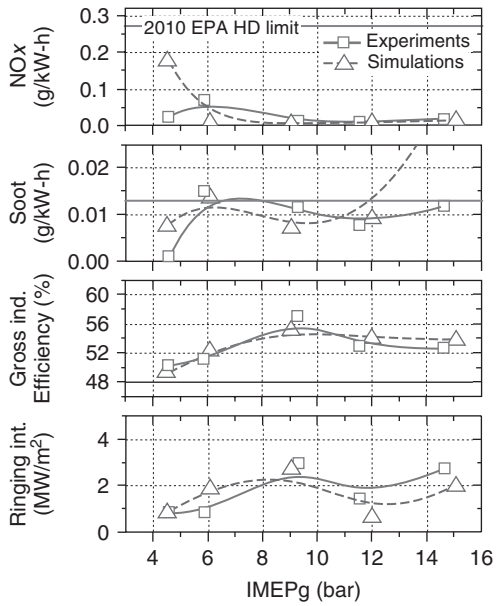

Figure 7. Measured and predicted emissions and performance of dual-fuel RCCI over a range of loads from 4.6 to 14.6 bar IMEP. The solid horizontal lines show the US 2010 environmental protection agency's on-highway truck emissions limits for NO*x* and soot. (Reproduced with permission from Kokjohn *et al.*, 2011a. © SAGE Publications Ltd.)

described by Shi, Ge, and Reitz (2011) to reveal the optimum in-cylinder fuel-blending strategy. The first diesel injection, known as the *squish conditioning pulse*, was delivered near 60° BTDC, targeting the squish region of the combustion chamber. The purpose of this injection is to control the fuel reactivity to ensure complete combustion of the premixed gasoline in the outer portion of the combustion chamber. The second injection occurred near 35° BTDC and targets the bowl region of the combustion chamber. This injection event generates a relatively high reactivity region that acts as an ignition source. Note from Figure 6 that second stage ignition indicated by the start of the main heat release occurs near TDC, and thus there is significant time for fuel–air mixing. Thus, RCCI is essentially a low temperature HCCI-like combustion process, but with fuel reactivity gradients providing control of combustion.

Figure 6 shows the measured and predicted cylinder pressures and apparent heat release rate (AHRR) over a load sweep from 4.6 to 14.6 bar indicated mean effective pressure (IMEP). The simulations are seen to be able to accurately capture the combustion characteristics over the entire load range. Figure 7 shows the corresponding measured and predicted emissions and performance. The gross indicated efficiency (defined as gross-indicated work/fuel energy) is seen to be ∼48% at the low load condition, peaks at ∼57% at 9.3 bar IMEP, and levels out near 52% for the higher loads. Also shown in Figure 7 are the US 2010 Environmental Protection Agency's HD on-highway truck limits for NO*x* and soot emissions (i.e., 0.268 g/kW-h and 0.0134 g/kW-h for NO*x* and soot, respectively). Notice that the measured NO*x* is near zero and significantly below the 2010 EPA HD limits. Furthermore, it can be seen that soot is extremely low and below the 2010 EPA HD limits for all but the 6 bar IMEP point, which is very near the limit. The predicted NO*x* and soot emissions also agree well with the measured data, as does the ringing intensity (RI). Because the engine operates under boosted conditions for all but the lightest load, the peak pressure rise rate is not representative of knock; therefore, the RI correlation of Eng (2002) is used. Ringing intensities below 5 MW/m^2 indicate acceptable combustion noise and knock-free operation (Dec and Yang, 2010).

3.3 Heat transfer, wall-film, and crevice flow models

Other models are needed in multidimensional engine simulations, such as wall heat transfer and liquid film models, radiation models, and crevice models, depending on the application. Heat transfer at the cylinder walls

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto124
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

significantly affects engine performance, efficiency, and emissions, and is mainly due to gas-phase convection, liquid fuel film conduction, and high temperature gas and soot radiation. In most SI engines, gas-phase convection is the dominant factor for heat transfer. However, in CI engines, radiative heat transfer can become important, as described by Wiedenhoefer and Reitz (2003), who used a discrete ordinates model. Their study showed that nonuniform combustion chamber surface temperature distributions have a significant effect on heat loss through combustion chamber walls and on NOx emissions. A conjugate wall heat transfer model was used by Wiedenhoefer and Reitz (2003) to couple the gas-phase spray and combustion model with the metal component heat conduction.

As wall boundary layers are relatively thin compared to computational mesh sizes, velocity and temperature wall functions are often used to describe the gas-phase near-wall shear stress and heat transfer. Traditional temperature wall functions are derived under the assumptions of a steady and incompressible flow using the Reynolds analogy. However, Han and Reitz (1997) noted that the gas density varies significantly in IC engines and unsteadiness and chemical heat release may invalidate the analogy. Their model accounts for variable-density turbulent flows and was applied to gas/wall convective heat transfer predictions in both a premixed charge SI engine and an HD diesel engine. Satisfactory agreement between predicted and measured wall heat flux data was obtained under both firing and motoring conditions. When liquid films are present, the heat transfer between the gas phase and the liquid phase, the energy used to vaporize the fuel, and the heat conduction between the liquid film and the wall must all be considered. This is considered in wall-film (spray/wall interaction) models, such as that proposed by Amsden (1999).

The crevice region between the piston, cylinder, and piston rings can also have significant effects on engine performance. In engine CFD simulations, the flow through the piston-cylinder-ring crevice can be accounted for by introducing an additional crevice grid, which is attached to the main computational grid in the crevice region (e.g., Lee and Reitz, 2010). The other way is to use a phenomenological crevice flow model, such as the one by Namazian and Heywood (1982) and extended for use in engine CFD by Reitz and Kuo (1989). A major reason for using a crevice grid or a crevice model is to ensure that the compression ratio in the modeled engine is the same as that in the real engine. Another reason is to model unburned HC emissions more accurately. Unburned fuel from the piston-liner ring crevices is one of the major sources for HC emissions in IC engines.

4 HIGH FIDELITY LES COMBUSTION MODELS

When LES is used for turbulence modeling, as described in Section 2.2, the combustion model should be adapted for the higher fidelity simulations. As in RANS, combustion modeling in LES is required to represent the chemical source terms in Equations 1 and 5. In many cases, the LES combustion models are similar to the RANS models, with modifications for LES. Thus, direct chemistry approaches, RIF, characteristic time, PDF, flamelet, and G-equation combustion models can be used in LES as long as the models are updated to be theoretically consistent with LES and adapted to work with LES variables (Rutland, 2011).

A key component of most combustion models is a turbulence timescale. This can be used in combination with "laminar" timescales or inverse reaction rates from direct chemistry solutions (Equation 18). The turbulence timescale can be used in models to account for mixing limited reactions in non-premixed combustion modeling (Equation 20) or flame propagation in premixed combustion modeling (Equation 19). In RANS, turbulent timescales are typically modeled using turbulent kinetic energy, k, divided by the turbulence dissipation rate, ε. In LES, these variables are not available and turbulence timescales are more difficult to obtain. A rudimentary timescale can be found using the inverse large-scale strain rate or the mesh size divided by the turbulent viscosity (Equation 16). LES models that use a transport equation for the sub-grid kinetic energy, k_{SGS}, are better suited to LES combustion modeling because a turbulent timescale is more easily obtained as follows:

$$t_{\mathrm{SGS}} \sim \frac{\Delta}{k_{\mathrm{SGS}}^{1/2}} \tag{23}$$

Another approach that can be used in mixing-controlled combustion modeling is to develop an expression for the sub-grid scalar dissipation rate (see Equation 20 for the basic term). For example, Zhang and Rutland (2012), use scale similarity and a dynamic coefficient to develop a sub-grid scalar dissipation rate model that is used in diesel combustion modeling.

LES modeling results in more flow structures being resolved and appearing in the simulations. An example of this is shown in Figure 8. This shows temperature contours at the start of injection for multiple, consecutive engine cycles. The RANS results show more uniform temperature contours compared to the rich flow detail of the LES results. This figure also demonstrates that LES simulations are able to capture cyclic variability in more detail than RANS simulations. Also, note that the LES results indicate

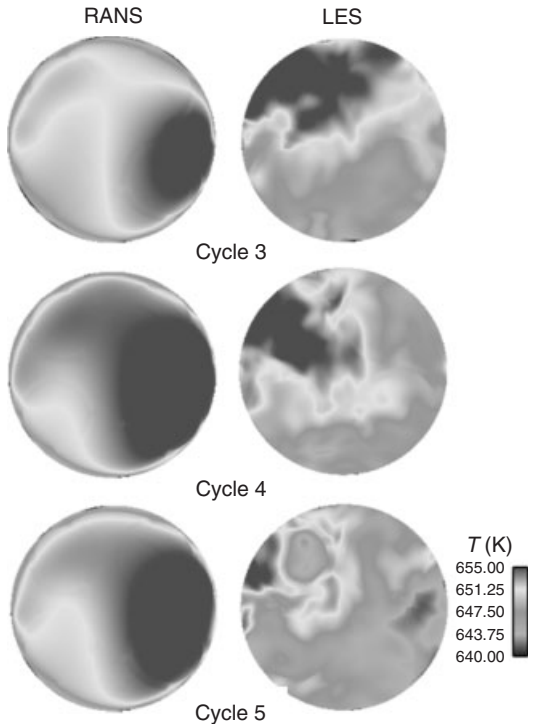

Figure 8. Comparison of RANS and LES simulations of multiple, consecutive engine cycles of a heavy-duty diesel engine showing temperature contours at the start of injection.

a slightly lower spatially averaged temperature than the RANS results owing to higher wall heat transfer resulting from the resolved large scales. These differences indicate that LES is more sensitive to flow details and more likely to correctly respond to changes in combustion system design. In addition, LES gives more accurate results in global parameters such as pressure traces and heat release profiles because more of the physics represented in the equations is solved directly on the mesh rather than being modeled (Rutland, 2011).

1 INTRODUCTION

The chemical composition of a fuel determines its properties, and the properties of a fuel determine its engine performance characteristics. Historically, the liquid-phase hydrocarbon (HC) fuels used for transportation and nonroad applications have been refined from crude petroleum recovered from beneath the surface of the Earth. HCs are compounds that contain only the elements hydrogen and carbon. A compound is defined as a pure chemical substance composed of two or more elements bonded in a specific structural arrangement and exhibiting fixed ratios of the different elements. The word "petroleum" is derived from Latin roots; its literal translation is "rock oil."

As supplies of readily accessible conventional petroleum are dwindling, the cost of petroleum production is increasing, and environmental and political concerns related to petroleum use are growing. This trend has intensified interest in "renewable" fuels that are currently created from biomass, and in the future might be created directly using solar energy, atmospheric carbon dioxide (CO_2), and water (H_2O). Renewable fuels can be beneficial from a greenhouse gas (GHG) perspective because they essentially recycle CO_2 (a GHG). For example, plants absorb carbon in the form of atmospheric CO_2 as they grow, which offsets the CO_2 released when fuels made from plants are burned. From a GHG perspective, this is preferable to continuing to convert petroleum carbon into new atmospheric CO_2. Although the histories of renewable fuels are significantly different from those of petroleum fuels, renewable fuels can contain many of the same kinds of chemical structures found in petroleum-based fuels, depending on how they are produced. One notable difference is that some common renewable fuels on the market today are oxygenates, that is, compounds that contain oxygen in addition to hydrogen and carbon.

Liquids composed primarily of hydrogen, carbon, and perhaps some oxygen are fuels of choice for transportation applications because of the high amounts of energy they contain per unit mass (specific energy) and per unit volume (energy density). For example, the specific energy of diesel fuel is approximately an order of magnitude larger than that of dynamite. This is primarily because effectively the entire mass of diesel fuel is fuel elements, while the mass of an explosive such as dynamite includes the mass of the oxidizer as well as fuel elements, and the oxidizer does not

carry any extra energy. The specific energies of liquid HC fuels also are many times larger than those of advanced batteries. This high specific energy means that only a small mass of fuel needs to be carried aboard a vehicle or machine to produce a large amount of useful mechanical work. For at least a century, the reciprocating internal combustion engine has been the device of choice for converting the chemical energy stored in liquid fuels into mechanical work for ground transportation and nonroad applications.

Currently, reciprocating internal combustion engines for passenger car and commercial applications fall into either of two broad categories: spark-ignition (SI) engines or compression-ignition (CI) engines. SI engines tend to be used in light-duty applications (e.g., passenger cars) because they are less expensive, quieter, and have lower exhaust emissions [thanks to the highly efficient three-way catalyst (Mooney, 2007)] than their CI counterparts. CI engines tend to be used in heavy-duty applications (e.g., truck, rail, and marine transportation) because of their higher efficiencies (i.e., lower fuel consumption per unit work output and hence lower fuel costs), better durability, and superior low speed torque capabilities.

The specific effects of changing a given fuel property depend upon many detailed parameters of the engine and combustion strategy in which the fuel is used, as well as the conditions over which the engine is operated. The fuel properties required for robust operation of SI and CI engines are different; as a result, different fuels have evolved for use with these different engines. SI engines typically burn gasoline, while CI engines typically burn diesel fuel. The primary differences between gasolines and diesel fuels are that gasolines are resistant to autoignition (i.e., spontaneous reaction of a mixture caused by elevated temperatures and/or pressures) and are more volatile (i.e., require less energy for vaporization and have lower boiling temperatures), while diesel fuels readily autoignite and are less volatile.

Covering all aspects of fuels for reciprocating internal combustion engines and the impact of fuel composition on engine performance in a single chapter of reasonable length is impossible. Hence, the objective of this chapter is to provide a broad overview of the relevant fuel science and a flavor of the key issues, while going into detail in selected areas of particular importance. The chapter starts with a discussion of fuel production techniques and fuel compositional attributes, followed by an overview of fuel properties that affect end-use characteristics and a discussion of the fuel specifications developed to ensure that fuels perform as required in their applications. The chapter concludes by summarizing the main points and offering some thoughts on what the future might hold for fuels and reciprocating internal combustion engines.

2 FUEL PRODUCTION

Fuels and fuel components can be produced from a wide variety of feedstocks including crude oil, oil sands, natural gas, biomass, coal, oil shale, methane hydrates, and even carbon oxides (CO and CO_2) reacted with hydrogen. This section reviews the primary fuel production pathways currently in use.

The huge scale of fuel production is a key factor to keep in mind when evaluating conventional and alternative technologies. In 2011, global oil consumption was ~88 million barrels per day (British Petroleum, 2012), and US consumption was ~19 million barrels per day (U.S. Energy Information Administration, 2012). At 42 US gallons per barrel, global oil consumption is ~3.7 billion gallons per day, or nearly four Olympic-sized swimming pools per minute, representing a market value of ~$9 billion per day at the present crude oil cost of ~$100 per barrel. Most of this oil is used to produce transportation fuels, with the balance used for heating oil and industrial processes.

2.1 Crude oil refining

The vast majority of the liquid HC components of fuels today are produced from petroleum-derived crude oil. Crude oils from different geographic locations and production processes can have a wide range of properties: from low densities and viscosities (“light”) to high densities and viscosities similar to tar (“heavy”), and from low sulfur (“sweet”) to high sulfur (“sour”). All crude oils are primarily composed of HCs of the alkane and aromatic classes (Section 3).

Refining is the process of converting crude oil into higher value products, including fuels for reciprocating internal combustion engines. A typical modern refinery is a complex combination of interdependent processes that can be divided into three basic categories: separation, upgrading, and conversion (Bacha *et al*., 2007; Gibbs *et al*., 2009).

Distillation is the most important and widely used separation process in a refinery. Distillation is a process at the front end of a refinery that divides crude oil into different boiling fractions. Petroleum fractions that undergo little or no processing beyond distillation are called *straight-run* products. In the early days of petroleum refining (when fuel demand was low, engines had low compression ratios, and sulfur specifications were nonexistent), refineries produced mostly straight-run products, but today significant further processing of the individual fractions is typically necessary to provide fuels with the required properties in quantities aligned with market demand.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Upgrading processes remove undesirable impurities such as sulfur, nitrogen, and metal compounds from fuel feedstocks. For example, bitumen (the tar-like HC derived from oil sands and a key feedstock for fuels in North America) requires extensive upgrading, after which it becomes "synthetic crude" that can be processed in a conventional refinery (Yui, 2008). The most common upgrading techniques in use today involve hydrotreating, a broad class of strategies involving reactions of the fuel species with hydrogen in the presence of a catalyst, usually at conditions of elevated temperature and pressure.

Conversion processes are used to enable the refinery to produce fuels meeting specifications in quantities that match the market demand. One class of conversion processes is cracking. Fluid catalytic cracking (FCC) and hydrocracking are used to lower ("crack") the molecular weights of the heavier fractions from the distillation column to those appropriate for the various fuel classes. Other conversion processes such as reforming and alkylation increase the octane number (ON) to levels suitable for gasoline by producing aromatics and branched alkanes, respectively.

Base fuels are produced by blending various intermediate streams in the correct proportions at the refinery. Other components can be blended into a base fuel at a pipeline or rail terminal downstream of the refinery. The blending of additives and/or other components (e.g., ethanol or biodiesel) results in finished fuels, which are subsequently distributed to their various points of sale.

2.2 Fischer–Tropsch processes

Another method of producing fuel components is to synthesize them from a mixture of carbon monoxide (CO) and molecular hydrogen (H_2), called *synthesis gas* or simply syngas. Such catalytic processes typically create HCs (e.g., alkanes, see Section 3.1) plus water (H_2O) as a by-product:

$$(2n+1)H_2 + nCO \rightarrow C_nH_{2n+2} + nH_2O \qquad (1)$$

The process name is derived from two German researchers who discovered effective catalysts and operating conditions to facilitate the reaction in Equation 1 and others like it. Depending on the specific catalysts and reaction conditions used, oxygenates also can be produced by Fischer–Tropsch (or simply F–T) synthesis. Syngas can be produced from coal, natural gas, or biomass feedstocks. Germany commercialized the process using coal to produce fuels during World War II. In South Africa during an oil embargo in the 1970s, Sasol made further technology developments and built F–T plants to produce fuels from coal, which remain operational even today. Several plants have recently been built in which natural gas is the feedstock that is converted to syngas. This can be advantageous because it can convert natural gas that might otherwise be stranded (uneconomical to transport to a market) or flared (burned in an open flame to reduce its global warming impact) into high value liquid fuels.

F–T synthesis can be used to produce diesel or gasoline fuels. Diesel fuel production is maximized by operating at lower process temperatures that favor the creation of waxy, long-chain, normal alkanes, and subsequently cracking the chains into the diesel range. To improve the cold-temperature properties of the diesel fuel, the normal alkanes are "isomerized" to produce branched alkanes (Section 3.1.2). The resulting product has a high cetane number (CN) (70+, Sections 4.1.2 and 4.1.2.2). The production of gasoline is maximized by operating at higher process temperatures and lower pressures.

One potential drawback of F–T fuels is that their near-zero aromatic contents can cause leakage issues for the elastomeric seals present in some fuel system that require aromatics to enable the seals to swell to form a tight fit (Section 4.4.2). Other potential disadvantages of F–T synthesis of fuels include the high capital costs for production, primarily due to the costs of syngas plants (at current fuel prices, F–T fuels are only economically viable if there is long-term availability of a large source of extremely low cost feedstock) and the significant emission of CO_2 during the process if the H_2/CO ratio of the syngas is sufficiently low (e.g., when using coal as a feedstock rather than natural gas). Regarding the last point, Figure 5.3.2-1b in Edwards, Larivé, and Beziat (2011) shows that the well-to-wheels (WTW) GHG emissions (Section 4.5.2) for coal-derived F–T diesel are more than twice as large as those for petroleum diesel or F–T diesel from natural gas.

2.3 Natural gas and liquefied petroleum gas

Natural gas and liquefied petroleum gas (LPG) are lighter petroleum-derived products. Natural gas can be used in compressed natural gas (CNG) or liquefied natural gas (LNG) forms. Compared to gasoline, these fuels have higher ONs and their combustion products have lower GHG footprints. Energy is required, however, for compressing to CNG and cooling to LNG. Furthermore, a principal component of natural gas is methane, and any leaked methane will have a global warming potential 21–25 times that of CO_2 over a 100-year time horizon [see Table 2.14 in Solomon *et al.* (2007)]. Although the lower energy densities of CNG, LNG, and LPG tend to limit the ranges of vehicles in which they are employed, these fuels are used in a number of Asian, South American, and European countries. In the United States, the larger personal vehicles and the

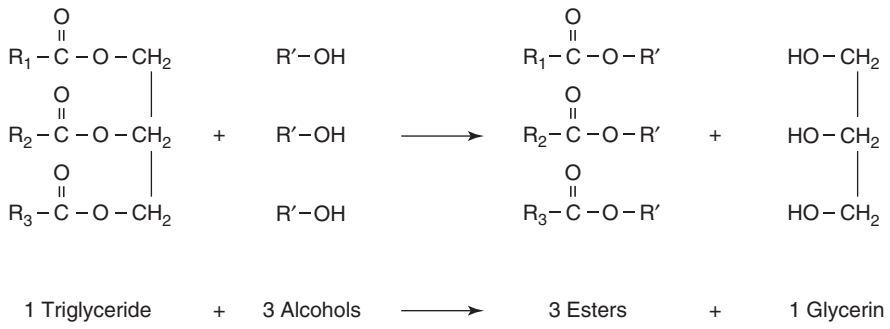

Figure 1. Transesterification reaction used to produce biodiesel esters (the reaction typically employs a catalyst).

limited distribution infrastructure for highly volatile fuels have largely restricted the use of CNG, LNG, and LPG to fleets with centralized refueling facilities. Nevertheless, the growing amounts of recoverable shale gas in some countries, and the corresponding decreased costs of natural gas and light condensed liquids relative to gasoline and diesel fuel, may lead to the wider use of these fuels in the future (NPC, 2012).

2.4 Biomass

2.4.1 Ethanol production

Ethanol is currently added to most of the gasoline sold in the United States and in many countries around the world. It is predominantly produced by fermentation (Schobert, 2013), and the primary feedstocks for ethanol production are the starches and sugars in crops such as corn, sugar beets, and sugar cane. The issues of whether food crops should be used to make fuel components (Section 4.5.4) and the limited life-cycle GHG reduction benefits of corn-based ethanol (Schobert, 2013, Chapter 4) have led to a significant amount of research and development on the conversion to ethanol of cellulosic materials found in sources such as wood and fast-growing nonfood crops such as switchgrass. Commercial production of ethanol from cellulosic material is presently negligible, however, relative to ethanol production from starches and sugars.

2.4.2 Biodiesel production

Biodiesel is an oxygenated bio-derived product composed of fatty acid methyl esters (FAMEs). Esters have the general structure R–(C=O)O–R′, where R and R′ signify HC chains. Typically, the R group is a straight HC chain with 5–21 carbon atoms and containing 0–3 carbon–carbon double bonds (i.e., the chain can be unsaturated, see Section 3.1.3). In the transesterification reactions that create biodiesel, the R-(C=O)O structures come from vegetable- or animal-derived triglycerides (or fatty acids), and R′ comes from an alcohol, as shown in Figure 1. The alcohol used in the reaction is commonly methanol, though sometimes ethanol or higher alcohols are used. Methyl esters are produced when methanol is used in the transesterification reaction, ethyl esters are produced when ethanol is used, and so on. The most common source of triglycerides for biodiesel in the United States is soybean-derived vegetable oil.

2.4.3 Renewable diesel production

An alternative to biodiesel production is to catalytically react vegetable- or animal-derived triglycerides (or fatty acids) with hydrogen instead of alcohols to produce renewable diesel: that is, alkane molecules that are essentially identical to, and completely fungible with, conventional petroleum-derived diesel. The hydroprocessing techniques required to produce these products are very similar to those currently used by refineries to upgrade crude oil, so conceivably these bio-derived feedstocks could be coprocessed with crude oil in refineries.

2.4.4 Other biofuel production approaches

A number of other possible paths are being explored to convert biomass to transportation fuels, and these can be grouped into two broad categories: thermochemical and biochemical. Thermochemical routes typically employ elevated temperatures (and/or pressures) and catalysts. Thermochemical routes such as pyrolysis (reactions occurring at elevated temperature, reduced oxygen content, and perhaps in the presence of catalysts) can convert even solid-phase biomass to liquids, but these liquids can require significant postprocessing (Christensen *et al*., 2011) before being suitable for use in modern engines (Mueller, 2013). Another thermochemical route, gasification, can be used

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to convert organic feedstocks to syngas, which can then be burned directly in engines or converted to liquid HCs through F–T type processes (Section 2.2).

Biochemical routes involve using microorganisms to produce fuels directly, or using microorganisms or their enzymes to break down biopolymers such as cellulose, hemicellulose, and lignin, as intermediate steps in the fuel production process. Examples include the direct production of HCs by *Botryococcus braunii* (Metzger and Largeau, 2005), methane production via anaerobic digestion, and conventional and cellulosic ethanol production processes via fermentation (Section 2.4.1).

3 FUEL COMPOSITION

Because the chemical composition of a fuel determines its properties, it is helpful to have some knowledge of the types of compounds found in modern fuels. Modern gasolines and diesel fuels have a high degree of compositional complexity, with typical fuel samples containing over 100 and 1000 distinct compounds, respectively. The compounds present in greatest abundance in current fuels are HCs and oxygenates, but trace components also are present, and they can have strong effects on engine performance. These three classes of fuel constituents are introduced in the context of liquid-phase fuels and discussed in this section. The section concludes with a brief discussion of gaseous fuel compositions.

3.1 Hydrocarbons

Crude petroleum and the fuels derived therefrom typically contain five classes of HC compounds: unbranched alkanes, branched alkanes, cyclic alkanes, olefins, and aromatics. The relative concentrations of the different HC classes in a given fuel are a function of the feedstocks and processing strategies employed in its production.

The total number of carbon atoms in a compound is known as its *carbon number*, denoted n. A representative molecule from each HC class having $n = 8$ is shown in Figure 2 using several common notational conventions. All elements are shown in the condensed structural formula for *n*-octane and the dash structural formulas for the other HCs in Figure 2. In contrast, only carbon bonds are shown in the bond-line structural formulas. In this latter notation, a carbon atom is assumed to exist at the end of each straight-line segment (unless the symbol of a different element is shown in its place), hydrogen atoms are not shown, two parallel line segments indicate a double bond between adjacent atoms, and a hexagon with a circle inside it indicates a benzene ring.

Hydrocarbon class	Unbranched alkane	Branched alkane	Olefin	Cyclic alkane	Aromatic
Representative compound	*n*-Octane	2,2,4-Trimethyl-pentane (*iso*-octane)	2,4,4-Trimethyl-1-pentene	Trans-1,2-dimethyl-cyclohexane	1,2-dimethyl-benzene (*ortho*-xylene)
Chemical formula	C_8H_{18}	C_8H_{18}	C_8H_{16}	C_8H_{16}	C_8H_{10}
Condensed or dash structural formula	$CH_3(CH_2)_6CH_3$	$CH_3-CH(CH_3)-CH_2-C(CH_3)_2-CH_3$	$CH_2=C(CH_3)-CH_2-C(CH_3)_2-CH_3$	CH_2-CH_2, CH_2, CH_2, $CH-CH$, CH_3, CH_3	$CH=CH$, CH, CH, $C-C$, CH_3, CH_3
Bond-line structural formula					

Figure 2. Representative molecules from the five HC classes with carbon number $n = 8$. Molecules within the gasoline boiling range have been selected for simplicity.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Different compounds with the same chemical formula are called *isomers*. As shown in Figure 2, *n*-octane and *iso*-octane are isomers, as are 2,4,4-trimethyl-1-pentene and *trans*-1,2-dimethylcyclohexane. These types of isomers, that is, those that differ in the sequences in which their atoms are arranged, are called *constitutional isomers*. Other types of isomerism exist, such as stereoisomerism, as discussed in the section on cyclic alkanes below. Isomerism is an important concept in fuel science because different isomers can have starkly different physical and chemical properties.

3.1.1 Unbranched alkanes

Also sometimes known as *normal alkanes*, *n-alkanes*, or *n-paraffins*, these "straight-chain" HCs have only single bonds between their carbon atoms, and their carbon atoms are all positioned along a single zigzagged but roughly linear chain (see the bond-line structural representation of *n*-octane in Figure 2). Their chemical formulas are of the form C_nH_{2n+2}, where n is the carbon number of the molecule. Unbranched alkanes are called *saturated compounds* because they contain the maximum possible number of hydrogen atoms for the given number of carbon atoms and general structure.

3.1.2 Branched alkanes

These branched-chain HCs are also commonly known as *iso-alkanes* or *iso-paraffins* (though technically the term *iso-alkane* refers only to an alkane with a single methyl group attached to the second carbon atom of its primary chain). Like unbranched alkanes, the branched alkanes are saturated HCs with chemical formulas of the form C_nH_{2n+2}, but the carbon atoms are no longer all arranged along a single linear chain. Instead, there are one or more alkyl branches extending from the main HC chain. For example, Figure 2 shows that *iso*-octane has three methyl branches, two from the second carbon atom of the main pentane chain and one from the fourth.

3.1.3 Olefins

Also sometimes known as *alkenes*, olefins are HCs that contain at least one carbon–carbon double bond. Olefins can exist as unbranched, branched, or cyclic structures. The olefin shown in Figure 2 has a branched structure with the double bond between the carbon atoms in the first and second positions. An olefin is an unsaturated compound because hydrogen atoms can be added to it without changing the general arrangement of its carbon atoms. For example, the olefin shown in Figure 2 could be converted to *iso*-octane by the addition of two hydrogen atoms. Although olefins are not typically found in crude petroleum in high concentrations, they can be produced during gasoline refining (e.g., via thermal cracking).

3.1.4 Cyclic alkanes

Also called *cyclo-alkanes* or *naphthenes*, cyclic alkanes are saturated compounds with their carbon atoms arranged in one or more ring structures. Cyclo-alkanes may have 3–9 carbon atoms in each ring structure, where the chemical formula of a single-ring cyclo-alkane is C_nH_{2n}. Five- and six-membered rings are the most stable (and hence the most abundant in petroleum-derived fuels) because of their lower carbon-bond strains. The carbon atoms in cyclo-alkane rings are not coplanar. In a five-carbon ring, one of the carbon atoms is raised above the plane of the other four. In a six-carbon ring, a number of conformations are possible, with the two most common being the "chair" and "boat" conformations. These two different conformations of cyclohexane are illustrated in Figure 3.

In these conformations, four of the carbon atoms are coplanar while the remaining two either lie on different sides of the plane (the chair conformation, which is the most stable) or on the same side of the plane (the boat conformation). The potential energy differences among the different cyclohexane conformations are low enough that the molecule can change conformations (or "interconvert") approximately 1 million times per second at standard conditions (Solomons, 1996). These and other conformational differences among molecules can lead to stereoisomerism, that is, molecules with the same chemical formula but different arrangements of their atoms in space that will not interconvert under standard conditions. Cyclo-alkanes with one or more unbranched or branched side chains, called *substituents*, are common and may exhibit stereoisomerism. When both substituents project above the nominal plane of the cyclohexane ring, the compound is a *cis* isomer; when one substituent projects above and one below, the compound is a *trans* isomer. For example, the *trans*-1,2-dimethylcyclohexane shown in Figure 2 has methyl substituents bonded to the carbon atoms in the 1 and 2

Figure 3. Conformations of cyclohexane. (a) Chair. (b) Boat.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

positions on the ring, with one projecting above the nominal plane of the cyclohexane ring and one below.

3.1.5 Aromatics

Aromatics are unsaturated compounds with their carbon atoms arranged in one or more ring structures. The most common aromatic HCs are those containing one or more benzene rings. A benzene ring has the formula C_6H_6. In contrast to cyclohexane, all six carbon atoms in a benzene ring lie in the same plane. The benzene rings in fuel-derived aromatic compounds can and often do have one or more alkyl substituents.

3.2 Oxygenates

The second most abundant class of compounds found in modern fuels is oxygenates. These are compounds composed of not just of hydrogen and carbon but also oxygen. The oxygenate classes most commonly used in fuels today are alcohols and esters, though other classes also have been and are used. Some common types of oxygenates are discussed below.

3.2.1 Alcohols

Alcohols have the general formula R–O–H, where R signifies an HC radical. Hence, the alcohol formed from the ethyl radical (C_2H_5) is ethyl alcohol, which is also known as *ethanol* (C_2H_5OH). Ethanol is by far the most commonly used oxygenate in gasolines, with nearly all gasoline sold in the United States currently containing some ethanol. Higher alcohols such as butanol isomers also are potential high octane bio-derived blendstocks for gasoline, and methods for scaling up their production are under development.

3.2.2 Esters

Esters have the general structure R–(C=O)O–R′, where R and R′ signify HC radicals. Esters are discussed in Section 2.4.2 on biodiesel production. Although esters most commonly enter fuels as biodiesel FAMEs, they also can be derived directly from various biological and other processes. Raw vegetable- or animal-derived lipids, however, typically are not esters. They are triglycerides and/or fatty acids.

3.2.3 Ethers

Ethers have the general structure R–O–R′, where, again, R and R′ denote HC radicals that may be different. The best-known fuel ether is methyl *tert*-butyl ether (MTBE), which was approved for use at levels up to 15 vol% in gasoline by the US Environmental Protection Agency (EPA) in the 1980s and added to Federal and California reformulated gasolines. This use was banned in California and a number of other states in 2004, after MTBE was found in certain drinking water supplies. Some humans can taste MTBE at concentrations below 0.1 ppm (parts per million) (U.S. Environmental Protection Agency, 2012a). Despite the US experience with MTBE, some countries continue to allow the use of MTBE in gasoline. Other ethers show some promise as additives for diesel fuel, because their oxygen content is beneficial for lowering soot emissions, and they can have CNs >60 (Upatnieks and Mueller, 2005).

3.2.4 Ketones

Ketones have the general structure R–(C=O)–R′. A common ketone is the solvent acetone, or dimethyl ketone: $CH_3(C{=}O)CH_3$. Ketones are not found in current fuels in high concentrations, but they can be produced efficiently by certain biological processes and hence may be important components of future biofuels.

3.3 Trace components

While trace components are, by definition, minor fuel constituents, they can have profound effects on engine performance through a number of mechanisms. These mechanisms include but are not limited to

- corrosion of fuel system components. For example, organic acids can react with iron, copper, and other materials in fuel systems to produce corrosion, which can lead to the failure of fuel injectors, pumps, and other fuel system components.
- deposit formation within fuel injectors, on engine valves, or inside the combustion chamber. For example, trace metals can catalyze liquid-phase polymerization reactions that lead to the formation of lacquers, gums, and products that are insoluble in the fuel that can foul close-tolerance fuel injector components.
- fuel-borne particulates that adversely affect fuel injector operation. For example, if the fuel filter is not functioning properly, fuel-borne particles can plug small orifices in the fuel injector and/or lead to accelerated wear of injector components.
- poisoning of exhaust after-treatment catalysts. For example, sulfur and phosphorus can cause active sites on catalysts in after-treatment devices to become temporarily or permanently inactive (see Section 4.4.3).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- raising the cloud point and/or plugging the fuel filter with crystals. For example, high melting-point impurities can be the first to freeze in colder climates, and their crystals can plug the fuel filter and thereby prevent the engine from running.
- causing fuel blends to separate into two or more distinct liquid phases. For example, even small quantities of water can cause some fuel blends, especially those containing both polar and nonpolar components (Section 4.3.2), to separate.
- decreasing autoignition delay time. For example, naturally formed peroxides can substantially decrease the autoignition-delay times of diesel fuels and gasolines. Potential issues associated with trace components are discussed in more detail in Section 4.

Not all trace components in fuels are detrimental to performance. Cetane improvers, oxidation inhibitors, lubricity improvers, metal deactivators, and detergents are examples of compounds that are routinely added to fuels at ppm levels to improve fuel performance in certain engine applications. The collection of these compounds used in a specific market fuel, called the *additive package*, depends on the base fuel characteristics, the engine application, the fuel provider, and economic factors.

3.4 Gaseous fuels

Gaseous fuels face two primary challenges in transportation and other mobile-engine applications. The first is that they tend to be difficult to be stored at high energy density, often requiring high pressure fuel tanks and/or cryogenic systems. The second is that they tend to lack a distribution infrastructure for transportation applications, that is, there is no nationwide network of gaseous-fuel filling stations as exists for gasoline and diesel fuel. Nevertheless, gaseous fuels are an important piece of the puzzle of meeting global energy demand. The gaseous fuels of primary interest are natural gas and hydrogen.

3.4.1 Natural gas

Natural gas is a mixture of HCs with carbon numbers typically in the range from 1–4 and existing in vapor form at standard conditions. The CN of natural gas is typically very low (<0), but its ON is typically high (>110), and its specific composition can vary widely depending on its geographical origin. The amount of recoverable natural gas in the world has dramatically increased in recent years because of the employment of hydraulic fracturing ("fracking") techniques for its extraction from subterranean deposits.

3.4.2 Hydrogen

There has been a great deal of interest in hydrogen because it does not contain carbon and hence its combustion does not produce the GHG CO_2. Nevertheless, the world currently lacks inexpensive and abundant sources of hydrogen, an established infrastructure for its distribution, and low cost techniques for storing it at high energy density. Until these significant barriers are overcome, hydrogen is likely to remain a fuel of the future.

4 KEY FUEL PROPERTIES

From a high level perspective, the processes occurring in modern internal combustion engines are quite simple: oxygen from the air surrounding the engine is mixed with a fuel in a carefully controlled fashion, and both participate in combustion reactions that produce elevated pressure and temperature in the engine cylinder, plus major and minor product species. The high pressure created within each engine cylinder during combustion causes the engine pistons to move, and this movement transforms some fraction of the chemical energy from the fuel into the desired power at the crankshaft.

Dry air is composed of approximately 78.08 mol% molecular nitrogen (N_2), 20.95 mol% molecular oxygen (O_2), and <1 mol% argon, CO_2, and other species. When a liquid fuel composed of hydrogen, carbon, and perhaps some oxygen, nitrogen, and sulfur is burned in an engine, the vast majority of the atoms react to form the major product species CO_2 and H_2O. The CO_2 and H_2O pass out of the engine through the exhaust valves with N_2 from the intake air, perhaps some O_2 that was not consumed during the in-cylinder reactions (depending on the combustion strategy), and other minor product species including nitrogen oxides (NO_x), particulate matter (PM), carbon monoxide (CO), sulfur oxides (SO_x), and products of incomplete combustion (also known as *unburned HCs*, see Thermodynamic Analysis). The amounts of the minor species that leave the engine can depend strongly on fuel characteristics.

While the processes above are straightforward from a high-level perspective, the devil is in the details, and there are a great many mechanisms by which fuel properties can affect engine operation in subtle and not-so-subtle ways. In this regard, it is sometimes helpful to distinguish between fuel properties that are determined by the bulk fuel composition (e.g., density, aromatic content, distillation curve) versus those that can be significantly affected by trace levels (~1% or less) of certain compounds in the fuel (e.g., autoignition quality, lubricity, sulfur content). For

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

instance, properties in the latter group sometimes can be improved using fuel additives, while those in the former group cannot. It is also helpful to recognize that fuel properties are often highly correlated (e.g., CN, density, and sooting propensity for diesel fuels). As a result, it can be very challenging to determine the effects of changing a certain fuel property when other fuel properties necessarily change with the property of interest.

The objective of this section is to provide an overview of a number of key fuel properties and explain why they are important. The broad categories treated below are combustion properties, physical properties, stability, materials compatibility, and environmental considerations.

4.1 Combustion properties

The primary combustion properties of a reciprocating-engine fuel are its energy content, its autoignition quality, and its emissions-formation characteristics. These topics are treated in turn in the sections below.

4.1.1 Energy content

As mentioned in the introduction, the energy content of a fuel, that is, the amount of chemical energy available per unit mass (specific energy) or per unit volume (energy density), is a key factor in mobile-engine applications, because it plays the primary role in determining the mass and volume of fuel that must be carried aboard the vehicle or machine to satisfy the application requirements. Also, because fuels are typically sold by volume, energy density typically influences operating costs. One way to better understand the effects of fuel energy content is to consider the similarities and differences among the concepts of efficiency, fuel economy (FE), and specific fuel consumption (SFC).

4.1.1.1 Efficiency, fuel economy, and specific fuel consumption. Other chapters of this encyclopedia cover engine and vehicle efficiency, FE, and SFC in greater detail (see Zero- and One-Dimensional Methodologies and Tools, Thermodynamic Analysis, Trends—Spark Ignition, and Trends—Compression Ignition), but certain aspects that are directly related to fuel effects bear mentioning here. For instance, an engine might run more efficiently when fueled with ethanol, but the corresponding FE could be lower and the SFC higher. How could this be? To answer this question, the definitions of efficiency, FE, and SFC must be considered within the context of variable fuel properties.

Efficiency, denoted η, is simply the engine work output per unit of chemical energy input, that is,

$$\eta = \frac{W_{\text{out}}}{m_{\text{f}} q_{\text{LHV}}} \tag{2}$$

where W_{out} is the work output per cycle of the engine, m_{f} is the mass of fuel supplied to the engine per cycle, and q_{LHV} is the lower heating value of the fuel (i.e., the specific energy of the fuel assuming the water in the products remains in the vapor phase). From a thermodynamic standpoint, an optimal engine design is one with maximum efficiency. Nevertheless, liquid fuels are priced on a volumetric basis rather than an energy-content basis, and hence the engine user often cares most about the FE of the vehicle, that is, the distance that can be traveled per unit volume of fuel. Because the distance that can be traveled is proportional to the work output of the engine, Equation 2 can be used to show that

$$\text{FE} \propto \frac{W_{\text{out}}}{V_{\text{f}}} = \frac{\eta m_{\text{f}} q_{\text{LHV}}}{m_{\text{f}}/\rho_{\text{f}}} = \eta \rho_{\text{f}} q_{\text{LHV}} \tag{3}$$

In Equation 3, V_{f} and ρ_{f} are the volume of fuel injected per cycle and the fuel density, respectively. So while the FE is proportional to the efficiency, as expected, it is also proportional to the fuel density and specific energy. Similarly, SFC is often used to quantify efficiency. SFC is the mass of fuel required per unit of work output, and again using Equation 2

$$\text{SFC} = \frac{m_{\text{f}}}{W_{\text{out}}} = \frac{1}{\eta q_{\text{LHV}}} \tag{4}$$

The presence of the specific-energy term in Equation 4 indicates that, like FE, SFC is not a direct measure of efficiency. The subtle differences among η, FE, and SFC can be the source of considerable confusion.

Consider a gasoline-fueled vehicle with an FE of 40 mpg (miles per gallon) and an engine efficiency of 30%. Assuming that the same engine running on neat ethanol achieves an efficiency of 40%, a substantial thermodynamic improvement, the corresponding FE would only be 35.6 mpg. (This analysis assumes that the specific energies of gasoline and ethanol are 42.6 and 27.0 MJ/kg, respectively; the densities of gasoline and ethanol are 749 and 789 kg/m^3, respectively; and all other vehicle parameters are the same.) The lower FE for neat ethanol is because even though the efficiency and density terms in Equation 3 increase when switching from gasoline to neat ethanol, the specific energy of ethanol is low enough to counteract these effects. Hence, even with the increased engine efficiency of neat ethanol and if neat ethanol were available for 10% less

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

cost per unit volume than gasoline, it would not make financial sense to switch from gasoline to neat ethanol based on the fuel cost per mile traveled. In this example, the lower specific energy of ethanol also leads to a higher SFC than that achieved with the gasoline-fueled vehicle. (Note: This is an example that was presented to illustrate some of the potential issues when considering the use of fuels with different energy contents; it is not a true cost/benefit comparison between gasoline and neat ethanol because the efficiency and FE values used were only hypothetical.)

As illustrated in the above example, efficiency (as defined in Equation 2) is the best parameter to use when evaluating fuel effects on the ability of an engine to convert chemical energy into useful work, while FE is likely a better parameter to use for fuel cost comparisons, and SFC might be desirable in situations that are very sensitive to the mass of fuel that must be carried aboard a vehicle.

4.1.2 Autoignition quality

Autoignition has been defined as "a rapid combustion reaction that is not initiated by any external ignition source" (Heywood, 1988). The susceptibility of a fuel to autoignition is called its *autoignition quality*. ONs and CNs are typically used to quantify the autoignition qualities of fuels for SI and CI engines, respectively. Fuels with high ONs are generally resistant to autoignition, and are hence desirable for SI engine applications because autoignition can lead to detrimental knock and preignition, as described in detail in the following section. Fuels with high CNs autoignite easily, and hence are generally desirable for CI engine applications, which rely on autoignition to initiate combustion. On the basis of these characteristics, high ON fuels would be expected to have low CNs, and vice versa, and this is observed in practice. Although ON and CN vary roughly inversely, there is no broadly accepted quantitative relationship between the two parameters.

Whether or not a given fuel mixture autoignites at a specific temperature/pressure condition depends on details of the chemical-kinetic reactions that lead to ignition, and these are strongly dependent on the fuel's molecular structure. An in-depth discussion of these processes is beyond the scope of this chapter but can be found in Fundamental Chemical Kinetics. In general, the presence or absence of certain molecular-structural functional groups can be used to roughly estimate the autoignition quality of a given compound. Straight-chain alkanes tend to autoignite most easily, especially as chain length increases beyond a few carbon atoms. Aromatics and highly branched alkanes/alkenes tend to be the most difficult to autoignite, with cyclo-alkanes being somewhat easier. Oxygenates can have varying effects depending on how the oxygen is bonded into the molecule; peroxides are used as CN improvers, but low molecular-weight alcohols such as ethanol and methanol have high ONs. In practice, the autoignition quality of a fuel is almost always measured because most fuel compounds contain more than one of these functional groups, most fuels are mixtures of many compounds that can interact during ignition, fuel composition is challenging to quantify, and models for estimating the autoignition qualities of mixtures have limited accuracies.

In SI engines, autoignition quality is arguably the single most important fuel property, determining the extent to which knock and preignition phenomena will limit engine performance. Owing to this critical role, fuel effects on SI engine knock and preignition are treated in detail in the following section. Autoignition quality also plays an important role in CI engines, affecting cold-startability, combustion noise, and emissions, and these are discussed after the section on SI engine effects.

4.1.2.1 Fuel autoignition quality effects in SI engines: knock and preignition.

4.1.2.1.1 Knock in SI engines. Knock is an abnormal combustion phenomenon that can damage SI engines (Heywood, 1988) and is determined by the integrated pressure and temperature history of the "end-gas" (i.e., the gas mixture ahead of the advancing flame front) and the antiknock or autoignition quality of the fuel. Knock occurs when the end-gas autoignites, centered on one or more "hot spots," causing a sharp rise in the heat release rate and setting up pressure waves in the cylinder that in turn manifest themselves as a metallic "pinging" sound. Knock intensity is usually defined as the maximum amplitude of this fluctuating pressure signal. When the knock intensity reaches some threshold value (it is common to use a value of 0.2 bar), the engine is said to knock (see Spark Ignition Combustion).

At a given engine operating condition, knock intensity increases as the spark timing is advanced, and the timing at which the engine knocks is known as the *knock-limited spark advance* (KLSA). The larger the KLSA, the more resistant a fuel is to knock at the particular operating condition. When the engine cannot be run at its maximum load and efficiency because of knock, it is said to be *knock-limited*. A modern car includes a knock detector and is knock-limited on normally available fuels over at least some of its operating range. When knock is detected, the engine management system takes corrective action (e.g., it retards the spark timing), and this usually reduces the power. In such engines, fuel antiknock quality also can be quantified by measuring the knock-limited power or acceleration performance at a given operating condition

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(Kalghatgi, 2005; Kalghatgi, Nakata, and Mogi, 2005). Using a fuel with an antiknock character higher than that required to avoid knock will not generally further improve engine performance, though use of a higher octane fuel may improve FE if the higher octane is achieved by a higher mole fraction of aromatic carbon in the fuel, because this type of fuel will have a greater energy density (Section 4.1.1).

Fuel antiknock quality is described by empirical measures because the fundamental autoignition chemistry cannot be quantified adequately for practical fuels because of their compositional complexity. It is traditionally measured by research octane number (RON) and motor octane number (MON) of the fuel used. The RON test is run in a single-cylinder Co-operative Fuel Research (CFR) engine at an engine speed of 600 rpm and an intake temperature of 52 °C, while the MON test is run at 900 rpm with a higher intake temperature of 149 °C. These tests are run in strict accordance with established procedures (ASTM, 2010b, 2012a, b). The octane scale is based on two alkanes, *n*-heptane (ON ≡ 0) and *iso*-octane (ON ≡ 100). The blends of these components are referred to as *primary reference fuels* (PRFs) and define the intermediate points in the RON and MON scales. The RON or MON is the volume percent of *iso*-octane in the PRF. Thus, a blend of 90 vol% *iso*-octane and 10 vol% *n*-heptane is assigned the ON of 90 in both RON and MON scales. A real-world fuel is assigned the RON (or MON) value of the PRF that matches its knock behavior in the RON (or MON) test. All practical gasolines are more complex than PRF, and are mixtures of aromatics, olefins, naphthenes, oxygenates, and/or alkanes. A practical gasoline will match the PRF of a higher ON in the RON test and hence has a higher RON when compared to the MON test. The difference between the RON and MON of a fuel is known as its *sensitivity*. The sensitivity, S = RON − MON, is a measure of how different the fuel autoignition chemistry is from that of PRF.

4.1.2.1.2 Pressure and temperature development in the unburned gas in an engine. The temperature of the unburned gas increases as pressure increases in the engine cylinder. For instance, at the RON test condition, the temperature at a given pressure is lower than in the MON test condition, as shown in Figure 4 (Kalghatgi, 2005). Modern engines are "beyond RON" because the temperature of the unburned mixture, at a given pressure, is even lower than in the RON test. Alternatively, the pressure for a given temperature is higher in modern engines compared to the RON test. An example of such a condition "beyond RON" is also shown in Figure 4. This is a consequence of the higher efficiency of modern engines. Engine designers have always tried to force more air into the cylinder while minimizing the temperature in order to improve power density and efficiency. Indeed, all the modern trends aimed at improving the efficiency of SI engines, such as increasing the compression ratio, direct injection, and turbo-charging aligned with engine downsizing, will push modern engines further "beyond RON."

4.1.2.1.3 Antiknock quality of gasolines in modern engines. Practical fuels contain components other than alkanes, and they behave like different PRFs at different engine conditions. Thus, the knocking characteristics of a gasoline of 95 RON and 85 MON will match those of an 85 PRF in the MON test, while it will be much less prone to knock, compared to PRF fuels, in the RON test condition and will match 95 PRF. This is because the autoignition chemistry of non-alkane components in gasoline is different from that of PRF. The antiknock quality of practical fuels in an engine is studied by measuring a parameter dependent on the autoignition quality of the fuel such as KLSA. At the same operating condition, many fuels of different chemical compositions and hence different RON and MON, are compared. In such autoignition studies, homogeneous charge compression ignition (HCCI) engines have been valuable complements to knocking SI engines because the fundamental mechanisms of knock and HCCI combustion are the same, as summarized in Kalghatgi (2005).

The true antiknock quality of a gasoline is best described by an octane index, OI (Kalghatgi, 2005; Kalghatgi, Nakata, and Mogi, 2005), which is the ON of the PRF that matches the knock behavior of the gasoline of interest at the conditions of the particular engine test. It is defined as

$$\mathrm{OI} = (1-K) \times \mathrm{RON} + K \times \mathrm{MON} = \mathrm{RON} - K \times S \quad (5)$$

where K is an empirical constant that depends only on the pressure and temperature history of the unburned mixture in the cylinder, and S is the sensitivity. The value of K depends on the design and operating condition of the engine. Thus, $K = 1$ in the MON test, and the antiknock quality of the gasoline is described by its MON, but $K = 0$ in the RON test, which runs at a lower temperature for a given pressure (Figure 4). Modern engines are "beyond RON" and K is negative, that is, for a given RON, a lower MON, higher sensitivity fuel has higher OI and is more resistant to knock. For instance, if $K = -0.5$, a gasoline with 95 RON and 85 MON will have an OI of 100 and will actually match a PRF of 100 (i.e., pure *iso*-octane) for knock. Modern engines usually have negative K values (Coordinating Research Council, 2011; Bell, 2010; Kalghatgi, 2005; Kalghatgi, Nakata, and Mogi, 2005; Mittal and Heywood, 2008).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

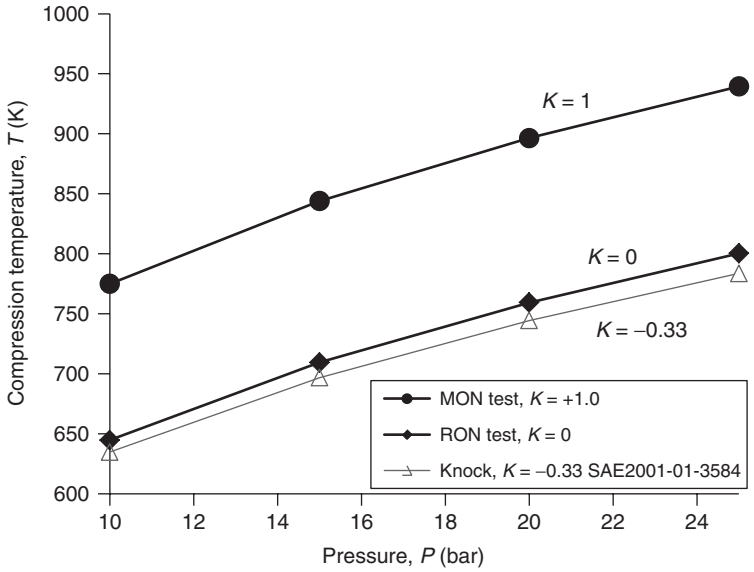

Figure 4. Unburned mixture temperature versus pressure. K decreases from 1 to 0, moving from the MON test condition to the RON test condition and becomes negative "beyond RON." The true antiknock quality is given by $\mathrm{OI} = (1-K) \times \mathrm{RON} + K \times \mathrm{MON}$ (Equation 5).

4.1.2.1.4 The value of K has been decreasing throughout recent history. The RON test was invented in 1930 when the average compression ratio was around 5 (Mittal and Heywood, 2009) and the engines had poor efficiency compared to modern engines. It was soon obvious that the RON test did not predict the antiknock quality of fuels on the road at that time. Hence, the MON test was developed, and it reflected the antiknock behavior of fuels in cars of that time much better. Clearly, the K value of the US car fleet then was around 1. The Coordinating Research Council (CRC) in the United States has conducted frequent surveys to establish the octane requirements of US cars between 1947 and 1996. On the basis of these data and other available sources, Mittal and Heywood (2009) showed that the K value has decreased from around 1 to 0 in 2008 because of reduced end-gas temperatures and higher pressures. A similar decreasing trend for K in the UK car fleet also has been reported in Kalghatgi (2005). Historically, in the United States, fuel antiknock quality has been assumed to be best described by (RON + MON)/2, which translates into $K = 0.5$. The US car fleet, on average, used to have such an octane requirement when this specification was first agreed upon; however, engine technology has moved on and with it, the octane requirement.

4.1.2.1.5 Why is K negative in modern engines? The autoignition chemistry of non-alkane components in practical fuels is significantly different from that of the PRFs used in the RON and MON scales. In general, for a given temperature T, a non-alkane fuel becomes more resistant to autoignition compared to an alkane fuel, as the pressure P increases. A fundamental measure of autoignition quality of a combustible mixture is the ignition delay τ, which is typically measured outside the engine in special equipment such as shock tubes or rapid compression machines (Fikri *et al.*, 2008; Gauthier, Davidson, and Hanson, 2004; Heywood, 1988). The smaller the value of τ, the more reactive the mixture. In general, τ can be expressed as a function of temperature and pressure (Fikri *et al.*, 2008; Gauthier, Davidson, and Hanson, 2004) in a given pressure/temperature range.

$$\tau = \tau_0 f (T/T_0)(P/P_0)^{-n} \tag{6}$$

Here, τ_0 is the ignition delay measured at some reference pressure P_0 and a reference temperature T_0. It is found experimentally that the value of the pressure exponent n is much smaller in magnitude for non-alkane fuels than for alkane fuels (Fikri *et al.*, 2008; Gauthier, Davidson, and Hanson, 2004) at high temperatures ($T > \sim 850$ K). Hence, non-alkane fuels become relatively more resistant to autoignition if the pressure is increased at a fixed temperature. Why this should be so, at the fundamental chemical-kinetic level, is not yet clear. The negative value of K could only be explained in HCCI engines (Bradley, Morley, and Walmsley, 2004) and in knocking SI engines (Kalghatgi, Nakata, and Mogi, 2005) by this difference in the value of the pressure exponent n between alkane and non-alkane fuels.

4.1.2.1.6 Specifications for fuel antiknock quality and engine octane requirement. High MON is considered to contribute to the antiknock quality of a gasoline in many areas, for example, in North America and in Europe. In Europe, there is a minimum MON specification of 85, and in North America MON is considered to be as important as RON. However, as discussed above, modern engines have pressure/temperature development regimes that make MON at best irrelevant ($K = 0$) or actually detrimental to fuel antiknock quality ($K < 0$). Thus, these octane specifications are inconsistent with the actual requirements of modern engines. Moreover, as improved engine efficiency is sought, this mismatch between specifications and engine requirements will get wider and will have to be addressed. Steps taken to improve engine efficiency such as downsizing and turbocharging will in general make future engines more prone to knock, necessitating higher antiknock quality in the fuel. Such engines will also be "beyond RON," and the K value will be negative so that for a given RON, a lower MON fuel will be more resistant to knock (Amer *et al*., 2012). The need to bring fuel specifications in line with engine requirements will increase.

4.1.2.1.7 Preignition and "Super-knock". Preignition is an abnormal combustion phenomenon where an expanding flame front is established before the spark plug fires in the engine. Preignition has been of intermittent concern at different stages of the history of SI engines. In the 1950s and early 1960s, compression ratios increased rapidly and preignition became a serious problem. Preignition again seems to have attracted attention in the 1980s primarily because of the problems encountered with using methanol after a relatively quiet period in the 1960s and 1970s. With the trend in downsizing and turbocharging, it has again become a concern in turbocharged DISI (direct injection spark ignition) engines (Kalghatgi *et al*., 2009; Zahdeh *et al*., 2011). The early start of combustion from preignition causes the pressure and the temperature of the unburned gas ahead of the advancing flame front, the end-gas, to rise more rapidly compared to normal spark timing. If autoignition occurs in the end-gas at high pressure and temperature, it can lead to extremely heavy knock, with knock intensities of 100 bar or more. Such events are informally described as *super-knock*, another abnormal combustion phenomenon that could potentially damage the engine (Kalghatgi and Bradley, 2012; Kalghatgi *et al*., 2009).

Preignition is a flame initiation problem and two separate criteria have to be met in order for it to occur. The first is an ignition criterion, which requires that the temperature must reach a minimum level locally so that runaway chemical reactions start. This might occur because of hot spots on the internal surfaces of the engine or because of autoignition and catalytic reactions centered around oil droplets or particulates in modern DISI engines. The additional initiation criterion requires that the incipient flame must reach a critical radius that is proportional to the laminar flame thickness δ before it becomes self-sustaining (Kalghatgi and Bradley, 2012). The smaller the value of δ, the larger is the probability of flame initiation and preignition, all else being equal. In the experiments reported in modern DISI engines (Dahnz *et al*., 2010; Zahdeh *et al*., 2011), the probability of both criteria being satisfied is low as preignition only occurs every 15,000 cycles or so.

δ can be related to pressure, temperature, and fuel properties as follows. δ, in terms of the dynamic viscosity μ, the density ρ, and the laminar burning velocity S_l, is given by (Kalghatgi and Bradley, 2012)

$$\delta = (\mu/\rho S_l) \tag{7}$$

Further, S_l is related to the pressure P and temperature T by

$$S_l = S_{l0}(T/T_0)^n (P/P_0)^{-m} \tag{8}$$

where S_{l0} is the laminar burning velocity at some reference pressure P_0 and temperature T_0, and m and n are constants (Bradley *et al*., 1998; Gulder, 1982). Using Equation 8 and with ρ_0 as the density and μ_0 as the dynamic viscosity at pressure P_0 and temperature T_0, δ can be written as (Kalghatgi and Bradley, 2012)

$$\delta = \left(\frac{\mu_0}{\rho_0 S_{l0}}\right)\left(\frac{P}{P_0}\right)^{m-1}\left(\frac{T}{T_0}\right)^{1.5-n} \tag{9}$$

The kinematic viscosity μ_0/ρ_0 of the fuel/air mixture for different liquid fuels can be assumed to be the same. The values of m have been reported to be between 0.16 and 0.28, whereas n is between 1 and 2.2 for different fuels (Kalghatgi and Bradley, 2012). Hence, for a given fuel (i.e., with S_{l0} fixed), the pressure exponent in Equation 9 is always negative so that, as the pressure increases, the laminar flame thickness decreases and preignition becomes more likely. Experimentally, for a given fuel, preignition is also found to be more likely if the mixture strength is slightly rich of stoichiometric, where S_{l0} is likely to be maximum (Ricardo and Hempson, 1972). We should also expect that, for a given fuel, use of cooled exhaust gas recirculation (EGR) will reduce S_{l0} and hence make preignition less likely, all else being equal. Ricardo and coworkers developed a test to quantify the preignition resistance (PR) of different fuels (Ricardo and Hempson, 1972). For a given operating condition, as we test different fuels, we should expect that, as S_{l0} increases, preignition becomes more likely and PR decreases. This is indeed

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

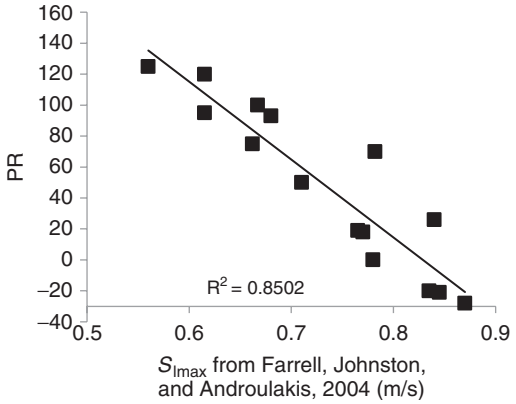

Figure 5. Preignition resistance (PR) from Ricardo and Hempson (1972) versus S_{lmax} from Farrell, Johnston, and Androulakis (2004) for different fuels, see Kalghatgi and Bradley (2012).

found to be the case (Kalghatgi and Bradley, 2012). Figure 5 shows the PR from Ricardo and Hempson (1972) for different fuels plotted against the maximum laminar burning velocity S_{lmax} measured at 30.4 bar (P_0) and 450 K (T_0) in Farrell, Johnston, and Androulakis (2004). PR in Ricardo and Hempson (1972) was measured at a mixture strength slightly rich of stoichiometric where the laminar burning velocity is likely to be maximum. There was little correlation between PR and RON or PR and MON, confirming what has been found in all previous studies (Kalghatgi and Bradley, 2012).

The mixture in the end-gas is never homogeneous and the autoignition that triggers knock is initiated at one or more centers or "hot spots." The pressure wave initiated by the autoignition changes as it traverses through inhomogeneities in the end-gas (Bradley, 2012). Similar phenomena also occur in HCCI engines (Sheppard, Tolegano, and Woolley, 2002). Hot spots are associated with gradients of reactivity, which lead to gradients of autoignition delay time. The pressure wave generated by the hot spot can couple with the autoignition reaction front when it moves into the unburned mixture at approximately the speed of sound. Under some circumstances, the fronts are mutually reinforced to create a large pressure spike propagating at high velocity within the hot spot in a *developing detonation* (Zeldovich, 1980). The probability of developing detonation increases if autoignition occurs at these high pressures and temperatures, and this is the most likely explanation for "super-knock" (Kalghatgi and Bradley, 2012; Kalghatgi *et al*., 2009).

4.1.2.2 Fuel autoignition quality effects in CI engines. In most modern CI engines, most of the fuel is injected directly into the combustion chamber when the piston is near the top of the compression stroke. Within a given time after the start of injection (SOI, i.e., the time at which fuel begins to enter the combustion chamber), fuel-rich regions of the stratified mixture in the cylinder autoignite, creating a rapid pressure increase. The rest of the fuel burns in a quasi-steady lifted jet diffusion flame (Dec, 1997). The time between SOI and autoignition is called the *ignition delay*. In general, a given change in the ignition delay time will have a larger effect in a high speed engine than a low speed engine because the crankshaft rotates through a larger angle per unit time in the high speed engine.

The autoignition quality of fuels for CI engines is typically quantified using the CN. In general, fuels with short ignition delays have higher CNs, and fuels with longer ignition delays have lower CNs. Diesel fuels in developed countries typically have CNs between 40 and 60, with values near the lower and higher ends of this range found in North America and Europe/Asia, respectively. High CN fuels are preferable for use in conventional CI engines. Their tendency to autoignite easily facilitates engine cold-starting. High CN fuels also lead to quieter engine operation, because the shorter time for fuel–air premixing during the ignition delay for high CN fuels leads to a smaller amount of chemical energy release during premixed autoignition (all other factors being equal).

The CN of a fuel is measured using an indirect-injection single-cylinder CFR engine with a pintle-type fuel injector and an adjustable compression ratio operated at a constant speed of 900 rpm, as described in ASTM International Test Method D613 (ASTM, 2008). The conditions used in the cetane engine test do not well represent those in modern CI engines. Other test methods employing constant-volume combustion chambers to measure the derived cetane number (DCN) also are becoming more widely used (ASTM, 2010f, 2012c), but their results are based on correlations with cetane engine data, so they are no more representative of conditions in modern engines. CN and DCN values for a number of pure HC and oxygenated compounds can be found in Murphy, Taylor, and McCormick (2004).

While the ignition delay is a function of the conditions within the engine cylinder (e.g., temperature, pressure, local mixture stoichiometry), it is also a function of the fuel-composition-dependent chemistry that occurs as the fuel begins to oxidize. The autoignition quality of a low CN base fuel can be improved without changing the bulk fuel composition by adding tens to hundreds of ppm of a highly reactive "cetane improver" to the fuel. The most common cetane improvers in use today are 2-ethylhexyl nitrate (EHN) and di-*tert*-butyl peroxide (DTBP). The effects of EHN addition on diesel-fuel CN have been discussed by Ghosh (2008).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

A treatment of the detailed processes leading from possible low temperature (or "cool-flame") reactions through high temperature ignition is beyond the scope of this chapter, but this area has been well addressed in the literature (Hwang, Dec, and Sjoberg, 2008; Mehl *et al*., 2012; Westbrook, 2000; Yang *et al*., 2011). Suffice it to say that kinetic effects on autoignition processes can be complex. Alkanes, aromatics, and oxygenates can and do exhibit markedly different behaviors under certain conditions. As mentioned in the preceding section, the need for new autoignition quality metrics to better characterize the ignition behaviors of modern fuels in modern engines has been acknowledged, but such new metrics have not yet found their way into widespread use.

4.1.3 Emissions formation characteristics

It is often easy to observe that changing the composition of the fuel supplied to an engine can change the emissions characteristics of the engine. Less straightforward, however, is understanding the mechanisms underlying the observed emissions changes. This is because fuel composition changes can directly alter the physical and chemical properties of a fuel, leading to complex and coupled variations in mixture formation, ignition, and combustion processes. Fuel composition changes also can indirectly affect emissions through engine-calibration-specific processes (an example of which is provided later in this section). The engine calibration establishes the exact values of the various input parameters required for optimal operation of the engine at each point in its operating space. Of these, engine-calibration-specific processes can be particularly difficult to understand because calibrations are usually proprietary in nature, costly to create, and only created for an "average" market fuel.

Examples of physical processes that can be affected by fuel composition changes include the following:

- fuel injection (e.g., injection pressure, timing, in-nozzle cavitation);
- fuel vaporization (e.g., liquid- and vapor-phase fuel penetration, entrainment rate, droplet characteristics);
- mixture formation (e.g., degree of fuel and thermal stratification, spray–wall interactions, presence of liquid fuel films).

Examples of chemical processes that can be affected by fuel composition changes include the following:

- fuel autoignition resistance (and dependence on in-cylinder thermal and mixture stratification and pressure);
- combustion kinetics (e.g., heat release rate, emissions formation and removal, combustion stability);
- mixture stoichiometry [i.e., the proximity of the charge gas mixture at each point in space to its stoichiometric condition (Mueller, 2005)];
- after-treatment system reactions and efficiency.

Examples of fuel-dependent engine-calibration-specific processes include the following:

- injection/ignition timing changes;
- turbocharger settings changes;
- EGR rate changes;
- intake manifold pressure and temperature changes;
- differences in any of the above between steady-state and transient conditions for different fuels.

On the basis of the above-mentioned processes, it should be expected that the magnitudes and even the directions of emissions changes will vary with fuel changes depending on which fuel properties are varied (it is almost always impossible to vary only one fuel property at a time); how fuel properties are varied (e.g., if the aromatic content of a fuel is decreased, what kinds of compounds are replacing the aromatics?); the ranges over which fuel properties are varied (the effects of raising CN from 30 to 40 are likely to be larger than the effects of raising it from 70 to 80); the specific engine and combustion strategy (fuel effects observed in a light-duty SI premixed combustion mode are likely to be different from those observed in a heavy-duty CI mixing-controlled combustion mode); the specific operating condition(s) and/or test cycle(s) employed (e.g., high vs low load conditions, steady-state vs transient cycle); and the presence, absence, nature, and/or age of any installed after-treatment devices.

The use of biodiesel in CI engines provides an illustrative example of how changing the fuel can have a number of interrelated, subtle, and complex effects on engine-out emissions. First, biodiesel has a lower volatility than conventional diesel fuel, which can lead to longer penetration of liquid-phase fuel within the combustion chamber and subsequent wall impingement (Fisher, Knothe, and Mueller, 2010). Wall impingement can lead to lower efficiency, reduced durability (due to loss of wear resistance when lubricant is diluted with fuel), and the formation of pool fires that can produce elevated emissions of smoke, NO_x, HC, and CO (Cheng *et al*., 2010; Martin *et al*., 2008). Second, the oxygen bound within biodiesel methyl esters pushes the fuel-rich autoigniting mixtures closer to stoichiometric conditions, leading to higher local temperatures, which are further elevated by less radiative heat loss from the flame due to the lower levels of soot produced

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(Mueller, Boehman, and Martin, 2009). The higher temperatures and leaner mixtures lead to faster combustion reactions, producing an effective combustion-phasing advance. The higher temperatures and longer residence times at high temperature for biodiesel can lead to increased thermal NO_x formation relative to an HC diesel fuel (Mueller, Boehman, and Martin, 2009). Third, the lower energy content of biodiesel means that a larger quantity must be injected to achieve a given load. An engine calibrated for diesel fuel could interpret the larger quantity of fuel injected as a signal to reduce the EGR level, further increasing the NO_x emissions when fueling with biodiesel (Eckerle *et al*., 2008). In principle, many of these factors can be overcome by recalibrating the engine for biodiesel use, resulting in lower smoke, HC, and CO emissions at equivalent NO_x and efficiency levels relative to HC diesel fuel (Bunce *et al*., 2010). There are costs and challenges involved, however, with recalibrating existing engines, as well as adjusting for different biodiesel blend levels (e.g., B5 vs B100) and differences in biodiesels made from different feedstocks (e.g., soy vs palm).

Trends in mixture stoichiometry and temperature effects on emissions from both CI and SI engines can be estimated using a ϕ–T plot, as shown in Figure 6 [from Kim *et al*. (2008)]. Soot production occurs in regions with $\phi > 2$, and the width of the temperature window over which it occurs increases with ϕ. NO_x production occurs in near-stoichiometric to lean mixtures with $T > 1900$ K. HC production occurs in mixtures with $T < 1000$ K and/or higher temperature mixtures with $\phi > 1.2$. CO production occurs mostly in rich, high temperature mixtures, though it can also occur in leaner mixtures where temperatures are insufficient to carry CO oxidation to completion. If the fuel is oxygenated, the oxygen equivalence ratio should be used in place of the conventional equivalence ratio to quantify the mixture stoichiometry (Mueller, 2005).

Emissions trends also can change with fuel composition. Fundamental studies have shown that sooting tendency generally goes in the order poly-aromatics > mono-aromatics > *cyclo*-alkanes > *iso*-alkanes > *n*-alkanes (McEnally and Pfefferle, 2009; Nakakita *et al*., 2005). This seems logical because aromatic rings are the fundamental building blocks of soot. Fuel effects on NO_x emissions tend to be small, provided comparisons are made at the same mixture stoichiometry (Cheng, Upatnieks, and Mueller, 2007), although there is some evidence that NO_x emissions increase with aromatics content (Khalek *et al*., 2002; Mitchell, 2000). Trends for HC and CO emissions tend to be similar. Lower emissions of these pollutants tend to be correlated with higher levels of the more reactive species [e.g., *n*-alkanes (Lilik and Boehman, 2011)]. Other review chapters that may be of interest regarding fuel effects on CI and SI engine emissions include Hochhauser (2008) and Hoekman *et al*. (2011). A good review of fuel effects on 1998 and earlier heavy-duty CI engines can be found in Lee, Pedley, and Hobbs (1998).

4.1.4 *Flash point and flammability limits*

The flash point is a parameter used to quantify the tendency of a fuel to form an explosive mixture, and it is often used to help assess potential safety issues related to fuel storage and handling. The flash point is the temperature at and above which the vapors over a layer of liquid fuel will sustain

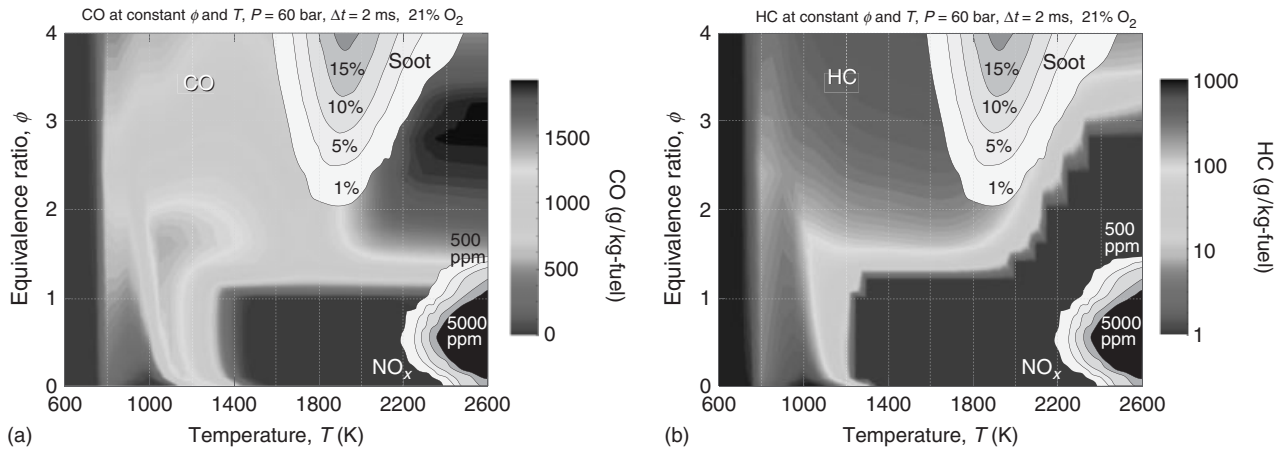

Figure 6. Emissions calculated in a constant temperature and pressure homogeneous reactor at a reaction time of 2.0 ms for *n*-heptane/air mixtures (i.e., no dilution) at the given local equivalence ratio ϕ and temperature T. Contours indicate emissions indices of soot and NO_x (Kitamura *et al*., 2002), whereas shades indicate emissions indices of (a) CO and (b) HC. (Reproduced with permission from the authors. © D. Kim, I. Ekoto, W.F. Colban and P.C. Miles.)

a flame if an ignition source is provided. Many methods exist to measure the flash point, and the values yielded by different methods for a given fuel will not necessarily be equal. Nevertheless, the flash point is the most widely used fire safety parameter in commercial practice.

Another way to assess the risk of fire or explosion resulting from an accidental fuel release is to measure the flammability limits of the fuel. Most gasoline and diesel-range HCs will sustain combustion only in a narrow range from ~1 to 7 vol% in air at standard conditions. Fuel storage systems are designed so that the mixture in the fuel tank remains above the rich flammability limit for gasoline-fueled vehicles and below the lean flammability limit for diesel-fueled vehicles over a wide range of ambient conditions. The lean flammability limits for methane and hydrogen are slightly higher than those of gasoline- and diesel-range HCs at 5 and 4 vol%, respectively, but the rich limits are significantly higher at 15 and 74 vol%, respectively. This phenomenon and the high tank pressures often associated with methane- and hydrogen-fueled vehicles require that special safety precautions be taken to protect against fire and explosion in the event of an accidental release when these gaseous fuels are employed.

4.2 Physical properties

4.2.1 Phase-change characteristics

A fuel must satisfy a few primary phase-change requirements to perform well in a given reciprocating engine application. First, the fuel must generally be a liquid when it is pumped to the injectors. Solid and vapor-phase fuels are not compatible with conventional liquid fuel pumps, and will generally lead to filter plugging and "vapor lock" (loss of fuel pressure due to vaporization in the fuel supply system), respectively. Second, any fuel must be vaporized before it can be burned in the combustion chamber. Liquids and solids cannot burn in the conventional sense; some of the condensed phase must be converted to vapor and mixed with a sufficient amount of oxygen before combustion can occur. Third, the fuel should not be so volatile that a significant fraction of it is lost from the tank and/or fuel transfer lines over time (these evaporative emissions can adversely affect fuel consumption and air quality), but it should be volatile enough that the engine starts easily under cold conditions. Most fuel specifications related to phase change characteristics exist to ensure that these three requirements are met.

4.2.1.1 Maintaining liquid-phase fuel in the fuel supply/injection system. Ensuring that the fuel remains in the liquid phase within the fuel system imposes different challenges depending on fuel type, composition, climate at a given geographical location and time of year, altitude, and engine application. For gasolines, the challenges typically occur because of excessive liquid-to-vapor transition. Gasoline volatilities have been limited to prevent vapor lock in hot weather (ASTM, 2011g). The vaporization characteristics of a fuel are typically quantified by measuring its distillation curve. The distillation curve is typically quantified using the ASTM D86 test method (ASTM, 2011a), though alternative methods with an improved grounding in thermodynamics have been proposed (Bruno *et al*., 2010). For diesel fuels, the challenges associated with phase change typically occur because of undesired liquid-to-solid transition. Fuel freezing or gelling can cause fuel filters to plug, thereby stopping the engine. A number of test methods have been designed to quantify the potential cold-weather issues with diesel fuels, including the cloud point (ASTM, 2011e), pour point (ASTM, 2011b), cold filter plugging point (ASTM, 2010e), and the low temperature flow test (ASTM, 2010c).

4.2.1.2 Achieving desired fuel vaporization in the engine. The lower volatilities of diesel fuels also can present problems with in-cylinder vaporization, which can lead to lower efficiencies and higher emissions, especially when advanced or retarded injection timings cause the fuel to be injected into a cooler in-cylinder environment (Cheng *et al*., 2010; Fisher, Knothe, and Mueller, 2010; Martin *et al*., 2008). The main parameter affecting adequate gasoline vaporization is the back-end volatility (i.e., the high temperature end of the distillation curve). Oxygenate addition also can introduce challenges; for example, blending ethanol into gasoline results in increased latent and specific heats and hence more energy required to vaporize the fuel.

4.2.1.3 Preventing excessive evaporative emissions while maintaining cold-start performance. Evaporative emissions are primarily an issue with gasolines, and they are governed by the vapor pressure of the gasoline under the given operating/storage conditions. Vapor pressure can be quantified using a number of different test methods; see ASTM (2011g) for a list. Oxygenate addition can also introduce challenges with vapor pressure. For example, blending ethanol into gasoline results in an increased vapor pressure of the blend. The "boil-off" of cryogenic liquid fuels like LNG and liquid hydrogen also can be a source of evaporative emissions. Excessive vaporization is not typically a problem with diesel fuels because of their lower volatilities; the notable exception is if gasoline has been blended into diesel fuel.

4.2.2 Density

Density is a fundamental physical property of a fuel, and it can influence fuel utilization through a number of mechanisms. As discussed in Section 4.1.1.1, the density of a fuel can affect FE and fuel consumption. Fuel density changes also can affect the penetration of liquid- and vapor-phase fuel within the combustion chamber, as well as the engine calibration. Aromatic HCs and oxygenates generally have higher densities than aliphatic HCs of the same carbon number.

4.2.3 Lubricity

The lubricity of a fuel is its ability to prevent the wearing of adjacent wetted parts that move relative to each other. Fuel lubricity is an important parameter, particularly in CI engine applications where the fuel pump and injectors are lubricated by the fuel, include close-tolerance parts, and may operate at pressures exceeding 250 MPa. The lubricity of a fuel is the combination of its hydrodynamic- and boundary-lubrication characteristics. Hydrodynamic lubrication is provided by the fuel viscosity, preventing adjacent parts from touching (higher viscosities are better), while boundary lubrication is provided by the fuel adhering (via intermolecular forces) to the adjacent solid surfaces (Bacha *et al*., 2007). Fuel lubricity can be quantified using a number of test methods, with the high frequency reciprocating rig (HFRR) (ASTM, 2011h) and scuffing load ball on cylinder lubricity evaluator (SLBOCLE) (ASTM, 2010d) being the most common in the United States. Lubricity is a property that can be significantly improved by fuel additives blended at treat rates significantly less than 1 wt%. Lubrication and Friction discusses these issues in more detail.

4.2.4 Viscosity

The viscosity of a fuel affects its hydrodynamic lubrication characteristics, as discussed above. Viscosity also influences fuel pumping and atomization. A fuel with low viscosity will tend to leak through small clearances in a fuel pump, which may lead to reduced delivery pressures and quantities. Lower viscosity (and lower surface tension) has been shown to enhance liquid fuel atomization, but this mechanism may be less important for the injection pressures and ambient conditions in modern CI engines (Dahms *et al*., 2013; Siebers, 1999).

4.2.5 Electrical conductivity

A static charge can accumulate when a fuel is being pumped from one location to another. In the absence of proper grounding, the electrostatic potential difference between a given fuel system component and ground can become large enough for a spark discharge to occur. This spark could act as an ignition source for fuel vapors, and a fire or explosion could ensue. Conductivity-enhancing additives are used when necessary to mitigate this potential hazard.

4.3 Stability

The stability of a fuel refers to its resistance to changes in its chemical composition and/or mixture characteristics over time. A fuel with excellent stability is desirable. There are two main types of fuel instability: chemical instability and mixture instability.

4.3.1 Chemical instability and deposit formation

A fuel that undergoes oxidation, polymerization, or other reactions in the liquid phase that change its composition has chemical instability. The chemical reactions of oxidation or polymerization can produce compounds with generally higher molecular weight that are insoluble in the fuel, such as lacquers, gums, and solids. These species are called *deposits* if they adhere to fuel-system, in-cylinder, or other engine components. Such deposits can plug fuel filters, prevent proper injector operation, foul in-cylinder components like piston rings and valves, and increase engine emissions. For example, the lower oxidative stability of biodiesel compared to conventional HC diesel fuel can lead to fuel system deposits, which is why a number of engine manufacturers only warranty their systems for fuels with up to 5 vol% biodiesel content. In-cylinder deposits in SI engines are formed by various mechanisms and can be correlated with lower volatility and higher aromatic content of the fuel. The deposits can lead to increased knocking that the knock sensor on modern engines will detect, causing the spark timing to be retarded and resulting in degraded acceleration performance as well as higher fuel consumption. Antioxidant additives are formulated to prevent the reactions leading to chemical instability, and detergent additives are formulated to control and, at higher concentrations, remove engine deposits after they have formed.

4.3.2 Mixture instability and the importance of polarity

The second type of fuel instability is mixture instability. A fuel mixture is unstable if it separates into two or more distinct liquid phases over time when exposed to different temperatures or with the addition of a trace contaminant. All

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

common fuels for reciprocating internal combustion engines are mixtures. These mixtures contain compounds composed of covalently bonded atoms. Some of these compounds have large permanent electrostatic dipole moments (i.e., they have a net positive charge in one area of the molecule and a net negative charge in another), some do not, and still others will take on a dipole moment in the presence of an imposed electric field. The magnitude of the permanent or induced electrostatic dipole moment of a compound is called its *polarity*. The polarities of different molecules have a strong impact on the types of mixtures they form and the stabilities of those mixtures.

Compounds with permanent electrostatic dipole moments are called *polar*. A high degree of polarity can be caused by the presence of one or more constituent atoms having different electronegativities. For example, the high electronegativity of oxygen tends to make oxygenated compounds polar. The attractive electrostatic forces between the positive and negative areas of polar molecules tend to hold polar molecules together, making their mixtures true solutions. For example, water and ethanol—both polar compounds—are miscible, that is, they are soluble in all proportions.

Compounds that exhibit small permanent electrostatic dipole moments are called *nonpolar*. HCs are generally nonpolar because the electronegativities of carbon and hydrogen are similar. HCs readily form stable solutions with other HCs. When nonpolar and polar molecules are combined, however, the attractive forces between polar molecules tend to keep them together rather than allowing them to mix with the nonpolar compounds: hence the adage "oil and water don't mix." The two types of compounds can be forced to mix through mechanical means (e.g., by putting them in a blender), producing an emulsion. An emulsion is essentially a suspension of droplets of high polarity in a distributed phase of low polarity, or vice versa. In general, buoyancy-driven stratification due to the different densities of the polar and nonpolar fractions, coupled with a finite rate of coalescence of droplets of similar polarity, will cause the polar (or "hydrophilic") compounds in an emulsion eventually to separate from the nonpolar (or "hydrophobic") compounds, unless other compounds are added to stabilize the mixture.

Finally, some HCs, while nonpolar, are "polarizable." The nonlocalized electron distributions of such compounds can allow them to take on an induced dipole moment because of the presence of polar molecules in the vicinity. Aromatic HCs are a classic example of polarizable compounds. Hence, ethanol is effectively insoluble in *n*-hexadecane, a largely nonpolar and unpolarizable compound, but it is quite soluble in gasolines that contain large concentrations of polarizable aromatic HCs.

Solutions generally will not separate over time, that is, they exhibit mixture stability. Nevertheless, solubility typically depends on factors such as temperature, solute concentration, and the presence of trace species. For example, the addition of a small amount of water to an oxygenate–HC mixture near its solubility limit also can cause the mixture to separate into two or more distinct liquid phases [see Tables 3 and 4 of Natarajan *et al.* (2001)].

4.4 Materials compatibility

Fuels come into contact with many materials as they move from their points of production through the engines they power, including materials in supertankers, pipelines, underground storage tanks, tanker trucks, dispensing pumps and lines, vehicle fuel tanks, fuel level sensors, fuel injection systems, engine components (valves, pistons, cylinder liners), lubricants, and after-treatment devices. The materials in these systems have been carefully selected and optimized over decades of experience. New fuel blendstocks can lead to incompatibilities with existing infrastructure, and these issues can be expensive to rectify.

4.4.1 Corrosivity

One of the most important material-compatibility properties of a fuel is its corrosivity. A fuel is said to be corrosive to a given metal if it chemically reacts with and degrades the surface quality of the metal over time at conditions experienced under normal system operation. It is important to use fuels with acceptable corrosivity characteristics to avoid, for example, the expense of repairing a corroded pipeline or the cost of replacing damaged fuel injectors in tens of thousands of vehicles. Fuels that contain organic or inorganic acids or highly polar compounds such as water or methanol often are corrosive. Fuel corrosivity is commonly quantified using a test method in which a polished strip of copper is submerged in the fuel at an elevated temperature for several hours and then visually compared to reference strips (ASTM, 2010a). Copper is used because it corrodes more quickly than ferrous metals, but in a similar manner. Sometimes, a silver strip is used in place of copper because many fuel level sensors contain silver (ASTM, 2011g).

4.4.2 Elastomer compatibility

Another important factor to consider with new fuels is their compatibility with common fuel system elastomers (i.e., the O-rings, gaskets, and hoses used in fuel injectors, pumps, and lines). Elastomers can swell, shrink, harden, soften,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

split, and even dissolve when exposed to different fuels. For example, nitrile-rubber elastomers used in conventional HC fuel delivery systems swell when wetted by fuels that contain aromatics, and this swell is factored into the system designs. If these systems are used with low aromatics fuels such as F–T diesel or hydrotreated vegetable oil, the seals will not swell adequately, leading to potential fuel system leakage and corresponding safety hazards. Oxygenates (e.g., ethanol and biodiesel) can present elastomer compatibility issues as well. While elastomers that are compatible with a wider range of fuels do exist (e.g., perfluoroelastomers), they tend to be more expensive than conventional rubber elastomers, and it is costly to install them into existing vehicles.

4.4.3 *Catalyst deactivation*

The third primary material-compatibility consideration with fuels has to do with the deactivation of the catalytic after-treatment systems used to lower the emissions levels of regulated pollutants from most modern powertrains. Catalyst deactivation is a rich area of study, and depends on the type of catalyst and the deactivation mechanism: chemical, fouling, thermal, or mechanical. Fuel properties most directly affect the first two of these mechanisms. Fuels that contain sulfur or phosphorus can "poison" a catalyst (i.e., lower its activity) by bonding or adsorbing to its active sites. Indeed, a key factor in the continual lowering of diesel-fuel sulfur levels in the United States (to 15 ppm by weight currently for on-road engines) is to enable the use of sulfur-sensitive catalytic after-treatment systems [for reference, the current sulfur limit for gasolines sold in the United States is 80 ppm by weight (ASTM, 2011g)]. Another fuel-dependent mechanism for catalyst deactivation is the physical blocking of active sites by fouling. The fouling agent could be soot, which can be burned from the catalyst during a regeneration event, or it could be alkali-metal ash or even silica particles from trace species in the fuel (ASTM, 2011g, Section 3.6.1). Alkali-metal levels in the fuel less than 10 ppm by weight have been found to lead to diesel particulate filter degradation (Williams *et al*., 2011). Gas Aftertreatment Systems and Solid/Condensed Phase Aftertreatment Systems also discuss catalyst poisoning issues.

Other potential fuel material-compatibility issues exist, including lube oil incompatibility, the fuel acting as a solvent for vehicle paint, and incompatibilities with plastic or fiberglass fuel tanks and liners. There are many important material-compatibility details to be considered when developing a new fuel blendstock.

4.5 Environmental considerations

Fuel usage in transportation and nonroad applications provides many benefits in our daily lives: from producing and distributing the food we eat, to building the communities and businesses in which we live and work, constructing roads and bridges, manufacturing and hauling goods for commerce, and enabling personal mobility for work and pleasure. As a result, fuel usage has increased to levels that can be challenging to physically comprehend (Section 2). Some of the environmental issues associated with this tremendous scale of fuel use are discussed in the following sections.

4.5.1 *Toxicity of fuel and combustion products*

The first major environmental consideration is the toxicity of the fuel and its combustion products. Sometimes, unburned fuel is inadvertently released into the environment; hence, it is important to know the toxicities of various fuel components, their solubility in water, and rates and strategies for biodegradation. Over the years, toxins in petroleum-derived fuels have been reduced. For example, lead (a neurotoxin) was phased out of gasoline between 1970 and 1996, and more recently the concentration of benzene (a known human carcinogen) has been limited in gasoline (Gibbs *et al*., 2009). Toxicity concerns are not restricted to petroleum-derived fuels; some alternative fuels also have toxicity issues. The ingestion of as little as 15 mL of methanol can cause blindness, with lethal dosages in the range 60–240 mL (ChemADVISOR, 2012). The jatropha plant and its seeds, which are considered a potential nonfood feedstock for biofuel production, also are highly toxic. The toxicities of many conventional and alternative fuel compounds have yet to be quantified.

Fuel combustion products are released whenever fuel is burned. The primary combustion products, carbon dioxide and water, are of little or no toxicity concern, but some minor products (e.g., NO_x) are highly toxic. The levels of many toxic combustion products have been on a decreasing trend in the United States since 1990 even though the total number of vehicle miles traveled, population, and energy consumption have been increasing (U.S. EPA (2012b), Figures 3 and 4).

4.5.2 *Climate change*

A second environmental consideration is global climate change due to human activities including the combustion of fossil fuels. Combustion produces CO_2, a GHG that inhibits radiative heat loss from the Earth by absorbing infrared radiation emitted from the Earth, becoming vibrationally

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

excited, and then reradiating a fraction of this energy back to the Earth when the molecule relaxes to a lower energy level. This "greenhouse effect" could play a role in the observed increase in global average temperatures, loss of polar ice, and rising sea levels in recent decades (Solomon *et al*., 2007). CO_2 is not the only GHG. For example, methane (an alternative fuel) has a GHG potential much greater than that of CO_2 (Section 2.3). The link between atmospheric GHG levels and global climate change is complex and not well understood.

A large number of academic, industrial, and governmental organizations have developed models to estimate GHG emissions. Models that combine all aspects from fuel production through end-use are termed WTW models. Values are generally reported in mass of CO_2 equivalent per unit volume of fuel or per unit distance traveled. Beyond WTW models, life-cycle models additionally include the emissions associated with processes to recycle vehicle components at the end of their useful lives. The specific GHG values for any fuel/engine combination are highly dependent on the modeling assumptions and the GHG emissions estimates for the individual processes that make up a given pathway. As a result, there can be large differences in estimates obtained by different organizations. Generally, compared to petroleum-derived gasoline and diesel fuels, bio-derived fuels have a smaller GHG footprint, while coal- and oil-sands-derived fuels have larger footprints, but there can be significant differences even among the biofuels. For example, in some parts of the world, forests have been cut down to create plantations for biofuel crops such as palm oil. The GHG impacts of such land-use changes can be significant. When land-use changes are included, the GHG emissions for corn-based ethanol rise to levels much closer to those for petroleum-based fuels than ethanol from sugar cane or cellulose.

GHG emissions for electric vehicles are highly dependent on the energy source used for electricity production. Approximately 50% of the electricity generated in the United States comes from coal. Electricity from coal has a larger GHG footprint than electricity from natural gas, and much larger than electricity from hydroelectric, geothermal, or nuclear energy. Of course, all of these energy sources have significant environmental aspects in addition to GHG emissions as well. When the GHG emissions of battery and electronic component production and end-of-life recycling are taken into account in life-cycle analyses, electric vehicles are not as environmentally friendly as they might seem based on the aspect that they produce no GHG emissions at the vehicle.

4.5.3 Sustainability

The key sustainability issue for petroleum-derived fuels is that they are not being created at a rate comparable to the rate at which they are being consumed. Although the discovery of large, new oil fields has diminished, proven oil reserves have continued to grow, even in the United States, because of the development and deployment of new petroleum-recovery technologies. One example is the recent development of technology to extract liquids and natural gas from tight shale formations that previously were inaccessible. For bio-derived feedstocks, sustainability issues include soil erosion and degradation, fresh-water consumption, and energy return on investment (i.e., the energy content of a given amount of fuel divided by the energy required to produce the given amount of fuel). For example, estimates of the energy return on investment for corn-based ethanol are near unity, see Schobert (2013, Chapter 4).

4.5.4 Food versus fuel

The final main environmental consideration is the diversion of resources from food production to fuel production. Examples of this include fuel-ethanol produced from corn, and biodiesel production from, for example, soy, canola, and palm oils. These "food versus fuel" concerns have shifted the focus of biofuel feedstock development from conventional food crops to inedible biomass. This has led to a longer term focus on the use of nonfood crops such as camelina or jatropha as sources of triglycerides for biodiesel production and inedible cellulose for ethanol production.

5 FUEL SPECIFICATIONS

The specific properties that make a fuel well suited to a given engine application have been determined over time through testing and the experience of many end-users. These properties are measured by test methods, and the set of test methods and corresponding fuel property ranges that have been found to be acceptable for a given application are established as fuel specifications. Fuel specifications are developed to increase the likelihood that all fuels marketed for a given application will meet or exceed all relevant requirements. Ideally, a fuel specification would take into account all of the potential fuel-property issues discussed previously in this chapter.

A fuel that meets or exceeds all relevant requirements is deemed "fit for purpose." Fuel specifications are developed on regional, national, and/or international bases by organizations composed of representatives from vehicle

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

makers, engine and parts manufacturers, fuel producers, and government agencies. In the United States, fuel properties must conform to ASTM specifications [D4814 for gasoline (ASTM, 2011g) and D975 for diesel fuel (ASTM, 2011c)]. In Europe, most countries require fuel to conform to the Comité Européen de Normalisation (CEN) specifications EN 228 for gasoline (British Standards Institution, 2008b) and EN 590 for diesel fuel (British Standards Institution, 2009). These specifications provide lower and/or upper limits on key fuel properties such as cetane, distillation characteristics, density, aromatic content, viscosity, and sulfur content to ensure that fuels are fit for the engines and the environments in which they will be used. The specification limits can be different for different regions/countries and can vary depending on the season (e.g., winter vs summer). For example, the minimum acceptable value for CN is 40 per ASTM specifications, but 51 per CEN specifications. Differences in specifications typically reflect differences in regional engine characteristics, area climate, and environmental regulations. In the United States, the EPA and local agencies such as California Air Resources Board (CARB) have additional specifications for lower emissions fuels sold in certain areas, and pipeline companies can set supplementary specifications for fuels transported in their pipelines. For example, some pipeline companies have limits for diesel density and pour point that are not covered by the ASTM D975 specification.

As some specifications have a range of acceptable values while others do not have both a lower limit and an upper limit, fuels sold in the marketplace have a range of properties and compositions that reflect differences in refinery conversion units and capabilities, crude-oil slates, and product slates (e.g., whether jet/kerosene and/or home-heating oil are competing for similar fuel components). Fuel composition and properties are also expected to change as larger quantities of alternative-fuel components derived from biofuels, oil sands, and F–T processes (from natural gas, coal, or biomass) are blended with conventional petroleum-derived fuels and enter the market. A considerable amount of testing has been conducted and more still needs to be conducted on these new blend components to relate observed engine performance with measured fuel properties and composition. The results of this testing can be used to improve the relevant fuel specification(s).

The use of detailed fuel specifications and careful engine design has largely mitigated noticeable effects of fuel property changes on engine performance in typical applications. Nevertheless, the growing use of bio-derived and other unconventional fuels with composition and property characteristics substantially different from those of conventional petroleum-derived HC fuels, coupled with the development of advanced high efficiency clean-combustion engines, highlights the need for the continual evolution and improvement of fuel specifications.

5.1 Gasoline

ASTM D4814 covers specifications for 10 gasoline properties, although these do not include ONs (RON and MON) or antiknock index [AKI = (RON + MON)/2], which are set by gasoline refiners and marketers to meet the requirements set by the vehicle original equipment manufacturers (OEMs) and must be clearly labeled on the fuel pumps. The properties covered are the following:

1. volatility on a geographic and seasonal basis (to enable good drivability);
2. solvent washed gum content (to limit the amount of gums formed by oxidation);
3. oxidation stability (to provide additional protection against gum formation);
4. water tolerance (to protect against phase separation due to dissolved water at colder temperatures—usually not a problem for blends of HCs, but can be for blends containing oxygenates);
5. sulfur content (to limit deactivation of exhaust after-treatment catalysts and to protect against engine wear, deterioration of engine oil, and corrosion of exhaust system components);
6. copper strip corrosion (to protect against corrosion of fuel system components due to reactive compounds);
7. silver strip corrosion (to protect against corrosion of silver components present in some fuel gauge systems);
8. lead content (to ensure that unleaded gasolines are free of lead);
9. appearance (to ensure product is visually free of undissolved dirt, sediment, and suspended matter);
10. workmanship (to be free of adulterants or colorants that may make fuel unfit for purpose).

ASTM D4814 references more than 30 other ASTM standards that describe the specific test methods and equipment required to measure the gasoline properties. Specifying a property has little value unless all parties measuring the property use the same procedure and can obtain the same answer within the defined precision of the method.

ASTM (2011f) provides specifications for ethanol that is to be blended into gasoline. Previously, the US EPA designated certain regions as environmental nonattainment areas and required the addition of specific amounts of oxygenates in the gasoline. Recently, the US Congress passed the Renewable Fuels Standard 2 (RFS2), which has delegated the authority to state and local agencies

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto125
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to set specific oxygenate blend level requirements, but does require a minimum total volume of ethanol use in gasoline, which increases with time. The EPA continually sets specifications on the maximum fraction of ethanol that can be contained in gasoline. Previously, the maximum amount was 10 vol% (except for the 85 vol% E-85 ethanol blend that is approved for flexible-fuel vehicles), but in 2012 the EPA granted a waiver to allow up to 15 vol% ethanol in gasoline (E-15) for vehicle model years 2001 and newer. OEMs have expressed concerns about the 15 vol% level because some tests conducted by CRC suggest that the fuel systems in some 2001 and newer vehicles not specifically designed for E-15 may be susceptible to failure when fueled with E-15 (Coordinating Research Council, 2012) and also that older vehicles may accidentally be fueled with E-15.

For 2012, the RFS2 total ethanol requirements for the United States are 13.2 billion gallons per year of corn-based ethanol and 500 million gallons of cellulosic ethanol. However, cellulosic ethanol is still in the research and development stages, and the amount produced commercially was essentially zero (Section 2.4.1). In future years, the amount of cellulosic ethanol required will continue to increase to a value of 10.5 billion gallons in 2020, but the amount of corn-based ethanol is capped at 15 billion gallons per year.

5.2 Diesel fuel

The US diesel-fuel specification, ASTM D975 (2011c), covers 11 diesel fuel properties. These include the following:

1. minimum flash point (relates to safety in fuel handling and use);
2. water and sediment (affects fuel filters and injectors);
3. back-end volatility (related to ease of starting and smoke formation);
4. viscosity (affects fuel spray atomization, fuel system lubrication, and fuel system leakage);
5. ash content (can damage fuel injection and after-treatment systems and cause combustion chamber deposits);
6. maximum sulfur content (affects after-treatment catalysts, particulate emissions, and cylinder wear);
7. cetane and maximum aromatic content (relates to autoignition quality and affects cold-start capability, combustion timing and performance, and emissions);
8. cold-temperature properties of cloud point, low temperature filterability, and cold-filter plugging point (affects low temperature operability and fuel handling);
9. carbon residue (measures coking tendency of fuel and may relate to deposit formation);
10. copper strip corrosion rating (indicates potential for corrosive attack on metal parts);
11. lubricity [relates to abrasive wear of components such as fuel pump and injector; has become poorer because of removal of certain compounds during hydrotreating to meet ultra-low sulfur diesel (ULSD) standards].

Two diesel fuel properties that can vary quite a bit in market fuels that meet specifications are CN and aromatic content. In the United States, CNs range from 40 to the mid-50s. The aromatic contents of US #2 ULSD fuels range from <10 vol% to >30 vol%. Although there is an ASTM specification maximum of 35 vol% for aromatics, it can be exceeded if the cetane index value (ASTM, 2011d) is 40 or higher. The aromatic values of 10 vol% and lower are found in some California fuels where the CARB #2 ULSD specification is 10 vol% maximum. However, alternative fuel formulations having aromatic contents higher than 10 vol% are allowed (and actually sold) in California, provided that the emissions of the alternative blends predicted by CARB-specified engine test methods and models are no higher than the official 10 vol% blend (California Environmental Protection Agency, 2004). In addition to wide variation in aromatic content, there also can be a wide variation in the other HC classes [*n*-alkanes, *iso*-alkanes, and mono- and poly-cycloalkanes (Farrell *et al.*, 2007)].

The US RFS2 mandates the use of 1 billion gal per year of "biomass-based diesel." Currently, this predominantly is biodiesel composed of FAMEs mostly prepared from soybean vegetable oil. Several state and local governments have set mandates on the minimum fraction of biodiesel that must be blended into each gallon of diesel fuel. Issues related to the limited stabilities, low back-end volatilities, and less-than-ideal cold-temperature properties of biodiesel blends have resulted in engine manufacturers setting upper limits on biodiesel content of 5 vol% for some older engines and up to 20 vol% for newer engines. The use of FAME biodiesel has resulted in the development of ASTM (2010g, 2011i) and CEN (British Standards Institution, 2008a) specifications for the biodiesel component.

6 SUMMARY AND OUTLOOK

The production and distribution of liquid fuels from petroleum has been optimized over more than a century and a half, and the development of reciprocating internal combustion engines to use these fuels has continued for nearly as long. Although fuel production and engine combustion technologies are well established, they continue

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to advance rapidly and play central roles in economy and society. This trend appears likely to continue for at least several more decades (NPC, 2012; Exxon Mobil, 2012). Substantial further improvements in engine efficiency and emissions are possible, especially on an equivalent-cost basis relative to competing technologies.

Significant concerns about environmental quality and energy security are currently driving the coevolution of fuels and engines. Cost-effective, regionally produced, non-food-based, nontoxic, renewable fuels created from biological systems or solar energy and used in high efficiency clean-combustion engines may be able to help address these concerns. These systems are being aggressively researched and developed. The optimal fuel/engine system may be different in different areas of the world, depending on local climate, population density, resources, and myriad other factors. A great deal of research remains to be done to develop optimal fuel/engine systems. The largest hurdle to be overcome in the area of fuels and internal combustion engines is to meet both the tremendous scale of fuel demand and the need for high efficiency, clean combustion engines in a manner that is cost effective and at the same time enhances environmental quality and energy security.

Intake Boosting

Nick Baines
Concepts NREC, White River Junction, VT, USA

1 INTRODUCTION

1.1 Motivations for intake boosting

The purpose of intake boosting is to increase the density of the air trapped in the cylinder, which enables the fuel flow and energy release from combustion to be increased. The result is an engine of higher power output, or more relevantly to automotive designers, the same power output can be achieved with a smaller engine. This is the direct result of charge boosting, but the indirect effects are often more profound. Boosting allows a smaller engine to be employed that operates at higher loads. The engine is more efficient because higher loads have proportionally less loss because of internal cylinder friction and heat loss due to the engine coolant. A smaller engine will also package better in a vehicle, with improvements to vehicle aerodynamics and a reduction in structural weight. Undoubtedly the greatest effect on engine technology, however, has been the impact on emissions.

All of the developments in engine combustion in recent years that are aimed at reducing emissions involve dilution of the charge. These include exhaust gas recirculation (EGR) that is widely used for this purpose, and other combustion technologies such as stratified charge, homogeneous charge compression ignition (HCCI), premixed charge compression ignition (PCCI), and adjustments to valve timing such as the Miller cycle. Oxides of nitrogen (NO_x) are formed primarily in the high temperature of the combustion flame, and the quantity of NO_x created can be controlled by diluting the charge to limit the flame temperature, reducing the compression ratio, or using excess fuel (although this conflicts with the need for fuel economy). Carbon monoxide, unburnt hydrocarbons, and particulates are the products of partial combustion, which can be controlled using a lean mixture. All of these measures, however, also reduce the specific power output of the engine. In the circumstances, charge boosting has become an essential technology to maintain the engine power output while retaining the advantages of low emissions and fuel economy. The following sections discuss performance characteristics of boosting technologies. Other details can be found in Turbocharging.

1.2 Boosting fundamentals

An internal combustion engine is a positive displacement device, and the mass flow rate of air into the engine is determined by the trapped mass in the cylinder, which is the product of the air density ρ_a, the swept volume of the cylinder V_{sw}, and the volumetric efficiency η_{vol} (Heywood, 1988). Together with the crankshaft speed N, the mass flow rate is

$$m_a = \frac{\eta_{vol}\rho_a V_{sw} N}{2} \quad (1)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

The volumetric efficiency accounts for losses in the induction process. The division by 2 is required for a four-stroke engine because there is only one firing stroke for every two rotations of the crankshaft.

The power that can be delivered is determined by the amount of fuel that is burned m_f, the energy available in the fuel per unit mass Q_f, and a fuel conversion efficiency η_f that allows for the incomplete nature of the combustion process

$$P = \eta_f Q_f m_f \tag{2}$$

The power delivered by a four-stroke engine is therefore

$$P = m_a \eta_f Q_f \left(\frac{m_f}{m_a}\right) = \frac{\eta_{vol} \rho_a V_{sw} N \eta_f Q_f}{2} \left(\frac{1}{AFR}\right) \tag{3}$$

Assuming that the engine combustion system has been well optimized, the only one of these parameters that the designer can influence to a large extent is the inlet air density. This is done by compressing the air before it enters the cylinder.

The simplest method of doing this is by means of a mechanical supercharger, such as a piston, sliding vane, or rotary compressor, driven by the crankshaft of the engine, as shown in Figure 1a. A supercharger enables very considerable increases in output power to be achieved, but at a cost to overall efficiency because the supercharger itself consumes shaft power from the engine. For relatively low boost pressures of about 1.5–2 bar, this may be 10–15% of the engine power, but it increases rapidly, so that at a boost pressure of 4 bar, the fraction is about 40–50%. This cannot be justified economically. The alternative solution is to drive the compressor using the energy of the engine exhaust gas, which is extracted by expanding that gas through a turbine. The turbine is linked to the compressor by means of a shaft that is independent of the engine output shaft. This is the turbocharger concept shown in Figure 1b. In a typical engine, roughly 30–40% of the energy released by combustion of the fuel appears as energy in the exhaust, which is thermodynamically waste energy. If this energy is extracted from the exhaust gases in a turbine, the compressor can be driven without need to draw power from the engine shaft.

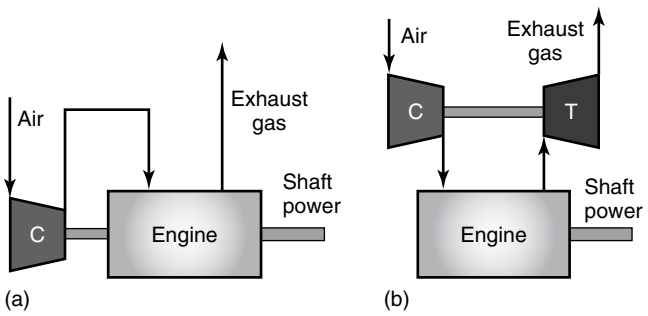

Figure 1. (a) Supercharged engine (b) turbocharged engine.

1.3 Turbocharger

The turbocharger has three principal components: a compressor, a turbine to drive the compressor and linked to it by a shaft, and bearing assemblies to support the shaft. In addition, shaft seals are required to separate the air and exhaust gases from the bearing lubricant, high temperature turbochargers may require cooling passages to limit the casing and bearing temperatures, and bleed valves or other active control devices may be included. Even with the basic turbocharger, considerable differences in detail are encountered.

Figure 2 shows a turbocharger designed for vehicle engines. The compressor is a single-stage centrifugal compressor, with the air entering axially and discharging radially, before being collected in the volute housing and delivered to the engine. The turbine is a single-stage radial turbine. A volute housing is again used to distribute the exhaust gas about the circumference of the turbine. The gas enters the rotor radially and discharges axially. Careful design and precision engineering of all components is necessary to ensure a high performance and long life. Vehicle turbochargers are made in very large numbers and must be designed from the outset for manufacture by mass production methods. The market is competitive, and a commercially successful design is one that achieves the right compromise between performance, service life, and cost.

The pressure ratios developed by turbocharger compressors range from low values for small gasoline engines where the boost pressure is limited to about 2 bar, up to about 3.5–4 bar for vehicle diesel engines that have to operate over a wide range of speeds and flow rates, or higher for power generation engines where the width of the operating range can be sacrificed for higher boost pressure at design point operating conditions. For high pressures, more than one stage of compression may be employed. Turbocharger speeds can range up to about 300,000 rev/min for very small turbochargers, and as low as 10,000 rev/min for large machines.

To be commercially viable, a turbocharger manufacturer must have products that match a range of engines of varying capacity. The flow range of any given compressor, and to a lesser extent the turbine, is limited, and so manufacturers will normally provide a range of models, or "frame sizes," similar in concept and often developed from the same basic designs, with different flow capacities. Additional variations can be achieved by trimming the compressor and turbine rotors. This involves removing material from the tips of the blade to reduce the flow areas of the blade passages. The rotor is cast to the maximum trim size required and then for smaller trims material is removed by machining. This process invariably introduces some compromise into the blade shape and thickness, and for this reason trimming can only be taken so far. Eventually, a change to a smaller frame size becomes necessary.

1.4 Supercharger

The supercharger is an air compressor, which may be either a positive displacement or a rotordynamic type (pressure wave superchargers are discussed in Section 4.5). Common types of positive displacement compressor are the Roots blower, Lysholm screw compressor, and sliding vane compressor (Figure 3). Positive displacement compressors deliver a fixed volume of air per revolution, and if the supercharger is driven directly from the engine shaft, it is ideally matched to the engine that also has a constant volume flow characteristic. Positive displacement compressors typically have high efficiency at low pressure ratio, but the efficiency decreases rapidly as the pressure ratio increases. They are, therefore, only suited to low boost applications. The drive from the engine shaft may be direct or via a belt or gear drive. In modern engines, a clutch is often included to decouple the supercharger at high engine speed so as to remove the load on the engine and improve the fuel economy. At low engine speed, the supercharger is connected to provide boost and increase the low speed torque of the engine.

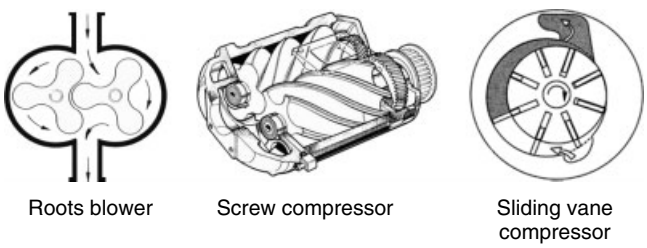

Figure 3. Positive displacement compressors for superchargers.

Rotordynamic superchargers are similar to turbocharger compressors and rotate at speeds much greater than that of the engine, so that a large gear ratio drive is necessary. Alternatively, the compressor may be driven by an electric motor. This requires a source of electricity on the vehicle, which is an engine-driven alternator unless regenerative braking can be utilized, as in a hybrid electric powertrain. Rotordynamic compressors have an airflow characteristic that is less well matched to the engine, making a clutch (for mechanical drive) or speed control (for electric drive) essential.

A two-stroke engine does not have an induction stroke, and a charge booster is essential for operation (Heywood, 1988). Small engines may use the crankcase as a supercharger, but larger engines require a mechanical or electrical supercharger, or a turbocharger, to induce air and scavenge the engine.

1.5 Charge air cooler

An unfortunate effect of the compression process is that the temperature of the air is increased as well as the pressure. This is the same for turbochargers and superchargers. For engine power boosting, the critical parameter is the mass of air trapped in the cylinder, and for a given cylinder volume, this depends on the air density, as is indicated in Equation 1. The increase in temperature reduces the air density. Furthermore, the inefficiency of the compressor increases the air temperature at the exit above what it would be if the compression were ideal.

Reducing the charge air temperature in a separate heat exchanger after compression has a direct effect on the trapped mass in the cylinder and on the mean effective pressure of the engine. Furthermore, it also results in lower temperatures throughout the operating cycle, leading to less thermal stress on the engine and the turbine. The charge air cooler, also known as an *intercooler* or *aftercooler*, is located between the compressor and the inlet manifold. The performance of a heat exchanger is measured in terms of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

its effectiveness

$$\varepsilon = \frac{\text{Actual heat transfer}}{\text{Maximum possible heat transfer}} = \frac{T_{2,\text{in}} - T_{2,\text{out}}}{T_{2,\text{in}} - T_{\text{c}}} \quad (4)$$

where $T_{2,\text{in}}$ is air inlet temperature from the compressor, $T_{2,\text{out}}$ is the air outlet temperature from the cooler, and T_{c} is the coolant temperature. An effectiveness of unity implies that the temperature of the air is reduced to that of the coolant, which is as low as it possibly can be; conversely, an effectiveness of zero means that no cooling occurs. Figure 4 shows the effect on density ratio of cooling effectiveness, assuming that the coolant is at ambient temperature. Even modest levels of cooling have considerable benefit, and this increases with boost pressure ratio.

For an automobile, the sources of coolant that are readily available are the engine cooling water and ambient air. The engine cooling water has the disadvantage that its temperature will be close to boiling for normal engine operation and this limits the scope for cooling. At low boost pressures, the air temperature at exit from the compressor may be lower than the coolant temperature. If operation is required for any length of time under these conditions, it is necessary to turn off the charge air cooler or allow the air to bypass it, otherwise, the charge air density will be reduced rather than increased. Using ambient air as a coolant increases the cooling potential, but air has a much lower convective heat transfer coefficient and thermal capacity than water. This means that to achieve the same amount of heat transfer, a larger surface area and heat exchanger volume is required.

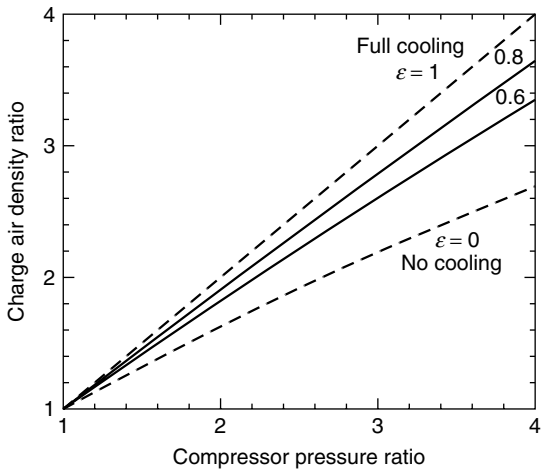

Figure 4. Effect of cooling effectiveness on charge air density ratio. Results are shown for a compressor isentropic efficiency of 0.8 and ambient and coolant temperatures of 288K.

In the circumstances, a separate water cooling circuit for the charge air cooler, with its own circulating pump and cooling radiator, is commonly used because it combines the benefits of the thermal properties of a water coolant with coolant temperatures closer to ambient. The effectiveness of the heat exchanger depends very largely on the area over which heat transfer occurs and thus the size of the heat exchanger. The design of the charge air cooler, therefore, must be a careful balance of cooling effectiveness, installation size, and packaging in the engine compartment.

2 TURBOCHARGER CHARACTERISTICS

2.1 Compressor

2.1.1 Components

A centrifugal compressor stage comprises rotating and stationary components. The air enters the impeller from the axial direction (Figure 5). The flow moves through the impeller and is pressurized by the action of the moving impeller blades. It is also turned toward the radial direction, so that it leaves with a combination of radial and tangential velocities. At this point, it still has substantial kinetic

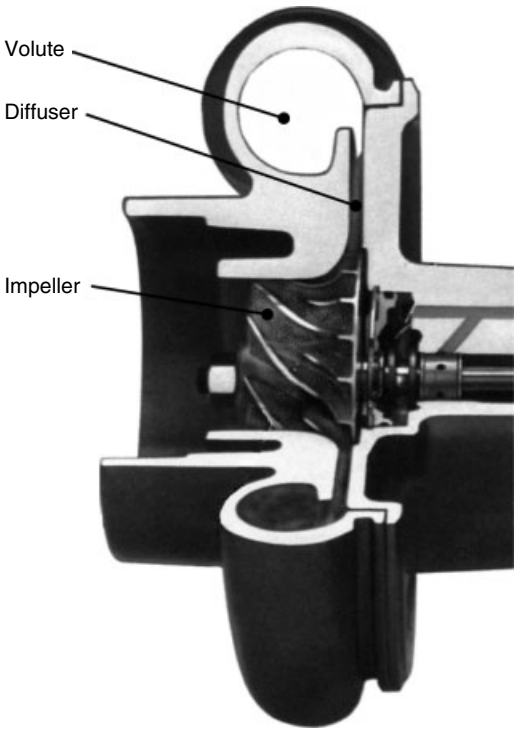

Figure 5. Components of a centrifugal compressor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

energy, and so for performance reasons as much of this as possible is recovered in a diffuser. The diffuser is a stationary component that can take several different forms, including the vaneless diffuser that can be seen in Figure 5, or vanes or channels can be used to guide the flow. Finally, the air is collected in a volute to direct it toward the inlet manifold.

2.1.2 *Compressor performance map*

To the turbocharger engineer, the compressor performance parameters of greatest interest are the pressure ratio, which determines the boost pressure and brake mean effective pressure (BMEP) of the engine, and the efficiency, which affects the turbocharger efficiency and the overall fuel economy of the system. In addition, engineers are usually concerned with range, which is the range of flow rates over which the compressor will operate stably and with acceptable performance.

A typical compressor operating map is shown in Figure 6. The pressure ratio is plotted as a function of the compressor mass flow rate and the speed of rotation, and contours of efficiency are superimposed on this graph, where efficiency is defined as

$$\eta = \frac{(T_{02}/T_{01}) - 1}{(p_2/p_{01})^{(k-1)/k} - 1} \tag{5}$$

where T is the temperature, p is the pressure, and k is the specific heat ratio. Subscript 0 refers to total conditions, 1 to the compressor inlet and 2 to the compressor exit.

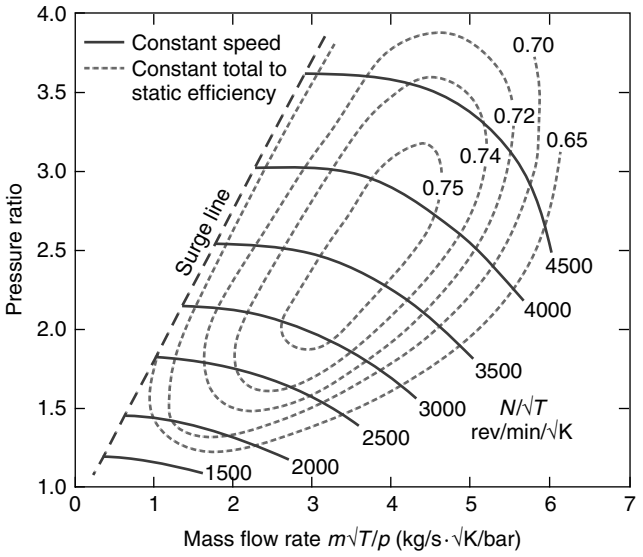

Figure 6. Compressor performance map.

The mass flow and speed parameters used here are corrected for the inlet or ambient pressure p and temperature T. This ensures that the same map can be used for engine matching even when the ambient conditions change, for example, when operating at altitude, and that a map measured on the gas stand at one set of inlet conditions will be applicable when the engine operates at different inlet conditions. It is evident that both pressure ratio and efficiency are strong functions of mass flow rate and speed. Maximum efficiency occurs over a relatively restricted range of operation, and for efficient operation of a turbocharged engine, it is important to ensure that the engine running line is in this region as far as possible.

The range of stable operation of a compressor is limited by choke at high flow rates and surge at low flow rates and is defined as

$$\text{Range} = \frac{m_{\text{choke}} - m_{\text{surge}}}{m_{\text{choke}}} \tag{6}$$

where m_{choke} and m_{surge} are the compressor mass flow rates at choke and surge. Choke occurs when the flow becomes sonic at the throat, or point of minimum area, of the gas path. For a compressor with a vaneless diffuser, choking invariably occurs at the throat of the impeller. For a compressor with a vaned diffuser such as a channel diffuser, the diffuser also has a throat, and depending on the match between the impeller and the diffuser, either component may choke first. Choking sets a maximum limit on the flow capacity of the compressor. As the flow approaches choking, so the aerodynamic losses accumulate, localized patches of sonic and supersonic flows occur, and the efficiency and pressure ratio developed both fall rapidly.

The onset of surge fixes the minimum flow rate of the compressor for any given speed of rotation. Surge is marked by a breakdown of the flow and the initiation of large-scale pressure oscillations that, if unchecked, can cause rapid deterioration and failure of the compressor blades or the turbocharger bearings. Great care must, therefore, be taken to avoid running the compressor into surge. Figure 6 shows a typical lower mass flow rate limit imposed on compressor operation by surge, labeled the surge line (the long-dashed line). The proximity of any stable operating point to surge is the surge margin

$$\text{Surge margin} = \frac{m - m_{\text{surge}}}{m_{\text{choke}} - m_{\text{surge}}} \tag{7}$$

The causes of surge are complex and are not all well understood, but it basically stems from a breakdown in the deceleration of the flow in the compressor. High pressure ratios require more deceleration and compressors are likely to operate closer to this point of breakdown

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

than at low pressure ratios. For modest boost pressures, the range of operation can be made relatively wide and such compressors do not impose severe operating restrictions on turbocharged engines. For high boost pressures, however, the range is narrow and it is this factor, more than any other design or performance limitations, which restricts the boost that can be developed by a single-stage compressor. Very high boost pressures require two stages of compression.

Surge cannot be predicted analytically except in very restricted cases. The problem is complicated by the fact that surge is a system phenomenon and depends not only on the compressor but also on such parameters as the charge air cooler and the inlet manifold volume and configuration. The same compressor may surge at different points on different engines because of the different intake arrangements. The deterioration in performance as choke is approached is also difficult to predict. It is essential to test new compressor designs on the gas stand and on the engine in order to make reliable estimates of the range. Gas stand testing should ideally be done with the actual engine intake hardware to be confident about the measured points of surge (Capon, Leong, and Morris, 2006).

2.1.3 Compressor design

The principal determinant of pressure ratio is the peripheral speed of the impeller, but this also controls the centrifugal stress in the impeller blades and hub. Aluminum alloys are satisfactory materials for pressure ratios up to about 3.5–4, and beyond that, titanium alloy is required. The operating range also decreases as pressure ratio increases, and for automotive applications demanding a wide range, this can be limiting. Two stages may be used to achieve high pressure ratio and range, but for single-stage compressors, other measures such as shroud bleed (sometimes described as ported shrouds) may be used to extend the stable operation to lower flow rates. Backsweep, which is the curvature of the impeller blades at exit away from the radial direction, is also influential in increasing the stable operating range. See Japikse (1996) for a full discussion of centrifugal compressor design.

2.2 Turbine

2.2.1 Components

For automotive turbochargers, the turbine is invariably a single-stage radial turbine or a mixed-flow turbine, which can be considered as a variant of the radial turbine. In the small sizes required for this application, axial turbines suffer unduly from tip leakage losses, and the blades are more prone to high cycle fatigue and foreign object damage. The radial turbine comprises two essential parts: a fixed, swirl generating component or stator in which the working fluid is expanded and turned to give it a circumferential velocity about the axis of the machine, and a rotor, through which the flow passes and, in doing so, does work. In the rotor, the fluid enters in the radial-inward direction, is turned in the meridional plane, and leaves in the axial direction.

The stator may take one of two basic forms. Figure 7a shows a radial turbine with a ring of stator, or nozzle, vanes. Upstream of these vanes is a volute housing that takes the flow from the exhaust manifold of the engine and distributes it around the periphery of the nozzle. The shape of the volute is such that the cross-sectional area normal to the flow direction decreases from a maximum at the inlet as the flow moves around the axis of the turbine. This has the effects of forcing the flow inward into the nozzle and imparting considerable swirl velocity to the gas before it enters the nozzle. The nozzle has only to turn the gas through a fairly small angle. Nozzle blades are often made with no camber at all and rely on the radial inward motion of the gas to accelerate and turn it. Nozzle blades are often arranged to pivot so as to change the spacing between the blades and hence the flow capacity of the turbine. This is a form of variable geometry turbine, which has significant advantages in engine matching.

A nozzleless turbine is shown in Figure 7b, in which the volute alone is responsible for accelerating and swirling the flow. The attraction of this is that by dispensing with the nozzle ring a cheaper assembly can be achieved. The disadvantages are that the volute alone is rarely as aerodynamically efficient as a nozzle and that the larger the expansion ratio, the larger the volute that is required to achieve the necessary acceleration.

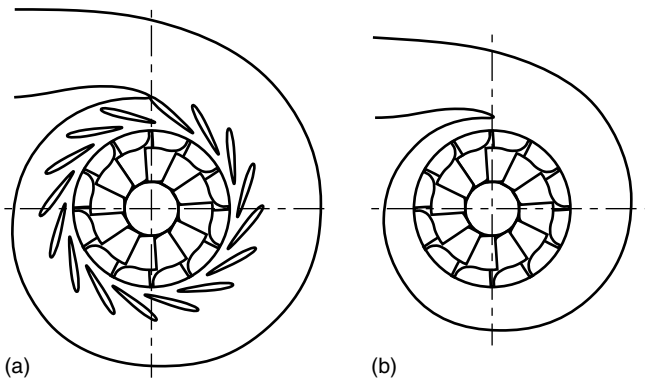

Figure 7. Radial turbines (a) with nozzle (b) nozzleless.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

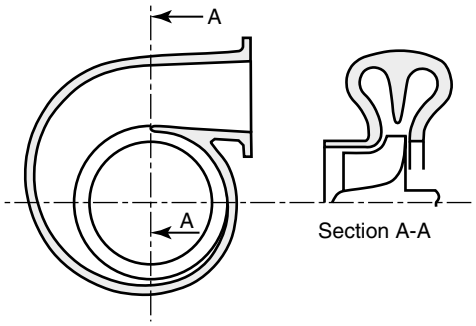

Figure 8. Twin-entry volute for a nozzleless turbine.

Volutes with multiple entries may be required for exhaust pulse energy utilization in multicylinder engines (Baines, 2005; Watson and Janota, 1982). Figure 8 is a section of such a turbine. The two entries are separated by a dividing wall that extends close to the inlet of the rotor. This helps to ensure that the exhaust pulse energy is transferred directly to the turbine rotor while avoiding exhaust interactions between cylinders that can inhibit scavenging.

2.2.2 *Turbine performance map*

The flow capacity of a turbine shows a rising characteristic with pressure ratio that flattens off and becomes constant as the turbine chokes (Figure 9). The flow rate is fairly insensitive to speed of rotation. These characteristics are very important for the matching of the compressor and turbine and the performance of a turbocharged engine. The turbine efficiency is also plotted in Figure 9 against pressure ratio. The efficiency plotted here is often described as the turbine mechanical efficiency and includes the loss of power

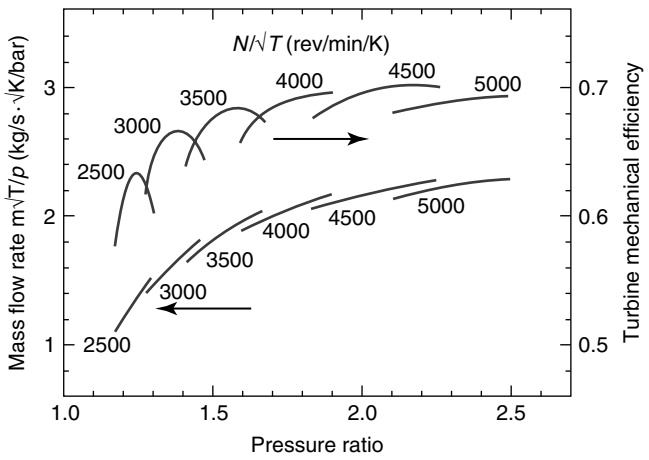

Figure 9. Radial turbine performance maps.

in the turbocharger bearings (as opposed to the aerodynamic efficiency, which excludes bearing loss). When testing a turbocharger, for practical reasons, the shaft power is not measured directly but by means of the temperature increase in the air passing through the compressor. Thus, the turbine mechanical efficiency is based on the power delivered to the compressor rather than the power developed by the turbine. An accurate measurement of the turbine gas temperature change is more difficult to make and is usually avoided. The range of operating conditions covered in testing is much smaller than the potential operating range of a turbine, but is limited by the need to match the compressor and the limits of stable compressor operation. When using the turbine maps in engine simulations, it is usually necessary to extrapolate the map characteristics considerably, and this is a source of possible uncertainty.

2.2.3 *Turbine design*

As with the compressor, the rotor blade speed has an important influence on the power developed by the turbine. However, the polar inertia of the rotating system is also important because it limits the rate of change of turbocharger speed during engine transients, and this has a major effect on "drivability" in automotive applications. Most of the rotating inertia resides in the turbine rotor, which must be made of a temperature-resistant nickel alloy that has a specific gravity approximately three times that of aluminum. The design of a turbine rotor, therefore, is a compromise between performance and inertia, with life and durability also having important roles. See Moustapha *et al*. (2003) for a full discussion of turbine design.

The trade-off between efficiency and inertia is illustrated in Figure 10. Here, the stage loading and flow coefficients are nondimensional expressions of power output and flow capacity, and the contours of efficiency are empirical observations based on a wide range of radial turbines tested. On the basis of this information, radial turbines designed for a flow coefficient of about 0.25 provide the best efficiency, but turbines for small turbochargers are typically designed for much higher values of flow coefficient, as represented by the gray area on the right enclosed in a dashed contour. As flow coefficient is proportional to mass flow rate per unit flow area, this implies smaller turbines for the same engine size. To emphasize this point, superimposed on the figure at the bottom are the approximate scales of turbine rotor size and inertia. Here, the datum case is a turbine designed for a flow coefficient of 0.25 where the achievable efficiency is a maximum. Alternatively, if a larger value of flow coefficient is chosen for the turbine (but still with the same flow rate, and therefore, the same engine application), these scales show approximately how the rotor

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

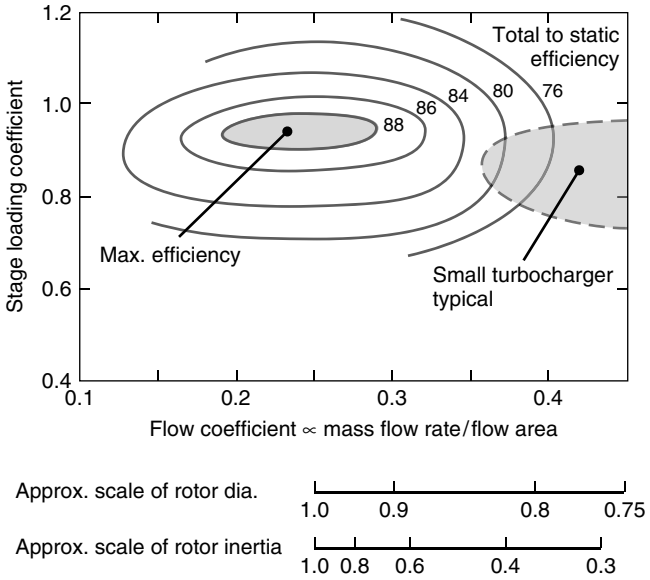

Figure 10. Correlation of stage loading and flow coefficients for conventional radial-inflow turbines, showing estimated scales of turbine size and inertia and the typical range of design for automotive turbocharger turbines. (Adapted from Chen and Baines (1994). © Elsevier.)

diameter and rotating inertia will change. For example, a choice of flow coefficient of 0.4 leads to a diameter that is approximately 80% and an inertia less than 40% of the datum turbine. These would normally be considered important attributes of an automotive turbocharger, but the graph shows that they come with a loss of more than 10 points of attainable efficiency. Large sacrifices in efficiency are often made in order to achieve low inertia. The demands of life and durability in the hot gas environment also impose limitations on the rotor blade design that limits the aerodynamic efficiency.

3 TURBOCHARGER MATCHING

The proper selection of turbocharger components to make up a complete engine–turbocharger system is a complicated balance of many design considerations. For many automotive applications, a single design point cannot be defined because operation is required for a wide range of different operating points. In a competitive market, high system performance will be required and good fuel economy will be necessary. Such criteria must be met with a turbocharger requiring as little space and adding as little weight as possible. To carry out an effective turbocharger matching calculation, it is necessary to have an accurate representation of each component of the turbocharger and the ability to determine how the entire system performs with all components operating together.

In fact, two separate tasks can be identified for the turbocharger engineer. The first of these is to determine the appropriate compressor and turbine that will match a given engine size and operating condition. This task is required whenever a new turbocharged engine project is considered, an existing engine is being rerated, or a change of turbocharger (perhaps for commercial, economic, or supply reasons) is being contemplated. The second task follows the first and is to analyze the performance of a defined engine–turbocharger system. Such analysis enables the engineer to predict the system performance at all of the various operating conditions required. The effect of changes to the system, such as different compressors and turbines, changes to the valve timing, and changes in manifold volume, can also be predicted. With the appropriate analysis tools, it is also possible to predict the transient response of the system.

3.1 Principles of matching

The engine, compressor, and turbine are linked by air and exhaust gas flow, transfers of energy, and a requirement that the air inlet pressure to the system and the exhaust gas exit pressure from the system are both ambient (Watson and Janota, 1982). The purpose of matching is to ensure that these compatibility conditions are satisfied. Mass flow matching can be simply stated as

$$m_e = m_a + m_f \tag{8}$$

or

$$m_e = m_a \left(1 + \frac{1}{\mathrm{AFR}}\right) \tag{9}$$

where m_e, m_a, and m_f are the exhaust gas, intake air, and fuel mass flow rates, respectively, in the engine and AFR is the air/fuel ratio (m_a/m_f). However, the operation of a turbocharged engine is complicated by the different flow characteristics of the various components. A piston engine operates like a positive displacement pump, delivering a certain amount of fluid per cycle, and its volume flow rate increases very nearly linearly with engine speed. For a naturally aspirated engine, the mass flow rate is identically affected. For a turbocharged engine, the mass flow rate increases with engine speed and also with the boost pressure. For the compressor, the mass flow rate of air is controlled by the inlet area and the axial air velocity into the impeller. The rotational speed of the compressor does not directly influence the mass flow rate. However, at high flow rates, the relative velocity within the impeller may

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

become sonic and choke the compressor. The turbocharger speed does have an influence on the maximum flow rate that the compressor can pass. At any compressor speed, there is also a minimum flow rate for stable operation.

The turbine acts like a simple throttle and is nearly independent of rotational speed. The curve of mass flow parameter $m\sqrt{T_0}/p_0$, where T_0 and p_0 are the turbine inlet temperature and pressure, respectively, against expansion ratio increases rapidly at low expansion ratios. Starting from a low engine speed (and low flow rate) condition and accelerating the engine, the turbine expansion ratio initially remains small, so that the exhaust manifold pressure and the energy available to the turbine are limited. At high engine speeds and flow rates, the turbine mass flow parameter reaches a limiting value as the turbine chokes. In this region, because $m\sqrt{T_0}/p_0$ is constant for the turbine, increases in mass flow rate require equivalent increases in the turbine inlet pressure and so the expansion ratio and the power developed by the turbine both increase rapidly.

The energy balance of the turbocharger demands that the power delivered to the compressor is equal to that developed by the turbine, minus power lost in bearing friction and windage. This can be written as

$$\left[\left(\frac{p_2}{p_{01}}\right)^{(k_a-1)/k_a} - 1\right] C_{pa} T_{01} = \left[1 - \left(\frac{p_4}{p_{03}}\right)^{(k_e-1)/k_e}\right] C_{pe} T_{03} \left(1 + \frac{m_f}{m_a}\right) \eta_{tc} \qquad (10)$$

where $\eta_{tc} = \eta_C \eta_T \eta_{mech}$ is the overall turbocharger efficiency, η_C is the compressor efficiency, η_T is the turbine efficiency, and η_{mech} is the mechanical efficiency (allowing for bearing friction, windage, etc.). In this equation, p_2/p_{01} is the compressor pressure ratio, p_4 is the turbine exit pressure, which is equal to ambient pressure plus the pressure loss in the exhaust system downstream of the turbocharger, and T_{01} and T_{03} are the compressor and turbine inlet temperatures, respectively. C_{pa} and C_{pe} are the specific heats at constant pressure, and k_a and k_e are the ratios of specific heat, for the air and exhaust gas, respectively. The turbine inlet pressure p_{03}, which is also the exhaust manifold pressure, is therefore determined by the turbocharger match and cannot be specified independently. This parameter is important because it determines the gas exchange pressure or the pressure difference across the engine, which in turn influences the engine pumping work and the ability to scavenge the engine.

3.2 Matching automotive diesel engines

In a road vehicle, there is normally a direct mechanical connection between the engine shaft and the road wheels, and this imposes considerable constraints on the power–speed characteristics that the engine can follow. For a naturally aspirated engine running at constant air–fuel ratio, the power is almost a linear function of speed and so the torque is nearly constant with speed (curve 1 in Figure 11a). This is maintained from maximum engine speed to some speed near idle. Because the range of road

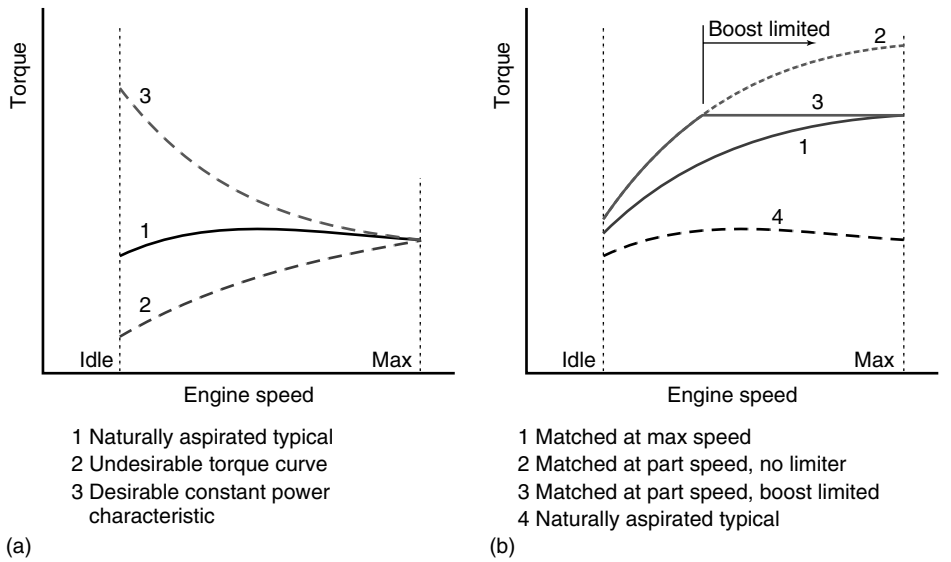

Figure 11. Torque-speed characteristics for (a) naturally aspirated engine (b) turbocharged engine for automotive application.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

speeds required is invariably much greater than the speed range of the engine, a gearbox in the transmission is necessary. A wide torque band is desirable to reduce the amount of gear shifting that is required. This flat torque characteristic is acceptable for normal driving purposes. A falling characteristic of torque with decreasing engine speed (curve 2) is very undesirable because at every grade that the vehicle encounters, the road speed decreases, and the engine speed with it. This would cause the torque to decrease, further reducing the vehicle speed. In every case, a down shift is necessary, and this torque characteristic gives rise to excessive gear shifting. A rising torque characteristic with reducing engine speed (curve 3) would be ideal, providing adequate power at low speeds for acceleration without changing gear, but in a conventional piston engine, this increase in power at low engine speed can only be achieved by a large increase in the fueling rate, leading to poor fuel economy and increased smoke.

For a turbocharged engine, a torque curve that is similar in shape to that of a naturally aspirated engine is desirable, but this requires that the boost pressure at full load is almost constant with speed. This cannot be achieved with a simple turbocharger because of the nonlinear flow characteristic of the turbine. If the turbocharger is matched at the full load, maximum speed condition, then as the engine speed is reduced, the volume flow of the engine decreases approximately in proportion, and the mass flow through the turbine and hence the turbine expansion ratio and the turbine power decrease. This leads to a reduced boost pressure developed by the compressor. At a constant fueling rate, this implies decreasing engine power and torque with speed, which is the undesirable characteristic (curve 1 in Figure 11b). If, alternatively, the turbocharger is matched at a lower engine speed, the turbine flow area is smaller, which means that the pressure ratio across the turbine is higher than it otherwise would be, more turbine power is developed, and the compressor boost pressure is higher at lower engine speed (curve 2). At engine speeds above the matching speed, however, the turbine power output must be limited (curve 3), or the compressor boost pressure will continue to rise. The engine must operate within limits on cylinder pressure, exhaust gas temperature, and turbocharger speed. Any one of these can impose a limit on the boost pressure of the compressor.

Physically, the boost pressure is determined by the power delivered by the turbine. The simplest way to control the turbine power output is by means of a wastegate, which allows some of the exhaust gas to bypass the turbine (Figure 12). By controlling the wastegate opening, it is possible to limit the compressor boost to give a roughly constant engine torque characteristic as shown in curve 3 of Figure 11b. At low engine speed, the wastegate is closed.

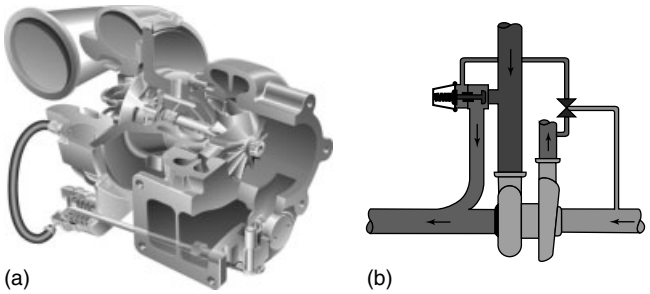

Figure 12. (a) Turbine with wastegate (b) wastegate operation. (Reproduced by permission of BorgWarner Turbo Systems.)

As the engine speed increases from idle, the compressor delivery pressure rises until the boost limit is reached. At this point, the wastegate starts to open and progressively diverts more exhaust from the turbine as the engine speed is increased to its maximum value, holding the boost pressure constant as it does so.

A more sophisticated approach is to use a variable geometry turbine. Variable geometry is a means to control the effective flow area of the turbine, which modifies the turbine mass flow–pressure ratio characteristic as shown schematically in Figure 13. Reducing the effective flow area of the turbine means that the pressure ratio must increase in order to maintain a constant mass flow rate. This increases the engine exhaust manifold pressure, the exhaust energy available, and the power produced by the

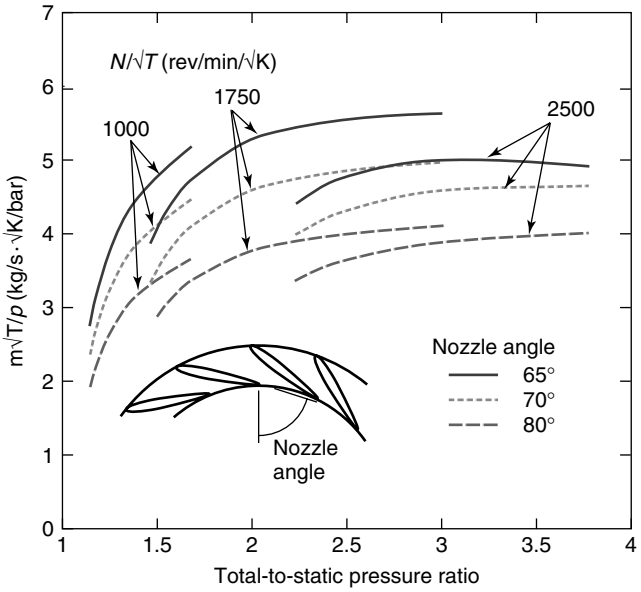

Figure 13. Mass flow–pressure ratio characteristics for a variable geometry turbine.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

turbine. The turbine should be sized to pass the full flow of the engine at the engine maximum speed while the compressor provides the limiting boost pressure. At this point, the variable element of the turbine must be set to give maximum area (a small nozzle angle in Figure 13). At engine idle, the variable element is set to give the minimum area configuration (a large nozzle angle in Figure 13). Thus, as the engine speed is increased, so the turbine area is increased to maintain optimum performance.

The problem of turbine matching can also be addressed by more complex turbocharging systems, including turbocompounding and multiple, switched, turbochargers described in Section 4. All of these are fundamentally methods to modify the basic turbine flow characteristic shown in Figure 9 to make it better matched over a range of engine conditions.

Even if the engine is well matched over most of its range, there is still likely to be an undesirable loss of torque at very low speeds, which can only be mitigated by increasing the fueling rate. This can be done but only within the limits imposed by the need for fuel economy and smoke formation at increasingly rich mixtures. The turbocharger is usually sized to match the engine with the wastegate closed or the variable geometry in the "design" position at about the peak of the engine load versus speed curve, and therefore high boost pressures can be achieved, and the limiting factor here tends to be the cylinder pressure. At higher engine speeds, the exhaust gas temperature and eventually the turbocharger speed (both of which affect the turbine operating life) limit the power developed by the engine.

The implications of this for compressor operation are shown in Figure 14 (Figure 6 shows the complete compressor map, from which details have been omitted here for clarity). For an engine with a fixed geometry turbocharger matched at maximum speed (Figure 14a), the compressor pressure ratio falls with decreasing speed, and the fueling rate is increased as far as possible to limit the decrease. Providing the match point is chosen to give an adequate surge margin, surge at low speeds is unlikely to occur. On the other hand, the match point must not be selected to be so far to the right of the compressor map that the compressor efficiency is poor at full load and full speed. For an engine matched at part speed and boost limited by a wastegate, variable geometry turbine, or some other means (Figure 14b), the match point is much closer to the surge line and the boost pressure at full load and low speed is considerably greater, giving a much better torque characteristic. The fueling rate below the match point speed must not be increased so much as to cause the compressor to surge, even if such an increase lies within the smoke limit. In a turbocharged engine, the available torque band is a function not only of the engine but also of the width of the compressor map. In automotive applications, a wide range of stable operation of the compressor is very important.

At high altitude, the inlet air density is lower and the air mass flow rate falls. As the diesel fuel pump still supplies the same quantity of fuel, the air–fuel ratio falls, the exhaust temperature rises, and the specific available energy of the exhaust gases entering the turbine increases. The turbine exit pressure falls because of the lower ambient

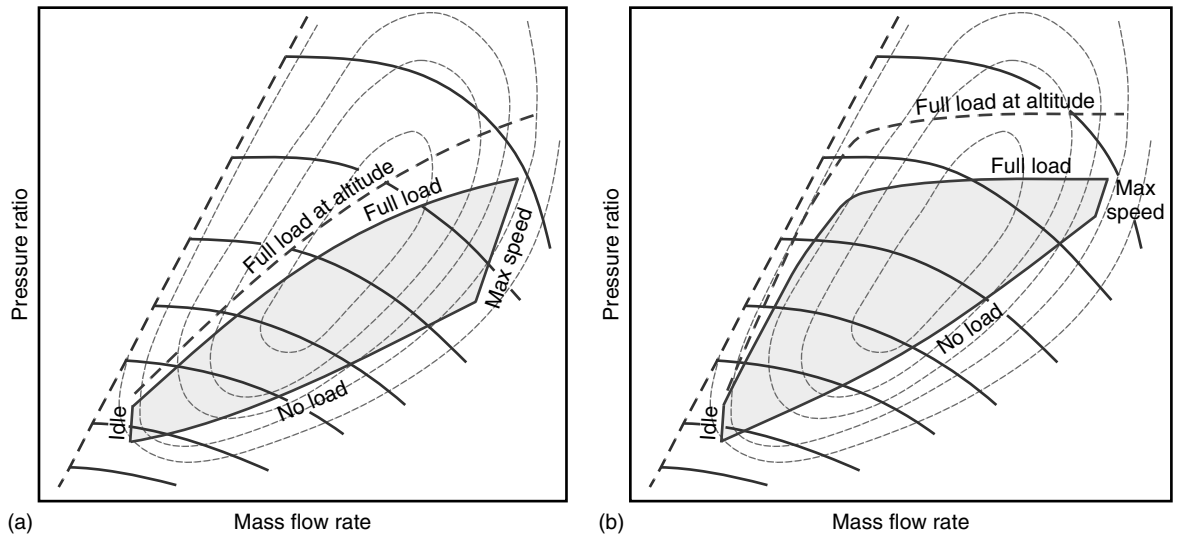

Figure 14. Compressor operation for an automotive diesel engine (a) matched at maximum speed and (b) matched at part speed and boost limited.

DOI: 10.1002/9781118354179.auto126
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

pressure. The combined result is to increase the specific power output of the turbine, and hence, the turbocharger speed and pressure ratio increase. On the compressor maps in Figure 14, the changes in the curves of maximum load with altitude are shown, and the limiting conditions are the turbocharger speed at full load, and in the case of a boost-limited engine, the surge margin near the matching point. If operation at high altitude is envisaged, these limits must be considered when the original turbocharger selection and matching is made.

3.3 Matching automotive gasoline engines

Similar considerations influence the matching of turbochargers to gasoline engines, but this engine has characteristics that give rise to further problems. Gasoline engines generally have a wider speed range than diesel engines and consequently a wider range of airflow rates. The mixture ratio must be carefully controlled within limits to ensure satisfactory combustion.

Because there is less control over the air/fuel ratio, the engine torque is more directly related to the mass of air and hence to the boost pressure. The continued rise of boost with engine speed presents major problems of drivability, and an increase in torque at low engine speed cannot be achieved by substantial increase in the fueling rate as it can in a diesel engine. The solution usually adopted is to use a low pressure compressor design to limit the available boost and to apply some form of boost limiter at high engine speed. A low pressure ratio compressor alone is not sufficient, for if the turbine is matched at the maximum speed and load, at low speed and part load conditions it will be too large, the expansion ratio will be very low and very little boost will be achieved. The use of such a turbocharger will not improve the low speed torque but it will increase the high speed torque, thus making the torque characteristic even more unfavorable.

The solution, therefore, is to match the turbocharger at a relatively low engine speed. This implies a small effective flow area of the turbine. At high engine speed, such a turbine would impose a very high exhaust gas pressure on the engine. To avoid this, a wastegate is used to bypass a fraction of exhaust gas around the turbine, thus limiting the expansion ratio and the power developed by the turbine. In turn, this keeps the exhaust manifold pressure at an acceptable level and prevents the compressor overboosting the engine. Variable geometry turbines would in principle give better control, and while they are widely used in automotive diesel engines, gasoline engines normally run at higher exhaust gas temperature, and the problems of thermal expansion and durability that this gives rise to have limited the application to these engines.

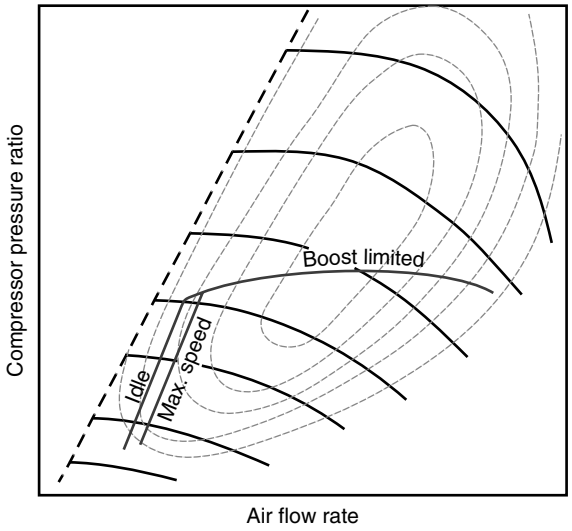

Figure 15. Compressor operation for a turbocharged gasoline engine.

The compressor characteristic for a gasoline engine takes the form shown schematically in Figure 15 (Figure 6 shows the complete compressor map, from which details have been omitted in Figure 15 for clarity). As the engine speed increases from idle, the boost pressure rises to its maximum value when the boost limiter is applied. Thereafter, the boost pressure remains nearly constant. Because of the large speed range of the engine, a wide compressor map width is important. At part speed, the engine is throttled, unlike a diesel engine, and the throttle largely overrides the influence of speed on mass flow rate and so the speed lines collapse into a narrow band.

4 OTHER BOOSTING SYSTEMS

4.1 Series turbocharging

Series or two-stage turbocharging is routinely used in heavy diesel engines for large trucks and off-highway vehicles as a means to achieve boost pressure ratios as high as 5–6 without unacceptable impact on efficiency or range. Such systems are constructed by selecting large and small commercial turbochargers to form the low and high pressure parts of the system. Wastegates or variable geometry may be incorporated in one or both turbines. The relative size of the turbochargers determines how the pressure ratios are split between them, and in general for steady-state operation, there is no advantage in biasing this split strongly in one way or the other.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

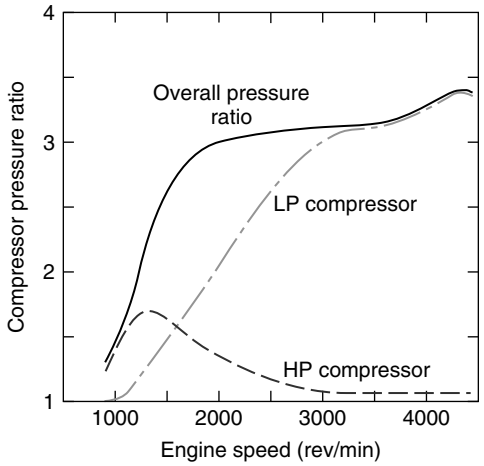

Figure 16. Divisions of pressure ratio in a controlled series turbocharger. (Reproduced by permission of BorgWarner Turbo Systems.)

For smaller diesel engines, the application of series turbocharging is more for low speed torque than for absolute boost level. In such cases, the high pressure (HP) turbocharger is selected to be considerably smaller than the low pressure (LP) turbocharger, so that at low engine speed, most of the exhaust pressure drop occurs across the HP turbine (Pflüger, 1998). The HP compressor can develop the necessary boost pressure and can also respond quickly to engine transients. At high engine speeds, the HP turbocharger must be bypassed completely to avoid overboosting, and the LP turbocharger is entirely responsible for boosting in this region (Figure 16).

4.2 Turbocompound

A turbocompound engine is one in which there is power transfer between the exhaust-driven turbine and the engine. A direct gear drive between the turbocharger shaft and the engine is unsatisfactory for automotive engines, because the limitations that this imposes on the turbocharger speed makes worse the already difficult matching problem. A more feasible solution is a separate power turbine downstream of the turbocharger turbine (Figure 17). At low engine speed, most of the exhaust pressure drop occurs across the turbocharger turbine because it has a smaller flow area than the power turbine, and the power turbine contributes little or no power to the engine. At high engine speed, the power turbine imposes a back pressure on the turbocharger turbine, which limits the turbocharger power and avoids overboosting, while at the same time, the power turbine provides additional power to the engine shaft. This means that the engine fueling can be reduced without a loss of power. Turbocompounding is thus better suited to engines that run for long periods at high load and high speed than for those with a more varied duty cycle (Walsham, 1990).

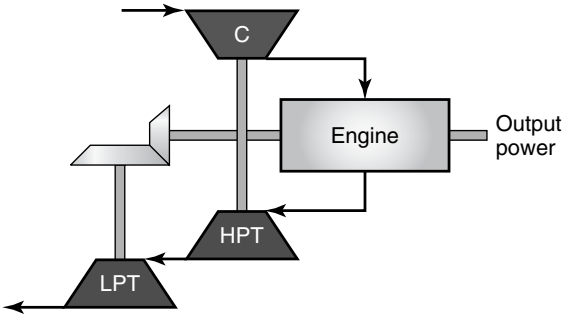

Figure 17. Turbocompound engine.

4.3 Electric assist

Modern developments in electric machines have made feasible small machines with a high power density, which run at shaft speeds comparable to those of turbochargers, and open the way to couple compressors and turbines directly to such machines. With the necessary electric storage capacity and control systems, it is possible to run the electric machine as a motor at low engine speed conditions, giving higher boost pressures and torque, and to run it as a generator at high engine speeds, recharging the batteries and preventing overboosting (Figure 18). The feasibility of such systems is crucially dependent on the

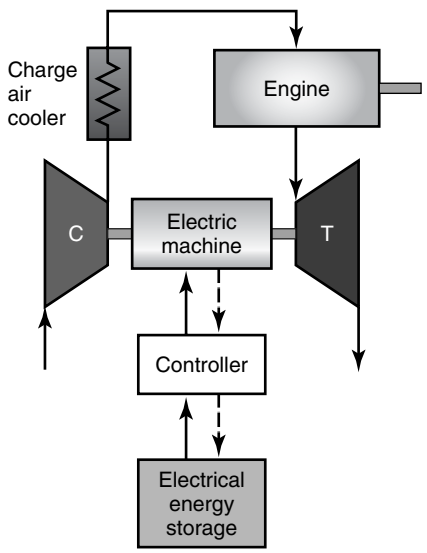

Figure 18. Schematic of an electric assist turbocharger.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

battery capacity, and for this reason may be better suited to hybrid diesel–electric or gasoline–electric powertrains than conventional engines.

Electric machines are also very sensitive to temperature, and cooling the machine in the high temperature environment of the turbocharger is still a considerable challenge. Locating the electric machine between the compressor and turbine gives good packaging but is difficult to manage thermally. Cooling is much easier if the machine is on the compressor end of the shaft, but this makes for a very long shaft with multiple bearings and the potential for rotordynamic instability, and also tends to block the air path to the compressor intake.

The addition of an electric machine also increases the inertia to the rotating system, to the extent that the transient response of the turbocharger following an engine load step may be slower, even though electrical power can be used to assist in accelerating it.

4.4 Hybrid super/turbocharger

A combination of supercharger and turbocharger may be used to boost the engine (Figure 19). The supercharger is required at low engine speed to give adequate boost pressure, but at high engine speed it is declutched and bypassed, and the intake charge is boosted by the turbocharger alone. A bypass or "blow-off" valve is required for the turbocharger compressor to prevent it surging when the supercharger is operating.

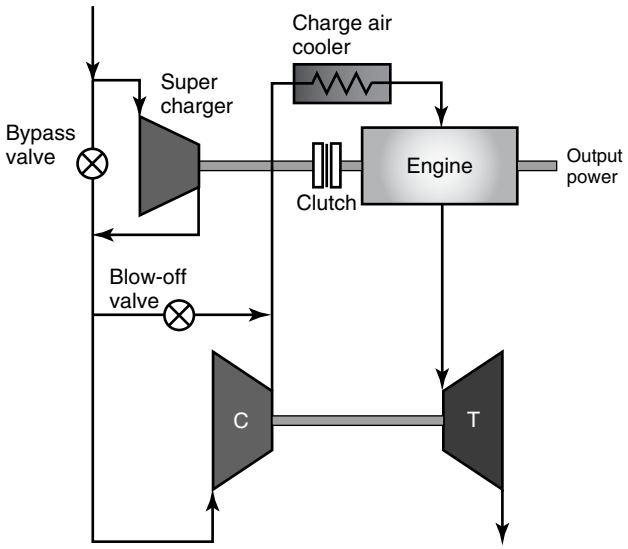

Figure 19. Schematic of a hybrid super/turbocharger.

4.5 Pressure wave supercharger

The pressure wave supercharger uses the pressure waves created by the engine exhaust pulsations to pressurize the intake air. The original and most widely used form of this technology is the Comprex developed by Brown Boveri (now ABB) and shown schematically in Figure 20 (Jenny, Moser, and Hansel, 1986; Jenny *et al.* 1987). A drum containing a set of axially disposed gas passages is rotated by the engine crankshaft. As each passage rotates, it is exposed for a fraction of time to the exhaust, creating a pressure wave that moves along the passage, pressurizing the intake air. Subsequently, the air is released to the intake manifold through a port on the air side of the drum, and the exhaust gas is released through a port on the exhaust side. As it does so, it depressurizes the passage, allowing fresh charge to be drawn in for the next cycle of the drum.

As with other types of supercharger, the device is directly connected to the engine shaft and gives very good transient response, but in this case, only a very small amount of power is required to drive the charger, as the energy to pressurize the intake charge comes from the exhaust. Problems in service include thermomechanical fatigue failures because the drum elements are repeatedly exposed to hot exhaust and cold air, poor off-design performance, and noise created by the pressure waves.

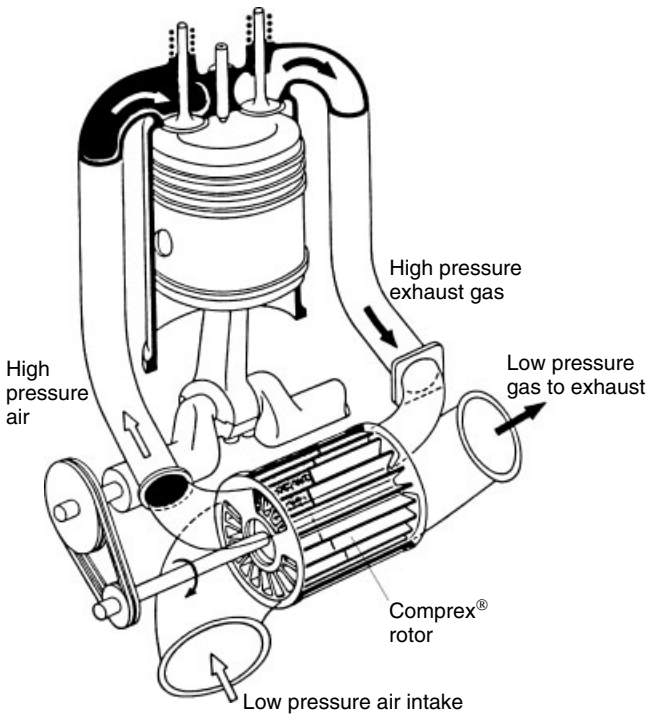

Figure 20. The Comprex pressure wave supercharger.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Cost and installation size have also limited the take-up of superchargers of this type.

1 INTRODUCTION

Engine waste heat recovery (WHR) systems have the potential to significantly improve vehicle fuel economy for conventional and hybrid electric power trains spanning passenger to heavy truck applications. The challenge will be to properly match the WHR system to the duty cycle of the power train and constraints of the vehicle. Depending on the circumstances, a WHR system may be relatively small and used only to supplement the alternator for vehicle electrical loads, or it may be a complicated multiloop system that is integrated into a hybrid electric drivetrain or mechanically coupled to the vehicle engine system. The fundamental thermodynamics of the WHR system will be the same regardless of the application or implementation.

Automotive WHR systems are not a new concept. A great deal of work on the design and development of these systems was performed in response to the fuel crises of the 1970s and 1980s in the United States (Patel and Doyle, 1976; Leising *et al*., 1978). Some of this work was performed in conjunction with the adiabatic engine research that was also under way at this time. Ultimately, the sharp decline in fuel prices through the 1980s eliminated the economic incentive for further development or deployment of these systems, and work was largely halted for two decades.

Toward the middle of the first decade of the twenty-first century, interest in WHR systems was rekindled in response to the increasing volatility in petroleum prices, the heavy dependence of national economies on imported oil, and increasingly aggressive fuel economy standards. These factors are providing the necessary economic conditions for a viable WHR business case. In recent years, systems have been developed and demonstrated for both light-duty and heavy-duty engines, including component development for integration of the systems in vehicle infrastructures. These systems are expected to become commercially viable and more available over the next decade.

2 THERMODYNAMICS

The feasibility of implementing an engine WHR system is dictated by the availability of recoverable heat. Figure 1, which shows the distribution of fuel energy usage on a first law basis for a diesel passenger vehicle engine [adapted from Edwards and Wagner (2010)], is an example of potential sources of recoverable heat. In general, about 25–30% of the fuel energy provides useful work through the crankshaft under road load conditions, and the balance is divided between heat losses and thermal energy discarded through the exhaust. These waste heat streams are often very different in terms of temperature and mass flow. Depending on the thermal quality of the waste heat

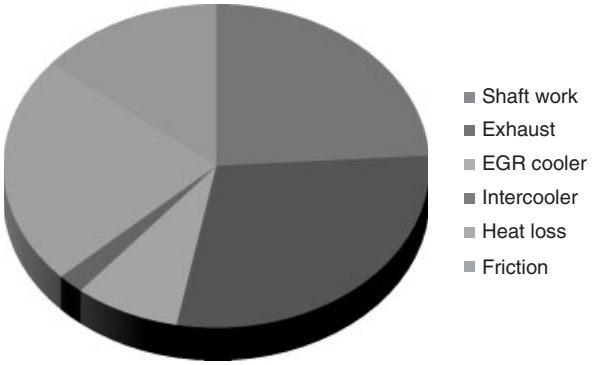

Figure 1. Example energy distribution from a light-duty diesel engine under road load conditions. (Reproduced by permission of ASME.)

streams, the potential for extracting additional work can vary widely.

The necessary approach to characterizing available energy for recovery is through a second-law analysis that focuses on exergy. Exergy is a measure of a system's potential to do useful work because of physical and chemical differences between the system and the ambient environment. An example of a second-law exergy balance for the same engine and operating conditions of Figure 1 is shown in Figure 2. A comparison of the energy and exergy distributions provides a better understanding of the recovery potential of different waste energy streams. For example, Figure 1 [adapted from Edwards and Wagner (2010)] shows a distribution of the fuel energy in a light-duty diesel engine. The energy lost through heating the coolant is the primary component of the "heat loss" segment. Comparing the size of the heat loss segment in Figure 1 with that of Figure 2, which represents the distribution of the fuel exergy, shows that the relatively low temperature of the coolant reduces the potential for extracting work from that heat flow. The exergy portion of the distribution is smaller because of the low temperature of the coolant, which is a much less valuable source of energy for the WHR system compared to the very warm exhaust gas (higher temperature delta with environment). The higher exergy of exhaust gases has made them the primary source of interest for most WHR systems.

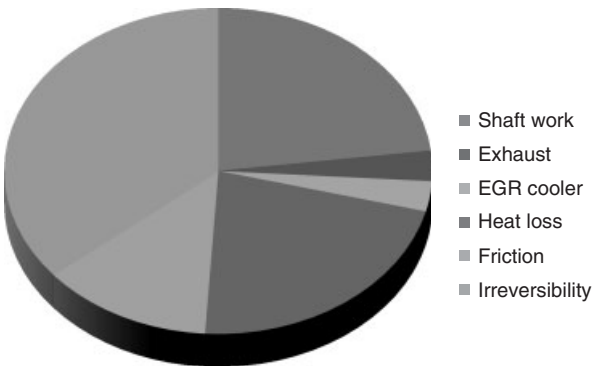

Figure 2. Second-law exergy distribution from a light-duty diesel engine under road load conditions. (Reproduced by permission of ASME.)

3 ENERGY RECOVERY TECHNOLOGIES

There are a variety of viable options for recovering waste heat from an engine system and converting it into usable energy. The three major classifications of energy recovery systems are thermomechanical cycles, thermoelectric (TE) devices, and turbocompounders. A thermomechanical cycle uses waste heat as an input source to a power cycle. These cycles are familiar to most engineers and include Rankine and Brayton cycles. TE devices make use of the Seebeck effect for direct electrical power generation from solid-state devices driven by a thermal gradient. Exhaust turbocompounders make use of the pressure and thermal energy of the exhaust to produce shaft work. These various approaches are discussed here.

3.1 Thermomechanical power cycles

3.1.1 Rankine power cycle

The Rankine vapor power cycle, which typically uses water as the working fluid, provides the basis for many stationary power plants. A diagram of a standard Rankine cycle is shown in Figure 3. The four components of the

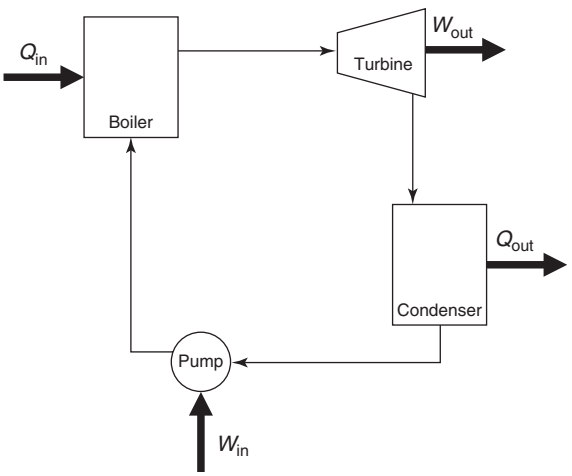

Figure 3. Standard Rankine vapor power cycle configuration.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto127
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

standard cycle are a boiler to vaporize the working fluid; an expander to extract work from the hot, pressurized working fluid; a condenser to cool the fluid back to a liquid state; and a pump to bring the fluid back to the boiler pressure. While a more complicated cycle design is used in stationary power generation to obtain the highest practical energy conversion efficiency, a simple cycle is preferable in automotive applications to minimize the weight and volume of the system.

The first critical design choice for a Rankine cycle system is that of the working fluid. Water is the most commonly used fluid in stationary systems because of its combination of thermodynamic properties and low cost. However, it has multiple disadvantages for an automotive WHR system. Most obviously, it freezes at a relatively high temperature, making it unsuited for year-round use in most markets. It also requires relatively large heat exchangers, compromising component packaging. Finally, as the steam expands in a turbine, it can easily expand to the point at which water condenses. This is unacceptable from a performance standpoint as the water droplets can be damaging to turbine blades spinning at high velocity. This two-phase state is readily achieved because of the slope of the vapor dome on the right side of a T-s diagram for water, as seen in Figure 4. A typical expansion process is shown; unless there is a significant degree of superheat, a large expansion ratio will easily cause the water to begin condensing during the expansion rather than remaining a vapor until entering the condenser.

Given the challenges of implementing a water-based Rankine system, many other working fluids have been evaluated. Ethanol is a compound that has received some attention and has been proposed as the working fluid for a heavy-duty vehicle project (Sisken, 2011). Ethanol has a more suitable freezing point than water; however, the thermal properties of ethanol limit the potential efficiency of a WHR system using it as a working fluid. The vapor pressure of ethanol at typical ambient conditions is subatmospheric, which limits the lower temperature limit for the power cycle, thus limiting cycle efficiency. If the system is permitted to operate subatmospherically, there is a significant chance for air to be drawn into the system past the pressure seals. At this point, the flammability of ethanol in air becomes a concern, particularly given the temperature of the exhaust gases and hot surfaces present in a WHR system.

Most experimental WHR system studies have used a refrigerant as the working fluid to obtain a reasonable compromise between thermal performance, working temperature range, vapor pressure, and safety. Early work tended to use R-12, as in a study by Patel and Doyle (1976). More recent studies by Nelson (2009) and Briggs *et al.* (2010) have used R-245fa because of its improved environmental characteristics, including a lower global warming potential (GWP) compared to other fluorinated refrigerants. These studies have noted the restricted operating temperature range of the fluid, but overall system performance within the available range has been acceptable. Newer refrigerants under development promise at least equal performance to R-245fa with even better environmental characteristics, which should permit them to be used into the future without concern for restrictions on their

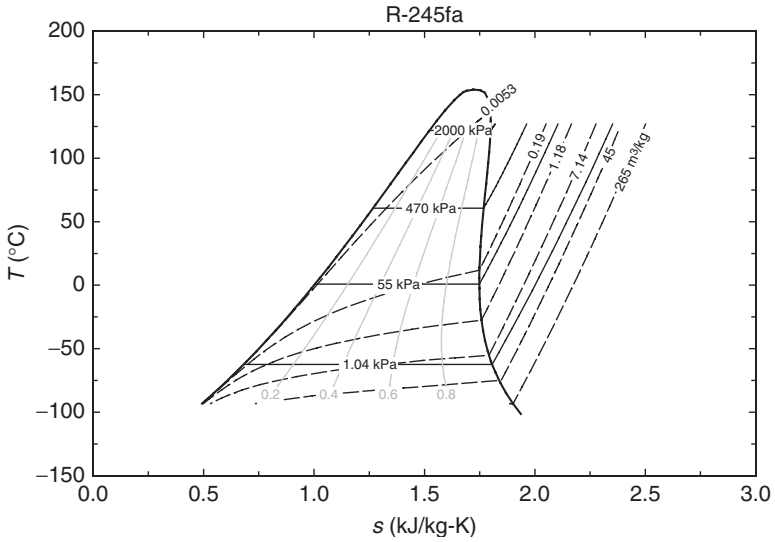

Figure 5. Temperature–entropy diagram for R-245fa.

use. Another advantage is that many refrigerants are "dry" fluids, which means that the slope of the right side of the vapor dome is negative, as seen in Figure 5. For the same type of expansion as described earlier for water, there is no possibility of condensing the fluid during expansion.

The choice of working fluid will impact the choice of expander technology. A wide variety of machinery has been used, including turbines (Nelson, 2009; Briggs *et al*., 2010), pistons (Endo *et al*., 2007), and scroll expanders (Sisken, 2011). Other expander designs will likely continue to be developed. It is well understood from power generation experience that turbines are not compatible with condensing fluids as the droplets lead to pitting and erosion of the blades as a result of the high relative momentum between the drops and the metal blades. Pistons and scroll expanders are more forgiving of liquid drops, making them compatible with condensing fluids. Considering the already-discussed working fluids, water has been shown to be prone to drop formation in an expander, making it more suitable for nonturbine systems. As a dry fluid, R-245fa will be more suitable for use with a turbine, as well as working with other designs.

Expander sizing is a complicated topic and is beyond the scope of this chapter. The approach is analogous to that used for matching a turbocharger to an engine or a pump to an application. The same tools that are used for these common design problems are suitable for the design of a WHR system.

Depending on the working fluid chosen, two or three heat exchangers will be required for a Rankine cycle WHR system. For a system using water or ethanol, the temperature–pressure relationship of the fluid will permit a two-exchanger system as the temperature of the working fluid drops significantly in the expander, leaving little remaining exergy to recuperate within the cycle. For many organic fluids such as R-245fa, the temperature does not drop significantly across the expander, and maximum cycle efficiency demands a recuperator to recycle the remaining thermal energy back to the cold working fluid. The recuperator transfers heat from the fluid leaving the expander to the fluid entering the boiler. This reduces the amount of heat rejected in the condenser and can significantly raise the efficiency of the Rankine cycle at the cost of an additional component.

The performance of the WHR system is highly dependent on the performance of the individual components. Assuming a fixed choice of working fluid, the overall flow rate of the fluid must be matched to the operating condition of the engine and the corresponding available thermal energy sources. An example of this design issue is shown in Figure 6, taken from Edwards, Wagner, and Briggs (2010). The figure shows that there is a significant difference in the optimum working fluid flow rate as the engine conditions are varied. Through the use of a variable rate pump, the working fluid flow can be controlled to better match the engine operation over transient cycles where both the exhaust temperature and the mass flow may vary significantly. The extent of matching engine operation is limited by other design considerations such as the thermal capacity of the system.

The expander efficiency will be the limiting factor for the transient capability of the WHR system. For many

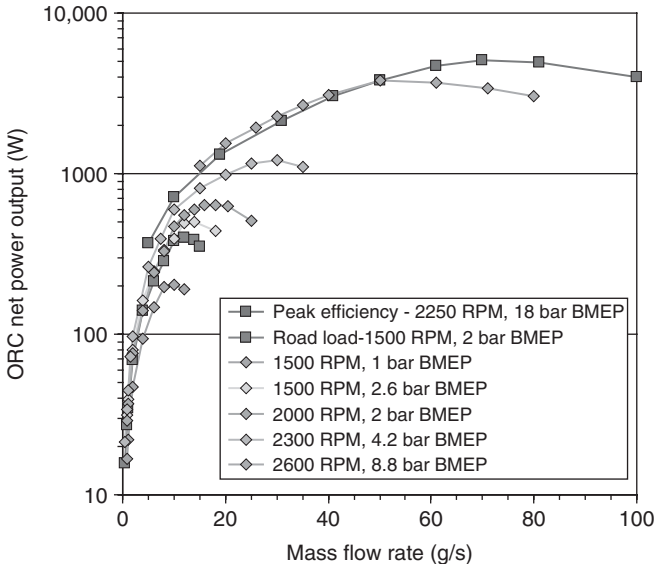

Figure 6. Organic Rankine cycle (ORC) working fluid flow rate for various engine conditions. (Reproduced by permission of ASME.)

expander designs, the efficiency map is quite narrow, with only a small operating range exhibiting high efficiency. The expander must be sized for a maximum efficiency corresponding to the most frequent operating condition of the engine. As the engine operates transiently, the efficiency of the WHR system will vary widely based on the efficiency map of the expander. Depending on the design of the system and operating point, it is even possible that the expander will need to be bypassed at very high engine loads and speeds to flow sufficient working fluid through the system to prevent overheating or over pressurization in the WHR system. Obviously, any bypassed flow produces no power and thus no energy recovery and potentially a parasitic loss.

An example of the performance of a Rankine-based WHR system is found in Briggs *et al*. (2010). In this study, a recuperated Rankine cycle was used to recover thermal energy from the post-turbine exhaust of a GM 1.9-L diesel engine. At the operating point specified in this chapter, the exhaust temperature was 436°C at a flow rate of 317.4 kg/h. The Rankine cycle, using R-245fa working fluid, used a radial inflow turbine expander directly coupled to a high speed electrical generator. The electrical output from the expander was 4.3 kW, and the Rankine pump required 0.3 kW, yielding a net electrical output of 4.0 kW. The authors claimed a Rankine cycle efficiency of 12.7% (thermal to electric) based on heat extraction from the exhaust of 31.4 kW_{th}. This additional output increased the brake thermal efficiency (BTE) of the base engine from 42.4% to 45%. While somewhat low relative to what might be expected in an ideal implementation of a recuperated Rankine cycle, this efficiency is reasonable. An extension of this study was performed by Valentino, Hall, and Briggs (2013) using a model tuned to the experimental data. The system efficiency was found to remain relatively constant over a wide range of operating conditions, with the power output from the WHR system scaling with the enthalpy flow in the exhaust stream.

A study presented by Nelson (2009) on a similar Rankine WHR system installed on a Cummins 15-L on-highway diesel engine indicated an estimated 6–7% increase in the BTE of the engine using waste heat from the exhaust gas recirculation (EGR) and exhaust streams (i.e., from 42% to 48–49%). This study suggested that a shift of 10% in BTE would equate to 1800 gal of fuel savings every year, so the demonstrated increase would yield 1100–1300 gal of fuel savings. The author did not discuss any assumptions about system weight or other details in the calculation of fuel savings.

3.1.2 Brayton power cycle

The Brayton cycle is a gas power cycle version of the Rankine power cycle. The key difference is that the working fluid is a gas and hence does not undergo a phase change in the heating and cooling processes. The standard Brayton cycle is a closed cycle with heat addition and rejection accomplished via heat exchangers. The most common application of the Brayton power cycle is in gas turbine engines such as those in aircraft, large ships, and natural gas fired power plants. These applications use an open cycle with heat addition supplied by combustion. To date, there has not been significant interest in using a Brayton cycle for automotive WHR. Caterpillar conducted a concept study (Kruiswyk, 2008) evaluating the feasibility of using an open Brayton cycle with air as the working fluid, but it was found that the size of the required heat exchangers was unacceptably large for on-truck use. One realization of a closed Brayton cycle is a supercritical CO_2 power cycle, which has been studied for application to nuclear power plants to increase the overall plant efficiency (Wright *et al*., 2010). The high operating pressures present challenges for on-road use as the system would require relatively heavy components to withstand the CO_2 pressure with an acceptable safety margin.

3.2 Thermoelectric devices

TE devices are an attractive option for WHR in vehicles because they are solid-state devices. As a result, their integration into an exhaust system presents fewer additional

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto127
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

moving parts and only enough active management to ensure sufficient cooling. This section focuses on the integration of TE exhaust heat recovery into vehicle systems; it does not provide a comparison or overview of TE materials. TE materials are only discussed to provide an understanding of their functionality in a vehicle system.

3.2.1 Thermoelectric figure of merit

TE materials take advantage of the Seebeck effect so that when a temperature differential is applied a voltage differential and a current flow result. There are a number of different classes of TE materials of interest for automotive WHR, including bismuth telluride, skutterudites, half-Heusler alloys, and nanomaterials. For more information on TE materials for automotive applications, see Nolas, Poon, and Kanatzidis (2006).

TE performance is characterized by a figure of merit, ZT_{AV}, defined by Equation 1, where α is the Seebeck coefficient, ρ is the electrical resistivity, and λ is the thermal conductivity.

$$ZT_{AV} = \frac{\alpha^2}{\rho \times \lambda}\left(\frac{T_{Hot} + T_{Cold}}{2}\right) \quad (1)$$

The TE figure of merit is related to the efficiency of the TE materials by the relationship provided in Equation 2.

$$\eta_{TE} = \frac{(T_{Hot} - T_{Cold})}{T_{Hot}} \frac{[(1 + ZT_{AV})^{1/2} - 1]}{[(1 + ZT_{AV})^{1/2} + T_{Cold}/T_{Hot}]} \quad (2)$$

Thus, TE material efficiency increases as the figure of merit increases and as the temperature gradient between the hot and cold sides of the TE material increase. However, the relationship between TE material efficiency and the efficiency at which a TE system recovers exhaust heat from an engine is complex, and high TE material efficiency does not necessarily mean efficient heat recovery. To illustrate this point, the following section focuses on TE heat recovery systems in vehicles.

3.2.2 Thermoelectric heat recovery systems

A schematic of the heat flow pathways, shown in Figure 7, is helpful in understanding the challenges associated with incorporating TE generators into the automotive exhaust system. First, the exhaust enters a heat exchanger with a thermal energy flux of $Q_{Exhaust}$, a portion of which is transferred to the heat exchanger wall (Q_{HX_wall}). A portion of Q_{HX_wall} is lost to ambient, but the remainder is transferred as heat to the TE devices (Q_{TE_in}). The TE

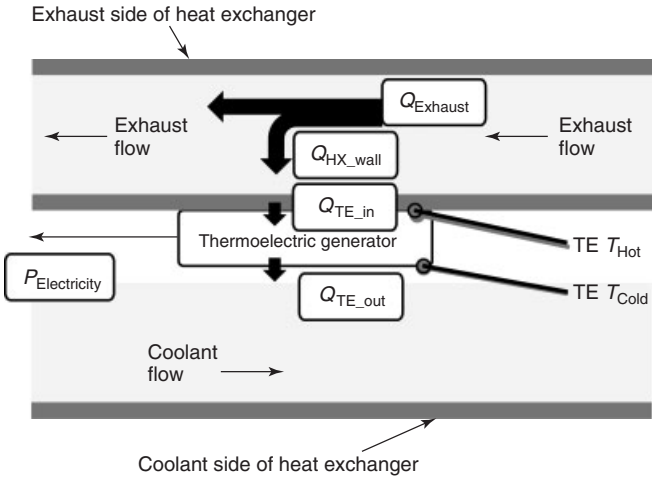

Figure 7. Schematic of heat flows for a thermoelectric heat recovery system in an engine exhaust.

device is capable of converting a portion of the Q_{TE_in} into usable electricity ($P_{Electricity}$), but the remainder exits the device in the form of waste heat (Q_{TE_out}). $P_{Electricity}$ is proportional to the temperature difference across the TE device, from the hot side temperature (TE T_{Hot}) contacting the exhaust duct to the cold side temperature (TE T_{Cold}), which is in contact with an air or liquid heat exchanger for heat rejection. The heat exchanger efficiency (η_{HX}) for this system is $Q_{TE\_in}/Q_{Exhaust}$, the TE efficiency (η_{TE}) is $P_{Electricity}/Q_{TE\_in}$, and the overall system efficiency (η_{System}) is $P_{Electricity}/Q_{Exhaust}$. Thus, it is desirable to have a high η_{TE}, but if this efficiency comes at the expense of η_{HX}, it will not result in an increase in η_{System}, and it may actually be a detriment to overall system efficiency.

As with other exhaust heat recovery systems, the heat exchanger design and sizing are critical. The exhaust system on a vehicle must be sized to accommodate full load operation, where the exhaust flows and temperatures are highest. An exhaust heat exchanger for TE heat recovery must be sized so that there is not a substantial backpressure at the highest engine loads that detracts from engine efficiency, but it also must operate well at low engine speeds and loads, where light-duty engines typically operate during normal driving cycles. Thus, the heat exchanger system for a TE exhaust energy recovery system must be designed to perform well over a wide range of exhaust flow rates and temperatures.

Extracting thermal energy with a heat exchanger is uniquely challenging for a TE system compared to other heat recovery methods because of the increased thermal resistance in the heat exchanger. In a Rankine cycle, for example, there is typically only one heat exchanger wall between the hot exhaust gas and the working fluid. In a

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto127
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

TE system, there are two heat exchanger walls, the TE materials, and typically ceramic coatings to electrically isolate the TE generators, with each layer reducing the system thermal conductivity and the heat flux into the heat exchanger (Q_{TE_in} in Figure 7). The thermal resistance of TE devices is not negligible, and research efforts focused on increasing the figure of merit achieve these improvements by decreasing the thermal conductivity of these materials. This approach results in a more efficient conversion of the heat flux to electricity but simultaneously reduces the heat flux through the TE generator.

Figure 8 further illustrates the relationship between power output of a TE generator module and the figure of merit for a constant temperature differential across the TE device with arbitrary changes in thermal conductivity and electrical resistance. Initially, power output increases with decreases in both thermal conductivity and electrical resistance. However, at $ZT_{AV} = 2.0$, the recovered power reaches a maximum with decreasing thermal conductivity because of the decrease in Q_{TE_in}. Conversely, continued decreases in electrical resistance are effective at continually increasing the TE power output. In reality, there are limits to the extent that thermal conductivity and electrical resistivity can be changed and neither can be changed in isolation from the other. Thus, Figure 8 illustrates that a higher figure of merit does not necessarily translate into an increase in recovered electrical power, but the trade-off point is highly dependent on the particular type of TE material.

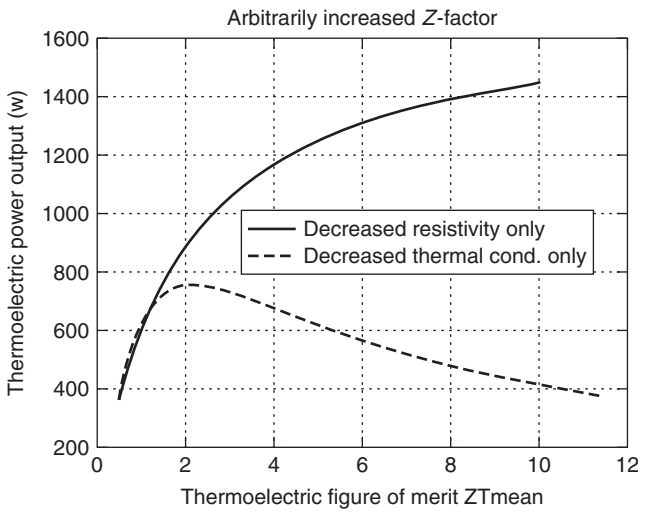

Figure 8. Thermoelectric power as a function of the figure of merit for constant hot- and cold-side temperatures. Changes in the figure of merit are accomplished by arbitrarily increasing the thermal conductivity or decreasing electrical resistivity.

3.2.3 *Thermal expansion and thermal management*

In other exhaust system heat exchangers, the heat is transferred from one fluid to another fluid (e.g., the exhaust gas to the working fluid of the organic Rankine cycle) through a heat exchanger made from a single material, typically stainless steel. With TE systems, the heat exchanger design is more challenging in many respects because there are different thermal coefficients of expansion for the heat exchanger material; the TE materials; and any other spacers, insulation, or thermal conductors.

In addition, the figure of merit is a function of temperature for each type of TE material, and it is essential not to exceed the maximum temperature of a TE material. For instance, bismuth telluride TE modules typically exhibit an optimal figure of merit between 100 and 200°C, with a maximum temperature around 250°C. As a result, incorporating bismuth telluride TE generators into an exhaust system may require an exhaust bypass to offer thermal protection at high exhaust temperatures. Conversely, skutterudites and half-Heusler alloys can offer good performance at temperatures as high as 800°C but have figures of merit that monotonically increase with temperature and therefore offer very poor performance at low temperatures. Thus, bismuth telluride may be more applicable to compression-ignition (CI) diesel engine TE generators, whereas the higher temperature materials may be more applicable to spark-ignition (SI) gasoline engines.

The last part of the TE system is the cold side of the heat exchanger for heat rejection (Q_{TE_out} in Figure 7). While it is possible to use either an air-cooled heat sink or a liquid heat exchanger, Haidar and Ghojel report that the cold-side temperature would have to be about halved for an air-cooled heat sink to be as effective as a liquid heat exchanger (Haidar and Ghojel, 2002). As a result, liquid-cooled heat exchangers are favored. Further, for the sake of simplicity and minimizing the system weight, it is desirable to use the existing engine liquid coolant system. Engine coolant is typically at a temperature of 90°C or higher, which is higher than an ideal cold-side temperature for a TE device. Figure 9, taken from Ibrahim, Szybist, and Parks (2010), shows that electrical power recovered decreases by more than 25% with a coolant temperature increase from 50 to 90°C. Thus, there is a substantial amount of electrical power to be gained with lower coolant temperatures. However, this again represents a trade-off because a dedicated exhaust coolant system will also require a significant amount of power for a pump and coolant fans. Whether a dedicated cooling system operating at a lower temperature is desirable will be dependent on a number of factors and will have to be assessed on a case-by-case basis.

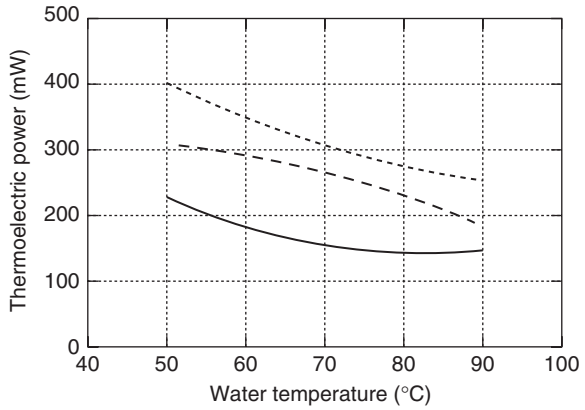

Figure 9. Thermoelectric power as a function of coolant water temperature for three different exhaust flow rates: 40 sL/min (——), 60 sL/min (– – –), and 80 sL/min (. . . .).

3.2.4 Energy recovery potential

The energy recovery potential of TE systems is dependent on the type of TE material used, the placement of the TE generator in the exhaust system, and the size of the TE generator. Ibrahim, Szybist, and Parks (2010) reviewed the TE electrical power recovery in vehicle demonstrations and found a range from 1 to 193 W for light-duty applications, with a large dependence on vehicle operating condition. Considering advancements in materials and system integration, this range of electrical power recovery is in-line with Mori *et al*. (2011) who estimate that a 3% fuel economy enhancement is possible by recovering approximately 450 W in a series hybrid configuration with a TE generator that uses both low and high temperature TE materials. Electrical power output of more than 1 kW from a TE generator has been reported from a heavy-duty truck at a high load condition (Haidar and Ghojel, 2001).

3.3 Turbocompounding

Most modern CI engines and many modern SI engines use turbocharging to recover some of the waste exhaust thermal energy by converting it into additional airflow through the engine. This alone is not generally considered a WHR technique as turbocharging is more useful for improving power density, transient response, and emissions. However, it is possible to use a second turbine after the turbocharger to extract additional energy from the exhaust by more completely expanding it to ambient pressure before exhausting it from the engine. This approach is not well suited to automotive applications though and is only briefly discussed here for completeness.

Turbocompounding has been implemented on a number of on-highway heavy-duty diesel engines such as the 2010–2012 DD15 engine by Detroit Diesel Corporation, n.d. (2012). In a turbocompounded engine, the post-turbocharger exhaust is expanded through a second turbine. This second turbine is not coupled to a compressor wheel but is instead coupled to the engine crankshaft through a fixed-ratio transmission. The expansion work across the turbine is then added to the crankshaft to increase the power delivery for a given fuel rate. Given the constraints of gear ratios, the rotational speed of the turbine is limited both in range and in maximum speed. The narrow operating range of a heavy-duty diesel engine is better suited to match the turbine speed range to aerodynamic designs than a wider-range light-duty engine. For a heavy-duty engine application, a useful increase in efficiency is possible, with a study quoted by Reinhart (2009) suggesting that a typical line-haul truck could see a 2.4–2.8% improvement in fuel economy. Other constraints, principally cost and durability, have limited the market penetration of turbocompounded engines in the heavy-duty market though.

The literature is sparse on the use of turbocompounding systems for light-duty applications. A study by Edwards, Wagner, and Briggs (2010) in which a turbocompound system was simulated on a light-duty vehicle indicated negligible benefit for light-duty applications. This minimal benefit, coupled with the added cost and significant engineering challenges in matching a turbine to the speed range of a light-duty engine, suggests that turbocompounding is not a suitable technology for improving light-duty engine efficiency.

4 SUMMARY

Engine WHR systems will be an important part of future high efficiency engine systems to meet increasingly aggressive CO_2 emissions regulations. The selection of a particular WHR technology will be highly application dependent. More specifically, the appropriate technology will be dictated by the quality of available thermal sources, duty cycle of the engine, acceptable complexity of the recovery system, and cost. The Rankine cycle WHR systems have been demonstrated both in-laboratory and in-vehicle to offer an attractive increase in engine efficiency, but the added cost has prevented manufacturers from putting systems into production. TE systems are available in production for niche uses but still require substantial development of the basic technology to achieve costs and component efficiencies that will justify production. All of the WHR technologies discussed in this chapter have been available for many years, and the technology is advancing

rapidly with specific focus on maximizing the recovery efficiency of low temperature sources and reducing complexity and cost for more widespread implementation. Given the continuing demand for better fuel economy, it is expected that ultimately both Rankine and TE WHR systems will be available for light- and heavy-duty automotive applications.

Lubrication and Friction

Victor W. Wong

Massachusetts Institute of Technology, Cambridge, MA, USA

1 INTRODUCTION

The trend toward greater energy conservation and the reduction of green house gases demands that fuel consumption of automotive engines continue to be improved. Although the useful work loss due to engine friction is relatively small for modern engines, the reduction of all parasitic energy losses, including friction, remains as a valuable contribution to overall efficiency improvement. A small gain in fuel consumption, even by 1% over existing levels, is an important achievement. The macroscopic energy and economic savings from improved engine efficiency are huge. Lubrication and friction play essential roles in energy conservation.

There are many moving parts in an engine. Proper lubrication keeps them in good working order, extends component longevity, and minimizes the energy losses due to friction. Many engine durability and reliability issues—such as excessive wear, component seizure, and catastrophic failure—are traced to problems in the inadequate lubrication of essential components. Proper lubrication and low friction are associated with engine integrity and good performance, which are attributes important to the engine user.

Lubrication involves the smoothing of the rubbing process between contacting surfaces. A lubricant film between the surfaces would prevent direct solid-to-solid contact. The degree of solid-to-solid contact and the oil film thickness depend on the applied mechanical load, relative velocity, surface profiles, roughness, textures, as well as lubricant properties. There are different types of lubrication conditions or regimes, the fundamentals of which are illustrated. There are many contacting surfaces in an engine system: in the piston assembly, valvetrain components, and multiple bearing surfaces. The relative magnitudes of friction in these components will be examined.

The lubricant itself is a multi-constituent fluid that strongly influences the lubrication regime of the lubricated parts. Various additives provide different functions in the oil: to maintain the temperature sensitivity of the oil viscosity, to protect against wear through formation of surface films, and to reduce solid-to-solid friction by making the surfaces more slippery. In addition, other additives keep the component surfaces clean and maintain the oil properties to within acceptable levels. In recent years, lubricant-additive derived ash in the exhaust stream has become an important issue in advanced diesel engines equipped with emission aftertreatment control systems. Engine design and lubricant-additive formulation need to be optimized together to simultaneously protect both the engine and the emission-control system from contamination by ash, sulfur, and phosphorus originating in the oil.

This chapter begins with clarifying the common descriptions of mechanical losses and friction in the engine, and the lubrication fundamentals. Then, the various lubrication regimes in the engine component subsystems and individual contacting parts are described. The lubrication regimes span a wide range from predominantly hydrodynamic lubrication

in the bearings to mixed-boundary lubrication in the valvetrain cam lobe and follower contacts. The final section discusses the roles of lubricants and additives.

2 ENGINE FRICTION AND MECHANICAL LOSSES

2.1 Types of mechanical losses, rubbing friction and engine work output

When fuel is burned in the combustion chamber of a reciprocating engine, the high pressure that is generated pushes on the piston to generate work. This work on the piston is termed *indicated work*. Owing to losses in the engine system, only part of the indicated work—the brake work—is delivered to the drive shaft to drive the transmission system to propel the vehicle. We define mechanical losses as the difference between the indicated work done on the piston and the brake work delivered to the drive shaft. These losses come from various sources and depend on a range of factors, such as engine operating conditions, mechanical design of the various components (see e.g., Engine Configurations, Piston and Ring Development, Cranktrain Development) and the lubricant.

The total mechanical losses that have been defined are occasionally called *total engine friction* (Heywood, 1988). When used in this context, total friction includes more than the usual connotation of the rubbing friction of the moving parts. Mechanical losses, in general, include the rubbing friction of the moving parts, the pumping work to pump gases into and out of the combustion chamber, and the accessories work to drive the oil and coolant pumps, alternator, and other engine-integrated accessories. Each of these losses contributes to the reduction of net engine work output.

In terms of the mean effective pressure (see Operating Principles), that is, work per engine cycle normalized by the engine displacement volume (Heywood, 1988), the losses and the net work output are related as follows:

$$\text{Total mechanical losses}: \quad \text{tfmep} = \text{rfmep} + \text{pmep} + \text{amep}$$

$$\text{Brake work output}: \quad \text{bmep} = \text{imep (gross)} - \text{tfmep}$$

where

tfmep = total friction mean effective pressure (i.e., mechanical losses)
rfmep = rubbing friction mean effective pressure
pmep = pumping mean effective pressure (of intake and exhaust gases)
amep = accessories mean effective pressure
imep (gross) = indicated mean effective pressure (from fuel combustion)
bmep = brake mean effective pressure (delivered to the engine drive shaft)

This chapter addresses rubbing friction only, that is, the simple connotation of friction, as this is the component of losses that is affected directly by engine lubrication. However, all contributions to total mechanical losses are important in affecting engine efficiency. Rubbing friction will be abbreviated hereafter simply as friction, or mechanical friction.

2.2 Lubrication regimes

Because of the wide range of forces and relative speeds at the lubricated surfaces in an engine, different regimes of lubrication can occur, as distinguished by the thickness of the oil film separating the surfaces compared to the surface roughness. Figure 1 illustrates the levels of separation of two rough surfaces. *Hydrodynamic lubrication*, or *fluid-film lubrication*, refers to the regime where the surfaces are separated by a sufficiently thick oil film so there is no direct solid–solid contact. The mean separation of the surfaces is much greater than the mean asperity height or surface roughness. Friction in this regime is determined by traditional fluid mechanics, where oil viscosity plays a primary role. *Boundary lubrication* occurs when the surfaces come into direct contact with each other as if there were no lubricant in between. Friction is governed predominantly by the surface or surface-film characteristics. This regime occurs when the mean separation between the surfaces is the same in magnitude as the asperity height variations. Between the two regimes is *mixed lubrication*, where the separation of the surfaces is close and, statistically, there

are significant areas of the rough surfaces that come into contact. Both lubricant and surface properties affect friction in this regime.

2.2.1 The Stribeck curve

The lubrication regimes and the friction behavior can be illustrated by a Stribeck curve, shown in Figure 2, where the coefficient of friction (tangential force/normal force) is plotted logarithmically against a dimensionless duty number, $\mu V/P$, where μ is the oil viscosity, V is the relative speed between surfaces, and P is the load per unit length. At a very low duty parameter, which can be a combination of low oil viscosity, low relative speed and/or high loading, film thickness is low, resulting in boundary lubrication with a high friction coefficient. For two sliding wedges, for instance, oil film thickness increases at higher relative speeds and lighter loads or higher viscosities, which correspond to conditions at higher duty parameters, toward the right side of the figure. When the film thickness is sufficiently high, hydrodynamic lubrication occurs. Notice that in the mixed lubrication region where an oil film is formed even at close separation of the surfaces, the coefficient of friction significantly drops from that of boundary lubrication. The Stribeck curve illustrates one fundamental effect that lubricant viscosity has on friction: reducing oil viscosity (thinner oil) lowers viscous drag in hydrodynamic lubrication, but will eventually increase friction when the film thickness becomes so thin that solid-to-solid contact begins to occur in the mixed lubrication regime and reaches a maximum in the boundary lubrication regime.

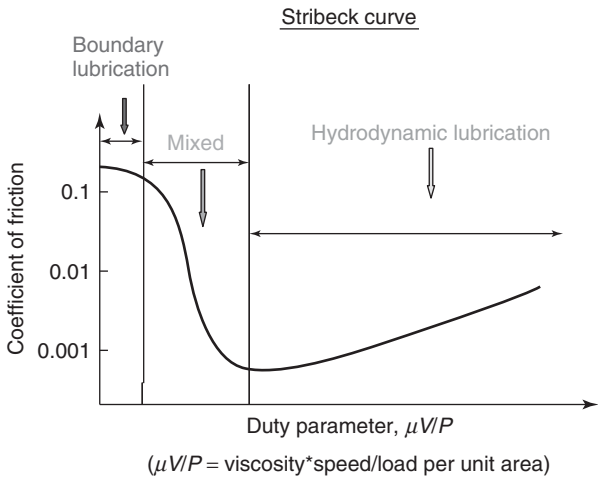

Figure 2. Stribeck curve.

2.2.2 Boundary lubrication

Under boundary lubrication, friction is determined by the characteristics of the surfaces, such as the asperities, material properties, and roughness or surface textures. Solid or nonsolid films, formed by various surface reactions, also affect friction and wear. These surface films include chemically formed tribofilms originating from antiwear additives, adsorbed layers of friction-modifier additives or other surface-active agents. The friction coefficient is relatively constant in this regime and does not vary significantly with the duty parameter, especially the oil viscosity. Lubricant additives can affect the coefficient of friction via formation of the surface films.

2.2.3 Hydrodynamic lubrication

Hydrodynamic lubrication occurs when the oil film thickness is much higher than the surface roughness or asperity heights, and the surfaces do not touch each other. Accordingly, the effects of material properties or surface characteristics are negligible. Friction comes primarily from viscous shear stress. The viscous shear is proportional to the oil viscosity to some exponent, considering film thickness variations between the particular surfaces, and to the relative velocity of the surfaces. Thus, the coefficient of friction shows an approximate linear slope in the Stribeck curve.

2.2.4 Mixed lubrication

This is an intermediate regime where the separation of the surfaces is close, and an effective oil film separates the surfaces from major direct contact. However, statistically, owing to asperity height variations, parts of the surfaces do make direct contact. The extent to which direct solid-to-solid contact occurs determines the friction coefficient. Friction reduces significantly as the oil film thickness or the duty parameter increases from pure boundary lubrication.

2.3 Relative magnitude of friction and distribution by components

This section first discusses magnitudes of friction relative to fuel energy consumed and relative to engine work output, and then summarizes estimates of the distribution of friction losses by engine components.

2.3.1 Friction compared to engine work output, fuel energy use and to other losses

While friction is a strong function of engine speed (rpm), it varies less directly with engine load. Increasing the power

output for a given sized engine at a given speed (viz. increasing the bmep, see Operating Principles) is a typical strategy for reducing friction as a percentage of engine work output. There are typical estimates of the relative magnitude of friction for common engine size and power output classes; however, these mostly empirically based estimates (Sandoval and Heywood, 2003; Taraza *et al*., 2007; Patton, Nitschke, and Heywood, 1989) span a wide range and do not point to a simple distribution quantitatively.

A typical estimate of friction for a fired engine (diesel or SI) as a fraction of total fuel energy used is shown in Figure 3 (Richardson, 2000), in which *mechanical friction is* shown to take up roughly 4–15% of the *total fuel energy*. This general estimate reflects typical in-use engine conditions on the aggregate over various operating conditions. It does not apply to unique extreme conditions such as at idling and at very light loads where most of the fuel energy is consumed to overcome friction, with no net power output. Peak thermal efficiencies (work output/fuel used) of modern engines vary between 33% and 50%, with passenger-car engines at the lower end of the range and larger bore engines doing better and targeting 50% as a common development goal (Koeberlein, 2012). Accordingly, *mechanical friction* is typically 10–30% of engine *power output*, although it could be 100%, at idling, at the extreme.

The above-mentioned estimate of mechanical friction is consistent with other estimates of total mechanical losses in an engine. Those estimates include pumping and accessory losses in addition to mechanical friction itself, at up to 40% of the gross (indicated) power output from the engine (Quillen *et al*., 2006, 2007; Nakada, 1995; Taylor, 1993). Most of the mechanical losses, about 75%, are rubbing friction, although the relative pumping losses become more significant at lighter loads (Heywood, 1988).

The mechanical efficiency, a measure of the mechanical losses, is defined as

Mechanical efficiency = bmep or (brake power)/gross imep (or indicated power) = 1 − mechanical power loss/gross indicated power × 100%

As engine power output from a given engine increases, friction becomes less as a percentage of power output. Therefore, mechanical efficiency typically increases with engine load, as shown in Figure 4. Friction could be a small fraction of engine power output, at 10% or less at high loads. Its relative importance increases at lighter loads, at 30% or more at part loads.

2.3.2 *Breakdown of friction by engine components*

This section compares the relative contributions to the total mechanical (rubbing) friction in the engine by the various component groups. The mechanisms of friction and lubrication of the various component systems are discussed in a later section.

Pumping losses result from the flow of intake and exhaust gases. Accessories include coolant and lubricant pump, fans, and other pneumatic systems that may be powered directly by the engine. The losses in these systems depend on parameters other than the traditional concept of lubrication or a lubricant. They comprise 20–30% of total mechanical losses for accessories for heavy-duty diesels and 30–50% for pumping loss for gasoline engines, depending on the operating speed and load. While important, these losses are not included in the current focused discussions on mechanical or rubbing friction.

With these exclusions, the three major subsystems of the engine contributing to mechanical friction are thus: (i) piston-ring-liner system, (ii) crankshaft and bearings system, and (iii) valvetrain system. The exact distribution of the friction among these three groups depends on the particular engine, the component design details, and operating conditions. However, prevalent reported results show that the crankshaft system (main bearing and seals) contributes roughly 50–100% higher friction than the valvetrain system, and the power cylinder friction approximately equals that from the valvetrain and crankshaft bearing systems combined. Figure 5 shows a typical partitioning of the mechanical friction in the engine, among the three major component groups (James, 2012; Richardson, 2000; Taylor, 1993). Friction and lubrication in these components groups are discussed next.

3 COMPONENT LUBRICATION AND FRICTION

3.1 The piston-assembly system

The piston assembly (see Piston and Ring Development) consists of the piston, piston rings, piston pin, connecting rod and bearings, as shown schematically in Figure 6. There are three main friction and lubrication groups: (i) the piston-skirt surfaces sliding up and down the liner, (ii) the ring-face surfaces of the ring pack likewise in reciprocating motion along the liner, and (iii) the bearing surfaces in rotating motion in the wrist pin and connecting rods. The friction and lubrication in the bearings are similar to that in the crankshaft main bearings and thus are discussed in the next section. Most of the piston-assembly friction comes from either (i) piston–skirt/liner interaction, or (ii) ring–pack/liner interaction. Strictly speaking, there is also lubrication and friction as the rings slide radially against the inside surfaces of the ring grooves in which the rings reside. However, the ring–groove interactions are only intermittent and do not contribute significantly to energy losses, but rather to ring–groove wear issues.

3.1.1 *The piston-skirt-liner subsystem*

Because of the kinematics of the connecting rod transmitting the piston reciprocating motion to rotating crank motion, side forces act on the piston laterally, causing what is termed the *secondary motion of the piston* inside the cylinder. Piston secondary motion results primarily in (i) a variable slight tilt of the piston as it rotates about the piston-pin, and (ii) an impact force, commonly called *piston slap*, of the piston as it switches from sliding up on one side of

the liner (minor-thrust or anti-thrust side) to sliding down on the other side (major-thrust or, simply, thrust side) of the liner. The piston tilt is affected to a large extent by the skirt profile, while the operating clearance between the piston and liner and the thickness of the oil film thickness between them significantly affect the side impact force. Although the piston rings provide vital sealing functions, the side forces on the piston are supported mainly by the piston skirts instead. The rings move relatively freely in their grooves and do not exert much side force on the piston other than through the friction on the ring groove surfaces.

The lubrication regimes and friction losses in the piston-skirt-liner subsystem are significantly influenced by the piston secondary motion. As one would expect, skirt-liner friction is higher when there is solid–solid contact in the boundary lubrication and mixed lubrication regimes. The axially barrel-shaped skirt profile, acting like a hydrofoil, generates the hydrodynamic pressure to sufficiently separate the skirt from the liner. Hydrodynamic lubrication is thus maintained during most parts of the piston travel. However, when the piston speed approaches zero at the ends of the piston travel up or down strokes, the hydrodynamic lift due to the sliding motion fades. Instead, the squeeze-film damping, occurring when the skirt moves sideways toward the liner, becomes the essential mechanism for maintaining a reasonable oil film, although often not thick enough to avoid solid–solid contact.

The important parameters governing piston-skirt-liner friction include the surface characteristics, such as textures or waviness patterns on the skirt and surface roughness; skirt design details such as ovality and axial profile, and lubricant thickness and rheology.

The piston skirt is considered compliant and flexible in response to mechanical loads such as the oil film pressure itself. The mechanical deformations add challenge in predicting skirt-liner lubrication. It was reported on the basis of modeling results (Mansouri and Wong, 2004) that a more compliant skirt provides a greater separation between the skirt and liner surface, thus lower friction, as shown in Figure 7, where computationally the flexibility (deformation response to applied load) of the skirt was reduced to zero (rigid skirt) or made several times more compliant in the model.

Figure 8a (Moughon, 2006) illustrates conceptually typical effects of increasing viscosity in piston-skirt friction, where the hydrodynamic friction increases and boundary friction decreases with increasing oil viscosity for a skirt design with a fair amount of boundary lubrication. In this case, a thicker oil maintains a larger skirt-liner separation and consistently reduces friction. In Figure 8b, however, in a different skirt design with less boundary lubrication, increasing oil viscosity would increase friction beyond an optimal point, as hydrodynamic lubrication becomes dominant and a lower viscosity would decrease friction.

The key in reducing piston skirt-liner friction lies in maintaining hydrodynamic lubrication of the skirt. With an adequate oil supply to the skirt, most other issues of skirt profile design and surface characteristics affecting boundary lubrication would disappear or diminish. This is illustrated in Figure 9, where it is shown (Mansouri and Wong, 2004) that piston-skirt friction can be reduced by reducing primarily the boundary contacts between the liner and skirt surfaces; this can be achieved by providing ample oil supply to the skirt.

3.1.2 The piston ring-pack subsystem

An automotive-engine piston ring pack usually consists of three rings as shown in Figure 6 (see Piston and Ring Development). Uninstalled, the top two rings have diameters larger than the cylinder bore. When compressed and installed in the grooves in the piston and fit into the cylinder liner, they expand against the liner, and this force is called the *ring tension*. The third ring from the top is the oil-control ring, which is either a two-piece design in many diesel engines or a three-piece design in gasoline engines. Ring tension in the oil control ring is provided by an expander piece. The top ring, or compression ring, primarily seals the combustion chamber gas from leakage past the ring. This action is accomplished by the ring tension and combustion gas pressure at the back of the ring. The function of the second ring, or scraper ring, is more intricate: first, the second ring performs an additional sealing function and its face profile is shaped to scrap oil

on the liner down, away from the combustion chamber. Furthermore, the second ring controls the inter-ring gas pressures, and thereby the flow of blow-by gases toward the crankcase or their reverse flow back into the combustion chamber. This subtle action is accomplished by the careful balance of a combination of design factors of the ring, such as ring twist (preferential bending and resulting contact with the ring groove), ring gap, and mass and geometry of the ring. As the name implies, the oil-control ring controls the amount of oil available to the upper rings for adequate lubrication but minimum oil consumption.

The relative sliding speed between the rings and the liner varies substantially over the engine cycle, and so does the lubrication regime for each of the rings. Boundary friction is dominant near the end strokes where the relative rubbing velocity is zero and oil film thickness minimal. Near the mid-strokes of piston travel, the reverse is true. While the exact proportion of boundary versus hydrodynamic friction varies with specific mechanical design and operating parameters, the oil-control ring is expected to operate preferentially with more boundary lubrication overall. Contributing to this oil-control-ring performance is the high ring tension and the relatively small rails against the liner. In general, both the top-ring and the oil-control ring friction are significant, while the second-ring friction is generally considered the smallest in the ring pack, owing to the relatively lower ring tension and lower gas pressure behind the ring.

Although shown with parallel top and bottom groove and ring surfaces in Figure 6, various shapes of rings are used in practice. The Keystone ring and groove, characterized by a tapered ring and groove for diesel engines, facilitates the removal of combustion residues due to the radial movement of the rings relative to the grooves. Moreover, the running surfaces of rings are often coated with wear-resistant materials. Significant engineering has gone into piston-ring designs (see Piston and Ring Development); the following subsections can only cover the general lubrication and friction characteristics of the rings rather than their detailed design and engineering.

3.1.2.1 Lubrication and friction in the ring pack.

3.1.2.1.1 Fundamental ring-liner slider analysis. The basic understanding of ring-liner lubrication is shown conceptually by a slider arrangement in Figure 10, where a slider (ring) executes a reciprocating motion relative to the liner. The radial load on the ring consists of the pressure force at the back of the ring in the groove acting

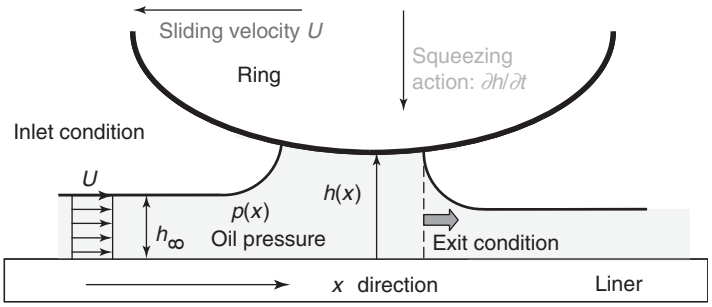

Figure 10. Fundamental ring-liner lubrication and friction model.

perpendicularly toward the liner surface as shown, plus the ring tension that tends to expand the ring against the liner. A hydrodynamic pressure is generated in the oil film that, from hydrodynamic theory, strongly depends on the sliding speed of the barrel-shaped wedge. A simple form of the Reynolds equation, with surface roughness and other features omitted, for the ring slider is shown in Equation 1, in reference to Figure 10, where x is the distance in the lubricant-flow direction, h the film thickness, U the sliding speed, and p the hydrodynamic pressure in the oil film, and μ the oil viscosity:

$$\frac{\partial}{\partial x}\left(\frac{h^3}{\mu}\frac{\partial p}{\partial x}\right) = 6U\frac{\partial h}{\partial x} + 12\frac{\partial h}{\partial t} \qquad (1)$$

To account for surface characteristics such as surface roughness, textures, or waviness, flow factors (Patir and Cheng, 1979) that modify the first two terms in Equation 1 can be added. The force balance of the radial load against the oil pressure, together with pressure and mass continuity boundary conditions at the wetted edges of the ring, determine the minimum oil film thickness. When the film thickness becomes small enough where boundary or mixed lubrication may occur, an asperity contact model (Greenwood and Tripp, 1971) is commonly used to determine the boundary contact pressure, which will also take part in the radial force balance. Similar analysis is carried out for the second ring and for each of the rails of the oil-control ring. The film thickness on the liner left by the passage of one ring provides an inlet film thickness condition for the following ring or rail. The effects of any piston tilt or groove angle when the rings rests on the ring groove will be to change the relative orientation of the ring-face profile relative to the liner.

3.1.2.1.2 Friction behavior of individual rings. Obviously, the exact magnitudes of the film thickness of the rings and friction depend on the ring design parameters, surface characteristics, lubricant properties, and operating conditions. Figure 11 shows an example of predictions of ring-pack friction in an advanced reciprocating engine (Smedley, 2004) that illustrates some basic features of ring-pack friction:

(a) Two types of friction power loss peaks occur in this illustration—(i) friction peaks periodically at mid-stroke that correspond to periods of high sliding velocity, as shown by the oil-control ring friction, and (ii) peak friction power loss around the top ring reversal position near top center, shown by the top ring. Upon closer examination, the peaks correspond to a high level of solid–solid contact in boundary lubrication.
(b) The other general feature is that the magnitude of the second ring friction is significantly less than either that of the top ring or oil-control ring, primarily due to the subdued inter-ring pressure adding to the outward radial load on the ring against the liner.

3.1.2.2 Ring dynamics and gas flows in the ring pack. In addition to the radial forces of ring tension and gas pressure holding the rings against the liner, providing ring-liner seals, axial forces (gas pressure, inertia, and friction) also act on the rings, pressing the rings against the surfaces of the grooves, sealing the combustion gases from leaking around the rings in the grooves. The rings are carefully designed with a positive or negative twist angle (relative to the ring groove edges), as shown in Figure 12, to control the point of sealing and the pressure distribution around the ring. The axial forces and moments determine the ring's axial motion and its tilt in the ring groove. These axial forces include primarily the gas pressure forces acting on the flanks of the ring—intricately controlled by the designed twist (static twist)—balanced against the inertial force on the ring due to the reciprocating piston motion. The rings typically sit flat on the bottom groove flank about three-quarters of the time and on the top groove flank about a quarter of the time because of the higher

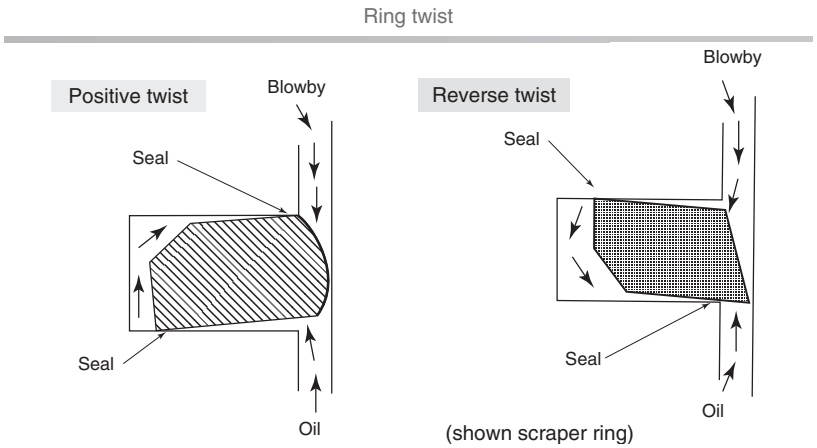

Figure 12. Schematic illustrating positive and negative static ring twists.

gas pressure on the combustion chamber side. There are two narrow time intervals, of a few crank angle degrees each, where a ring makes a transition from primarily one side of the groove toward the other. During ring transition, enhanced leakage of gases occurs. If the flow is toward the bottom, toward the crankcase, there is increased blow-by. Reverse flow can also occur because of the inter-ring pressure variations. This happens when the cylinder pressure decreases faster than the reduction of inter-ring pressures. Oil consumption could increase when reverse flow occurs, either due to flow around the grooves or through the ring gaps.

The stability and dynamics of the rings in the grooves affect the leakage of gases and oil around the rings in the grooves. Figure 13 (Smedley, 2004) shows a second ring with a negative twist (drooping downwards at the outer ring edge) and the rapid up-and-down motion of the ring in the groove (flutter) between −90 and 90 crank angle degrees that can occur. The second-ring instability or flutter occurs when the inertial force on the ring is high near TDC compared to the pressure force holding it down in the groove. When the ring is seated at the bottom of the groove with a negative twist, as shown in Figure 13, it is held down with a small pressure differential as the pressure above the ring penetrates around the ring to the bottom, as there is no flow. When the ring begins to lift, the gas flow and pressure differential forces the ring to seat at the bottom again. The ring flutter thus generates the additional

flow path for gases and oil. The second ring instability incidentally relieves the second land gas pressure, which potentially could have caused reverse flows through the top ring gap (or top-ring groove when it flutters). The top-ring reverse flow contributes to oil consumption and emissions.

3.2 The crankshaft and connecting-rod bearing systems

The lubrication modes at the main bearings of the crankshaft, at the connecting-rod/crankshaft interface (big-end bearings), and at the interfaces between the piston pin and the piston pin bosses, and between the connecting rod and the piston pin are all journal-bearing lubrication. Hence, categorically they are discussed under this section.

3.2.1 The crankshaft main-bearing subsystem

3.2.1.1 Journal-bearing friction. Apart from its interfaces with the connecting rods, the crankshaft's friction comes primarily from the main bearings that support the crankshaft in its rotational motion. The bearing seals also generate some friction attributable to the crankshaft. The crankshaft rests on a layer of oil between the shaft and the outer bearing shell. The axis of the crankshaft is off center from that of the bearing center. This offset, called *bearing eccentricity*, generates the hydrodynamic pressure during shaft rotation. Oil is amply supplied to the bearing surfaces through oil feeds along the crankshaft. With adequate oil supply and under normal loads, the lubrication at the main bearings is primarily in the hydrodynamic regime. Journal-bearing calculations usually apply the Reynolds equation, in cylindrical coordinates, to the lubricant in the journal bearing in determining the oil pressure distribution, the locus of the journal relative to the bearing surface, and thus the minimum oil film thickness. The minimum oil film thickness is an important design parameter and is usually kept larger than the surface asperity heights to avoid mixed or boundary lubrication. The dynamic loading originates from the rapidly varying cylinder pressure pushing against the piston and the connecting rod, and then to the crankshaft.

The friction in the journal bearing is proportional to the surface shear stress integrated over the entire bearing surface area. A dimensional analysis indicates the following functional dependence holds (Heywood, 1988):

Average shear stress $\approx \mu(\pi D_b N/h_m)$

where

μ is the oil viscosity
D_b is the bearing diameter
N is the rotational speed
h_m is the mean radial clearance
bearing surface area $\approx \pi D_b L_b$
L_b is the bearing length

Accordingly, the bearing friction, $F_b \approx \mu(\pi^2 D^2{}_b L_b N/h_m)$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto129
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The mean oil film thickness, h_m, in the journal bearing is a function of the applied loading and other geometric factors of the journal bearing and lubricant viscosity. Thus, the friction scaling law for journal bearings often used is simply (Sandoval and Heywood, 2003; Patton, Nitschke, and Heywood, 1989):

$$F_b \alpha \mu D^2_b L_b N \quad (2)$$

The proportionality constants are often empirically determined and are specific for a certain bearing design. Thus, the connecting-rod/piston-pin bearing takes on a different proportionality constant from the con-rod big-end bearing, which is also different from that for the crankshaft.

3.2.1.2 Main-bearing seal and other friction. The bearing seal lips and the crankshaft surfaces are generally considered to be in constant solid-to-solid contact, with a constant friction coefficient, as in boundary lubrication, and a constant normal force, thus constant friction force. Obviously, the friction power loss from the seals is thus proportional to the rotational speed and the bearing diameter and the total contacting surface area. The proportionality constants depend on how tightly the seals are maintained and the surface characteristics of the surfaces. These constants, which vary from seal to seal, are determined empirically. Some researchers (Patton, Nitschke, and Heywood, 1989) consider another loss mechanism due to the power loss from pumping oil through the crankshaft oil feeds. However, strictly, this is not "rubbing" friction as discussed earlier in this chapter, but could actually be considered part of the power losses of the accessories.

3.2.2 The connecting-rod subsystem

3.2.2.1 The connecting-rod/piston-pin friction. The cylinder pressure force on the piston is transmitted to the crankshaft via the connecting rod, the top end of which connects to the piston via a piston pin and pin bosses that form part of the piston (see Piston and Ring Development). Figure 14 shows the piston, pin, and connecting rod system. There are actually two sets of interfaces: (i) the bearing between the piston-pin and the small end of the connecting rod, and (ii) the bearing between the piston pin and the pin bosses. However, as in the crankshaft bearings, lubrication in either case is characterized as a dynamically loaded journal-bearing system. For high cylinder pressures—a trend in producing more power for given engine displacement—the pin/boss, pin/connecting-rod bearing interfaces represent some of the most highly loaded areas in the engine. Lubrication is predominantly in the hydrodynamic regime, although analyses assuming the more general condition of mixed lubrication have been reported (Nishikawa, 2012; Wang, Du, and Zhang, 2011; Ligier and Ragot, 2005). Some measurements of pin friction (Takiguchi, Suhara, and Tsuneo, 1998) also suggested mixed lubrication. However, in those experiments, the pin showed significant bending, perhaps partially explaining the observed mixed or boundary lubrication. Assuming predominantly hydrodynamic lubrication, then the friction coefficient is roughly proportional to the term $\mu V/P$, where μ is the oil viscosity, V is the relative speed between surfaces which is proportional to engine RPM, and P is the load per unit area.

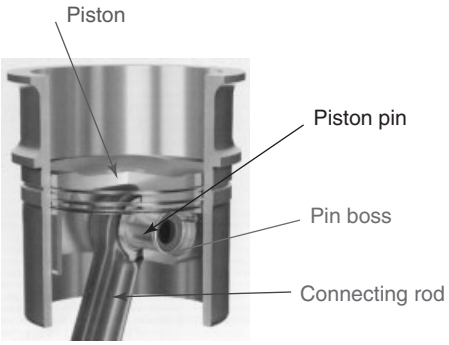

Figure 14. Schematic of piston, piston-pin, connecting rod, showing bearing interfaces.

3.2.2.2 The connecting-rod/big-end friction. The connecting-rod big end refers to the connection between the connecting rod and the crank. Lubrication here is also primarily in the hydrodynamic regime. Adequate oil is supplied to the bearing surfaces through feeds along the crankshaft. As in the case with crankshaft main bearing and piston-pin bearings, the bearing friction is proportional to the bearing surface area and mean linear velocity, which in turn is proportional to the bearing diameter at a given engine RPM.

For both the piston-pin and con-rod big-end bearing lubrication, the friction is proportional to the square of the bearing diameter, D_b, and the bearing length, L_b, (i.e., $D^2_b L_b$). Earlier estimates indicate that connecting-rod bearing friction is comparable to but somewhat less than piston-skirt friction (Richardson, 2000). In view of the increasing trend of higher cylinder pressure (bmep) engine operation for improved efficiency, the contribution to total friction from the connecting-rod bearings could become more significant, especially when and if asperity contacts in the mixed lubrication mode begin to be felt. However, the design of an adequate lubricant flow to the bearings will keep solid–solid contact to a minimum.

An early analysis by Bishop (1965) derived an expression for the crankshaft and connecting-rod journal-bearing friction combined, where the additive terms from the various subsystems are apparent. The friction, normalized by the displacement volume (α bore$^2 \times$ stroke), in the form of friction mean effective pressure (fmep), in kilopascal, is given by (Lee *et al.*, 1999; Bishop, 1965):

$$\text{Combined bearings fmep} = 41.4 \left(\frac{N}{1000}\right) \frac{(D^2_{\text{mb}}\, L_{\text{mb}} + D^2_{\text{rb}}\, L_{\text{rb}}/m + D^2_{\text{as}}\, L_{\text{as}})}{(B^2\, L)}$$

where N is the crankshaft rotational speed in rev/min, B = bore, L = stroke, D_{mb} = the main bearing diameter, L_{mb} = the total main bearing length divided by the number of cylinders, D_{rb} = the connecting-rod bearing diameter, L_{rb} = the total connecting bearing length, m = the number of pistons per rod bearing, D_{as} = the accessory shaft bearing diameter, $L_{\text{as}} = k$ the total length of all accessory shaft bearings divided by the number of cylinders.

3.3 Valvetrain system

The valvetrain system consists of a series of mechanical parts that serve primarily to open and close the intake and exhaust valves. The valvetrain converts the rotary motion of the camshaft, at one end, to oscillatory motion of the valves at the other end. The cam lobes on the camshaft determine the valve timings. There are several prevalent configurations of the component layouts (primarily of the rocker arm) between the camshaft and the valves themselves, as shown in Figure 15:

1. Direct-acting, overhead cam (OHC): cam lobe on tappet directly, no rocker arm
2. End-pivot rocker arm, OHC: cam lobe drives follower between pivot and valves
3. Center-pivot rocker arm:
   (a) OHC: cam lobe acts on end of rocker arm directly
   (b) OHC: cam lobe acts on end of rocker arm via lifter
   (c) Cam in block, overhead valve (OHV), cam lobe acts on rocker arm via extended pushrod

These configurations differ in simplicity, the number, size, and mass of the parts involved, and thus the stiffness of the system. The stiffness determines how fast the response of the oscillatory valve motion follows the actuating cam motion. They also differ in size/packaging and inertia, and thus their suitability varies depending on specific engine applications.

3.3.1 *Tribological contacts and sources of friction*

There are four main categories of contacts and sources of friction in the various configurations of valvetrains described. The lubrication modes range from predominantly hydrodynamic to boundary lubrication and mixed lubrication. The major contact and friction categories are as follows:

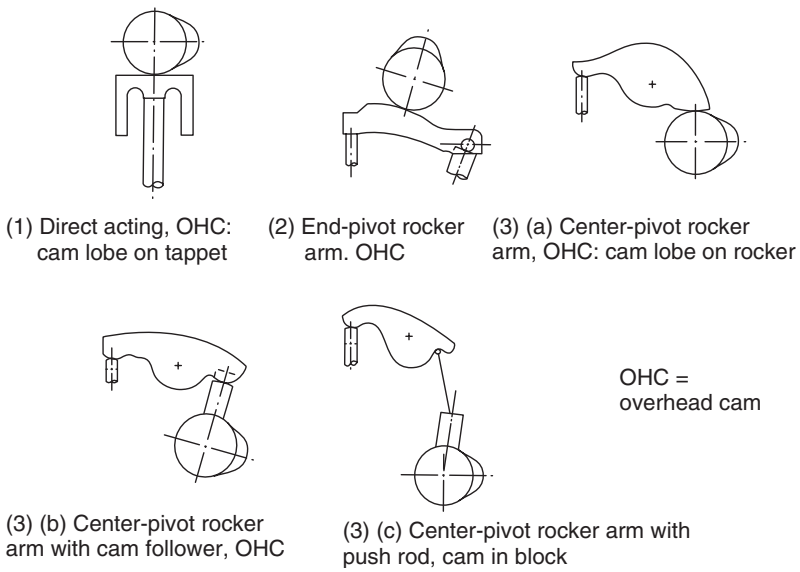

Figure 15. Major types of valve train configurations. (From Armstrong and Buuck (1981). © SAE International. Copyright © 1981 SAE International. Reprinted with permission.)

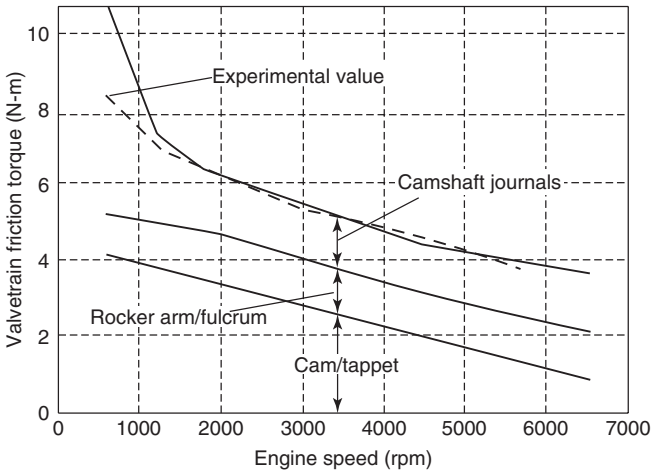

Figure 16. Effect of engine speed on valvetrain friction components for nonfriction-modified SAE 30 oil at 100°C. (From Wang (2007). © SAE International. Copyright © 2007 SAE International. Reprinted with permission.)

1. The camshaft bearing friction: the camshaft is supported by camshaft bearings (journals) similar to the crankshaft main bearings. The applied bearing load on the camshaft is significantly less than the load from the cylinder pressure through the connecting rod to the crankshaft. The journal-bearing lubrication at the camshaft bearings is mostly hydrodynamic. Estimates of the percentage contribution to total valvetrain friction from camshaft bearings varies from 12% or higher in earlier estimates (Staron and Willermet, 1983; Wang, 2007), as shown in Figure 16. Recent estimates (Comfort, 2003), however, suggest a smaller contribution from camshaft bearings. In reality, the relative contribution is a function of engine speed and it depends on the magnitude of the other components, specifically that of the cam followers.
2. The cam/follower interface friction: the cam–follower interface can be the cam lobe against a flat follower or a roller follower. In the flat follower configuration, the local load, film thickness, and friction vary with the relative position of the cam lobe to the follower. At the tip of the lobe, the local load is high and concentrated in a small area, and boundary lubrication is dominant. For the rest of the cam–follower contact, mixed lubrication prevails. The cam/follower interface is often modeled as a narrow elliptical or line contact from which the contact pressures are calculated. In the mixed lubrication regime, the viscosity of the lubricant depends on the pressure and elastohydrodynamic lubrication is assumed. Friction in the cam/flat-follower interface, consisting mostly of boundary-contact friction and some viscous drag, contributes to most of the valvetrain friction (Comfort, 2003). Roller followers, however, significantly reduce the cam/follower friction recently, by an order of 50% or better (Beloiu, 2010).
3. The rocker arm pivot/shaft friction: similar to the crankshaft seals, lubrication at the rocker arm pivot/shaft interfaces is mostly boundary lubrication. This is also due to the fact that there is very little lubricant supply to the surfaces. The boundary friction force at these interfaces is proportional to a constant friction coefficient and the applied contact load. Overall, friction at the rocker arm pivots can be as low as 10%, as Figure 16 shows at low speeds. Obviously, this percentage depends on the friction in the other components, which have come down as well in recent years, making the rocker arm pivot/shaft friction not negligible.
4. Friction in linearly oscillatory components: the components in the valvetrain in this category include the valve stem and seals, valves and guides, valve lifter and lifter bore—components that experience relative reciprocating or oscillatory motion. When the velocity in the oscillatory motion is small, we assume boundary lubrication. In general, the oscillatory motion, similar to the piston rings against the liner, also shows hydrodynamic lubrication at higher speeds during parts of the oscillatory motion. Both experiments and computations show that the percentage of valvetrain friction contributed from oscillatory motion is of the order of a few percent (Comfort, 2003).

Valvetrain friction has been studied in great detail computationally and by experiments (Gangopadhyay, Soltis, and Johnson, 2004). Typically, the reported contribution of valvetrain friction to overall engine mechanical losses is on the order of 15–20%, although estimates of valvetrain friction as high as 40% have been reported (de Paula Pignatti, Mizaiara, and da Cunha, 2011). Valvetrain friction is relatively more significant at lower speeds, indicating that most of the valvetrain friction comes from boundary and mixed lubrication.

3.3.2 Lubrication, lubricant composition, and supply to the contacts

Similar to the piston-motion reversal positions along the liner, the valvetrain cam/follower interface also exhibits significant boundary lubrication. The resulting metal–metal contact increases wear, through various wear mechanisms. Antiwear additives are formulated for lubricants to reduce valvetrain wear substantially. Friction modifiers are also

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto129
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

effective in reducing valvetrain friction. An adequate supply of fully formulated lubricant to the valvetrain is required. Engine lubricant is supplied to the camshaft through passages along the camshaft where, through oil relief holes, oil is airborne and made available to the cam/follower interfaces as well as other oscillating valvetrain components. The oil film thickness in these valvetrain interfaces depends on the oil entrainment rate into the contacting zones. Excess lubrication does not increase oil film thickness beyond the fully flooded level. However, inadequate oil supply, however minimal required, would reduce oil film thickness. The thinner oil films and reduced supply of antiwear agents in the lubricant could be detrimental to the contacts in both friction and wear. In view of the significant boundary and mixed lubrication in the valvetrain system, the proper design and selection of the chemistry and supply of oil to the valvetrain system is particularly important.

4 EFFECTS OF LUBRICANTS AND ADDITIVES

An engine lubricant is expected to perform several functions in the engine and to maintain satisfactory levels of performance for a considerable time period between oil change intervals. These functions are categorically: (i) to reduce friction and wear between rubbing surfaces; (ii) maintain cleanliness: minimize deposits, corrosion; contain contaminations in particulate (such as soot), liquid (such as fuel), or gaseous (such as acidic gases from products of combustion) forms; and (iii) maintain the oil properties, such as flow, vaporization, and other characteristics. The lubricant also acts as a sealant to minimize leakage of gases, and a coolant to remove heat from some components. To perform all these functions, the base lubricant, base oil, or "base stock," is blended with typically about 5–25% of additives, each of which performs one or more characteristic functions. The major constituents of the lubricant are discussed here, together with how the engine combustion process may contaminate the oil and the effects of the oil byproducts on the emission-control systems.

4.1 Base oils

A traditional mineral base oil is typically derived from the heavier hydrocarbons during the refining processes. A synthetic base oil is one which is synthesized from highly processed chemicals beyond those directly from the crude-oil refining stream. Some base oils being studied use exploratory fluids such as ionic—for example, water based—liquids (Fox and Priest, 2008), and some environmentally friendly lubricants use biodegradable base stocks (Schramm, 2004; Perez, Cheenkachorn, and Lloyd, 2002).

The most significant performance parameter of base oils is the viscosity. The oil viscosity characteristics include the sensitivity of changes in the viscosity to temperature, such as the viscosity index, VI. Lubricants tend to become thinner (lower viscosity) as temperature increases and become more viscous at low temperatures. American Society for Testing and Materials (ASTM) D2270 provides formulas for quantifying the VI given kinematic viscosities at 40 and 100°C. A high VI means a lubricant does not thin out much as it heats up nor becomes too thick at cold temperatures. These characteristics are important to ascertain that the oil film at the critical regions in the engine, such as at the hottest point of the top piston-ring (see Engine Thermal Management) and cylinder-liner contact region, does not become too thin at peak engine loads. The same oil also cannot be too thick to hamper its circulating freely around the engine during low temperature start-up operation. Another characteristic is the dependence of the oil viscosity on shear rate measured by the relative velocities and the film thickness between the parts. Specifications for the limits on the viscosities of the oil, including the high temperature high shear viscosities, at low temperatures and high temperatures, are given in the Society of Automotive Engineers (SAE) oil grade classification system (Haycock, Caines, and Hillier, 2004). Oils showing viscosity variations at high and low temperatures are multigrade oils. By carefully controlling the engine oil-film temperature via strategic thermal management techniques (such as by increased or decreased cooling of the liner), piston-liner friction can be affected (James, 2012); computations show friction improvements of 20–30% by increasing the temperature of the oil in the midsection of the liner (James, 2012).

For mineral oils, the major classes of heavy distillates deriving from the crude oil for the lubricant are paraffinic or napthenic hydrocarbons. Paraffinic oils show high VI, and napthenic oils show low VI—large viscosity variation with temperature. Depending on the relative composition of the base oil, the VI can vary. The American Petroleum Institute (API) designates different groups of base oils based on the level of saturates and sulfur in the oil and the VI. Groups I to III represents increasing level of saturates (either below or over 90%), decreasing sulfur (either greater than 0.03% or less than 0.03%), and increasing VI (between 80 and 120 or over 120). Group IV is for synthetic oils such as polyalphaolefins (PAO), and Group V is for all others, such as napthenics, polyalphaglycols, esters, and so on (Haycock, Caines, and Hillier, 2004).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto129

VI improvers can be added to the base oil to modify the VI of the formulated oil. Designing or using a proper oil for a given application or optimizing engine operation for given base oil characteristics, or both, provide opportunities for reducing engine friction and improve engine efficiency.

4.2 Additives

Additives are materials added to the base oil to improve the performance or properties of the oil. There could be 10–15 additives in the engine oil (Rudnick, 2009). These additives perform different functions, such as to affect friction and wear, or to maintain engine cleanliness, or to maintain the fluid properties, such as pour point or antifoam properties. Most of these additives are organic compounds and several involve metallic compounds that could adversely affect the emission aftertreatment system operation. The major additive types, especially those that affect friction and wear, are discussed in turn in two categories. The list is not exclusive as it does not include minor or special additive types.

4.2.1 Additives that directly affect friction and wear

This category of additives includes primarily the viscosity modifiers, friction modifiers, and antiwear additives.

4.2.1.1 Viscosity modifiers. Viscosity modifiers are additives, typically high molecular-weight polymers, added in small quantities to the base oil to reduce the temperature sensitivity of oil viscosity. As discussed in the section on base oils, high VI index is needed to ensure that the oil does not become too thin at high operating temperatures nor too thick for start-up and low temperature operations. Hence, viscosity modifiers have been called *VI* improvers in the past. Without viscosity modifiers, the viscosity of most mineral oil base stocks increase sharply with temperature. Generally, viscosity modifiers are added to increase the viscosity of the base oil, but more so at elevated temperatures, thus lowering the variation of viscosity with temperature. Typical viscosity modifiers are olefin copolymers (OCP), polymethacrylates (PMA) and styrene-butadiene copolymer. Some of these compounds also affect oil properties to some extent in other ways, such as the ability of the oil to flow freely at low temperatures and the ability to suspend particles in the oil as well (Rudnick, 2009).

4.2.1.2 Friction modifiers. Friction modifier additives in crankcase oils are designed to reduce friction in mixed or boundary lubrication, in contrast to transmission applications where increased friction is desired for additional traction. These friction-reducing additives are designed to form a slippery layer on the surfaces, and the layers have very low shear strength and thus low friction coefficient. Typical materials are long-chain molecules with polar heads that anchor to the metal surface. Common friction-reducing organic modifiers include oleylamide and glycerol monooleate (GMO).

4.2.1.3 Antiwear additives. The most common antiwear additive is zinc dialkyldithiophosphate (ZDDP) in its various forms, which also has antioxidant properties. The additive first decomposes thermally into reactive byproducts that form tribofilms or deposits on the surfaces. These surface films serve as protective layers during the wear process, which are continuously formed from the tribochemical reactions between the additive and the metal surface. During high pressure operating conditions, such as in gears, special sulfur and phosphorus compounds are used in place of ZDDP; these are called *extreme-pressure* (*EP*) antiwear additives.

4.2.2 Additives that maintain engine cleanliness and oil properties

This category of additives includes detergents, dispersants, antioxidants, pour point depressants, antifoam agents. Brief descriptions follow.

Detergents are designed to control engine deposits and to neutralize acids generated from the products of combustion that have migrated into the oil. Detergents are usually made up of metal salts of organic acids—the sulfonates, phenates, or carboxylates—of which sulfonates of calcium or magnesium are very common. They are characterized by two essential parameters: the ash level and the basicity. ASTM procedures have been defined to quantify the sulfated (i.e., treated with sulfuric acid and burned) ash level, as well as to determine the total base number (TBN). The TBN is a measure of the detergent's ability to neutralize acids in the lubricant.

Dispersants are designed to keep particles from separating from the oil and forming sludge and deposits that may block lubricant passageways. These particles in the oil could come from combustion products such as soot from diesels, wear debris, condensed water, or other particulate matter. Dispersants have polar heads that attach to the particles and keep them from agglomerating and thus dispersed as fine particles in suspension in the lubricant. Many totally organic (ash free) formulations of dispersants are available in the market, such as succinimides and OCP, which also show viscosity-modifying properties.

In maintaining or regulating the lubricant properties, antioxidants are designed to protect the oil itself from oxidation and thereby degradation. ZDDP, discussed earlier, also has excellent antioxidation properties. Various forms of ZDDPs can also be combined to enhance the overall thermal stability of the lubricant. Besides ZDDP, various amine and phenol compounds are available as supplemental antioxidant additives. Other additives are also available to extend the low temperature at which the oil remains fluid—pour point depressants—or to minimize the formation of foam, especially in the engine crankcase with significant churning and foaming of the lubricant.

Additives are essential to lubricant performance in engine lubrication. The oil will not function the way we expect it to function in the absence of additives. The various additives are carefully formulated to ensure that antagonistic interactions among the additives are minimized.

4.3 Effects of engine operation on lubricant properties

Besides the warm-up period during which the oil viscosity gradually increases with increasing temperature, the oil composition as well as oil properties vary during engine operation in time and location in the engine because of various other processes. These processes include vaporization of volatiles, local fuel dilution, oxidation, and contamination. The friction and wear at critical components depend on the local lubricant conditions at the points of contact under actual operating conditions. The processes that affect the local oil conditions include the following:

(a) Increased vaporization of the light hydrocarbon fractions of oil near the top piston ring zone, for instance, resulting in oil having different rheology at the top-ring zone compared to that referenced at the sump. Additive concentrations are also expected to vary. Figure 17 (Watson, 2010) shows "enrichment factors" of metallic compounds of oil sampled from the piston-ring groove. The enrichment factor is defined as the ratio of the concentration of a given elemental mass to its concentration in the sump. The metallic concentrations in the piston ring zone are much higher than those in the sump.

(b) During combustion, acidic gases such as oxides of nitrogen and sulfur are generated and absorbed in the lubricant, gradually decreasing the basicity of the oil, as evidenced by typical decreases in the TBN over time.

(c) Fuel and particulate matter contaminate the oil, especially from direct injection diesel (or gasoline) engines where some level of fuel impingement on the cylinder liner walls may occur. Some fuel may get into the oil via entrainment or diffusion, resulting in fuel dilution of the oil. This phenomenon also occurs in diesel engines equipped with diesel particulate filters (DPFs) that employ late fuel injection as a means to raise the exhaust temperature. Repeated fuel impingement on the cylinder walls will significantly increase the fuel fraction in the crankcase oil. It has been generally understood that soot from diesel combustion continuously increases the soot content in the oil over time.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(d) Blowby gases traveling from the combustion chamber to the crankcase carry unburned fuel, and products of combustion in gaseous or particulate form. These heavily polluted gases contaminate oil in the oil sump. The contaminants are, in turn, carried to the valvetrain system in the lubricant circulation circuit.

(e) There is significant oxidation and degradation of oil on the upper portions of the cylinder liner and in the top-ring areas. High shear operation at the piston-ring/liner interface, as well as in the bearings, also contributes to lubricant degradation. As a result, lubricant properties, friction and wear in the lubricated parts, and the overall engine fuel economy change over time between oil changes.

(f) Foam and aeration: oil bubbles form in the oil churning action in the sump or cavitation elsewhere in the lubricant system. Actual lubrication performance is affected by this phenomenon. Antifoam additives alleviate the problem somewhat, but not entirely.

4.4 Major effects of additives on component friction and wear

The effects of additives on engine components depend on the lubrication regimes at the prevailing conditions at the local contacts. The lubrication regimes at the various components in most warmed-up conditions are: hydrodynamic (for bearings); mostly boundary (for valvetrain cam-follower), and mixed for the piston/ring-liner interface except around the mid-stroke of the piston travel, where significant hydrodynamic lubrication is expected in most cases. There are variations among the different rings and the piston-skirt surfaces, however. Accordingly, the effectiveness of the different additives—viscosity modifiers versus friction modifiers—varies at the different components and operating conditions.

Lubricant formulation affects friction primarily via (i) viscosity control—base oil selection and viscosity (VI) modifiers, which can change the shear and temperature dependency of the viscosity, and (ii) (boundary) friction modifier additives, which affect the boundary friction by forming surface layers with low shear strength. Some organic polymers both affect the viscosity and form surface layers, for example, Polyalkylmethacrylates, PAMAs (Muller, Fan, and Spikes, 2007; Hedrich *et al*., 2003). The performance of these additives varies greatly with temperature and in the presence of other additives.

4.5 Lubricant/additives effects on engine emission-control system

While lubricants and additives perform vital functions in an engine, the lubricant-derived emissions have serious impact on the exhaust aftertreatment system (Sappok, Munnis, and Wong, 2012). For gasoline engines, the three-way catalyst (TWC) has been around for close to 40 years, where it has been shown that significant levels of phosphorus from engine oils could deteriorate the TWC prematurely. Since 2007, world-wide diesel regulations have been in place at mandated particulate emission levels that essentially need to be met with DPFs. Since 2011, use of NO*x* emission aftertreatment devices—mostly SCRs (selective catalytic reductions) for heavy-duty diesels and LNTs (lean NO*x* traps) for light duty diesel engines—has also become widespread in the United States, Europe, and Japan.

Lubricant-derived compounds in the exhaust that affect the emission-control aftertreatment system include the following:

- Incombustible ash from lubricant additives
- Sulfur and phosphorus compounds

Ash is problematic because it can build up inside the channels of DPFs. Unlike soot, ash cannot be oxidized into gaseous species. In as little as 56,000 kilometers, there is more ash accumulated in a DPF between regeneration intervals (for active regenerations) than soot (Sappok, Kamp, and Wong, 2012). The ratio of ash to soot in the DPF is even higher for continuously regenerated DPFs. Figure 18 (Aravelli *et al*., 2006) shows a DPF with channels clogged with incombustible ash matter.

Over the past several years, lubricant specifications have been in place to limit the sulfur, phosphorus, and ash levels in lubricants, as well as volatility limits in the CJ-4 oil category (McGeehan *et al*., 2006). The API, the European Automobile Manufacturers Association (ACEA), and the

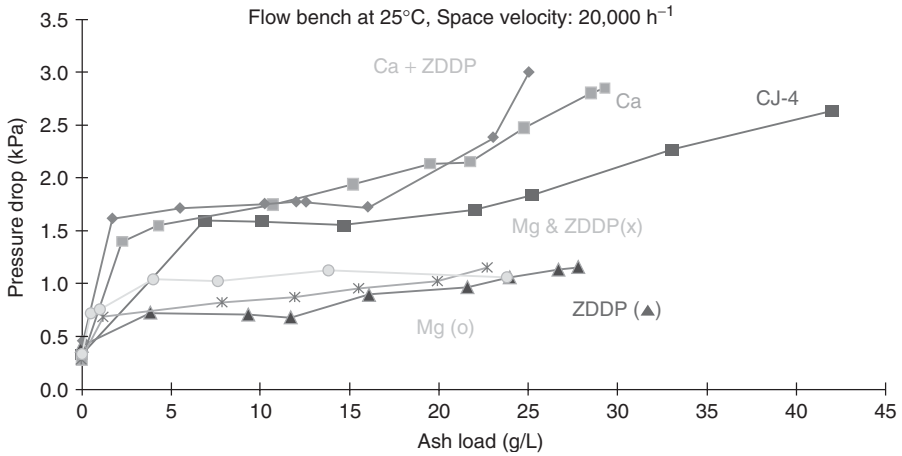

Figure 19. Sensitivity of pressure drop across diesel particulate filter for several lubricant formulations. (Reproduced with permission from Sappok, Munnis, and Wong (2012). © ASME.)

Table 1. International "low ash" engine oil specifications.

Specification	Sulfated ash (%)	Sulfur (%)	Phosphorus (%)
API CJ-4	1.0	0.4	0.12
ACEA E6	1.0	0.3	0.08
JASO DH-2	1.0	0.5	0.12

Japanese Automotive Standards Organization (JASO) have all introduced new "low ash" heavy-duty diesel engine oil specifications (Table 1).

Significant studies have been conducted to characterize the ash compounds in the DPF. It has been shown that the engine back pressure doubles in about 290,000 kilometers of normal operation (Bodek and Wong, 2007), and that the type of lubricant additive seems to have a difference in how DPFs are affected. Figure 19 shows very clearly that for the same mass quantity of ash in the DPF, verified gravimetrically, ash from calcium compound shows the highest flow restriction, while zinc compounds produce the least effect (Sappok, Munnis, and Wong, 2012).

Lubricant-derived sulfur compounds affect LNT performance, as SO_2 does compete with NO*x* for storage sites in the LNT system. However, desulfation cycles that will drive the occupation of catalyst sites by SO_2 can be designed. However, the repeated high temperature desulfation cycles could compromise the DPF substrate integrity in the long term. It is not clear that phosphorus chemically interferes with conversion efficiencies of NO*x* reduction systems. However, phosphorus affects the catalytic operation of diesel oxidation catalysts (DOCs), which are important in the conversion of NO to NO_2—a step that is important in both NO*x* reduction and soot oxidation.

Tremendous efforts are continuing to understand the characteristics of the lubricant-derived compounds in the emission aftertreatment systems, so that optimum formulations of lubricants and additives that meet the simultaneous requirements of emission control and adequate engine protection can be further developed. Moreover, these requirements are expected to continue to evolve as engine and aftertreatment systems advance to meet increasing fuel economy and tighter emissions standards in the coming decades.

ACKNOWLEDGMENTS

The author acknowledges and thanks the support of the many sponsors of a multitude of engine lubrication and lubricant-related programs at MIT, in which the author served as PI or co-PI in the past 25 years. The author is also grateful to the wonderful work of many graduate students and colleagues at MIT over the years that contributed to the understanding of the subject matter in this chapter.

Gas Aftertreatment Systems

James E. Parks II
Oak Ridge National Laboratory, Knoxville, TN, USA

1 INTRODUCTION

The internal combustion engine (ICE) serves a vast array of transportation needs. Modern ICEs are finely controlled to achieve optimal fuel combustion inside the cylinder; however, gaseous pollutants are emitted and need to be controlled to protect the environment and public health. This chapter describes the control of gaseous emissions from engines in the exhaust system with catalyst technologies.

2 POLLUTANT CONCERNS

During the combustion of fuel inside the engine cylinder, vaporized fuel is mixed with oxygen in air and oxidized to produce power. Although the process is highly controlled, combustion is not perfect and does not complete entirely; thus, some unburned or partially burned fuel products are emitted into the exhaust system as hydrocarbons (HCs) and carbon monoxide (CO) (see UHC and CO Formation and Models for more detail). Furthermore, during the high pressure and high temperature conditions of combustion, nitrogen (N_2) in the intake air reacts with oxygen in the intake air to form nitrogen oxide (NO) and nitrogen dioxide (NO_2) emissions that together are referred to as NO_x (*oxides of nitrogen*) (see NO_x Formation and Models for more detail). Together, HCs, CO, and NO_x are the primary "criteria" gaseous pollutants and the focus of emission control exhaust systems. Particulate matter pollutants are emitted by the engine, too, and in some cases, must be controlled in the exhaust (see Solid/Condensed Phase Aftertreatment Systems for more on the control of particulate matter emissions).

Emission regulations exist to insure that minimal amounts of HCs, CO, and NO_x pollutants are emitted into the atmosphere. Release of HCs, CO, and NO_x pollutants into the environment may cause various health and environmental effects that depend on the pollutant type, pollutant level, and often the atmospheric conditions where the pollution occurs. In the United States, the Clean Air Act, enacted in 1963 and 1970 with major amendments in 1977 and 1990, establishes the authority for federal regulations to protect the environment and, thereby, human health (http://epa.gov/oar/caa/caa_history.html). Current U.S. EPA (United States Environmental Protection Agency) emission regulations are known as *Tier 2 Exhaust Emission Standards* (http://www.epa.gov/otaq/standards/light-duty/tier2stds.htm.), and a new set of emission standards with lower required emissions from vehicles was proposed in 2013 and is known as "Tier 3".

2.1 Hydrocarbon pollution concerns

HC emissions consist of a variety of HC-based chemicals that are derived either directly or indirectly from fuel or oil in the engine. The health and environmental concerns are specific to the HC chemistry. Direct exposure to HCs can affect human health with health effects ranging from irritants for respiratory systems to carcinogens, which can cause cancer (http://www.atsdr.cdc.gov/phs/phs.asp?id=422&tid=75). Indirectly, HCs can affect human health by interacting with NO_x in the atmosphere to form ozone (Seinfeld and Pandis, 1997a), which affects respiratory systems and causes smog. In addition, smog limits the visibility in the environment and can have negative impacts on the economy especially for tourism-based companies.

U.S. EPA Tier 2 emission regulations refer to HCs as non-methane organic gases (NMOG) and include a wide range of HCs except for methane under this category. Specific species of HCs are more carefully monitored because of their potential harmful effects. The U.S. EPA defines 21 pollutant species as mobile source air toxics (MSATs) because of their potentially harmful nature (http://www.epa.gov/oms/toxics.htm). Formaldehyde is one of the MSATs and receives specific attention in emission regulations. U.S. EPA Tier 2 regulations require minimum levels of formaldehyde emissions to be met. Although formaldehyde is not generally present in fuel, it can be formed in the engine as an intermediate combustion product and thus, formaldehyde emissions can result in the exhaust.

2.2 CO pollution concerns

CO is a poisonous gas that directly impacts human health. CO exposure to humans can cause headaches, nausea, and other effects at low exposure levels. At higher levels, CO exposure can lead to death by limiting oxygen uptake (http://www.osha.gov/SLTC/healthguidelines/carbonmonoxide/recognition.html). While CO pollution dilutes readily in the atmosphere during normal driving conditions, its potential danger to human health requires careful control. Eventually, CO will react with hydroxyl radicals in the atmosphere to form CO_2, but the reaction leads to the formation of the hydroperoxyl radical HO_2, which reacts with NO to form ozone precursors (Seinfeld and Pandis, 1997b).

2.3 NO_x pollution concerns

The primary concern related to emissions of NO_x is the formation of ozone in the atmosphere. NO_x together with energy in the form of sunlight are directly involved in the chemical reactions to form ozone (Seinfeld and Pandis, 1997c), and ground-level ozone can have harmful effects on human respiratory systems. NO_x can also affect particulate formation in the atmosphere by forming nitric acid and reacting with ammonia to form ammonium nitrate particles (Seinfeld and Pandis, 1997d) (Figures 1, 2).

3 CATALYST-BASED AFTERTREATMENT SOLUTIONS

Careful and precise control of engine operation can minimize the amount of pollutants emitted by the engine, but

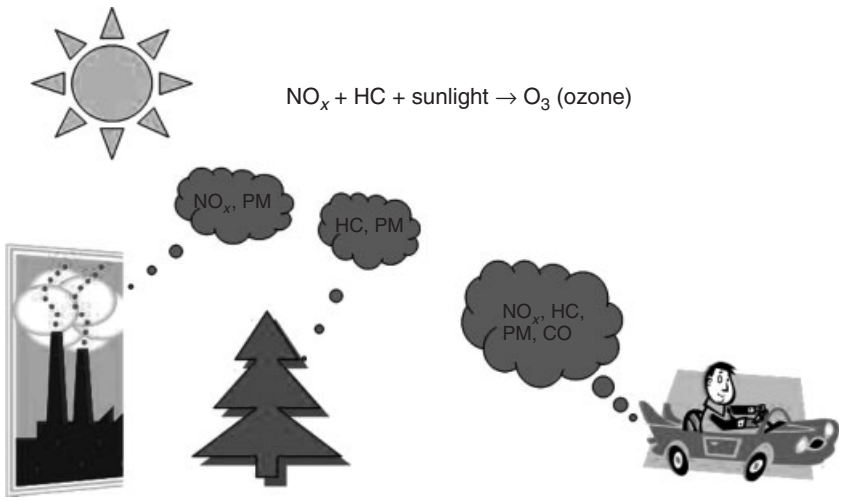

Figure 1. Pollutant emissions interact with energy in the form of sunlight in the atmosphere to form ground-level ozone.

catalyst-based aftertreatment is required to obtain near-zero levels of pollution emissions at the tailpipe of the vehicle. The term *aftertreatment* is used to note that the emission control is occurring postcombustion or downstream of the engine. Primarily, pollutant reduction with aftertreatment occurs by passing the hot engine exhaust over a catalyst or series of catalysts. The catalyst increases the rate at which the chemical reactions occur that consume pollutant species.

The catalyst, also commonly called a *catalytic convertor*, is made of a variety of materials that can both *function* and *survive* under the exhaust conditions over many years and hundreds of thousands of miles of operation. In general, the catalyst is composed of a substrate that is coated with a mixture of metal oxides and metals. The purpose of the substrate is to hold the active coating materials in the exhaust flow and maximize the interactions between the gases and the catalyst materials in the coating. The coated substrate is mounted in a metal can with a vibration damping thermally insulating fibrous material between the hard substrate and can to adsorb shock and provide room for the differential expansion of the metal can and ceramic part (Figure 3).

Substrates are typically made of the ceramic material cordierite, which has a low expansion coefficient that

enables durability against thermal expansion and shock. In some cases, substrates are made of metal foil, which is oxidized to form a surface that the catalyst coating can adhere to. In both cases, the substrate, alternatively called a *monolith*, is composed of thousands of small channels that the exhaust gas flows through. The walls of the channels are coated with the catalyst material, so that the exhaust gases interact with the catalyst as they flow along the length or "flow axis" of the catalyst. Ceramic substrates are manufactured with an extrusion process that forms an array of channels. Metal substrates are generally manufactured by rolling corrugated metal foil into a circular or elliptical structure that contains thousands of channels for exhaust flow. While more channels improve the surface area available for the catalyst coating, care must be taken to avoid too many channels and thick coatings, which restrict exhaust flow and increase backpressure on the engine leading to some loss in engine efficiency (Figure 4).

While the substrate forms the structural foundation, the coating contains the actual catalytic materials that accelerate chemical reactions; often, the coating is called the "*washcoat*".[1] In general, coatings are composed of a mixture of metal oxides and active components. The primary role of the metal oxides is to form a high surface area support to disperse the active components on the catalyst surface for maximum reactivity with the exhaust gases. Surface areas for the support metal oxides commonly exceed $100\,m^2/g$, and a coated substrate with these metal oxides can provide over an acre of surface area ($>4000\,m^2$) on a catalyst that can fit in one's hand. This large surface effectively enables the chemical reactions to occur between the exhaust gases and the catalysts when the exhaust is flowing at high rates over the catalyst in the engine exhaust system. In the manufacturing process, the coating materials are ball milled in an aqueous suspension that resembles paint in viscosity and color. The applied coating is dried and calcined (heated to a high temperature) to form a strong bond to the substrate. The milling process controls the size of the particles that make up the porous coating. High porosity improves gas diffusion into the coating layer to maximize the interaction between the exhaust and the catalyst surface.

The active components of the catalyst are coated onto the high surface area metal oxide support. Different materials form the active components for different catalysts. Common active components include precious noble metals such as the platinum group metals (PGMs) Pt, Pd, and Rh. These metals are unique in their ability to lower the activation energy of many chemical processes and thereby accelerate the kinetic rate of chemical reactions. However, while excellent catalytic materials, the PGMs, are also very expensive. In order to cost effectively utilize them in commercial products, PGMs such as Pt are finely dispersed over the high surface area metal oxide support to the point where Pt exists as tiny nanometer-sized balls on the coating surface. The high dispersion of Pt results in a high surface area of Pt per total mass of Pt applied and thereby maximizes the performance as a function of cost. Thus, the importance of the high surface area metal oxide support not only provides overall surface area to enable exhaust gas reactions to the surface materials but also provides a high surface area for effective dispersion of the active components across the surface (Figure 5).

During the development of catalysts, researchers utilize specialized tools to measure the surface area of both the support metal oxide and active components such as PGMs. A technique named "BET" after the work of three scientists Brunauer, Emmett, and Teller (1938) is utilized to measure the total surface area of catalyst coatings by determining the amount of N_2 gas that adsorbs on the surface. A similar technique measures the chemisorption of H_2 onto PGMs such as Pt to specifically measure the active component surface area. These measurements are routinely made by catalyst researchers and form the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

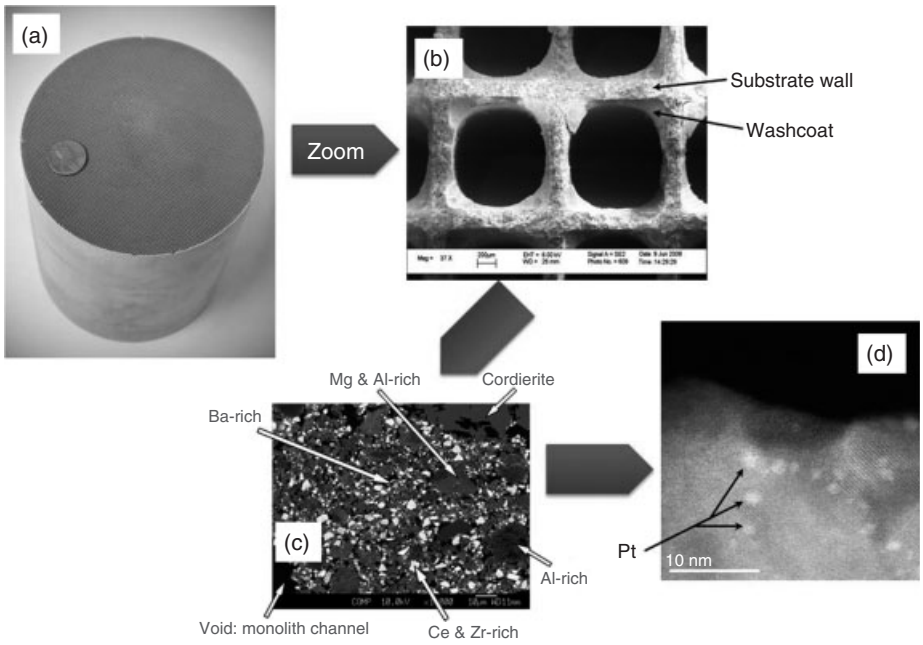

Figure 5. Various scales of catalysts. (a) A full-size catalyst contains hundreds of channels, called *cells*, per square inch of the catalyst face for gas to flow through. (b) Each cell contains an inner coating of catalyst materials collectively known as the *washcoat*. (c) The composition of the washcoat can be quite complex with 1–10 micron size particles of various metal oxides that serve different functions for the catalyst. (d) Ultimately, gases flowing through the catalyst interact with finely dispersed nanometer scale particles of platinum group metals and other active components to complete the chemical reactions that process the pollutant gases.

basis for practical development of catalyst technologies that depend on nanoscale materials.

In many catalysts, exhaust gases briefly chemically adsorb onto the active component where they react with other chemisorbed gases and then release into the gas stream. However, in some catalysts, the active component may also form a stronger chemical bond and effectively store an exhaust gas for further control of the chemical processes. For instance, in three-way catalysts, metal oxides such as ceria are used to store oxygen, which better enables the three-way catalyst to reduce NO_x pollutants. Thus, catalyst coatings tend to be a complex mix of various materials that often provide multiple aspects of functionality for treating pollutant species in the exhaust gas.

The critical physical and chemical reactions occur on the nanometer scale on the catalyst surface. Efficient interchange of gas species to the active catalyst surface sites is essential to enable the catalysis to occur. Limitations to the gas–surface interactions are due to kinetic and mass transfer issues. If the catalysis reaction rate is kinetically limited (or slow), the catalyst site will remain ineffective for other reactions, as the unreacted chemisorbed gas species block access to the surface site for other gas species. As temperatures increase, kinetic rates of reaction generally increase too. Mass transfer limitations occur when the gas species of interest cannot get to the catalyst surface site at a rate rapid enough to fully utilize the surface site. Diffusion into coating pores is one mass transfer limiting process. Once the gas does interact with catalyst surface site at the suitable temperature, the activation energy of the desired chemical reaction is lowered and the reaction can occur. The rate at which the catalyst sites can enable the reactions of the chemisorbed species and receive more gas species for more reactions is called the *turnover frequency* and is one parameter of interest in studying catalysis.

While in action on the vehicle, the catalyst is exposed to a wide range of conditions that challenge meeting the requirements for high emission control efficiency and durability. Cold vehicle starts in winter climates cause rapid extreme catalyst temperature changes. Transient driving conditions cause highly variable exhaust gas chemical conditions. In addition, vehicles driven over rough roads in all types of climates create challenging mechanical vibrations and stress conditions. All of these conditions need to be addressed through the design and control of the catalyst system while maintaining durability and longevity of the catalyst, so that emissions can be controlled over the useful life of the vehicle.

4 EMISSION COMPLIANCE TESTING (DRIVING CYCLES)

While a great deal of effort goes into the development of a catalyst, the complete vehicle is subjected to emission regulations and thus must pass emission compliance tests known as *driving cycles*. Driving cycle tests are conducted on a chassis dynamometer, which is similar to a treadmill for vehicles. During the drive cycle, the speed and load of the engine are varied by fixing the vehicle speed to a standard transient speed profile that mimics real world driving. An example U.S. EPA drive cycle is the federal test procedure (FTP). The FTP lasts 1874 s with vehicle speeds ranging from 0 to 57 mph. The test represents 11.04 miles of driving and includes a cold start (http://www.epa.gov/nvfel/testing/dynamometer.htm). Emissions over the course of the test are diluted with air and collected in bags, which are analyzed after the test for pollutants. The resulting emissions measured are expressed in mass (grams) per mile and compared to the emission standard (Figure 6).

A key challenge for virtually all catalyst technologies is the cold start portion of the drive cycle test. Catalysts are essentially inactive below 100°C. During cold-start conditions, the catalyst warms up but first must desorb condensed H_2O from the surface before becoming effective. Above 100°C, the catalyst surface is free from adsorbed H_2O but the catalyst will still not be very effective until the "light-off" temperature is reached. The *light-off* temperature is a term used to describe the point at which the kinetics of the catalytic reaction reach a level at which significant catalytic reactivity is present. It varies with catalyst technology and pollutant species. For instance, for a particular catalyst, CO may begin to oxidize at 150°C, but HCs may not start oxidizing to 220°C. As very little pollutant reduction occurs before light-off, emissions during the cold start portion of the drive cycle test are major contributions to the overall integrated emissions measured over the entire drive cycle. Thus, engine control strategies are designed to rapidly warm the catalyst, and catalysts are designed for improved low temperature performance (Figure 7).

5 DEGRADATION ISSUES AND DETERIORATION FACTORS

In addition to meeting the emission regulation level by demonstrating low emissions over the prescribed drive cycle test, catalysts must prove durability over the "full useful life" of the vehicle. The definition of useful life

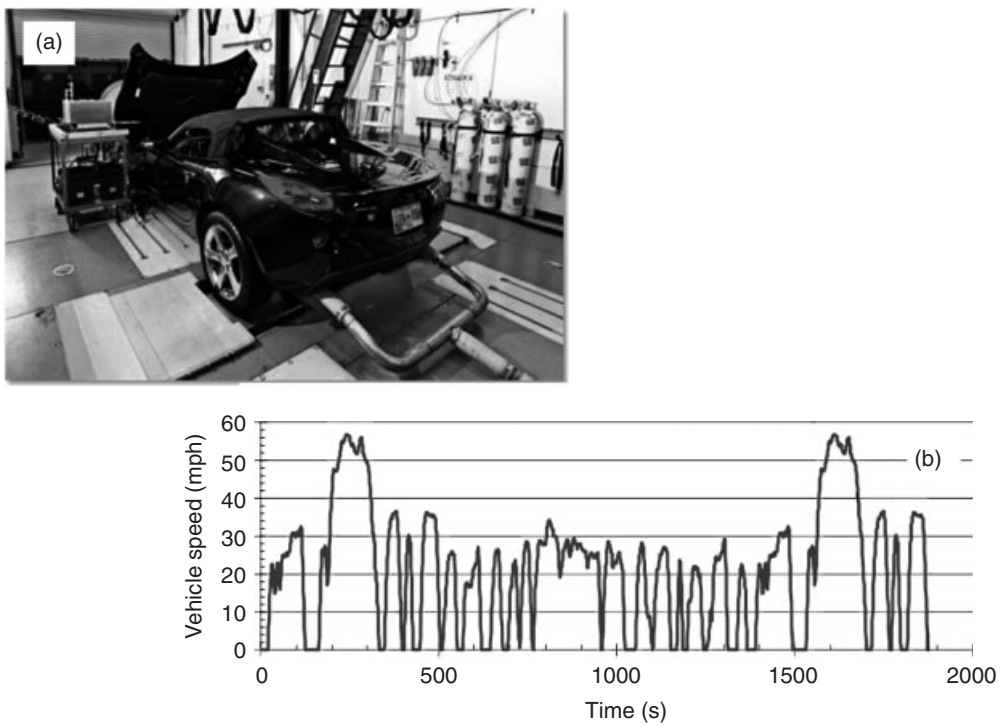

Figure 6. Emission compliance for passenger cars involves driving the vehicle on a chassis dynamometer (a) over a set driving cycle with transient speeds (b) and measuring total vehicle emissions.

DOI: 10.1002/9781118354179.auto130
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

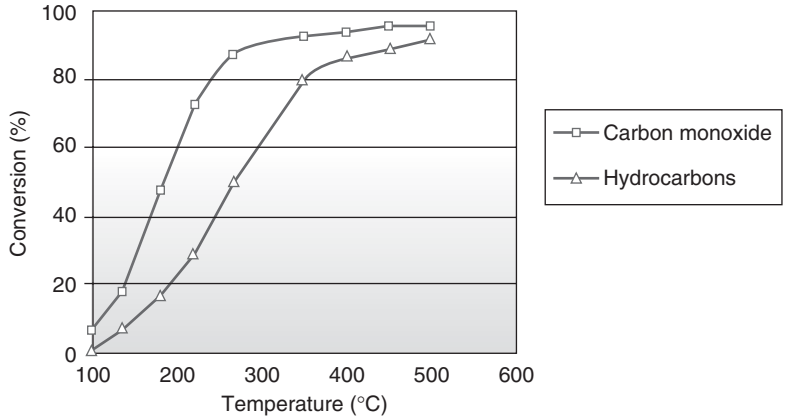

Figure 7. Example data showing the "light-off" in catalyst activity of CO and hydrocarbon conversion as temperature increases. At temperatures greater than the light-off temperature, excellent conversion is obtained. (From Nett Technologies Inc, n.d. Reproduced by permission of Nett Technologies Inc.)

is part of the regulation; U.S. Tier 2 emission regulations define full useful life as 120 k miles and also include a standard for 50 k miles (http://www.epa.gov/otaq/standards/light-duty/tier2stds.htm). In order to demonstrate catalyst durability to meet the useful life requirement, automotive companies together with catalyst suppliers perform extensive aging tests of catalysts on vehicles and on test rigs. The testing enables the measurement of the catalyst "deterioration factor," which expresses the loss in emission reduction efficiency per vehicle miles traveled (VMT). In effect, new catalysts must reduce emissions to a level significantly below the emissions standard, and the deterioration factor must be low enough that the rate of increase in emissions per VMT does not result in emissions higher than the standard at the end of the useful life period.

Many degradation processes can contribute to catalyst performance loss. The catalyst operates in a harsh environment with rapidly changing temperature and flow conditions. Furthermore, mechanical vibrations and shock experienced over the course of driving can potentially cause loss of the active catalyst coating. Studies of catalyst performance durability have identified several degradation mechanisms that include poisoning, fouling, thermal degradation, vapor compound formation, vapor–solid reactions, and attrition/crushing (Bartholomew, 2001).

Poisoning occurs when specific chemicals in the exhaust permanently degrade catalytic activity by covering the catalyst surface. An example poison is phosphorous, which is an additive in oil. Over time, some oil is consumed and combusted by the engine, which results in the release of phosphorous and other additive chemicals to the exhaust. The poison chemically bonds to the catalyst surface and prevents other gas species from interacting with the catalyst, thereby reducing catalyst effectiveness. Fouling is a similar process but is characterized by physical blockage of catalyst pores, which leads to similar damaging effects.

Thermal degradation affects almost all catalysts because of the harsh temperature exposure in automotive applications. When extreme high temperatures occur, the catalyst metal oxide structure can collapse and the coating can be severely compromised. However, careful thermal management generally prevents such catastrophic failure, and instead, the more common thermal degradation effect that occurs is sintering or the loss of dispersion of the active catalyst components (Figure 8). For example, the ideal catalyst has a well dispersed array of precious metal spheres distributed over the metal oxide surface to maximize the interactions with the exhaust gas; however, at high temperatures, these precious metal spheres can migrate and coalesce to form larger spheres, which have less total surface area and, therefore, lower overall catalytic performance. This effect is known as *Ostwald ripening* after the German scientist Wilhelm Ostwald (http://en.wikipedia.org/wiki/Ostwald_ripening#cite_note-1). Overall, careful control of the catalyst exposure conditions and design of durable catalysts must be combined to meet the durability required by regulations.

6 COMMON CATALYSTS FOR VEHICLE APPLICATIONS

The most common individual catalyst technologies for vehicle emission control are presented here with follow on sections for degradation issues and ongoing catalyst research and development challenges.

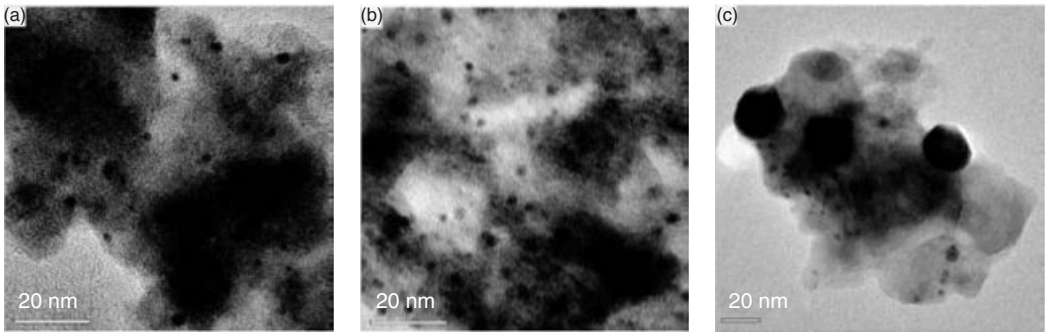

Figure 8. Electron micrographs showing the occurrence of sintering. With operation at high temperatures, the finely dispersed 1–2 nm Pt particles shown by the small dark specks in (a) agglomerate together to form larger particles (b) and eventually, particles >10 nm (c), which have significantly less surface area and, thereby, less catalytic activity. (With kind permission from Springer Science+Business Media: *Catalysis Letters*, Coarsening of Pt particles in a model NO_x trap, 93, 2004, pp. 129–134, G. W. Graham, H.-W. Jen, W. Chun, H. P. Sun, X. Q. Pan and R. W. McCabe.)

6.1 Three-way catalysts

Three-way catalysts are the most common catalysts on automotive vehicles. The name *three-way catalyst* comes from the fact that a single catalyst takes care of three pollutants (NO_x, CO, and HCs) simultaneously. The active components in three-way catalysts are PGMs. The PGM sites oxidize CO and HCs and reduce NO_x to N_2. Equation groups 1 through 4 show the main chemical reactions that occur.

[CO oxidation]

$$2CO + O_2 \rightarrow 2CO_2 \quad (1)$$

[HC oxidation, for example, HC propene]

$$2C_3H_6 + 9O_2 \rightarrow 6CO_2 + 6H_2O \quad (2)$$

[NO reduction]

$$2NO + 2CO \rightarrow N_2 + 2CO_2$$
$$10NO + 4HC \rightarrow 5N_2 + 2H_2O + 4CO_2$$
$$2NO + 2H_2 \rightarrow N_2 + 2H_2O \quad (3)$$

[NO_2 reduction]

$$2NO_2 + 4CO \rightarrow N_2 + 4CO_2$$
$$10NO_2 + 8HC \rightarrow 5N_2 + 4H_2O + 8CO_2$$
$$2NO_2 + 4H_2 \rightarrow N_2 + 4H_2O \quad (4)$$

Accurate control of engine air-to-fuel ratio (AFR) is critical to enable the TWC (three-way catalytic *converter*) to function. If the engine is operated with a fuel lean AFR, excess oxygen will be in the exhaust causing CO and HCs to be oxidized, but preventing NO_x from being reduced to N_2. Conversely, if the engine is operated with a fuel-rich AFR, NO_x is reduced to N_2, but CO and HCs are not oxidized. Only control of AFR to near stoichiometric conditions will allow simultaneous CO and HC oxidations with NO_x reduction (Figure 9).

In modern gasoline-fueled vehicles, the AFR is carefully controlled with feedback from exhaust gas oxygen (EGO) sensors in the exhaust system. Fuel injection into the engine can be adjusted based on the EGO sensor reading to create stoichiometric combustion. Typically, two EGO sensors are located in the exhaust system—one upstream and one downstream of the TWC. To further improve the efficiency of the TWC, the AFR of the engine is modulated in a narrow band around the stoichiometric combustion point. The modulating condition serves two purposes. Firstly, oxygen storage components of the TWC will adsorb and desorb O_2 from/to the exhaust, which effectively adds more accurate control to the stoichiometric condition on the TWC catalyst surface; this leads to lower NO_x, CO, and HC emissions. Secondly, by comparing the upstream and downstream EGO sensor signals, changes in the modulation of AFR due to the TWC can be monitored, and if damage occurs to the TWC, EGO signal analysis can determine whether the TWC has been damaged. This second function related to EGO sensing of air-to-fuel modulation is an important element of on-board diagnostics (OBD) for insuring continued emission control as the vehicle ages.

DOI: 10.1002/9781118354179.auto130
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

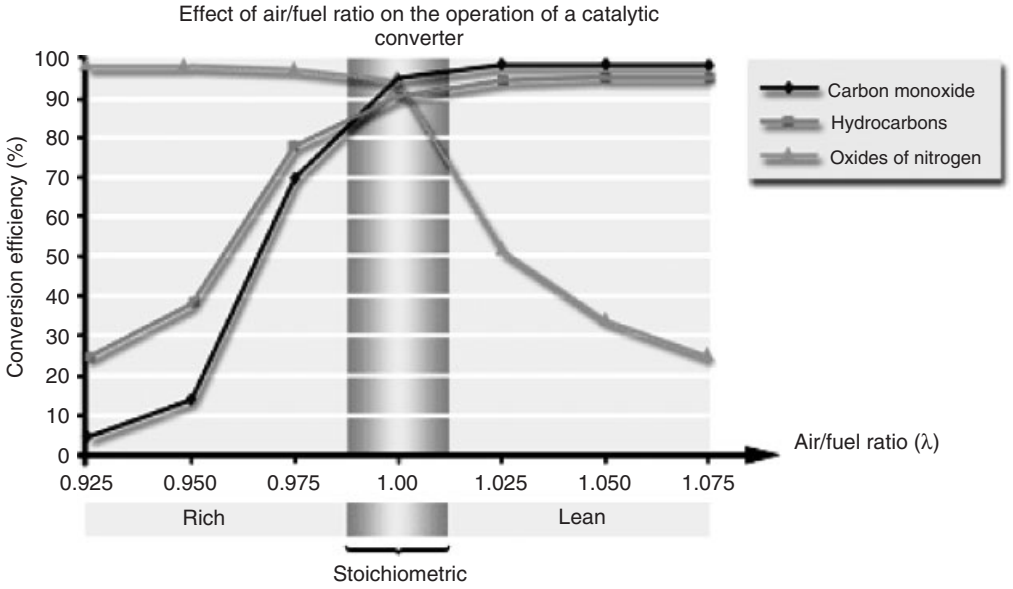

Figure 9. The three-way catalyst is named for its effective treatment of the three pollutants CO, NO_x, and hydrocarbons; however, proper air-to-fuel ratio control to stoichiometric combustion conditions must occur for >90% conversion of all the three species. (From Blackthorn, UK. Reproduced by permission of Blackthorn.)

For spark-ignited gasoline engine vehicles, the TWC is typically the only catalyst required to meet emission regulations. Often, two TWCs will be used in the exhaust system: one very close to the engine in the "close-coupled" position and the other further downstream in the "underfloor" position of the vehicle. The temperature of the close-coupled catalyst will increase more rapidly during cold start of the vehicle and enable the vehicle to have lower emissions during engine warm-up. More space is available on the vehicle for the underfloor catalyst, and lower overall temperatures in the underfloor position help enable better durability of the underfloor catalyst.

6.2 Diesel oxidation catalysts

Diesel oxidation catalysts (DOCs), as their name implies, control pollutant emissions from diesel engine vehicles. The primary pollutants that DOCs control are CO and HCs; the DOC oxidizes CO and HCs in the oxygen-rich exhaust that is produced by the fuel lean operation of diesel engines. In addition, some control of particulate matter is achieved by DOCs. As the diesel engine's main mode of operation is fuel lean, NO_x emissions reduction is not achieved by the DOC. Instead, additional catalysts are required to reduce NO_x from the engine exhaust. However, the DOC does play a critical role in supporting the NO_x reduction in downstream catalysts by oxidizing NO to NO_2; control of the NO to NO_2 ratio is important in optimizing NO_x reduction performance over downstream catalysts.

In addition to controlling CO and HCs, the DOC also serves other functions on diesel engine systems. Often, the DOC is utilized to heat the exhaust for thermal management of diesel particulate filters (DPFs), which require periodic heating to oxidize stored particulate matter. Such exhaust heating is achieved by adding extra fuel to the exhaust upstream of the DOC and converting the fuel to heat via exothermic oxidation reactions of the fuel over the DOC.

DOCs primarily consist of PGMs that are dispersed over high surface area metal oxide coatings. In some cases, the metal oxide support will be composed of oxygen storage materials. The primary goals of DOC design are to enable low emissions with minimal cost and to enable low temperature functionality. There is an extra challenge, as diesel engines have inherently lower temperature exhaust as compared with stoichiometric gasoline engines. Other than thermal management, the DOC requires little control by the engine system to function well for CO and HC emission control.

6.3 Selective catalytic reduction

A challenging emission control objective for automotive catalysts is reducing NO_x emissions from fuel lean engines. Engines that operate with lean fuel and air mixtures

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto130
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

inherently intake more oxygen than can be consumed in the combustion process; thus, the exhaust from lean engines contains significant (percentage) levels of oxygen. For NO_x emission control, the goal is to reduce the NO_x to N_2, but achieving NO_x *reduction* in the *oxidative* oxygen-rich exhaust atmosphere is chemically unlikely. Thus, special catalyst approaches are required to reduce NO_x in oxygen-rich exhaust. One such approach is selective catalytic reduction (SCR). In SCR, the catalyst utilizes a reductant gas to reduce the NO_x. Two SCR technologies based on different reductant chemistry are presented here.

6.3.1 Ammonia SCR

SCR can effectively be performed with ammonia (NH_3) as the reductant; this is the most common form of SCR-based NO_x control. During NH_3 SCR, NH_3 is stored on the SCR catalyst and interacts with NO_x on the catalyst surface to reduce NO_x to N_2 via the chemical reactions shown in Equations 5 through 7. NH_3 is an excellent reductant for NO_x and enables NO_x reduction in oxygen-rich exhaust over a broad range of exhaust temperatures. Typically, the NH_3 required is equal to the NO_x rate on a mole basis to achieve maximum NO_x reduction efficiency; the ratio of NH_3 to NO_x is known as *ANR* (*ammonia to NO_x ratio*) or "α" with $\alpha = 1$ being optimal. Equation 7 shows the "fast" SCR reaction that occurs with equal NO and NO_2 and has higher kinetic rates than the "standard" reaction (Equation 5) that only involves NO as a reactant.

["standard" SCR reaction]

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O \quad (5)$$

["NO_2" SCR reaction]

$$8NH_3 + 6NO_2 \rightarrow 7N_2 + 12H_2O \quad (6)$$

["fast" SCR reaction]

$$NO + NO_2 + 2NH_3 \rightarrow 2N_2 + 3H_2O \quad (7)$$

NH_3 can be stored on a vehicle in various ways for use in the emission control system. Gaseous tanks are one option for NH_3 storage but not commonly utilized because of potential dangers of ammonia leakage and challenges with storing large amounts of NH_3 in pressurized tanks. A newer technology utilizes solid-state materials for onboard NH_3 storage (Johannessen *et al.*, 2008). The material releases NH_3 when heated to control dosing of the NH_3 into the exhaust system. $SrCl_2$ is one of the solid-state materials utilized for the NH_3 storage. The solid-state NH_3 approach has safety advantages because of the containment of NH_3 even under rupture of the solid-state container.

The most common form of NH_3 SCR utilizes urea as the NH_3 storage medium. Urea is represented by the chemical formula $CO(NH_2)_2$. It is a solid material but readily dissolves in water. Thus, in practice for SCR applications, the term *urea* generally refers to an aqueous solution of urea. The industry standard concentration of urea in the solution is 32.5% by mass,[2,3] and the solution is commonly called *diesel exhaust fluid* or *DEF* (http://www.discoverdef.com/).

The urea solution is stored onboard the vehicle in a liquid form with some heating capability in the tank and lines to prevent freezing, which occurs at $-11^{\circ}C$. The urea solution is injected directly into the exhaust upstream of the SCR catalyst. Once in the exhaust, the urea solution evaporates and decomposes to NH_3 via the hydrolysis reactions shown in Equations 8 and 9. Of the two reactions, Equation 8 occurs more rapidly after the injected urea evaporates, and Equation 9 occurs slower and commonly occurs in the SCR catalyst (van Helden *et al.*, 2004). Careful engineering of the injection system and exhaust flow upstream of the SCR catalyst is required for the appropriate mixing of urea into the exhaust, so that the hydrolysis reaction can occur without urea deposits forming along the exhaust pipe.

$$CO(NH_2)_2 \rightarrow NH_3 + HNCO \quad (8)$$

$$HNCO + H_2O \rightarrow NH_3 + CO_2 \quad (9)$$

Once hydrolysis is complete, NH_3 is in the exhaust system and can be utilized by the SCR catalyst. The SCR catalyst is an excellent storage media for NH_3, and the storage functionality greatly improves performance under the transient conditions experienced during vehicle driving. By maintaining a steady supply of NH_3 on the catalyst via storage, the SCR catalyst can reduce NO_x emissions that vary rapidly with time without having to match injection of urea exactly to the rapid NO_x emission variations. The urea–SCR system containing urea storage, urea injection capability, and the SCR catalyst has been successfully commercialized on diesel engine passenger cars as well as heavy-duty diesel trucks. Often a DOC and DPF are used in conjunction with the SCR for control of CO, HC, and particulate emissions. An upstream DOC can also improve SCR performance by oxidizing some NO to NO_2 to achieve overall higher NO_x reduction efficiencies via the "fast" SCR reaction shown in Equation 7 (Figure 10).

SCR catalyst formulations have evolved over time as material advancements have occurred. Early SCR catalysts based on stationary power NO_x control were composed of vanadia (V_2O_5) on a titania (TiO_2) support; these catalysts were often modified with tungsten oxide (WO_3) or molybdenum oxide (MoO_3) and other materials for improved

performance (Bartholomew and Farrauto, 2006a). The V-based site acts as the catalytic reduction of NO_x with NH_3. Modern SCR catalysts are based on zeolite materials. Zeolites are a class of aluminoslicate materials that have unique pores in their structure on the scale of the size of gas molecules (Bartholomew and Farrauto, 2006b). They are also known as *molecular sieves* because of their ability to filter and/or trap various gas molecules of different sizes based on the zeolite pore size, which can be as small as 0.3 nm. Owing to these unique characteristics, they can adsorb large quantities of NH_3 for the SCR reaction. Metals are ion-exchanged with zeolite materials to add catalytic function. The most common metals added are Fe and Cu; thus, SCR catalysts are relatively lower in cost compared with catalysts that rely on PGMs. Cu-zeolite SCR catalysts generally have better low temperature NO_x reduction performance when compared with Fe-zeolite SCR catalysts (Figure 11). Further improvement has also occurred with the zeolite materials themselves. Original zeolites have been replaced with newer chabazite zeolite materials that have different structural features that significantly improve their thermal durability and limit the adsorption of HCs on the SCR catalyst. The adsorption of HCs can be detrimental to SCR performance by fouling the catalyst and preventing the SCR NO_x reduction reaction from occurring.

Although it is important to maintain a supply of NH_3 on the SCR catalyst during operation, the stored level of NH_3 is constrained by the control strategy to prevent excess NH_3 from being emitted downstream of the SCR catalyst. While not regulated as a mobile source, NH_3 emissions are not desired and can lead to NO_x formation in the atmosphere; moreover, NH_3 can react with sulfates in the atmosphere

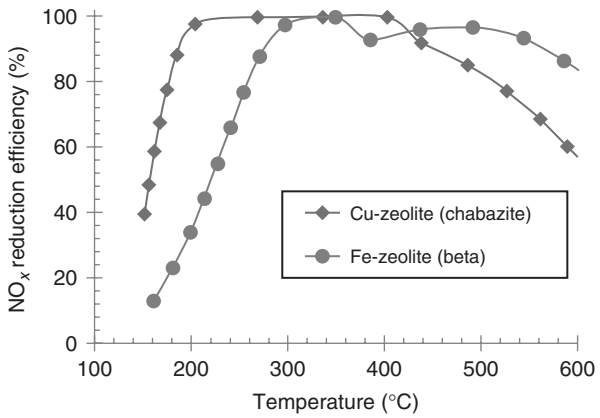

Figure 11. The NO_x reduction efficiency of two SCR catalysts as a function of catalyst temperature. The terms *chabazite* and *beta* refer to the type of zeolite that forms the basis for these catalysts.

to form ammonia sulfate particulate matter. To further minimize the potential for NH_3 emissions to occur, some SCR catalyst systems utilize a downstream NH_3 oxidation catalyst, which oxidizes the NH_3 to N_2 before the exhaust exits the tailpipe. NH_3 oxidation catalysts are typically based on Ni or Fe metals to provide a low cost oxidation function.

6.3.2 *Hydrocarbon SCR*

Although urea-based SCR effectively reduces NO_x in oxygen-rich exhaust, the requirement of a second tank on vehicles to store, handle, and refill adds cost and complexity to the system. Another form of SCR catalysis utilizes HC

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

reductants for the NO_x reduction process and is called *HC-SCR*. The intent of HC-SCR is to utilize the vehicle fuel itself as the reductant for the NO_x reduction process. As fuel contains a wide range of HC chemistries, the HC-SCR approach can be quite complex, and the HC-SCR efforts have primarily been limited to research activities. Research has shown that the effectiveness of HC-SCR approach is extremely dependent on the HC type. The most effective HCs are alcohols such as ethanol, and Ag-based catalysts supported on Al_2O_3 have been shown to give the highest NO_x reduction efficiencies. Other HCs studied include diesel fuel, propane, and propene; other catalyst materials studied include Pt on Al_2O_3 and Cu on Al_2O_3. A key challenge for all HC-SCR fuel and catalyst combinations is achieving high NO_x reduction efficiencies over a broad temperature range. Typically, peak NO_x reduction efficiencies do not exceed 80% and occur only over a narrow temperature window associated with the light-off temperature of the HC-catalyst combination.

Improving the NO_x reduction performance of HC-SCR has been a key objective for catalyst researchers. New approaches such as the addition of H_2 to the exhaust gas stream upstream of the HC-SCR catalyst and modification of catalyst formulations can greatly improve the low temperature NO_x reduction performance of the HC-SCR process (Burch and Coleman, 2002). Further research in this area is ongoing in hopes of achieving sufficient NO_x reduction efficiency to implement fuel-based SCR systems in the marketplace.

6.4 Lean NO_x trap catalyst

Another catalyst technology specifically designed for controlling pollutants from lean engines is the lean NO_x trap (LNT) catalyst. The LNT operates by storing or "trapping" NO_x on the catalyst surface when the engine operates lean; then, during brief rich modes of engine operation, the LNT releases and reduces the stored NO_x to N_2. The LNT is also known by the name *NO_x storage and reduction catalyst*, which also characterizes its operation. LNTs have been commercialized for diesel and lean gasoline passenger car applications with the lean gasoline commercialization occurring primarily in European countries.

An LNT catalyst is composed of materials similar to a TWC but with the addition of a storage component for NO_x. The catalyst is commonly coated to a ceramic monolith, as high coating levels are preferred to maximize NO_x storage capability. The coating composition is similar to the TWC with high surface area metal oxides supporting PGMs. The NO_x storage component is typically an alkali or alkaline earth material and is often based on K (potassium) or Ba (barium). The storage chemical form of the storage component changes during the operation of the LNT. For a K-based LNT system, K may be in the form of K_2CO_3 (potassium carbonate) originally then convert to KNO_3 (potassium nitrate) or KNO_2 (potassium nitrite), as the K stores NO_x under lean conditions. Then, under rich conditions, the NO_x is released from the K and reduced to N_2 with the K left as KOH (potassium hydroxide) on the surface, which quickly converts back to K_2CO_3 with the adsorption of CO_2 in the exhaust. The cases shown in Equations 10 through 12 are example reactions for a K-based LNT. In actuality, other surface chemistry forms of K may exist and differ based on nanoscale properties of the dispersed K and PGMs on the catalyst surface. Similar reactions occur for Ba-based LNTs with BaO also being a potential moiety of interest. Ongoing studies seek to precisely characterize these critical surface reactions that are central to the operation of the LNT technology (Broqvist *et al*., 2004; Toops, Smith, and Partridge, 2006).

[lean NO_x adsorption]

$$K_2CO_3 + 2NO_2 \rightarrow KNO_3 + KNO_2 + CO_2 \quad (10)$$

[rich NO_x release and reduction catalyzed by Pt]

$$KNO_2 + KNO_3 + 4H_2 \rightarrow 2KOH + N_2 + 3H_2O \quad (11)$$

[revert back to original carbonate form]

$$2KOH + CO_2 \rightarrow K_2CO_3 + H_2O \quad (12)$$

The LNT operates in a cyclic manner that parallels the surface chemistry changes of the catalyst. During lean operation of the engine or "storage phase," NO_x in the oxygen-containing exhaust travels into the catalyst where it is trapped by the alkali or alkaline earth component. The NO_x is bound to the alkali/alkaline earth material as a nitrate or nitrite species. Trapping of NO and NO_2 can differ, but the PGM in the LNT can also convert NO to NO_2 for greater trapping efficiency. In general, the NO_x trap reaction causes CO_2 to be released by the catalyst, as the carbonate form of the alkali or alkaline earth component changes. Ultimately, after a period of time, the LNT begins to fill up with NO_x. The upstream section of the LNT will become saturated with NO_x first, and as the downstream sections of the LNT fill with NO_x, NO_x begins to slip through the catalyst untreated. At this point, a process known as *regeneration* is initiated to reduce the stored NO_x to N_2 and ready the LNT for more NO_x storage (Figure 12).

The "regeneration" phase of the LNT cycle is achieved by creating net-rich exhaust conditions that contain reductant species and depleted oxygen levels. Typically, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto130
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

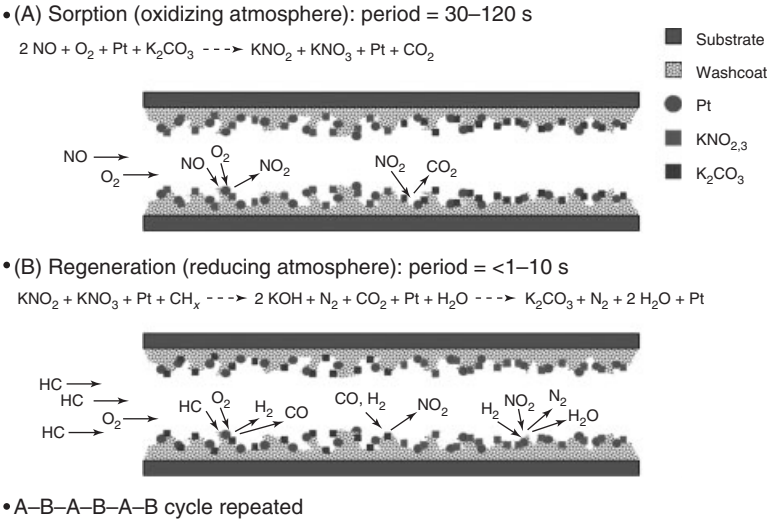

Figure 12. Diagram of the processes that occur for an LNT catalyst. The catalyst operates in a cyclic manner alternating between sorption and regeneration phases to trap and reduce NO_x, respectively.

net-rich exhaust is created by operating the engine with rich AFRs; this brings oxygen down to very low levels and creates CO, H_2, and HC reductants in the exhaust. Any stray oxygen can be further eliminated in the LNT by oxidation over the PGM component with the reductants. Once the rich exhaust conditions are achieved, the alkali/alkaline earth storage components will release the NO_x and the NO_x will be reduced to N_2 over the PGM component of the catalyst. The alkali/alkaline earth component rapidly reforms as a carbonate and becomes ready for more storage once the lean portion of the cycle begins.

The period of both the lean and the rich portions of the LNT cycle are carefully controlled to minimize the downstream pollutant levels. The lean period ends when NO_x slip downstream of the catalyst begins to occur; map databases or downstream NO_x sensors can be used by the vehicle to control the period end. The storage capacity depends on temperature and other parameters; LNTs are sized by application with typical lean periods ranging from 30 to 120 s. In contrast, the rich period is comparably short and generally lasts 1–5 s. As the overall objective of lean engine operation is to reduce fuel consumption, minimizing rich operation is important. Any extra fuel required to operate the engine rich for LNT regeneration is referred to as a *fuel penalty*. Shorter rich periods reduce the fuel penalty and also minimize unwanted pollutants downstream. During the rich conditions of regeneration, the NO_x is released rapidly from the alkali/alkaline earth components and can be rapidly reduced with the reductants in the exhaust stream; however, once the bulk of NO_x is released, lower levels of NO_x present in the reductant-rich exhaust stream tend to get further reduced to NH_3. Therefore, shortening the rich period to end just after the core NO_x storage sites are regenerated helps to minimize NH_3 emissions; smaller levels of N_2O emissions are also minimized in this manner. Furthermore, once the core NO_x storage sites are regenerated, less reductants are consumed; therefore, CO, H_2, or HCs can be released from the LNT. Although NH_3 and reductants can be oxidized by additional "clean up" catalysts downstream, the extra cost and complexity associated with this solution is not as preferred as the more cost-effective careful control solution (Figure 13).

Many aspects of LNT performance are affected by temperature. As mentioned, the storage capacity of the LNT varies with temperature. Different levels and mixtures of alkali/alkaline earth components are designed into LNTs to optimize storage performance for a given application. While higher levels of alkali/alkaline earth materials increase storage capacity, negative impacts can occur as well when the PGM component is physically covered by the alkali/alkaline earth materials. Moreover, at high temperatures, the alkali/alkaline earth materials, especially in nitrate form, can essentially melt and migrate into the cordierite substrate where they weaken the cordierite material. Ideally, the level of alkali/alkaline earth material is controlled to the point where evenly dispersed coverage of the metal oxide surfaces is achieved; this maximizes NO_x storage while minimizing other negative effects.

At higher temperatures, the nitrate species are not stable and NO_x storage diminishes. The actual temperature range where this occurs depends on the alkali/alkaline earth species type. Ba tends to have a higher temperature of

DOI: 10.1002/9781118354179.auto130
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

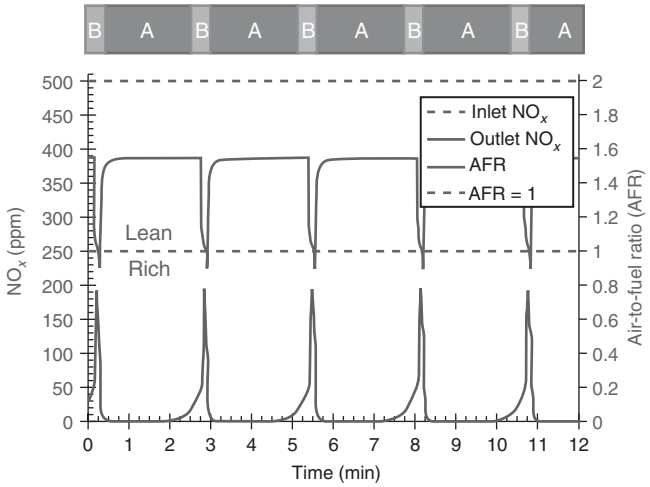

Figure 13. Plot of the NO_x and air-to-fuel ratio (AFR) for an LNT over the course of several cycles of operation. During the sorption phase ("A"), NO_x is trapped on the LNT under the lean conditions. Toward the end of the sorption phase, NO_x begins to slip past the catalyst as apparent by the rise in NO_x levels in the outlet NO_x data, and the regeneration phase ("B") must be conducted to clear the LNT for more NO_x trapping to occur. During regeneration, rich conditions enable the reduction of the stored NO_x except for a short spike of NO_x emitted as seen in the outlet NO_x data. On average over time, the LNT converted 97% of the inlet NO_x to N_2.

instability and is thus preferred in many automotive applications where high exhaust temperatures can occur.

At low temperatures, the LNT effectively stores NO_x, but the regeneration process can limit the overall performance. The release of NO_x is limited at low temperatures meaning that the LNT cycle can fail to completely regenerate the catalyst. The degree of regeneration that does occur on the LNT is also a function of the reductant chemistry in the exhaust. H_2 is the most effective reductant for regenerating the LNT at low temperatures, and CO is the second best reductant at low temperatures. HCs are often not effective for LNT regeneration below the 200–250°C range where the PGMs on the LNT have difficulty partially oxidizing the HCs to produce more reactive reductant species. The level and types of PGMs on the LNT have a major effect on low temperature LNT performance, as the PGMs affect the reductant utilization during regeneration and the NO to NO_2 oxidation efficiency, which effects low temperature NO_x storage (Figure 14). PGMs affect reductant utilization by enabling reforming-type reactions to occur such as the water–gas shift reaction (Equation 13) and steam reforming (Equation 14); these reactions alter the reductant chemistry mixture for LNT regeneration.

[water–gas shift reaction]

$$CO + H_2O \rightarrow H_2 + CO_2 \qquad (13)$$

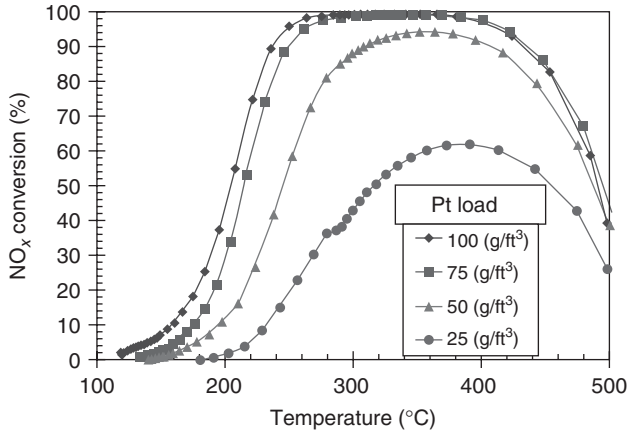

Figure 14. NO_x conversion as a function of temperature for LNTs with varying Pt load. As the Pt load decreases, conversion at the lower temperatures is lost first.

[steam reforming, for example, HC methane]

$$CH_4 + H_2O \rightarrow CO + 3H_2 \qquad (14)$$

A notable drawback to LNTs is their sensitivity to sulfur poisoning. Sulfur is a known catalyst poison and negatively impacts many catalytic processes, but for LNTs, sulfur has major impacts. Sulfur present in the exhaust, typically as SO_2, can be trapped by the alkali/alkaline earth storage components, and the resulting sulfate species that are formed on the catalyst surface are more thermodynamically stable than the nitrate or carbonate moieties. The more stable sulfates do not release SO_2 at typical regeneration temperatures, which prevents the sulfated alkali/alkaline earth site from trapping NO_x. Thus, upon significant sulfur exposure, the LNT cycle is effectively broken and overall NO_x reduction efficiency of the LNT is diminished. The negative impact of sulfur on LNTs is managed on several fronts. First, low sulfur fuels are required. For instance, the U.S. EPA reduced the maximum level of sulfur in diesel fuel from 500 to 15 ppm to enable emission control technologies such as LNTs. Even with ultra-low sulfur fuels, some sulfur will be present in the exhaust, and over time, sulfur will accumulate on the LNT (oil consumption by the engine also contributes to sulfur in the exhaust, as oil has high levels of sulfur). Once this occurs, the sulfur can be removed during vehicle operation in a process called *desulfation*. Desulfation is essentially the same process utilized for NO_x regeneration of the LNT except that the SO_x removal requires higher catalyst temperatures (typically >500°C) and longer time periods. Owing to the extra complexity of desulfation, it is only done as required at intervals of tens of hours or thousands of miles of operation.

As with all catalysts, the most effective application of the LNT catalyst technology is in an optimized system. The engine controls have a major effect on LNT performance, as the rich conditions for LNT regeneration are created primarily by engine operation. Fuel-rich combustion is monitored in the exhaust by oxygen sensors, and downstream oxygen and NO_x sensors also aid control of the LNT process. Engine operation is also controlled for careful thermal management of the LNT during both trapping and desulfation processes. In general, an upstream catalyst is paired with the LNT for optimal operation. In diesel engine applications, a DOC upstream of the LNT can assist in reductant control and thermal management of the LNT. In gasoline engine applications, a TWC is commonly placed upstream to control NO_x during stoichiometric operation and also aid in reductant optimization for LNT regeneration. Moreover, as DPFs require occasional high temperature exposure for regeneration, often the LNT desulfation process is coupled to the DPF process to reduce the overall fuel penalty for the emission control system.

6.5 Hydrocarbon trap catalysts (cold start)

HC trap catalysts are a specialty catalyst that can greatly assist cold start emission control. HC traps operate by trapping HCs during cold temperature conditions; then, at higher temperatures, the HCs are released and oxidized by another catalyst on the system. They are typically composed of zeolite materials or other high surface area metal oxides that can provide a large storage capacity for HCs. HC traps are designed for cold start emission reduction and function by trapping HCs during the warm-up phase of the driving cycle; subsequently, after warm-up occurs, the HCs are thermally desorbed from the HC trap and released to a downstream oxidation catalyst or TWC where they are oxidized to CO_2 and H_2O. Commercialization of HC traps has been limited to date but may increase, as lower exhaust temperatures from more efficient engines and stricter HC emission regulations demand more effective HC emission control.

7 ONGOING CHALLENGES

Although great progress in catalysis for automotive applications has been achieved, a multitude of challenges still exist in the application of catalysts for automotive emission controls. Current and future vehicles are addressing the dual challenges of better fuel economy and lower emissions in an atmosphere of overall concern for the environment. These challenges are spurring the introduction of new drivetrain technology as well as alternative fuels.

Hybrid electric vehicles (HEVs) are gaining ground in the marketplace and greatly improving fuel economy especially for city driving conditions where brake energy recovery enables greater efficiency. The engine for HEVs is predominantly a stoichiometric gasoline engine, and TWCs are utilized to control emissions. Future movement toward more electrification in HEVs including the plug-in hybrid electric vehicle (PHEV) may challenge the TWC technology during repeated near-cold start conditions, which are caused by greater time operating in pure electric modes. Thus, advanced catalyst technologies to address repeated starting in HEVs is of interest.

While growth of HEVs in the marketplace is occurring, vehicles with only ICE power sources are expected to persist in the marketplace. Several approaches will drive improvements in the fuel efficiency of ICE vehicles. Two major trends expected for emissions control of future ICE vehicles are lower exhaust temperatures and lean operation. Lower exhaust temperatures will result from vehicle fuel efficiency gains via both smaller boosted engines and more efficient combustion processes. In both cases, lower exhaust temperatures and increased time for warm-up result. The challenges for catalysts will be lower temperature operation and advanced strategies for cold start emission control.

Lean engine operation will be driven by the need for greater fuel economy, and as described, lean engine exhaust presents unique challenges for NO_x control. While urea-based SCR and LNT catalyst technologies have been commercialized for lean diesel and gasoline engine vehicles, more development and advancements can be made on these technologies that have relatively less experience on automotive applications in comparison to the mature TWC technology. Key development thrusts for lean engine emission controls will be expansion of the temperature window for operation, lower cost, and improved reductant supply and control. Better integration with other catalyst components is also an area of interest. In some cases, hybrid catalyst systems that combine different catalyst technologies may prove to give better emission control performance. One example system is the approach of combining an LNT catalyst with an SCR catalyst; NH_3 formed by the LNT during the regeneration process can be used for further NO_x reduction by the downstream SCR catalyst (Theis, Dearth, and McCabe, 2011).

In addition to drivetrain changes in the future, a growing variability in fuel supply is also occurring. Driven in large part by efforts to produce sustainable fuels from biomass feedstocks, new fuels are likely to have greater biofuel content, which results in changes in fuel chemistry and exhaust chemistry. The major exhaust gas chemistry changes will occur to HC emissions. Fuel HC chemistry differences will carry through to exhaust unburned HCs

and challenge oxidation catalysts during cold start, and some durability issues from impurities introduced in biofuel processing will need to be addressed.

A continued focal point for catalyst development will be lower cost. The competition for marketplace acceptance of new vehicle technologies will be affected greatly by price; therefore, efforts to minimize catalyst system costs will continue by the automotive companies and suppliers. Complicating the cost issue are highly volatile PGM prices that are affected by global supply and demand. Continued interest in the practice of optimizing PGM content and composition in TWCs and other catalysts (also known as *thrifting*) is expected to continue to allow products to manage swings in PGM pricing (Figure 15).

8 CONCLUSION

The collective total number of vehicle miles traveled (VMT has continuously increased over decades of years with a VMT in the United States exceeding three trillion miles in 2010. Catalyst technology has played a critical role in minimizing the emissions from vehicles that meet our transportation needs. Highly effective automotive catalysts have reduced pollutants from vehicles and protected our air quality, which has led to improved human health and an improved quality of living with clearer views of our natural surroundings. As global needs for transportation continue to increase, the automotive catalyst will continue to play a central role in enabling personal transportation in an environmentally sustainable way (Figures 16, 17).

1 INTRODUCTION

This chapter examines the issues surrounding the nature of particulate matter (PM), its regulation and the technology used for its control. The topic is introduced by first giving the legal and physical definitions of PM, followed by a discussion of the impacts of particulates and a brief overview of the regulatory landscape. The discussion then turns to the primary control technology for particulates, that is, filtration. The mechanisms of filtration are described along with the physical description of real-world approaches. Finally, this chapter concludes with a discussion of how particulate filtration devices are integrated into the overall vehicle system, the performance implications, and practical concerns regarding their reliability.

2 PARTICULATE MATTER FROM INTERNAL COMBUSTION ENGINES

2.1 What is diesel particulate matter?

If one would ask the typical motorist to describe diesel particulates, they would likely point to the exhaust stack of an older diesel-powered truck and highlight the cloud of black smoke that billows out as the driver does a hard acceleration. What the motorist is primarily witnessing are large carbonaceous particles formed from the incomplete combustion of fuel. This smoke is not unlike the soot that comes off the tip of a flickering candle flame. In reality, diesel particulate matter (DPM) is not so easily described. While it is true that a large weight percentage of the particulates are in the form of this visible smoke, there are many other components that are potentially more harmful and are not visible. Ironically, it has been pointed out that the large visible particles are potentially the least harmful as they settle out of the atmosphere quickly and are not easily transported into the alveolar sacks in the human lung during respiration. This observation is at the root of the current debate on regulation of PM, which is discussed in more detail later. In addition to the carbonaceous compounds (both visible and invisible), particulate emissions also include metals, ash, sulfates, and adhered organic compounds as illustrated in Figure 1. These components may potentially have even more severe health impacts than the black carbon. As such, the control of particulate emissions would ideally address all these constituents. It is not sufficient to simply eliminate the visible nuisance.

A further complicating fact of DPM is its dynamic nature. From the first moment of nucleation to the moment of deposition in the lung, the PM evolves and changes its characteristics. The life cycle of a DPM particle begins

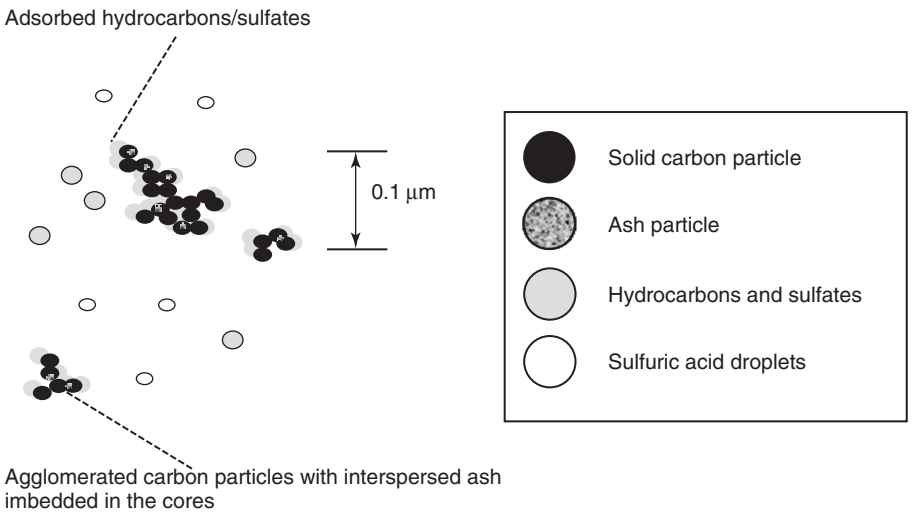

Figure 1. Image depicting the composition of diesel particulate matter.

in a high temperature, high pressure oxygen lean environment inside the combustion chamber. This particle is quickly quenched as it exits into the exhaust manifold and is transported through the exhaust system of the vehicle. At this stage, the particle may undergo agglomeration with other particles, it may adsorb vapor-phase compounds, or entirely new particles may begin nucleating. The actual specific sequence of events is controlled by the design of the vehicle, the fuel quality, operating conditions, and the presence of catalytic emissions control devices. As the particles exit the stack (or tailpipe), they undergo yet another sudden quench and a dramatic dilution within the atmosphere. At this point, the particles are transported through the air while undergoing further reactions with other compounds in the atmosphere under the action of sunlight, rain, and other naturally occurring PM. In addition to the PM emitted from the exhaust, new particulates may also form in the atmosphere from gas-phase emissions of sulfur and nitrogen compounds. These compounds interact with materials in the air to form what are known as secondary DPM. This evolution continues until the final moment of deposition. It is only at this moment in time when the specific nature of the particulate has a potential health impact. It quickly becomes apparent that the precise understanding of this evolution is a daunting challenge.

In the face of these uncertainties, researches have (and continue to) grapple with the most impactful way to monitor, control, and regulate diesel particulate emissions. At the heart of the debate are the precise conditions under which the particulate sample is derived and the metric by which the particulate standards are promulgated. Ideally, the sampling process would exactly mimic the entire transport chain of the DPM to the moment of inhalation and the metric would encompass the specific qualities of the DPM that have the most detrimental impact on human health. In practice, the research community has settled on standardized testing that can be done repeatably and cost effectively while capturing many of the salient phenomena described earlier, especially atmospheric dilution. Perhaps, the more contentious issue relates to the metric by which the standards are set. Traditionally, the metric has been gravimetric, that is, by the weight of the PM released, as this is a convenient and economic approach toward measurement. Clearly, this is driven more by the practicality of implementation than by specific health effect consideration. Because of this, there have been recent moves to implement a metric based on the particulate number density of the smaller diameter particles that are more likely to penetrate into the deepest recesses of the lung. The United States Environmental Protection Agency (US EPA) has not yet promulgated these standards. If they ever do become law, it has the potential to dramatically impact the technologies currently deployed for emissions control.

2.2 Why do particulate emissions need to be controlled?

Diesel particulates have both known and suspected impacts to our environment. There is little dispute that excessive soot causes issues with visibility and deposition on structures such as buildings and monuments. There is some recent speculation that DPM in suspension in the atmosphere may have an impact on global climate change but

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

there is still much work to be done before definitive cause and effect can be determined. The most recent results have indicated that the PM may have either a net cooling or a net heating effect depending on the specific characteristics of the particles (Solomon *et al*., 2007). While these are important environmental issues, they have not been the primary driver for regulation of particulate emissions.

The suspected impact that has been the dominant issue over the past several decades has been the impact on human health. There is a large body of evidence implicating DPM in human morbidity and mortality. However, the very complexity of particulates makes the precise understanding of human health effects challenging. The many studies of DPM health effects (mostly toxicological and epidemiological) have often been inconclusive and, in some instances, contradictory. However, when taken as a whole, the body of literature led the Environmental Protection Agency (EPA) to conclude that sufficient evidence existed to take regulatory action. What has become clear is that particular attention needs to be placed on the smallest particles, especially those which can penetrate into the deepest portions of the lung, as these are the most likely to contribute to potential health effects. Once in the alveolar sacks, these particles may attack the lung cells through either physical or chemical action. As alluded to already, the issues regarding size effects are of paramount concern and are driving ongoing discussions of PM2.5 number regulations in addition to the current PM10 gravimetric regulations (the numbers 2.5 and 10 refer to the effective diameters of the PM in micrometers). In 1997, EPA promulgated National Ambient Air Quality Standards (NAAQS) specifically for PM2.5 while retaining the existing PM10 standards. In 2006, EPA made further revisions to the NAAQS by tightening the PM2.5 standards to 35 mg/m^3 for a 24-h period while maintaining a 15 mg/m^3 annual standard. At the same time, EPA eliminated the annual PM10 standard in recognition of the fact that there was a lack of evidence linking these coarse particle exposures to health effects. It did, however, retain the existing 24-h PM10 standard of 150 mg/m^3. These modifications to the NAAQS are the first step toward the processes of implementation of potentially more stringent automotive emissions regulations.

In addition to size effects, there is concern with carbonaceous particulate material because of its propensity for adsorbing other chemical components, which may be most harmful. For example, polycyclic aromatic hydrocarbons (PAHs) and nitro-PAH are known carcinogens and have been detected on DPM. Organic compounds are also suspected of inducing allergic reactions and acting as irritants. The metallic particles found in DPM are known to participate in oxidation–reduction reactions while the smallest of particles ("ultra-fines") are believed to be able to translocate to other organs in the human body. The earlier work on health effects focused primarily on the carcinogenic aspects of PM, whereas more recent work has expanded to encompass cardiovascular effects and a focus on asthma and other degradations in lung function.

There remains much work to be done in understanding the impacts of PM on the environment and, especially, on human health. Pathophysiologic studies have typically involved model particles at high concentrations casting some uncertainties on the results. Similarly, epidemiologic studies have difficulties in precisely quantifying exposures to DPM as unique markers for diesel particulates are difficult to devise leading to uncertainties in exposure correlation. Regardless of these uncertainties, the preponderance of evidence does support some form of control over the release of excessive PM into the environment.

2.3 Legal definition

A fundamental understanding of the primary PM is critical for the design of efficient controls technologies, for example, its composition, morphology, and kinetics. These properties are required for the efficient capture and regeneration of filtration devices as described later in this chapter. For a comprehensive discussion of particulate formation and modeling (see Thermodynamic Analysis). However, the legal definition of DPM is just as important to the engineer as it sets the standard by which the effectiveness of the controls technology can be assessed. The EPA defines DPM implicitly through a prescribed sampling method and through the formulation of the legal standard, for example, 0.10 g/bHp-h. In this approach, particulates are anything that adhere to a filter patch (typically made of polytetrafluoroethylene, i.e., Teflon™, with 2 mm pore size) subjected to diluted exhaust flows and that add weight to the gravimetric measurement. The standards dictate that the exhaust is cooled and diluted to a temperature at or below 52°C in a system known as a *constant volume sampler* (*CVS*). The "grams" in the numerator do not discriminate as to size, density, or composition of the actual particulate material. It is simply the difference in weight between a dirty patch and a clean one. As the emissions standards have been reduced, this procedure has required modifications. Current engines, especially those equipped with particulate filters, now emit such low levels of PM that extreme care and precision must be used to obtain reliable and consistent gravimetric measurements. In fact, there have been concerns whether this testing approach is still reliable. To address these concerns, in 2007, the EPA modified the definition of PM by making numerous changes to the sampling procedure, most notably a requirement to maintain a narrow

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

range of temperatures on the filter face from 42 to 52°C. Despite these changes, meeting satisfactory coefficients of variation (COV) in repeatability tests remains a challenge. Clearly, an intimate understanding of this sampling process and the testing cycles are critical to the design engineers. At these very low emissions levels, even the subtlest changes to a design can have a profound impact on the measured results.

Over the years, researchers have spent countless hours developing an agreed on procedure for these particulate measurement tests. As stated earlier, the ultimate objective is for this single weight measurement to have a correlation with real-world hazardous particulate emissions. Regardless of the remaining uncertainties, a legal consensus has been reached and is prescribed in the Code of Federal Regulation (CRF). The clarity and stability of this agreement is critical to engine and vehicle manufacturers as it provides the basis for the design and optimization of the emissions control systems. For specific details of the CVS sampling procedure, the reader is directed to Title 40 of the CFR at the National Archives and Records Administration (Note: access to the CFR can be found at http://www.gpoaccess.gov/fr/index.html).

2.4 Regulation standards

The tremendous complexity of DPM regulation standards throughout the world prohibits a detailed survey in this work. The reader is directed toward the relevant regulations for the class of vehicle and the specific locale of interest. In the United States, the federal regulations for automotive particulate emission standards, as with the test procedures, are also found in Title 40 of the CFR and are promulgated by the EPA. The EPA maintains web sites that are valuable sources of information, and the interested reader is encouraged to explore those resources. A brief overview of the topic is given here to give a general sense of the approach, especially as it pertains to the design of particulate controls systems.

Typically, vehicle emissions regulations are set at the national level, as vehicles are mobile sources that often travel across regional boundaries. The United States has a notable exception in the authority that has been given to the State of California's Air Resources Board (CARB). This has a historic origin rooted in the fact that CARB promulgated regulations before the formation of the EPA and was, thus, "grandfathered" into the federal program. Both the CARB and EPA programs share many similar attributes although the CARB standards tend to be somewhat more stringent. Both programs partition the transportation sector along functional lines. Standards for on-road vehicles are separated from standards for off-road. Further distinctions are made within each category according to use. The on-road standards are largely divided into light-duty (LD) and heavy-duty vehicles. The off-road vehicles are divided into functional areas such as rail, marine, aircraft, and specialty vehicles such as mining, agricultural, and construction. This final category is typically further subdivided by horsepower ratings. For the on-road categories, the primary subdivisions are based on gross vehicle weight with numerous variations in each subdivision. The need for this complexity in regulation is unfortunate but understandable when viewed in light of the realization that each segment has very unique attributes and market drivers. Similarly, despite long-standing efforts at global standardization, global regulations are varied and reflect diverse geographical and historical influences.

Although specific regulations are unique, they all share general features that are ubiquitous. All regulations attempt to test the engine or vehicle in ways which best represent the actual in-use application. Countless studies have been performed to determine the drive cycles that would be most applicable. For particulate regulation, the transient cycles are most problematic as sudden, hard accelerations are the source of the majority of emitted DPM. In addition, all regulations have useful life provisions that set durability targets for the emissions controls system. Of particular concern to diesel particulate filtration are limitations on maintenance intervals as this has implications on ash build up in the devices. Many regulations have mandates for on-board diagnostics (OBD) to ensure the viability of the control system while in operation. These mandates implicitly drive high reliability standards while proper methods of sensing filtration device effectiveness are an active area of research. Finally, most regulators employ multiple test procedures that force stringent product variability requirements.

For illustrative purposes, the on-road heavy-duty segment will be briefly described, as it has been the segment of the transportation market at the forefront of particulate regulations in the United States.

Heavy-duty vehicles in the United States are defined as vehicles exceeding a gross vehicle weight rating (GVWR) of 8500 lbs (3855 kg) [note: CARB definition is 14,000 lbs (6350 kg)]. This category consists primarily of vehicles involved in the enterprise of moving large volumes and/or mass of materials. The tremendous variety of forms has led to the need to certify the engines as opposed to the vehicles themselves. In this segment, engines are certified by the engine manufacturer on motoring dynamometers in specialized test cells equipped with constant volume sampling equipment as described earlier (see Engine Performance and Exhaust Emissions for discussion on test cells and emission measurements, respectively). Furthermore, in this

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

segment, the emissions standards are normalized by the horsepower output of the engine. This is done in recognition of the primary function of the vehicles, that is, their function is to do work. In contrast, LD vehicles are dominated by passenger cars and light trucks where the entire vehicle is certified and the emissions standards are weighted by miles, for example, grams per mile. The heavy-duty segment is further divided into three categories by GVWR. Of these, the heavy heavy-duty diesel engines (HHDDEs) are the most numerous and are defined as vehicles above 33,000 lbs GVWR, typified by the line-haul tractor-trailers (aka "18 wheelers"). Historically, engines in this category would undergo the "transient FTP (Federal Test Procedure)" while the exhaust was diluted, then measured via filtration in a CVS tunnel. This transient test requires a motoring dyno that can not only adsorb energy but also drive power into the engine to simulate vehicle decelerations. This test cycle contains four unique portions that were derived from three individual cycle simulations (the fourth portion is a repeat of the first portion) as illustrated in Figure 2. They attempt to simulate driving in urban settings of New York City and Los Angles as well as a freeway portion in Los Angles. Combined, these portions total 1200 s of prescribed speed and torque as a percentage of rated values.

Beginning in 1998, two additional tests were incorporated and are run in addition to the transient FTP. The first is known as the *supplemental emission test* (*SET*). The emission limits are the same as for the FTP test but the SET is a steady-state test that attempts to better simulate line-haul operations on the freeway. The second test is the not-to-exceed (NTE) test. This test attempts to cap maximum emissions in a prescribed operating regime of the engine and is run in both steady and transient modes with varying ambient conditions. As of 2007, the particulate standards for heavy-duty trucks in the United States are 0.01 g/bhp-h. This level must be achieved on both the transient and SET tests, whereas the NTE limit is a factor of 1.25 higher. For additional details on the US regulatory standards, the reader is directed to Title 40 of the CFR at the National Archives and Records Administration (note: access to the CFR

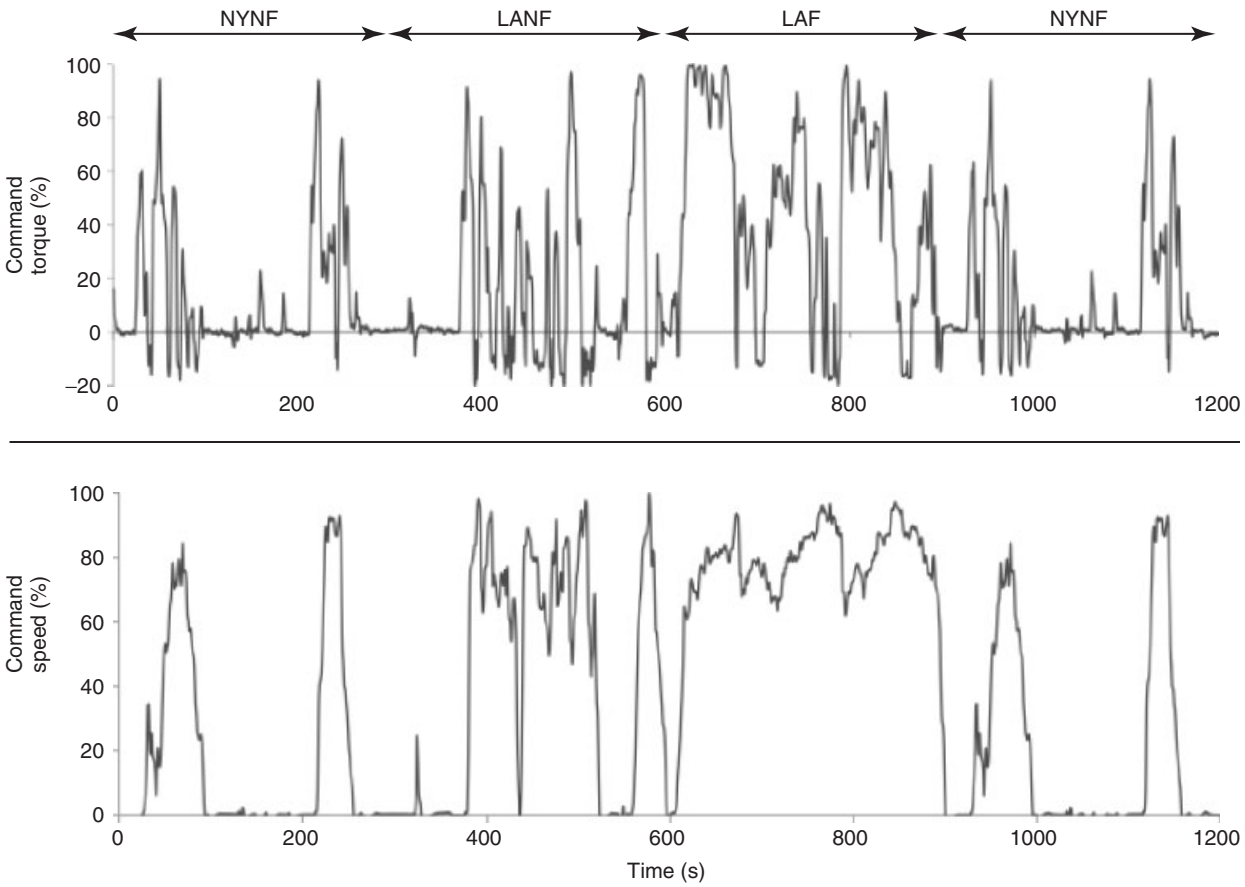

Figure 2. The US EPA heavy-duty transient Federal Test Procedure. NYNF is the "New York Non Freeway" section. LAF is the "Los Angles Freeway" section. LANF is the "Los Angles Non Freeway" section.

can be found at http://www.gpoaccess.gov/fr/index.html or through the EPA web site).

Taken as a whole, the three test cycles attempt to ensure that particulate control is maintained throughout the entire operating range of the engine. Anomalous release at off-cycle operating points is restricted and transient operations are thoroughly covered. Little leeway is given for designs that attempt to simply optimize to the original transient certification cycle.

2.5 Control of diesel particulate emissions

Over the years, the primary approach to reducing particulate emissions has been through the control of its initial formation in the combustion chamber. Tremendous advances were made early on through improvements in air handling and fuel injection systems. As described in earlier chapters, higher injection pressures, optimized swirl, four valve cylinder heads, central vertical injection, and combustion chamber designs helped improve the mixing of the fuel with the air in the cylinder. Similarly, air handling equipment, such as variable geometry turbocharging, helped optimize air/fuel ratios to control particulate formation. In the future, continued improvements in combustion systems will likely further reduce particulate formation. Advanced fuel systems employing rate shaping and/or multiple injections will further optimize mixing, whereas strategies enabling low temperature combustion [e.g., PCCI (premixed charge compression ignition)] will help eliminate stratification of air/fuel mixtures. Ultimately, however, particulate emissions standards were reduced to levels that required additional control. Most significant were the changes to ultralow sulfur fuel (which lowered sulfate particles and allowed catalyzed emission control systems) and the use of physical filtration systems in the exhaust stream, that is, diesel particulate filters (DPFs). Wide-scale introduction of these devices in the United States began with the implementation of the 2007 heavy-duty on-highway rulemaking by the EPA. The fundamental processes associated with filtration in such devices are discussed in the next section followed by a brief discussion of practical issues encountered in these devices when deployed on vehicles.

3 DIESEL PARTICULATE FILTRATION

3.1 DPF overview

3.1.1 Description of a typical DPF

A number of different materials and configurations have been proposed as DPFs, but porous ceramic honeycombs

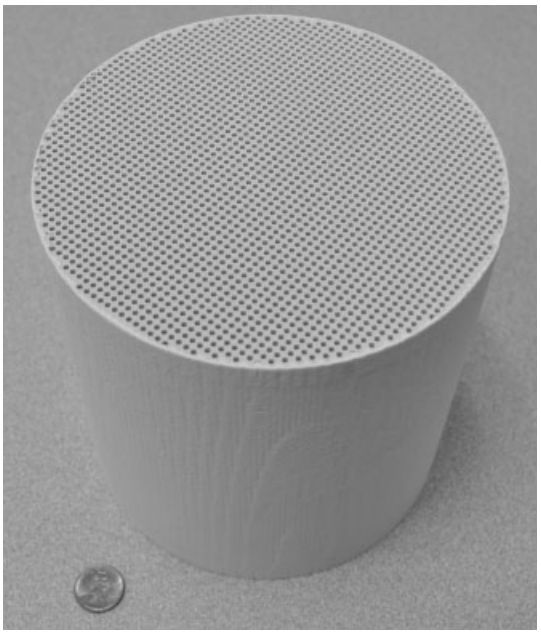

Figure 3. Ceramic diesel particulate filter.

(Figure 3) are currently the dominant technology for new cars and trucks. These devices evolved from the flow-through catalyst supports used in three-way catalytic converters on gasoline vehicles. Alternate channels are plugged at either end of the monolith to force the exhaust flow through the porous filter walls, as shown in Figure 4.

Typical properties of commonly used filter substrates are as follows

- wall porosities of around 50%
- mean pore sizes of around 10–20 μm
- filter wall thicknesses in most applications fall within the range 0.30–0.48 mm (12–19 thousandths of an inch)
- filters are available in sizes ranging from 143.8 mm (5.66 inch) in diameter by 152.4 mm (6 inch) long, for LD automotive applications, to 508.0 mm (20 inch) in

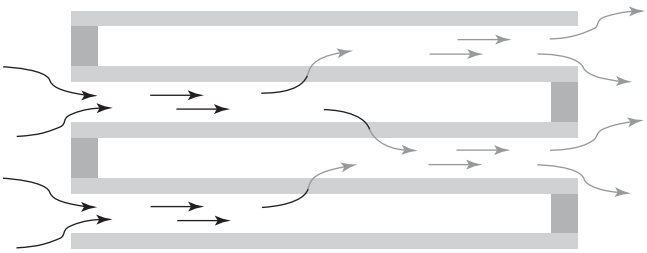

Figure 4. Exhaust flow through a ceramic DPF.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

diameter by 381.0 (15 inch) long, for large displacement heavy-duty applications
- 31 cells per square centimeter (200 cells per square inch) is a common channel density, but other cell densities are also available (Corning, 2010a).

3.1.2 Basic operation

As soot collects in a DPF, the backpressure increases. Accumulated soot must be burned away before the backpressure becomes excessive. This process is referred to as *filter regeneration*. Some oxidation of the soot in the filter happens during normal operation (passive regeneration), but rates are dependent on exhaust temperature and composition. In many systems, it is necessary to periodically raise the exhaust temperature to insure oxidation in order to reduce the inventory of soot in the filter (active regeneration).

3.1.3 Design goals

A DPF must have high enough filtration efficiency to allow the vehicle to meet particulate emissions limits. Backpressure must be minimized over the entire operating cycle in order to limit the negative impact on fuel economy. Similarly, maximizing overall system efficiency requires keeping the amount of energy used to raise the exhaust temperature during active regenerations to a bare minimum. Balancing these competing goals is a significant challenge for designers of DPF systems.

The total backpressure caused by a DPF unit is the sum of several resistances to flow, including entry and exit effects, resistance to flow down the inlet and outlet channels, and resistance to flow across the soot layer and filter wall (Konstandopoulos and Johnson, 1989; Masoudi, 2002). The relative importance of each of these resistances depends on the system design and operating parameters. Higher cell densities not only lead to higher channel resistance but also provide more filter area per monolith volume. Flow resistance through porous media, such as soot and filter substrates, is often expressed in terms of permeability (Masoudi, 2002), as described in Equation 1.

$$\frac{\Delta p}{t} = \frac{\mu v}{k} \tag{1}$$

where Δp is the pressure drop (N/m^2), t is the thickness of the layer through which the flow is passing (m), μ is the dynamic viscosity ($N{\cdot}s/m^2$), v is the velocity of the flow (m/s), and k is the permeability (m^2).

An approximate permeability value for a cordierite filter wall is 3E-13 m^2 (Konstandopoulos *et al.*, 2000). Permeability becomes greater for larger pore sizes and higher porosities (Geankoplis, 1993). This means that the resistance of a clean filter can be lowered using a substrate with higher porosity and larger pores. Unfortunately, these features would also lower the clean filtration efficiency.

Durability is also a very important design consideration for DPFs. Ceramic monoliths are subjected to stresses during canning for mounting in exhaust systems. They can also experience high temperatures and steep temperature gradients during active regeneration events. Improper management of regenerations can lead to temperatures above the substrate melting points. Thermal gradients can cause abrupt cracking, whereas thermal cycling may lead to long-term degradation of mechanical properties. High melting points, high strength, high thermal capacitance, and low coefficients of thermal expansion (CTE) are therefore desirable from the standpoint of mechanical durability.

3.2 Soot filtration

3.2.1 Capture mechanisms

In filtration, suspended particles in the fluid are removed when they adhere to the solid structure of the filter medium. If particles had infinitesimal size and followed the fluid streamlines perfectly, no contact would be made with the walls of the filter medium pores, and none of the particles would be captured. Several physical mechanisms bring real particles into contact with the solid structure of the filter medium. Which mechanisms come into play in a given system depends on particle size, the geometry of the porous filter material, and a variety of other factors. Usually, one or two mechanisms dominate for particles of a given size. Important capture mechanisms include

- Diffusion: Diffusion moves particles between streamlines via the random Brownian motions arising from collisions with individual gas molecules. Diffusion capture often dominates for the smallest aerosol particles.
- Interception: Interception refers to the capture of particles that follow fluid streamlines almost perfectly, but are brought into contact with solid surfaces because of the finite size of the particles. In other words, capture by interception occurs when a particle's center of mass follows a streamline that passes within one particle radius of a solid surface. Interception tends to be important for particles of intermediate size.
- Momentum: A particle's inertia may cause it to move between fluid streamlines as they change direction

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

moving through a tortuous network of pores. This mechanism becomes important for heavy particles moving at high speeds.
- Gravity: Gravity forces cause heavy particles to drift downward within the flow field. This mechanism is often called *settling* in aerosol systems or *sedimentation* in liquid systems and becomes important for heavy particles in regions of slower flow.
- Other mechanisms, such as thermophoresis and electrostatic attraction, can also dominate in aerosol systems where the associated forces are present.

For flow rates and fluid and particle properties typically seen in DPF systems, the diffusion and interception mechanisms are usually considered to be the most important (Konstandopoulos and Johnson, 1989).

A unit collector model uses a simple shape to represent elementary obstructions making up a porous filter medium (Elimelech, 1995). Cylindrical unit collectors are often used to represent fiber filters, whereas spherical unit collectors are often used to represent granular beds. The flow field around the unit collector is usually assumed to be adequately approximated by some known analytical solution. This allows estimates to be made for capture rates of particles moving with the fluid flowing around the collector. Capture rates are estimated for fundamental capture mechanisms individually using simplifying assumptions, and then the capture rates are summed to estimate the total efficiency. Figure 5 illustrates several mechanisms for particle capture on a spherical unit collector. Unit collector models have been used extensively to predict DPF behavior and explain experimental data (Konstandopoulos and Johnson, 1989; Miyairi *et al*., 2006; Thalagavara *et al*., 2005; Tandon *et al*., 2010).

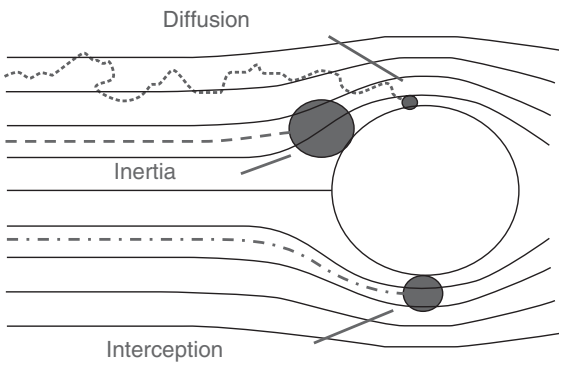

Figure 5. Several mechanisms leading to particle capture on a spherical unit collector.

3.2.2 *DPF system mechanics*

Soot deposits have very high porosities, between 90% and 99%, depending on operating conditions (Konstandopoulos, Skaperdas, and Masoudi, 2002). However, as the feature sizes of the soot particles are as small as tens of nanometers, soot permeability is much lower than that of a clean DPF wall, perhaps between 2.0×10^{-15} and 5.0×10^{-14} m^2 (Konstandopoulos, Skaperdas, and Masoudi, 2002; Suresh, Khan, and Johnson, 2000).

When a clean DPF is first exposed to particle-laden exhaust, there is some penetration of the soot particles into the porous filter wall. This is referred to as *depth filtration*. Initially, soot can form a thin coating on the inside pore surfaces, resulting in modest increases in backpressure per mass of soot captured. This is not always seen in practice, however, because the soot quickly begins to block pore throats within the medium. This blockage results in more dramatic increases in pressure drop per mass captured, as the soot deposits form in locations where flow restrictions result in high fluid velocities. At some point, all of the pore throats on the upstream filter wall surface become blocked, and soot begins to accumulate as an even cake on the filter wall, which is referred to as *cake filtration*. Backpressure then increases less quickly per mass of soot collected, as the incremental soot volume is now spread over a relatively even layer, where fluid velocities are lower than in the pore throats (Merkel *et al*., 2003). These stages of filtration are illustrated in Figure 6, which shows a computational simulation of the pressure drop through a silicon carbide (SiC) DPF wall as a function of filter loading.

From the description earlier, it can be seen that not all of the soot trapped in a filter contributes equally to

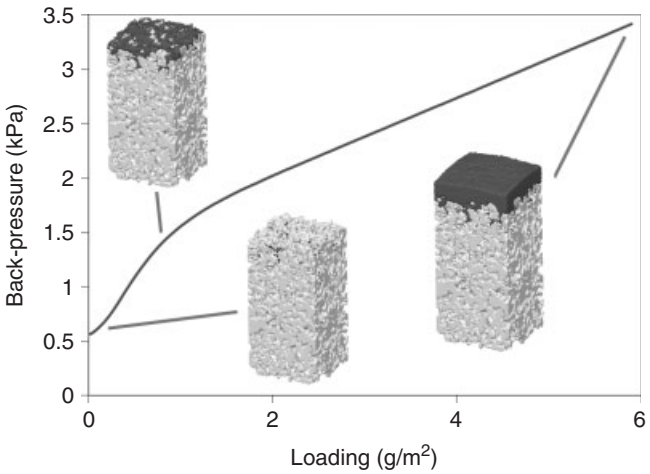

Figure 6. Pressure drop through a silicon carbide DPF as a function of filter loading.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

flow resistance. One practical result is that it is difficult to estimate the soot inventory in the DPF solely from the backpressure. Hysteretic effects can occur when operating conditions cause changes in the distribution of soot with respect to the filter walls. For example, passive regeneration can burn away soot within pore throats, whereas the soot cake remains intact because of continuing collection of new soot. In this case, the observed backpressure could decrease significantly, whereas the soot inventory in the filter remains constant (Premchand *et al*., 2007).

3.3 DPF regeneration

3.3.1 Soot oxidation

Removal of soot by oxidation is a requirement for continued operation of a DPF. Lean combustion in diesel engines means that there is ample oxygen present in the exhaust stream for oxidation of soot. Unfortunately, reaction rates at exhaust temperatures are generally too low to keep up with rates of soot accumulation. Exhaust temperatures must therefore be raised significantly to initiate soot combustion by oxygen in the filter, either by modifying engine operation or by injecting fuel into the exhaust stream before an upstream oxidation catalyst. Soot can also be oxidized by NO_2 in the exhaust. Reaction rates are much faster than for oxidation by oxygen, so NO_2 oxidation is very important for passive regeneration at normal exhaust temperatures.

Regeneration strategies that depend heavily on the participation of nitrogen oxide (NO_x) can require a minimum ratio of NO_x to soot in the engine-out exhaust. As NO_x is also a regulated pollutant, downstream NO_x abatement processes may be necessary to comply with emissions standards. As fuel efficiency, soot production, and NO_x production cannot be independently set by engine design and operation, close coordination is necessary between engine and aftertreatment engineers to achieve a system that balances competing factors.

The rate of soot oxidation (mass per time) at a given temperature and exhaust composition is proportional to the total mass of soot in the filter. A "balance point" is a set of conditions where the rate of new soot accumulation is equal to the rate of soot oxidation. Soot oxidation rates also depend on the extent of soot oxidation because of changes in surface area and composition. Initial soot oxidation rates are typically higher, possibly because of the presence of reactive functional groups and semivolatile organics. Oxidation rates drop off after the initial stages of oxidation and then increase again as shrinking particles result in higher surface areas (Messerer, Niessner, and Poschl, 2006). Oxidation rates and behavior of soot during oxidation can also vary significantly depending on fuel and engine operating conditions.

3.4 Catalysts

Catalysts to promote oxidation of soot have played an important role in DPF systems, and their continuing development is an active research area. Most approaches to the application of catalysts in DPFs fall within one of two broad categories:

- Direct, or contact catalysis, which accelerates oxidation where physical contact exists between the soot and catalytic sites
- Indirect catalysis, where oxidation is mediated by an active gaseous species, namely NO_2.

An early approach to direct catalysis of soot oxidation was to introduce the catalyst in the fuel (Konstandopoulos *et al*., 2007), resulting in small catalytic particles embedded within the soot particles. Although effective in accelerating oxidation rates, fuel-born oxidation catalysts have not found common application.

Contact catalysts such as ceria have an oxygen storage function, making molecular oxygen available for reactions with soot very close to the catalyzed surface. Direct oxidation catalysts have shown great promise in a number of laboratory studies (Southward and Basso, 2008), but maintaining a consistent degree of soot/catalyst contact is a major challenge in field applications. Studies have shown that soot loaded onto a catalyzed monolith reacts much more slowly than soot mixed with a powdered sample of the same direct oxidation catalyst.

Indirect catalysis has been used extensively to promote passive oxidation of soot by NO_2. Catalytic function is similar to that provided by diesel oxidation catalysts (DOCs). Less reactive NO is converted to the more reactive NO_2. Back diffusion of NO_2 from a catalytic site within the filter wall upstream to a soot deposit means that a single molecule of NO_x can be "recycled" multiple times to participate in soot oxidation (Vlachos *et al*., 2008). It should be noted that oxidation catalysts in the DPF can also play an important role in oxidizing CO and hydrocarbons, which are themselves regulated pollutants. In this way, a catalyzed DPF can augment functions of an upstream DOC, as well as oxidizing CO, which might be produced by partial oxidation of soot in the filter itself.

3.4.1 Ash

While the majority of the PM is consumed by oxidation and removed with the gas phase during DPF regeneration,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a small fraction [0.5–1.0% (Sappok and Wong, 2010)] stays behind as ash. Ash accumulation is a major design consideration for DPF systems. At 150,000 miles, ash may account for as much as 80% of the particulate mass trapped in a DPF (Sappok and Wong, 2010). DPF ash originates from a variety of sources including engine wear and corrosion, trace impurities in the fuel, and lubricant additives. Ash derived from the lubricant is thought to comprise the majority of the mass accumulated and is composed primarily of oxides, sulfates, and phosphates of metals including Ca, Zn, and Mg (Sappok *et al*., 2009).

Observations suggest that ash initially forms a layer on filter walls, but then is subsequently transported to the back of inlet channels, where it forms a porous plug. Ash deposits act to increase filter backpressure by obstructing surface pores and taking up volume in the inlet channels. However, ash deposits are very porous (Sappok *et al*., 2009) (roughly 85% or higher void fraction) and may have much higher permeability than soot or the underlying filter substrate (Young *et al*., 2004). A thin coating of ash on the filter wall can actually result in lower backpressures during subsequent soot loading cycles and limit the hysteric effects discussed earlier by reducing penetration of soot into pore throats (Zarvalis, Lorentzou, and Konstandopoulos, 2009; Sappok *et al*., 2009). Higher ash loadings, however, can dramatically increase the sensitivity of backpressure to soot loading level as the ash comes to occupy a significant fraction of the inlet channel volume (Sappok and Wong, 2010). The presence of ash can also significantly improve filtration efficiency over an ash-free filter (Zarvalis, Lorentzou, and Konstandopoulos, 2009).

3.5 DPF substrates

Table 1 lists properties for several example DPF products. Note that the manufacturers can vary properties such as porosity and mean pore size over a considerable range by tuning manufacturing parameters, and development of new products and processes continues.

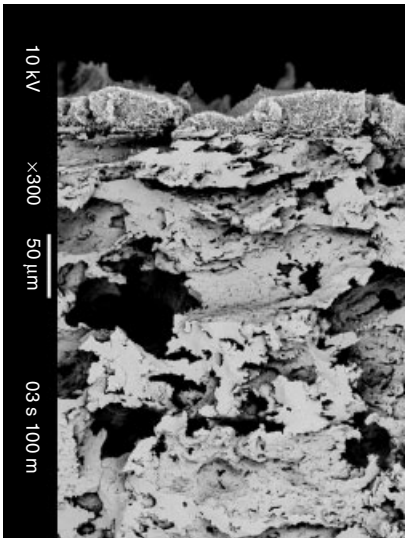

Figure 7. Cordierite filter, lightly loaded with diesel soot.

Cordierite (Figure 7) is possibly the most important ceramic substrate for current DPFs. It is favored by OEMs, especially in the United States, because of its relatively low cost. Cordierite is less susceptible to thermal shock than some competing materials, but it also has a lower melting point. Pore size distributions tend to be somewhat broader than in sintered granular substrates, such as SiC, and the connectivity of the pores is not as uniform.

SiC DPFs (Figure 8) have been deployed mostly in Europe and Japan. SiC filters have a higher melting point than cordierite, but are much more sensitive to thermal shock. This limitation is overcome by manufacturing the DPF bricks in multiple longitudinal segments, which are

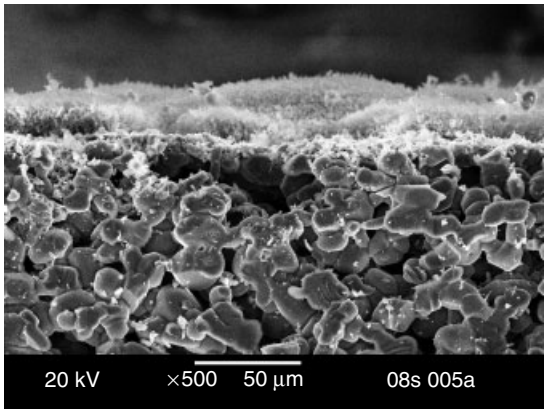

Figure 8. SiC filter, lightly loaded with particulate.

then cemented together with materials that can absorb thermal strain.

A number of porous ceramic substrates have been explored for use in DPFs, some of which are at various stages of commercialization. Aluminum titanate was introduced as an alternative to SiC filters. This material has a significantly higher melting point than cordierite. It is also more robust with respect to thermal shock than SiC, making segmented construction unnecessary. Acicular mullite (Li *et al*., 2004) has a unique microstructure characterized by narrow, interpenetrating crystals (Figure 9). Crystals that extend from the filter walls into the inlet and outlet channels provide additional surface area for coating and filtration, as well as high average porosity. Thermal shock resistance is somewhat less than in cordierite filters, and large filter bricks may be segmented, although the segments may be larger than those typically used in SiC filters.

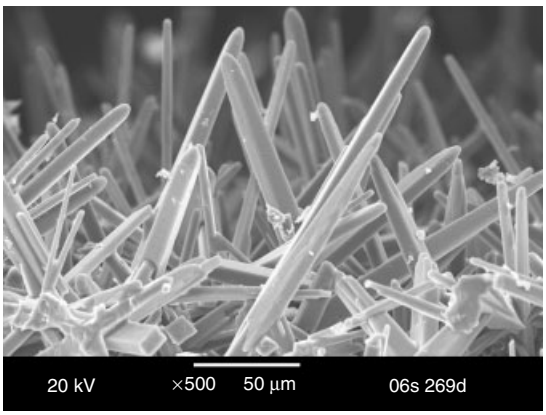

Figure 9. Acicular mullite filter wall surface. This image was taken at Pacific Northwest National Laboratory.

Although ceramic wall-flow monoliths have received most of the attention thus far for meeting stringent particulate emissions limits on new vehicles, many other concepts have been proposed for vehicle exhaust filtration. Partial flow structured metal filters (Emitec, 2009) represent a compromise between no filtration and ceramic wall-flow monoliths. Although they do not have the extremely high mass filtration efficiencies of wall-flow DPFs, they can nevertheless significantly reduce particulate number by capturing the majority of very small particles. As active regeneration is not necessary, such technologies are especially attractive for retrofit applications.

4 INTEGRATION OF PARTICULATE FILTRATION WITH VEHICLE SYSTEMS

4.1 Soot mass estimation, sensing, and control

As previously discussed, accumulation of soot in DPFs leads to an increase in exhaust flow resistance. To alleviate this resistance, it is necessary to regenerate the filter (or oxidize the soot in the filter) periodically when the vehicle is in operation. This can be achieved by either passive regeneration or active regeneration. Passive regeneration is when the soot is oxidized by the NO_2 present in the exhaust stream and occurs at temperatures less than 400°C. Active regeneration, on the other hand, is when the soot is oxidized by excess O_2 and occurs at higher temperatures ($T > 500$°C). In the following section, we discuss techniques to estimate the soot mass in the filter, state-of-the-art soot sensors, and control strategies that are widely used in the emission control industry. We also discuss the consequences of incorrect estimation of the soot that can lead to filter deactivation and/or performance degradation. Various aging mechanisms, owing to both thermal and chemical effects, the effect of ash plugging, and diagnostic methods to adapt the filter to deal such scenarios, are also discussed. Finally, we conclude with a discussion of the impacts of alternate fuels such as biodiesel on DPF performance and with a discussion on the impact of other aftertreatment system components such as DOC and SCR on DPF performance.

4.1.1 Soot mass estimation

Accurate estimation of soot in a DPF is critical for its smooth operation and is one of the key inputs for the filter regeneration control strategy. This is important because underestimating the soot mass could lead to larger accumulation of soot, and on regeneration, the faster soot burn-out

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

rate could lead to filter melting and cracking. Overestimating soot mass results in frequent DPF regenerations, leading to lower fuel economy and a higher CO_2 penalty. Frequently, regenerating the DPF also exposes the filter to excessive thermal cycling that could result in cracking and catalyst deactivation because of cumulative high temperatures exposure.

Various open-loop and closed-loop soot mass estimation strategies are proposed in the literature (Rose and Boger, 2009; Dabhoiwala *et al*., 2008; Benaicha *et al*., 2011; Perrin *et al*., 2004; Su, Gordon, and Hong, 2007). Almost all of these strategies are model based. Open-loop models estimate the engine-out soot as a function of engine speed and load and determine the DPF soot mass from the engine-out calculation. A limitation of such an approach is the ability to map soot emissions during transient engine operating conditions, which is extremely complex and involves extensive parameterization efforts (Rose and Boger, 2009; Wang *et al*., 2011). The closed-loop models, on the other hand, rely on the pressure drop measurement from the sensors upstream and downstream of the DPF, airflow measurements from the flow meter, and temperature measurements upstream of the DPF. The challenge in using a pressure drop measurement for soot estimation is that the pressure drop is a cumulative effect of various phenomena such as friction in the inlet and outlet channels and flow resistance through wall and soot layers, whose individual contribution to the overall pressure drop vary based on the filter operating conditions. Several efforts are ongoing in this area to quantify and develop high fidelity modeling tools, based on engine dynamometer tests, to understand the relationship between the pressure drop and soot mass and its precise location (Dabhoiwala *et al*., 2008).

Advanced state estimation/observer techniques for DPF systems are also reported in the literature (Benaicha *et al*., 2011; Perrin *et al*., 2004; Su, Gordon, and Hong, 2007; Hsieh and Wang, 2011; Surenahalli *et al*., 2012). A majority of these techniques are based on a reduced order DPF model and use linear/nonlinear systems theory to estimate the soot mass and help in OBD. An estimator to estimate the soot mass based on the pressure drop measurement across the filter was developed by Benaicha *et al*. (2011). The estimator uses an extended Kalman filter (EKF) technique and was validated against data collected on both engine dynamometer and vehicle. Motivated by future OBD legislations, studies on detecting filter degradation through model-based algorithms were also reported (Perrin *et al*., 2004).

A reduced order model of the physical system forms the basis of an estimator design. It is important to realize a reduced order model that is mathematically consistent and maintains its accuracy, while being implementable in real time. One advanced realization technique was developed by Su, Gordon, and Hong (2007). The authors used a singularly perturbed sliding manifold approach to reduce a DPF model and then designed a sliding mode observer to estimate the soot mass. Model-based estimators were also developed for DOC to understand the impact of DOC states such as temperature, NO, NO_2, and hydrocarbons (during active regeneration) on DPF performance (Hsieh and Wang, 2011; Surenahalli *et al*., 2012).

4.1.2 Soot (PM) sensors

As the accuracy of the soot mass estimate is affected by the types and combinations of sensors, feedback from PM sensors is vital for soot estimation and regeneration control strategy development, especially in light of the future 2014–2018 fuel consumption regulations (US EPA, 2009). Various types of PM sensors are currently being explored for diesel aftertreatment applications (Moos, 2005; Ochs *et al*., 2010; Roesch *et al*., 2010; Kondo *et al*., 2011; Katsuyama *et al*., 2011; Sappok *et al*., 2010).

PM sensors that are reported in the literature are broadly classified into two categories—(i) sensors that accumulate the soot over a period of time and provide a response and (ii) sensors that provide the soot measurement in real time. Sensors that belong to the first category mostly use the conductometric principles where a good relationship between the sensor resistance and accumulated soot mass measurements (from measuring the pressure difference across the filter) was reported (Moos, 2005). Bosch developed an EGS-PM (exhaust gas sensor for particulate matter) sensor based on similar principles for OBD purposes (Ochs *et al*., 2010; Roesch *et al*., 2010), and a diagnostics concept for DPF state of health monitoring was proposed based on the sensor signal. Soot deposits between the electrodes of a sensing element form an electrical contact, decreasing the resistance. After a predefined current threshold is reached, the heater element within the sensor heats the sensor above typical soot regeneration temperatures ($>600^{\circ}C$) and regenerates the adsorbed soot. The sensor signal, which correlates the exhaust soot concentration, is the time between regeneration and the time when the current reaches a predefined threshold.

A PM sensor capable of detecting lower soot concentrations, typically found during New European Drive Cycle (NEDC) and FTP modes, was developed by NGK insulators (Kondo *et al*., 2011; Katsuyama *et al*., 2011). The sensor operates in three sequential stages including forced collection, detection, and burn-off. In the first stage, soot is forcibly collected using an electric field and a thin

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

soot layer is formed on the surface of the detecting electrode. The second stage involves soot detection where the accumulated soot is determined by measuring electrostatic capacitance changes followed by the third stage when the accumulated soot is burnt off allowing the sensor to return to its initial state.

An example of a sensor that measures the accumulated soot mass in real time is an RF (radio-frequency) sensor developed by Filter Sensing Technologies (Sappok *et al*., 2010) where antennas are mounted upstream and downstream of the filter and an RF signal from the sensor control unit is used to detect the soot in the filter. The characteristics of the signal are influenced by the dielectric properties of the material through which it propagates. While accurate sensor feedback forms a key component in triggering filter regeneration, the other important component is the control strategy that ensures that the filter is regenerated only when required, considering the key filter dynamics discussed in the next section. The RF measurement system was tested on a 1.9-L GM turbocharged diesel engine under a variety of engine operating conditions and advanced combustion modes and has generated encouraging results demonstrating the feasibility for measuring the soot levels directly in the DPF using RF sensing.

4.1.3 Regeneration control strategies

Active regeneration control strategies reported in the literature are mainly based on the temperature and soot mass dynamics in the filter and the temperature and pressure measurements across the filter. Singh *et al*. (2005) proposed a model-based control strategy that filters the high frequency components in DPF inlet temperature and pressure drop to avoid the negative effects associated with responding to high frequency measurements. On the basis of their strategy, the fuel penalty associated with DPF active regeneration was reduced with higher soot mass and higher DPF inlet temperatures. An advanced control strategy for DPF regeneration was proposed by Van Nieuwstadt and Tennison (2006) that includes both feed-forward and feedback components. The *feed-forward* term computes a nominal hydrocarbon (diesel) injection quantity to raise the predetermined DPF inlet temperature based on the oxidation catalyst temperature, whereas the feedback quantity is the output of a PI controller, which takes the error in temperature as the input signal.

Such active regeneration control strategies in DPFs are crucial to realize the future fuel economy targets (US EPA, 2009) for heavy-duty vehicles. In addition, they also help avoid unnecessary regenerations that could affect the health and durability of the filter, discussed in the next section.

4.2 DPF failure modes and diagnostics

A DPF needs to survive its vehicle lifetime and hence ensuring its durability is a critical component in DPF product development. Several filter durability studies and performance evaluations are reported in the literature (Zhan, 2008; Wilcox *et al*., 2004; Watkins *et al*., 2009). This section summarizes the common failure modes in DPFs such as thermal deactivation, chemical poisoning, and cracking. Further, techniques to diagnose the failure modes and adaptive measures are discussed.

4.2.1 Thermal deactivation

The DPF is typically exposed to large exotherms (650–750°C) during active regeneration. Therefore, it is important to understand the impact of such high temperatures on the filter substrate. For example, Wilcox *et al*. (2004) investigated thermal stresses on the DPF and explored the likelihood of cracking, given the part geometry, material properties, temperature distribution, and failure criterion. A 3D DPF model was developed using Ansys, and a continuum approach was followed accounting for anisotropy, core, plugs, and skin. The authors report that the thermal stress analysis was successfully used to develop base materials and coatings, to impose the max soot mass criterion for failure, and for durability studies. Similar analysis tools were developed by Watkins *et al*. (2009) using nondestructive evaluation (NDE) techniques (applied to DPF ceramic substrates), to compare the properties of field-aged DPFs with virgin filters.

4.2.2 Impact of aging

DPFs age because of both thermal and chemical effects (DaCosta, Shannon, and Silver, 2006). One of the serious issues with DPF performance degradation is filter aging because of ash. Ash particles, which originate from the lubricant oil accumulate in the filter, may cause false triggers for filter regeneration. A rapid ash aging technique that evaluates the ash-aged filter samples as a function of soot loading behavior, regeneration, and filter efficiency was developed (Zarvalis, Lorentzou, and Konstandopoulos, 2009). While ash layer caused a significant increase in filtration efficiency, it has been concluded that the impact of ash depends on the catalyst layer morphology.

4.2.3 Diagnostic methods

To meet the future OBD legislations, state of health of DPF systems needs to be constantly monitored. A survey of various diagnostic methods for DPFs was presented

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

by Mohammadpour, Franchek, and Grigoriadis (2011). The diagnostic method based on pressure drop measurement across the filter was found to be of limited capability because of sensor noise not measured by the engine control unit. Suggested by the California Air Resources Board, researchers explored various signal processing and statistical analysis techniques to correlate the pressure drop measurement to model-based DPF diagnostics (Cunningham, Meckl, and Shah, 2007; Van Nieuwstadt and Brahma, 2008). A DPF fault detection algorithm based on energy spectral analysis obtained through temperature and pressure measurements pre- and post-DPF was developed by Surve (2008). The approach was successfully implemented to detect failure in a lightly failed DPF (small crack), and the dynamic pressure signal analysis was extended to transient engine operations as well. A similar model-based failure detection technique was discussed (Gupta *et al*., 2011), which uses orthogonal least squares method to estimate the model coefficients based on the dynamic pressure drop signal. By comparing the coefficients as a function of time, the filter failure can be detected. This approach does not require additional sensors, is robust to sensor noise and process variability, and was validated using FTP data in a test cell for both healthy and failed filters.

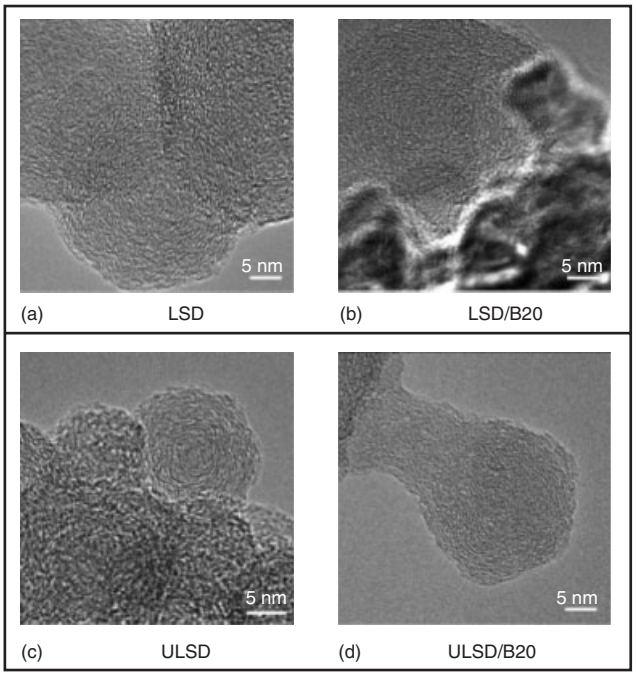

Figure 10. (a–d) HR-TEM Images of soot nanostructure showing the effect of biodiesel blending for four test fuels. As mentioned by (Boehman *et al*., 2005), the soot particles from B20 blending in ULSD have a less ordered structure. (Reprinted with permission from Boehman *et al*. 2005. Copyright (2005) American Chemical Society.)

4.3 Effect of alternate fuels on DPF performance

Biodiesel is attractive for its renewable properties and reduces dependence on foreign oil. The US EPA conducted a comprehensive analysis of biodiesel on vehicle exhaust emissions in 2002 based on statistical regression analysis, correlating the biodiesel content in diesel fuel to regulated and unregulated pollutants (US EPA, 2002). Biodiesel consisting of mono alkyl esters is derived from various vegetable oils; it reduces tail-pipe PM, CO, and HC emissions whereas increases NO_x emissions. Recent EPA analysis indicates that PM emissions are reduced by as much as 12% using the B20 blend and by 47% using B100 (US EPA, 2002). This section introduces the impact of alternate fuels such as biodiesel on DPF performance.

A comprehensive review on the impact of biodiesel fuels on engine emissions with specific focus on PM and NO_x was reported in Lapuerta, Armas, and Fernandez (2008) and Szybist *et al*. (2007). This body of work gives a big picture comparison between the conventional diesel fuel and the biodiesel blends. In particular, there has been a lot of work in characterizing the soot from biodiesel exhaust. Boehman, Song, and Alam (2005) observed that the soot generated from biodiesel blend (B20) varies in nanostructure and oxidative reactivity as shown in Figure 10. They concluded that the amorphous structure and higher oxygen content in biodiesel soot (B20) are partly responsible for soot reactivity.

The break-even temperature (BET) or balance point temperature (BPT) is defined as the temperature at which soot deposition is equal to the oxidation rate. This equilibrium point is typically lower for biodiesel when compared to conventional diesel fuel, indicating that it may improve the passive regeneration process in the DPF (Buono, Senatore, and Prati, 2011). In this report, the DPF regeneration procedure was reported as different for the biodiesel fuel and needs to be recalibrated and optimized for better fuel economy. These findings were supported by the findings from Williams *et al*. (2006) who concluded that lower BET temperatures and higher regeneration temperatures for biodiesel were due to higher soot reactivity in biodiesel fuels. Vehicle tests conducted on a 2006 MY 2.8 L, 120 kW VM Motori DI diesel engine with a DOC and CPF or cDPF (catalyzed particulate filter) aftertreatment system using B20 fuel indicated lower regeneration temperatures (~33°C) and higher loading times because of less engine-out PM when compared to ULSD fuel (Peterson *et al*., 2009). This could be advantageous from a fuel

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto131
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

economy standpoint, decreasing the number of active regenerations. However, constant monitoring of the biodiesel dilution in engine oil is required to prevent engine deterioration. Even though NO_2 concentrations upstream of the DPF increased by 6% (due to higher engine-out NO_x from biodiesel fuels), lower regeneration temperatures were attributed to higher soot reactivity for biodiesel blends.

Owing to the potential for residual alkali and alkaline earth metals in biodiesel to form ash, it is critical to understand the impact of biodiesel on ash emissions (Sappok and Wong, 2007). Researchers concluded that the presence of metals might impact ash loading and catalyst performance and noticed increased debris and metals in biodiesel ash and attributed to solvent properties of the fuel.

4.4 Systems integration and interaction

A typical 2010 aftertreatment system for heavy-duty diesel engines consists of an oxidation catalyst, an NO_x reduction catalyst, and a DPF as shown in Figure 11.

In addition to the transients imposed by engine operating conditions in terms of flow rate, temperature, and concentrations, the reductants such as diesel and urea add interesting dynamics to the overall aftertreatment system. Of particular interest are the DOC and SCR dynamics that would impact the performance of DPF. Selective catalytic reduction (SCR) is a widely used technology to reduce NO*x* emissions from engine exhaust through injection of a reductant such as urea solution, ammonia, or hydrocarbons upstream of the SCR catalyst.

4.4.1 Impact of DOC and SCR on DPF

The DOC that oxidizes hydrocarbons, NO and CO on the active platinum sites, is important for passive regeneration of soot in the DPF, as it converts NO to the more active oxidizer NO_2. As the catalyst ages and the oxidation conversion efficiency of DOC decreases, it would have a direct impact on the DPF performance, especially during a heavy-duty scenario (as shown in Figure 11) where DPF is located right after the DOC. If the DPF is catalyzed (also called as *CPF* or *cDPF*), then the impact of aged DOC could be compensated by the catalyst on the filter to a certain extent. It is also reported that DOC depletes the organic compounds in the soot (Lizarraga *et al*., 2011).

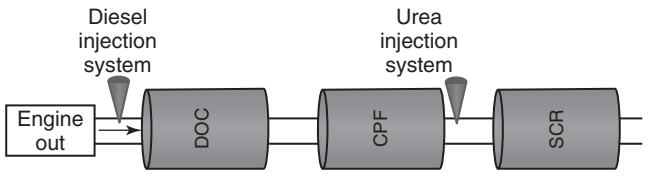

Figure 11. A schematic of a typical 2010 aftertreatment system for heavy-duty diesel engines with an oxidation catalyst, diesel particulate filter, and a urea-SCR catalyst.

Under an LD scenario where active regeneration in DPF is much more frequent, DPF is placed downstream of the SCR catalyst. Here, the impacts of both the DOC and SCR catalysts on the filter should be considered. Passive regeneration in DPF is not as important in this case as NO and NO_2 are consumed in the SCR catalyst. As a result, the DPF has to heavily rely on active regeneration to burn the accumulated soot. However, when the SCR catalyst ages, the NO oxidation (especially for base metal zeolites) and the SCR capability reduce and there could be some benefit to the DPF for achieving passive regeneration. On the downside, oxidation of NH_3 from the SCR process decreases because of aging and the DPF might experience clogging problems because of NH_3 and other urea derivatives from the SCR such as HNCO (isocyanic acid), occupying the filter pores.

4.4.2 Integrated DPF/SCR (2-way) devices

Urea-SCR catalysts and DPFs are proved technologies in reducing the NO_x and particulate emissions from diesel engines, respectively. These are the technologies at the forefront to meet the HD emission standards of NO_x (0.2 g/bhp-h) and PM (PM—0.01 g/bhp-h). From an exhaust aftertreatment standpoint, a minimum of three catalytic converters, that is, an oxidation catalyst, a particulate filter, and an NO_x reduction catalyst, are necessary to meet these standards. To decrease the overall volume of the catalysts and the costs of the precious metals in the catalysts to mitigate these harmful pollutants (CO, HC, NO_x, and PM) in the exhaust, researchers have been investigating an integrated NO_x/PM aftertreatment system on a single substrate. One such technology involves the integration of urea-SCR and DPF in a single substrate. The following paragraph summarizes the current efforts in developing and deploying such an integrated device.

The overarching goal of these efforts has been to develop an integrated device that reduces the overall aftertreatment volume while maintaining optimal NO_x conversion efficiency with minimal backpressure. Tan, Solbrig, and Schmieg (2011) have evaluated a combined SCR/DPF system to meet 2010 and beyond EPA/CARB regulations that reduces SCR catalyst volume, improves vehicle packaging, and reduces cost. Experiments were carried out on a Euro IV compliant V6 diesel engine operating on an engine dynamometer and on a fixed bed reactor in the laboratory. The system was able to meet the HD dynamometer and

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

chassis certification requirements with significant reduction in overall aftertreatment catalyst volume. The impact of EGR on the SCR/DPF system was also evaluated and compared to a conventional DOC-CSF-SCR system (Naseri *et al*., 2011). Cu/Z catalyst was coated on a high porosity filter similar to many other reports found in the literature (Guo *et al*., 2010). With EGR system turned off, SCR/DPF systems performed better than the conventional because of higher SCR catalyst volume that allows flexibility for HD engines to operate at higher out NO_x. SCR/DPF systems showed better light-off and demonstrated better passive regeneration capabilities (due to higher engine-out NO_x and hence high NO_2) resulting in lesser active regeneration events and hence better fuel economy. On the LD side, Boorse *et al*. (2010) tested SCR/DPF system on a 2.7 L V6 Land Rover to achieve T2B5 standards for LD trucks. Two systems, DOC-SCR-SCRF (SCR on filter) and DOC-SCRF-SCR, were tested (washcoat loading on SCRF was 60% of the washcoat loading on a flow-through SCR). A combo cycle involving FTP-75, HWFET, and US06 was tested to evaluate the two systems. DOC-SCR-SCRF showed higher NO_x conversion efficiency because of high washcoat loading allowing higher NH_3 storage. Oven aging tests indicate that the DOC-SCRF-SCR was able to meet the T2B5 tailpipe NO_x and TMHC standards through 120 k miles. Alternate DPF substrates such as SiC have also been tested for the integrated device and reports indicate better SCR catalyst utilization because of its microstructure (Boorse *et al*., 2010).

Even though a few reports indicate a minor effect of soot on NO_x conversion (Bush, Iretskaya, and Tadrous, 2009), there exist significant design challenges in catalyst coating process optimization and washcoat loading to develop an optimal, integrated SCR/DPF system for simultaneous NO_x and PM conversion. In addition, bench reactor evaluations and modeling tools (Park, 2011) are invaluable in understanding the impact of species diffusion and competitive adsorption in the integrated system and could lead to a better SCR/DPF system design.

1 OPTICAL ENGINES AND OTHER FACILITIES

1.1 Optical engines

An "optical engine" is designed with transparent windows to allow processes occurring inside the cylinder of the running engine to be viewed. A normal production metal engine may be modified for optical access, or a stand-alone optical engine may be specifically designed for the task. With optical access, not only can the cylinder contents be passively observed, but laser-based measurement techniques may also be applied to extract specific information about the physical and chemical in-cylinder processes occurring rapidly in the harsh, high pressure, high temperature environment inside the engine.

Optical access to combustion chambers can be created in different ways and to different extents. Small-scale (a few millimeters) windows can accommodate laser beam input and endoscopic viewing through the cylinder head or cylinder wall, whereas large-scale (tens of millimeters or more) windows can provide access to the whole cylinder liner (using a toroid window) or the piston-top (using a disk window) for full-field imaging. In keeping with the generally accepted meaning of optical engine within the engine research community, this section describes engines with large-scale optical access that requires significant engine modifications. In some optical engines, the windows alter the engine geometry somewhat (such as using flat windows to avoid optical distortion), and in other engines, the windows are contoured to conform to the production engine geometry, although image postprocessing may be required to correct for optical distortions, as described later.

Optical engines are typically single-cylinder versions of multicylinder production engines. A typical example of a modern design with optical access through the cylinder liner, piston crown, and cylinder head is shown schematically in Figure 1. The key features are as follows:

- Optical access through a spacer ring with flush mounting, curved spacer-ring windows. Typical window materials are fused silica (excellent UV light transmission) or sapphire (ultrahard and strong).
- Correspondingly lowered piston ring pack keeping the rings from sliding over the spacer-ring windows (and creating a large ring-land crevice volume and lower compression ratio).
- Piston rings from self-lubricating polymer mixtures to allow operating the upper engine nearly oil free. Oil would greatly contribute to window fouling.
- Optical access through a window in the piston crown, which forms the top part of an extended piston with a tall vertical slot for viewing access ["Bowditch" piston (Bowditch, 1961)]. A range of compression

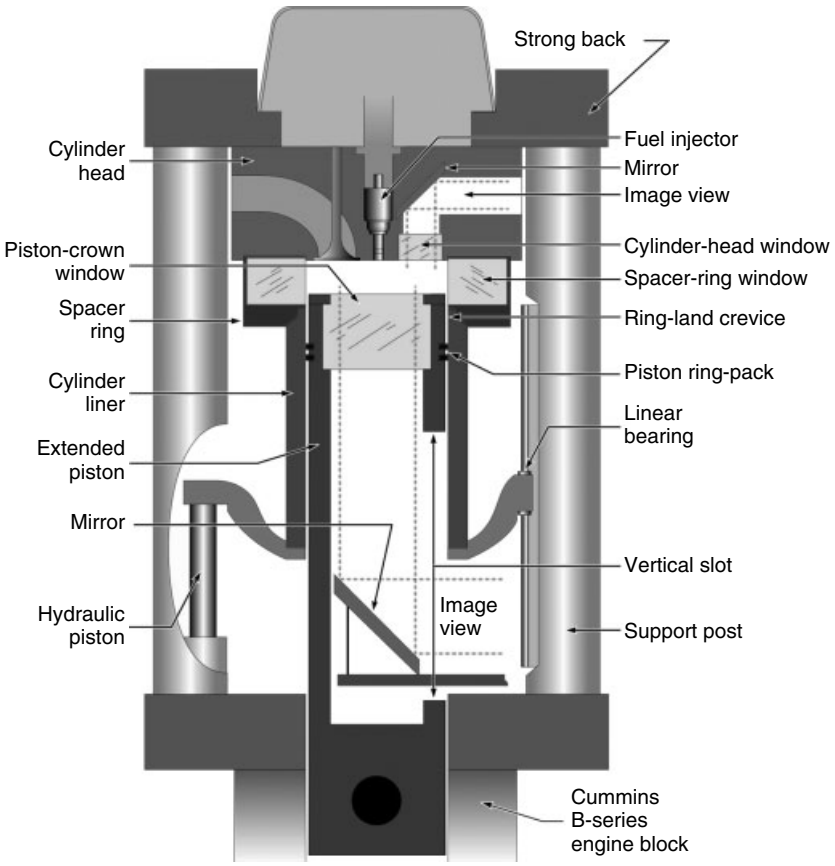

Figure 1. Schematic example of an optically accessible engine with piston extension (and cylinder-head window illustrated). All key components of the upper engine are shown. The base engine block (here a Cummins B-series) is below, with its optical piston extending upward into the optically accessible part of the engine. (Adapted with permission from Dec, Hwang and Sjöberg, 2006. © J.E. Dec, W. Hwang, and M. Sjöberg.)

ratios and combustion chamber configurations can be realized by installing pistons of different dimensions and geometries.

- A stationary mirror at 45°, inserted from the side into the piston slot, allowing upward viewing through the piston window at all times in the cycle.
- Additional small-scale windows and mirror in the engine head, for example, inserted in place of one of the exhaust valves. Figure 11 originates from such an arrangement.
- A means of quickly separating the engine head from the cylinder liner to allow for cleaning the inside surfaces of windows. Here, the cylinder liner can be lowered and raised hydraulically. Other solutions exist.
- A stiff connection of the base engine's crankcase to the cylinder head, which is elevated because of the extended piston. In Figure 1, four massive support posts are bolted to a "strong back" that holds the cylinder head down against the cylinder pressure and upward force from the hydraulic pistons that hold the liner tight against the cylinder head.
- A base engine providing the piston kinematics and forces. For the engine in Figure 1, the first cylinder of a suitably modified six-cylinder block is used. More typical bases are robust single-cylinder research engines.

Many variations of the concept outlined earlier are possible. Perhaps, the most important ones pertain to the optical ports. Compared to Figure 1, other designs have the following:

- A short transparent ring instead of the metal spacer with small windows. This large-scale window option gives 360° optical access to the top 10–20% of the combustion chamber but limits the safe peak pressure to about 50–100 bar.
- A full-height transparent liner with the piston rings sliding over the liner. This configuration provides 360°

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

optical access to the entire piston stroke, but it is much more fragile than other designs and is almost exclusively used in motored operation only.
- A shaped piston-crown window. For example, in a diesel engine, a bowl with a complex geometry may be machined into a suitably mounted glass crown. Such a feature may be necessary to investigate salient aspects of in-cylinder phenomena, but the accompanying optical distortions make imaging more difficult.
- No piston-crown window. Particularly, for laser-based imaging, this not only severely limits the possible configurations but also obviates the need for a piston extension.

Owing to the optical access modifications, the many aspects of optical engine performance differ from those of a similar production engine. Replacing liquid-cooled metal components with largely uncooled windows having different material properties alters the heat transfer between walls and the gas phase. In addition, oil-free polymer piston rings can have much more blow-by than their production metal counterparts. Gapless rings can help to reduce blow-by, but their friction is very temperature-dependent because they expand significantly when heated. Polymer rings, limited cooling, and lower thermal gradient tolerance of optical materials limit the thermal load the engine can tolerate, so optical engines are often "skip fired." In this mode of operation, one or several fired cycles for data acquisition are followed by (∼10) motored cycles to allow the engine and optical components to cool down somewhat. With skip firing, engine systems that use the exhaust gas stream, such as turbocharging or exhaust-gas recirculation (EGR), cannot function as in a normal engine. To simulate turbocharging or EGR, optical engines typically are supplied with an externally pressurized and heated mixture of air with nitrogen, carbon dioxide, and/or water vapor and other gases properly metered to mimic EGR.

Further limitations in the operating range come from the mechanical properties of the optical materials (fused silica or sapphire), which are reasonably strong, but very brittle, with a low coefficients of thermal expansion that are mismatched with most metals. When an extended piston is used, the additional weight of the piston requires not only redesign of the engine's mass balancing but also a reduction in maximum speed. Typical top speed of a light-duty optical engine may be 2000–2500 rpm, compared to 5000–8000 for similar metal engine designs. Together with blow-by, the reduced axial stiffness of the slotted, extended piston also means the real compression ratio can be significantly different from the geometric compression ratio (Kashdan and Thirouard, 2009). Particularly, the calculation of apparent heat-release rate is affected by this (Aronsson *et al*., 2008, 2011). Adjusting intake temperature and pressure allows matching thermodynamic conditions of the intended all-metal counterpart over a limited range of crank angles, which may be sufficient to study, for example, injection and ignition in diesel combustion under realistic conditions (Colban *et al*., 2008).

Because of these thermodynamic differences and often much greater crevice volumes, exhaust gas composition will also differ from that of a nominally identical all-metal engine. With careful operation, however, trends over a parameter variation can be reproduced well with an optical engine (Colban *et al*., 2008).

Naturally, then, an important line of advancement in optical engines is to extent their limits of operation. For example, the engine shown in Figure 1 is designed to withstand 155 bar peak pressure. Other designs have been developed for operation at peak pressures as high as 20 MPa (Fuyuto *et al*., 2012). In the past, less emphasis has been put on extending the speed limit, but it is possible to design optical engines to operate at 6000 rpm (Fuyuto *et al*., 2012). Progress has also been made in improving the realism of the optical engine, that is, the correspondence to its all-metal counterpart in the aspects that are important for a particular investigation. For example, if the details of the flow in and around the bowl of a diesel engine's piston bowl are to be examined, the bowl of the optical engine needs to retain the production geometry. This is mechanically possible, but the downside can be optical distortion that is difficult to correct, as shown in Figure 2.

1.2 Rapid compression machines

A rapid compression machine (RCM) is similar to an engine, in that it features a closed cylinder with a sliding piston that compresses gases within the cylinder. Unlike an engine, however, the RCM is designed so that the piston remains stopped at the end of compression, so that the compressed gases do not expand. The compressed gases thus remain at high temperature and pressure for an extended period of time (10–100 ms), during which in-cylinder processes may be studied.

Optical RCMs generally share the same five operational elements: a "driver section" that applies force to accelerate a sliding piston, a closed piston-cylinder "driven section" in which gases are compressed, a mechanism to decelerate and hold the piston, a compression (combustion) chamber at the end of the piston's stroke, and transducers/windows for optical and other diagnostics. A schematic representation of the operation of one RCM, based on a design from the University of Michigan (Donovan *et al*., 2004), is shown in Figure 3. Many other designs for RCMs exist, a number of which are listed in Table 1.

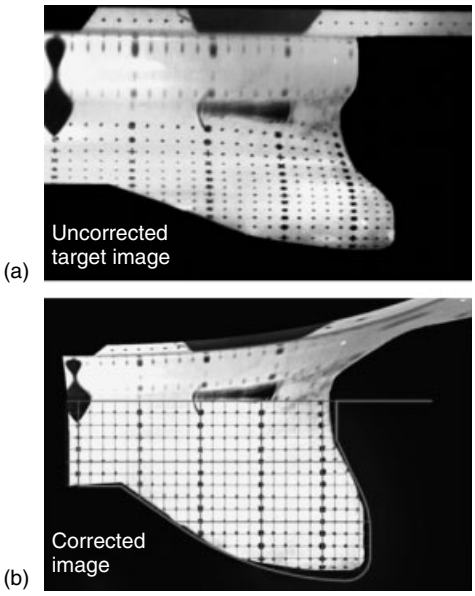

Figure 2. Raw (a) and distortion-corrected bowl region (b) image of a calibration grid in the bowl of a quartz piston crown with the geometry of a production diesel-engine bowl. (Reprinted with kind permission from Springer Science+Business Media: Experiments in Fluids, "The influence of fuel injection and heat release on bulk flow structures in a direct-injection, swirl-supported diesel engine," 43(2–3), 2007, 273–283, Miles, P. C., Hildingsson, L., and Hultqvist, A., Figure 4, Copyright Springer-Verlag, 2007.)

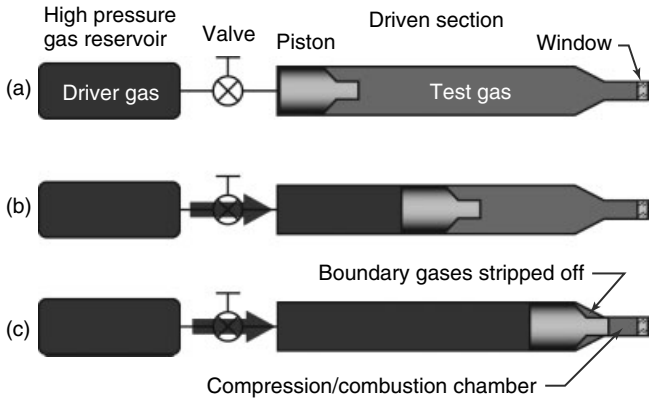

Figure 3. Example of RCM operation for design similar to that of the University of Michigan (Donovan *et al.*, 2004). (a) The driven section is filled with the test gas (light gray) to be compressed. (b) A control valve is opened to release high pressure gas (dark gray) that accelerates piston, which compresses the test gas mixture. (c) At the end of its travel, the piston decelerates and locks in place as it wedges into the end of the driven section. Cooler and more turbulent boundary gases are stripped off into the shoulder region outside the compression/combustion chamber.

The RCM driving system is typically pneumatic or hydraulic, and it can act on the piston directly, as in Figure 3, or it can drive a second piston-cylinder arrangement that is mechanically connected to the compression piston. Other less-common driving systems include mechanical cams/ramps or even gravity-driven free-fall/impact. After compression, the piston must be decelerated at the end of its stroke and held in place to maintain compression. Deceleration may be accomplished by crushing/wedging elements as in Figure 3, by controls on the drive side, or by hydraulic or pneumatic braking. Piston rebound after deceleration also must be avoided to maintain compression, by wedging elements that hold the piston tight (Figure 3), feedback control of the driver system, or mechanical locks.

RCMs are free from residual gas effects and can generate more quiescent charges with less cycle-to-cycle variation than reciprocating engines, which can make the RCM a better platform for fundamental measurements, such as flame speed for spark-ignition (SI) applications. RCMs are often utilized to study chemical kinetics, for which it is desirable to create a uniform gas temperature and composition as quickly as possible. Precompression nonuniformities, heat losses creating cooler gases near the cylinder wall, and flows generated by compression all can contribute to nonuniformities in the compressed gases. Some RCM designs, such as the one illustrated in Figure 3, use a tapered/stepped piston to strip off the cooler and more turbulent boundary gases and prevent them from entering the compression chamber, thereby improving charge uniformity.

Most RCM compression times vary from 20 to 200 ms, whereas engine compression times range from 5 to 50 ms for crankshaft speeds from 600 to 6000 rpm. The fastest RCM listed in Table 1, from Nihon University in Japan (Watanabe *et al.*, 2008), uses a piston-collision design to generate a rapid 5 ms compression time. RCMs typically measure the piston position and velocity during the compression stroke for diagnostics and/or feedback control of the driver system. Optical access to the compression/combustion chamber is typically achieved either with a large-scale disk window at the top of the compression chamber or by full large-scale optical ring or small-scale windows around the side of the compression chamber.

1.3 Static high temperature, high pressure spray chambers

While experimentation in optical engines and RCMs simulates the time history of compression of practical engines, uncertainties in the charge gas temperature and EGR

distribution at the time of fuel injection can be significant. Consequently, the details of combustion that unfold can also have significant uncertainty. Furthermore, the maximum pressures and temperatures achievable in reciprocating optical facilities are limited, as discussed in Section 1.1. As an alternative, devices that generate sustained charge-gas conditions typical of full compression have been developed, intending to isolate certain variables and to provide a more fundamental understanding of combustion than can be achieved in engine experiments and at more extreme operating conditions. Fundamental understanding over a wide range of conditions is especially needed for development of improved CFD models where specification of exact boundary conditions is critical. Many constant-volume chambers equipped with ignition systems have been developed to understand the details of flame propagation for various fuel–ambient mixtures (e.g., flame speed as a function of pressure, temperature, and equivalence ratio). These chambers can also be utilized to prepare well-controlled high temperature ambient conditions that will subsequently mix with the spray. Different research facilities that produce high temperature, high pressure environments for subsequent spray injection are reviewed in this section.

A schematic for one type of pressurized high temperature spray chamber is shown in Figure 4. The chamber shown

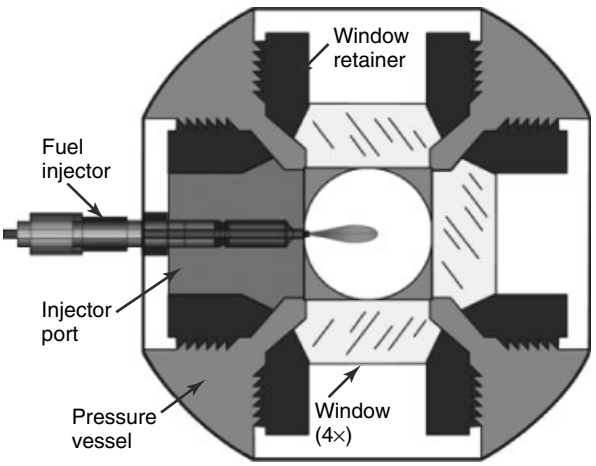

Figure 4. Schematic of high temperature, high pressure constant-volume preburn chamber (Siebers and Higgins, 2001).

is cube shaped with ports available on the six faces of the cube. In Figure 4, the chamber is configured with four optical windows to allow full view of the spray, by line-of-sight, head-on, or side access. A custom fuel injector with a single axial hole is mounted in one of the other ports, producing a spray that penetrates into the middle of the chamber. Intake and exhaust of gases occurs via small valves located at the chamber corners. The valves are closed during injection such that flow within the vessel is mainly generated by the spray itself. While highly simplified, this type of static chamber offers advantages in terms of optical access, maximum pressure and temperature capability, and isolation of variables compared to a running engine configuration.

The operational challenge for these types of chambers is to simultaneously generate high pressure and high temperature conditions representative of engines at full compression. Several different approaches have been developed, each with different design tradeoffs and capabilities. A summary of current device capabilities in terms of pressure and temperature is given in Table 2.

The first type of device listed is constant-volume heating (CVH), wherein the gases are directly heated by the walls of the chamber or by heating elements placed inside a closed chamber. An alternative is to highly preheat gases and quickly ingest them into the chamber before valve closure. Either way, the vessel walls must be heated significantly. Because of the high optical and metal material temperature and associated lower mechanical strength, the maximum pressure and temperature rating for these devices tends to be relatively low. Table 2 indicates that CVH design ratings fall below 80 bar and 900 K, which does not encompass the full range applicable to engines. Another disadvantage is that significant time (~10 min) is typically required to prepare a single charge, which limits the rate of experimentation.

The second approach listed is constant-pressure flow (CPF). For these devices, the system is open and controlled to a specific pressure. A flow of hot, pressurized gases is continuously delivered to the injector region. Fuel is injected into these gases periodically and then naturally scavenged away from the injector by the flow of air. Like CVH chambers, a significant challenge is attaining high temperature and pressure conditions because of material limitations. A solution is to separate and insulate components that direct the flow of high temperature gases from

Table 2. Summary of reported constant-volume heated (CVH), constant-pressure flow (CPF), and constant-volume preburn (CVP) chambers.

that of a cooled, outer pressure vessel, thereby creating a double-hull structure of hot and cold windows and housing. Table 2 shows that temperatures as high as 1000 K and pressures as high as 150 bar are possible with this type of CPF design. A substantial benefit of a CPF chamber is that injections may be repeated quickly (∼one per second), permitting fast experimentation. A disadvantage for a CPF chamber is that a pressure rise event is not available to correlate with heat release.

The third device is a constant-volume preburn (CVP) chamber, which is the type depicted in Figure 4. Table 2 shows that CVP chambers have been designed to reach temperatures of 1400 K and pressures as high as 350 bar, which is significantly higher than either CVH or CPF chamber. CVP chambers use SI and combustion of a premixed, fuel–lean mixture to raise the temperature within the vessel (Oren, Wahiduzzaman, and Ferguson, 1984). The gases and walls may be preheated, as in CVH or CPF design, but it is the "preburn" combustion that primarily raises the temperature and pressure. Chamber wall and gas heating to only 450–500 K is typical, whereas lean preburn flame temperatures approach 2000 K. Because of this temperature differential, the preburn combustion products cool over time and the vessel pressure and temperature slowly decrease. Fuel injection may occur at anytime during this cool down when the desired pressure and temperature is reached, thereby producing an extensive range of possible gas states at the time of injection. However, in practice, a time delay after completion of the premixed burn is needed to finish reaction and produce a more homogenous gas core to mix with the spray; hence, the upper estimate of 1400 K for peak temperature listed in Table 2 is lower than the lean flame temperature of about 2000 K. With fuel injection times of only a few milliseconds, the temperature and pressure at the time of fuel injection is approximately constant (Siebers and Higgins, 2001) because the mass of the ambient gases is much larger than that of the fuel injection mass.

For CVP chambers, the composition of the initial reactant mixture is chosen so that, following its complete combustion, the product gas composition simulates air (21% O_2) or even EGR-diluted engine intake conditions (e.g., 10–19% O_2). As such, the spray will autoignite as it does in diesel combustion. Alternatively, a preburn mixture that yields 0% O_2 can be produced to simulate high temperature and pressure conditions, but as the mixture is inert, no spray combustion occurs. In this way, the spray mixing and vaporization processes may be separated from that with ignition and combustion. In addition, when spray combustion does occur in an oxygenated environment, the measured pressure rise within the constant-volume chamber (CVP or CVH) may be related to the spray heat release rate, including ignition delay and combustion duration. While CVP chambers can traverse a wide range of temperature, pressure, and ambient compositions compared to other devices and provide quantitative heat release rate, a disadvantage is that the preparation steps to produce the preburn take several minutes, thereby limiting the rate of experimentation, particularly compared to continuous-flow CPF chambers.

Beyond being a tool for understanding spray mixing and combustion, constant-volume preburn CVP chambers have contributed significant understanding about SI and flame propagation processes at the conditions most appropriate to engines. Heat release from the flame propagation continuously increases the pressure and temperature of the unburned reactants, or end gas, which modifies the local conditions of the flame as in an actual engine. Idealized experimental configurations, such as the development of a laminar, spherical flame originating from an ignition site, are utilized to understand the temperature of the unburned gases with respect to time, thereby providing a measurement of flame speed as a function of reactant temperature and pressure (Metghalchi and Keck, 1982). Such CVP experiments provide the most pertinent data (e.g., laminar flame speed, autoignition or knock, and soot formation dependency on equivalence ratio) for fuels, charge-gas compositions, and charge-gas temperatures and pressures appropriate to engines.

2 OPTICAL DIAGNOSTIC TECHNIQUES

A variety of in-cylinder phenomena may be probed by optical diagnostics, including flow structures and turbulence associated with gas exchange, compression/expansion, and transient fuel jets; liquid-fuel atomization and vaporization; mixing of vapor fuel with ambient gases; ignition and combustion; and SI kernel growth, premixed flame propagation and quenching, and pollutant formation and destruction. The light measured by the optical diagnostics may arise naturally from combustion processes, or it may be artificially introduced and/or induced using external light sources, including lasers, flashlamps, arcs, and light-emitting diodes. Many optical diagnostics are available, and it is beyond the scope of this chapter to present all of them. The following is a brief overview of several of the more commonly used diagnostics.

2.1 Naturally occurring luminescence

Combustion processes emit light from chemical reactions (chemiluminescence) and combustion-heated particles may

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

also emit light (incandescence). Both the intensity and the spectrum (color) of the naturally occurring luminescence can provide information about the local temperature and concentration of the emitters.

2.1.1 Chemiluminescence

Chemical reactions during combustion can emit light either directly, during the reaction, or indirectly, by producing electronically excited species that later emit light when they spontaneously return to an electronic ground state. For direct chemiluminescence, excess reaction energy is emitted as light (photons). One important direct chemiluminescence reaction is the CO continuum

$$CO + O \rightarrow CO_2 + hv \quad (1)$$

In Equation 1, hv represents the emission of a photon from the reaction. The wavelength (color) of the emitted photon depends on the excess energy in the reaction collision, which is not quantized. Hence, the photon wavelength can vary continuously. In the case of the CO continuum, the emission is in the blue to ultraviolet (UV), over the approximate range from 350 to 450 nm.

For other chemiluminescence reactions, excess chemical energy is not released immediately, but rather it is temporarily stored in the electron cloud of one of the product species. A few important reactions producing electronically excited species are

$$CH + O_2 \rightarrow CO + OH^* \quad (2)$$

$$C_2 + OH \rightarrow CO + CH^* \quad (3)$$

$$CH_2 + C \rightarrow H_2 + C_2^* \quad (4)$$

$$CH_3O + OH \rightarrow HO_2 + CH_2O^* \quad (5)$$

In Equations 2–5, the "electronically excited" species are denoted by an asterisk superscript. In the excited species, one electron occupies a quantum manifold (shell) that is one or more electronic levels above the lowest, or ground manifold. The electron does not remain in the excited manifold indefinitely, but rather spontaneously "relaxes" to a lower (usually ground) manifold, and in doing so, emits a photon. Both the excited and ground manifolds can have a multitude of slightly different, yet discrete (quantized), energy states, depending on the vibrational and rotational quantum numbers of the occupied states. The spontaneous transition of each excited molecule must occur between discrete quantum states. As a result, the wavelength (color) of the emitted photon must correspond exactly to the energy difference between the two states. Among the population of all emitting molecules in a probed region, many different transitions will occur between many different vibrational and rotational states, so that the collection of emitted photons will have many different, yet discrete, colors. The chemiluminescence emission thus bears the spectral "fingerprint" of the excited species.

The intensity of chemiluminescence emission depends on the reaction rate and/or the concentration and temperature of the emitters. High temperature combustion reactions that produce CH^*, OH^*, and $C_2{}^*$ are often detectable with photodiodes or unintensified cameras at bandwidths or frame rates on the order of 10 kHz. For weaker low temperature (cool flame) combustion reactions, emission from CH_2O^*, or for conditions with weaker high temperature reaction emissions (e.g., with dilution by exhaust gases or late in combustion), photomultiplier tubes or intensified cameras may be required.

A few notable examples of chemiluminescence measurements are using chemiluminescence of OH^* as a marker for high temperature reactions in diesel sprays to measure the lift-off length (Siebers and Higgins, 2001); using relative CH^*, $C_2{}^*$, and OH^* chemiluminescence intensities to infer the local equivalence ratio (Ikeda, Kaneko, and Nakajima, 2001); tracking ignition and combustion in compression-ignition engines (Table 3) (Augusta *et al*., 2006; Kokjohn, Musculus, and Reitz, 2012); and kernel development and flame propagation in SI engines (Smith and Sick, 2005; Aleiferis *et al*., 2004).

Limitations of chemiluminescence include the line-of-sight nature of the signal and interference by other emitters. Emitters all along the line of sight contribute to the emission that reaches the detector, so that the signal represents an accumulation along the line of sight. Hence, two-dimensional images are effectively projections of a three-dimensional source. Spectral measurements also represent an integration along the line of sight. Spectral filters or dispersion techniques (e.g., spectrographs) can help to isolate specific emitting species, but the spectral emission of multiple species often overlap, which limits the specificity of the chemiluminescence signal. Furthermore, other emission sources, especially including soot incandescence, can be orders of magnitude stronger and overlap spectrally with the chemiluminescence emission.

2.1.2 Soot incandescence

Under fuel-rich conditions, combustion reactions can synthesize carbonaceous soot particles, some of which

survive combustion and are ultimately exhausted from the engine, along with adsorbed hydrocarbons and sulfates, as particulate matter (smoke) (see Particulate Formation and Models for more information about particulate matter). The soot is of practical interest because it is a primary component of particulate matter, and emissions of particulate matter from engines are regulated in most markets. Hence, knowledge of the in-cylinder processes that control the formation and destruction of soot is important for designing combustion systems that comply with air quality standards.

While inside the engine, the combustion-generated soot particles are heated to high temperatures such that they glow by incandescence. In an aerosol (cloud) of soot particles, some of the light emitted by each particle is scattered and absorbed by other particles, and the amount of absorption and scattering within the aerosol depends on the amount of soot and the light wavelength. The spectral intensity

of light that is ultimately emitted by a soot aerosol can be approximated as a fraction ε (emissivity) of that of a blackbody, according to the Planck equation

$$I = \varepsilon \frac{375\ [\mathrm{W \cdot nm^2}]}{\lambda^5 \left(\exp\left(\frac{14.4 \cdot 10^6 [\mathrm{nm \cdot K}]}{\lambda T}\right) - 1\right)} \tag{6}$$

In Equation 6, I is the total spectral intensity in watts per cubic nanometer (radiative power per source area per wavelength) emitted into a hemisphere, λ is the light wavelength in nanometers, T is the soot temperature in Kelvin, and ε is the emissivity (which would have a value of one at all wavelengths for a blackbody).

Assuming scattering is negligible, the emissivity ε of the soot aerosol can be expressed as

$$\varepsilon = 1 - \exp(-k_a L) \tag{7}$$

where k_a is the soot absorption coefficient and L is the path length of the light traveling through the cloud. The

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

product k_aL is often termed the *KL factor*. The absorption coefficient depends on both the soot concentration in the aerosol and the soot optical properties, which vary with the light wavelength. Various approaches, either fundamental or empirical, can provide a functional relationship between k_a and the soot aerosol concentration. The optical properties of soot and the importance of scattering are highly uncertain, however, which translates to high uncertainty in the relationship between k_a and soot concentration. Nevertheless, using the two above-mentioned equations together, the broadband spectrum and intensity of the soot aerosol emission thus becomes characteristic of the soot temperature and concentration. Hence, simultaneous measurements at multiple light wavelengths can provide sufficient information to determine both the soot temperature and its concentration. Measurements at a minimum of two wavelengths are required, which yields two equations for the two unknowns (temperature and concentration).

Figure 5 shows an example of soot KL and temperature maps for *n*-heptane diesel spray combustion (Svensson *et al*., 2005). The KL and temperature data were calculated from two-color soot incandescence images acquired with a single color camera with relatively broad blue (400–550 nm) and red (570–700 nm) channel sensitivities. The two-color data were compared with laser extinction measurements of soot (Section 2.3.1), which showed that the two-color KL values were consistently lower than the extinction measurements, although the trends were consistent.

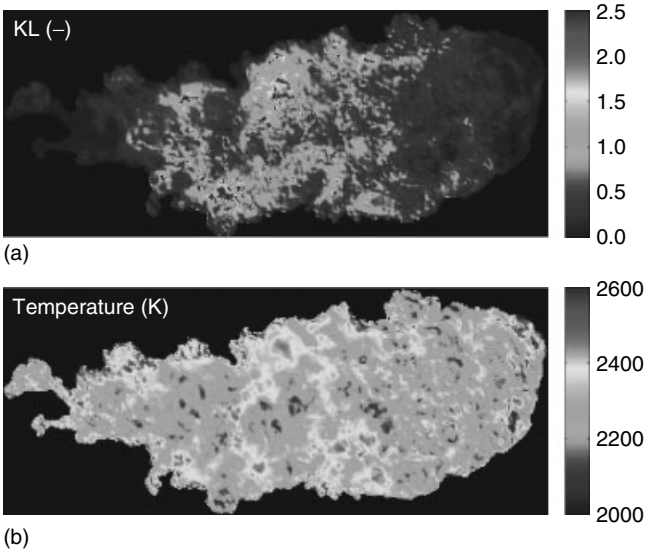

Figure 5. (a, b) Soot KL and temperature in an *n*-heptane diesel jet measured by the two-color method. (From Svensson *et al*., (2005). Copyright © 2005 SAE International. Reprinted with permission.)

In addition to the study in Figure 5, a few other notable examples of soot incandescence measurements are total soot incandescence imaging of diesel soot (Mueller and Martin, 2002); total soot incandescence, two-color, and laser-induced incandescence (LII) imaging in diesel spray flames (Pastor *et al*., 2005); and two-color uncertainty assessment with computer modeling and measurements under conventional and low temperature diesel combustion conditions (Musculus, Singh, and Reitz, 2008).

While broadband measurements (imaging) of the soot emission can provide some information about in-cylinder soot formation and destruction, the data are confounded because variations in soot intensity may be due to variations in either soot concentration or temperature, or both. Two-color techniques, in theory, can separate the temperature and concentration effects on the emission intensity, so that soot formation and destruction can be quantified. In practice, however, the measurement uncertainty can be considerable. In addition to uncertainty in the soot optical properties and absorption and scattering processes, variations in the soot temperature along the line of sight, additional extinction from window deposits, and the contribution of reflections off in-cylinder surfaces and other luminous interferences can further increase the uncertainty.

One other laser-based option for measuring temperature in engines is coherent anti-Stokes Raman spectroscopy (CARS). The technique is based on interaction of several laser beams in the probe volume and yields highly resolved anti-Stokes Raman spectra of (usually) nitrogen, which are fit to calculated data to obtain temperature. Its main advantages are high accuracy, broad applicability, and resistance against interfering signals. To its disadvantage, it is mature only as a point measurement and data evaluation requires a relatively high degree of spectroscopic expertise. A recent application example is Birkigt *et al*. (2011).

2.2 Beam refraction: shadowgraphy and schlieren

Variations in local density and composition in combustion systems and evaporating sprays create gradients in the refractive index, so that light passing through the region is bent. Optical techniques sensitive to refractive index gradients can probe such regions. Schlieren and shadowgraph imaging systems exhibit different sensitivities to the variations in refractive index and are conveniently applied wherever there is line-of-sight optical access. The lighting and imaging arrangement also lends itself easily to high speed imaging, wherein the entire cycle or injection and combustion event can be resolved with hundreds or thousands of images.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

A Z-type schlieren or focused shadowgraph setup may utilize inexpensive lighting, such as lamp or LED point sources, coupled to camera imaging systems (Settles, 2001; Pickett, Kook, and Williams, 2009). The diverging point source light is collected and collimated by a concave mirror, passed through the combustion chamber, refocused using a second concave mirror, and then directed into a camera equipped with lenses appropriate for the desired image magnification.

Schlieren stops are placed at the collection focal point to adjust system sensitivity to refractive index gradients. A knife-edge is the classic schlieren stop. When rays are steered by refractive index gradients within the combustion chamber, they may be steered into or away from the knife-edge, thereby identifying these regions in the collected image. The degree of knife-edge cutoff affects the sensitivity. With 0% cutoff (no knife-edge), the sensitivity is weakened and the system is technically no longer a schlieren setup but rather a "focused shadowgraph" (Settles, 2001). With high cutoff, the sensitivity to refractive index gradients increases. A round aperture can be used as a schlieren stop producing a "bright field", as it tends to leave the background bright, and darken regions where there is a schlieren effect. Alternatively, a full light cutoff at the focal spot with a pin shape produces a "dark field" because schlieren-effected regions appear bright above a dark background.

For vaporizing fuel sprays, schlieren imaging shows the boundary between vaporized fuel and background ambient gases because (i) refractive index differences exist between the fuel and ambient gases and (ii) density gradients are created in the ambient gases as the vaporized fuel spray cools the ambient. An example is shown in Figure 6. The technique also works well to identify the boundary of nonvaporizing sprays because of light extinction by droplets (Naber and Siebers, 1996) (Section 2.3.2). Light extinction by droplets is clearly shown in the upstream region of the spray in Figure 6. Strong density (and refractive index) gradients are also easily detected at combustion interfaces as high temperature combustion forms distinct low density regions. In addition, first-stage ignition in a fuel jet, where the parent fuel breaks down and the temperature rises only modestly, produces a vanishing schlieren effect as these ignition steps change the refractive index of the jet to match the ambient more closely (Pickett, Kook, and Williams, 2009).

Flame fronts in premixed combustion, such as in an SI engine, create steep thermal gradients that can be detected with schlieren methods. In particular, the development of the early flame kernel has been examined this way, both in combustion vessels (Metghalchi and Keck, 1982) and in engines (Salazar and Kaiser, 2011).

2.3 Beam extinction

Light passing through an engine combustion chamber may be absorbed and/or scattered by the in-cylinder contents. The sum of absorption and scattering, termed *extinction*, can be indicative of the properties and quantity of matter along the beam path. The transmitted intensity of a light beam directed through the combustion chamber can be measured to quantify the amount and/or temperature of in-cylinder soot particles, liquid fuel sprays, and in-cylinder gases.

2.3.1 Soot

The transmitted intensity I of a light beam passing through a uniform soot cloud (aerosol) can be described by the Beer–Lambert law

$$I = I_0 \exp(-k_e L) \tag{8}$$

In Equation 8, I_0 is the incident intensity of the light entering the soot cloud, L is the path length of the light passing through the cloud, and k_e is the extinction coefficient, which can include both scattering and absorption.

With measurements of the incident and transmitted intensities, the value of $k_e L$, often called the *KL factor*, can be determined using Equation 8. The KL factor is a relative measure of the amount of soot along the path of the beam. An absolute measure of the soot may be estimated using

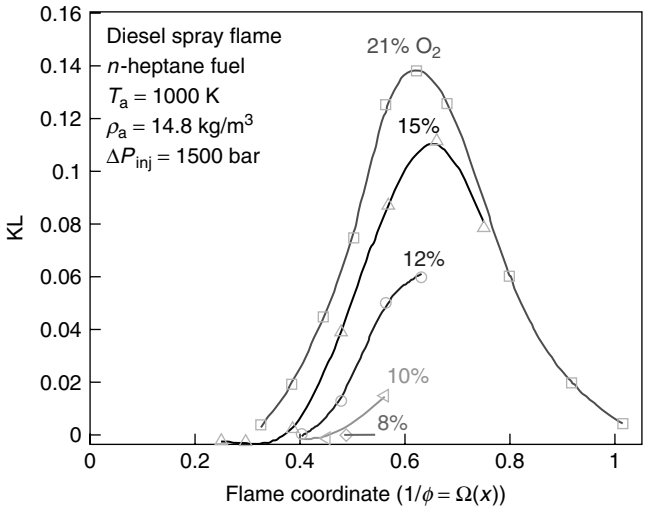

Figure 7. Laser extinction measurements of soot KL in a diesel spray flame using *n*-heptane fuel at different ambient oxygen concentrations, plotted as a function of flame coordinate. (From Idicheria and Pickett, 2005. Copyright © 2005 SAE International. Reprinted with permission.)

correlations for k_e that are either empirically based or from scattering theory using the optical properties of the soot particles. For small soot particles, extinction is typically dominated by absorption, such that the extinction coefficient in Equation 8 can be approximated as the absorption coefficient k_a used in Equation 6 of the two-color incandescence method.

The light source for extinction measurements is usually a laser source, although other light sources could be used as well. Figure 7 shows soot KL measurements in a diesel spray flame using *n*-heptane fuel at several different ambient oxygen concentrations (Idicheria and Pickett, 2005). The data are plotted versus the "flame coordinate, $\Omega(x)$," which is the reciprocal of the nominal equivalence ratio, ϕ, along the jet axis. The data show how soot is formed and consumed along the jet axis and how dilution by EGR reduces soot formation.

In addition to the study highlighted in Figure 7, a few notable examples of soot extinction measurement are combined soot extinction and LII in a gasoline direct injection engine (de Francqueville, Bruneaux, and Thirouard, 2010), fundamental soot extinction measurements in several laminar diffusion flames (Williams *et al*., 2007), and a modified forward-illumination extinction technique that can be particularly useful in engines with limited optical access (Xu and Lee, 2005).

Properly applied, the soot extinction technique can provide quantitative measurements with relatively low uncertainty, and hence, it has been used frequently as a calibration for other soot measurement techniques. Nevertheless, many of the same uncertainties in the soot optical properties and window transmission involved in the two-color soot incandescence measurements described in Section 2.1.2 must also be considered in the functional relationship between the KL factor and the total soot mass or volume fraction along the beam path. Furthermore, the technique usually needs to be designed to minimize interference from combustion luminosity, and the sensing optics must accommodate any bending of the extinction beam that may occur as it passes through regions of varying density within the combustion chamber.

2.3.2 *Sprays*

Like soot, fuel spray droplets cause light extinction of transmitted laser beams or other light sources. The attenuation of light is a convenient diagnostic to characterize the spray position and concentration of droplets or to determine the position where all liquid droplets are vaporized as they mix with hot, in-cylinder gases. Liquid droplet extinction is labeled in the vaporizing spray of Figure 6. Another example of light extinction in a low temperature hollow-cone gasoline spray is given in Figure 8. Rather than a collimated light source, as with a laser beam or schlieren imaging (Section 2.2), in this case, the spray is illuminated from the back with a diffuse light source (Ghandhi and Heim, 2009; Gasoline Fuel Injection Standards Committee, 2007). Dark regions indicating light extinction by droplets are readily apparent.

Quantifying the total liquid fuel volume along the light path is difficult because of complex extinction relationships for fuel droplets. The measured intensity and the

Beer–Lambert law (Equation 8) can be applied to assess the extinction coefficient k_e for a cloud of droplets, with $k_e = \sigma_{ext}N$ where σ_{ext} is the extinction cross section of a droplet and N is the number density of droplets. However, fuel droplets have much different σ_{ext} characteristics compared to soot particles. Fuel droplet extinction is dominated by light scattering, rather than absorption. In addition, fuel droplet size is much larger (tens of micrometers) than that of soot particles (tens of nanometers). As shown in Section 2.4.1, Mie scatter theory predicts significant changes in σ_{ext} depending on the size of the particle/droplet, thereby making quantification difficult, especially as droplet size is nonuniform in most applications. Another challenge is that many engine sprays are dense, with either high σ_{ext} or N, causing nearly complete extinction, as well as multiple photon scattering with illumination originating from many directions other than the original source. Techniques to suppress multiple scattering are therefore being developed and applied, with both advanced laser systems (Berrocal *et al*., 2008; Linne *et al*., 2009) and X-ray sources (Kastengren *et al*., 2009). While difficult to quantify the fuel volume within the spray, light extinction is particularly useful for rapid characterization of the spray envelope as depicted in Figure 8.

2.4 Elastic scattering

Direct elastic scatter from laser or other light sources is applied to characterize in-cylinder fuel–air mixing, liquid evaporation, and combustion. Unlike the diagnostics covered thus far in previous sections, light collection at angles to a precisely directed light source allows spatially resolved, rather than line-of-sight, measurement. The application of elastic scattering depends strongly on the size of the particle. Complex Mie scatter theory is required for particles and droplets, whereas a simpler Rayleigh scatter assumption can be applied to small particles and molecules.

2.4.1 Mie scatter

Gustav Mie developed an analytical solution to describe the scattering of light by spherical particles or droplets, given the light wavelength, the droplet diameter, and refractive index. Figure 9 shows the angular scattering intensity calculated from Mie's solution for an *n*-dodecane droplet with a diameter of 5 μm, a size that is typical for engine fuel sprays. Figure 9a indicates that the strongest scatter (by a factor of 10 or more) occurs in the forward direction (0°), but some light is also scattered sideward and backward. Scattering peaks and valleys (or lobes) also exist at discrete angles, for example, near 30°, and these angles vary with droplet diameter.

The total scatter is also very sensitive to droplet diameter. Figure 9b shows the extinction cross section σ_{ext} versus droplet diameter d, where σ_{ext} is proportional to the summation of light lost through the scattering process at all angles. Larger droplets more typical of a spray exhibit a d^2 dependency on σ_{ext}, whereas smaller droplets and particles with diameters approximately less than the light wavelength fall into the Rayleigh-scatter regime and exhibit a d^6 dependency, as well as a simpler angular scattering pattern.

Because of the difficulties associated with understanding the exact droplet diameter and collection angle, as well as the actual incident intensity after attenuation and scatter by

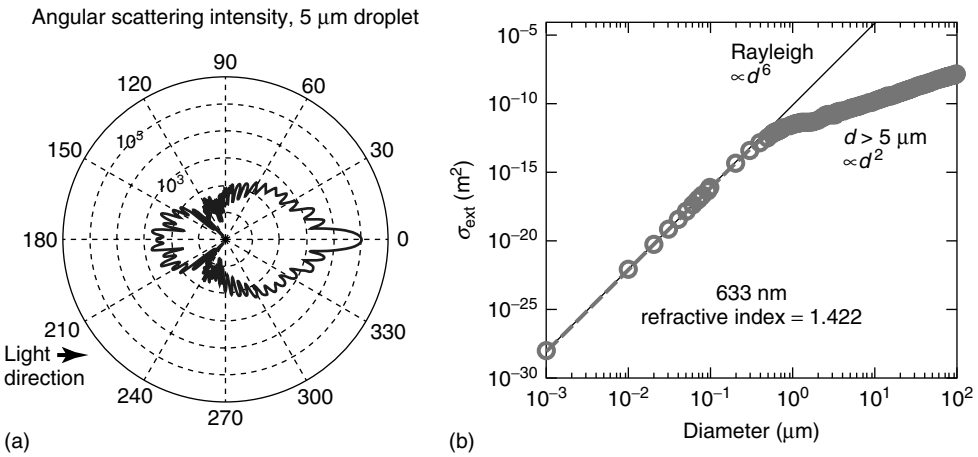

Figure 9. (a) Angular scattering intensity distribution (logarithmic scale) for a 5-μm *n*-dodecane droplet in air. (b) Extinction cross section as a function of droplet diameter (logarithmic scale). Wavelength is 633 nm and unpolarized; droplet refractive index is 1.422.

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

other droplets, Mie scatter is typically not used to quantify total droplet concentration in engine applications. However, it can be used to identify if droplets do or do not exist at a particular location and is therefore widely used for imaging in engines. In addition, Mie scatter optical techniques, such as phase-Doppler interferometry, capitalize on the existence of angular scattering lobes indicated in Figure 9 as means for measuring droplet diameter size distributions within sprays (Sankar *et al*., 1991).

2.4.2 *Rayleigh scatter*

Elastic scatter from small, nanometer-sized particles exhibits Rayleigh scattering behavior when using typical light sources. Soot particles or even gaseous fuel molecules fall into this regime. For example, the molecular size of vaporized *n*-dodecane is less than 2 nm and the extinction cross section $\sigma_{ext} = 8.5 \times 10^{-29}$ m^2 (Pickett *et al*., 2011), consistent with the relationships shown in Figure 9. By comparison, σ_{ext} for a typical droplet is more than 15 orders of magnitude higher. This major difference effectively means that Rayleigh scattering measurements must be performed in an environment without droplets or larger particles, and other scattering sources such as window reflections must be minimized. If this can be achieved, Rayleigh scattering offers the potential for quantitative measurement because, unlike droplet Mie scattering, the scattering cross sections for gaseous fuel and oxidizer molecules are known (Idicheria and Pickett, 2007).

Figure 10 shows a composite of a Mie scattering (left) and Rayleigh scattering images (top right) acquired in a vaporizing *n*-heptane fuel spray. The Mie scattering and Rayleigh scattering images are shown as a composite, but they were actually obtained at different instances with different experimental setups. The Mie scattering image shows that as the spray entrains and mixes with the hot ambient, all of the liquid fuel is eventually vaporized downstream of about 10 mm. A laser sheet positioned downstream of this liquid droplet region induces Rayleigh scattering from fuel vapor and ambient gases without interference from liquid droplets.

The Rayleigh scattering signature from the ambient gases outside of the spray creates reference data that permits corrections for laser sheet intensity variations caused by energy variation in the delivery beam as well as beam steering in the high pressure combustion vessel. The laser energy variation is apparent in the raw Rayleigh image. Not only is the incoming laser intensity nonuniform, but as the laser beam propagates through the vaporized fuel spray from bottom to top, there is additional beam refraction caused by temperature variation within the spray (see Section 2.2 for more discussion on beam refraction). The success of these corrections is indicated by image at the bottom of the figure, where intensity in the right image is proportional to the local mixture fraction (or fuel mass fraction).

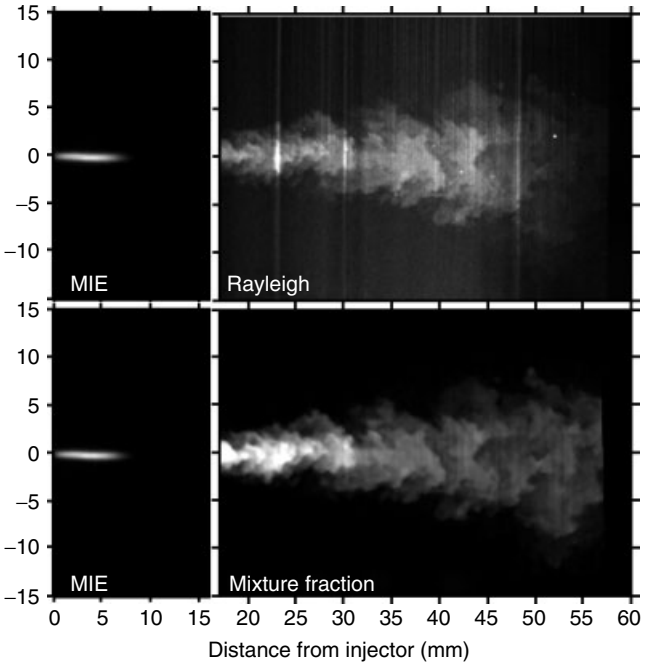

Figure 10. Composite image of Mie scattering (left) and Rayleigh scattering (right). Ambient conditions: 1000 K, 14.8 kg/m^3, 4.2 MPa, and 0% O_2. Injector conditions: 0.100-mm orifice, 154 MPa, and *n*-heptane. (From Pickett *et al*., 2011. Copyright © 2011 SAE International. Reprinted with permission.)

2.5 Fluorescence

Like chemiluminescence (Section 2.1.1), fluorescence refers to light emitted when an electronically excited molecule spontaneously transitions to a lower energy state. For fluorescence, the molecule is excited not by chemical reaction but by absorption of light photon(s), typically from a laser source (laser-induced fluorescence, LIF). The photon absorption is typically very strong, so combustion intermediate species can be detected down to ppm-level concentrations. As described in Section 2.1.1, each molecular species only absorb photons at specific wavelengths (colors), so specific species may be targeted if the available laser output wavelengths can be matched to the absorption wavelength of the target species. In combustion, many of the practically useful absorption lines are in the UV wavelength region.

After excitation into a specific energy state, various energy transfer processes (e.g., collisions) populate other

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto132
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

rotational, vibrational, and even electronic states, typically with lower energy than the directly excited state. When these lower energy states transition back to the ground state, the emitted photon has less energy than the original excitation photon. Spectrally, this means the fluorescence emission occurs at a longer wavelength than excitation. This redshift is of great practical importance, because it allows *blocking* the incident laser wavelength by suitable color-selective filters while still *detecting* the fluorescence signal. Thus, the detector sees only the redshifted fluorescence signal, not unwanted reflections and scattering of the laser light at the unshifted color off windows, particles, and so on.

Not all excited molecules emit a fluorescence photon. Collisions with other molecules can deexcite the excited molecule without emission of a photon, a process called *quenching*. The likelihood of quenching depends on pressure, temperature, and the collisional partner, that is, on the gas composition. There are also other noncollision deexcitation mechanisms, such as intersystem crossing and internal conversion, which depend on temperature. The overall likelihood of absorbing light and then returning to the ground state via fluorescence, or equivalently, the fraction of excitation photons that yield fluorescence photons, is called *quantum efficiency*.

As a result of the multitude of energy pathways in the fluorescence process, determination of the quantum efficiency requires knowledge of both the photophysical properties and the thermochemical environment of the molecule to be detected. The former is often not available from the literature for high temperature and pressure; the latter may not be known in combustion. Hence, quantification of fluorescence signals to determine concentration can be challenging or even impossible. On the other hand, these dependencies can sometimes be exploited to gain additional knowledge about the local temperature or gas composition. For these reasons, advancement of fluorescence measurements in engines crucially depends on improving our understanding of photophysics at engine-relevant conditions via fundamental experiments in pressurized, heated cells and shock tubes.

2.5.1 Combustion intermediates

Among the educts and products of complete combustion, nitrogen, oxygen, water, or carbon dioxide cannot be detected by fluorescence in engines in a practically useful manner. However, some important combustion intermediates and fuel components have accessible electronic transitions making LIF a powerful tool for their in-cylinder measurements. Table 4 summarizes key features of fluorescence measurements in engines for five commonly detected combustion intermediates. All have fluorescence signals strong enough for spatially resolved, two-dimensional planar laser-induced fluorescence (PLIF), although barely so in the case of CO. Note that, except for C_2, all excitation wavelengths are in the UV, which is typical for electronic absorption bands of small molecules.

The hydroxyl radical (OH) is one of the most common targets for fluorescence measurements of combustion intermediates. Strong absorption features around 283.5 nm can be excited by use of tunable UV lasers such as a frequency-doubled, Nd:YAG pumped dye laser or an optical parametric oscillator (OPO). In nonpremixed combustion (classic diesel), OH is formed in hot, stoichiometric or slightly fuel–lean mixtures. In premixed auto-ignition (HCCI), OH indicates the active second-stage ignition and the main phase of heat release. In premixed SI, the initial appearance of OH delineates the flame front, and it persists later in the burnt regions.

In addition to those listed in Table 4, many other species can be detected, although most of them not in the single-shot measurements that are necessary to "freeze" turbulent fluid motion. The main limitations are the lack of powerful, tunable, UV lasers that could utilize the weak transitions of the more "exotic" species and also interference of more common species.

Quantitative concentration measurements of combustion intermediates in engines are difficult and correspondingly

Table 4. Qualitative overview of the most commonly used schemes for fluorescence measurements of combustion intermediates in engines.

Species	λ_{exc} (nm)	λ_{det} (nm)	Laser	Indicative for	Signal
OH	(248) 283	310	(KrF excimer) dye, OPO	High T reactions	Strong
H_2CO	353, 355	400–475	dye, Nd:YAG	Low T reactions	Strong
NO	226 (248)	225–300	OPO (KrF excimer)	High T, pollutant	Weak
CO	230	484	OPO	Incomplete or rich combustion	Very weak
C_2	355, 532	435–640	Nd:YAG	Soot and its precursors	Medium

The excitation and detection wavelength given in columns 2 and 3, respectively, are not the only possible choices. Like all other entries, they merely represent the dominant literature values. Entries in parentheses represent less common choices.

Dec and D.R. Tree.)

uncommon. Major challenges are the lack of literature data on the species' high pressure, high temperature photophysics, difficulties in calibrating against a known concentration (particularly for unstable intermediates), complicated dependencies of fluorescence on usually unknown local temperature and gas composition.

Fortunately, much can be learned from qualitative, spatially resolved measurements. Even more information can be extracted from combined measurements, for which LIF is very suitable, because often the signal is limited to a narrow spectral region and can be separated from other, simultaneously detected channels. For instance, consider the images in Figure 11. We learn *where* OH is located in the spray flame, *when* it appears during the injection, and *where* it is in *relation* to the soot. From this, we can infer that the edge of the spray flame is hot and stoichiometric to slightly fuel−lean and that this remains the case throughout the entire injection. Furthermore, OH and soot have very little spatial overlap, which indicates that the OH-containing edge is likely actively oxidizing soot.

2.5.2 *Fuel and fuel tracers*

Most commercial fuels, with the notable exception of biodiesel, emit strong fluorescence when illuminated by UV lasers. Therefore, LIF can be used to detect both liquid- and gas-phase fuels with good sensitivity. Two-dimensional, PLIF is possible with several laser types, including excimer or Nd:YAG lasers. In some circumstances, conversion of the LIF signal to fuel concentration is possible; however, in general, quantification is difficult because commercial fuels are mixtures that contain multiple fluorescing components, many of which have unknown photophysical properties.

In quantitative LIF measurements, a nonfluorescing *model fuel* is typically doped with a *tracer*, which exhibits fluorescence with known characteristics. Ideally, the tracer behaves like the fuel in all physical and chemical aspects and the mixture of nonfluorescing model fuel and the tracer behaves like the commercial fuel it is supposed to model. Conveniently, none of the aliphatic components in the traditional primary reference fuels for gasoline and diesel (*n*-heptane + iso-octane and *n*-cetane + iso-cetane, respectively) fluoresces significantly at near UV wavelengths. The most common types of tracers are one- or two-ring aromatics, ketones, aldehydes, and amines. The aromatic compounds also are also found in significant quantities in commercial fuels. Unlike the small combustion intermediate molecules with narrow absorption lines in Table 4, the larger tracer molecules have broad absorption spectra, covering tens of nanometers. Therefore, complicated and weak tunable lasers are usually not necessary. Tracer LIF is most often used to image the mixing of evaporated fuel and intake air, as for example shown in Fuel Introduction.

In engine applications, the photophysical processes of LIF are dependent on excitation wavelength, gas composition, pressure, and temperature. Each of these dependencies can be an obstacle in quantification of the measurements but, once known, can also give the opportunity to measure the quantity of influence. For example, the dependence of toluene fluorescence on temperature has been characterized in shock tube and flow cell experiments (Koban *et al*., 2004). It can be exploited to determine that quantity based on either the redshift of the emission spectrum with increasing temperature (Luong *et al*., 2008) or the overall decrease of signal with increasing temperature (Dec and Hwang, 2009).

Two important limitations in the applicability of tracer LIF are the presence of liquid-phase fuel (spray) and the onset of combustion reactions. Fluorescence from a simultaneously present liquid phase is hard to quantify, although techniques exist to at least reliably separate it from gas-phase fluorescence ("Exciplex" fluorescence). The chemical

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

reactions of combustion convert the tracer via usually unquantifiable intermediates into nonfluorescing species.

2.6 Laser-induced incandescence of soot

As described in Section 2.1.2, soot heated to high temperatures by combustion emits light by incandescence, and the intensity of the incandescence increases nonlinearly with temperature. For instance, according to Equation 6, a 10% increase in temperature from 2400 to 2500 K results in a 60% increase in light emission at 500 nm (green color). Using high energy pulsed lasers, the soot particles can be heated by absorbing laser light to much higher temperatures. The laser heating limit is the vaporization temperature of the soot, which is approximately 4000–4500 K. At 4000 K, the emission at 500 nm increases by a factor of 120 relative to 2400 K. As a result, LII emission captured over the duration of the short (typically ~10 ns) high power laser pulse can be dominated by the laser-heated soot.

In theory, the LII technique can be quantitative. The soot temperature should remain at a steady level during vaporization (akin to boiling water), so that the signal becomes independent of laser intensity. Hence, above the vaporization threshold intensity, the LII emission should be independent of the local laser intensity. At a constant temperature, the LII signal is approximately proportional to the soot volume fraction.

One advantage of the LII technique over other line-of-sight techniques such as two-color soot incandescence technique described in Section 2.1.2 is that the laser-induced emission arises only from sooty regions that intersect with the path of the laser beam. Hence, LII of soot can provide spatial resolution along the line of sight of the detector.

To achieve the laser light intensities required to heat soot particles to their vaporization temperature, even high power beams typically must be focused on a small region. For imaging techniques, the laser beam is focused into a thin sheet (1 mm thick or less) for PLII of soot. Figure 11 shows a series of composite images of PLII of soot (dark gray) with PLIF of OH (light gray) for one of the eight diesel jets in an optical diesel engine (Dec and Tree, 2001).

In addition to the images in Figure 11, a few other notable examples of soot LII measurements are soot LII in a DI diesel engine (Pinson *et al*., 1993), combined soot extinction and LII in a gasoline direct injection engine (de Francqueville, Bruneaux, and Thirouard, 2010), and high speed soot LII in a laboratory burner and an optical engine (Sjöholm *et al*., 2011).

Although soot LII can be quantitative in principle, several factors introduce significant uncertainty. The vaporization temperature signal plateau predicted by theory is not observed in practice because of nonuniform laser beam intensity distributions and obliteration of soot particles by excessive vaporization at high laser beam intensities. Interferences from other effects, including fluorescence of photolysis products such as C_2 and C_3, as well as fluorescence of polycyclic aromatic hydrocarbon soot precursor species, can also spectrally and temporally overlap with the LII emission. In addition, while the LII emission is much stronger than the combustion-heated soot emission within the measurement volume, integration of the combustion-heated soot along the whole line of sight from the detector can be a significant interference, depending on the soot cloud geometry.

2.7 Velocimetry

In-cylinder convection and turbulence are two flow properties of paramount importance to engine operation because they determine transport and mixing, discussed in detail in In-Cylinder Flow. Two families of diagnostics have been applied in engines to measure velocity. The two-dimensional techniques are particle image velocimetry (PIV) and particle tracking velocimetry (PTV), and a point-measurement technique is laser-Doppler velocimetry (LDV).

The velocity of spray droplets can be measured directly. On the other hand, in engines, gas-phase velocity almost always needs to be measured indirectly using small particles seeded into the intake gas. Seeding is far from trivial. Particles need to be

- present at all measurement locations and timings in the right density, which is dependent on the technique;
- small enough to follow the flow with the required fidelity, but large enough to enough scatter light for reliable detection;
- not interfere with the measurement by fouling the windows or disturbing the flow itself;
- survive the high temperatures of compression or even combustion as required by the measurement timing.

In fact, ongoing development aside, the diagnostics described later are fairly mature. The challenge in engines is proper seeding. Typical seed particles are droplets from liquids with high boiling point, such as silicone oil or di-ethylhexyl-sebacate (DEHS), or (less commonly) solid particles from silicon dioxide, graphite, or hollow glass spheres. Liquid seeding does not survive combustion, which

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

can also be an advantage, because the absence of seeding then approximately marks the burned gas.

For engines, particles with diameters on the order of 20 μm follow the mean bulk flow with sufficient fidelity, while investigating small-scale turbulence or highly rotational flows may require particle sizes of less than 1 μm. If quantitative results are the goal, a case-based comparison of the expected accelerations (i.e., particle inertia) and aerodynamic drag is required.

The development of velocimetry has greatly profited from the broad range of applications. Uniquely among the diagnostics discussed here, complete systems including lasers, detectors, and computer units for timing, data acquisition, and data evaluation are commercially available from several companies. This should not detract from the fact that reliable measurements in engines are still not easy.

2.7.1 PIV and PTV

Both PIV and PTV are based on the same principle. Particles in an extended probe volume, typically a plane of about 1 mm thickness, are illuminated by two (or more) laser pulses separated by known time interval(s). An image of the light scattering from the particles is acquired with each laser pulse. The measured particle displacement divided by the interpulse time yields velocity vectors throughout the field of view. In the basic configuration, the two in-plane components of the velocity vector are determined, but extensions exist for capturing all three, and potentially not only in a plane but also within a volume. Extracting more information requires more cameras and better optical access, which limits the applicability in engines.

The difference between PIV and PTV is in the data evaluation, which corresponds to a difference in seeding density. In PTV, the seeding density is low, thus bright spots (i.e., particles) in the images are sparse. This allows for tracking the displacement of individual particles between the two images with little ambiguity. Each particle yields one velocity vector. In PIV, seeding is dense in the sense that the displacement of individual particles cannot be determined unambiguously. Instead, the image is partitioned into many "interrogation areas," each large enough to contain at least several particles. Via cross correlation of two corresponding interrogation areas in the two images, the average displacement within the area is calculated. Each velocity vector relies on data from all particles in the interrogation area, increasing precision. In addition, PIV can achieve higher resolution when seeding is sufficiently dense. When dense seeding cannot be achieved, PTV is advantageous. Hybrid techniques for spatially very inhomogeneous seeding exist. Figure 6 in In-Cylinder Flowshows examples of flow fields acquired by PIV.

In engines, viewing the probe volume through curved windows introduces particular challenges for PIV and PTV. As for measurements of scalar quantities, distortion needs to be corrected. However, the cross-correlation algorithm relies on information on the pixel level. Residual aberrations, inevitable in a case like that shown in Figure 2, degrade the accuracy of the cross correlation and thereby the velocity measurement. Distortion also can result in significant bias of the two measured in-plane velocity components by the unknown out-of-plane component (Miles, Hildingsson, and Hultqvist, 2007).

2.7.2 LDV and PDA

While PIV and PTV provide instantaneous measurements across an extended field of view, LDV delivers a nearly continuous stream of velocity data from particles passing through a small, point-like probe volume. In LDV, also called *laser Doppler anemometry* (LDA), two coherent laser beams of the same (or very nearly the same) wavelength are focused into the probe volume at a small angle such that an interference pattern is formed. Particles moving through this spatial intensity modulation cause temporally varying scattering, which is detected by receiving optics. The transverse component of the particle velocity can be determined from the modulation frequency. Each passing particle yields one data point. The data rate depends on flow velocity and seeding density, but rates of tens of kilohertz are achievable. Extensions with multiple lasers and detectors can measure more than one vector component.

Another important extension of LDV is phase Doppler anemometry (PDA), applicable to transparent particles such as droplets from a spray (Sankar *et al*., 1991). In this technique, a suitably located second receiver allows for determination of droplet size in addition to velocity. PDA is a powerful tool for the quantitative study of injection sprays and as such is indispensable for the development of computational spray models.

Material and Process Selection—Cylinder Blocks and Heads

Marc C. Megel and George E. Bailey

Southwest Research Institute, San Antonio, TX, USA

1 INTRODUCTION

Cylinder heads and blocks are subjected to cyclic pressure and thermal loading. There are also assembly loads that must be withstood. In blocks, the cylinder head is clamped tightly to the block with head bolts, and there is also pressure from the head gasket that must seal the combustion pressure. The main bearing caps are installed at a high torque to carry the loads from the crankshaft. The cylinder head is also subjected to the loads from the head bolts and head gasket. Valve seats and valve guides are often made of a different material than the head, and are installed with interference fits.

These assembly loads that may at first seem constant are also cyclically loaded as the members react loads from both combustion and changes in dimensions because of thermal expansion. Thermal gradients can be great, for example, when a cold engine is started. When an engine is started, the combustion gases rapidly heat the walls of the combustion chamber. The walls will try to expand because of the nonzero thermal expansion coefficient of the material, but the bulk material of the block and head that is still cold will constrain this expansion putting the bulk material in tension. The material must have sufficient strength to withstand this tension, on top of the forces from combustion and assembly loads. If the material has high thermal conductivity, the heat will travel through the block and head faster and these stresses will be reduced. This brief discussion begins to illustrate how the properties of the block and head interact. If the material has a higher thermal expansion coefficient, it will need higher strength. However, if thermal conductivity is high, then the strength of the material will not need to be quite so high.

The design of the head and block influences the material choice, as thinner sections will have lower thermal gradients but will require stronger material. As the loading is cyclical, the material will need to possess adequate fatigue life at all operating temperatures. There are three fatigue cases that need to be considered. The engine is subjected to high cycle fatigue (HCF) loading from combustion forces. The structure must be designed for infinite HCF life. The engine is subjected to low cycle fatigue (LCF) loading during start-up. The LCF durability target needs to be chosen according to a projected number of cycles determined for a particular application. Thermal shock loading also needs to be considered. This occurs when the engine is started from its coldest condition and needs to make maximum power rapidly.

Except in rare cases, the cost of the engine must be kept as low as practically possible for the manufacturer to capture and maintain a share in the market. The block and cylinder head have complicated shapes as they must house the moving components, have passages for coolant and lubricant, and provide mounting points for accessories,

ISBN: 978-0-470-97402-5

pumps, manifolds, fuel injectors, ignition systems, and so on. In most cases, it is impractical to fabricate blocks and heads from plates or machine them from solid, so castings are employed. In the casting process, molds are prepared, which include cores. The inside of the mold forms the outer shape of the component to be cast. Cores form the interior passages, such as water jackets and gas ports. When a component is cast, liquid metal alloy is either poured or injected into the mold, where it flows into the mold around the cores until the cavity is filled, and all of this is happening as the molten alloy is cooling. The resulting casting must have consistent properties and not possess significant voids or porous regions. The cooling rate of the metal alloy will affect its material properties, so that rate must be understood and controlled. The collective behavior of materials during the casting process is referred to as *castability*. Some alloys behave well when cast in thin sections, whereas others are required for thick sections. Of course, these different alloys have different mechanical properties, which must be considered during the design of the component.

The choice of materials for blocks and cylinder heads is thus a very involved and complicated process. The proper choice is the difference between an engine that only runs well when it is new, and a durable engine that has consistent performance over its intended lifetime.

2 MATERIAL SELECTION

The primary choices for engine blocks and heads are cast irons and aluminum alloys. Magnesium alloys are sometimes used, but are not as common. A recent example would be the hybrid magnesium/aluminum cylinder block casting produced by BMW, which claims to reduce the block weight by 24% versus 100% aluminum alloy using a magnesium skeleton. Cast irons do not conduct heat as well as aluminum or magnesium alloys; they take longer to reach operating temperature, and they are heavier but have significantly higher tensile and fatigue strengths depending on the grade. Typical densities of cast iron and aluminum are 7.2 g/cm^3 and 2.7 g/cm^3, respectively, so the same volume of cast iron is almost three times as heavy. While the strength of cast iron and aluminum casting alloys varies significantly, the strength of both cast irons and heat-treated aluminum alloys typically used in lower cost cylinder heads is 250 MPa. The raw material cost for common gray cast iron grades can be roughly half the cost per ton of common aluminum alloys. The specific heat of cast iron (0.46 kJ/kg-K) is roughly half that of aluminum (0.96 kJ/kg-K), but the melting point is almost double (1200°C for cast iron and 600°C for aluminum), so the energy cost per ton is similar. As aluminum castings are lighter, the energy cost per casting will be less, but aluminum castings often require thicker walls than cast iron (high peak cylinder pressure (PCP) applications), which complicates energy and material cost comparisons. Differences in costs of molds, machining, and yield must also be considered. There are cases where cast iron blocks and heads can be cheaper to manufacture than aluminum castings. These are primarily cases where (i) volume does not support permanent die molding, (ii) regional technology for product localization does not support high quality aluminum casting, or (iii) PCPs in the engine start become high enough to require significantly more material in aluminum to have the same structural integrity, noting that some applications may require cast wall thicknesses beyond what can be achieved with aluminum alloys. For light-duty, lower PCP automotive or industrial castings, aluminum can possess significant piece price advantages, primarily through high volume and the use of die molds. Cast iron also possesses higher internal damping than the nonferrous alloys, which influences engine NVH.

2.1 Specific weight

Specific weight is a key consideration when selecting a cylinder block or head material during a new engine design program. The units of specific weight are mass/power (e.g., kW/kg). This parameter helps a designer consider the impact performance requirements such as high PCP have on the overall design and the resultant weight of an engine and not just the volume and density of the material. Therefore, an optimal design should have the highest specific weight, but may not be cast from the lightest material (this is especially common for highly boosted diesel and gasoline engines).

2.2 Geometric considerations

When considering cylinder block materials for highly boosted engines, one is likely to find trade-offs between packaging dimensions and cylinder spacing. A good illustration of this comes from a comparison of the Mercedes 4.0L V8 with an aluminum block to the Audi 4.2L V8 with a CGI block (Dawson and Indra, 2007). The larger Audi engine exhibits a specific weight of 0.94 versus 0.89 for the Mercedes with a 7 mm smaller bore spacing and 120 mm shorter overall length. Each factor is extremely important when designing a light-duty, passenger car engine.

As the bore diameter of an engine decreases, the structure becomes inherently stiffer and deflects less under cylinder pressure. This deflection is what generates HCF in the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

cylinder head and block. It is this phenomena, coupled with a light-duty cycle, that allows high speed direct injection (HSDI) engines to still operate at cylinder pressures in the 180–200 bar range reliably, even with the reduced tensile and fatigue properties of aluminum.

A final geometric consideration is desired/required wall thickness. Typically, cylinder heads utilizing cast iron have a minimum production wall thickness limit of 5–6 mm with some allowances for locally thinner sections. It is possible to design cylinder heads in cast iron around a 4 mm general wall thickness, but these designs require significant development time in the foundry to ensure quality and may have cost trade-offs in scrap to achieve the lighter weight component. Aluminum can typically be sand cast in a cylinder head with a minimum wall thickness of 3–3.5 mm.

2.3 Power density

Power density, power/engine displacement (e.g., kW/L), is another critical parameter to consider when selecting materials, especially for cylinder heads. Heavy-duty diesel (HDD) engines, which normally run cylinder pressures over 200 bar, usually target specific powers of 30–35 kW/L to meet the extended durability (typically 1 million miles between overhaul) and reliability requirements of the demanding duty cycle for that application. At these levels, cast iron has sufficient thermal conductivity to transfer the heat generated by combustion. At around 40 kW/L, cast iron becomes limited in its ability to transfer sufficient heat out of the cylinder head to maintain fire deck temperatures at the material limit ($<400^{\circ}$C) even with the consideration of mixed-mode cooling (forced convection plus nucleate boiling). At these levels, a limited-duty cycle and reduced durability requirement for higher cylinder pressure operation verses heavy duty must also be assumed. At or above this level, aluminum should be considered for light-duty engine designs. These applications are also typically very weight sensitive, which also makes aluminum attractive. State-of-the-art gasoline and high speed, light-duty diesels (HSDI) operate at specific powers in the range 75–100 kW/L. At these levels, aluminum must be utilized as the cylinder head material to transfer sufficient heat from the fire deck. Even with the high thermal conductivity of aluminum verses cast iron, mixed-mode cooling will likely be prevalent at these levels.

2.4 Overview of aluminum alloys

Alloying elements are added to aluminum to change or enhance its properties. Alloying elements have different degrees of solubility in aluminum and diffuse at different rates. The combination of these properties allows various alloying elements to have different influences on aluminum alloy properties. Major aluminum alloying elements are zinc, copper, manganese, magnesium, silicon, and iron. Zinc and copper are used in high strength alloys, and manganese, magnesium, silicon, and iron are used to tailor strength, ductility, and toughness. Silicon also improves the fluidity of molten aluminum. Iron hurts ductility but improves mold-sticking behavior. Adding manganese to half the levels of iron corrects iron's influence on ductility. Copper adds high temperature strength but reduces ductility, corrosion resistance, and thermal conductivity.

Aluminum casting and wrought alloys are generally considered separately because of the requirements for castability and hot formability. Therefore, there is a different designation system for each. The European, US, and ISO designations for wrought alloys are similar but there are different systems for cast alloys. The US (Aluminum Association or AA) system will be used in this chapter. AA cast alloy designations have a decimal, which designates whether the alloy properties being reported are for castings (.0), ingot (.1), or ingot with narrow composition ranges (.2). All of the properties in this report apply to castings so the .0 suffix is implied and not written. The AA temper designation system is also used in this chapter.

Aluminum alloys classified by the AA system are given a three-number designation, where the first number represents the combination of major alloying elements. The 100 series are pure aluminums with less than 1% alloying elements. The 200 series are aluminum with copper. The 300 series are aluminum and silicon with magnesium, copper, or both as major alloying elements. The 400 series is aluminum and silicon, the 500 series is aluminum and magnesium, the 700 series is aluminum and zinc, and the 800 series is aluminum and tin. The 100 series have low strength and are primarily used where electrical conduction is important. The 800 series casting alloys are bearing grade aluminums. The 700 series alloys are age hardening alloys and do not have very good castability. The 500 series are used for automotive frames, cookware, and applications where a good surface finish is required. These alloys generally have poor pressure tightness, which makes them unattractive for use in engine blocks and cylinder heads. Some of the 400 series alloys are used for pistons. The majority of engine block and cylinder head castings are from the 300 series. As cylinder pressures and operating temperatures increase, however, there is greater interest in the 200 series, which maintain their high strength at elevated temperatures, although these alloys have limitations as is discussed below.

Some common aluminum alloys for light-duty engines are 319, 356, and 357. As cylinder pressures and temperatures increase, alloy 319 is being replaced by 356 as

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

that alloy allows tighter control of microstructure. Alloy 357 is similar to 356 but some beryllium is added to improve strength and high temperature performance. For high performance engines, these alloys are modified to enhance certain properties. Copper is added to increase strength, particularly at high temperatures, but it decreases thermal conductivity. The amounts of silicon and magnesium are also adjusted to achieve the desired balance of properties for a given application. To illustrate the differences between alloys, some properties at room temperature are compared to 319 alloy in Figure 1.

There are many variables to consider when casting aluminum that directly affect the alloy choice. Cooling the alloy faster generally produces a finer microstructure and higher strength. However, if the outside of the alloy cools too fast while the bulk is shrinking, it can tear or crack the surface. Hypoeutectic alloys (with silicon concentrations less than 11.7%) such as 390 will cool as they solidify, whereas hypereutectic alloys will tend to solidify isothermally. Therefore, it will be more difficult to cast large or complex shapes with hypoeutectic alloys. Hypereutectic alloys such as 390 will have a hard primary silicon phase, which adds to wear resistance. Compared to a hypoeutectic alloy such as 356, they have lower thermal expansion and lower thermal conductivity. Considering the case of a cylinder head, a decrease in thermal conductivity will result in a hotter combustion chamber surface, and higher thermal gradients. As strength and fatigue life decrease with temperature, these locally higher temperatures can result in lower durability.

The 200 series of casting alloys retain more strength at higher temperatures, but there are several challenges for their use in high volume production engines. Alloy 201 has exceptional strength after heat treatment and maintains this strength at high temperatures. Silver is added to improve

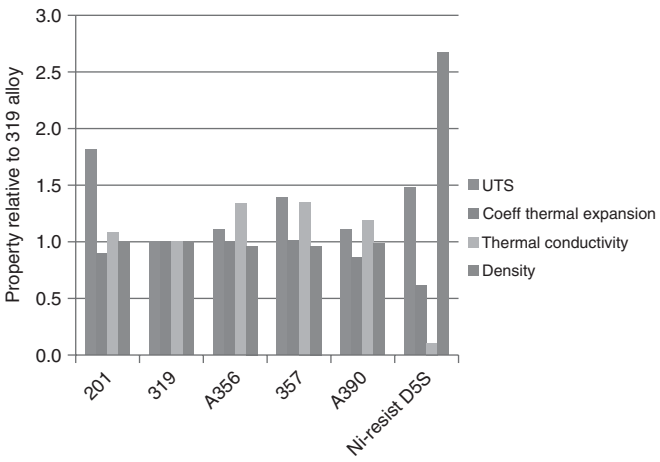

Figure 1. Room temperature properties relative to 319 alloy.

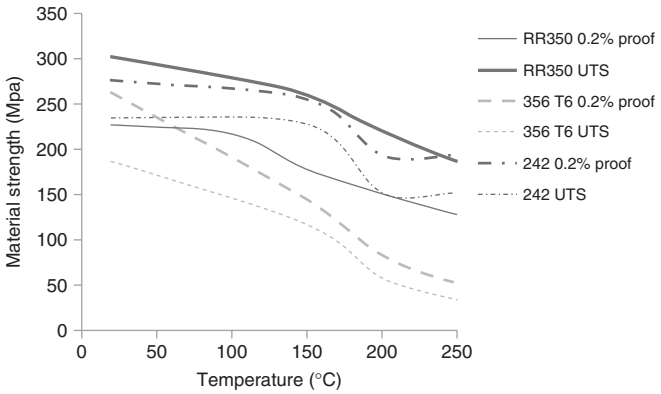

Figure 2. Strength versus temperature for three aluminum alloys.

resistance to stress corrosion cracking and to increase the response to heat treatment. This alloy is used for pistons and cylinder heads, and many aerospace applications. Alloys 242 and RR350 (in the same alloying family and also referred to as *Hiduminium* or *203*) are used for pistons and air-cooled cylinder heads. They do not contain silver such as alloy 201, so the price premium over 356 on a per-ton basis is not as great. They are low silicon alloys, so they maintain their mechanical properties at higher temperatures. Grainger and Worrall (G&W) Foundry in the United Kingdom estimated that the per ton raw material cost of RR350 would be 1.7 times that of 356. By contrast, 201 is five times that of 356 and a 200 series alloy specifically optimized for high performance engines is six times that of 356. The strength of 242 is similar to 356 but it retains much more of its strength up to 250°C as shown in Figure 2. Creep properties are better than 356 but the thermal conductivity is lower. It is more difficult to cast than 356, which could lead to increased production costs, but the biggest drawback is its lack of corrosion resistance. RR350 is stronger yet than 242 but also suffers from a lack of corrosion resistance.

2.5 Overview of cast iron alloys

Cast iron is a general term used to describe the family of iron-based casting alloys. One method of classifying the various types of cast iron is by the structure of the carbon in the microstructure. Gray iron contains lamellar graphite flakes. Ductile iron (DI) contains spheroidal graphite. Compacted or vermicular iron contains graphite that is interconnected within eutectic cells such as gray iron, but the graphite is coarser and more rounded, that is, its structure is between gray and DI. These three types of cast iron are the most common utilized in cylinder block and head castings. Within these three basic types of cast iron are

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

various strength grades, which are formed based on the quantity of alloying elements added to the melt.

2.5.1 Gray iron (GI)

Basic gray iron is probably one of the cheapest and most commonly used casting materials. Grade 250 (250 MPa tensile strength) iron is used for low cylinder pressure, low cost cylinder blocks and heads. This iron is typically good up to cylinder pressures of 160 bar and normally results in a heavier engine because of the addition of material to make up for the low tensile and fatigue properties. An exception, however, would be heavy-duty, in-line cylinder blocks (even at higher cylinder pressures) where the simplified geometric structure allows the use of a lower strength and lower cost material, and weight is not a chief design concern.

2.5.2 High strength gray iron (HSGI)

Alloyed high strength gray iron (HSGI) is the standard cylinder head material for HDD engines. This material has a flake graphite structure and derives its elevated tensile and fatigue strength levels from a minimized carbon equivalence (CE) and the use of alloying elements such as chromium (Cr) and molybdenum (Mo). While these elements are effective at increasing the strength of gray iron, there is a limit to which they can be applied and thus a limit to the maximum tensile strength, which can be achieved in gray iron for complex engine castings. Increasing the level of Mo significantly increases the risk of shrinkage porosity within the casting and thus increases production scrap rates. An increased level of Cr along with a reduced CE level increases the hardness of the material and introduces the risk of carbide formation. Therefore, production with these irons requires a foundry with good process and quality control. Typical tensile strength of these grades used in block and head castings ranges from 275 MPa for mild amounts of alloying to a maximum of 320 MPa. Fatigue strength of gray iron is highly influenced by graphite flake size, cooling rate, and the amount of alloying elements. Development of a material should target minimum fatigue strength of 42% of the target tensile strength (e.g., 135 MPa minimum fatigue strength for 320 HSGI). The casting should exhibit Type A flake graphite with a size of 3 or finer to help maximize the fatigue strength/tensile strength ratio. Figure 3 shows an example of evaluating graphite flake size during casting development.

2.5.3 Ductile iron (DI)

DI is also known as *spheroidal iron* because of the shape of the graphite contained in the microstructure. DI has

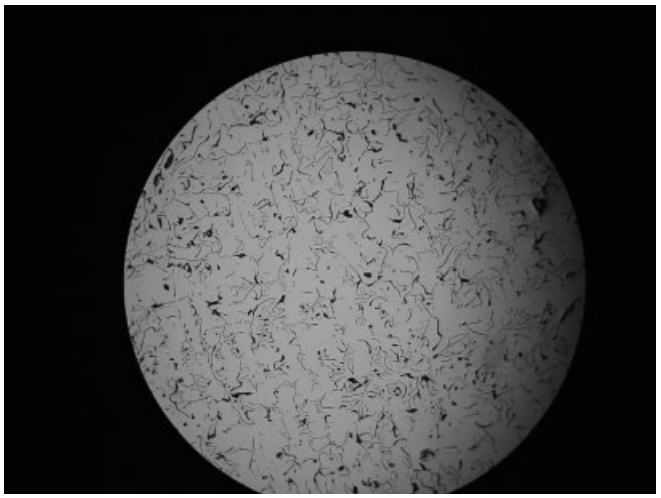

Figure 3. Graphite flake size evaluation during casting development (type A flake, size 2–4).

significantly improved tensile and fatigue strength over standard gray iron. DI derives its name from the fact that the spheroidal graphite structure makes the material significantly more ductile than gray iron where the interface between the flake graphite and the pearlitic structure essentially forms interstitial cracks within the material. While examples exist where DI has been used for unit cylinder heads (one head per engine cylinder), no slab heads have been cast in DI because of the issues associated with casting DI in a large volume, complex geometry. DI is most commonly used for exhaust manifolds and turbine housings in HDD engines as it also exhibits good high temperature fatigue properties when alloyed with silicon (Si).

2.5.4 Compacted graphite iron (CGI)

Compacted graphite iron is essentially a cross between flake gray and DI. The graphite formation yields a "worm"-shaped graphite structure. As a result, its physical and strength properties lie between gray and DI. CGI is created by inoculating the molten iron with magnesium (Mg) just before pouring into the casting mold pack. The resultant microstructure and thus strength properties are highly influenced by cooling rates within the mold pack. As cylinder heads have extremely nonuniform geometry and internal wall thicknesses, this results in a casting with varying material properties. In addition, if the iron cools too quickly, a lay of flake graphite can be formed on the surface where maximum fatigue properties are desired. This layer of flake graphite can reduce the effective fatigue strength by up to 20%. Even with this reduction, however, the fatigue strength is still higher than traditional HSGI. Controlling

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the variation of these properties is the biggest challenge for using CGI in block and head castings successfully.

Table 1 shows some example material properties obtained from separately cast test bars for versions of HSGI and CGI typically used for cylinder block and head castings. This data would be typical for castings that achieve a target UTS of 320 and 400 MPa respectively in critical sections.

One of the key factors associated with CGI or DI is the decrease in thermal conductivity as compared to high alloy gray iron. This reduction in thermal conductivity will cause an increase in peak fire deck temperatures when compared to high alloy gray iron. As a result, thermal stress in the cylinder head can increase for CGI or DI, which creates higher fatigue stress levels. Therefore, it may be difficult to realize the full strength advantage of these materials in cylinder head castings. In order to minimize the reduction in thermal conductivity of CGI versus HSGI, nodularity must be carefully controlled and minimized.

For cylinder blocks on the other hand, CGI presents many opportunities for reduced weight and package size in high cylinder pressure applications. Cylinder blocks typically exhibit more uniform material cross sections with larger sand cores for more uniform cooling versus cylinder heads, yielding more consistent material properties throughout the casting when using CGI. While thermal conductivity is still a concern for parent cylinder bore designs, the increased stiffness of CGI verses gray iron or aluminum allows for a significantly thinner cylinder wall thus counteracting the heat transfer impacts of reduced thermal conductivity while still retaining proper bore distortion characteristics. For wet-liner block designs such as heavy-duty and large-bore diesel/natural gas engines, thermal conductivity is not a concern as the cylinder heat transfer occurs through the wet-liner material. Another inherent advantage of using CGI versus gray iron or aluminum for cylinder block castings is the ability to have fractured main bearing caps because of the higher fatigue strength of the base material. Common cylinder block gray iron alloys do not exhibit the required fatigue strength required for the main bearing cap design.

Figure 4. Heavy-duty diesel main bearing cap comparison: machined-ductile iron cap with ring dowel locators (left) and fractured-CGI cap (right).

Therefore, gray iron blocks (especially for heavy-duty and large-bore diesel engines) normally use DI main bearing caps. This leads to additional cost, assembly, and machining steps in the manufacturing of the block. In addition, a common issue with high cylinder pressure blocks is main cap fretting. The use of a fractured cap eliminates all of these issues. Figure 4 shows a common, fully machined, DI main bearing cap from a heavy-duty diesel gray iron block verses a fractured CGI cap from a similar design.

2.5.5 Heat treatment

Typically, cast iron alloys will undergo some form of heat treatment process, minimally to stress relieve the casting. During solidification, the casting can develop significant residual stress, especially in the internal structure of cylinder head castings around injector and bolt boss sections. The most common form of stress relieving is in-mold stress relieving where the casting is left in the

Table 1. Example material properties for HSGI and CGI obtained from separately cast bars.

Material Property	Units	Material	
		G320	CG1400
UTS	MPa	360	483
Modulus of elasticity	GPa	115	132
Density	g/cm^2	7.2	7.1
Specific heat	J/g—°C	0.46	0.47
Thermal conductivity	W/m-K		
	At 100°C	46	39
	At 400°C	43	38

sand mold for an extended period of time to allow the casting to cool slowly and minimize residual stress. For prototype castings, a furnace heating process is typically used as the prototype mold packs are often smaller and cool faster than the production molds thus not providing sufficient stress relief. Once broken out of the mold, the castings will be reheated and held at temperature until sufficient stress relief is achieved. This is a critical part of iron casting development as high residual stresses can lead to failures in parts at cylinder pressure and thermal loads much lower than what might be predicted by FEA.

2.6 Material testing

Material testing must be performed to qualify the casting process. Test bars are frequently cast to qualify the material chemistry, strength, microstructure, chosen cooling rate, and heat treatment. While test bars provide useful data, there are many influences on the final material property distribution in the castings that need to be understood to produce durable engines. It should be noted that textbook values for properties of cast materials are typically obtained from these separately cast specimens. The microstructure of the casting material is a function of the cooling rate, which will never be constant throughout a casting. While impurities can be present, voids, shrinkage porosity, and cracking will be present, and the distribution of the various phases of the alloy will never be completely evenly distributed. As these separately cast bars cool at a significantly faster rate than the actual casting, they typically do not exhibit the same impurity characteristics and utilize different processing; they will normally exhibit vastly different material properties than the actual part. This is especially true for cast irons where it is not uncommon to have a 20–30% difference in tensile strength between the separately cast test bars and the actual part. Therefore, it is critical to understand the material properties (strength and microstructure) at the critical high stress areas within the actual cast part. Once a new casting is fully developed and a correlation between the cast part and separately cast bars has been developed for microstructure and strength, then the results from the separately cast test bars can be utilized for continuing process quality audit purposes.

2.6.1 Cylinder block specimen locations

Specimens for material testing are typically cut from the bulkhead area (Figure 5) as this is one of the highest stress locations in the block. While high stresses do occur around the top deck and cylinder wall in parent bore blocks, it is normally difficult to find a section thickness in the bore or top deck sufficient for a properly sized specimen, especially in cast irons.

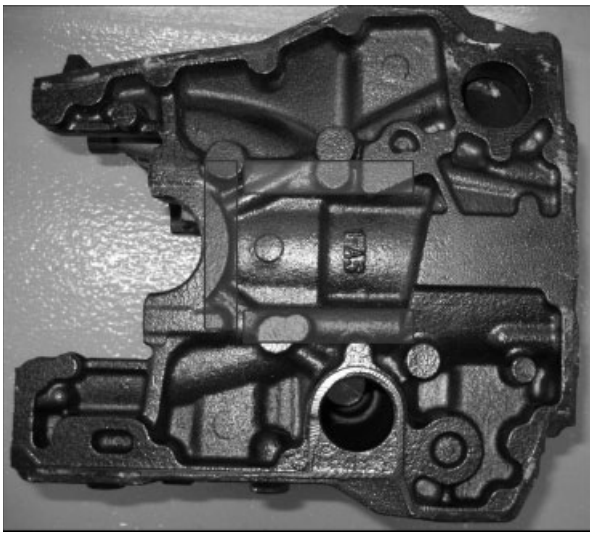

Figure 5. Cylinder block material test specimen location.

2.6.2 Cylinder head specimen locations

Specimens for material testing are typically cut from the fire deck in the valve bridge areas (Figure 6) as this the most critical location for material properties within the head. Samples can also be cut from the top deck, which play a critical role in cylinder head structure (especially for high PCP diesel designs), and head bolt bosses to understand material strength variation throughout the casting.

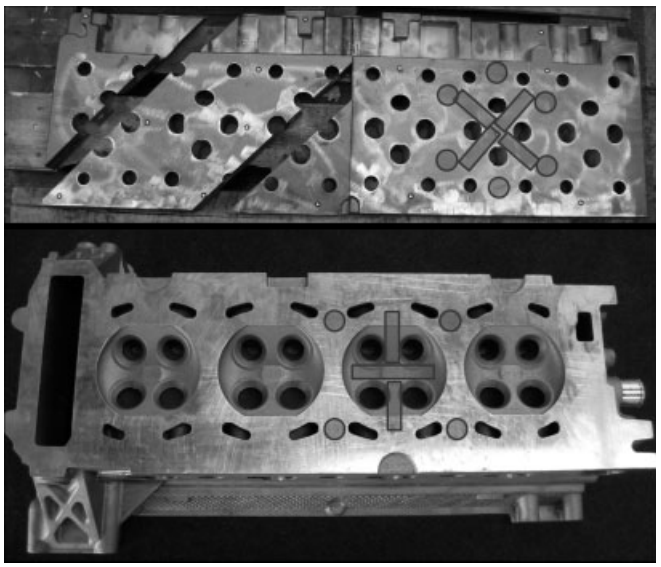

Figure 6. Cylinder head material test specimen locations (cast iron HD diesel-top, aluminum LD gasoline-bottom).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135

During the development process, complete characterization of the material is necessary to understand the tensile strength, yield, and fatigue life, and any significant influences of temperature. With cast irons, the material properties can often be assumed constant over the operating temperature. This is not the case with the nonferrous alloys. The modulus of elasticity, tensile strength, yield strength, ductility, thermal conductivity, and fatigue strength are all a function of temperature and change significantly over the operating temperature range of the engine for most alloys.

At a minimum, the development material testing program should include tensile testing, compression testing, and fatigue testing with specimens taken from critical areas in production-intent cast parts. For nonferrous alloys, this testing should be repeated at ambient temperature and an elevated temperature equal to the maximum predicted operating temperature. The microstructure should be inspected from the same locations. Typically, specimens are cut using the following ASTM test procedures: ASTM E-8(04) for tensile testing and ASTM E-468-90 for fatigue testing. Rotating beam fixtures are commonly used for fatigue testing of cast irons, whereas axial testing is preferred for fatigue of nonferrous alloys. Figure 7 shows an example of tensile and fatigue test specimens for gray iron cylinder head, whereas Figure 8 shows a sample fatigue specimen from an aluminum cylinder head.

Figure 9 shows an example of the scatter in gray iron fatigue strength, which may be expected throughout a cylinder head casting and between castings of different batches for a controlled/developed process.

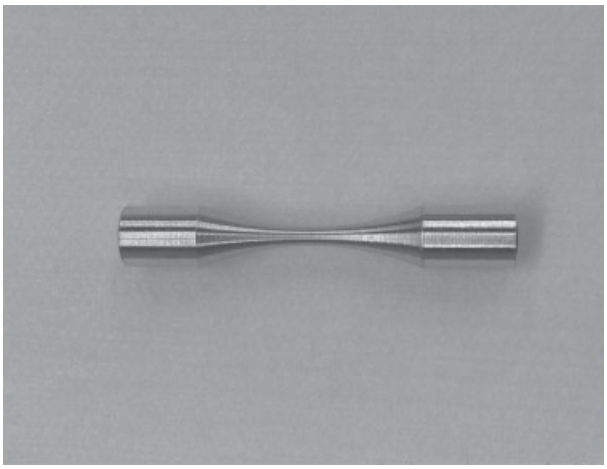

Figure 8. Example aluminum fatigue (left) and tensile (right) test specimens.

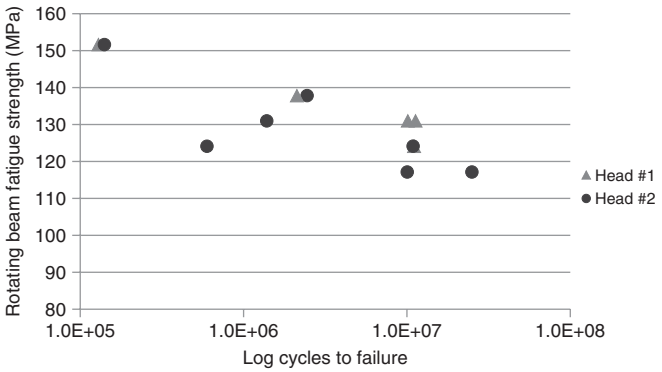

Figure 9. Example gray iron fatigue test data.

3 CASTING PROCESS DEVELOPMENT

There are many casting processes including sand casting using molds made of clay, water, or chemically bonded sand, permanent mold casting, and pressure die casting. Each of these processes has its variants, and the casting process needs to be selected at the same time the casting material is selected. Not all materials can be cast using any of these methods, and not all of these methods are suitable for all geometries and wall thicknesses. Manufacturing volume is a major factor in choosing a process. Small volumes are often produced by sand casting, but as volumes increase permanent mold or die casting becomes more attractive. The costs for molds required for permanent mold or die casting can be absorbed in large volume production. The sand casting process can be automated, using machines to produce and fill sand molds. Quality is another consideration when choosing a process as solidification influences the material properties.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

It is absolutely vital to get the production foundry, and if applicable, the prototype foundry involved in the design process at the very beginning to prevent rework or delays during the casting development process.

The molten alloy can be introduced into the mold by pouring or injecting it at elevated pressure. The pressure casting methods typically use permanent molds or dies that are nonexpendable, but do have a finite life because of wear, fatigue, or cracking. The molten metal is usually introduced into the mold using a gating system. The metal is poured into the top of the mold and travels down the side in a chute called a *sprue*. It then runs horizontally along the bottom of the mold, then up into the cavity through runners called *gates*. As the metal enters the cavity from the bottom, any gasses will rise out of the mold. This method also creates less turbulence of the molten metal. Gating design is absolutely critical in achieving castings with premium material properties and minimal defects. Additional areas called *risers* (Figure 10) are added to control shrinkage porosity during solidification by providing pockets of molten metal at strategic locations. Bodies of cool material, called *chills*, can be placed on the side of the mold to remove heat quickly as the molten metal first comes in contact to rapidly solidify specific areas of the casting to locally improve material properties. This is often done in the combustion chamber, for example, to provide improved strength in the material between the valves called the *bridges*. Casting orientation within the mold also plays a critical role in the final material properties. For example, cylinder heads are typically cast fire deck down (fire deck at, horizontal and parallel to gating) to achieve the best properties in the critical sections. Orientation can also have positive or negative affects on factors such as core float and gas venting. Therefore, these factors must be thoroughly evaluated and quantified during casting development.

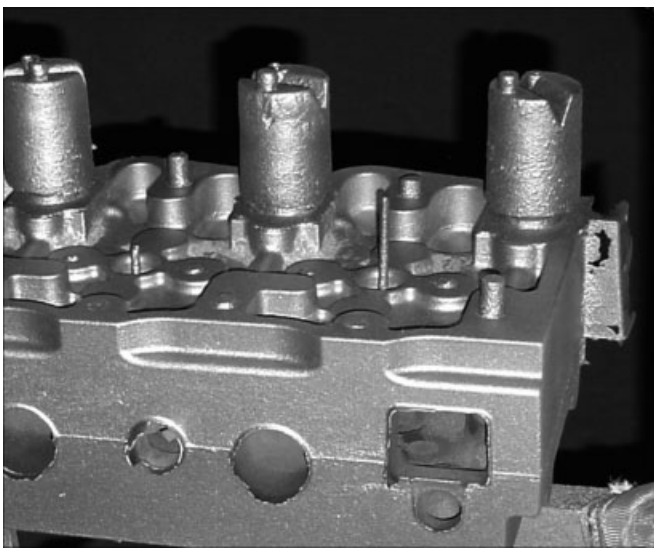

Figure 10. Example showing risers placed on the top deck of a cast iron diesel cylinder head casting to control shrinkage porosity.

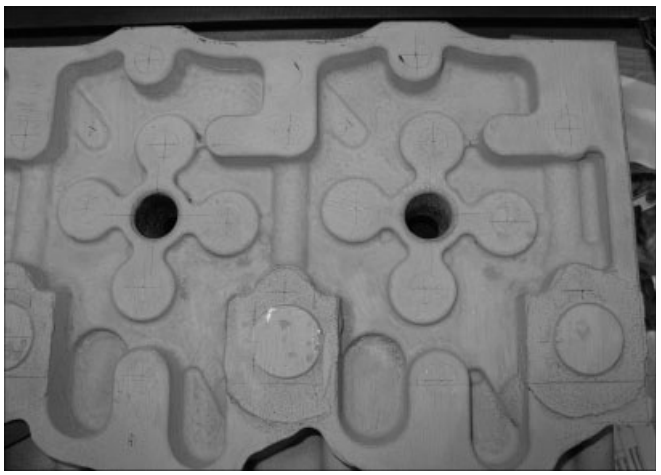

Figure 11. Conventional casting geometric qualification using markup technique.

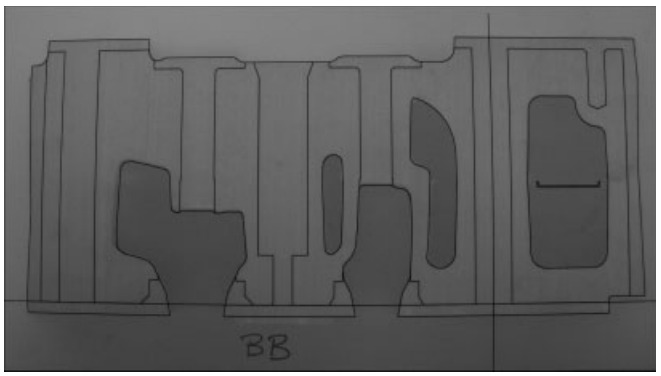

Figure 12. Casting geometric qualification of internal features using mylar sections from CAD geometry (injector bore cross section).

As the integrity of block and head castings is critical to the quality of an engine, and as the casting process has so many variables, casting process simulation is employed to ensure quality and help develop the process, locate risers, and identify areas to enhance cooling. Dedicated simulation packages have been developed over many years, including Magma, PAM/CAST, and EKK CAP. These sophisticated packages simulate the flow of the molten metal into the mold and the solidification process.

Typical steps in the development of the cylinder head or block casting process are to:

1. Select a candidate alloy.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto135
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

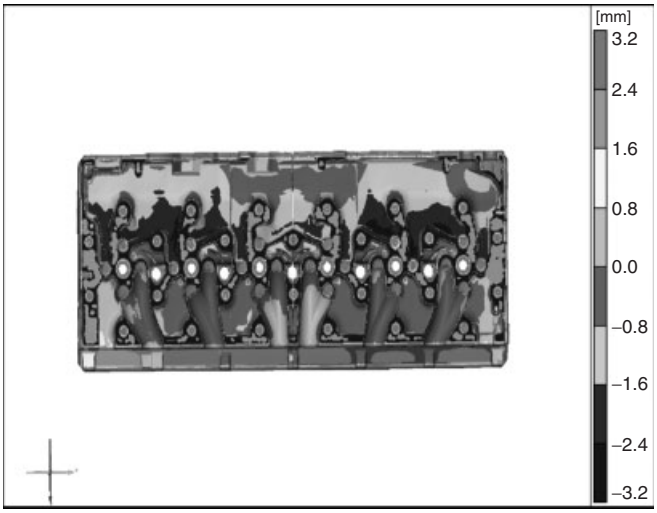

Figure 13. Laser scan of head casting section to map core shift (vertical direction shift).

2. Design the head or block.
3. Choose an appropriate casting process considering manufacturing volume, cost, cycle time, and quality.
4. Perform a casting analysis studying filling and solidification rate and predicting locations of high residual stress and potential shrinkage porosity.
5. Iterate through steps 1–4 as required, changing the gating system or using chills (aluminum for strength) or risers (cast iron for porosity) as required.
6. Make a test melt of material and cast test bars and cylinder heads or blocks using production-intent molds.
7. Perform tensile, compression, and fatigue tests and check hardness and microstructure of both the test bars and the samples cut from critical areas in the casting as identified by analysis.
8. From the results, develop procedures for periodic checks in production. These checks may include chemical analysis of the molten metal before casting, casting and testing of test bars, and mechanical testing of samples taken from castings. Wherever possible, checks should be performed on the inputs to the process, such as checks on raw materials, measurement equipment, and molds. Special care should be taken with components subject to wear, such as molds. If a process is fully understood and the inputs are controlled, the output will remain in specification.
9. Make any required changes to the process, material, or design.
10. Make a limited-volume casting run using production-intent tooling and processes for production qualification. Use the actual production line if possible. The quantity of parts in this run must be representative of actual production volumes. Perform all of the defined process checks.
11. Thoroughly inspect and test the qualification castings. If issues are found, improve the process controls or make process or design changes as needed and requalify the modified process. In addition to material testing, X-ray (cast iron) or CT scan (aluminum) must be performed to look for shrinkage porosity and voids along with geometric qualification. Geometric qualification is performed to ensure that the part meets the designed tolerance (typically ISO CT 7–8), does not exhibit excess shrinkage, and validate that all of the cores are in the correct place and did not shift. This qualification can be performed using several methods. The classic method involves painting the casting with layout paint and then scribing centers for all machined features on the exterior of the casting (Figure 11). These centers are then compared to their respective bosses for shift during the casting process. Other methods to validate internal wall placement include sectioning the casting and then comparing to mylar sections generated from the CAD geometry (Figure 12) or using laser scanning techniques to generate a 3-D map of any core shift (Figure 13).
12. Have all involved personnel and departments sign off on the process.
13. Commence production, performing the process checks and material quality audits at regular intervals.

Block and Head Analysis

Marc C. Megel
Southwest Research Institute, San Antonio, TX, USA

1 INTRODUCTION

Computer-aided engineering (CAE) analysis is a key component of the design/development process for engine components. While not a complete replacement for mechanical development testing, effective application of advanced analysis can significantly reduce design cycle times and minimize prototype redesign iterations during development testing. Two of the most complex and time-consuming components to design and analyze within an engine system are the cylinder block and head. With respect to these two components, this type of analysis can normally be broken into two main categories: computational fluid dynamics (CFD) and finite element analysis (FEA). Figure 1 shows a high level overview of the normal process for a new engine design and development. Figure 2 outlines the detailed process commonly utilized for a new cylinder head design and identifies how various analyses and tests feed into the design and development process. A similar approach is utilized for the cylinder block. From this flowchart, it can be seen how instrumental CAE analysis has become in modern cylinder head or block design and development.

A few brief comments regarding CAE software packages are probably warranted given the multitude of products in the market today. Packages such as ANSYS, ABAQUS, STAR CCM+, and NASTRAN are well established and commonly utilized in the engine design field for advanced analysis. These programs are widely used by numerous engine and vehicle original equipment manufacturer (OEM)'s (both light duty and heavy duty) and as such, face continual review and scrutiny from a multitude of users. Caution should be exercised when considering an entry-level package for the analysis of complex components such as blocks or heads as all software packages are not created equally. Users should always bear in mind that finite element or CFD analysis of blocks and heads is a mathematical approximation of various physical phenomena within a geometrically complex structure. Key considerations for selecting a software package should include accuracy (especially regarding entry-level systems), transparency, and control of operations and functions such as meshing and contact, and the ability run the program from controlled user macro's and scripts. Ease of use should never be a primary consideration when choosing a software package.

2 EFFECTIVE APPLICATON OF ADVANCED ANALYSIS TECHNIQUES

The most effective analysis that can be applied to engine design and development is that which produces the necessary outcome in the required timeframe at the lowest cost.

Simply put, this means the analysis with the fewest features and minimum necessary level of complexity that gives an adequate result is the best. The time spent on simplifying the analysis processes to the minimum complexity required and developing robust procedures will pay off during the design process or when issues arise during production.

It has been proposed that analysis (CFD or FEA) can be broken into four basic categories: relative–comparative, relative–predictive, absolute–comparative, and absolute–predictive.

2.1 Relative analysis

This technique has proven to be a very effective approach for the analysis of engine components. One of the major obstacles to absolute analysis of engine components is lack of input data. This primarily stems from the fact that engines are relatively low cost, general consumer commodity items. This type of product does not have a cost structure to support extensive research and testing to exactly determine all of the necessary material behavior and boundary condition inputs required for accurate absolute analysis.

In a relative analysis approach, standardized process are developed and utilized consistently for all product development. They are intentionally seldom changed to maintain a connection for all products to a historical database. The objective is to create a process that correctly captures the general physics of the component operation. This process allows for the use of a nominal set of boundary conditions and material properties. Normal variation in boundary conditions and properties experienced by the component in service are accounted for in the process using a historical failure database to determine a component fatigue limit rather than a material fatigue limit. This process has proven especially valuable for blocks and heads, which are manufactured using either an iron or an aluminum casting process. Casting processes contain significantly more variability in end material properties than those used to manufacture billet material. As a result, design and foundry engineers work to control properties within an allowable range, provided that the range and processes do not shift for a given product database, a nominal value can be assumed and variability is addressed in the component limits.

Relative–comparative analysis refers to a process whereby a modification to a product (either for a new product requirement or for addressing an issue) is being compared back to the current design by the way of a standardized analysis process to determine reductions in stress at critical locations.

Relative–predictive analysis refers to a process whereby a standardized process is used to analyze a clean sheet design and the results are compared to a historical limits database to determine the acceptability of a design.

2.2 Absolute analysis

The most recognizable application of absolute analysis is probably the aerospace industry, although others exist for similar reasons. Factors driving product development in the aerospace industry are in direct contrast to those discussed previously for automotive engine components. Reliability and durability of an aircraft turbofan engine are paramount above cost and development schedule given the ramifications of failures. Exact fatigue behavior of materials must be thoroughly understood to ensure robust designs and develop maintenance/repair schedules.

Occasionally, situations will arise in engine design and development where an absolute type analysis approach may be required. Bracket analysis is a common instance where common designs seldom exist. Even at that, standardized processes with common approaches to meshing and load application will help reduce variability. The other most common instance is during failure resolutions activities where a unique problem has arisen that maybe a previous analysis process did not identify. In this instance, mechanical development mapping such as strain gauge measurements may be required to calibrate a model to identify the proper failure mode. Even in this scenario, absolute–comparative (establish a baseline for the current issue and use the calibrated model to compare proposed solutions to the current design) analysis is probably the best approach.

The following discussions throughout this chapter assume a relative (comparative or predictive) approach to block and head analysis unless otherwise specified.

2.3 Standardized analysis processes

Standardized analysis processes are critical to implement a relative analysis approach and achieve consistent results between multiple analysts as well as expediting the analysis process. Development of simplified analysis approaches is a key to effectively move the analysis upstream in the design process to have maximum impact on the end product design and minimize redesign iterations. While inclusion of every detail and nonlinearity in a given system "might" improve the accuracy of the model, it has little benefit if the time to perform the calculation causes delays in the overall design cycle or is not completed in sufficient time to influence predetermined engine build milestones. In addition, continual changes such as these invalidate a relative analysis approach. A simplified process that can rapidly

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

produce reasonable results and evaluate multiple design options provides significantly more value to the overall engine development program than a complex analysis of a single design. Another key to develop an effective analysis processes is to have properly trained analysts who understand pitfalls of the work and software and have significant experience in component development, so the process focuses on evaluating the component. Application of analysis to cylinder block and head design/development should be process and component centric, not software centric. The software should be viewed simply as a tool to acquire the necessary information to make design decisions and progress component development.

Development of a standard analysis process that is used consistently will also allow creation of a historical product database over time, which allows an analyst to compare results from a new design to previous benchmarks. It is this database which is utilized to develop analysis limits rooted in real historical engine failures and component fatigue as opposed to material specimen fatigue. The value of this approach is twofold. First and foremost, this approach allows the analyst to account for variations in manufacturing (casting and machining), material properties, duty cycle, on a given product and process. Uses of analysis processes with limits such as this have been shown to correlate extremely well to crack locations throughout the water jacket and provide valuable insight into head gasket joint integrity.

To the extent possible, a good standardized process should control all key aspects of FEA or CFD modeling.

Meshing
Boundary condition application
Load steps
Solution and solution controls
Post processing

Variation in any of these parameters will result in variation between analysts and analysis runs and invalidate the use of a component-based fatigue evaluation approach. Specifically when considering meshing, the maximum amount of manual mesh control possible should be utilized. Automated meshers with default settings should never be used as they exhibit unacceptable random behavior. While the development of automated meshers within CAE codes greatly improved the ability to mesh complex geometries, they also introduced one of the most significant sources of variation within CAE modeling. The results calculated in a CAE model are entirely dependent on the mesh. Therefore, variation in mesh equals variation in results and prohibits the use of a relative analysis process. A good approach is to manually define the line element size for all lines and the target area element size. From there, the automated mesher can grow the mesh to fill the areas. Once areas have been meshed, then a volume mesh can be generated, again by setting a target element size. This method has proven to generate consistent meshes acceptable for a relative analysis process. This approach does require the analysts to maintain the connection between the solid geometry and the mesh.

It should be noted that application of this type of analysis process to aluminum components can be more difficult given the extreme nonlinear behavior and material property sensitivity to temperature compared to iron (see Material and Process Selection—Cylinder Blocks and Heads). However, many of the aspects can still be applied.

2.4 Component versus system analysis

With development of good analysis procedures, component analysis of blocks and heads has proven to be extremely effective (both cost and time) for initial analysis and rework of designs, especially those cast from iron materials. This use of component analysis is critical to move the analysis upstream in the design process. One of the major advantages of component-only analyses is the fact that they do not require highly nonlinear elements, such as contact, springs, bolt pretention, or gasket elements. These types of elements, especially contact, significantly increase the computational requirements of the model from both a solution time and hardware perspective. As a result, an analyst can progress through significantly more design iterations if required in a given amount of time. In addition, as these models only require input loads and not details of components such as head gaskets or bolts, they can be employed very early in the design process. Only a basic CAD model with completed port, valve, injector, and water jacket geometry is required to start the component CFD or FEA. In this approach, the designer will first focus on modeling the basic geometric features including internal water jacket rounds to provide a CAD model to start CFD and FEA, then work to incorporate details such as bolting and flanges, which has minimal to no impact on the key thermal and structural areas of the block and head. Having a well-developed component analysis process capable of rapid design iterations is also very valuable for rapidly addressing test or field failure issues, which may arise during development or over the life cycle of the product.

Through the analysis process development, methods to model interactions among the block, head, gasket, liner, and bolts using forces, displacements, and reactions can be established. This process development may require

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

mechanical development testing such as pressure-indicating film, strain gauging, ultrasonic length measurements, or hydraulic rig testing.

Should the situation arise where a detailed analysis of the head gasket joint or cylinder bore distortion is required, then a system model must be utilized. Owing to the level of complexity, resulting assembly and solution time, and lack of sufficient design details for supplier components (head gasket, liner, and bolts), this type of model has little value early in the process to affect the design. If performed correctly, this type of modeling can be very valuable in setting up simplified component analysis procedures or when more detail is required to investigate a particular problem.

2.5 Developing limits and guidelines

2.5.1 Empirical component/process-based versus material fatigue limits

The development of empirical, component-based fatigue limits is critical to the relative analysis process. By utilizing a historical component performance database, all of the normal variations for a given material, process, duty cycle, and so on are accounted for in a single limit value. This then allows for the ability to compare analysis fatigue results against a single limit for a given type of engine and application thus significantly simplifying the analysis by reducing the sources of variation that must be accounted for/analyzed. Once this limit is in place, the only variation that must be accounted for are those which produce significantly different boundary conditions to the baseline such as duty cycle or application.

This process also allows for the assessment of different materials by the scaling of the single limit, provided the two have similar production variations. This is most commonly used for evaluating various grades of cast iron in a design assuming similar casting processes.

2.5.2 Duty cycle considerations

Understanding of duty cycle and load variations (peak cylinder pressure for example) for a given product is absolutely critical to developing a robust, effective relative analysis process. Different empirical component-based fatigue limits will need to be developed for distinctly different duty cycles and applications. Figures 3 and 4 are included below to help illustrate the differences in duty cycle that a given engine can be exposed to. Although not exact duty-cycle plots from a specific application, emissions certification test cycles provide a good general approximation of the average duty cycle to be expected in a given application for the purposes of this discussion. When developing component fatigue limits for relative analysis approaches, engineers should always rely on actual average duty cycle data obtained for their specific application and not general approximations. Figure 3 shows the differences between the light-duty chassis certification and heavy-duty engine certification test cycles for a medium-duty engine, which could fall into either or both of these applications. Figure 4 shows a similar comparison, but this time for a heavy-duty diesel engine used in either Europe or North America. Note the difference in average engine speed and load that may be expected between the two cycles. This leads to the development of significantly different component fatigue limits and even material choices (see Material and Process Selection—Cylinder Blocks and Heads) depending simply on the geographic use of the engine.

3 COMPUTATIONAL FLUID DYNAMICS ANALYSIS

CFD analysis should be utilized to optimize flow distribution throughout the block and head and maximize coolant velocities in critical areas such as valve bridges and around injectors/spark plugs. The CFD model is also used to calculate heat transfer coefficients (HTC's), which will be inputted into the FEA models as coolant side boundary conditions. CFD should be performed as a system model to include the following water jacket cavities: block, head, thermostat housing, oil cooler housing, and water header if equipped.

Most modern engines use orifices in the head gasket for control between the block and head water jackets to optimize flow distribution front-to-rear and side-to-side in the block. These orifices are typically modeled as the connection between the block and head water jackets with a length equal to the thickness of the head gasket. The head gasket orifices along with cast-in geometric features are used to control flow distribution and velocities in the head. Typically, both the inlet and outlet meshes are extended for some distance from their actual location to reduce numerical instabilities at the boundaries which otherwise has no impact on the calculated results. Figure 5 shows an example of the mesh for a heavy-duty, in-line six-cylinder water jacket configuration.

Typical boundary conditions for the water jacket system model would be coolant inlet flow rate and system outlet pressure. Critical coolant physical properties such as density, viscosity, specific heat, and thermal conductivity must be input as well. If the CFD analysis is being performed stand-alone from the FEA (non-conjugate heat transfer analysis), then wall

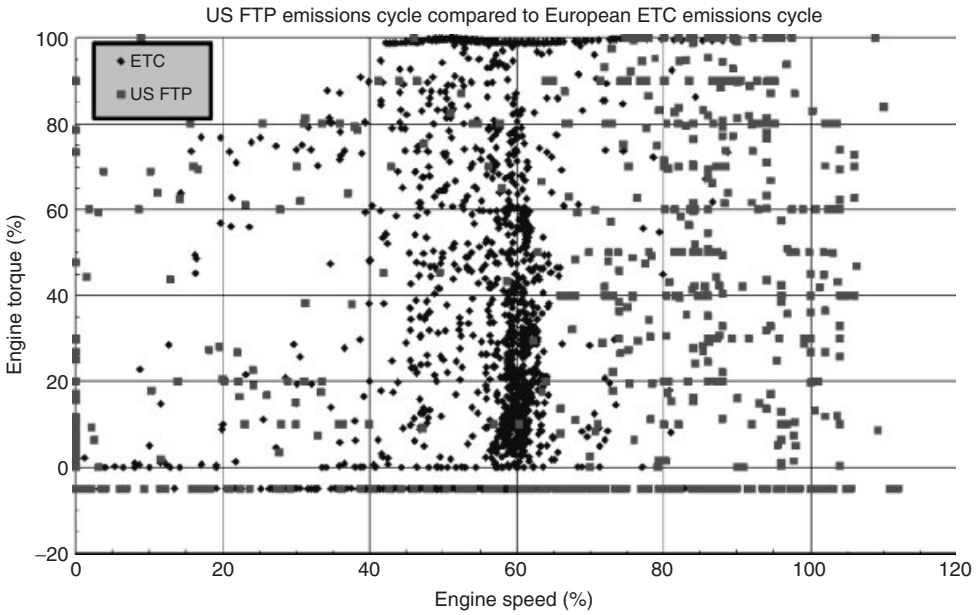

Figure 4. Comparison of US versus European certification test cycle for a heavy-duty diesel engine.

temperatures must be inputted for the calculation of HTC's. From these boundary conditions, the model solution will develop the pressure drop profile across the engine and provide input to the required water pump flow versus pressure characteristics. In addition, coolant velocities and resultant HTCs will be calculated for input into the FEA thermal models. Figure 6 shows a typical plot of coolant velocities and associated HTCs for a cylinder head lower water jacket on a heavy-duty engine.

On the basis of the component thermal profiles calculated from FEA, iterations on the head gasket orificing should be performed as necessary to achieve both the desired component temperature distribution and the uniform temperature distribution, front-to-rear and bank-to-bank (vee engine configurations).

4 FINITE ELEMENT ANALYSIS

Discussion in this section focuses primarily on cylinder block or head component simulation. When establishing a process for a given configuration of cylinder head or block, the benefit of symmetry should be utilized to the maximum extent possible. For instance, an in-line six-cylinder head configuration utilizing a repeating pattern of structure for each cylinder (as opposed to a pattern mirrored about the cylinder head centerline) can be cut through

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the center head bolts on the cylinder 3–4 split plane. This instantly reduces the model size and computational requirements by half over analyzing the entire cylinder head, which produces no added value. The new three-cylinder section utilizing symmetry allows analysis of the structure utilized on the four interior cylinders and the end cylinder configuration. Stresses and displacements are evaluated on the two cylinders farthest from the symmetry plane as they are not affected by the local application of boundary conditions at the symmetry plane (St. Venants Theory) (Shigley and Mischke, 1989) and the symmetry boundary conditions replicate what those cylinders actually see in the full configuration. A similar approach can be used to analyze the cylinder block bulkhead and main cap.

In addition to the use of symmetry, further simplification of the model and reduction of solution times can be achieved through targeted meshing of critical locations. Take for instance, the example stated earlier with symmetry already applied. Utilizing meshing controls, the analysts can create a consistent, refined mesh that encompasses the central and/or end cylinder to allow proper calculation of stresses and mesh the remainder of the geometry with a coarser grid to reduce computational time and requirements but still allow sufficient resolution for calculations of temperatures and displacements. An example as seen in Figure 7 would be to fine mesh the central cylinder with 3–5 mm elements while meshing the remainder of the head at 7–8 mm. Figure 5 shows how a CFD mesh can be coarsened as you move away from the wall to the center of the flow stream.

4.1 Cylinder head component analysis

The primary objective and focus of the cylinder head component FEA should be to optimize water jacket design to satisfy cooling and structural requirements. It is not uncommon for a new design to require multiple (5–10) analysis/design iterations to achieve a structure that satisfies the component fatigue limits established in a given procedure. With a well-developed, simplified, relative analysis approach, iterations can normally be completed in 1–5 days.

FEA of the cylinder head component can be broken into two primary tasks: thermal and structural analyses. Thermal analysis is utilized for prediction of component metal temperatures and input to the structural analysis for calculation of thermal stress.

4.1.1 Thermal analysis

Thermal FEA utilizes the cooling side HTC values obtained from CFD coupled with the combustion side boundary conditions developed from empirical correlations, 1D cycle simulation such as GTPower, 3D in-cylinder combustion, CFD simulation such as Kiva and Converge, or a combination of all the three. Well-calibrated empirical correlations have proven very effective for developing combustion boundary conditions for a given type of combustion. This method is a critical piece of moving the FEA simulation upstream in the design process as in-cylinder CFD models tend to have lengthy solution times as you have to run the entire two- or four-stroke cycle to develop cycle-averaged (not instantaneous) HTC values as that is what the FEA is simulating. Even with the advanced 3D combustion CFD capability, experience has shown that these results may still need adjustment through the empirical relationships to achieve temperature predictions from FEA, which match measured values. The difficulty in accurately predicting in-cylinder, cycle-averaged HTC values likely stems from the fact that in-cylinder heat transfer is a complex interaction

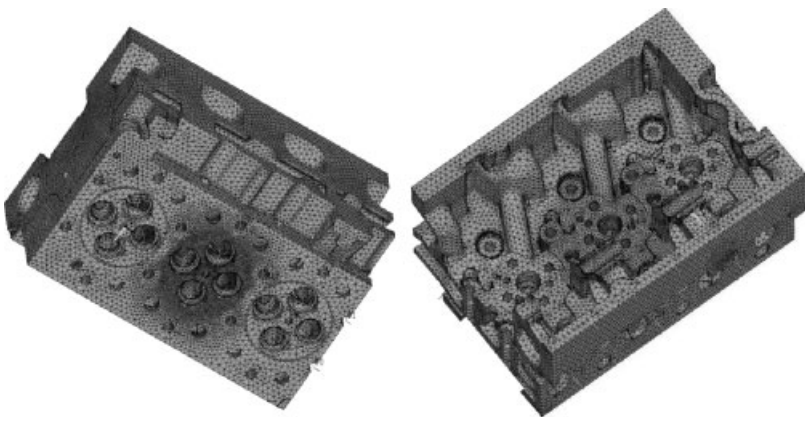

Figure 7. Example of in-line six-cylinder head utilizing symmetry and focused mesh refinement.

of convection and radiation/adsorption from combustion chamber surfaces and combustion particles (most notably soot in diesel and gasoline direct injection). In addition to HTC values for combustion surfaces, the thermal FEA model must also include all other heat input or extraction sources such as ports, oil splash, and ambient conditions. Within the cylinder head component model, the option exists to include or exclude valves and seats. As with the other boundary conditions, the option exists to develop empirical boundary conditions, which address the heat transfer across the valve/seat/head interfaces thus allowing for further simplification of the model.

Primary results of the thermal analysis will be predictions of peak fire-deck temperatures (a critical design constraint) and temperature distributions along the length of the cylinder head. As mentioned in Section 3, an iterative loop among design, CFD, and FEA will likely be required to try and maximize the uniformity of temperature distribution along the length of the head. Designs that produce a significant gradient along the length of the head should be avoided. Nevertheless, some variation along the length of the block or head is often present in many designs. Any comparison of peak fire-deck temperature or stresses against limits must consider this variation and be based on the hottest cylinder. Figure 8 shows an example of predicted fire-deck temperatures from a thermal FEA simulation.

4.1.2 Structural analysis

Cylinder head component structural analysis incorporates nodal temperature results with the necessary loads such as cylinder pressure, head bolts, injector clamping, press-fits, and valve train loads (if required) along with reactions from the head gasket and symmetry conditions to calculate deflections and stresses. The four critical load steps for a cylinder head structural analysis are as follows.

Assembly loading (A)
Assembly + cylinder pressure loading (AP)
Assembly + thermal loading (AT)
Assembly + cylinder pressure + thermal loading (ATP)

Using principle (cast iron materials) or equivalent stress (ductile materials) calculated from these four primary load steps, all critical fatigue states can be analyzed. Two of the most important and most commonly analyzed fatigue states are ATP-AT for high cycle fatigue and AT-A for low cycle fatigue.

Both stress-life and strain-life fatigue analyses are utilized for the evaluation of cylinder block and head stresses, especially with iron components. Stress life is highly effective at evaluating high cycle fatigue because of cylinder pressure loading. This method is commonly utilized for the fatigue analysis of iron components but can be used for aluminum components (provided the strain state is still relatively elastic and likely employing a Neuber type correction (Bannantine, Comer, and Handrock, 1990). In addition, stress life fatigue analysis of low cycle fire-deck stresses for iron components can provide a useful initial assessment assuming that the thermal stress state is lower than the compressive yield point of the material. Stress life analysis of FEA results can be performed very efficiently using user subroutines or macros. Owing to the simple calculations involved, macros can be written to process the entire set of results in a minimal amount of time. One very effective method is to calculate an equivalent fully reversed or EFR stress for each critical location based on modified Goodman theory with basic material data for true fracture or tensile, yield, and fatigue strength. This calculation converts

Figure 8. Example of cylinder head peak fire-deck temperature predictions from thermal FEA.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the various mean and alternating stress states found at different locations throughout the cylinder head into a zero-mean equivalent stress (Equation 1). Using this method, the fatigue stress at each critical location can then be compared against a single set of limits for the component.

EFR stress under tensile loading can be calculated using Equation 1.

$$\sigma_{efr} = \frac{(\sigma_{tfs} \times \sigma_{alt})}{(\sigma_{tfs} - \sigma_{m})} \quad (1)$$

where: σ_{efr} = EFR stress
σ_{tfs} = true fracture strength
σ_{alt} = calculated alternating stress
σ_{m} = calculated mean stress

Note: for brittle materials such as cast iron, TFS can be approximated as ultimate tensile strength (UTS)

Strain life calculations are much more involved and require significantly more material input data to perform. Strain life analysis of a full set FEA results for a cylinder head typically requires the use of additional software (such as fe-safe) to perform calculations in a timely manner. Strain life fatigue analysis should be reserved for locations or conditions in which stress life analysis is not valid. Situations that warrant strain life fatigue analysis are the use of highly nonlinear material such as aluminum or conditions occasionally found on fire-decks of iron cylinder heads where the thermal stress is high enough to induce compressive yielding either from high thermal loads, an insufficient material cross section through the valve bridge or a combination of the two. The outcome of the strain life analysis is a prediction of cycles to failure.

For either the stress or the strain life fatigue analysis approaches, the resultant parameter (EFR stress or cycles to failure) is compared with the component fatigue limit determined during the development of the analysis process and not a specific set of endurance cycle data.

For naturally aspirated, spark-ignited (SI) applications, cylinder head loading is primarily thermal driven (both low and high cycle thermal fatigues) as component temperatures can be very high and cylinder pressures are very low. Thermal loading, creep and the resultant low cycle fatigue are also very important considerations when dealing with aluminum cylinder heads. With high cylinder pressure applications such as diesel or highly boosted SI engines, cylinder pressure loading, and high cycle fatigue become the predominant fatigue mechanism and play a much more significant role in component durability.

Critical areas for low cycle thermal fatigue stress are primarily located on the fire-deck of the cylinder head between valves (also known as the valve bridge area) and adjacent to the injector or spark plug. Depending on the cylinder head design, certain locations between the port walls and fire-deck on the water jacket side of the head will also exhibit sensitivity to thermal low cycle fatigue loading. Figure 9 shows an example of an EFR stress plot on the cylinder head fire-deck for AT-A low cycle fatigue case.

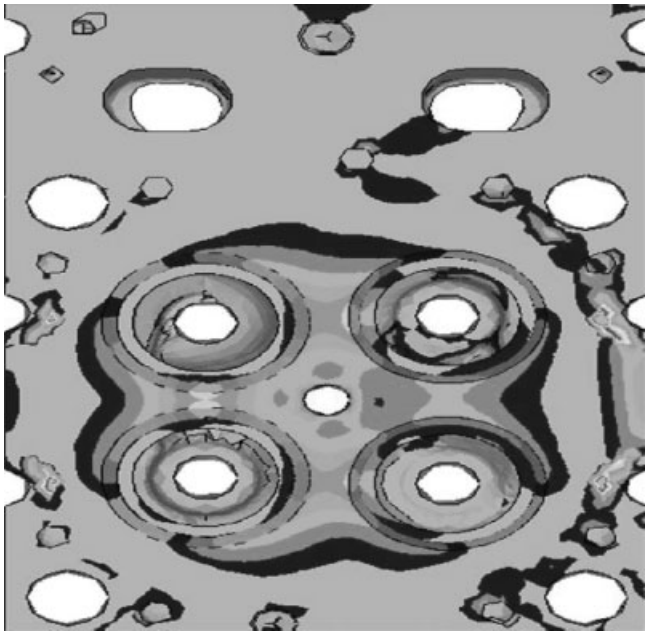

Figure 9. AT-A low cycle EFR stress plot example (cylinder head fire deck).

Critical areas for high cycle fatigue stress are typically found throughout fillets in the water jacket and the top deck of the cylinder head. In addition, rare situations exist in certain cylinder head designs where the fire-deck actually experiences issues with high cycle fatigue. This condition occurs when the thermal mean stress component exceeds the yield strength of the material (high thermal loading or insufficient material to react load). Figure 10 shows an example of an EFR stress plot in a cylinder head lower water jacket for ATP-AT high cycle fatigue case.

Before finalizing any fatigue results, it is good practice to verify that the mesh quality is sufficient at all high stress locations identified. One approach is to check the error bounds of stress calculation on the highest stressed element. It should be noted that this assessment must be performed on the calculated principle or equivalent stress for a given load case and not EFR stress as this is a post-processed parameter. This is a feature of most software programs and provides a quick method for ensuring mesh quality and consistency for a standardized procedure. If the error bounds are always kept, for example, below 10%, then any variation between analyses can be assumed to be accounted for in the process and does not invalidate the relative analysis approach.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

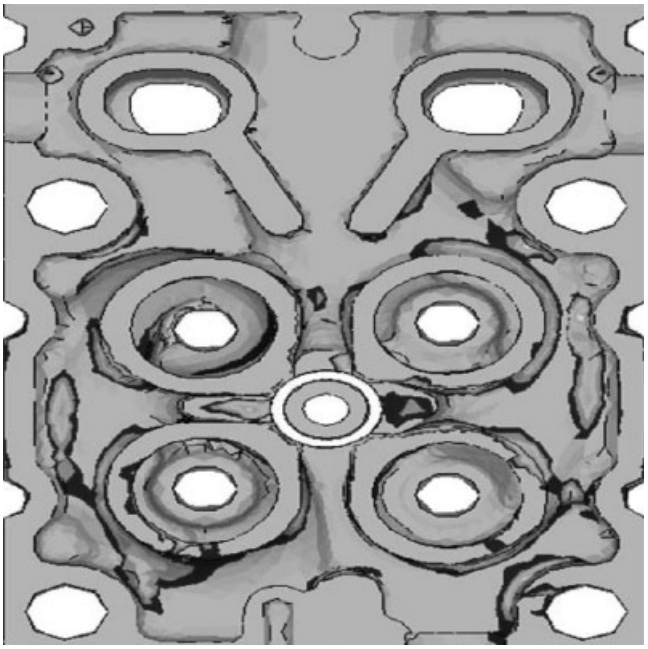

Figure 10. ATP-AT high cycle EFR stress plot example (cylinder head lower water jacket).

In addition to evaluation of fatigue stress, correlations can be developed, which utilize parameters such as displacement of the cylinder head fire-deck (or block if a parent bore design) above the combustion seal under assembly loading to evaluate the head gasket bolted joint. This displacement is a direct indication of the stiffness (or lack thereof depending on the design) of the clamp members in the bolted joint and thus a direct indication of potential leak spots for the combustion seal. The more uniform the block and head stiffness around the circumference of the combustion seal is, the more uniform will be the head gasket combustion seal loads and unloads minimizing locations and conditions prone to leakage. Therefore, limits for variability in displacement at this location can be developed and applied early in the design to ensure head gasket durability, even before the head gasket has been designed.

4.2 Cylinder block component analysis

The most critical cylinder block locations requiring FEA can be broken down into the following component analyses.

4.2.1 Liner/cylinder bore thermal analysis

This analysis is used to predict the peak cylinder surface temperatures and assess temperature distributions to identify hot spots, which could create issues with bore distortion or wear. As with the cylinder head thermal analysis, HTC values from CFD are transferred onto the water jacket surface of the liner, and boundary conditions for combustion are applied to the cylinder surface. The most critical temperature on the cylinder liner surface occurs at the top ring reversal location. This temperature must be kept below design limits to ensure proper wear behavior of the ring/liner interface and prevent oil coking on the liner and top ring.

4.2.2 Bulkhead analysis

This analysis focuses on the bulkhead area of the cylinder block (Figure 11). The bulkhead area of the block forms the load reaction path for cylinder pressure from the head bolts to the main cap. The bulkhead contains numerous locations required for critical features such as main bores and oil drillings, which result in high stresses under application of the cylinder pressure load. Stresses in these locations must be kept below applicable limits to ensure a robust design. Failure at this location typically results in a complete separation of the main bores from the cylinder section of the block. Like the cylinder head, analysis of the bulkhead can typically utilize symmetry (especially for in-line engine configurations) to simplify and speed up the analysis process. As the areas of concern are typically far away from the load reaction points, this model can utilize

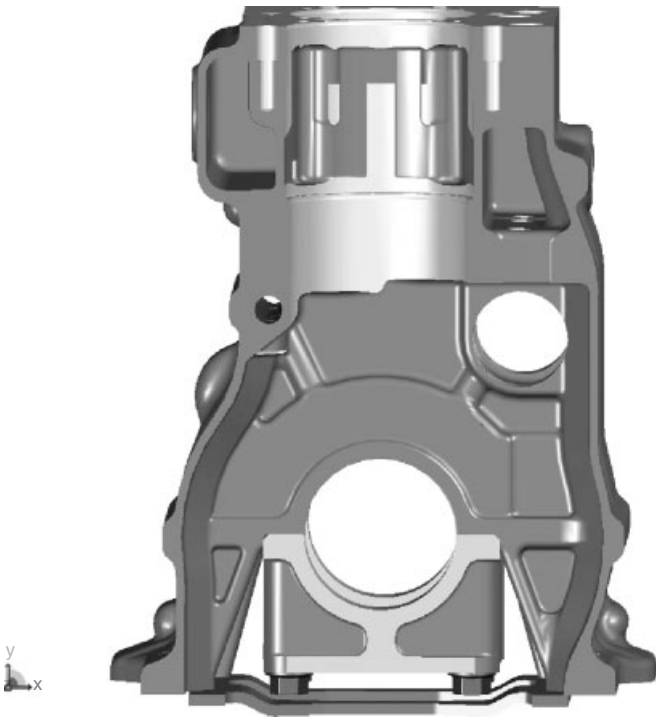

Figure 11. Cylinder block bulkhead section (in-line engine configuration).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto136
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a rigidly attached main cap to react the cylinder pressure load. Analysis of stresses around the main cap detail must be evaluated with a main cap analysis model. Because potential high stress locations within the bulkhead can be distributed throughout its entirety, a mesh suitable for stress analysis must be utilized for the entire component. Given that thermal loading does not affect stresses in the bulkhead and main cap areas of the block, the same high cycle fatigue analysis utilizing the EFR stress approach outlined in the cylinder discussion can be employed for iron blocks.

4.2.3 Main cap analysis

This analysis is used to evaluate the main cap design and ensure stresses are within an acceptable range. With proper meshing, cylinder block stresses in the region of the main cap can also be evaluated. Proper modeling of contact is required for the main cap to ensure correct modeling of load transfer in the bolted joint. All processing operations assorted with the main cap and main bore must also be accounted for.

4.2.4 Cylinder bore-top deck stress (parent bore block)

Analysis to evaluate stresses between the top deck and the cylinder wall should be considered for parent bore block designs depending on operating conditions. Under high thermal loading or increased combustion seal load conditions, the stress in this location can increase significantly and lead to fatigue cracks. This is not an issue for wet-liner engines as the top of the liner is not connected to the top deck of the block. This analysis will require application of the loads and boundary conditions from the head gasket. These may be developed empirically, from testing, or from system modeling of the complete head gasket joint.

4.3 System analysis

Certain situations exist where a system analysis may be required. The two primary conditions aside from boundary condition development discussed earlier are assessment of head gasket loading or bore distortion. As discussed earlier, this type of modeling is very time consuming and should not be utilized to drive the early stages of design. This type of modeling has proven very useful for analyzing issues that may occur in the field or during development testing regarding head gaskets loading or bore distortion. One of the most beneficial outputs for this type of analysis is to provide a visual understanding of complex physical loading and reactions happening within the engine. Indecently, this also turns out to be a very beneficial use of in-cylinder CFD analysis. Figure 12 shows the assembled geometry and mesh for a typical head gasket system-level analysis.

4.3.1 Mechanical development testing feedback

Mechanical development testing provides valuable feedback to the design and analysis process in the form of calibration data and design validation. Use of each type of testing on existing mature products is essential for developing effective analysis procedures. Mechanical development testing can be broken down into three main categories: mapping tests, rig tests, and engine overload tests.

4.3.1.1 Mapping tests. Two of the most common mapping tests performed during cylinder head or block development are thermal and strain mappings. During thermal mapping, the cylinder head, valves, valve seats, and cylinder liner are instrumented using thermocouples, temperature check materials, or a combination of both. Installation of thermocouples in the cylinder head fire-deck and cylinder liner allows real time temperature measurement across the full operating range of the engine. The thermocouples do not however measure the peak component temperature at either the fire-deck or the cylinder surface. The measured thermocouple values must be used to calibrate the thermal FEA models at the specific measurement points and subsequently revise peak component temperature predictions.

Temperature check materials are materials that exhibit a specific characteristic of hardness verses exposure to a specific temperature. They come in the form of small plugs (1.6–3 mm diameter) which can be installed in components and actual components such as valves and seats machined from the temperature check materials. Most of these materials require stable, constant operation at a given engine operating condition for at least 2 h to develop the proper hardness for the exposed temperature. The advantage of temperature check materials is that they effectively measure the surface temperature of the component. The down side is that they can only measure temperatures for a single engine operating point. New plugs or components must be installed to evaluate different engine operating points.

4.3.1.2 Strain gauge. Strain gauges can be installed in various locations on the block and cylinder head to measure strain during either rig or engine operation. The measured strain values can then be used to help develop analysis procedures. Strain gauges are still the most effective method for evaluating residual stress caused by the casting process. Strain gauges are installed on a complete component in the area of concern and zeroed. The strain gauged location is then sectioned out of the full component and the resultant strain reading indicates the residual stress at that location.

4.3.1.3 Pressure-indicating (Fuji) film. Pressure-indicating film is very useful for evaluating the contact pressure between members in a bolted joint. Pressure-indicating film testing can provide very valuable information when developing boundary conditions for a component analysis procedure. The film is available in different pressure ranges depending on the joint to be evaluated (head gasket cooling passage seals verses head gasket combustion seal for instance). While the film itself only provides a measure of pressure in varying shades of red from imprint, some suppliers of pressure-indicating film have developed digital analysis techniques to provided detailed color contour plots (both two and three dimensional) of the measured pressure distributions. Figure 13 shows an example of using pressure-indicating film to evaluate a multilayered steel head gasket joint. From left to right: raw film after test, 2D digital analysis, and 3D digital analysis.

4.3.1.4 Hydraulic fatigue test. Hydraulic fatigue testing is typically the first step in validation of a design. Before calibrations are available, a system can be assembled to cycle the block and head assembly under simulated cylinder pressure using hydraulic fluid. This test provides very early feedback to the design process and validation of the analysis results for cylinder head, block, and main cap stresses as well as head gasket integrity and main cap fretting. The test is typically performed at some predetermined overload pressure from the target maximum

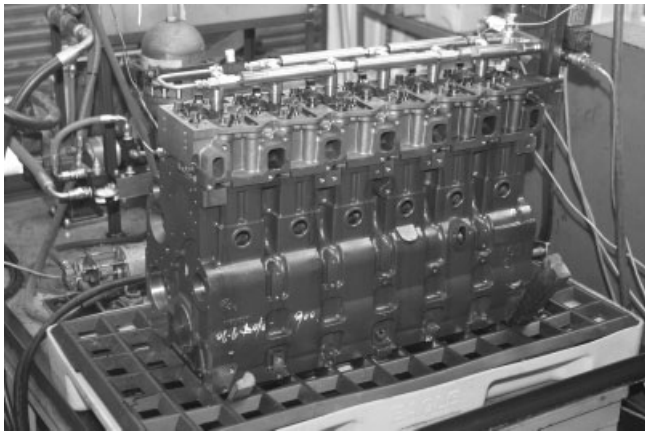

Figure 14. Block/head assembly hydraulic fatigue test.

engine operating peak cylinder pressure. Figure 14 shows an image of a hydraulic fatigue test for a block and head assembly.

4.3.1.5 Overload engine durability testing. Overload durability testing represents the final hurdle to production of a new engine design. As such, this step also represents validation of the analysis results. Manufacturers typically have a specified set of tests at various conditions, which must be run in order to release a new design to production. As with the relative analysis process, it is critical to use consistent procedures and test methods for durability testing in order to establish a historical baseline for pass/fail criteria. This baseline, in addition to any field history data, is the primary piece of data necessary to develop component-based fatigue limits for the analysis procedures. On completion of either engine or rig testing, it is imperative that the component be thoroughly inspected. While secondary failure symptoms such as coolant pressurization or leakage can indicate complete propagation of a crack to failure, the most robust designs and procedures would address crack initiations as well. In a complex block or head casting, these initiations can only be identified through destructive testing. The block or head must be sectioned through each cavity (water jacket, port, oil drain back, etc.), so all surfaces are visible. Crack detection is then accomplished through Magnaglo or Magnaflux (ferrous components) or dye penetrant (nonferrous components). Figure 15 shows an example of a sectioned cylinder head under Magnaglo inspection.

5 GEOMETRY CONSIDERATIONS

5.1 Geometry issues created by CAD

Even with the advances in modern CAD programs, issues still exist in the conversion of CAD geometry to good FEA or CFD meshes. The complex geometries required for cylinder head and block water jackets can lead to generation of very poor geometric features such as thin slivers or slices within the CAD model (Figure 16). These features in turn can lead to poor mesh quality and elements with high calculation errors. To the extent possible, areas with geometry issues should be corrected, and the analysts should verify an adequate mesh quality for valid results.

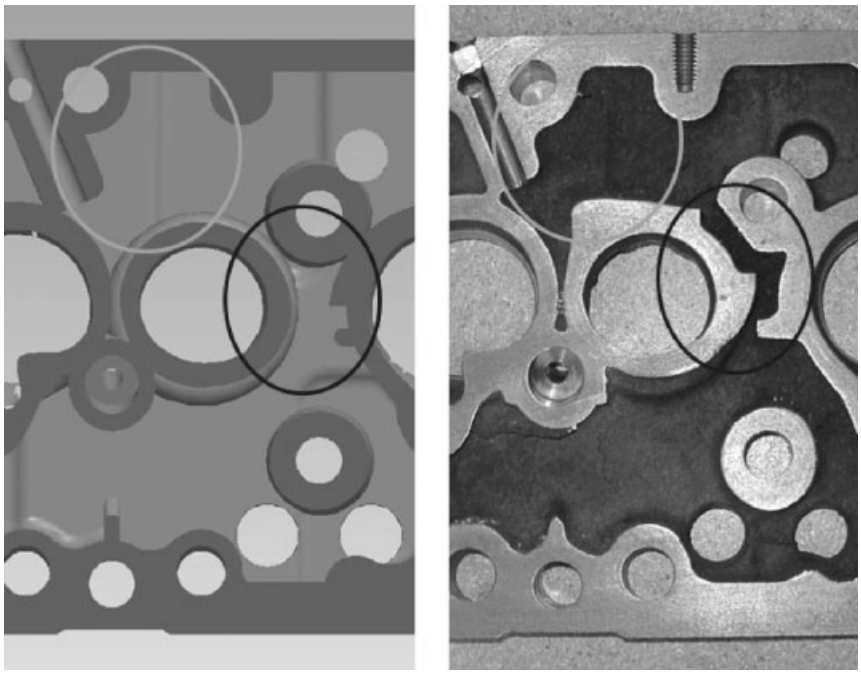

Figure 17. Potential differences between CAD geometry and actual cast production parts.

5.2 Inaccurate geometry

The issue of inaccurate geometry is especially prevalent when analyzing production or legacy designs to develop analysis procedures and component-based fatigue limits or address field issues, which may occur during production. CAD systems continually progress in capability with every release. Early versions of CAD systems could not handle the complex geometry and rounds required for cylinder head and block water jackets. Therefore, legacy CAD

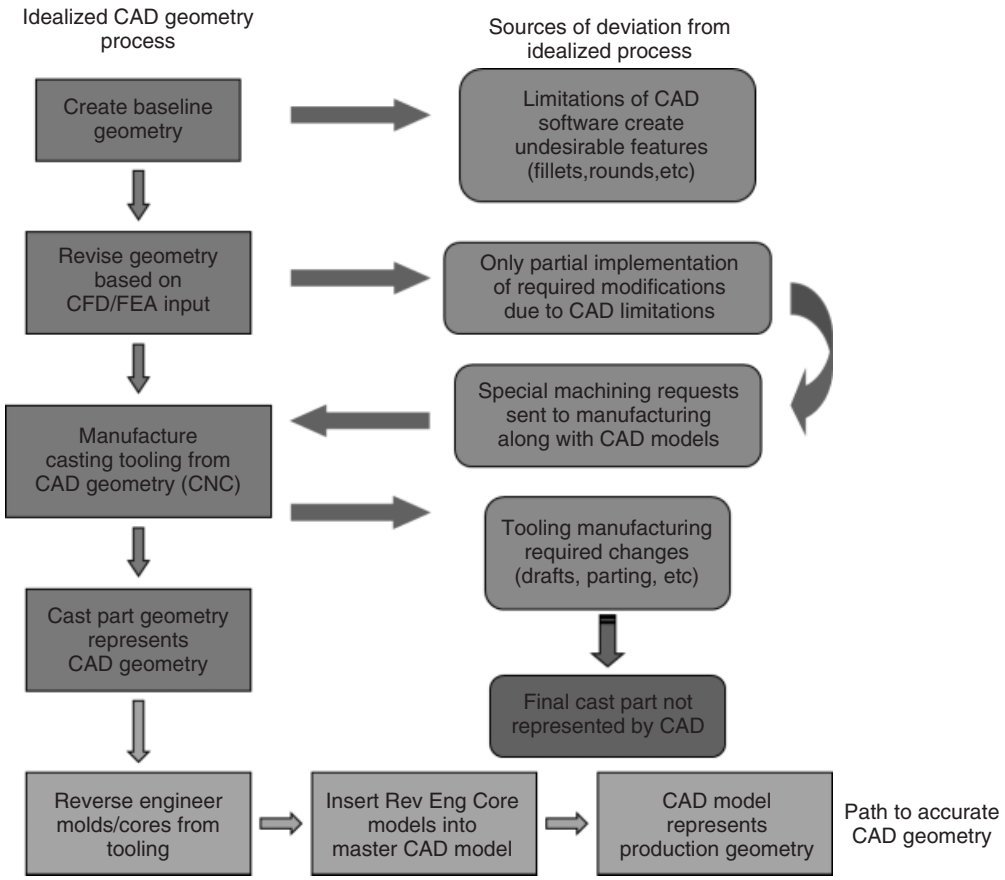

Figure 18. Actual CAD geometry process from design to production.

models typically have significant geometry differences from the actual production part.

This problem is not relegated to legacy products however. Once the CAD geometry leaves the designer and progresses to manufacturing, the potential exists for multiple sources of modification compared to the geometry originally analyzed during the design process. This is especially true for the manufacture of complex castings such as blocks or heads. Figure 17 shows an example of differences between CAD and actual cast geometry. Figure 18 shows the idealized process for progressing CAD geometry from design to production and highlights the potential sources of modification to a given block or head geometry and the process most often followed to take a new design to production.

NVH Considerations in Engine Development

Thomas E. Reinhart
Southwest Research Institute, San Antonio, TX, USA

1 INTRODUCTION

Engines are one of the primary noise and vibration sources in most vehicles and machines. Under certain operating conditions, engine-radiated noise can dominate both interior and exterior noise levels, and under some conditions, engine-generated vibration dominates the vibration perceived by the driver and passengers.

1.1 Engine noise

Engines generate noise in a number of ways. Engine-radiated noise comes directly from vibrating surfaces of the engine. Engine surfaces function as loudspeakers, broadcasting the effects of internal engine forces as audible noise. There are a number of approaches available to the designer to reduce engine-radiated noise, and some of these approaches are explored in this chapter. Engines also put pressure pulsations into the intake and exhaust systems. These pulsations can propagate through the intake and exhaust systems, resulting in audible noise from the air inlet and exhaust outlet. Intake and exhaust pressure pulsations can also cause vibration of the intake and exhaust systems, which lead to noise being radiated from the surfaces of these systems. There is generally little that an engine designer can do to reduce intake and exhaust pressure excitations, without having a significant effect on the engine's performance. Therefore, intake and exhaust pressure pulsations are generally accepted as a given. The intake and exhaust systems are designed to achieve the desired levels and frequency content of noise, given the pressure inputs provided by the engine. The design of intake and exhaust systems is covered in Gas–Breathing and Air Management.

Over a range of engine size and type ranging from small gasoline passenger car engines to heavy-duty truck diesel engines, noise levels at the rated condition (maximum speed and load) tend to be similar. In general, engine-radiated noise is a significant issue from 300 or 400 Hz up through 20,000 Hz, the maximum frequency of human hearing. Intake and exhaust noises are often a lower frequency phenomenon. For example, a four-cylinder four-cycle engine running at 2000 rpm has a firing frequency of 67 Hz. Intake and exhaust noises can be expected at this frequency, and at several harmonics (multiples) of this fundamental frequency. Intake and exhaust noises are not limited to low frequencies, however. Compression brakes, common on heavy-duty truck engines in some markets, produce high exhaust noise levels over a wide frequency range (Reinhart and Wahl, 1997). Turbochargers can produce high frequency tones related to once per revolution frequency of the turbocharger shaft, and to

ISBN: 978-0-470-97402-5

blade pass frequencies. These very high frequency sounds (sometimes beyond the range of human hearing) will propagate through the intake and exhaust systems. Overall, engines can generate significant noise over the entire range of human hearing (20–20 kHz).

1.2 Engine vibration

Engines vibrate as a result of internal forces generated by the operation of the engine. This vibration can reach the chassis or cabin through the engine mounting system, or via any other linkage between the engine (or powertrain) and another vehicle component. Thus, coolant and hydraulic hoses, the intake and exhaust systems, wiring harnesses, cables, and any other attachment may provide a transmission path allowing engine vibration to reach the vehicle.

Once engine vibration has been transmitted into the vehicle structure, it may become apparent as either tactile vibration or audible sound. Audible sound results when engine vibration causes some vehicle component to vibrate in a way that generates sound. Tactile vibration appears in forms such as steering wheel or seat track movement, mirror vibration, and many other common vibration responses in a vehicle or machine.

Tactile vibration is generally a low frequency problem, as human sensitivity to vibration rolls off rapidly as frequency increases. When vibration frequency increases to 200 Hz, it must have very high acceleration amplitude for a human to sense it (Brüel & Kjær, Inc., 1998). The most common source of tactile vibration is engine firing frequency. For example, a four-cylinder, four-cycle engine will have a firing frequency of 20 Hz at 600 rpm idle speed. It is very difficult to fully isolate a frequency this low from the chassis; therefore, it is common to feel some vibration in the vehicle as a result. As the engine speed increases, however, the mounting system is more effective at isolating higher frequency vibration, and as the human body is less sensitive to higher frequency vibration, the perception of vibration fades away. Often, unfortunately, the tactile vibration is replaced by an audible response generated by the cabin from the remaining vibration input from the engine. In the case of our four-cylinder example, this audible noise is often referred to as *four-cylinder boom*.

The lowest frequency vibration issue that is common to an engine occurs at half order (once per two engine revolutions), which is the firing frequency of any given cylinder in a four-cycle engine. This half-order vibration is the result of variation in combustion from cylinder to cylinder. The worst case example of this is complete misfire in one cylinder.

2 VIBRATION

Vibration can be split into two categories. Rigid body vibration occurs when the engine (or the complete powertrain, consisting of all components rigidly attached to the engine) moves as a rigid body. Nonrigid vibration occurs when the engine or powertrain deflects as it vibrates. Typically, nonrigid vibration occurs at or near resonant modes of the engine or powertrain. An example of a resonant mode is a powertrain bending mode, where the engine and transmission move out of phase with each other.

Vibration is caused by forces generated inside the engine. These forces are caused by events such as cylinder pressure fluctuations, impacts between engine components, and unbalanced reciprocating forces and moments.

2.1 Unbalanced forces and moments

As the crankshaft rotates, the piston and rod experience alternating accelerations as they move up and down the bore. Most crankshafts have counterweights in an effort to balance these forces. In a single-cylinder engine, it is impossible for crankshaft counterweights to fully cancel the forces involved in the reciprocating motion of the piston and rod because the counterweights develop a rotating force rather than a reciprocating force. When the engine has more than one cylinder, the combination of reciprocating and rotating forces may add up in such a way as to cause a moment. This is a force that causes the engine to rotate about the roll axis, or another axis perpendicular to the roll axis. The roll axis is the axis of least inertia for an engine or powertrain. In multicylinder engines, there are certain configurations where it is possible to fully cancel both reciprocating forces and moments. Inline six-cylinder engines and V-12 configurations with the proper bank angle (60° or a multiple of 60) are examples of this. Other common engine configurations have some remaining unbalanced force and/or moment.

In some cases, balance shafts can be added to cancel forces or moments that cannot be dealt with in the crank train design. For example, inline four-cylinder engines often use two counterrotating balance shafts to eliminate the second-order free force generated by this configuration. The Bosch Automotive Handbook has a very good section on engine balancing, including a table showing equations for the unbalanced free forces and moments for many common engine configurations (Robert Bosch GmbH, 2000).

Because diesel engines typically use higher cylinder pressures than spark-ignition (SI) engines, it is common for diesel engines to have a higher piston and rod mass for a given engine displacement. This makes the unbalanced forces and moments of diesel engines larger, and thus more of a challenge, than those of an SI engine.

2.2 Gas pressure reaction forces

As a piston goes up the compression stroke, work is put into compressing the charge in the cylinder. This causes a negative torque on the crankshaft, which has the effect of slowing down the crank. As the piston goes down the power stroke, positive torque is applied to the crankshaft, speeding it up. Thus, the crankshaft experiences speed fluctuations from the alternating torques applied by the pistons and rods. The alternating torque that causes these crankshaft speed fluctuations reacts against the engine block. As the crankshaft accelerates in one direction, the engine block accelerates in the opposite direction. The result of this is that the engine rocks back and forth in response to gas pressure forces. This rocking motion is called the *roll response* of the engine, where the engine moves about the "roll axis."

The roll response does not necessarily occur about the crankshaft axis. It occurs about the axis of least inertia of the powertrain—the roll axis. This axis typically starts at the front of the engine above the crankshaft centerline and ends at the rear of the engine somewhere near the crankshaft centerline. The exact location of the roll axis varies with the mass distribution of the engine and all rigidly attached components, such as the transmission and transfer case.

The amplitude of vibration about the roll axis depends on a few simple parameters:

- powertrain mass
- cylinder pressure
- cylinder displacement.

Vibration amplitudes owing to gas pressure reaction forces increase with cylinder pressure and displacement and decrease with mass. This does not give the engine designer much room to work with. Reducing the displacement or cylinder pressure will decrease the performance, while increasing the mass is detrimental to the overall vehicle design. One way to decrease gas pressure reaction forces for a given power level is to increase the number of cylinders in the engine, thus decreasing the displacement of each cylinder. While this is an attractive approach from a smoothness viewpoint, it tends to decrease engine efficiency and increase cost.

The gas pressure reaction forces of diesel engines pose a larger challenge than those of SI engines. There are two reasons for this. First, diesel engines typically have a higher compression ratio than SI engines. The higher compression ratio creates higher cylinder pressures, which in turn lead to higher gas forces. Second, diesel engines typically operate unthrottled, except where throttling is used for emission control reasons, such as to drive exhaust gas recirculation (EGR) flow or to regenerate emissions after treatment devices. The air/fuel ratio of a diesel engine varies widely, becoming very high at light load. In most SI engines, the air/fuel ratio is maintained at or close to the stoichiometric value by throttling. Thus, at light load, an SI engine has very little air in the cylinder, leading to low gas pressure reaction forces. A diesel engine operating at light load, on the other hand, typically has a large quantity of air in the cylinder, giving higher gas forces. Gas force reactions can be a particular issue for diesel engines operating at low speed and light load, where the driver expects the engine to be smooth. Some diesel engines use an intake throttle during shutdown, to reduce gas forces as the engine firing frequency passes through powertrain mounting resonance frequencies at speeds between idle and zero.

2.3 Minimizing vibration transmission to the cabin

The engine designer has some control over two issues that cause vibration issues in a vehicle. The engine should be designed to achieve the highest possible powertrain bending natural frequency. For an inline four-cylinder engine, the powertrain bending natural frequency should be well above the second order at maximum engine speed. For an inline six-cylinder engine, the powertrain bending frequency needs to be well above the maximum driveshaft speed in the highest (typically overdrive) gear. If the engine operates at the speed where the powertrain bending frequency is excited, the vibration of the powertrain is substantially amplified by the resonant response, leading to high vibration excitation of the vehicle.

The other issue that is at least partly under the control of the engine designer is the natural frequency of accessories mounted on the engine. Where possible, the accessories should have a mounted natural frequency that is significantly above the firing frequency at maximum engine speeds. This goal is absolutely critical for inline four-cylinder engines, which have very high excitation amplitudes of the second order from unbalanced inertial forces as well as gas reaction forces.

Engine mounting systems need to be designed to isolate the engine vibration at low speed. This can be a challenge because excessively soft mounts lead to a loss of control of powertrain position when the vehicle is subjected to road input (such as a large bump). Engine mounts may be designed with nonlinear stiffness to allow relatively free engine motion near idle while still providing control of engine position under high loads and during road input events. Hydraulic damping is also sometimes used to improve mount performance. In a few cases, actively

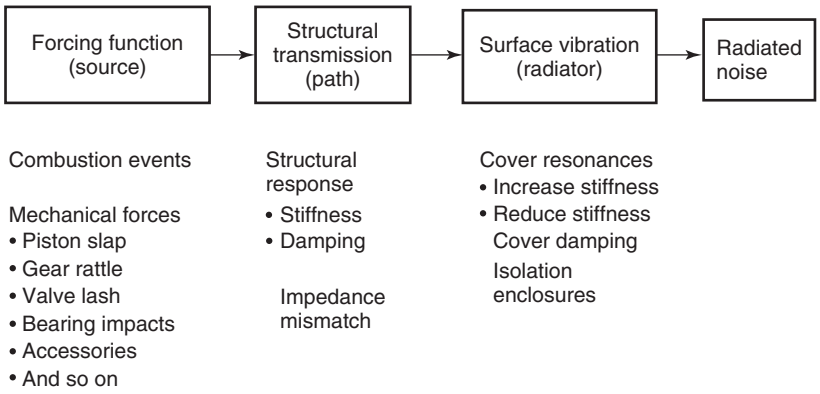

Figure 1. Source–path–radiator model of engine noise generation.

controlled mounts are used. This relatively expensive approach involves generating forces that offset inputs from the engine, or actively varying hydraulic damping based on operating conditions.

Vehicle designers also have a responsibility to help isolate engine vibration from the vehicle. In addition to mounting systems, it is important to avoid a situation called *modal alignment*. This occurs when vibration modes of the vehicle line up with a common excitation force from the engine, such as firing frequency at idle. Another source of trouble is when more than one vehicle component or substructure has resonances at the same frequency as another vehicle component. This issue is called *modal alignment*.

Driven by both regulatory and customer requirements for increased fuel efficiency, engines are tending toward lower cylinder count and higher cylinder pressure (higher brake mean effective pressure, BMEP) for a given application. These trends make the job of an NVH (noise, vibration, and harshness) engineer more difficult, as a lower cylinder count typically involves larger free forces and moments. These larger forces occur at lower frequencies, which make them harder to isolate. The higher cylinder pressures also create larger gas reaction forces—another challenge for the NVH engineer.

3 ENGINE RADIATED NOISE GENERATION

The sources of noise include combustion pressure and a range of mechanical events. These sources do not radiate noise directly because they generally occur deep within the engine structure. However, they do apply large forces to internal engine components. These forces excite vibration in the engine structure (block, cylinder head, crankshaft, etc.). When the vibration reaches exterior surfaces, noise is radiated. The process can be viewed as a source (forcing function), path (structural vibration transmission), and radiator (vibrating surface) model, as shown in Figure 1.

3.1 Combustion excitation in diesel engines

Diesel and SI engines have fundamentally different approaches to controlling combustion, differing in their combustion excitation. In a diesel engine, air is compressed in the cylinder until it is hot enough to cause the fuel to burn without any ignition source. Combustion is controlled by the fuel injection system. Injection timing, rate, and pressure are three parameters that are typically controlled by the injection system. Once fuel enters the combustion chamber, it takes some time to evaporate and warm up to the temperature that enables combustion to start. The time between the start of fuel injection and the start of combustion is called *ignition delay*. Depending on the operating condition, injection may continue well after the start of combustion. Figure 2 shows a typical cylinder pressure trace for a diesel engine operating at high load, but with low boost pressure. This condition is typical of a naturally aspirated engine or a turbocharged engine under transient acceleration.

At the start of combustion, virtually all of the fuel injected during ignition delay ignites and burns very rapidly, causing a spike in cylinder pressure. This event is called the *premix burn spike*, and this spike in cylinder pressure is what gives diesel engines their characteristic sound. The step increase in cylinder pressure acts similarly to an impact force, which is applied to both the piston crown and the cylinder head. The size of the premix burn spike determines the rate of pressure rise in the cylinder and thus the amplitude of the combustion excitation applied to the engine structure.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto137
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

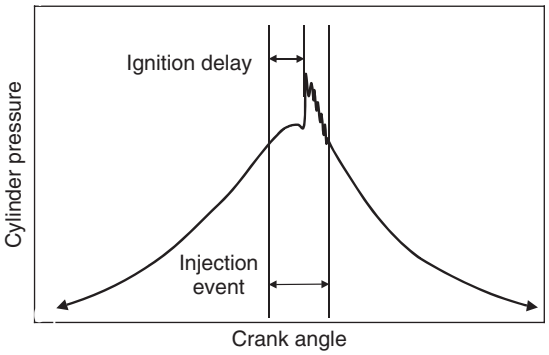

Figure 2. Cylinder pressure trace of a diesel engine operating at high load, but with low boost pressure.

Several parameters influence the size of the premix burn spike and thus the level of combustion noise. These include the following:

- *Intake Manifold Temperature*. A higher temperature shortens ignition delay, reducing the excitation.
- *Compression Ratio*. A higher compression ratio provides a hotter, denser charge at the start of injection, reducing ignition delay and combustion excitation.
- *Injection Timing*. Timing near top dead center (TDC) produces the shortest ignition delay, whereas very advanced or retarded timing causes a longer ignition delay.
- *Boost Pressure*. Turbocharging can greatly reduce ignition delay because of the higher temperature and pressure in the cylinder. At full load, many turbocharged engines have an ignition delay of only 2 or 3 crankshaft degrees, and the start of combustion becomes invisible on the cylinder pressure trace. In general, combustion noise tends to become insignificant with boost pressures over 70 kPa.
- *Injection Characteristics*. The use of a pilot injection (a small quantity of fuel injected ahead of the main event) can greatly reduce combustion excitation by establishing combustion with a very small amount of fuel, and then injecting the remaining charge into the already burning mixture. Injection pressure is also an important parameter. Lower injection pressure leads to a slower rate of heat release once combustion begins because droplets of fuel are less fully atomized. This reduces the rate of pressure rise.
- *Cetane*. This measures the willingness of the fuel to auto-ignite. Higher cetane values give a shorter ignition delay, and thus lower combustion noise. Unfortunately, cetane values vary significantly in markets around the world and are outside of the engine maker's control
- *EGR*. The use of EGR slows combustion, reducing the excitation from a given level of ignition delay. EGR also tends to increase ignition delay; therefore, it is not always beneficial for noise.

With stringent emission regulations, some diesel engines use more than one combustion mode. There may be step changes in the number of injection events, air/fuel ratio, EGR rate, and so on. Engine designers must find ways of minimizing the potential for step changes in combustion noise that can result from these combustion mode changes (Reinhart, 2009).

3.2 Combustion excitations in SI engines

SI engines typically draw a mixture of air and fuel into the cylinder during the intake stroke, or, if they use direct injection, the injection event is not directly the cause of combustion. In an SI engine, it is the spark timing that determines the start of combustion, and combustion propagates from the ignition location across the combustion chamber. Overall rates of combustion (rates of heat release) tend to be lower in an SI engine than in a CI engine. This typically results in much lower rates of pressure rise than are found in a diesel engine, and thus lower combustion noise.

Combustion noise can still be a challenge in SI engines, depending on the combustion strategy chosen by the designers. Combustion systems that are developed to maximize the rate of combustion typically have the most issues with noise. Increasing the combustion rate is often desired for emissions or efficiency reasons. In general, any measures taken to increase charge motion in the cylinder, such as increased tumble or squish, tend to increase the rate of combustion and thus combustion noise. The use of dual spark plugs is another approach that tends to increase combustion rates and noise by providing two flame fronts, each of which can consume a significant portion of the available air/fuel mixture simultaneously, before the two flame fronts merge.

3.3 Mechanical excitations

Engines can radiate noise because of forces from a range of mechanical sources. Some of the most common sources are listed:

- Gear backlash impacts, driven by
  - crankshaft torsional vibration
  - fuel system torque inputs
  - valve train and other sources of torque input.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto137
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- Axial shaft motion and impacts
  - often driven by a combination of gear backlash impacts and helical gears.
- Gear meshing frequency pure tones
- Meshing impacts from chain or belt timing drive systems
- Turbocharger blade pass, once per revolution, and other pure tones
- Piston slap
- Valve and injector train clearance impacts
- Bearing impacts, as clearances are taken up
- Fuel system hydraulic and mechanical dynamics (diesel and direct injection gasoline)
- Crankshaft bending, driven by cylinder pressure and crankshaft distortion in response to cylinder pressure and inertial forces
- Forces generated by accessories.

At higher speeds and loads (with the exception of naturally aspirated diesels), most engines are dominated by mechanical noise sources, and some engines are mechanically dominated across the full operating range. Most diesel engines are combustion dominated at idle and under transient operation where boost pressure is low.

3.4 Separating combustion and mechanical sources

Many mechanical and combustion noise sources sound alike: impact-like events that repeat at firing frequency. Impact-like events are broadband, which means they excite a wide range of frequencies. This allows them to excite many engine and component resonances. In the case of a highly resonant structure, the frequency spectrum of the vibration or noise response will show distinct peaks, even though there may not be distinct peaks in the excitation force spectrum. Because all of these impact-like events share similar characteristics, they are very hard to separate from each other, either by listening or by analyzing the results of a noise measurement.

A few mechanical noise sources, such as gear whine, turbocharger noise, and certain types of accessory noise, can be identified and quantified using frequency analysis. Knowledge of the engine speed and number of gears in a mesh, for example, can be used to quantify gear meshing whine amplitude. (Note that for a single plane gear train, all meshes in the train have the same meshing frequency. As a result, it is possible to identify and quantify gear whine, but it is not possible to assign responsibility for the noise to any specific mesh in a train.)

Three basic approaches are available to help separate combustion and mechanical noise sources. One approach is to intentionally modify the combustion noise. In a diesel engine, this can be done by modifying injection timing, by changing fuel cetane, by changing intake air temperature, or by turning pilot injection on and off. Changing injection timing has the drawback that it may also substantially change a mechanical noise source such as gear rattle, in addition to changing combustion noise. The other methods are less prone to this error, but all approaches come with the risk of unintentionally changing mechanical noise. In SI engines, combustion noise can be changed by modifying tumble or squish, or by disconnecting one spark plug in a dual-plug system. Again, changes made in an effort to modify only combustion noise sometimes have an unintended effect on mechanical noise.

Another method for evaluating the amplitude of combustion noise is to measure cylinder pressure and feed the signal into a combustion noise meter. The meter will provide an estimate of the sound pressure level emitted by the engine, based only on combustion excitation. The combustion meter level can then be compared with the measured noise level to determine the portion of noise related to combustion. A limitation of this approach is that the meter uses an assumed transfer function between the cylinder pressure spectrum and radiated noise. In practice, engine designs vary in their transfer functions, and hence this method is prone to some error.

A third method for separating combustion and mechanical noise sources is to eliminate some particular mechanical source. A gear train can be replaced with a belt drive for test purposes, or teflon-padded pistons can be used to eliminate the possibility of piston slap. Accessories not essential to engine operation can be simply removed or remotely operated for a test. These tests can give reliable measurements of the contribution from a particular noise source.

3.5 Gear rattle

Gear rattle is of particular concern in medium- and heavy-duty diesel engines (Zhao and Reinhart, 1999). These engines typically have fairly large timing drive systems with several gear meshes. The methods available to reduce gear rattle noise include reducing the torsional input to the gears or suppressing the rattle with devices that eliminate lash. Torsional input to the gear train can be reduced by increasing the capacity of the crankshaft damper or by adding damping to gears in the timing drive. Some unit injector engines use viscous dampers on the camshaft gear to reduce fuel system torsional input to the gear train. Other engines use scissors gears to reduce or eliminate

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto137
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the last in gear meshes. Putting the gear train at the flywheel end of the engine is another effective noise reduction technique. Crankshaft torsional vibration tends to be lower at the flywheel because of the high inertia at that point. This effect is most pronounced at high speeds and high loads, where crankshaft deflections are largest.

4 NOISE TRANSMISSION PATH

Engine noise is not typically radiated directly from the points where forcing functions are applied to the structure. In most cases, these points are buried within the engine structure. The forces induce deflections and vibration in the structure. This vibration propagates out to exterior surfaces, which in turn radiate noise.

One goal of engine structural design is to minimize the vibration of exterior surfaces in response to a given forcing function input. The most effective way to achieve this is to provide an impedance mismatch (step change in stiffness) between the exciting force and the exterior surface. Ideally, the structure should be very stiff where the force is applied, then relatively compliant, and then stiff again at or just below the exterior surface. While this approach can be very effective, it is also very difficult to realize in a cast component such as a cylinder block or head. As a result, the degree of improvement that can be achieved by structural optimization is limited compared to what can be achieved with control of input forces or the design of engine covers.

The design tools used for structural optimization are finite element model (FEM) and boundary element model (BEM). FEM is used to determine the dynamic response of a structure to a given force input. The input force may be measured on a running engine, or it may be an assumed force. The model is iterated to reduce the vibration response at selected points because of force inputs at selected locations. For example, a block model may be modified to reduce vibration at the oil pan mounting flange or on the block skirt. If a direct calculation of radiated noise is desired, the FEM results can be fed into a BEM to determine the radiated noise that results from a given force input and structural characteristics.

5 ENGINE EXTERIOR SURFACES

Exterior surfaces vibrate in response to the movement of the underlying structure. As the surface vibrates, it creates pressure fluctuations in air that propagate as audible noise. There are a number of techniques available to minimize noise radiation from exterior surfaces.

5.1 Damping

Highly resonant covers will amplify the input from the underlying structure at resonance frequencies. Adding damping to a resonant cover will reduce the amplitude of these resonant peaks, bringing down the overall noise level radiated by the cover. Damping can be added by changing the material used to make the cover, by modifying the bolted joint between the cover and the structure, or by adding damping features such as constrained layer treatments.

A constrained layer damping treatment consists of the cover wall, a thin layer of polymer adhesive, and a secondary wall (the constraining layer). As the cover vibrates, there is relative motion between the cover wall and the secondary wall. This relative motion imposes strain on the polymer layer, and the viscoelastic properties of the polymer layer enable it to absorb some of the vibration energy in the component. Adding an effective damping treatment to a highly resonant cover can achieve a noise reduction of up to 3 dB.

Covers made of cast aluminum, cast magnesium, cast iron, or stamped steel tend to be lightly damped, and hence they often benefit from the addition of damping treatments. Composite covers with a high level of reinforcing fiber may also be lightly damped. Composites with low fiber content often enjoy high inherent damping levels, depending on the material properties of the material used.

5.2 Stiffness increase

Many designers respond almost instinctively to a noise issue by trying to increase the stiffness of the responsible cover. The goal of a stiffening exercise should be to increase the first resonance of the cover to a frequency beyond the range of significant excitation. Unfortunately, in most SI engines, there is significant excitation up to 3 or 4 kHz, whereas in diesel engines, there can be significant excitation at even higher frequencies. As a result, increasing stiffness tends to be successful only when applied to relatively small components. It is fairly easy to achieve a first resonance of 5 kHz in a component that is $<$100 mm long, but it is impossible to do this on a 1 m $\times$ 200 mm valve cover on a large engine.

5.3 Stiffness decrease

Reducing the stiffness of an engine cover that has high noise levels is counterintuitive, but for large covers on larger engines (especially engines of 8 L or more in displacement), it can be a very effective noise reduction

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto137
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

approach. Vibration of a cover does not translate into sound on a 1 : 1 basis. Depending on the mode shape (vibration pattern) of the component, only part of the vibration may translate into radiated sound. The relationship between vibration amplitude and radiated sound is called *radiation efficiency*, and this will be described in more detail in Section 6.

In general, thin, flat surfaces achieve the lowest radiation efficiencies. Therefore, large, flat stamped steel components tend to be quieter than the same component made in thicker, stiffer cast aluminum. It is generally impossible to do a large casting with a wall thickness small enough to achieve low radiation efficiency.

5.4 Isolation

Isolating a cover from the underlying structure can provide a large noise reduction. The goal of isolation is to separate the cover from the underlying structure with a soft isolation gasket and grommets. This provides a large impedance mismatch (Section 4), and can greatly reduce the amount of vibration transmitted to the cover. Noise reductions of up to 7 or 8 dB can be achieved with a very effective isolation system. Many engine isolation gasket systems are designed to achieve vibration isolation above 200 or 300 Hz. The choice of isolation frequency represents a trade-off between noise reduction performance and other desired characteristics such as accurate location of the cover, prevention of oil leaks, and durability of the isolation system. Typical examples of isolated covers on engines include valve covers and oil pans.

One of the challenges of isolation design is to avoid leaks. Leaks are typically at a minimum when there is very high unit loading between the gasket and the mounting flange. Unfortunately, high unit loads tend to go along with high overall joint stiffness. Small beads on the gasket can achieve high unit loads with relatively low overall stiffness, thus minimizing leaks while achieving good isolation performance.

5.5 Enclosures

Noise enclosures are typically a last resort. In a sense, they are an admission of failure: we could not fix the noise, so we had to cover it up. Enclosures also tend to be expensive and difficult to package. On the other hand, enclosures can be very effective in achieving a given noise requirement quickly.

Enclosures work on the principle of isolation (impedance mismatch). They are mounted on the engine in such a way as to minimize vibration transmission to the enclosure. Most acoustic enclosures are designed to have high internal damping, to reduce the tendency for resonances to increase noise radiation. Enclosures may also have a noise-absorbing material on the side facing the engine to absorb the noise radiated by the underlying engine components and to prevent the noise from leaking out from gaps between the enclosure and the underlying engine.

6 RADIATION EFFICIENCY

Radiation efficiency is a measure of how much of a surface's vibration gets translated into radiated sound. The efficiency is measured in percentage, such that a value of 100% indicates that all vibration is translated into sound. Radiation efficiency is a very important concept for engine NVH engineers to understand and make use of, particularly for large covers on larger size engines. Because radiation efficiency is counterintuitive, engineers employing techniques to reduce radiation efficiency may need some salesmanship in order to get their ideas approved for implementation (or even for consideration).

6.1 Explanation of radiation efficiency

Consider the example of a loudspeaker. The speaker is designed so that the cone moves as a rigid body in the frequency range of interest. This results in the entire cone moving uniformly. As the cone moves, it pushes on the surrounding air, creating a pressure fluctuation in the air. At very low frequency, as the cone moves, the air can easily move out of the way of the cone. There is a local acoustic pressure near the cone, but this pressure decays rapidly to zero as you move away from the cone. As the frequency increases, some of the air cannot move back and forth to get out of the cone's way; therefore, compression waves are formed, which radiate as sound. Higher the frequency of cone movement, lesser the air that gets out of the way, and more the sound that is radiated. At the critical frequency, where the wavelength of sound in air matches the diameter of the cone, 100% radiation efficiency is achieved. Further increases in frequency have no significant effect on radiation efficiency.

The wavelength of sound at 10,000 Hz in air is around 25 mm, so that a 25-mm speaker will achieve 100% radiation efficiency at 10 kHz. On the other hand, at 100 Hz, the wavelength of sound in air is around 3 m. Thus, a huge speaker cone would be required to achieve 100% radiation efficiency at 100 Hz. This effect explains why tweeters are small and woofers are large, and why bigger is generally better for woofers. The same situation applies to the exterior

surface of an engine. If a large surface area moves in a uniform manner, radiation efficiency is high. If the large surface area has a very complex mode shape (vibration pattern), radiation efficiency can be very low.

6.2 Radiation efficiency examples

Figure 3 shows a comparison of oil pan surface velocities for a thin-wall stamped steel oil pan and a thicker, ribbed cast aluminum oil pan. Both oil pans were tested on an 11-L heavy-duty diesel engine. In comparing the two oil pans, the steel pan has higher vibration levels up to about 1000 Hz and again from 2000 to 3000 Hz. On the basis of measured vibration levels, we would expect a higher noise level. However, Figure 4 shows the measured sound power levels for the two oil pans. The steel pan is quieter than the aluminum pan at all frequencies, and above 1000 Hz, the advantage is around 10 dB.

The steel pan suffers somewhat higher vibration levels than the aluminum one because it is much less stiff. However, this lower stiffness translates into a large advantage in terms of lower radiation efficiency and thus lower radiated noise.

6.3 Parameters that control radiation efficiency

Several parameters influence radiation efficiency; one is size. A larger cover has the potential to achieve higher radiation efficiency, especially at low frequencies. Shape is another important factor. Adding shape to a surface adds a lot of stiffness, increasing radiation efficiency. Large, flat surfaces lend themselves to a low radiation efficiency design. Material modulus and density both play a role. Higher modulus increases stiffness, and thus radiation

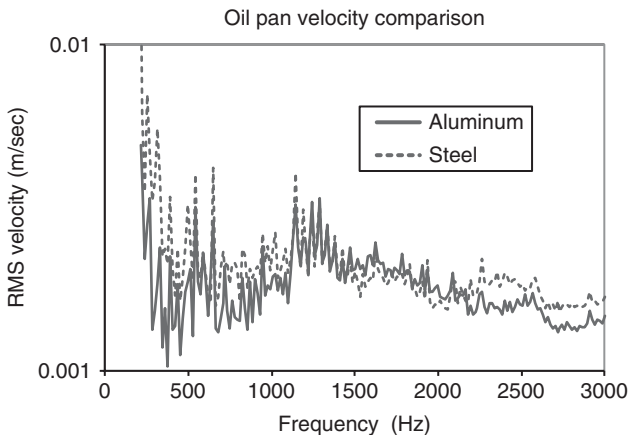

Figure 3. Comparison of stamped steel and aluminum oil pan mean square velocities on an 11-L HD diesel engine.

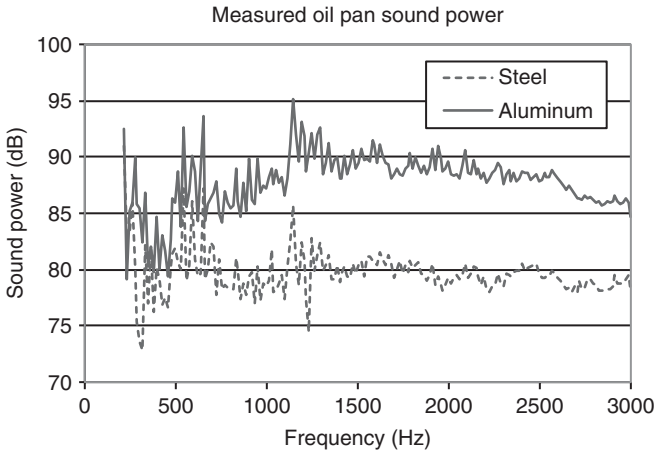

Figure 4. Comparison of stamped steel and aluminum oil pan radiated sound power on an 11-L HD diesel engine.

efficiency. Higher density reduces natural frequency by adding mass to the component. In the case of steel and aluminum, the two factors roughly cancel each other out. Steel has both higher modulus and higher density; therefore, a component with identical dimensions will have a similar radiation efficiency in either material. The advantage of steel is that components can often be made much thinner, which results in lower natural frequencies, more complex mode shapes at a given frequency, and thus lower radiation efficiency. In the case of the two oil pans in the earlier example, the steel pan had mostly flat surfaces of 1.5 mm thickness, whereas the aluminum pan had stiffening ribs and a wall thickness of 5 mm.

6.4 Designing for low radiation efficiency

Designing large covers with a thin, flat surface is the easiest way of obtaining low radiation efficiency. Care must be taken to avoid introducing other problems when using this approach. For example, components with a low natural frequency can be excited by engine firing frequency, resulting in high vibration levels and high stress. FEM can be used to tweak a design in ways that limit stress, even when a vibration mode is excited by firing frequency. The cover design must also meet other structural requirements of the engine, which can be a challenge in a low stiffness design.

7 VIBRATION MODELING

Tactile vibration is a low frequency issue. At low frequencies, the engine (and assembled powertrain) typically moves as a rigid body. Thus, for purposes of engine mount

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto137
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

development, simplified rigid body models of the powertrain can often be used. In the simplest case, the chassis is assumed to be infinitely stiff. This approach often leads to significant errors; therefore, the model is usually set up to include the stiffness and dynamics of the chassis or frame that the engine mounts on.

Many powertrains can suffer from powertrain bending frequencies that occur within the operating range of the engine. In larger powertrains, these resonances may occur at frequencies where the vibration can be felt by the operator. Powertrain bending resonances can also lead to fatigue and failure of components such as flywheel housings and transmission bell housings. To deal with this, a simplified FEM of the entire powertrain structure can be used. The model only needs sufficient detail to calculate the first few mode shapes and natural frequencies of the overall powertrain so that the models can be much less detailed than those used for stress or thermal calculations.

8 NOISE MODELING

More detailed FEMs are used to model vibration that will result in radiated noise. These models need to cover all the mode shapes in the frequency range of interest. The size of finite elements should be selected to have at least five or six elements over the length of the highest frequency mode shape of interest. Consider a flat rectangular valve cover that is 200 mm wide and 600 mm long. To define the first mode shape, only 5 or 6 elements across are required, along with 15–18 elements down the length of the cover (to keep elements roughly square). To handle the $n = 6$ mode shape across the cover, 30–36 elements across would be required, and three times that number down the length. This is a far simpler model than that required for any sort of stress analysis. Most models that are actually used are far finer than this example would suggest, but unlike in the case of a stress model, additional resolution does little to improve the accuracy of the result.

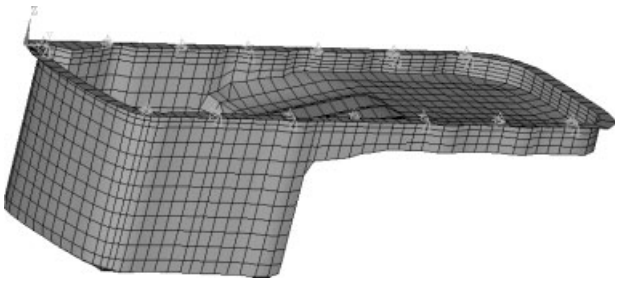

Figure 5. Finite element model of stamped steel oil pan.

Noise models can be done at the component level, at the engine level, or at the full powertrain level. Modeling individual components has advantages. It is far easier to determine the input to an engine cover, for example, than to the block or cylinder head. Vibration at the mounting flange of a cover can be directly measured and fed into the model as an input. Another advantage of small models is run time. With faster run times, it is easy to explore many design options. A very large model with a very long run time may limit the analyst to only two or three runs. This greatly reduces the scope for design optimization.

8.1 Noise modeling examples

Figure 5 shows a very simple FEM of the stamped steel oil pan that produced the results shown in Figures 3 and 4. Figure 6 shows the vibration response of this model at 240 Hz and the calculated radiated sound power of the oil pan at 240 Hz. Figure 7 compares the results of the analytical model to measured sound power data obtained by using the acoustic intensity method. Despite the very simple structural model used, excellent agreement between the analysis and experiment was obtained. In fact, at frequency where some discrepancies can be found, it is likely that the discrepancy is caused by experimental error.

9 LOW-NOISE ENGINE DESIGN GUIDELINES

The engine block structure should be as stiff as possible. One way to achieve this is to split the block at the crankshaft centerline. The lower section, called the *bedplate*, carries the main bearing caps. A low-cost way of achieving high block stiffness is to use a long skirt block with a simple flat plate tying the oil pan flanges together. A flat plate is very stiff in shear, and when the block tries to bend or twist, it will have to deflect the plate in shear. A long skirt is needed with this approach, as the stiffening plate needs to be below the main caps so that the plate does not need holes to accommodate the caps. The plate will still need holes to accommodate the rod envelope.

The stiffness of main bearing bulkheads is particularly important. During firing, the crankshaft deflects and applies forces to the bulkheads that act along the crank axis. As the bulkhead deflects, it causes deflection in the skirt, which will directly radiate noise as well as pass vibration into the oil pan. If the natural frequency of the bulkhead can be increased as much as possible in the fore–aft direction, this will reduce deflection and thus noise. The natural frequency target for heavy-duty engine bulkheads should be 800 Hz. Smaller engines need a higher target value.

Another alternative for stiffening the bulkheads is to tie the main bearing caps together. This should be done without tying the caps to the block skirt. Cross-bolting of main caps, which ties them directly to the block skirt, tends to be counterproductive from a noise point of view. In highly loaded V-type engines, it may be required for structural integrity, however.

Large, flat cast panels should be avoided. These tend to be lightly damped, and have resonances within the range where significant forcing functions are present. Adding shape is a good way to add stiffness to a cast panel without adding too much weight.

The mounting flange for the flywheel housing or transmission bell housing should be as tall, wide, and stiff as possible. This helps ensure a high powertrain bending natural frequency. A good target for powertrain bending natural frequency is equal to high idle rpm divided by 24, for a four-cylinder engine. This puts the resonance at 2.5 order at top speed, providing margin to the large second-order force input.

Large engine covers should be designed with a low first natural frequency of 100–150 Hz. If this is not feasible, the large cover should be stiffened and isolated. Smaller covers should be designed for a first resonance of 5 kHz or more. If this is not feasible, isolation should be considered.

If the engine is likely to be used in noise-sensitive applications, it is a good practice to design in space to allow for close-fitting noise enclosures.

Combustion noise targets should be set early in the design phase. Achieving a good combination of performance, emissions, and noise requires close collaboration between the engineers responsible for these often competing characteristics.

For diesel engines, the selection of the fuel system and how it is driven has a huge effect on the noise of the engine. A low cyclic torque high pressure pump will reduce torsional inputs to the timing drive, helping to reduce noise. This is especially important in engines that use gears for the timing drive. Flexibility on the number of injection events, injection timing, and injection pressure are keys to controlling combustion noise.

Engines that use gears for the timing drive should focus on minimizing the size of the gear train and the torsional inputs to the gear train. This suggests, for example, putting the cam in the block rather than in the head, and selecting a low cyclic torque fuel system. More gear meshes provide more opportunity for gear rattle, and thus more noise.

Exhaust Emission Control Considerations for Diesel Engines

Timothy V. Johnson

Corning Incorporated, Corning, NY, USA

1 INTRODUCTION

Advanced emission control technologies have been utilized to clean engine exhaust since 1999 for light-duty (LD) diesels and since 2005 for heavy-duty (HD) diesels. Criteria pollutant tailpipe regulations are tightening quite significantly, and all modern diesel engines now have some form of exhaust emissions control.

This chapter focuses on key developments related to emissions and technologies for diesel engines in the automotive and HD markets: diesel PM (particulate matter) control, lean NO_x control, diesel oxidation catalysts (DOCs), and comments on system design.

This chapter is not intended to be all-encompassing and comprehensive. Representative papers and presentations were chosen here that provide examples of new, key developments and direction.

2 DIESEL PARTICULATE FILTERS (DPF)

Diesel particulate filters (DPFs) are the most effective means of reducing PM from diesel exhaust. They can remove more than 99% of the hazardous soot particles. Although DPFs have been in commercial production for first-fit applications since 1999, there is still much optimization activity in the field. Work is continuing on DPF substrate design, DPF regeneration, and ash characteristics and management.

2.1 Substrate characteristics

Boger *et al*. (2011a, b) reported on a new substrate for reducing back pressure in DPFs. They tightened the pore size distribution and decreased porosity in the next-generation aluminum titanate filter to provide either a 2–3 g/L increase in soot mass limit or a 20–25% back pressure reduction, depending on cell geometry. Catalyzed samples of the low pressure-drop version has 20–30% lower back pressure with no soot on the filter and 15–20% lower back pressure with 6 g/L soot loading (Figure 1). The soot mass limit was similar to that of an SiC (silicon carbide) filter with the same cell geometry, but the SiC version has 50% higher back pressure. As a result of lower thermal conductivity, the regeneration efficiency of the new filter in a standard drop-to-idle test at 575°C is 6% higher than the earlier version, and 16% higher than the SiC comparison.

To facilitate the addition of deNO_x catalyst to the DPF, Warkins *et al*. (2011) increased the porosity in a new aluminum titanate high porosity (AT-HP) filter. Figure 2 shows that with a heavy catalyst coating and high soot loading, the pressure drop of the new DPF is 25%

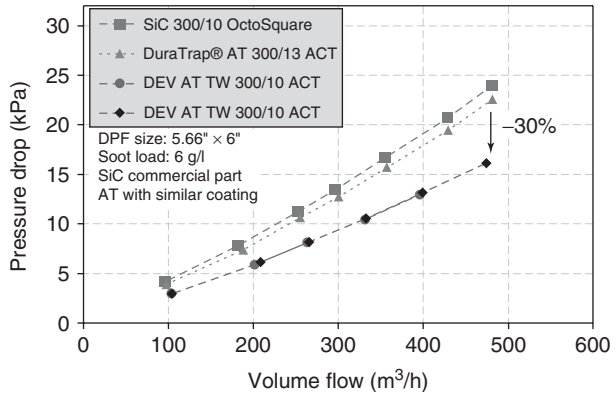

Figure 1. Pressure drop comparisons for the next generation aluminum titanate filter (DEV AT), in the low pressure-drop thinwall (TW) version. 300/10 refers to 300 cells/inch^2 with 10 mil wall thickness (Boger *et al*., 2011a, b). (From Boger *et al*., 2011. Copyright © 2011 SAE International. Reprinted with permission.)

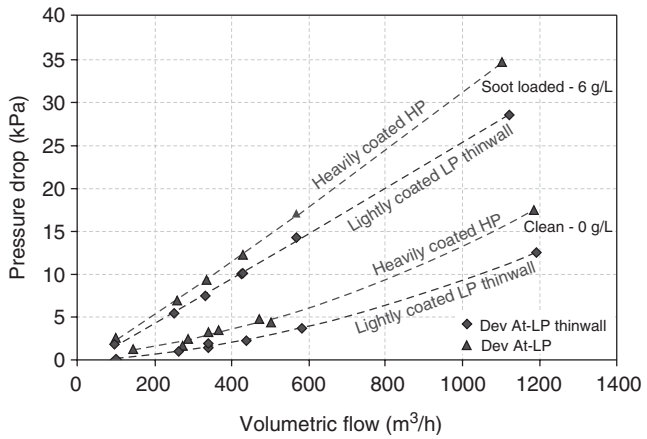

Figure 2. A new AT high porosity filter (AT-HP) with high catalyst loading has slightly higher back pressure than a lightly coated LP low back pressure filter. However, the overall system back pressure is reduced 20% if a separate SCR catalyst is eliminated (Warkins *et al*., 2011). (Reproduced with permission from Warkins *et al*., 2011. © J. Warkins *et al*., Corning, Inc.)

higher than a lightly coated low porosity (LP) thinwall version designed for low pressure drop (−25% vs current). However, if the AT-HP filter does not require a separate SCR (selective catalytic reduction) catalyst, overall system back pressure is reduced upwards of 20%. The new AT-HP filter also has 2 g/L higher soot mass limit than the current commercialized AT filter. Cycle-averaged deNO$_x$ efficiency with SCR catalyst on the HP filter was 62% (urea injection starts at 400 s), versus 23% (injection at 1100 s), when a separate SCR catalyst is placed behind the uncoated DPF.

Taking advantage of improvements in SCR technology, future HD engines will be calibrated to higher NO$_x$ and lower PM to save fuel. This will result in favorable conditions for passive oxidation of soot by NO$_2$ and dramatically decrease the need for active regeneration of the DPF at high soot loads. Less thermal mass will be needed in the DPF to provide a buffer against uncontrolled active regenerations. Boger *et al*. (2011b) reported on the next-generation thinwall cordierite filter to address this trend. Relative to the current offering, the pore size distribution was tightened and made nominally smaller, and the porosity was increased to ∼55%. Wall thickness was reduced 33% in the 200-csi (cells/square inch) geometry. To enable this, the inherent strength of the cordierite was increased. As with membrane technology, this redesigned porosity allows little, if any, soot penetration into the wall that causes rapid build-up of back pressure. Moreover, coated and uncoated filters have little back pressure differences. The result is that soot-laden filters have 40–50% lower back pressure than their 2010 predecessors under a variety of conditions. Interestingly, because of the reduced thermal mass, skin temperatures are higher but centerline temperatures are the same during active regeneration, reducing the thermal stress in the part. Although the authors made no mention of soot mass limit impacts, the filter survives worst-case drop-to-idle testing at 3.5 g/L soot. The lower thermal mass of the DPF allows faster heat-up of a downstream SCR catalyst, resulting in 10% more time for urea injection in the US certification test cycle. This can result in 15% lower cumulative NO$_x$ emissions in the cold-start test (Heibel, 2010).

Inorganic membranes can be added to filter surfaces to enhance filtration and reduce back pressure (Iwasaki *et al*., 2011). In vehicle testing, pressure drop was reduced 30–40% depending on speed and soot load, relative to the same filter without a membrane. This membrane benefit was also demonstrated on SCR-coated DPFs in engine dynamometer testing. Alternatively, in engine tests, the investigators demonstrated that the membrane can be used to increase the soot mass limit of a cordierite DPF about 2 g/L without a back pressure penalty by applying it to a lower porosity substrate.

When high catalyst loadings are added to DPFs, such as when applying deNO$_x$ catalysts, particle number (PN) emissions can counter-intuitively increase if excessive catalyst is applied (Kuwajima *et al*., 2009). The effect is illustrated in Figure 3. PN emissions are correlated to porosity: emissions go down as 10–20 μm porosity increases, but they go up if pores >30 μm increase in volume fraction. As coating load increases, large pore volume goes down but 10–20 μm pore volume remains flat. The net result is decreased PN emission. However, if coating load increases further, the opposite occurs: coating decreases 10–20 μm porosity but

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto138
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

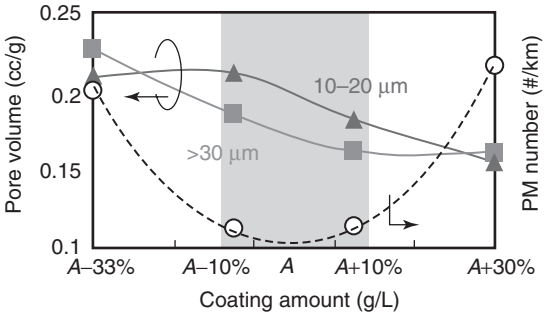

Figure 3. PN emissions (dashed line) reach a minimum with catalyst coating amount, because of the counteracting impact of loading on 10–20 μm and >30 μm pore volume (Kuwajima *et al*., 2009). (From Kuwajima *et al*., 2009. Copyright © 2009 SAE International. Reprinted with permission.)

large pores remain largely unaffected, giving the net result of increased PN emission.

Of a more fundamental nature, Rakovec, Viswanathan, and Foster (2011) used wafers machined out of commercial DPFs to look at how filter wall permeability varies with gas flow rate, PM loading, and PM type. Most of the wall permeability impacts are due to the substrate. Normalized wall permeability starts out similarly for high face velocity, independent of PN levels in the exhaust. But later, exhaust with low PN levels produces higher permeability because of more particles going into wall and forming a thinner cake. Low flow, high PN allows low cake density and higher ending permeability, but with a thicker cake. High nucleation-mode particle loading allows particle penetration into the wall and early bridging, resulting in a fast drop in permeability and low final permeability. The results should be useful in refining filter back pressure models that are used to manage filter regeneration.

2.2 DPF regeneration methods

More than 10 years ago, in the first wide-scale application of DPFs for particulate control on LD diesels, Peugeot chose a ceria-based fuel borne catalyst (FBC) to facilitate the regeneration of the DPF. A new generation of FBC is based on iron, and further improves DPF regeneration characteristics with or without platinum group metals (PGM) catalyst on the DPF (Rocher *et al*., 2011). Compared to the original of 30 ppm Ce and 10 ppm Ce/Fe in the previous version, the new formulation uses only 5 ppm Fe with similar performance, resulting in half the ash load on the DPF. The authors estimate that for a car with a fuel consumption of 7 L/100 km (33 miles/gallon), the DPF ash cleaning interval is 300,000–400,000 km, depending on filter design. The new FBC drops the DPF regenerating start temperature of a stock PGM-catalyzed DPF (CSF, catalyzed soot filter) from 410 to 360°C, and increases the total soot burn from 12% in the baseline ramp-up test (to 500°C) to 75% with the FBC–CSF combination. The improved regeneration efficiency and decreased temperature will reduce thermal exposure of the SCR catalyst in Euro 6 systems, as well as reduce DPF regeneration fuel penalty when the SCR system is located upstream of the DPF.

Warner, Dobson, and Cavataio (2010) investigated the current DPF regeneration dynamics. Active regeneration efficiency, wherein exhaust temperature is increased to ~600°C and the soot is burned by oxygen, is not strongly dependent on oxygen content at levels >2% nor on whether the filter contains precious metal, although the precious metal does oxidize the resultant CO to form CO_2. However, the efficiency is strongly dependent on soot loading because of the build-up of heat. Passive regeneration, wherein the soot is oxidized by NO_2, is much more effective (>3×) at 370°C than at 485°C, as the decomposition of NO_2 back to NO at the higher temperatures overwhelms the faster soot oxidation rate at these temperatures. A DPF with Cu-zeolite behaves similarly to the uncoated filter, and has minimal impact on DPF regeneration. This indicates that NO_2 prefers to oxidize soot rather than be reduced on the zeolite. HNCO (isocyanic acid) is a byproduct of active regeneration without catalyst, and needs to be considered in the mass balance when examining regeneration effectiveness. Active regeneration "costs" about 2–3% fuel consumption, and passive regeneration strategies can drop this penalty by about 20%.

Soeger *et al*. (2005) analyzed the balance between exhaust flow rate, temperature, and soot burning kinetics, as they relate to passive regeneration. The amount of NO_2 available for soot oxidation depends on engine out NO_x, NO_2 conversion, and flow rate (RPM, engine revolutions per minute). High RPM with 350°C exhaust gives highest NO_2 production. However, at temperatures <380°C, the burn rate is controlled by soot oxidation kinetics, so, NO_2 availability generally does not limit soot oxidation rate with properly designed catalyst systems.

Direct oxidation catalysts have been of interest in the field for more than 5 years. These catalysts use oxygen conducting materials (such as ceria, zirconia, or manganate) to burn the soot at the soot–catalyst interface, rather than by oxygen in the gas phase. Southward, Basso, and Pfeifer (2010) showed that a complex ceria material can begin oxidizing soot with model gas at 160°C with completion at 220°C using no or very little precious metal. The exotherm from CO or hydrocarbon (HC) oxidation initiates the reaction. Once started, the exotherm causes soot not in contact with the catalyst to oxidize via the gas phase oxygen. When tested using vehicle exhaust, the balance

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto138
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

point temperature (BPT; soot accumulation rate is the same as the oxidation rate) is 20°C lower than with a commercial filter coated with 0.2 g/L of 1 : 1 platinum and palladium (BPT = 420°C). The regeneration efficiency is much better than for a lightly catalyzed filter at 550°C, but similar at 620°C. Iretskaya *et al*. (2010) showed that a rare-earth base metal oxide catalyst has a BPT of 350°C in the absence of NO_2.

Soot can also be burned by adsorbed oxygen on the surface of an SiC fine-particle membrane. Karin and Hanamura (2010) showed much lower activation energy for a DPF with the SiC membrane compared to one without (80 kJ/mol vs 130 kJ/mol), indicating a shift in reaction mechanism. In the paper, they showed anecdotal evidence of the surface oxidation phenomenon, but the presentation had new data confirming this mechanism using thermal desorption spectroscopy. In another study, it was shown that membranes cause the soot to deposit as a layer rather than being dispersed through the porous wall of the filter (Mizutani *et al*., 2010). This creates a more localized exotherm that improves regeneration efficiency upwards of 10–15%.

Biodiesel can impact soot loading and DPF regeneration properties. Vertin, He, and Heibel (2009) conducted a comprehensive investigation of B20 impacts on cordierite DPFs. They blended soy-based methyl ester biodiesel with ultra-low sulfur diesel fuel, and ran dynamometer tests to generate results. PM emissions were reduced 20% with B20 in transient tests, but were similar in steady state tests, indicating that PM differences are cycle dependent. Back pressure relationships are the same for B20 as for standard fuels. Regarding regeneration, at 300°C, B20 does not burn as effectively in the DOC, requiring more fuel to regenerate the DPF. The excess fuel likely collects on the soot, resulting in a larger exotherm during uncontrolled regenerations. At temperatures >300°C, the fuel burns better. There is a minor improvement in passive NO_2 regeneration with B20. No deterioration in catalyst performance was observed after ~120 active regenerations. Soot formed from burning fuel containing 20% biodiesel burns 3× faster than soot from fuel without (Austin *et al*., 2010). The increased reactivity is due to increased particle surface area (Strzelec *et al*., 2010).

2.3 Ash behavior and management

MECA (Manufacturers of Emission Controls Association) published a paper on the state of ash management (MECA, 2005). The reader is directed there for a much more comprehensive review of the topic than can be covered here. The report covers sources and composition of ash, filter designs, filter maintenance intervals, and cleaning procedures.

New filter designs enable extended ash clean intervals. Young *et al*. (2004) showed how increasing the inlet cell size of DPFs relative to the exit cell can increase the ash storage capacity by 50%.

Fujii (2011) looked at how DPF cell geometry and porosity affect filtration efficiency and back pressure as ash (from lube oil and wear) is collected in the filter. He studied filters with 200- and 300-csi and 12 mil (0.3 mm) wall thickness, containing 50% porosity with 15 μm average pore size and 65% porosity with 20 μm pore size. As early ash loadings prevent soot from penetrating into the wall, the lowest back pressure with high filtration efficiency appears with an ash loading of 4–10 g/L. Low back pressure sensitivity to soot and ash loading depends on DPF designs and materials: larger open frontal area gives lower sensitivity, as does higher porosity. Interestingly, filters that were continuously regenerated (like with NO_2) achieve high filtration efficiency (>97%) only after 20 g/L ash is accumulated. Filters managed by periodic regeneration need 140 g/L ash to achieve the same level of efficiency, because the ash generally collects in the back of the filter without forming much of a filtration membrane.

Sappok and Wong (2009a, b) showed in more detailed analyses that an ash membrane is formed before it migrates to the end of the DPF cell to form a plug at the exit side of the DPF. Zinc has a lower packing density than calcium or CJ-4 lube oil mixed ash, so it forms a membrane first (Sappok and Wong, 2009b). Back pressure is generally linear with ash and soot accumulation, as shown by region I in Figure 4. However, after about 12.5 g/L of ash accumulates (~50,000 miles), back pressure rapidly increases with

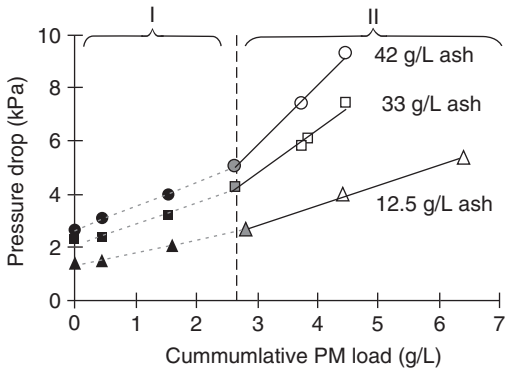

Figure 4. Pressure drop increases faster with increasing soot and ash loading beyond a certain threshold (region II) because of compressing of the membrane from higher back pressure (Sappok and Wong, 2009b). (Reproduced from Sappok and Wong, 2009b. © ASME.)

increasing soot beyond about 3 g/L, zone II. This effect is thought to be caused by the compression of the soot/ash membrane caused by increasing back pressure.

2.4 PM sensors for on-board diagnostics (OBD)

PM on-board diagnostic (OBD) regulations are expected to require a post-DPF soot sensor. Five general types have been reported. The most common type collects soot between two electrodes and measures changes in electrical conductivity (Weigl, Roduner, and Lauer, 2010). It is periodically heated to remove soot, the frequency of which indicates PM level over the period. Resolution is acceptable, but the early 2009 version could not detect DPF failure within the timeframe of the new European drive cycle (NEDC) test, as the regulation requires (Finch, Hnilicka, and Sindano, 2010). The second type also collects soot, but between two parallel plate electrodes (Kondo *et al*., 2010). The change in capacitance indicates the amount of soot that is collected, and hence, the soot PM level in the exhaust. The soot is also periodically burned out. The investigators show acceptable resolution and the ability to detect a failure within the NEDC test. The third type is a real-time sensor and measures soot carrying an electrical charge as it passes between two electrodes (Besch *et al*., 2010). This is the only type that does not accumulate soot and is apparently capable of measuring PN and PM. The fourth type is different from the others, as it is not based on electrical properties of soot (Zidat, 2010). A slip stream contains a small monitoring DPF that begins filling with leaked soot. This results in reduced flow in the slip stream, which is detected with a thermocouple. The device has the required resolution and has potential to take a reading within the NEDC. The fifth device uses radio frequency to measure soot loading on the filter.

3 LEAN NO_X CONTROL TECHNOLOGIES

Lean NO_x control (lean $deNO_x$) technologies will be integral to meet the emerging criteria pollutant regulations for diesel engines. Minimum removal efficiencies on the order of 85% will be needed, but levels up to 97–98% are desired to allow HD engines to operate in high NO_x low fuel consumption regimes. For LD applications, the efficiency is as important, but light-off or low temperature (LT) performance characteristics are even more so.

Two broad approaches to lean $deNO_x$ control are SCR using ammonia and HC-based approaches (HC-$deNO_x$) primarily using lean NO_x traps, but also lean NO_x catalysts (LNCs) (or HC-SCR).

3.1 Selective catalytic reduction

SCR technology is entering its third or fourth generation since commercial introduction in Europe in 2003. Then, systems were removing upwards of 75% NO_x over the European HD transient cycle to meet Euro IV regulations. To meet the emerging Euro VI regulations in 2013, cycle-average $deNO_x$ efficiencies approaching 95% may be realized. Work is continuing in the United States to go even higher in efficiency to meet the current and emerging LD NO_x regulations.

Currently, good SCR performance is limited by urea injection issues (evaporation and hydrolysis) at temperatures <200°C. Improved mixers allow urea injections at temperatures as low as 180°C and thus drops NO_x ~30% over the United States cold HD transient cycle relative to no mixer (Zhan *et al*., 2010). Alano *et al*. (2011) described a compact mixer that needs only 75 mm of urea mixing length, compared to 350 mm in some commercial LD SCR systems, enabling the SCR catalyst to be placed closer to the engine for faster heat-up. The mixer achieves a urea mixing index of 0.95 (all cross-section NH_3 measurements are within 5% of one another) over a range of gas flows, with a maximum increase in back pressure of 0.4 kPa (4 mbar) during accelerations relative to a conventional system. In the closer position, in tests, the SCR catalyst was up to 25°C hotter and achieved 67% $deNO_x$ efficiency on the NEDC versus 37% for a catalyst place further back. The mixer could be useful if SCR catalyst is placed on a DPF for faster light-off or better DPF regeneration versus two separate systems (DPF–SCR or SCR–DPF).

To accomplish the same objective, urea hydrolysis catalysts are emerging. Kröcher *et al*. (2010) showed that upwards of eight different decomposition products are emitted from urea upon heating, but with a titania decomposition catalyst, as shown in Figure 5, ammonia is produced at temperatures as low as 150–160°C in model gas with no other unexpected decomposition products.

Although the urea infrastructure is well developed in Europe, Japan, and the United States, finding alternative sources for ammonia is still of significant interest to enable SCR catalysts to function better at low exhaust temperatures, decrease the size and cost of the system, and enable the use of the system at very low ambient temperatures. Johannessen (2011) updated the developments on a gaseous ammonia system using chloride-based adsorbents. Both HD and LD systems were described, showing 100× dosing ranges within 5% accuracy and <1.5% deviation in set-point under a range of exhaust conditions. Start-up units are used that initially draw 550 W in HD and 250 W in LD applications, but go down to 100 W range during normal operation. Safety and durability issues

appear addressed, and system optimization through testing and simulation is continuing. Jackson (2011) described an alternative approach that utilizes ammonium carbamate (NH_2COONH_4). It is available as pellets that release ammonia upon heating with auxiliary hot water. Ammonia salts dissolve in the water and depress the freezing point to −30°C. Development issues include faster start-up and better, more-efficient heating. Thomas and Highfield (2011) described some early performance data with an ammonium formate and urea system containing 54% water, versus 67.5% for standard urea solutions. Advantages include reduced freezing point (−30°C), better high temperature (HT) storage stability, lower hydrolysis temperature, no polymerization like with urea (fewer or no deposits), and they demonstrated full "drop-in" capability in a urea system on a new diesel pick-up truck with and without SCR system.

SCR catalyst formulations and design are improving both low and high temperature performance, as well as sensitivity to HC and sulfur poisoning. Vanadia SCR catalysts are used in Europe and emerging markets, but not in the United States or Japan because of durability issues related to thermal exposure when DPFs are regenerated. Advances are now reported (Chapman *et al*., 2010) on vanadia SCR catalysts that have no volatility up to 750°C or higher, versus 550–600°C for some commercial catalysts, giving them similar HT durability to zeolites. $DeNO_x$ performance at 250–350°C is 5–10 points better after HT aging (>700°C) than for a benchmarked commercial catalyst, but less-severely aged catalysts have lower efficiencies than the base catalyst. Walker (2010) reported that new Cu-zeolite formulations now sustain aging to 900°C and form less N_2O.

Reichert (2011) and Narula *et al*. (2011) showed some new advancement in the zeolite SCR catalyst activity. Reichert showed a new zeolite material that exhibits the same LT performance of copper-zeolites and the same HT performance of iron zeolites. Results are shown in Figure 6. Narula showed that it is possible to modify zeolite structures systematically to influence the electron density at metal

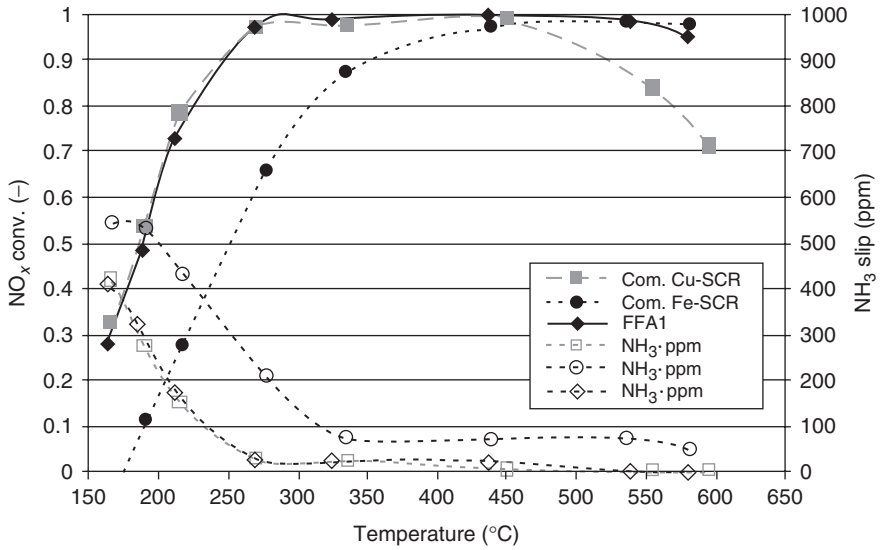

Figure 6. Performance characteristics of Cu- and Fe-zeolite SCR catalysts. "FFA1" is a new Cu-zeolite that has the same low temperature performance of standard Cu-zeolites, but with comparable high temperature performance to Fe-zeolites (Reichert, 2011). centers and to provide ammonia bonding sites in the vicinity of the metal centers. They replaced alumina in the structure with several trivalent cations. In another contribution, Yang and Narula (2010) showed that chemical mixtures of copper and iron zeolites can improve LT performance over than copper alone, and when lanthanum is added to the binary formulation, performance is improved further.

Han *et al*. (2011) showed that LT performance and reduced HC effects can be achieved if a ceria oxygen storage catalyst is layered on top of an iron zeolite catalyst. The catalyst helps urea decomposition, thus improving the LT deNO$_x$ capability from 32% to 58% at 200°C, an LD steady-state test. After 8 h of exposure to high HC levels from a burner, the layered catalyst maintained a deNO$_x$ efficiency of 80% at 240°C, whereas the original version was only at 60% under the same conditions because of HC poisoning.

On sulfur poisoning, Tang, Huang, and Kumar (2011) used SO_2 levels equal to those obtained with ultra-low sulfur diesel fuel (<15 ppm sulfur), the copper zeolite catalyst started losing deNO$_x$ efficiency after about 400 h of operation at temperatures of 200–300°C. Through 1300 h of operation, the catalyst had deteriorated continuously from 98% deNO$_x$ efficiency to 60% efficiency. Moreover, the $NO_2 : NO_x$ ratio from the filter deteriorated from 0.60 to 0.30 during the first 600 h, but then remained the same. They found that most of the sulfur was in the top layer of washcoat in the first third of the catalyst. Most of the poisoning was attributed to ammonium sulfate, which comes off at 400–500°C, and to a much lesser extent, copper sulfate, which comes off at 500–850°C. When heated to 500°C, the SCR catalyst performance recovered, and this was done every 700 h of operation at the lower temperatures.

For US LD diesels, removing cold-start NO$_x$ emissions is key to meet the tailpipe emissions regulations. A new combination NO$_x$ adsorber and SCR catalyst configuration was shown by Henry *et al*. (2011a). Figure 7 shows some performance characteristics. The system consists of an upstream passive NO$_x$ adsorber (PNA) that might capture 65% of the NO$_x$ at temperatures <150°C, and then passively releases it at temperatures greater the 150°C. At these temperatures, a copper zeolite is just becoming active and can reduce some of this released NO$_x$.

Nowadays, SCR substrates are generally have 300 or 400-csi. Heibel (2010) showed that in the mass transfer controlled regime (230–350°C), 600-csi substrates react 35% faster than 400-csi catalysts.

Work is continuing on the combined SCR + DPF system, wherein SCR catalyst is coated onto the DPF. This allows SCR catalyst to be placed on the vehicle without using an added component, and can get the SCR catalyst closer

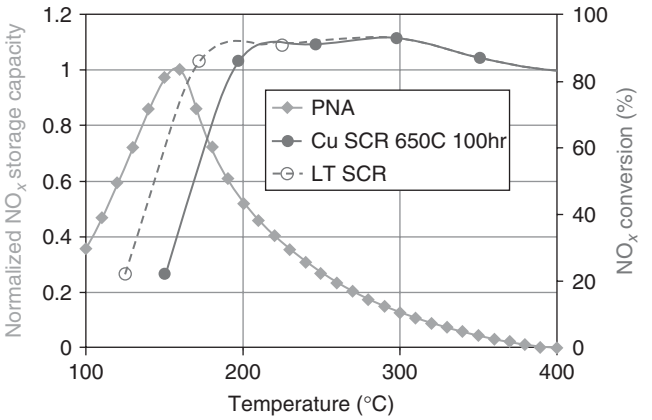

Figure 7. An upstream passive NO$_x$ adsorber (PNA) captures NO$_x$ generated at $T < 150$°C. An LT urea SCR catalyst can then convert this NO$_x$ upon release at $T > 150$°C (Henry *et al*., 2011a). (Reproduced from Henry *et al*., 2011a.)

to the engine for faster light-off. Numerous reports dating to 2008 showed that total NO$_x$ removal efficiency is thus improved, with little compromise in DPF regeneration. Tan, Solbrig, and Schmieg (2011) showed a new issue when soot is accumulated on the DPF + SCR: ammonia storage capacity decreases for fresh samples at all temperatures and soot loadings tested (200–350°C, 1.0–2.5 g/L), but is not affected by soot loading for aged samples (except at 200°C). Loss of ammonia storage capacity impacts SCR performance at 200°C, but not at 300°C at a soot load of 2 g/L. The researchers also showed that DPF regeneration calibration needs to be adjusted to longer times or higher temperatures to get the same cleaning performance as the base DPF system.

The US Environmental Protection Agency (EPA) capped nitrous oxide (N_2O) emissions in the HD greenhouse gas (GHG) rule, and is proposing a cap in the LD GHG rule. Kamasamudram, Henry, and Yezerets (2011), showed that N_2O is very stable, and forms by three mechanisms in an SCR catalyst:

LT ($T < 250$°C) decomposition of ammonium nitrate by the reaction

$$NH_4NO_3 \rightarrow N_2O + 2H_2O \quad (1)$$

HT oxidation of ammonia by copper zeolites by the reaction

$$2NH_3 + 2O_2 \rightarrow N_2O + 3H_2O \quad (2)$$

Reaction of excess NO_2 (>50% of NO$_x$) to form ammonium nitrate by the reaction

$$2NH_3 + 2NO_2 \rightarrow NH_4NO_3 \downarrow + N_2 + H_2O \quad (3)$$

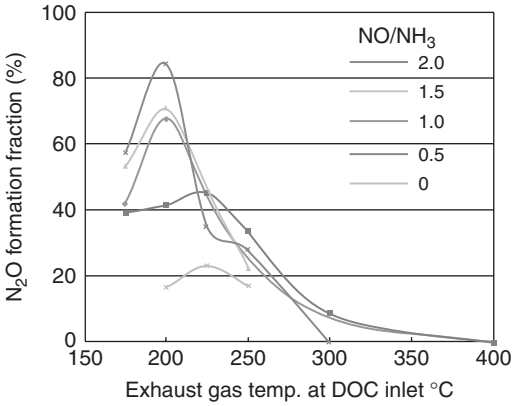

Figure 8. Nitrous oxide formation in ammonia slip catalysts is promoted by high NO : NH_3 ratios coming out of the SCR catalyst (Matsui *et al*., 2011). (Reproduced with permission from Matsui *et al*., 2011. © Society of Automotive Engineers Japan.)

Ammonium nitrate then decomposes by reaction 1.

SCR catalyst improvements can decrease N_2O formation by the first two mechanisms, and better DOC design and control can prevent the third mechanism. Kamasamudram, Henry, and Yezerets (2011) showed that it is possible to reduce N_2O to nitrogen, but these reactions occur at much higher temperatures than those at which they are formed.

For high efficiency SCR deNO_x, excess urea injection is needed, perhaps up to 20% more. Ammonia slip catalysts are needed to prevent ammonia release, but these catalysts can also form N_2O. Matsui *et al*. (2011) showed (Figure 8) that ammonia up to 80% going into the slip catalyst can convert to N_2O if there is also a relatively high amount of NO (2× vs NH_3); the reaction is

$$4NH_3 + 4NO + 3O_2 \rightarrow 4N_2O + 6H_2O \qquad (4)$$

A high NO : NH_3 ratio coming out of the SCR catalyst can occur, for example, if there is poor urea mixing before entering the SCR catalyst and urea is injected at less than stoichiometric requirements, or if ammonia is partially oxidized (by Cu-zeolite, for example) to form NO. Kamasamudram, Henry, and Yezerets (2011) showed that slip catalysts with lower precious metal content minimize N_2O formation.

3.2 HC-based NO_x control

3.2.1 Lean NO_x traps (LNT)

The lean NO_x trap (LNT) is currently the leading deNO_x concept for the smaller lean-burn (diesel and direct-injection gasoline) passenger cars, and is of interest in applications with limited space or in which urea usage is difficult. The deNO_x efficiency is nominally 70%, much lower than that of the next-generation SCR system at 95%, and the precious metal usage is high (∼10–12 g for a 2-L engine). As a result, efforts are focused on improving efficiency while reducing precious metal usage. One of the leading concepts is to use the LNT to generate ammonia during the periodic rich regeneration part of the cycle, and then to store and use this ammonia in a downstream SCR catalyst.

The first LD diesel sold in the United States to meet recent tailpipe regulations had the BlueTec™ 1 emission control system, utilizing an LNT followed by an SCR catalyst. The unique system used the rich cycle of the LNT to generate ammonia, which was captured and used by the downstream SCR for lean NO_x reduction. Weibel *et al*. (2009) reported that ammonia selectivity increases with aging and rich period, and decreases with increasing the air/fuel ratio (λ). Under conditions of $\lambda = 0.88$ and rich periods of 5 s (180 s lean), ammonia selectivity is >70% in the temperature range of 225–350°C for all aging tests temperatures greater that 600°C and 50,000 miles. The SCR adds about 20% deNO_x efficiency over an LNT only configuration.

Theis, Dearth, and McCabe (2011) reported on an interesting study whereby they alternated LNT and SCR slices in one can to check the effect of NO_x, ammonia, and HC distributions on deNO_x performance. The system performance improved as the number of alternating slices of the LNT and SCR increased, keeping the total volume constant. The deNO_x efficiency for the eight-segment system (four pairs of LNT and SCR catalysts) was 81% in a reference test at 275°C, whereas 78% for four segments and 60% for two segments. The reference single LNT with no SCR catalyst had only 30% deNO_x efficiency. The authors also show reduced N_2O, NH_3, HC, and CO emissions with the segmented systems. Various dynamics are operative, but the segmented systems tend to better-match the NO and ammonia concentrations in the SCR, and alternating SCR slices better-adsorb HCs for enhanced utility.

Xu *et al*. (2011) reported vehicle and laboratory testing on a second-generation LNT + SCR system. The DOC + LNT + SCR + DPF system was installed on a prototype F-150 pick-up truck (2610 kg, 4.4 L V8, turbodiesel). The aged system (64 h, 750°C) reduced NO_x by 96% to 13.5 mg/mi, and HC emissions were 14 mg/mi (−99%), bringing the vehicle to within the emerging California LEVIII (low emission vehicle 3) limit values (30 mg/mi HC + NO_x) on the standard certification test cycle. The laboratory work focused on HC reductions from the system. The SCR component reduced HCs about 75%, mainly by adsorption under rich conditions and oxidation under lean conditions.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto138
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Cavataio *et al*. (2011) compared this capability to that of a urea SCR system for meeting the US EPA Tier 2 Bin 2 (or California LEVIII fleet average) standards. Although the LNT + SCR system is 18% smaller, it had met the target emissions while the SCR system fell short. Further, the LNT + SCR system is estimated to be slightly cheaper, but has most of the cost tied up in precious metal (with its inherent price volatility). On the downside, the fuel penalty was high at 10%, versus 2% for the SCR system. Moreover, sulfur management of the LNT + SCR system was not considered.

LNTs are sensitive to sulfur poisoning, wherein a stable alkali-earth sulfate forms displacing the desired nitrate. They need to be periodically desulfated, even in low sulfur fuel. Chen *et al*. (2009) added PO_x (partial oxidation) catalyst to partially reduce HCs to hydrogen and CO. The result is a 150°C drop in desulfation temperature with double the amount of sulfur coming off. In addition to this benefit, LT performance slightly improves, and expensive rhodium could be replaced with cheaper palladium, reducing precious metal costs.

LNT durability has improved significantly over the years, mainly because of better materials and to the need for lower desulfation temperatures. Ottinger *et al*. (2009a) developed a rapid thermal aging test protocol, and then determined (Ottinger *et al*., 2009b) the thermal aging mechanisms of the three unit operations in an LNT: NO oxidation, NO_2 adsorption, and NO_2 reduction. NO oxidation is hampered by the loss of precious metal surface area. The adsorption of NO_2 is largely affected by the loss of alumina surface area, especially at the lower adsorption temperatures. As baria is relatively unaffected at the higher temperatures and alumina loses surface area at ~900°C, this overall effect is not as significant to the LNT function as the loss of precious metal oxidation kinetics. Aging actually helps the reduction unit process, because the larger baria grains release the nitrate slower, reducing NO_x slip.

In what might be a newly discovered reaction phenomenon, the temperature range of the LNT was extended from 350°C to well over 600°C by managing it differently. Some results are shown in Figure 9. Bisaiji *et al*. (2011) at Toyota oscillated the air–fuel ratio between 16 and 24 depending on conditions, but all within the lean regime using an auxiliary exhaust injector. They proposed a mechanism involving partially oxidized HC intermediaries (observed) reacting with chemisorbed nitrate species, in a type of HC-SCR reaction. The frequency of fuel injection is in 0.5 Hz range and the $deNO_x$ efficiency increases with amplitude of the oscillation, up to about three air : fuel ratio points. Fuel penalties are on the order of 1.5%–3.0% at medium to high load, and running at about 80% $deNO_x$ efficiency (Inoue *et al*., 2011). The

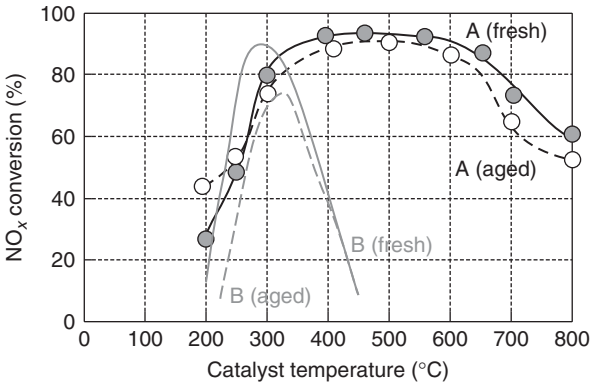

Figure 9. NO_x reduction curves for a standard LNT operation (B) and for the same LNT run using the new method (A) of lean air : fuel oscillations at ~0.5 Hz (Bisaiji *et al*., 2011). (From Bisaiji *et al*., 2011. Copyright © 2011 SAE International. Reprinted with permission)

method is sensitive to sulfur poisoning, but can take loadings 3.0× higher than a standard LNT before dropping off below 80% $deNO_x$ efficiency. At inlet NO_x levels of 100 ppm and temperatures of 370–420°C, the method delivers >80% $deNO_x$ efficiency at a space velocity (SV) of 125,000/h with a 2% fuel penalty. The new method is best operated at >50% load (lower loads at higher RPM), and complements standard LNT operation at the lower loads.

Finally, to wrap up the representative studies on $deNO_x$, Jackson (2011) updated the industry on using an LNC (silver-alumina) with E85 reductant (15% gasoline and 85% ethanol). Converse to urea, E85 does not freeze and leave deposits when injected at LTs. The system performs well (>90% efficiency at 350–450°C, SV = 38,000^{-1}) after 500 h of aging at 650°C and 100 h at 800°C. The catalyst was coated onto a DPF and demonstrated 60% $deNO_x$ efficiency at 350°C with a C : N level of 3 : 1. When E100 is used, reductant consumption is 25%–35% less than for urea SCR at similar levels of performance: >90% $deNO_x$ efficiency in the 275–375°C range (SV = 38,000 h^{-1}).

4 DIESEL OXIDATION CATALYSTS (DOC)

DOCs play two primary roles in commercial emission control systems:

1. Oxidize HCs and CO, either to reduce emissions coming from the engine or to create exothermic heat used to regenerate a DPF.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto138
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2. Oxidize NO to NO_2, which is used for continuously oxidizing soot on a DPF, and/or for enhancing the SCR deNO_x reactions, particularly at LTs.

Henry *et al*. (2011b) looked at the interplay of these two functions using a series of iterative reaction-decoupling experiments to explain interactions between HC and NO oxidation. They showed that NO oxidation is inhibited on Pt/Pd because of the reduction reaction with NO_2 by HCs. Long-chain alkanes had a more adverse effect than short-chain alkenes because of slower oxidation rate with oxygen. Decreasing SV was shown to help NO_2 formation in the presence of HCs. Prestoring HCs on the DOC improved NO oxidation up to 300°C. The interplay of CO and HC removal and NO_2 generation takes another tack as well. Spurk *et al*. (2010) investigated NO_2 coming from a catalyzed DPF for use in a downstream SCR system. Surprisingly, they found the NO_2 coming out of the DOC and going into the DPF is not as important as the HCs coming from the DOC. Essentially, the HCs going into the DPF can interfere with the NO_2 formation in the DPF. The Pt/Pd ratio is much more important to NO_2 formation than precious metal loading on the DPF.

A critical HC and CO issues has largely gone unresolved. Premixed combustion strategies offer advantages in low load operating points because of significantly reduced NO_x and PM emissions. However, these advantages come at the price of greatly increased HC and CO emissions, lower exhaust temperature, and lower oxygen content, intuitively presenting a significant challenge to DOCs. Indeed, Sumiya *et al*. (2009) showed that the light-off temperature of DOCs increases with decreasing oxygen and increasing HC and CO. They enhanced a catalyst formulation using materials to supply oxygen, applying a CO adsorption suppressant, and creating a plurality of active sites for multiple functions. As a result, the light-off temperature (T50, temperature of 50% conversion) for aged catalysts dropped from 260 to 180°C for exhaust with 500 ppm HC, 500 ppm CO, and 2% oxygen. The values for 5000 ppm HC and CO levels were 225°C from 280°C previously.

Jen *et al*. (2009) showed that platinum can migrate from DOCs (or presumable DPFs) to SCR catalysts if they are exposed to temperature >670°C for extended periods of time (16 h). SCR efficiencies can decrease, especially if the DOC is exposed to temperatures >750°C, as even minute quantities of platinum can cause oxidation of ammonia. Later, Cavataio *et al*. (2009) showed that if palladium replaces some of the platinum in the DOC, less migration can occur. Although the 2 : 1 Pt : Pd mixture shows some deterioration in SCR deNO_x efficiency, it is much worse for the Pt-only formulation. Washcoat formulation and/or processing can make a difference, and NO, HC, or CO oxidation is unaffected or enhanced with the Pd additions.

Kim *et al*. (2011) did a systematic study on the effects of varying the Pt : Pd ratio on DOC HC and NO oxidation and durability in a variety of conditions. All bimetallic Pt–Pd catalysts show better HC light-off activity and thermal stability than the Pt- or Pd-only catalyst. NO oxidation to NO_2 was found to always depend directly on platinum content, with similar durability trends as with HCs. Figure 10 shows a schematic representation of these findings. They found that HC–CO mixtures synergistically have ~20°C lower light-off temperatures than either one alone.

Glover and coworkers (2011) also did a study on Pt : Pd effects on DOC properties, adding N_2O formation and looking more at fundamentals. CO plays a key role on the overall catalyst performance by its positive effect on propylene oxidation which, in turn, is responsible for NO reduction to N_2O and the onset of NO_2 formation. On the Pt : Pd = 4 : 1 catalyst, propylene partially reduces NO to form N_2O at about 200°C, but this temperature shifts to 250°C when is CO added. The effect of higher Pd concentration on NO conversion is detrimental for NO oxidation to NO_2, but is positive for producing less N_2O, especially at high oxygen concentrations. NO_x storage and release may play an important role in NO_2 formation over the lightly loaded full Pt DOC formulation studied. A 40 g/ft^3 (1.4 g/L) bimetal formulation (Pt : Pd = 4 : 1) is comparable on CO and HC light-off to a 113 g/ft^3 Pt formulation. Closing on N_2O formation, Kamasamudram, Henry, and Yezerets (2011) showed that propylene forms much more N_2O than dodecane ($C_{12}H_{26}$).

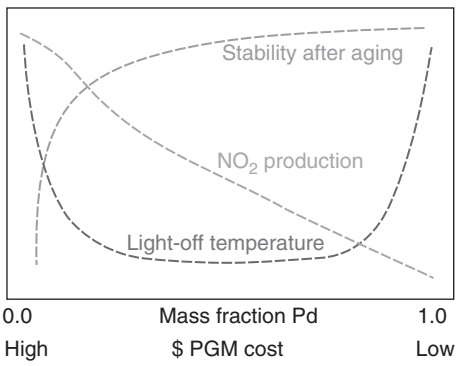

Figure 10. Conceptual impact of increasing Pd content at the expense of Pt in DOCs. Moderate substitutions improve durability and HC oxidation, without significant deterioration of NO oxidation (Kim *et al*., 2011). (From Kim *et al*., 2011. Copyright © 2011 SAE International. Reprinted with permission.)

Potential adverse effects of biodiesel ash on DOCs and other emissions control components were described by a large research group led by the National Renewable Energy Laboratory (Williams *et al*., 2011). The group reported that after a simulated 150,000 miles of durability testing, HC slip increased nominally 20–25% over the range of temperatures in steady-state tests (240–390°C) as a result of alkali exposure from the biodiesel ash. NO_2 formation declined from 35% to 20%. In addition, the thermal shock parameter of the DPF, as indicated by mechanical property measurements, declined 69% after simulated exposure of 435,000 miles (700,000 km), again because of alkali attack of the cordierite substrate. NO_x emissions from the SCR increased about 50%, but more work was needed to determine if this was due to alkali attack of the zeolite catalyst. The group concluded that operating with fuel at the maximum alkali ash specification will significantly deteriorate emission control system performance.

5 EMISSION CONTROL SYSTEM DESIGN

By 2017, most vehicular diesel engines in the United States, Japan, and Europe will have both DPF and SCR technologies. Exceptions are the smaller cars in Europe, some non-road applications in the United States and Europe, and some HD trucks in the United States.

For LD applications, Holderbaum and Kwee (2009) evaluated the placement of the SCR relative to the DPF. Considering the added fuel needed to heat the SCR system for cold start, and to regenerate the DPF with different frequencies because of changes in passive NO_2 regeneration, the authors conclude that for 1800 kg car with a 2-L engine, if cold starts occur more frequently than once every 60 km it is better to place the SCR in front of the DPF. Figure 11 shows some results. Note that 60 km threshold is greater than the distance used in certification cycles, wherein placing the SCR behind the DPF incurs a 2% fuel penalty versus a front placement. The forward SCR placement aids certification for both CO_2 and NO_x emissions.

Casarella (2011) showed the layout of a LD diesel emission control system with the DPF system in the front Figure 12. In the HD applications, the DOC and DPF are placed in front of the SCR and system is quite similar, except there may be a return line for the urea (called DEF, or diesel emissions fluid, here).

The DPF and the SCR subsystems both require their own control strategies. These can be quite complex. Looking at the filter management portion first, one needs to consider the amount of passive soot burn by NO_2. If this is not enough, then active regeneration is needed. Figure 13 shows a DPF regeneration map for an LD vehicle, wherein the light greyregion represents passive regeneration regimes (Boretto *et al*., 2004).

If the engine is run extensively in the active regeneration regime, the soot will build up on the filter and it will eventually need to be regenerated by active heating with fuel. In LD applications, this is usually done with a post injection in the cylinder. For HD applications, auxiliary fuel is injected into a DOC or, less commonly, a burner system is used in the exhaust. Active regeneration requires a control strategy. An example (Schommers, 2004) of which is shown in Figure 14. Key component models

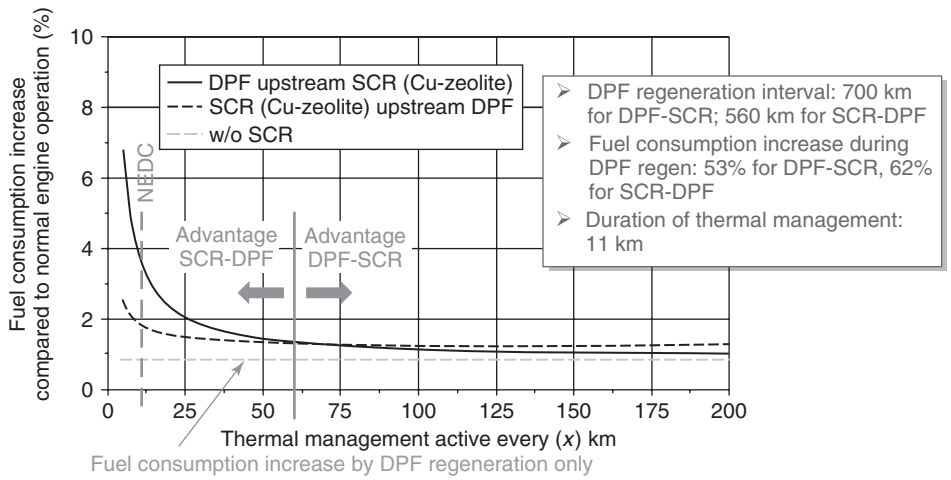

Figure 11. Considering fuel consumption for heating and regenerating the system, placing the SCR in front of the DPF in light-duty applications is beneficial if there is <60 km between cold starts (Holderbaum and Kwee, 2009). are shown in the grey diamond decision boxes, with the filter soot loading model being the most important ("Filter Full?"). Konstandopoulos *et al*. (2000) introduced many of the concepts that are presently used in many DPF soot models. The transient filtration algorithm, a deep-bed-to-cake-model, side-stream reactor technology, and NO_2 turnover/recycling are first described here. In a follow-up paper, Konstandopoulos *et al*. (2005) provide an overview of the multiscalar/multitemporal approach to DPF modeling. The paper addresses simulation from the micro-flow level with three-dimensional computer reconstruction of filter materials, including asymmetric channel designs and ash transport dynamics.

If too much soot builds on the filter and it is burned too quickly, filter damage can occur. Craig *et al*. (2005) described the various regeneration properties of cordierite filters. As shown in Figure 15, peak filter temperatures and gradients and completeness of regeneration are a function of DPF inlet temperature. Flow rate, soot loading, catalysts, and filter thermal mass also have significant impacts. The authors suggest that to increase soot loadings and improve regeneration efficiency, initial inlet temperatures of 550°C might be used, which are then increased as soot loading decreases.

If frequent active regenerations are contemplated, proximity of the DPF to the turbocharger can impact control strategy. For example, by moving the filter system from an under floor position to a close coupled position, the amount of regeneration fuel goes down because the system is inherently hotter. As such, the optimum soot loading, which balances fuel consumption because of increased pressure drop with regeneration frequency, drops from 10–11 g/L

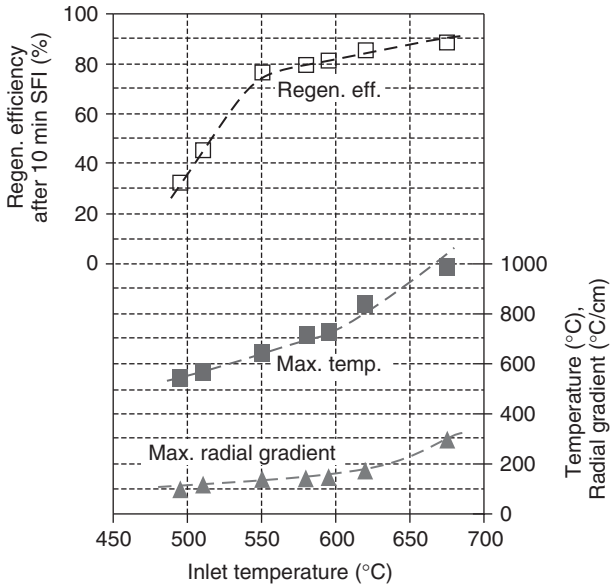

Figure 15. DPF inlet temperatures of >55°C are needed to efficiently regenerate catalyzed cordierite filters with 4 g/L soot loading. To further enhance regeneration, the inlet temperature can be increased later in the process (Craig *et al*., 2005). (Reproduced with permission from Craig *et al*., 2005. © A. Craig *et al*., Corning, Inc.)

down to 6–8 g/L for SiC filters (Oya *et al*., 2005). Such a placement may open up more filter material options.

Much of the work on DPFs is focused on improving regeneration. Chilumukuru *et al*. (2009) concluded that to minimize DPF regeneration fuel penalty, partial regenerations at high soot loadings are preferred. Figure 16 shows

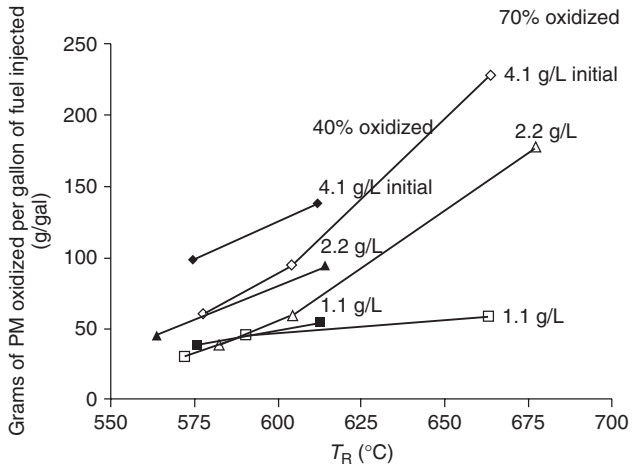

Figure 16. More soot is burned per unit of fuel for high soot loadings and for up to 70% regeneration efficiency (Chilumukuru *et al*., 2009). (From Chilumukuru *et al*., 2009. Copyright © 2009 SAE International. Reprinted with permission.)

the results leading to the conclusion, wherein more soot is burned per unit of fuel at the higher soot loadings, and up to 70% regeneration, the point of diminishing oxidation and increased fuel consumption. Leaving some soot membrane on the filter improves back pressure by keeping soot from penetrating into walls (no ash membrane). It should be noted, however, that one should be very careful in leaving soot on the DPF for too long, as it can age (graphitize or become poisoned) and become very difficult too oxidize, but may occasionally burn unexpectedly.

Post injections are not used for regenerating DPFs in HD application because cylinder wall wetting by fuel can dilute the lube oil. As these engines are expected to run 5–10× longer than an LD engine, this can compromise long term durability. Krüger *et al*. (2004) reported that oil dilution can be minimized or eliminated if several small post injections are done instead of a few larger ones.

SCR system control is becoming more important, as system deNO$_x$ efficiency demands increase to 95%. Urea injection parameters are determined by NO$_x$ quantity in the exhaust (concentration and flow rate), temperature, and the amount of ammonia stored in the catalyst. There is normally closed-loop feedback control using an NO$_x$ sensor at the SCR exit, and in many applications, an NO$_x$ sensor is used upstream to determine inlet NO$_x$ levels.

As urea generally cannot be injected at temperatures <180°C because of evaporation and hydrolysis kinetics, it is important to properly manage ammonia storage in the catalyst for low load applications. Murata *et al*. (2008) showed that SCR efficiency at temperatures <265°C is strongly dependent on the amount of ammonia that is stored in the catalyst. They developed an algorithm that kept stored urea within control limits, resulting in improving deNO$_x$ efficiency from nominally 50–75% in the Japanese HD transient cycle with an average temperature of only 160°C.

6 SUMMARY/CONCLUSIONS

6.1 Diesel particulate filters

Filter technology is advancing to provide systems with incrementally 20–30% lower back pressure, similar or higher soot mass limit to improve DPF management, and better filtration efficiency. DPF designs can help deNO$_x$ performance through reduced thermal mass, allowing faster heat-up of the downstream deNO$_x$ catalyst or by allowing incorporation of the catalyst on the filter, allowing faster light-off with reduced system back pressure. Fundamental knowledge on ash and soot membranes will allow the trend to continue.

6.2 Lean NO$_x$ treatment

Lean deNO$_x$ control is the leading area of interest in the field of vehicular emissions for good reason—NO$_x$ and GHG regulations are tightening, and deNO$_x$ translates to "deCO$_2$" using diesel or lean gasoline strategies. Work is continuing on alternative reductant forms involving gaseous and solid reagents, as well as fuels. Urea-SCR is accomplishing deNO$_x$ efficiencies of 95% with reasonable systems and temperature ranges. SCR catalysts are evolving with improvements at both the low and HT regimes. HC-SCR approaches are also improving. New system designs for LNT + SCR (*in situ* ammonia) improve performance further, and the potential to meet the tightest NO$_x$ regulations is demonstrated. When run in novel ways, the applicable temperature range of a standard LNT can be significantly expanded (to 650°C), with modest deNO$_x$ efficiencies (80%) at high space velocities (125,000/h), and modest fuel penalties (<3%). Traditional HC-SCR (LNC) methods are getting renewed attention in commercial applications and with E85 reductant.

6.3 Diesel oxidation catalysts

Much of the new reports on DOCs concerned the interplay of precious metal formulations on HC oxidation, NO oxidation to NO$_2$, and the formation of N$_2$O. HC and CO oxidation is promoted by replacement of platinum with palladium, but NO$_2$ formation is compromised. NO$_2$ cannot form if HCs are present, as the HCs will reduce any NO$_2$

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

back to NO. HCs are also instrumental in reducing NO to N_2O, particularly at ~200–250°C if CO is not present.

6.4 Emission control system design

Most modern diesel engines will have DOC + DPF + SCR. Placement of the SCR in front or behind the DPF depends on application. If cold start emissions are important, like for LD certification requirements, the SCR is placed up front. The control strategies for the system can be complex, and is generally segregated by the DPF and the SCR. DPF control requires an understanding of passive and active regeneration regimes. Active regeneration is done by heating the filter to soot burning temperatures, the control of which is very important to avoid filter damage. SCR system control depends on proper urea injection strategies, in low load conditions, this will depend on knowing the amount of ammonia stored in the catalyst.

Communication of Electric Vehicles

Christian Rehtanz, Willi Horenkamp, and Johannes Rolink

TU Dortmund University, Dortmund, Germany

1 INTRODUCTION

The filling station system does not readily lend itself to electric vehicle (EV) charging because today's vehicle batteries have such long charging times. Instead, a new widespread charging infrastructure is needed with charging points at home, at work, and in parking garages, shopping centers, and similar locations. Not only will charging power have to be provided from the grid, but the vehicles will also have to communicate with the grid operator or energy supplier.

As described in the previous chapters, bidirectional charge management is an essential precondition for integrating large numbers of EVs into the power grid and providing ancillary services with EVs. "Bidirectional charge management" refers to two-way communications between EVs and the grid operator, energy supplier, or service center via the charging stations.

This chapter describes various ways to enable data communications between the grid operator, energy supplier, charging station, and EVs. First, though, the charging infrastructure must be efficient and fit for everyday use. The charging process must be as user-friendly as possible, especially when deployed in the mass market. Users would ideally only have to plug in the charging cable. Once the cable is connected, the charging process should automatically start and configure itself based on the battery's state of charge, user behavior, supply of electricity, and current load on the grid. Billing information would have to be securely and reliably transferred between the charging station/vehicle and the grid operator/energy supplier. In addition, value-added services could be integrated into the future communications infrastructure, such as traffic congestion forecasts, map updates for navigation systems, or the remote control of air-conditioning (AC) systems or independent car heaters.

Suitable communications structures are needed to serve the mass market. They will have to be standardized not only nationally but also internationally wherever possible. In addition, the charging infrastructure should also be built cost-effectively. It could use the kind of smart metering technology currently being tested by grid operators in pilot projects on automatic meter reading. This would allow the information technology (IT) requirements to be integrated into a future smart grid.

2 COMMUNICATIONS BETWEEN CHARGING STATION AND VEHICLE

This section describes ways to extend standardized communications processes between the charging station and the

ISBN: 978-0-470-97402-5

vehicle charge controller in order to support the integration of EVs into a smart grid. It focuses on internet protocol (IP) communications between the charging station and the vehicle using power line communications (PLC) technology.

2.1 Communications in accordance with IEC 61851

IEC 61851/SAE J1772 describes the technical requirements for connecting EVs to the electricity supply system. These standards differentiate between four charging modes:

- Mode 1: single-phase or three-phase connection, standardized plug-and-socket connections. Requires ground fault circuit interrupter (GFCI) and overcurrent protection.
- Mode 2: same as charging mode 1, but uses a control pilot between the charging station and the vehicle.
- Mode 3: uses a type-specific charging station.
- Mode 4: indirect connection, uses an external charger (DC charging).

Mode 1 is used whenever an EV is plugged into a normal power socket at home. The grid and the vehicle do not need to communicate with each other. Modes 2 and 3, by contrast, cover home-based or public charging stations with charging currents >16 A. These situations require an additional controller and, consequently, a charging station with a control unit. The control unit has three main functions: verifying that the EV is connected properly, constantly monitoring the protective earth conductor, and turning the charging socket on and off. However, it can optionally detect and set the available charging current and lock and unlock the connector. This is done via a control pilot that is integrated in the charging cable alongside the live conductors (Figure 1).

The charging station contains a 1 kHz signal generator with an adjustable duty cycle between 10% and 80%. The duty cycle (pulse-width modulation, PWM signal) communicates the charging station's maximum possible charging current to the vehicle charge controller. The PWM signal is applied across various resistors that indicate the vehicle's operating state to the charging station. When it receives the signal, the charging station can detect the operating state based on the PWM voltage as described later (Figure 1) and control the charging process accordingly:

- State A (12 V): connector not plugged in/vehicle not connected.
- State B (9 V): connector plugged in/vehicle connected, not ready for charging.
- State C (6 V): vehicle ready for charging.
- State D (3 V): vehicle ready for charging, external ventilation required.

IEC 61851 describes the exact charging sequence over the control pilot, so there is no need to detail it in this chapter.

2.2 Communications in accordance with IEC 61851 with extended transfer of parameters

IEC 61851 allows additional parameters to be transmitted before or after charging. They can include the customer/vehicle identification (ID) or the state of charge before or after charging. Parameter transmission over the control pilot is restricted during charging, however, so as not to interfere with the control pilot's protective function. The following section describes the typical process for transmitting a customer's contract number (customer ID) before charging. This requires more hardware and software (ID/PWM control unit) in the charging station and the vehicle than the standard IEC 61851 charging process

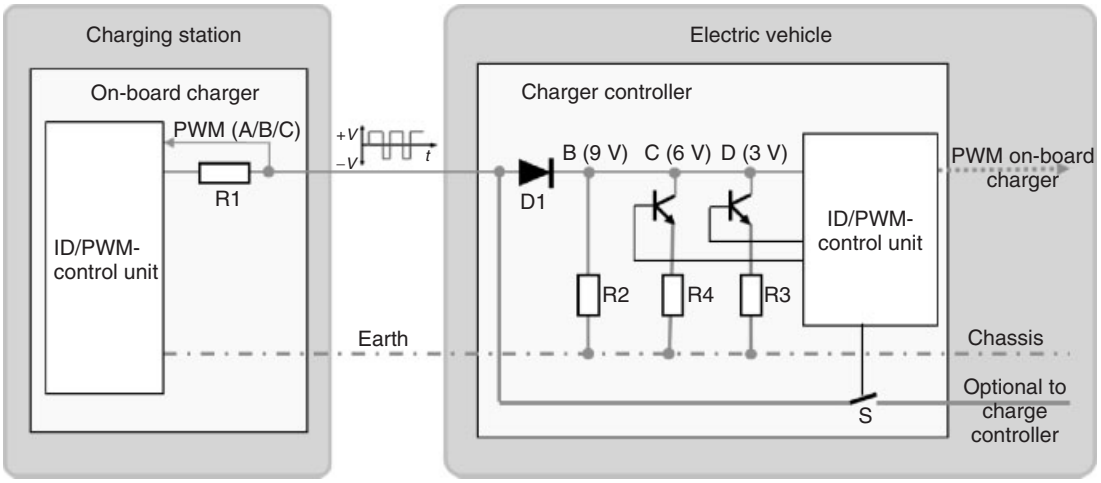

Figure 2. Block diagram of ID transmission over the control pilot.

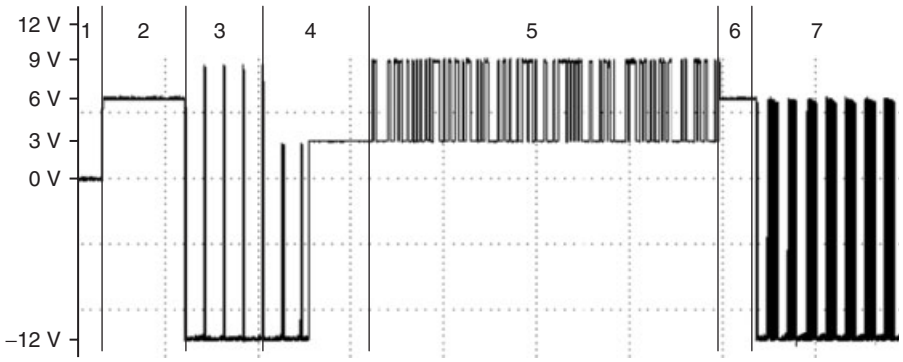

Figure 3. Waveform of an ID transmission.

(Figure 2). The customer or contract ID must either be stored in the charging station or be retrieved by the service center, grid operator, or energy supplier.

Figure 3 shows the waveform of the PWM signal during the transmission of a customer's contract number over the control pilot.

The PWM signal is not sent until the charging station detects that a vehicle is connected. This ensures that the charging station is only turned on after a vehicle has been connected. Table 1 describes the sequence of the ID transmission over the control pilot.

If the charging station does not recognize the ID as valid, the vehicle resends the ID. If another error occurs, the user has to disconnect the vehicle from the charging station and restart data communications. As the data transmissions are encrypted, both the ID module and the charging station must have the encryption key. The key is recalculated for each new ID transmission.

Table 1. Sequence of ID transmission over the control pilot.

State	Function
1	Vehicle is properly connected to the charging station, the charging station subsequently turns on PWM voltage
2	PWM signal 100/0, vehicle sends state C (6 V)
3	Charging station generates PWM duty cycle of 5/95 or 90/10, the vehicle then sends state B for 500 ms
4	Vehicle sends 500 ms state D (3 V) in response
5	Vehicle waits for PWM 100/0, then ID transmission is started (amplitude modulation of the PWM signal between 9 and 3 V)
6	ID transmission complete, vehicle sends state C PWM signal (6 V)
7	Charging station sends maximum charging current and turns on the charging voltage

If a PWM circuit is integrated in the vehicle, the PWM signal can be sent through the ID module logic (cf. Figure 2, Relay S). In this case, the ID/PWM module only identifies

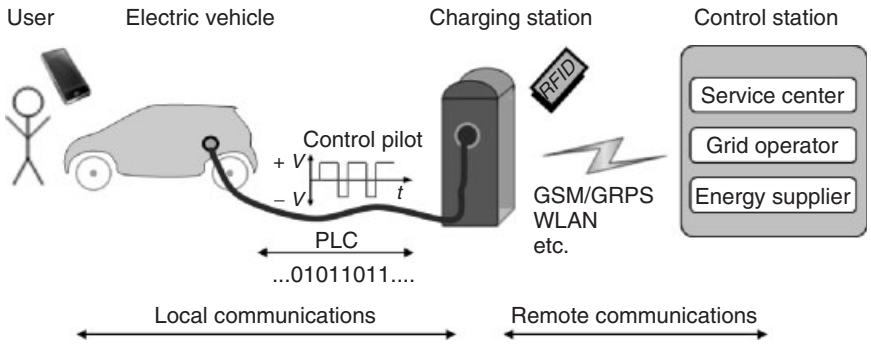

Figure 4. Stakeholders directly involved in the charging process.

the contract ID. All other communications take place in accordance with IEC 61851.

To minimize the ID module's energy consumption in battery mode, the PWM signal sent by the charging station turns the ID/PWM module on and off. This allows the ID/PWM module to run on an integrated battery without requiring a connection to the on-board power supply. The ID/PWM module can, therefore, also be used to activate the charging station for vehicles that only support low charging outputs, such as electric scooters.

2.3 Alternative communication links

Development has focused not only on the actual charging process but also on integrating value-added services such as checking the state of charge during charging. Smart charge management can ensure that the vehicle's battery is charged during periods when there is an abundance of renewable energy or when the load on the grid is low. If the charging station can communicate directly with the vehicle, it can also provide other services such as on-board internet, traffic congestion forecasts, map updates for navigation systems, or the synchronization of e-content (music, videos, and news) with the vehicle's entertainment system. Figure 4 shows communications flows between the various stakeholders during charging. There are two basic types of communications: remote and local. In remote communications, the charging station communicates with a control center belonging to the grid operator, energy supplier, or service center. The control center can then deliver additional services to the user. In local communications, the charging station communicates with the vehicle. The following section examines local communications.

Charging station solutions can be grouped into five different categories of local communications (Table 2):

1. Communications between charging station and vehicle in accordance with IEC 61851.

Table 2. Comparison of local communications categories.

Category	1	2	3	4	5
Transmission of contract information	Not possible	Yes, before and after charging	Specific to the card/person	Specific to the device/person	Specific to the vehicle
Several variable charging profiles	Possible (PWM)	Possible (PWM)	Possible (PWM)	Possible (PWM)	Possible (PLC)
Status messages during charging	Not possible	Not possible	Only via display on charging station	On site via the device	In the vehicle
Dynamic vehicle data, for example, state of charge	Not possible	Not possible	Not possible	Not possible	Possible, regular updates
Charge management in a smart grid	Not possible	Partially possible	Only possible offline	Only possible offline	Possible
Value-added services for the vehicle	Not possible	Not possible	Not possible	Not possible	Possible

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto139
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2. Communications with extended transfer of parameters in accordance with IEC 61851.
3. Charging stations with a static user interface but no data interface to the vehicle. This includes smart cards, radio frequency identifications (RFIDs), or similar solutions. User can authenticate himself or herself using the data stored on the card and then start the charging process.
4. Charging stations with an interactive user interface but no data interface to the vehicle. For example, charging stations can be operated from a display or a separate device such as a smart phone.
5. Charging stations with a bidirectional data interface to the vehicle. The data of the vehicle or vehicle owner is sent over an IP-based protocol.

In all categories except category 1, an internet platform aggregates all the information that the charging station receives about the charging process and associates it with the charging station ID. If users can access the platform (e.g., from a smart phone), they can look up status messages before or during charging, or choose from different charging profiles or tariffs.

The following section describes one approach for implementing end-to-end communications between the grid operator, energy supplier, and vehicle/customer using PLC between the charging station and the vehicle. Not only does it enable effective demand-side/charge management for the grid, but also it supports internet value-added services for the vehicle.

2.4 Power line communications

The smart charge communications (SCCs) protocol specified by RWE and Daimler is in the process of being standardized (ISO/IEC 15118; SAE J1772; RWE, Daimler, Insys Microelectronics, and Emsycon, 2010a, b). It specifies an IP communications format for providing the information needed for identification, billing, and charge management and exchanging this information between the vehicle and the charging station. All data is transferred using PLC over the phase and neutral conductors, so there is no need to integrate another communications contact in the charging cable. Communications are implemented by control/communications units integrated in the vehicle and the charging station. The units set up the PLC connection over the charging cable (Figure 5). The charging station communicates with a higher level data center over a wide area network (WAN) to verify the customer/contract data.

PLC between the vehicle and the charging station enables complete automation of the charging process, which are:

- unambiguous identification of the vehicle, vehicle owner, or vehicle operator;
- billing based on kilowatt hour, person, or vehicle;
- integration of value-added/internet services during charging, for example, managed charging;
- updating the navigation system with traffic data supplied by internet traffic services;
- internet-based remote control and/or remote monitoring of the charging process, for example, checking the state

of the battery, turning on independent car heaters/AC systems.

The specified functions provide a high degree of transparency during and after charging for vehicle operators, grid operators, and electricity suppliers.

2.4.1 *Smart charge communications protocol*

The SCCs protocol defines bidirectional communications between the vehicle and the charging station. The current communications medium is the latest version of the PLC physical layer, HomePlug1.0 Turbo, which supports a maximum bandwidth of 100 Mbps. The network layer is based on IP Version 4 or 6. To protect against potential attacks, the connection is encrypted at the transport layer using Transport Layer Security Version 1.2. At the beginning of each connection, the encryption key is exchanged using the Diffie–Hellman key exchange method (Rescorla, 1999), which offers strong security against eavesdropping. The session layer consists of the SCC session protocol, which allows a connection to be uniquely assigned to a charging session. The application layer and the presentation layer define the content and presentation of the messages. Figure 6 shows the protocol stack for the SCCs protocol.

2.4.2 *Smart message language*

The smart message language (SML) protocol was developed specifically for smart metering. The specification's current version, 1.03, is freely available on the internet (Forum network technology/network operation in the VDE, 2008b). There is also a reference implementation based on Java. SML messages can be highly compressed using byte encoding and so require very little bandwidth during transmission. Individual messages can also be streamed, so the sender and the receiver can process messages directly without needing to buffer them. This can reduce controller size and thus cut costs, especially for embedded systems, which is an important consideration in the automotive sector.

SML defines several data types such as strings, (unsigned) integers, and Booleans as well as data types specifically suited to transfer meter readings. Complex data structures can be defined and transferred as messages using a generic container. This allows the protocol to be used for EVs in addition to smart metering.

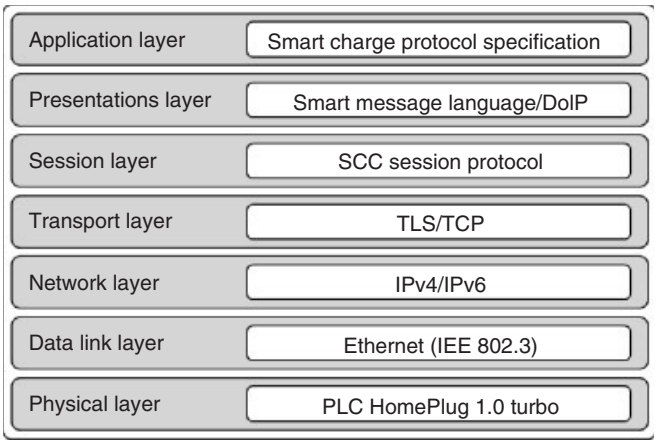

Figure 6. Protocol stack of the smart charge protocol.

2.4.3 *Alternative protocols*

Extensible markup language (XML) and/or JavaScript Object Notation (JSON) are also possible protocols. These data representation formats have the advantage of being much more common than SML, especially internationally. Moreover, XML and JSON can draw on a large pool of development tools and reference implementations. JSON offers an advantage over XML; JSON messages can also be highly compressed using byte encoding and transmitted much more efficiently. Figure 7 shows a section of the identification message in SML and XML as a comparison. As JSON represents data much like SML in terms of presentation and size, it will not be described in any further detail.

XML uses ASCII (American Standard Code for Information Interchange) encoding, which needs one byte per character. As a result, over six times, as many bytes have to be transmitted with XML (282 bytes) than SML (45 bytes). Table 3 shows the summary and evaluation of the protocols.

2.5 PLC over the control pilot

One way to transmit additional information over the control pilot during charging is by modulating the amplitude of the PWM signal (Section 2.2). However, this process should not breach the upper or lower limits of the voltage range as described in IEC 61851. To prevent this, the system can use a variable base voltage with a predetermined offset. If the voltage generated by the charging station's PWM generator is near the lower limit of the range, the circuit logic will have to ensure that only positively amplitude-modulated signals are applied to the control pilot. The opposite applies if the voltage is near the upper limit. The disadvantage of this approach is a relatively low data

rate and considerable extra effort, especially if bilateral communications are required between the vehicle and the charging station.

PLC technology can also be used. In this case, data is sent and received over the control pilot instead of a live conductor. This approach enables much higher data rates in bidirectional communications than amplitude modulation. Figure 8 (Area A) shows a PLC signal at −12 V and during a PWM pulse (Area B). The same data packet was sent and received at (A) and (B). The PWM signal edge interferes with the PLC signal. Appropriate error handling can be used to ensure that data transmissions are error-free. In this case, the question is whether the data rate reduction at time (B) is acceptable. As PLC requires the charging station to constantly transmit a 5/95 PWM signal, it may be possible to only allow PLC in the periods when the PWM signal voltage is constant. Data could then be transmitted without interference 95% of the time, or 950 μs. Additional hardware and software would, however, be needed to synchronize the PLC signal with the PWM signal.

As with the previous approach, the additional data transmissions over the control pilot should not violate the limits of the voltage range or rise and fall times of the PWM signal during charging. This can be done by configuring the control pilot circuit upstream from the charge controller or by optimizing the interface circuit for the PLC signal. Optimizing the input power of the PLC signal with respect to the maximum charging cable length will also reduce electromagnetic compatibility (EMC) disturbances.

Transmitting data over the control pilot with PLC technology offers one key benefit: the control pilot is much shorter than a live conductor and so is much less susceptible to disturbances. As a result, a PLC signal can be transmitted with much less power over a control pilot than over the grid. In addition, the PLC signal does not propagate throughout the power grid, which makes it much easier to comply with EMC limits.

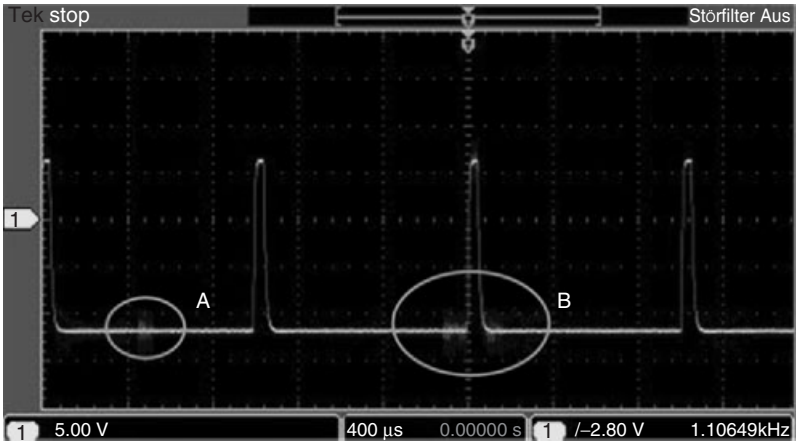

Figure 8. Sending a PLC signal over the control pilot.

3 EXAMPLE OF A CHARGE MANAGEMENT IMPLEMENTATION

Universal charge management can be implemented by combining PLC with the control pilot. The charging station controller (CSC) handles PWM signal generation, management, and PLC modem control. The meter readings are captured from the optical port of an electronic power meter and processed in the CSC. The implementation can use either the SML protocol or the D0 interface specified in DIN EN 62056-21 as the data protocol. Remote communications with the control center use a WAN connection (e.g., cellular connection).

The vehicle communications unit is designed so that the charging station can be activated even if PLC is not used. In this case, the charging station can be activated by ID communication or a service center.

3.1 The charging process

Once the charging station and the vehicle have been physically connected, the charging station applies a PWM signal across resistor R2 (state B). If the PWM controller detects a PWM signal between 10% and 80%, this means the charging station does not support PLC. The PWM signal will instead be used to specify the current for the charge controller. The charge controller tells the PWM controller to apply power across resistor R3 (state C). This starts the charging process and activates the socket in the charging station (Figure 9).

If the vehicle's PWM controller detects a 5/95 PWM signal, the charging process is managed via PLC (Figure 10). State B is indicated using R2. The charging station then instructs the vehicle to use IP communications and activates the Dynamic Host Configuration Protocol (DHCP) server. The vehicle obtains an ID address via DHCP and initiates the communication process by sending the vehicle ID to the charging station. The charging station responds with the charging point ID, among other things. This is followed by the service selection: the vehicle looks up for the available services, and the charging station responds with a list of available services and optional parameters. After selecting the service, the grid/tariff parameters for the charge are negotiated. The vehicle sends the contract ID, the energy supplier, and the estimated energy requirements. The charging station responds with the maximum charging current, the nominal voltage, and a list with tariff information linked to the preferred charge curve (for load management). Next, the vehicle sends out a message to lock the connector (line lock) followed by the initial meter reading lookup request (metering request and metering receipt). The vehicle then prompts the charging station to turn on the voltage. The charging station checks the status word sent by the vehicle and the pilot signal for state C (ready for charging), and then turns on the voltage. During charging, the vehicle constantly sends data packet requests via metering request and metering receipt messages. These include not only the meter reading but also the current tariff, the maximum permitted charging output, and the status word of the vehicle and/or the charging station. The vehicle checks the meter reading and the charge parameters and, to confirm the amount of energy charged, sends a signed copy of the parameters received.

If the maximum charging output changes because the load on the grid has changed, the charging station may prompt the vehicle to renegotiate the grid parameters (power discovery). To end the charging process, the vehicle

sends a power delivery message with the request to turn off the voltage and unlock the connector (line lock).

4 COMMUNICATIONS IN A SMART GRID

This section describes the integration of vehicles into a smart grid. It presents various approaches, from managed charging to bidirectional communications using smart metering technologies.

In future, charging infrastructure will likely consist of various charging station designs and functions:

1. Charging socket at home, charging output up to 3.7 kW single phase or 11 kW three phase, standard socket.
2. Charging at work, charging output up to 3.7 kW single phase or 11 kW three phase, possibly with energy consumption metering.
3. Parking lots and shopping centers, charging outputs >3.7 kW, DC charging stations.
4. Park and ride parking lots, low charging outputs per vehicle because of the long timeframes, with energy consumption metering.
5. Parking spaces with short vehicle-standing times, DC charging stations.

The combination of managed charging and a smart grid is ideal, especially if many vehicles are parked for long periods of time and the energy stored in the vehicle batteries is fed back into the grid. Figure 11 shows what parameters affect charge management. Charging output depends on two parameters: power supply and current grid load. However, it is also indirectly affected by the current state of the grid and the connection and disconnection conditions. Vehicle charge times, by contrast, depend on the current state of charge and the distance traveled by the vehicle operator.

The Section 4.1 describes several options in connection with smart grid applications, which are managed charging and grid and energy management.

4.1 Managed charging using the control pilot

Managed EV charging can play a significant role in load balancing—particularly in low voltage supply systems—as long as the vehicles are charged at home or work and the charging time window is long enough (Figure 12).

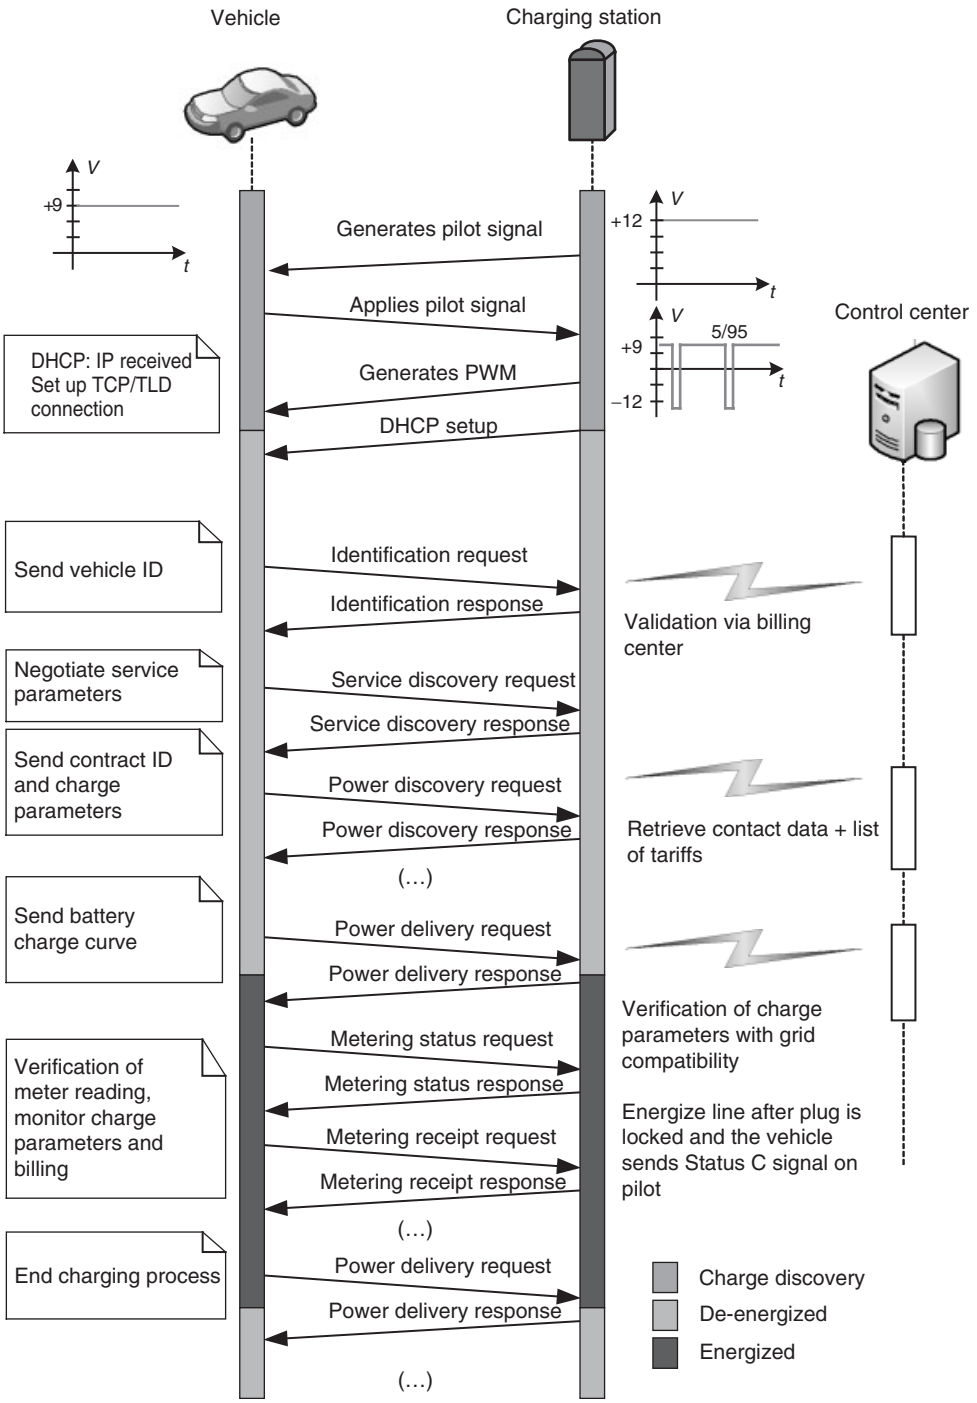

Figure 10. Smart charge communication protocol (developed by RWE and Daimler).

The shaded area shows charging time windows specified by a grid operator along with the maximum charging current.

The charging current is specified by the charging station via the pulse duty cycle (PWM signal) and processed by the charge controller in the vehicle. The PWM signal can be generated by a microcontroller (PWM generator) that can be controlled by an external signal (Figure 13).

In the simplest case, the charging process (charging time and charging current) can be controlled by a time switch. Time switches with multiple switching contacts can be used

to specify variable charging times and varying charging currents. Another possibility is to turn loads on and off with a ripple control signal. Many modern-day low voltage supply systems support the use of ripple control to turn loads on and off or to switch to certain tariffs. Ripple control signals can also set charging times and maximum charging currents for PWM signal generation. The advantage of this approach is that it does not require any additional communications structures. Once smart metering has been widely deployed, the smart meter can take over this function, possibly in connection with the multiutility communications (MUCs) controller. The charging station, grid operator, and energy supplier can communicate over PLC, wireless (global system for mobile communications, GSM and general packet radio service, GPRS), or internet (digital subscriber line, DSL) (Rehtanz, Horenkamp, and Ruthe, 2011).

4.2 Active grid and energy management with smart metering technologies

Active grid/charge management refers to the bidirectional transfer of energy between the grid and vehicle batteries. Energy stored in vehicle batteries can not only power the vehicle but also be fed back into the grid. However, this requires additional charging cycles, which can reduce battery's operating life with current technologies. Users also expect batteries to be charged by a particular time. As power flows in both directions, these charge time expectations can only be met if the vehicle charging controller and the charging station (service connection point) are configured accordingly. IT and grid requirements are even higher if EV batteries are also used to provide control power.

The universal availability of smart metering, in the medium term, will enable the integration of distributed energy generation units into a data network and active EV-based grid and energy management. Smart metering technology represents a key pillar in this strategy, particularly when it comes to smart charging of EVs.

4.2.1 *Grid and charge management with a smart metering system*

This section describes how a charging control unit can be connected to a smart metering system made by Echelon Corporation (2010a,b,c). The smart meters have to be equipped with an MEP (multipurpose expansion port) interface®. This is a serial interface that enables communications between the server and an external MEP device. Data can be exchanged bidirectionally between a central computer and the end-user device. The MEP device can also access the meter directly. Data communications between the server and the MEP device are prioritized. High priority data is transmitted as quickly as possible and immediately relayed to a control center by the meter. The MEP protocol is a vendor-specific, bidirectional single layer protocol. Messages can optionally be encrypted with 128-bit RC4 encryption to prevent unauthorized users from accessing the data. Figure 14 shows how the system has been implemented with a grid operator. It is currently being trialed to determine performance parameters such as latency time and communications reliability.

The smart meter captures billing-related data and establishes a narrow band PLC connection to the secondary

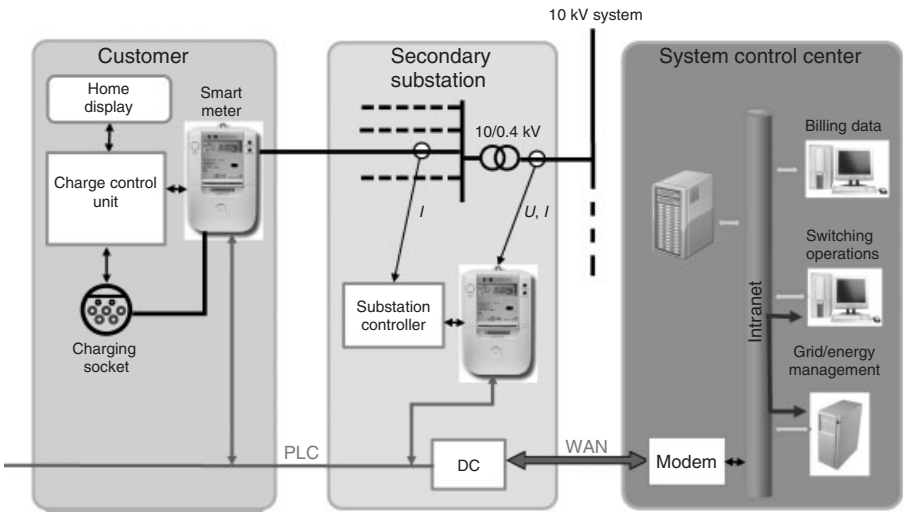

Figure 14. Charging control unit with an Echelon smart metering system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto139
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

substation. The charging control unit communicates with the meter over the MEP interface, generates the PWM signals, and verifies that the charging cable is properly connected to the vehicle. A separate serial or Ethernet port can be connected to a home display to enable the customer to control charging output based on considerations such as the current tariff or planned trip distance.

The secondary substation has a data concentrator in addition to the smart meter. The data concentrator transmits data to the control center over a WAN. No additional meters are needed to track current flowing through individual low voltage feeders. Current levels on individual feeder conductors are captured by current transformers and transmitted to the smart meter over the MEP interface by the substation controller. This allows feeder current levels in the substation to be transmitted to or retrieved by the control center in response to certain events.

The secondary substation and the control center communicate over a WAN (PLC, cellular, optical fiber, etc.). The control center can, for example, provide the customer's charging control unit with tariffs that reflect the current load on the grid or current power supply levels. Charging can then either be performed automatically or initiated manually by the customer.

4.2.2 *Grid and charge management using MUC*

MUC offers another way to use smart metering technology for grid, energy, and charge management (Forum network technology/network operation in the VDE, 2008a). One of the goals of MUC's developers was to separate the electric meter from the data collector used for communications between users (customer, grid operator, etc.). The MUC Requirements Specification V1.0 does not, however, explicitly support bidirectional communications for managing EV charging. Figure 15 shows how MUC can be used in more advanced applications.

Unlike the previous approach (Section 4.2.1), in which all communications went through a control center, this approach enables local and central grids and energy management systems to communicate directly with one another. Energy and grid management is optimized at four levels:

1. Local, autonomous optimization of the building's energy consumption. This is done in conjunction with local controllable loads, such as vehicle batteries or heat pumps together with distributed generation (photovoltaics, PV, and micro combined heat and power, CHP). The actual optimization method varies depending on parameters such as the current supply of electricity and the current tariff. Customers can also set charging output as needed on home displays or similar devices.
2. Energy requirements are also coordinated at the secondary substation level in connection with grid management. If only certain secondary substations are overloaded, the load only needs to be limited on

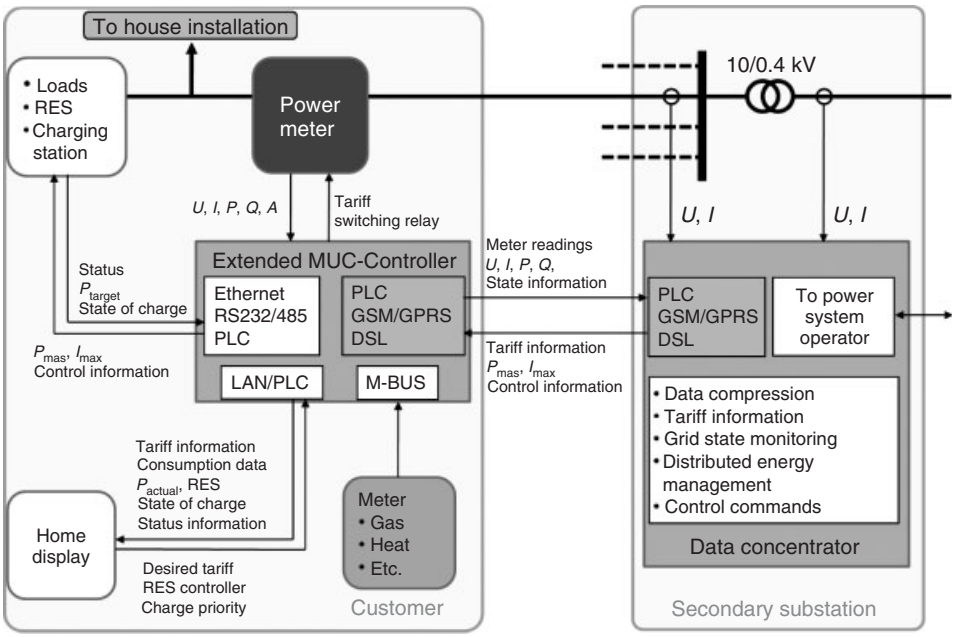

Figure 15. Grid and charge management using MUC.

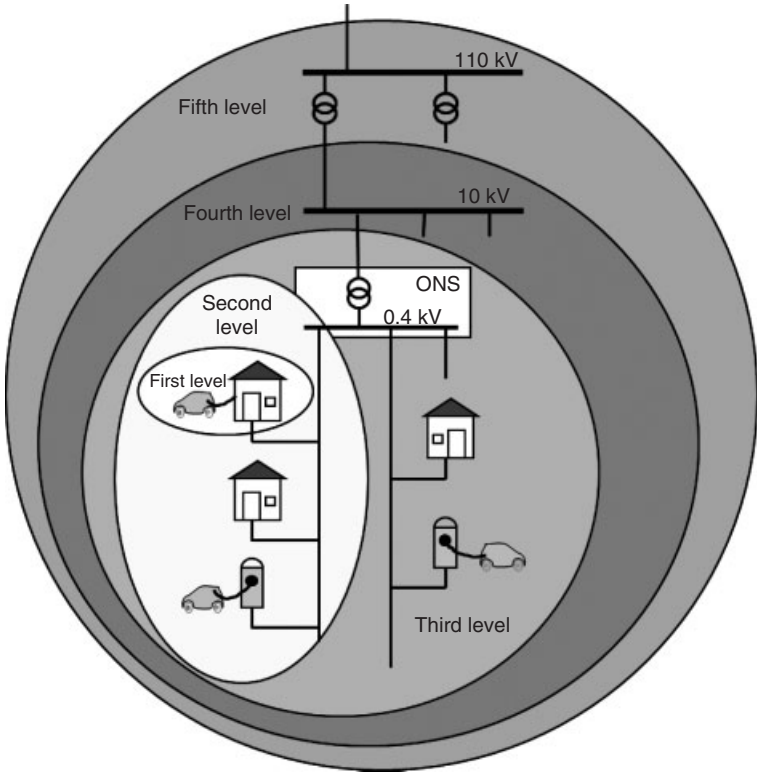

Figure 16. Energy and grid management for various voltage levels.

the overloaded line. If the load includes EVs that are being charged, a PWM control unit can limit the charging output.

3. Once the secondary distribution transformer or high voltage conductor is overloaded, the grid operator will need to be notified, so it can limit charging power or take other steps.
4. This level involves the coordination and optimization of energy and grid management for secondary substations connected to the medium voltage network.
5. Grid and energy management in connection with large power.
6. Plants such as wind farms on the transmission network.

Figure 16 shows the various levels of multilevel grid and energy management.

5 INTEGRATING DC-FAST CHARGE CHARGING STATIONS INTO THE GRID

DC fast charging stations are also being discussed. In most cases, they would be installed at public parking lots. DC charge times currently range from 20 to 30 min. Contemporary battery technologies allow fast charging of up to 80% of battery capacity.

Pros:

- The vehicle only needs a small charger.
- Fewer fast charging stations than AC charging stations.

Cons:

- Stations are only connected to vehicles during charging and then vacated for the next customer to use.
- Service point requires relatively high supply voltage.
- Charge parameters have to be adapted to the battery.
- Relatively heavy plugs and charging cables.

Figure 17 shows one way to integrate DC charging stations into a power grid. This setup only requires an AC/DC converter to the grid. PV systems can feed power directly onto an unregulated DC bus bar via a DC/DC converter. Charge parameters have to be tailored to the vehicle battery using a step-up or step-down converter, as battery voltages and battery charging characteristics will probably not be standardized in the foreseeable future.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto139
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

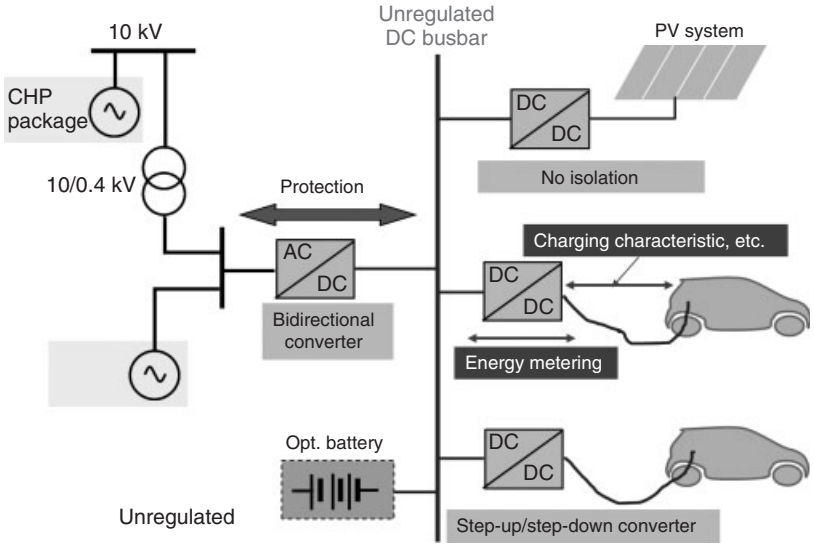

Figure 17. Integration of a DC charging station into the grid.

Stationary battery storage can optionally be integrated in the station, too.

This scenario requires bidirectional communications between the charging station and the vehicle in order to transmit the vehicle's battery charge parameters. The CAN bus is generally used for communications, but some experts have also considered using PLC technology based on IP-based communications.

6 SUMMARY

This chapter described how to extend data communications over the control pilot using standardized procedures for vehicle-to-charging station communications (IEC 61851/SAE J1772), illustrated using the transmission of a customer contract number. It then discussed alternative structures for local and remote communications between the customer, grid operator, and energy supplier. These included not only smart card/RFID solutions but also IP-based communication using PLC technology. The pros and cons of various protocols (SML/XML) were evaluated, with the focus on the SCCs protocol specified by RWE and Daimler.

The discussion touched on the use of live and control pilots to transmit data between the vehicle and the charging station using PLC technology. Several approaches to integrate EVs into the smart grid were examined. Bidirectional charge management, that is, using smart metering technologies to manage vehicle charging, was presented alongside the integration of DC charging stations into the grid.

7 OUTLOOK

A smart grid requires bidirectional communications between customers, grid operators, energy suppliers, and, possibly, service centers. Many different communications structures and approaches are currently being developed and field-tested. Researchers have begun to examine the real-world applicability of various login procedures, transmission media, and data transfer protocols. An ideal first step would be to implement managed vehicle charging. While this can theoretically be done with standardized processes and systems and existing communications structures, it would be restricted to a very small scale. Mass EV deployment would require fully automated charging that can immediately adapt to changes in electricity supply and grid conditions. Bidirectional charge management is essential in these cases, especially if EVs are used to provide ancillary services. If smart metering becomes widely adopted, the communications infrastructure built for smart metering could also be used for smart, fully automated charge management.

Ultracapacitors in Hybrid and Plug-in Electric Vehicles

Andrew Burke
University of California, Davis, CA, USA

1 INTRODUCTION

This chapter is concerned with ultracapacitors (ECCs) and their applications in electric drive vehicles in place of or in combination with batteries. The electric drive vehicles considered are battery-powered electric vehicles and hybrid vehicles (HEVs and PHEVs). The first major section of the chapter deals with ultracapacitor concepts and performance, including a description of the assembly and construction of devices and materials used in them; testing methods; and comparison of the performance of ultracapacitors and batteries. The second major section is concerned with the present and future costs of ultracapacitors, their calendar and cycle life, and a comparison of the cost and cycle life of ultracapacitors and batteries. The final section presents vehicle simulation results for electric and hybrid vehicles that incorporate ultracapacitors in the electric driveline. Special attention is given to sizing the ultracapacitor unit to minimize volume and cost and the control strategies that take advantage of the high efficiency and charge acceptance of ultracapacitors compared to batteries. Simulation results are also given for vehicles using combinations of ultracapacitors and advanced batteries having high energy density (300 Wh/kg).

The most common electrical energy storage device used in vehicles is the battery. Batteries have been the technology of choice for most applications, because they can store large amounts of energy in a relatively small volume and weight and provide suitable levels of power for many applications. Shelf and cycle life have been a problem/concern with most types of batteries, but people have learned to tolerate this shortcoming due to the lack of an alternative. In recent times, the power requirements in a number of applications have increased markedly and have exceeded the capability of batteries of standard design. This has led to the design of special high power, pulse batteries often with the sacrifice of energy density and cycle life. ECCs are being developed as an alternative to pulse batteries. To be an attractive alternative, capacitors must have much higher power and much longer shelf and cycle life than batteries. By "much" is meant at least one order of magnitude higher. ECCs have much lower energy density than batteries and their low energy density is in most cases the factor that determines the feasibility of their use in a particular high power application.

2 ULTRACAPACITOR CONCEPTS AND PERFORMANCE

2.1 Cell construction, energy storage, and materials

An ultracapacitor, often referred to as an *ECC*, is an electrical energy storage device that is constructed much like a battery (Figure 1), in that it has two electrodes immersed in an electrolyte with a separator between the electrodes. The electrodes are fabricated from a high surface area, porous material having pore diameters in the nanometer (nm) range. The surface area of the electrode materials used in an ECC is much greater than that used in battery electrodes being 500–2000 m^2/g. Charge is stored in the micropores at or near the interface between the solid electrode material and the electrolyte. The energy stored in the capacitor is given by $\frac{1}{2}\,CV^2$, where C is its capacitance (Farads) and V is the voltage between the terminals. The maximum or rated voltage of the capacitor is dependent on the characteristics of the electrolyte used in the device. The charge Q (coulombs) stored in the capacitor is given by CV. The charge and energy stored in the ECC are calculated using the same expressions as for a simple dielectric capacitor. However, calculation of the capacitance of the ECC is much more difficult as it depends on complex phenomena occurring in the micropores of the electrodes.

It is convenient to discuss the mechanisms for energy storage in ECCs in terms of double-layer and pseudocapacitance processes separately. The physics and chemistry of these processes as they apply to ECCs are explained in great detail in Conway (1999) and Béguin and Frąckowiak (2013). In the following sections, the mechanisms are discussed in terms of how they relate to the properties of the electrode materials and electrolyte.

2.1.1 Double-Layer capacitors

Energy is stored in the double-layer capacitor as charge separation in the double layer formed at the interface between the solid electrode material and the liquid electrolyte in the micropores of the electrodes (Figure 1).

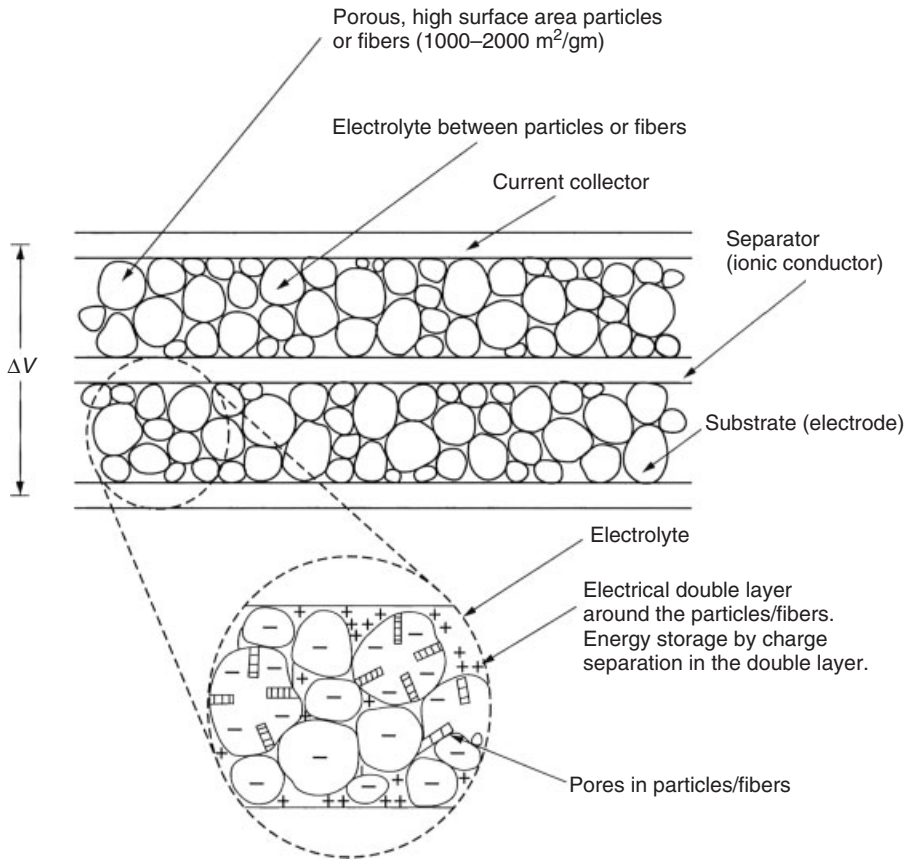

Figure 1. Schematic of an electrochemical capacitor. (Reproduced with permission from A.F. Burke, Lindel's Handbook of Batteries (Burke, 2010) © The McGraw-Hill Companies, Inc.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto140
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The ions displaced in forming the double layers in the pores are transferred between the electrodes by diffusion through the electrolyte. The capacitance is dependent primarily on the characteristics of the electrode material (surface area and pore size distribution). The specific capacitance of an electrode material can be written as

$$\frac{C}{\text{g}} = \left(\frac{F}{\text{cm}^2}\right)_{\text{act}} \times \left(\frac{\text{cm}^2}{\text{g}}\right)_{\text{act}}$$

where the surface area referred to is the active area in the pores on which the double layer is formed. In simplest terms, the capacitance per unit of active area is given by

$$\left(\frac{F}{\text{cm}^2}\right)_{\text{act}} = \left(\frac{K_{\text{eff}}}{\text{thickness of the double-layer}}\right)_{\text{eff}}$$

where K_{eff} is the dielectric constant of the electrolyte.

Determination of the effective dielectric constant K_{eff} of the electrolyte and the thickness of the double layer formed at the interface is complex and not well understood (Conway, 1999; Béguin and Frąckowiak, 2013). The thickness of the double layer is very small (a fraction of a nanometer in liquid electrolytes) resulting in a high value for the specific capacitance of 15–30 μF/cm^2. For a surface area of 1000 m^2/g, this would result in a potential capacitance of 150–300 F/g of electrode material. As indicated in Table 1, the measured specific capacitances of the carbon materials being used in ultracapacitors are much less than these high values, being in the range of 75–175 F/g for aqueous electrolytes and 40–120 F/g for organic electrolytes. This is the case, because for most carbon materials, a relatively large fraction of the surface area is in pores that cannot be accessed by the ions in the electrolyte. This is especially true for the organic electrolytes for which the size of ions is much larger than in an aqueous electrolyte. Porous carbons for use in ultracapacitors should have a large fraction of their pore volume in pores of diameter 1–5 nm. Materials with small pores (<1 nm) show a large falloff in capacitance at discharge currents >100 mA/cm^2 especially using organic electrolytes. Materials with the larger pore diameters can be discharged at current densities of >500 mA/cm^2 with a minimal decrease in capacitance.

Table 1. Specific capacitance for various electrode materials.

Material	Density (g/cm^3)	Electrolyte	F/g	F/cm^3
Carbon cloth	0.35	KOH	200	70
		Organic	100	35
Activated carbon	0.7	KOH	160	112
		Organic	100	70
Aerogel carbon	0.6	KOH	140	84
Particulate carbon from SiC	0.7	KOH	175	122
		Organic	100	70
Particulate carbon from TiC	0.5	KOH	220	110
		Organic	120	60
Advanced graphitic carbon	0.7	Organic	180	126
Anhydrous RuO_2	2.7	Sulfuric acid	150	405
Hydrous RuO_2	2.0	Sulfuric acid	650	1300
Doped conducting polymer	0.7	Organic	450	315

The cell voltage of the ultracapacitor is dependent on the electrolyte used. For aqueous electrolytes, the cell voltage is about 1 V and for organic electrolytes, the cell voltage is 2.5–3.5 V depending on the carbon being used.

2.1.2 *Electrochemical capacitors utilizing pseudo-capacitance*

For an ideal double-layer capacitor, the charge is transferred into the double layer and there are no Faradaic reactions among the solid material, the ions, and the electrolyte. In that case, the capacitance (dQ/dV) is a constant and independent of voltage. For devices that utilize pseudo-capacitance, most of the charge is transferred at the surface or in the bulk near the surface of the solid electrode material. Hence, in this case, the interaction between the solid material and the ions/electrolyte involves Faradaic reactions that in most instances can be described as charge transfer reactions. The charge transferred in these reactions is voltage dependent resulting in the pseudo-capacitance ($C = dQ/dV$) also being voltage dependent. Three types of electrochemical processes have been utilized in the development of ultracapacitors using pseudo-capacitance. These are (i) surface adsorption of ions from the electrolyte, (ii) redox reactions involving ions from the electrolyte (Long, 2008), and (iii) the doping and undoping of an active conducting polymer material in the electrode (Chandrasekhar, 1999). The first two processes are primarily surface mechanisms and are hence dependent on the surface area of the electrode material. The third process involving the conducting polymer material is more of a bulk process and the specific capacitance of the material is much less dependent on its surface area although relatively high surface area with micropores is required to distribute the ions to and from the electrodes in a cell. In all cases, the electrodes must have high electronic conductivity to distribute and collect the electron current. An understanding of the charge transfer mechanism can be inferred from $C(V)$, which is often determined using cyclic voltammetry (Barsoukov and Macdonald, 2005).

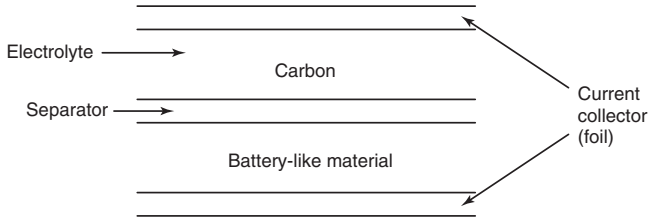

Figure 2. Schematic of a hybrid electrochemical capacitor.

For assessing the characteristics of devices, it is convenient to use the average capacitance (C_{av}) calculated from

$$C_{av} = \frac{Q_{tot}}{V_{tot}}$$

where the Q_{tot} and V_{tot} are the total charge and voltage change for a charge or discharge of the electrode. This permits a determination of the specific capacitance (C_{av}/g) of the material for the electrolyte of interest. As shown in Table 1, the specific capacitance of pseudo-capacitance materials is much higher than that of carbon materials. It is thus expected that the energy density of devices developed using the pseudo-capacitance materials will be higher.

2.1.3 Hybrid capacitors

ECCs can be fabricated with one electrode being of a double-layer (carbon) material and the other electrode being of a battery-like material (Figure 2). Such devices are often referred to as *hybrid capacitors*. Some of the hybrid capacitors developed to date have used metal oxides (e.g.,, lead or nickel oxide) as the battery-like material in the positive electrode and an aqueous electrolyte. Others have used graphite, lithium doped graphite, or lithium titanate oxide in the negative electrode and an organic electrolyte. The energy density of these devices can be significantly higher than that for double-layer capacitors (Table 2), but as shown in Figure 3b, their charge/discharge characteristics (V vs Q) can be very nonideal (nonlinear). Hybrid capacitors can also be assembled using two non-similar mixed metal oxides or doped conducting polymer materials (Chandrasekhar, 1999).

2.2 Characterization of ultracapacitor cells

The characterization of the performance of ultracapacitors requires testing of devices over a wide range of test conditions. The test procedures for evaluating ultracapacitors are discussed in detail in Burke and Miller (2010) and FreedomCar (2004). The device characteristics to be determined from the tests are summarized in Table 3. The testing includes constant current, constant power, and pulsed discharges of the devices. The capacitance and resistance of the devices are determined from constant current discharges and the energy density from the constant power tests. The resistance for both charge and discharge pulses are determined from the pulse tests. A typical set of test data for a carbon/carbon double-layer ultracapacitor device is given in Table 4.

Many commercially available and advanced prototype devices have been tested at the University of California, Davis (Burke and Miller, 2009; Burke, 2009). A summary of the test results are given in Table 5. All the devices (except those designated HC) use carbon in both electrodes. The energy densities vary in a relatively narrow range

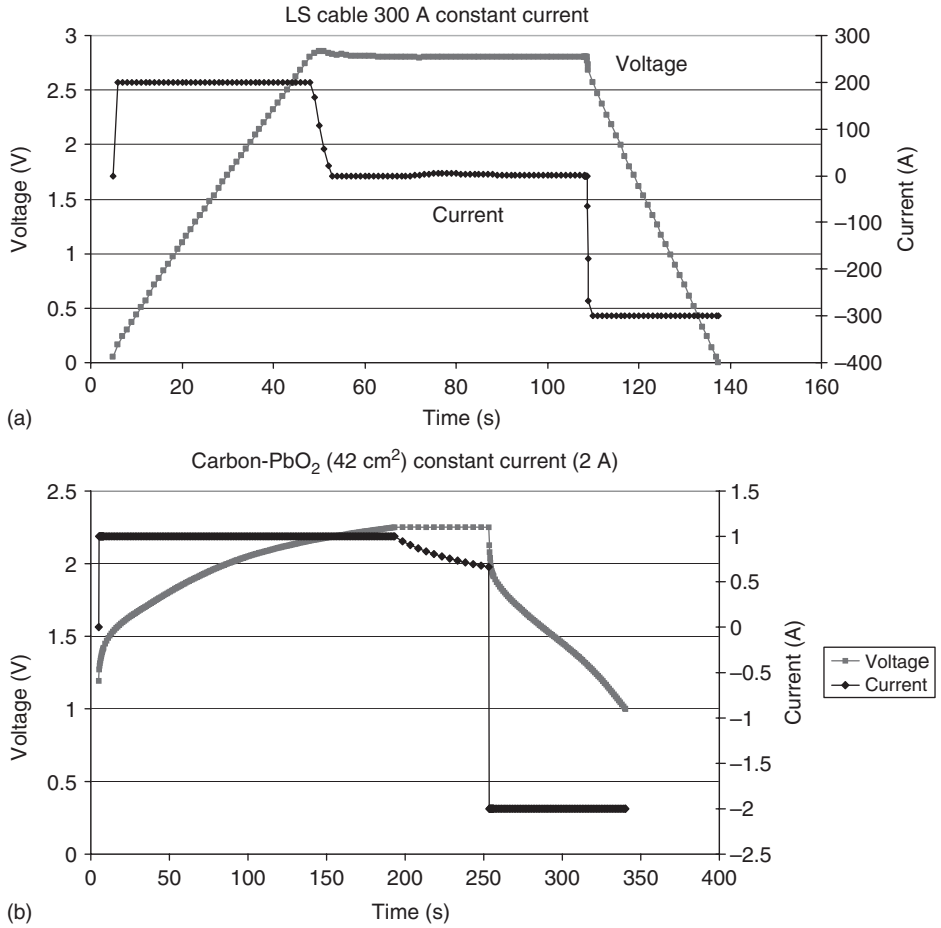

Figure 3. (a) Voltage versus current trace for a double-layer capacitor (C/C). (b) Voltage versus current trace for a hybrid capacitor (C/PbO_2).

(4–6 Wh/kg), but the power capabilities vary over a much larger range (900–10000 W/kg for 95% efficient pulses). Hence, there is much greater uncertainty concerning the power capability of a device than its energy density. As result, it is advisable to test a particular device to determine its power capability before using it in a vehicle design.

Hybrid devices (HC) have a higher energy density than the carbon/carbon devices and are in an early stage of development Figure 3 (Burke, Kershaw, and Miller, 2003; Long, 2008; Ruch, Kotz, and Wokaun, 2009; Naoi *et al*., 2012). The energy densities of the hybrid devices vary between 8 and 30 Wh/kg. In general, the power capabilities $(W/k)_{95\%}$ of the hybrid devices are lower than that of the carbon/carbon devices, which would make it difficult to take full advantage of their increased energy density in some vehicle applications. It seems likely that further development of the hybrid devices will result in improved power capability. Future development of the lithium doped graphite and lithium titanate oxide/carbon devices at cell voltages up to 3.8 V could result in energy densities in the 30–40 Wh/kg.

2.3 Characterization of ultracapacitor modules and packs

The ultracapacitor pack in vehicle applications will consist of many cells in series (80–200) in order to meet the relatively high voltage (200–400 V) of the electric driveline. It is likely that the cells will packaged in modules having a voltage of 16–125 V. The electrical characteristics (*C* and *R*) of the modules follow directly from those of the cells. However, the weight and volume of the module will be significantly greater than the sum of the weights and volumes of the cells (see Table 6 for a 48 V module). The weight and volume packaging factors are likely to be in the range of 0.6 and 0.5, respectively, when the thermal and cell management functions are included in the modules (Burke, 2010). However, the energy storage and power capability

[a] weight of device — 57 gm as tested.

of the modules can be calculated from the characteristics of the cells with confidence. Large ultracapacitor packs have been developed for bus and train applications storing up to 5 kWh (Hooks, 2011); therefore, developing packs storing 50–150 Wh for automobile applications should not be difficult.

2.4 Comparisons of the power capabilities of ultracapacitors and batteries

There has been considerable discussion in the literature (Chu and Braatz, 2002; Burke and Miller, 2011; Burke, 2007) comparing the power capability of lithium-ion batteries and ultracapacitors. The conclusions vary from statements that lithium batteries have power capability equal to that of ultracapacitors to statements that ultracapacitors have an order of magnitude higher power capability than lithium batteries. The pulse power capabilities of ultracapacitors and batteries can be calculated from the following expressions which are derived in Burke and Miller (2011):

Ultracapacitors

$$P = \frac{9}{16}\ (1 - \text{Eff})\ \frac{V_{\text{rated}}{}^2}{R}$$

where the pulse is at $V = 3/4 V_{\text{rated}}$

Eff is the pulse efficiency, $\text{Eff} = 1 - (IR/V_{\text{pulse}})$

Batteries

$$P = \text{Eff}\ (1 - \text{Eff})\ \frac{V_{\text{oc}}{}^2}{R}$$

where Eff is the pulse efficiency, $\text{Eff} = V_{\text{pulse}}/V_{\text{oc}}$

Table 5. Summary of ultracapacitor device characteristics (Burke and Miller, 2009; Burke, 2009).

In the case of the ultracapacitors, a significant fraction of the energy stored in the device can be in the pulse; for the battery, only a small fraction of the energy is in the pulse.

Detailed comparisons of the power capability of ultracapacitors and batteries taken from Burke and Miller (2011) are shown in Table 7. As indicated in the table, neither of the extreme statements concerning the relative power capabilities of ultracapacitors and batteries is valid in general and comparisons should be made between specific devices for specific applications. Comparisons are often made based on the matched impedance power of the two types of devices. These comparisons indicate that most ultracapacitors have a power capability (W/kg) of 3–6 times that of lithium batteries. However, for vehicle applications, the matched impedance power is not appropriate and should not be the basis for comparison.

For charge sustaining HEV applications, a good basis of comparison is the W/kg at 95% efficiency at the SOC at which the devices will be used in the vehicle. On this basis, there are lithium batteries with the same power capability as some carbon/carbon ultracapacitors, but there are some ultracapacitors with power capability 4–8 times that of the highest power lithium batteries presently available for vehicle applications. In other words, it is not possible to make general statements that are applicable to all devices of either type. The issue is further complicated when one notes that the density of the lithium batteries is about twice that of carbon/carbon ultracapacitors (2.2 g/cm^3 for the batteries and 1.2 g/cm^3 for the ultracapacitors). Hence, on a volume basis W/L at 95% efficiency, the differences between the batteries and ultracapacitors are often quite small. Hence, for HEVs, batteries alone and ultracapacitors alone can be an option with the decision being based on cycle life and cost in addition to relative power capability (Burke and Miller, 2010; Burke, Miller, and Van Gelder, 2007).

For plug-in hybrid and battery electric vehicle applications, the maximum useable power density from the lithium-ion battery can be higher than in an HEV because the peak power of the driveline is used less frequently and

consequently charge/discharge efficiently is less important. For example, a pulse power efficiency of 80% is probably sufficient and most of the lithium batteries have a power capability of >1000 W/kg, 2200 W/L for that efficiency. In addition, the battery is larger (heavier) in these vehicles, and as a result, the power density requirement is less demanding. For PHEVs and EVs, the best application of ultracapacitors is likely to be in combination with batteries designed for high energy density, long cycle life, and low cost. In those cases, as discussed in a later section of the article, the ultracapacitors greatly reduce the peak currents and dynamic stress on the batteries and thus extend their cycle life.

3 ULTRACAPACITOR COST AND LIFE

3.1 Present and future costs

Reducing the present high cost/price of ultracapacitors is a key issue in achieving high market penetration in the future especially of midsize and large devices. There are many applications for which ultracapacitors are presently precluded or even seriously considered because they remain too expensive even though their selling price has decreased significantly in recent years. The cost of manufacture of any product is closely tied to production volume with the cost decreasing rapidly with increased volume up to relatively high production rates. Sales of capacitors in the many millions of units per year are necessary to reduce the unit costs to levels at which the large markets are likely to develop. Semi-automated production facilities presently exist at a number of companies for ultracapacitors of all sizes. In fact, production capabilities exceed sales volumes for most devices and that is the reason the price of devices has decreased markedly in recent years. It is common to speak of the price of devices in terms of cents per Farad (cents/F) or $/Wh stored. It is easier to interpret the price information on the cents/F basis as it does not concern the cell voltage or what fraction of energy stored can be used in a particular application. For example, for a 10 F device, if the price is quoted as 10 cents/F, the device cost would be $1. Similarly, a 2500 F device would cost $25 at 1 cent/F.

The cost to manufacture a carbon/carbon device depends on the material and production costs. At the present time, material costs are high. The cost of carbon suitable for use in ultracapacitors can be as high as $100/kg with the average price being in the $30–$50/kg range. The cost of the electrolyte solvent is also high in the range of $5–10 per liter for both propylene carbonate and acetonitrile. The ionic salts that dissociate in the solvent into the positive and negative ions that move into and out of the double layer in the microporous carbon to store the energy are also expensive being $50–$100/kg. As the analysis of ultracapacitors is straightforward, material costs can be calculated (Burke, Kershaw, and Miller, 2003; Burke, 2010) with good accuracy. The result of a typical costing exercise is shown in Table 8. Note the strong dependency of the cents/F and $/Wh unit costs for the device on the unit material costs. Presently, the price of ultracapacitors is high because both the material and the manufacturing costs are high. With more automated production and reduced material costs, it is anticipated that the price of ECCs in high volume can be in the range of 1–2 cents/F for small devices and 0.25–0.5 cents/F for large devices such as those needed for vehicle applications.

Ultracapacitors cannot compete with batteries in terms of $/Wh, but they can compete in terms of $/kW and $/unit to satisfy a particular vehicle application. Both energy storage technologies must provide the same power and cycle life and sufficient energy (Wh) for the application. The weight of the battery is usually set by the system power requirement and cycle life and not by the minimum energy storage requirement. Satisfying only the minimum energy storage requirement would result in a much smaller, lighter battery than is needed to meet the other requirements. On the other hand, the weight of the ultracapacitor is determined by the minimum energy storage requirement. The power and cycle life requirements are usually easily satisfied. Hence, the ultracapacitor unit can be a more optimum solution for many applications

1000	100	0.84	1.12	11947	23.9

[a] Battery 100 Wh/kg, 1000 W/kg;
[b] capacitor 5 Wh/kg, 2500 W/kg.

and its weight can be less than that of the battery even though its energy density is less than one-tenth that of the battery.

Consider the example of a charge sustaining hybrid such as the Prius. If the energy stored in the capacitor unit is 125 Wh and that in the battery unit is 1500 Wh, the unit costs of the capacitors and battery are related by

$$\left(\frac{\$}{\text{Wh}}\right)_{\text{cap}} = 0.012\left(\frac{\$}{\text{kWh}}\right)_{\text{bat}}$$

The corresponding capacitor costs in terms of cents/F and $/kWh are given by

$$\left(\frac{\text{cents}}{\text{F}}\right)_{\text{cap}} = 0.125 \times 10^{-3} \times \left(\frac{\$}{\text{kWh}}\right)_{\text{bat}} \times V^2{}_{\text{cap}}$$

$$\left(\frac{\$}{\text{kWh}}\right)_{\text{cap}} = 9.6 \times 10^4 \left(\frac{\text{cents}}{\text{F}}\right)_{\text{cap}} / V_{\text{r}}{}^2$$

Table 9 shows the ultracapacitor costs calculated using the above equations for a range of battery costs ($/kWh).

The results indicate that for the charge sustaining hybrid application, ultracapacitor costs of 0.3–1.0 cent/F will be competitive with lithium battery costs of $300–$1000/kWh. Present (2010) ultracapacitor costs are about 1 cent/F and future costs are expected to be significantly lower. Note also that the $/kW costs of the capacitor units are about one-fourth those of the batteries.

3.2 Factors affecting calendar and cycle life

One of the advantages of ultracapacitors relative to batteries is their long cycle life, which may be as long as one million (10^6) deep discharge cycles for cells at room temperature and less than rated cell voltage. The calendar life or the time over which the cycling takes place is also highly dependent on cell voltage and temperature. In most life testing of ultracapacitors, it is assumed that cycling (even dynamic cycling at high rates) is not the principal cause of degradation and the life testing is done with the devices held at constant voltage and temperature for long periods of time (Miller, Butler, and Goltser, 2006; Miller and Butler, 2006). These are often referred to as *float* tests. Analysis of ultracapacitor life (years) for these conditions is considered in this section.

Unfortunately, estimating the lifetime (years) of a pack of capacitor cells in a particular application is much more complicated than simply testing cells at room temperature. One primary reason for this difficulty is that in most applications (vehicles in particular), many cells are connected in series to attain the required system voltage. In addition, the temperature varies across the pack even with cooling and the cells spend some time at voltages approaching their maximum rated voltage even with cell balancing circuitry. These factors significantly reduce the pack lifetime from that expected based on single cell testing.

The estimation of cell and pack lifetime is considered in detail analytically in Miller, Butler, and Goltser (2006); Miller and Butler (2006). The analysis is based on the assumption that the cell lifetime statistics can be expressed in terms of a Weibull distribution.

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\alpha}\right)^{\beta}\right], F = \text{the fraction of cell failures}$$

where t = time, α = characteristic life, and β = shape factor

Cell lifetime testing must be done using test conditions that result in the same aging mechanisms (cell failures) as in the application of interest. For ultracapacitors, the testing could be either cycling at specified power levels, voltage ranges, and temperatures or float at specified temperatures and voltages. As noted previously, for vehicle applications, it is likely that lifetime data (Miller, Butler, and Goltser, 2006; Miller and Butler, 2006) from the cell float tests are the most appropriate. Such data can be curve fit to obtain values for α and β for the single cells. Both parameters can vary over wide ranges depending on the cell voltage and temperature of the tests. In the case of activated carbon cells, the characteristic time (α) can vary from > 10,000 h at room temperature and 2.3 V to < 500 h at 60°C and 2.8 V. The shape factor (β) can vary between about 4 for room temperature and 2.3 V to about 15 for 60°C and 2.8 V. A low value of β means that cell failures occur gradually over time, whereas a high value of β indicates that nearly all the cells fail together over a short period of time.

The lifetime characteristics of a pack of ultracapacitors depend strongly on the number (M) of the cells connected in series. Assuming the pack failure statistics are also Weibull, the shape factor of the pack is the same as that of the cells

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto140
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in the pack, and each cell failure is independent of other cells, the pack failure function F_{pack} can be written as

$$F_{pack} = \left\{1 - \exp\left[-\left(\frac{t}{\alpha_c}\right)^{\beta}\right]\right\}^{M}$$

$$F_{pack} = M\left(\frac{t}{\alpha_c}\right)^{\beta} \text{ for a small fraction of failed cells}$$

If we express F_{pack} as

$$F_{pack} = 1 - \exp\left[-\left(\frac{t}{\alpha_p}\right)^{\beta}\right], \alpha_p$$

$$= \text{characteristic time of the pack}$$

One finds

$$\alpha_p = \frac{\alpha_c}{M^{1/\beta}}$$

Hence, the characteristic time of the pack is much less than that of the cells. For example, for a pack with 200 cells in series, the characteristic time is reduced by a factor of 3.76 if β is 4 and by a factor of 1.42 if β is 15. For most packs, the characteristic time would likely be 1/3 to 1/2 that of the cells.

The next factor to consider in the estimation of the lifetime of a pack is the effect of nonuniformities in voltage and temperature of the cells. Even with cooling and cell balancing circuits, there will be nonuniformities in the pack. This will especially be the case for applications in which the pack provides dynamic, high power as in vehicles. The effects of nonuniformities are considered analytically in Miller, Butler, and Goltser (2006); Miller and Butler (2006). The analysis is based on the following assumptions concerning the effect of temperature and voltage on the failure of single cells: in the case of temperature, a 10°C decrease in temperature doubles the cell life; in the case of voltage, a 0.1 V decrease in voltage doubles the cell life. The analytical forms of the temperature (T °K) and voltage (V) effects on the cell characteristic life time τ are

$$\tau = a\ \exp\left(\frac{b}{T}\right), \frac{\tau}{\tau_0} = \exp\left[-6155\ \left(\frac{T - T_0}{{T_0}^2}\right)\right]$$

$$\tau = A\ \exp(-BV), \frac{\tau}{\tau_0} = \exp[-6.93(V - V_0)]$$

These relationships project a reduction in characteristic time of about $1/\sqrt{2}$ for variations of 0.5°C in temperature and 0.05 V in voltage. This corresponds to a maximum temperature difference of 10°C with an average difference of 5°C for an average temperature of 30°C. Similarly, the maximum voltage difference is 0.1 V with an average difference of 0.05 V.

Applying these relationships to a particular application requires detailed knowledge of the application and specification of the cell operating conditions and tolerable cell failure rates. Consider the following example of a capacitor pack in a hybrid passenger car. The pack failure requirements are 98% reliability for 5 years and 80% reliability for 12 years. The corresponding mileage values are 50,000 and 120,000 miles. If the average speed is 25 mph, the operating time requirements are 2000 and 4800 h for the pack. The pack voltage is 300 V with 125 cells in series. The question to be answered is what cell characteristic time (hours) is needed for the cells if the shape factor of their failure distribution is 10. For a Weibull distribution, the relationship among the proportion (P) of failures, time to failure (t_F), and distribution characteristics (α_{pack}, β) is

$$t_F = \alpha_{pack}[-\ln(1 - P)]^{1/\beta}$$

For the times to failure (2000 and 4800 h), the corresponding α_{pack} values are 2954 and 5581 h. Taking the maximum value of 5581, the cell α_c is 9041 h for $M = 125$ and $\beta = 10$. Assuming the average temperature variation is 5°C and the average voltage variation is 0.05 V/cell in the pack from the base values of 30°C and 2.5 V/cell, the cell statistics on a float type test at the base values of temperature and voltage should exhibit a α_c of 18082 and a $\beta = 10$. This corresponds to a float time of about 2 years at 30°C and 2.5 V/cell.

Next consider cell balancing to reduce cell-to-cell variations in voltage (Burke and Miller, 2005; Jung, 2002). The capacitor pack will consist of many cells (20–200) connected in series. If each of the cells were identical having exactly the same capacitance, series resistance, and parallel resistance, the voltage of all the cells would be same at all times and be equal to the average cell voltage (V/number of cells). There would not be concern that the voltage of some of the cells would exceed at times a maximum specified by the cell manufacturer. This maximum voltage is often referred as the working (continuous) voltage limit of the cell and experiencing voltages above that limit for times longer than a few seconds can significantly reduce the life time of the cell. This is not a safety issue per se as the cells can withstand considerably higher voltages without the pressure relief vent being activated. Limiting the maximum cell voltage in the pack is then primarily an issue of cell life, the maximum useable energy of the unit, and system efficiency in high power cycling. Controlling the variability of the voltage between the cells is referred to as cell balancing. The objectives of the cell balancing are primarily to minimize the differences

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto140
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in the cell voltages and to restrict the maximum voltage of any cell to less than the continuous working voltage. It is desirable that the cell balancing system provide a means of monitoring the voltages of the cells in order to ensure that it is maintaining the voltages in the proper range. Monitoring the voltage and temperature of the cells is needed to ensure long cycle life (10 years or longer).

The complexity of the balancing approach required and the absolute need for cell balancing depends to a large extent on the magnitude of the differences of the characteristics of the cells (capacitance and resistances) (Kotz *et al*., 2007). These differences are dependent on the uniformity of the materials used in the cells and quality control in the manufacture of the cells. The specification of ±15% or 20% variability for capacitance and resistance often seen on spec sheets is grossly greater than tolerable for high voltage strings of ultracapacitors. Experience (available test data (Rafik *et al*., 2006)) has shown that the variability in the capacitance can be quite small for relatively large cells with the variation between the maximum and minimum being 1–1.5% and the standard deviation of the distribution of the capacitance being about 0.5%. Experience has shown larger percentage variations in the resistance of low resistance (fraction of a mΩ) cells, but the standard deviation is close to the accuracy of the resistance measurement (0.01 mΩ). Experience for the self-discharge voltage of a batch of cells after 1 h has shown a maximum variation of <5 mV and a standard deviation of <1 mV (Rafik *et al*., 2006). Hence, present manufacturing practice for ultracapacitor cells seems to be reasonably good and improving so that the prospects for use of relatively simple approaches to cell balancing seem to be better than was the case several years ago.

Relating the variability in cell characteristics to the cell-to-cell voltage variability for complex discharge/charge cycles is not a simple matter (Miller, Butler, and Goltser, 2006; Miller and Butler, 2006). Of primary interest are the magnitude of the maximum cell variations, especially those in the direction of high voltage, and whether the magnitudes of the voltage variations tend to increase for long-term cycling without cell balancing and/or equalization. Available data (Kotz *et al*., 2007) seem to indicate that the magnitude of cell-to-cell voltage variations do not increase with cycling, but rather seem to stabilize even without cell balancing. This seems to be the case even as the cells age.

Variations in cell capacitance will lead to the largest cell-to-cell voltage variations, but those variations will not tend to increase with extended charge/discharge cycling because the capacitance differences have self-compensating effects for charge and discharge pulses. Variations in cell resistances (series and parallel) lead to smaller cell-to-cell voltage variations, and those variations also tend to be self-compensating for cycles that consist of sequential charge/discharge pulses. Variations in self-discharge (parallel resistance) can lead to significant differences in cell voltages during extended rest periods without cell balancing. This could lead to large differences in cell voltages when charge/discharge cycling is resumed. For vehicle applications involving charge/discharge cycling, the effect of variations in cell characteristics on cell-to-cell voltage variations can be determined from cycle testing of the capacitor unit for relatively short times. The cycling time should be long enough to reach thermal equilibrium.

All the ultracapacitor manufacturers are developing cell balancing circuits for use with long series strings of their cells. Modules are supplied with balancing circuits installed. There are a number of approaches to cell balancing. These approaches (Figure 4) range in complexity from placing a simple resistor in parallel with each cell to connecting an active circuit with a power source to charge or discharge each cell separately as needed to reduce cell-to-cell voltage variations. The simple approaches are likely to be adequate for most applications if the variability of the cell characteristics is relatively small (a few percent); the more complex approaches will be needed if the cell variability is relatively large due to poor manufacturing quality control, large temperature gradients in the capacitor pack, and/or the effects of aging. It should be recognized at the outset that the currents involved with the balancing of the cells are small being 1A or less so that they are in most applications much smaller than the pulse currents in/out of the cells. This means that during the high power portions of the charge/discharge, the effects of the cell balancing on the cell voltages is small. Cell balancing has the largest effect during periods of low power demand or rest. Hence, regardless of the cell balancing approach used, the variability of the characteristics of the cells must be relatively small if cell-to-cell voltage variations are to be tolerable.

As discussed previously, the life time (time to significant failures) in the cells decreases by about a factor of 2 for a 0.1 V increase in cell voltage if that voltage increase is experienced in a significant fraction of the time. In general, the life time of the cells decreases markedly as the maximum set voltage for the cell balancing circuit is increased beyond about 2.4 V/cell for the present (2009) cell technology. Hence, it appears that the cell voltages should be limited to an average of about 2.4 V/cell with a cell-to-cell variation of < 0.1 V/cell. This should result in long float and cycle life times of >500,000 cycles and 15,000 h on float at near room temperature (25–30°C).

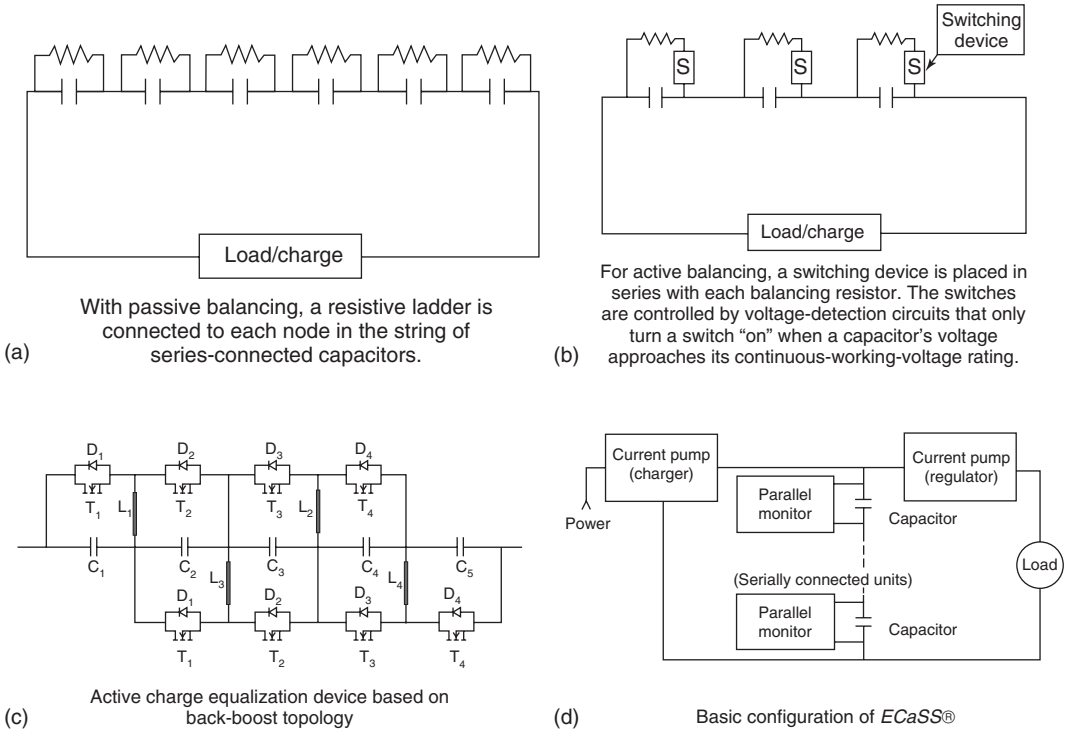

Figure 4. Cell balancing circuits.

3.3 Comparisons of the characteristics of ultracapacitors and batteries

In general terms, ultracapacitors have long life and high first cost and batteries have lower first cost and shorter life. Neither ultracapacitors nor lithium batteries are mature technologies in terms of high volume production and consequently cost. It is expected that the cost of both ultracapacitors and lithium batteries will decrease significantly in the next 5–10 years if they are used in mass marketed vehicles. Comparisons of the cost and life characteristics of ultracapacitors and lithium batteries for HEVs and PHEVs are shown in Table 10. The physical and performance characteristics of both technologies reflect their status in 2010. In the case of the ultracapacitors, the values shown in Table 10 follow from the results

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto140
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

shown in Tables 4, 8, and 9. In the case of the lithium batteries, the values in Table 10 are based on the results in Nelson (2008); Nelson, Santini, and Barnes (2009). The performance of ultracapacitors in HEVs is discussed in the next section. The information in Table 10 indicate that first costs of carbon/carbon ultracapacitors and lithium batteries for use in HEVs will be the same if the cost of the capacitors is 0.5 cents/F and the cost of the batteries is $600/kWh.

However, it is likely that the cycle life of the ultracapacitors would exceed significantly that of the lithium batteries. The weight and size of the lithium batteries would be smaller than that of the carbon/carbon ultracapacitors, but that of hybrid capacitors could be smaller than the lithium batteries if their cycle life proves to be sufficiently long for the HEV application. Information for lithium batteries for use in a PHEV are also given in Table 10. The batteries in a PHEV must have good cycle life for both deep cycle discharges and shallow cycling in the HEV mode of operation of the vehicle. The PHEV lithium batteries will be more expensive than the HEV batteries simply because they store much more energy. Ultracapacitors will have application in PHEVs only if the lithium or other advanced batteries do not have sufficient power capability to meet the power (kW) and energy storage (kWh) requirements of the vehicle without oversizing the battery. The application of ultracapacitors with advanced batteries having high energy density (>300 Wh/kg) is discussed in the next section.

4 SIMULATIONS OF HYBRID (HEV) AND PLUG-IN (PHEV) VEHICLES USING ULTRACAPACITORS

4.1 Powertrains and control strategies using ultracapacitors

Schematics of hybrid powertrains using ultracapacitors are shown in Figure 5. When the ultracapacitor is used alone, there is no need for special electronics if the motor electronics can handle the increased voltage swing of the ultracapacitors. When the ultracapacitors are used in combination with batteries, there is a need for additional electronics to control the power from either the battery or the ultracapacitors.

When ultracapacitors are used alone as the energy storage unit in a charge sustaining hybrid (HEV), the objective of the control strategy is to permit the engine to operate near its maximum efficiency. As shown in Burke, Zhao, and Van Gelder (2009); Burke (2007); Burke and Zhao (2010), this can be done by operating the hybrid vehicle on the electric drive when the power demand is less than the power capability of the electric motor; when the vehicle power demand exceeds that of the electric motor, the engine is operated to meet the vehicle power demand plus to provide the power to recharge the ultracapacitor unit. In this mode, the electric machine is used as a generator and the engine operating point is selected along its maximum efficiency line (torque vs RPM). The recharging power is limited by the power of the electric machine because

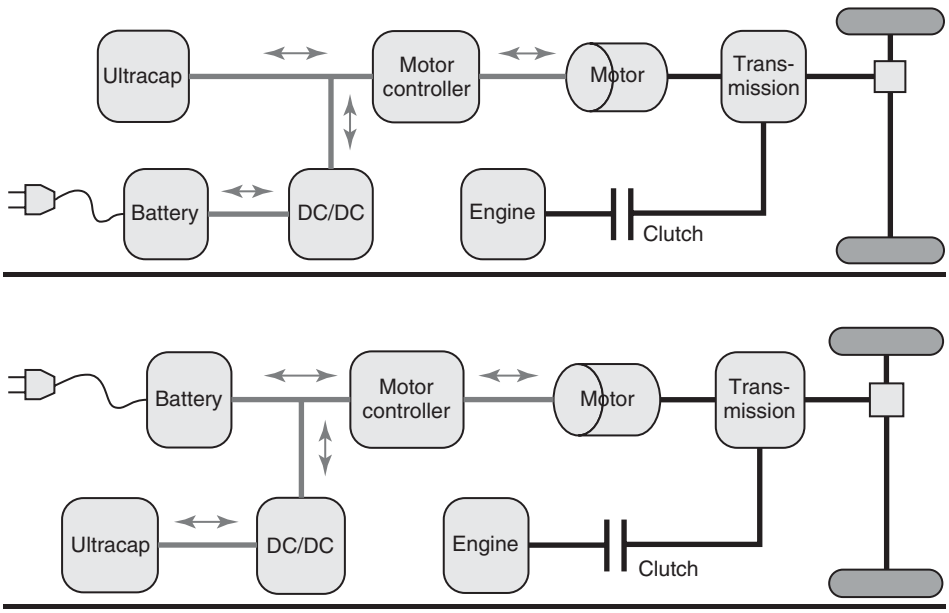

Figure 5. Schematics of powertrains using ultracapacitors and batteries.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto140
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ultracapacitors can have pulse power efficiency >95% for W/kg values of over 2000 W/kg (Table 7). This control strategy is referred to as the *sawtooth strategy* because a plot of the ultracapacitor SOC has the form of a saw blade. This strategy can result in frequent on–off operation of the engine and its effect on vehicle drivability needs to be evaluated in actual vehicles.

4.2 Hybrid-Electric vehicles (HEV) using ultracapacitors in place of batteries

Simulations of midsize passenger cars using the ultracapacitors in micro-hybrid and charge sustaining hybrid (HEV) powertrain designs are discussed in this section. The simulations were performed using the Advisor vehicle simulation program modified with special routines at UC Davis (Burke, Zhao, and Van Gelder, 2009; Burke, 2007; Burke and Zhao, 2010). All the powertrains were in the same vehicle having the following characteristics: test weight 1660 kg, $C_d = 0.3$, $A_F = 2.25\,m^2$, and RRCF = 0.009. The engine map used in the simulations was for a Ford Focus 2L, four-cylinder engine. The rated engine power was 120 kW for the conventional internal combustion engine (ICE) vehicle and the micro-hybrid and 110 kW for the charge sustaining hybrids. All the hybrids use the single-shaft arrangement similar to the Honda Civic hybrid. The same electric motor map was used for all the vehicle simulations. The simulation results are summarized in Table 11 for a conventional ICE vehicle and each of the hybrid designs. It is clear from Table 11 that large improvements in fuel usage are predicted for all the hybrid powertrains using ultracapacitors for energy storage. The simulation results will be discussed separately for each hybrid design.

The results for the micro-hybrids indicate that significant improvements (10–25%) in fuel economy can be achieved using a small electric motor (4 kW) and small ultracapacitor units (5–10 kg of cells). In the micro-hybrid designs, the rated engine power used was the same as that in the conventional ICE vehicle in order that the performance of the hybrid vehicle when the energy storage in the ultracapacitors is depleted would be the same as the conventional vehicle. The ultracapacitors were used to improve fuel economy with only a minimal change in vehicle acceleration performance.

The fuel economy simulation results for charge sustaining hybrids are also shown in Table 11 using carbon/carbon and hybrid ultracapacitors. The fuel economy improvements range from 70% on the Federal Urban Drive Schedule (FUDS) to 22% on the US06 driving cycles. The prime advantage of the high power electric driveline and the larger energy storage possible with the hybrid ultracapacitors is that the larger fuel economy improvements can be sustained over a wide range of driving conditions. All the advanced ultracapacitors have high power capability and thus can be used with the higher power electric motor used in charge sustaining hybrid drivelines. The hybrid ultracapacitor technologies give the vehicle designer more latitude in powertrain design and in the selection of the control strategies for on/off operation of the engine even if the improvement in

Table 11. Mild-HEV and micro-HEV advisor simulation results using carbon/carbon and hybrid ultracapacitors and a midsize passenger car (weight = 1660 kg, $C_d = 0.3$, $A_f = 2.2\,m^2$, fr = 0.009).

fuel economy is about the same as using carbon/carbon devices.

The control strategy used was the "sawtooth" strategy discussed in the previous paragraph. As shown in Figure 6, this results in a large improvement in average engine efficiency from 19% in the ICE vehicle to 30% in the hybrid vehicle even though the electric motor had a peak power of only 6 kW.

Additional computer simulations were made for higher motor power (up to 12 kW) and larger ultracapacitor energy storage (up to 50 Wh). It was found that the improvements in fuel economy were only marginally greater. Using a motor power of 3 kW reduced the fuel economy improvement on the FUDS by more than 50%.

4.3 Plug-in hybrid-electric vehicles (PHEV) using ultracapacitors in combination with atteries

For PHEVs, ultracapacitors could be used in combination with batteries if the power capability of the batteries was insufficient to meet the power requirement of the vehicle. Powertrains of this type are shown in Figure 5. The control strategy in the charge depleting mode is to limit the power from the battery to the average power needed by the vehicle with the ultracapacitor providing the additional power during vehicle accelerations (Miller, Bohn, and Deshpande, 2008; Dixon, Nakashima, and Ortuzar, 2010). The ultracapacitors also accept all the energy recovered during regenerative braking. If engine operation is needed, the "sawtooth" strategy is used with the ultracapacitors being recharged using engine power. In the charge sustaining mode of operation of the PHEV, the electric drive is operated using only the ultracapacitors like that previously described for the HEV.

A detailed study of plug-in hybrids using advanced batteries is presented in Burke and Miller (2010); Burke (2011). The characteristics of the advanced batteries used in the simulations are given in Table 12.

The battery and ultracapacitor units used in the simulations are given in Table 13. Simulations were performed with the batteries alone and in combination with the ultracapacitors. The nominal energy storage unit voltage was 240 V (approximately) in all cases with the maximum currents limited to about 300 A even in the cases of the batteries alone. In all cases, the batteries were depleted to 30% SOC from 100% SOC.

All the PHEV simulations were performed using the following vehicle inputs:

$C_D = 0.27$, $A_F = 2.2\ m^2$, $f_r = 0.008$, test weight = 1650 kg
Engine: Honda 1.3L, iVTEC engine map, scaled to 90 kW
Electric motor: Honda hybrid Civic AC PM 2006 efficiency map, scaled to 70 kW
DC/DC inverter: constant efficiency 0.96
Transmission: 5-speed manual (3.11, 2.11, 1.55, 1.0, 0.71, FD = 3.95), automatically shifted in the model

4.3.1 PHEV fuel and electricity use characteristics

The simulation results are summarized in Tables 14 and 15 showing results for the charge depleting and charge sustaining modes of the PHEV.

With the batteries in combination with the ultracapacitors, the PHEVs were able to operate in the all-electric mode until the battery SOC = 30% on the FUDS and HW highway driving cycles. In all cases for the US06 driving cycle, the vehicle had blended operation (engine and electric drive both needed) in the charge depleting mode. The use of the ultracapacitors with the batteries permits all-electric operation of the vehicle over a wide range of driving conditions with higher Wh/mi for all the driving cycles. Hence, in the charge depleting mode, the fuel economy (mpg) is higher by 50–100% using the ultracapacitors for all the batteries. The fuel economy in the charge sustaining mode is also higher for all the driving cycles using the ultracapacitors. The acceleration times of the vehicle were lower using the ultracapacitors than for the batteries alone. With the ultracapacitors, the acceleration times were 2.7 s for 0–30 mph and 6.9 s for 0–60 mph. For the batteries alone, the acceleration times varied somewhat with the battery used ranging from 2.9–3.2 s for 0–30 mph and 8.6–9.8 s for 0–60 mph. Hence, in all respects, vehicle performance was improved using the ultracapacitors for all the batteries studied.

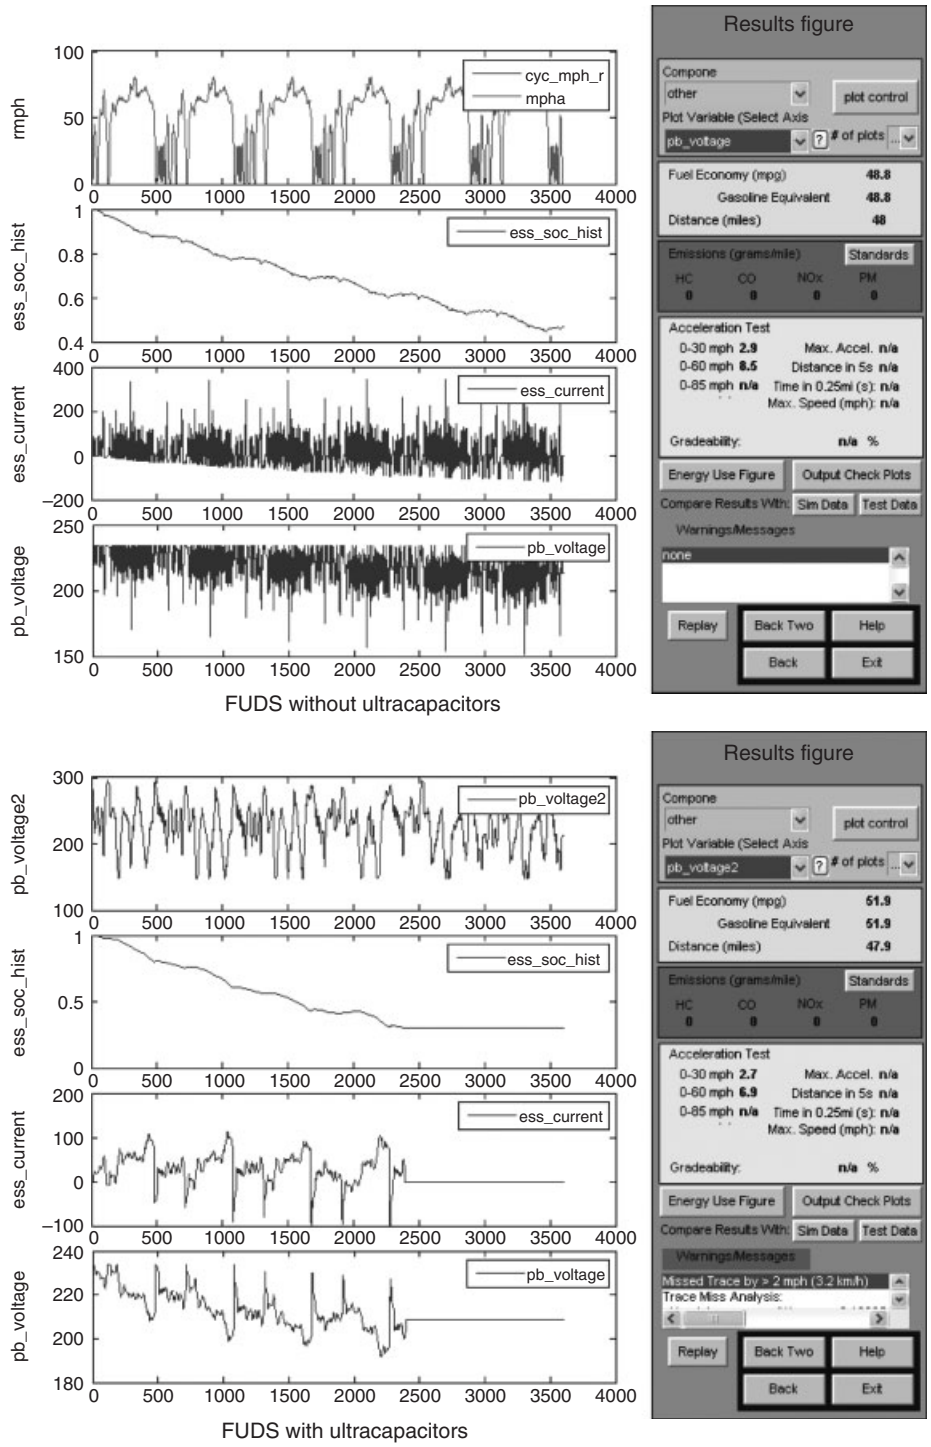

Figure 8. The silicone carbon lithium battery on the US06 with and without ultracapacitors.

the ultracapacitors are evident in the figures. The batteries provide the average current and the ultracapacitors meet the current fluctuations. The peak currents from the batteries are lower by a factor of 2–3 using the ultracapacitors. The minimum voltages of the batteries are significantly higher using the capacitors, and the voltage dynamics (fluctuations) are dramatically reduced. Hence, the stress on the battery and resultant heating are much reduced. The simulation results in Figures 7 and 8 also show that the ultracapacitors are utilized over a wide voltage range,

indicating that a large fraction of their usable energy storage (100 Wh) is being used to load level the batteries. This is only possible using a DC/DC converter between the battery and the DC bus.

The simulation results also indicate that using ultracapacitors, batteries with a wide range of power characteristics can be used in PHEVs and also EVs without sacrificing vehicle performance and subjecting the batteries to high stress and resultant shorter cycle life. This could be especially important in the future as high energy density batteries such as zinc-air and possibly lithium-air are developed. It is likely that these battery types will not have commensurate increases in useable power density, and without ultracapacitors, the battery unit in PHEVs and EVs would be sized by the maximum power requirement (kW) rather than the range (mi)/energy requirement (kWh). This would significantly increase weight, volume, and the cost of the battery unit. It is also unlikely that the air electrode will have charge acceptance capability and thus regenerative braking performance approaching that of ultracapacitors or even lithium-ion batteries. This is another advantage of the use of ultracapacitors with the air-electrode batteries.

5 SUMMARY AND CONCLUSIONS

In this chapter, ultracapacitor concepts and performance are reviewed. Test data are presented for carbon/carbon and hybrid ultracapacitors based on testing at the University of California, Davis. It was found that carbon/carbon devices are commercially available with energy densities of 4.5–5 Wh/kg and power densities of 1–2 kW/kg with a pulse efficiency of 95%. Hybrid ultracapacitors using carbon, graphite, and metal oxides were also tested. The hybrid devices had energy densities between 12 and 30 Wh/kg and power densities of 1–3 kW/kg. Comparisons of the power densities of ultracapacitors and lithium batteries indicated that the best ultracapacitors had power densities a factor of 2–3 higher than the high power batteries, but there are some batteries with higher power capability than the lower power capacitors. For use in hybrid vehicles, high power density is very important for ultracapacitors.

The cycle life and cost of ultracapacitors were also considered. It was found that the life (hours) characteristics could be expressed as a Weibull distribution and that the life of an ultracapacitor pack is dependent on the cell life characteristics, voltage and temperature variations, and the number of devices in series. A cost analysis indicated that the material costs depended primarily on the cost of carbon and that a cell cost of about 0.5 cents/F cell or less seemed likely for volume production of ultracapacitors. This could make ultracapacitors cost competitive with high power lithium batteries for HEV applications.

The application of ultracapacitors in hybrid-electric vehicles is considered in detail utilizing vehicle simulation results. The use of ultracapacitors alone is analyzed for micro-hybrids and mild/full charge sustaining hybrids and in combination with high energy density batteries for plug-in hybrids. It was found that ultracapacitors could be used in place of batteries in the charge sustaining hybrids, resulting in fuel economy improvements of 25–50% even for relatively small electric drive systems of 6–10 kW. The ultracapacitor units only stored 50–100 Wh of useable energy and their efficiency was high being 95–98%.

Vehicle simulations were also performed for plug-in hybrid vehicles that used ultracapacitors combined with advanced, high energy density batteries. The batteries had energy densities of 200–400 Wh/kg, but only moderate power capability of 300–1000 W/kg for 90% efficient pulses. The simulation results indicated that the advanced batteries combined with ultracapacitors could provide all-electric operation on the FUDS and Federal Highway cycles in the charge depleting mode and excellent fuel economy in the charge sustaining mode. Vehicle operation with the advanced batteries without the ultracapacitors required blended operation on all driving cycles. Comparisons of the current/voltage/power profiles of the batteries with and without the ultracapacitors indicated that the peak currents and thus the stress on the batteries were reduced by about a factor of three using the ultracapacitors. This reduction could lead to a large increase in battery cycle life.

Thermodynamic Analysis

Jeffrey D. Naber, Jaclyn E. Johnson, and Charles H. Margraves

Michigan Technological University, Houghton, MI, USA

1 INTRODUCTION

In this chapter, we will layout and summarize the thermodynamic fundamentals for analysis of internal combustion (IC) engines including the constitutive relations, thermochemistry, and first and second law analysis. Many excellent texts on the subject exist for both outlining the fundamentals of thermodynamics with applications (e.g., Van Wylen and Sonntag, 1986; Wark, 1988; Myers, 2007) and IC engines analysis through thermodynamics (Taylor, 1985a, 1985b; Obert, 1973; Heywood, 1988). This chapter provides a concise summary with a consistent framework for analysis and introduction of advanced topics in the remaining chapters.

First, a brief discussion on units is presented. Most analysis and published work is now done in SI units (s, m, kgmol, kg, N, W, K/°C); however, there is a persistence of English units (s, ft, lbmol, lbm, lbf, hp, °R/°F) in application of IC engines, and centimeter–gram–second (CGS) units (s, cm, gmol, g, dyne, erg or cal, K) in application of chemistry and kinetics. Even in application of SI units, there is a need to rationalize and thoroughly check units. A mechanism as applied by Myers (2007) is used and illustrated in this example for determination of power (P) from torque (T) and engine speed (N) (which can be defined in terms of angular speed ω) for an engine producing 350 ft-lbf of torque at 3500 rpm. Power is the product of rotational speed and torque, as given by

$$\begin{aligned} P &= \omega \cdot T \\ &= 2\pi \cdot N \cdot T \\ &= \frac{3500\,\text{rev}}{\text{min}} \left| \frac{350\ \text{ft-lbf}}{-} \right\| \frac{2\pi\,\text{rad}}{\text{rev}} \left| \frac{1\ \text{min}}{60\,\text{s}} \right| \frac{0.3048\,\text{m}}{1\,\text{ft}} \\ &\quad \left| \frac{1\,\text{N}}{0.2248\,\text{lbf}} \right| \frac{1\,\text{kW s}}{1000\,\text{N m}} \\ &= 174\ \text{kW} \end{aligned} \tag{1}$$

In this formulation, the engineering values for the parameters are first evaluated with units written in a ratiometric form and separated by single vertical lines (|). This is followed by the application of the necessary conversion factors (e.g., 1 min = 60 s) written as ratios (1 min/60 s = 1). A double line (||) separates the applied parameters in the equation and conversion factors. In this formulation, cancellation of units is easily analyzed and checked. In addition to the standard conversion factors, those for rotational position are important for a number of engine characteristic factors including engine speed, torque and work, as outlined here for a four-stroke engine:

$$1\ \text{rev} = 360^\circ\ \text{crank angle} = 2\pi\ \text{rad}$$

$$1\ \text{cycle} = 2\ \text{rev} = 720^\circ\ \text{crank angle} = 4\pi\ \text{rad}$$

ISBN: 978-0-470-97402-5

Additionally, care is required in the use of the mole, which is confusing for those having initially studied chemistry using a gram-mole (gmol and often just given as mol) and then thermodynamics where kilogram mole (kgmol) is often used.[1] The mole equivalencies are given as

$$1\ \text{kgmol} = 1000\ \text{gmol} = 2.2\ \text{lbmol}$$

with the corresponding changes in Avogadro's constant that defines the number of elementary entities or constituent number of particles (CNP) per mole of a substance

$$\begin{aligned} &6.02214 \times 10^{23}\ \text{CNP/gmol} \\ &= 6.023 \times 10^{26}\ \text{CNP/kgmol} \\ &= 2.732 \times 10^{26}\ \text{CNP/lbmol} \end{aligned}$$

1.1 Constitutive relationships

For thermodynamic analysis and simulation, one must develop an equation set that comprises an accurate constitutive relationship between the knowns and unknowns to provide a closed solution to the problem. These can be set up to solve for state-to-state transitions as in ideal cycle analysis or to solve for the continuous or discrete time-varying dynamics of the problem. The primary equations used in the area of IC engines for this purpose are as follows:

- equations of state (EOSs) including mixture rules
- intrinsic property relationships between T, P, v, u, h, s, g, and so on
- conservation of mass
- conservation of atomic elements (O, N, C, H, etc.)
- species molar balances
- conservation of linear and angular momentum
- conservation of energy
- entropy/availability/exergy
- rate and flux relationships for flow, mass transfer, heat transfer, and kinetics.

The conservation equations may be closed (e.g., fixed mass) or open and include rate terms for the fluxes of mass, momentum, and energy along with generation and consumption/destruction terms. Development of a constitutive set of relations requires first the definition of an appropriate control volume or control mass and the related control surface. The remainder of this section covers the primary equations above.

1.1.1 Equation of state

EOSs provide a means to represent pressure, volume, and temperature relationships of different fluids, with varying levels of complexity depending upon the desired accuracy of the representation. These range from the simplified ideal gas law to relationships with numerous parameters to improve the accuracy of fluid property representation with a trade-off of increased computational demand (Martin, 1979). EOSs are represented either in the standard absolute pressure (P), molar volume (ratio of volume to mole) ($\overline{v}$), and absolute temperature (T) form, or through the use of compressibility Z, which is defined as $Z = P\overline{v}/R_u T$, where R_u is the universal gas constant (8.3145 kJ/kgmol K).

The simplest EOS is the ideal gas EOS, which will be discussed in the next section. Complexity increases with two-constant EOS including the Redlich–Kwong EOS, which is valid at higher pressures, and the Van Der Waals EOS, which considers that gas molecules occupy a finite volume and that there are attractive forces between molecules (Moran and Shapiro, 2008). Under simplifying assumptions, these EOSs reduce to the standard ideal gas law. Further EOSs exist such as the Beattie–Bridgeman EOS, which includes five constants determined based on curve fitting to experimental data of pressure, volume, and temperature, and the eight-constant Benedict–Webb–Rubin EOS valid for light hydrocarbons (Moran and Shapiro, 2008). Additional EOSs exist, with different applicability, complexity, and number of constants, including cubic EOSs, and other modified EOSs (Martin, 1979; Slavinskaya, Zizin, and Aigner, 2010; Wei and Sadus, 2000).

1.1.1.1 Ideal gas. Much of the analysis in IC engines is based upon the evaluation of the working gas, which can be assumed for many problems with minimal error as a perfect or ideal gas and with a compressibility of 1. This approximation is typically valid for combustion as these systems are usually at high temperatures and low densities (Turns, 2000). Under these perfect gas conditions, the relationship between pressure, temperature, and volume is defined as the *ideal gas law* (Equation 2):

$$\begin{aligned} PV &= NR_u T \\ P &= cR_u T \\ PV &= mRT \\ Pv &= RT \\ P &= \rho RT \end{aligned} \tag{2}$$

where V is volume, N is moles of the gas, c is the molar concentration[2], m is mass of the gas, R is the gas constant

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

for the specific gas, v is the specific volume (ratio of volume to mass), and ρ is density. The universal and specific gas constants are related by

$$R \equiv \frac{R_u}{M} \tag{3}$$

where M is the molecular weight[3] of the gas (e.g., 28.01 kg/kgmol for N_2). As an example, the molar concentration and density of air ($M_{air} = 28.97$ kg/kgmol) at standard conditions ($P = 101.325$ kPa, $T = 25^\circ C = 298.15$ K) is

$$\begin{aligned} c &= \frac{P}{R_u T} = \frac{101.325\ \text{kPa}}{-} \left| \frac{\text{kgmol K}}{8.3145\ \text{kJ}} \right| \frac{-}{298.15\ \text{K}} \\ &\quad \left\| \frac{1000\ \text{N}}{\text{kPa m}^2} \right| \frac{1\ \text{kJ}}{1000\ \text{N m}} \\ &= 0.0409\ \frac{\text{kgmol}}{\text{m}^3} = 0.0409\ \frac{\text{kgmol}}{\text{m}^3} \\ &\left\| \frac{6.023 \times 10^{26}\ \text{molecules}}{\text{kgmol}} = 2.46 \times 10^{25}\ \frac{\text{molecules}}{\text{m}^3} \right. \\ \rho &= c \cdot M = \frac{0.0409\ \text{kgmol}}{\text{m}^3} \left| \frac{28.97\ \text{kg}}{\text{kgmol}} \right. \\ &= 1.18\ \frac{\text{kg}}{\text{m}^3} \end{aligned} \tag{4}$$

A useful form for the ideal gas EOS when developing analysis for closed systems with varying volume is in differential form

$$\frac{dP}{P} + \frac{dV}{V} = -\frac{dM}{M} + \frac{dm}{m} + \frac{dT}{T} \tag{5}$$

In a closed system where either there are no reactions or where the products and reactants have similar molecular weights, which is often a good first approximation for hydrocarbon fuels, this simplifies to

$$\frac{dT}{T} = \frac{dP}{P} + \frac{dV}{V} \tag{6}$$

In the case of mixtures of ideal gases, a partial pressure mixing rule is applied. Each constituent i in the mixture has its own partial pressure P_i, and the total mixture pressure is the sum of the partial pressures multiplied by the mole fraction for each species (which is known as *Dalton's Law*). To apply Dalton's law requires the assumption that each component can be treated as an ideal gas at the mixture temperature and volume.

Correspondingly, a partial volume rule exists, known as *Amagat's model*, which assumes that each mixture component can be treated as an ideal gas at the mixture pressure and temperature. Therefore, the partial volume V_i of the component in the overall mixture is determined based on the product of the constituent's mole fraction with the total mixture volume.

Similar relationships exist for other thermodynamic properties of ideal gases, including internal energy, enthalpy, entropy, and specific heats. Here, the representing mixture properties are the sum of the product of the constituent mole fraction with its individual constituent thermodynamic property for each of the constituents in the mixture (Moran and Shapiro, 2008). In a manner similar to the molar basis, a mass basis can be used to determine mixture properties. Note that the above discussion applies to ideal gas mixtures that are already formed. As an alternative case, ideal gases can form a mixture with gases initially being separate, which is an *irreversible* mixing process that produces entropy. This will involve an energy balance and, for simplification, typically requires assumptions of no work and no heat transfer (adiabatic process), and application of a closed system or an open system (control volume) energy balance, depending on the process.

1.1.1.2 Liquids. Under many circumstances, liquids can be treated as incompressible, meaning their density is constant, thereby simplifying the analysis. One exception, however, is for high pressure injection systems where compressibility of the fuel is important and should be considered.

Liquid fluid compressibility is characterized by the bulk modulus of elasticity E, which defines for the given fluid how easily a unit volume of fluid (or density) can be changed when the working pressure is changed (Munson *et al*., 2009), that is,

$$E = -\frac{dP}{dV/V} = \frac{dP}{d\rho/\rho} \tag{7}$$

An increase in pressure will yield a volume reduction, and therefore E is always positive. A large bulk modulus means a large pressure change is needed to yield a small volume change, and is representative of an essentially incompressible fluid.

An understanding of fluid compressibility also comes into consideration for the speed of sound, an intensive property (intensive properties are scale-invariant, meaning independent of system size or amount of material) defined based on the medium through which sound (pressure pulse) is moving. The speed of sound defines the velocity at which small disturbances propagate through the fluid. The speed of sound c is defined as

$$c = \sqrt{\frac{dp}{d\rho}} = \sqrt{\frac{E}{\rho}} \tag{8}$$

1.1.1.3 Real fluids.

1.1.1.3.1 Applicability. Under the high pressures that occur in engines and injection, there is sometimes a need to consider real fluids and their behavior. Real fluids remove the assumptions of incompressible flow (constant density) and inviscid flow (viscosity is zero, friction effects are negligible), which are applied to ideal fluids.

1.1.1.3.2 General compressibility. Compressibility is a dimensionless ratio of the product of pressure and volume to the product of the ideal gas constant and temperature. For a compressibility of 1, the ideal gas law is valid. As the compressibility deviates from unity, different EOSs or corrections are needed to define species pressure, volume, and temperature data. To understand conditions for which compressibility may approach 1, critical pressure and temperature can be considered. The critical pressure (P_c) is the maximum pressure at which the liquid and vapor phases can simultaneously exist, with the critical temperature (T_c) being the maximum temperature at which the liquid and vapor phases can simultaneously exist. When the pressure of a substance is small in comparison to the critical pressure, or temperature is large relative to the critical temperature, meaning at low pressures and high temperatures compressibility is near unity and the ideal gas equation is valid (Moran and Shaprio, 2008).

Generalized compressibility charts exist for gases, which provide compressibility as a function of reduced pressures and temperatures to assist in specifying pressure–volume–temperature states for a gas (Moran and Shapiro, 2008). Reduced pressure (P_r) is the ratio of the pressure to the critical pressure of the substance, and reduced temperature (T_r) is the ratio of the temperature to the critical temperature of the substance. The generalized compressibility chart for gases provides a reasonably accurate substitute for tabulated pressure–volume–temperature data for a given substance (Moran and Shapiro, 2008). These charts are generalized, meaning they are valid for a range of gases, within reasonable accuracy.

For more exact and fluid-specific dependent relationships, EOSs are expressed as pressure–volume–temperature relationships, but also can be expressed in terms of compressibility. For example, EOSs can be cubic in compressibility, such as the Van der Waals or Redlich–Kwong EOS (Moran and Shapiro, 2008).

1.1.1.3.3 EOS example. All EOSs exhibit advantages and disadvantages in regards to applicability, complexity, and accuracy for the given fluid. Therefore, careful consideration is needed when choosing an EOS, weighing all the important parameters. These more complicated EOSs possess numerous constants, which must be analytically or experimentally determined. For example, in cubic EOSs, being cubic in compressibility, the EOS constants are determined in terms of critical properties of the fluid of interest, with the first two pressure–volume derivatives evaluated at constant temperature equaling zero when evaluated at the fluid's critical point (Martin, 1979).

Various nonideal gas EOSs exist, with one example being the Peng–Robinson cubic EOS, which is defined by Equation 9, and is relevant and used in diesel fuel modeling (Nesbitt, 2011; Desantes *et al.*, 2007).

$$
\begin{aligned}
P &= \frac{R_u T}{\overline{v} - b} - \frac{a\alpha}{\overline{v}^2 + 2b\overline{v} - b^2} \\
\alpha &= 1 + \kappa(1 - T_r^{0.5})^2 \\
\kappa &= 0.37464 + 1.54226\omega - 0.26992\omega^2 \\
a &= 0.45724\frac{R_u^2 T_c^2}{P_c} \\
b &= 0.07780\frac{R_u T_c}{P_c}
\end{aligned}
\tag{9}
$$

where a, b, and κ are EOS constants and vary depending on the species considered, α is an EOS parameter which is a function of temperature, and ω is a species-acentric factor, a species property. If the volume and temperature data are known, along with species properties (critical properties and acentric factor), the pressure of the species can be determined at these defined conditions using Equation 9. Other EOSs exist, all with different accuracies and applicability (Reid, Prausnitz, and Poling, 1987).

1.1.1.4 Intensive properties (u, h, s, g).

In addition to pressure, volume, and temperature, other properties of interest are used to define species. These properties can be classified as *extensive* or *intensive*. *Extensive* properties depend on the size, or mass, of the systems, with examples including mass, volume, energy, and others. *Intensive* properties are independent of the size of a system, with examples being specific volume, pressure, and temperature. Important thermodynamic properties include internal energy (u), enthalpy (h), entropy (s), and Gibbs free energy (g), all being intensive (independent of mass). These can also be referred to as *specific properties*, for example, specific internal energy. Some properties are related, as will be further discussed. For example, enthalpy h is the combination of internal energy (u) and the product of pressure (P) and specific volume (v). Properties denoted with a lower case letter are defined as specific properties; when written in upper case, these are extensive properties with the exceptions of pressure and temperature.

1.1.1.5 Mixture relations. Thermodynamic properties, such as those just discussed, are available for single-component species. However, fuels and other constituents are composed of several components, and therefore methods to determine mixture properties are imperative in the study of fuels and combustion as they relate to IC engine analysis. Previously discussed were mixture rules for ideal gases; however, to uphold accuracy, mixtures cannot always be treated as ideal gases and therefore alternative approaches for mixture relations are needed.

In order to apply EOSs or methods to determine thermophysical properties of mixtures, the mixture parameters must be known, such as composition, mass fraction, and mole fraction. Mixture parameters can be specified if the independent properties of the components are known. Mixture compositions can be related on a mass or molar basis using mass fractions (mass of species divided by the total mass of the mixture), or mole fractions (moles of species divided by the total number of moles in the mixture). These two fractions will each, independently, sum to 1 and can be related to each other by molecular weights. Once the composition is specified, intensive properties can be used to fully define the mixture state, with two intensive properties needed for a complete definition, such as pressure and temperature, or pressure and volume.

In order to evaluate pressure–temperature–volume properties of gas mixtures, one method is to use mole fraction relationships to evaluate coefficients for the EOS, being combination rules for constants in the EOSs (Moran and Shapiro, 2008). Another mixture relationship is *Kay's Rule*, which is a principle of corresponding states, enabling calculation of mixture critical properties such as temperature and pressure. Mixture critical properties are just the mole-fraction-weighted sum of the individual constituents (Moran and Shapiro, 2008). Additionally, there exist empirical mixing rules, such as the additive pressure and additive volume rules, which just state that the total pressure (volume) is a sum of each of the component pressures (volumes) at a given temperature and volume (pressure). The properties of pressure (volume) for each component would be independently determined from an EOS or from tabulated data (Moran and Shapiro, 2008).

1.1.1.6 Two-phase mixtures. Another set of mixture relations involves a fluid that has two phases, such as liquid and vapor phases. For a single-component liquid, a two-phase liquid–vapor mixture at equilibrium is defined as being in the *saturation state* above which both vapor and liquid phases exist. Between the saturated liquid and saturated vapor states, the liquid and vapor coexist to form a saturated mixture, which has a given percentage in the vapor phase and the remaining percentage in the liquid phase. In the state of saturation, the pressure and temperature are dependent and this dependence is a line in a pressure–temperature (P–T) diagram, as shown in Figure 1 for *n*-heptane. This line defines the saturation curve, or vapor pressures at the corresponding temperatures, effectively separating the liquid and vapor states. The last point (with regard to highest pressure and temperature) defines the critical point of the fluid (*n*-heptane, $T_c = 540.0\,\text{K}$, $P_c = 27.4\,\text{bar}$), with conditions above this being defined as supercritical.

The saturation dome separating the compressed liquid from the superheated vapor can be shown in a pressure–volume (P–v) or pressure–enthalpy (P–h) diagram with the illustration of a P–h diagram for *n*-heptane shown in Figure 2. As P and T are dependent in the saturated state (Figure 1), a second independent intrinsic property must be used to define the state. The quality (x) is thus used, which is defined as the mass fraction of the mixture that is vapor (calculated from vapor

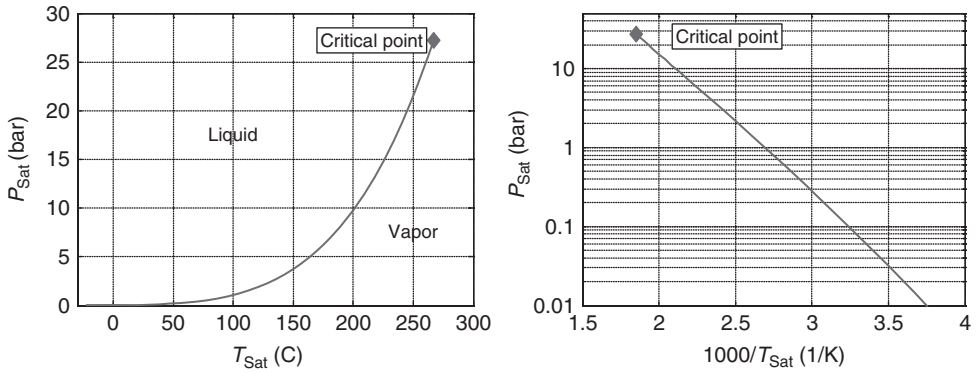

Figure 1. Pressure–temperature diagram for *n*-heptane showing the saturation curve and dependency of pressure and temperature.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

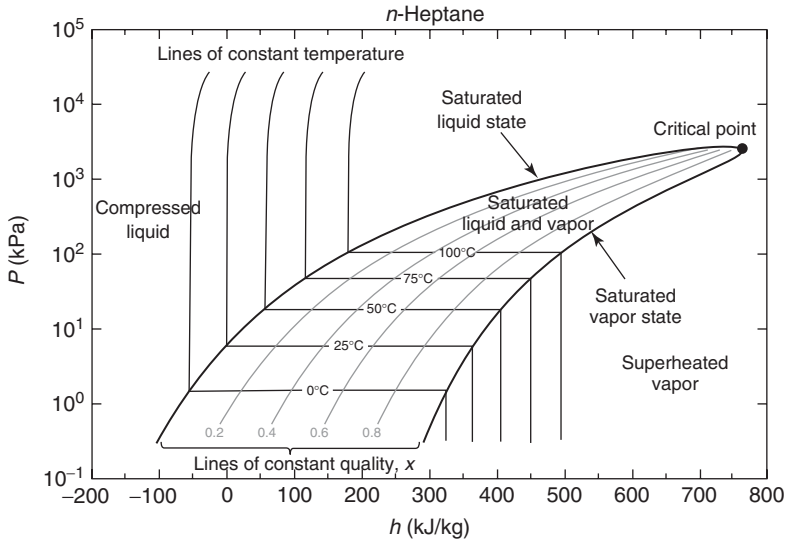

Figure 2. Pressure–enthalpy diagram for *n*-heptane fuel, showing the vapor dome, along with saturation states and quality lines.

mass m_{vapor} and liquid mass m_{liquid}):

$$x = \frac{m_{\text{vapor}}}{m_{\text{vapor}} + m_{\text{liquid}}} \tag{10}$$

Lines of constant quality are shown underneath the saturation dome in Figure 2. The left side of the dome represents the saturated liquid state conditions, and the right side of the dome defines the saturated vapor conditions. Temperature is constant horizontally underneath the dome, with the change being in the quality of the mixture between the vapor and liquid fractions. The specific energy required to transition from liquid ($x = 0$) to vapor ($x = 1$) is the internal energy (u_{fg}) or enthalpy of vaporization (h_{fg}). The enthalpy of vaporization is often referred to as the *latent heat of vaporization*.

The dependence between P and T for saturation can be estimated by the Clausius–Clapeyron equation

$$\frac{\mathrm{d}P}{P} = \frac{h_{\text{fg}}}{R_{\text{u}}T^2}\mathrm{d}T \tag{11}$$

With small changes of P and T, where h_{fg} remains nearly constant, the equation can be integrated to yield

$$\ln(P) = -\frac{h_{\text{fg}}}{R_{\text{u}}}\left(\frac{1}{T}\right) + C \tag{12}$$

This discussion on saturation and two-phase mixtures is increasingly important in IC engines. As diesel engines are primarily direct-injection and spark-ignition(SI)engines are transitioning to direct-injection, understanding the fuel injection process in terms of thermodynamics is imperative to understand the overall process. During this injection process, there exists a two-phase mixture, with liquid fuel during injection transitioning to vapor during mixing and penetration across the combustion chamber. A pressure–enthalpy diagram (Figure 2) can provide the path of the fuel states through the injection and vaporization process. Fuel is injected at an elevated pressure through an injector nozzle in a constant enthalpy process. The pressure is decreased during injection for this constant enthalpy process down to the charge gas pressure in the combustion chamber. Once the fuel is injected into the chamber, it will mix with the typically hotter charge gas, and the enthalpy of the fuel portion will increase. As a result, the mixture will transition from a liquid fuel to a saturated fuel–air mixture as it traverses the vapor dome.

1.1.2 Control volume/surfaces

Another set of important constitutive relationships are conservation equations. Applying conservation laws of mass, momentum, and energy to define thermodynamic processes requires definition of the system under consideration. A *system* defines what is being studied, and the shape or volume of the system may vary. There are two types of systems that will be considered, a *closed* system and an *open* system.

1.1.2.1 Closed system with discrete states. One type of system is a *closed* system, which is a fixed amount of matter, also known as a *control* mass, meaning there is no mass transfer across the closed system's boundary. Although a closed system does not have mass flow, there

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

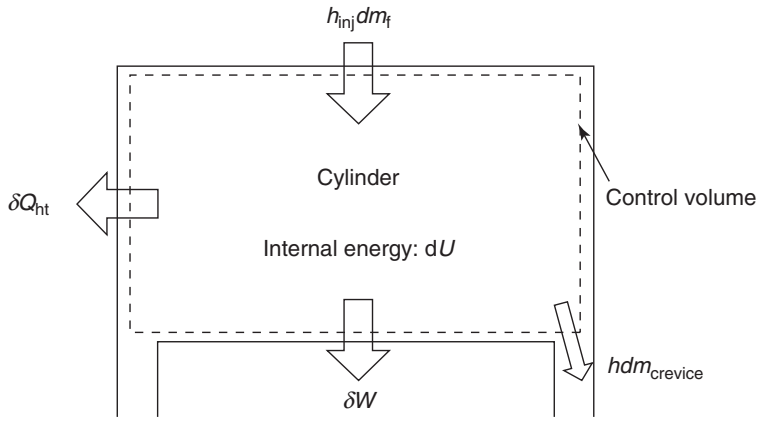

Figure 3. Open system (control volume) thermodynamic processes for an internal combustion engine. (Adapted from Gatowski *et al.* 1984).

still may be work done on or by the system, heat transfer across the system boundary, and reactions occurring within the system, which change the composition (mole and mass fractions of the species) but not the total mass.

1.1.2.2 Open dynamic system. An *open* system, synonymous with *control volume*, is defined as a region in space through which mass, or matter, can flow. A *control surface* is the boundary of the defined control volume, typically represented as a dashed line (Figure 3) around the system it is representing. Open systems can therefore exchange mass, work, and heat.

1.1.2.3 General conservation. General conservation can be applied to a control volume or an open system with flows across the control surface. This general conservation defines that the change in a system is equal to "in" minus "out," plus "generated" minus "destroyed," for any given type of property such as mass or energy. As another definition, general conservation can be inflow plus what is produced, equal to the outflow plus what is stored and what is destroyed.

1.1.3 Conservation relationships

Various conservation laws or relationships exist that govern the laws of nature. Conservation laws include conservation of mass, linear and angular momentum, and energy. These laws can be applied using the previously discussed systems.

1.1.3.1 Conservation of mass. The law of conservation of mass states that, for a system, the mass is neither created nor destroyed. Conservation of mass can be represented through the continuity equation when using control volume analysis. Applying the conservation of mass to a control volume of a system, it is determined that the time rate of change of mass within the control volume (m_{cv}) is equal to the sum of all mass flows into the control volume ($\dot{m}_{in}$) minus the sum of all mass flows out of the control volume ($\dot{m}_{out}$) as expressed by

$$\frac{dm_{cv}}{dt} = \sum_{in} \dot{m}_{in} - \sum_{out} \dot{m}_{out} \tag{13}$$

where the subscript "in" denotes the inlet, the subscript "out" denotes the exit of the control volume, and the subscript "cv" denotes the control volume.

1.1.3.2 Conservation of momentum. The conservation of momentum for a system is Newton's second law, which states that the time rate of change of linear momentum of the system (linear momentum being mass times velocity) is equal to the sum of the external forces acting on the system. The linear momentum equation is expressed by

$$\frac{\partial}{\partial t}\int_{cv} \text{Vel} \times \rho dV + \int_{cs} \text{Vel} \times \rho \times \text{Vel} \cdot \hat{n} dA = \sum F_{\text{contents of the cv}} \tag{14}$$

where the subscript "cs" denotes the control surface, the quantity Vel $\times \rho dV$, which (velocity multiplied by mass) is the momentum of a particle, $\hat{n}$ is the direction of the outward normal of the control volume, dA is the infinitesimal area of the control surface, and F is the external forces acting on the system.

1.1.3.3 Conservation of energy. The conservation of energy, also known as the *first law of thermodynamics*, states that for a system the time rate of increase of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

total energy (E) stored in the system is equal to the energy transfer by heat (Q) and work (W), and the difference in energy transfer rates into and out of the control volume boundary (across the control surface) due to kinetic energy ($\mathrm{Vel}^2/2$, where Vel is velocity), potential energy (gz, where g is acceleration due to gravity and z is height relative to reference location), and specific enthalpy h. This is expressed as

$$\frac{\mathrm{d}E_{\mathrm{cv}}}{\mathrm{d}t} = \dot{Q}_{\mathrm{cv}} - \dot{W}_{\mathrm{cv}} + \sum_{\mathrm{in}} \dot{m}_{\mathrm{in}} \left(h_{\mathrm{in}} + \frac{\mathrm{Vel}_{\mathrm{in}}^2}{2} + g z_{\mathrm{in}} \right) - \sum_{\mathrm{out}} \dot{m}_{\mathrm{out}} \left(h_{\mathrm{out}} + \frac{\mathrm{Vel}_{\mathrm{out}}^2}{2} + g z_{\mathrm{out}} \right) \tag{15}$$

As an example for the application of the conservation of energy, we can consider a combustion chamber of an engine that can have mass flows in and out of the valves, fuel injection into the cylinder, and flows from crevice regions in the chamber. Mass flows are typically defined as positive when the flow of mass is out of the control volume. Once the fuel is burning, either via a compression-ignition (CI) or an SI event, there is energy conversion from chemical energy stored in molecular bonds to sensible (thermal) energy (temperature change), with this being treated as an internal energy term. In addition, there are also heat transfer losses to the chamber walls from the hot combustion products and work done, which is the useful work to push the piston down and provide energy to rotate the shaft and produce work. Depending on the desired analysis, certain flows can be neglected, for example, flows through valves when interest is on the portion of the cycle occurring when valves are closed (i.e., compression and expansion strokes as opposed to a full cycle analysis). This conservation process is shown schematically in Figure 3.

The overall conservation relationship in terms of energy (first law of thermodynamics) is defined as

$$\mathrm{d}U = \delta Q_{\mathrm{ht}} - \delta W - \sum_i \mathrm{d}m_i h_i \tag{16}$$

which considers change in internal energy $\mathrm{d}U$, heat transfer to the system δQ_{ht} work transfer from the system $\delta W = p\ \mathrm{d}V_{\mathrm{CV}}$, and enthalpy exchange across the control volume boundary for fuel injection into the cylinder and flows from crevice regions, $h_{\mathrm{inj}}\mathrm{d}m_{\mathrm{f}}$ and $h\mathrm{d}m_{\mathrm{crevice}}$, respectively.

1.1.4 *Second law of thermodynamics (entropy, exergy)*

While the first law of thermodynamics discusses the movement and storage of energy, which is a conserved property that cannot be created or destroyed, the second law provides information on the direction in which a process will naturally occur (i.e., energy flows from high temperature to low temperature). The property used to determine this direction is known as *entropy* (S), which can be defined, using statistical thermodynamics, as:

$$S = k \ln \Omega \tag{17}$$

where k is the Boltzmann constant and Ω is the thermodynamic probability (Schroeder, 2000). From this approach, entropy can be viewed as a measure of the disorder of the molecules in a system.

For most system analyses, the change in entropy is what is desired rather than the actual value. Because entropy is not a conserved value like energy (it can be generated but not destroyed), tracking the changes requires a balanced rather than a conserved equation:

$$\frac{\mathrm{d}S_{\mathrm{cv}}}{\mathrm{d}t} = \dot{S}_{\mathrm{in}} - \dot{S}_{\mathrm{out}} + \dot{S}_{\mathrm{gen}} \tag{18}$$

The subscripts "cv," "gen," "in," and "out" stand for control volume, generated, in, and out, respectively for the time rate of change of entropy $\dot{S}$. Using the Clausius inequality, it can be shown that

$$\mathrm{d}S \geq \frac{\delta Q}{T} \tag{19}$$

When the process is reversible, in which case no entropy is generated, the equal sign is enforced. When the process is irreversible (through mechanisms such as friction, heat transfer, and chemical reactions), the inequality is applied and entropy will be generated. It is this generation term that leads to less efficient systems, which will be shown in the discussion of exergy.

Changes in entropy between two states (denoted as subscripts "1" and "2" in the following equations), like any other thermodynamic property in a simple compressible system, can be calculated using two other measured properties such as temperature and pressure. For ideal gases, the change in specific entropy s can be calculated as follows:

$$s_2 - s_1 = \int_1^2 c_{\mathrm{p}} \frac{\mathrm{d}T}{T} - R_{\mathrm{u}} \ln \frac{P_2}{P_1} \tag{20}$$

$$s_2 - s_1 = \int_1^2 c_{\mathrm{v}} \frac{\mathrm{d}T}{T} + R_{\mathrm{u}} \ln \frac{v_2}{v_1} \tag{21}$$

where c_{p} and c_{v} are the specific heat at constant pressure (CP) and volume, respectively, and v is the specific volume.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The specific heat for most ideal gases is a function of temperature only (see Pressure and Heat Release Analysis for a discussion on the dependence of specific heat on pressure). If this relationship is linear, or, in the case of many monatomic gasses, constant, the change in specific entropy can be calculated using the following equations:

$$s_2 - s_1 = c_{p,avg} \ln \frac{T_2}{T_1} - R_u \ln \frac{P_2}{P_1} \tag{22}$$

$$s_2 - s_1 = c_{v,avg} \ln \frac{T_2}{T_1} + R_u \ln \frac{v_2}{v_1} \tag{23}$$

where $c_{p,avg}$ and $c_{v,avg}$ are determined by taking the specific heat at the average of the two temperatures.

If the relationship between the specific heat and temperature is highly nonlinear, then a relationship must be determined, often using fourth-order polynomials, and the first integral shown in Equations 20 and 21 must be completed to accurately determine the change in entropy.

Variable specific heats at CP and constant volume are tabulated in various reference books or have defined equations for approximating values as a function of temperature, for common gas and liquid working fluids. Refer to Moran and Shapiro (2008), Turns (2000), Reid, Prausnitz, and Poling (1987), and Reynolds (1979), as examples.

While entropy can be somewhat vague and difficult to understand, an alternative approach is to examine a property of a system known as *exergy* or availability. This property is used to determine the maximum potential work a system has at a given state relative to the so-called dead state. The dead state, often chosen to match the local environmental conditions, serves as a common ground to measure changes in exergy within a system. Exergy, like entropy, is not a conserved property but, unlike entropy, exergy cannot be created but can be destroyed.

The exergy ψ, of a system at any point can be determined through the following equation:

$$\psi = (h - h_o) - T_o(s - s_o) + \frac{(\text{Vel} - \text{Vel}_o)^2}{2} + g(z - z_o) \tag{24}$$

All values with subscript "o" represent the values at the dead state.

An exergy balance is shown below:

$$\frac{d\psi_{cv}}{dt} = \dot{\psi}_{in} - \dot{\psi}_{out} - \dot{\psi}_{des} \tag{25}$$

where the subscript "des" denotes destroyed. A change in exergy between any two states is given as

$$\psi = (h_2 - h_1) - T_o(s_2 - s_1) + \frac{V_2^2 - V_1^2}{2} + g(z_2 - z_1) \tag{26}$$

Now a link can be established between the entropy generated in the system and the exergy destroyed, as

$$\dot{\psi}_{des} = T_o S_{gen} \tag{27}$$

This equation indicates that, as more entropy is generated within a system, the potential for work decreases. Therefore, in order to make a system more efficient (i.e., more work is possible through the same amount of energy input), the reduction of the entropy being generated is important.

1.1.5 *Isentropic processes of compression, expansion, and work*

In order to determine the efficiency of work-producing or work-consuming devices, it is often preferable to use isentropic devices as an idealized model with which to compare the actual devices. Generally, the inlet conditions and outlet pressure for the isentropic device are set to match those of the actual device while all other outlet conditions of the isentropic device must be calculated. This is done by using relationships between pressure, temperature, and volume established from the entropy change relations provided earlier.

If a constant specific heat approximation is appropriate, then Equation 22 can be used to determine a relationship between pressure and temperature across the device being considered. The left-hand side of the equation will be equal to zero (for an isentropic, or constant entropy process) leaving the following:

$$0 = c_{p,avg} \ln \frac{T_2}{T_1} - R_u \ln \frac{P_2}{P_1} \tag{28}$$

where 1 represents the inlet and 2 the outlet. Using the relationships between the ratio of specific heats ($k = c_p/c_v$) and the gas constant ($R_u = c_p - c_v$), the following equality can be established:

$$\left(\frac{T_{out}}{T_{in}}\right) = \left(\frac{P_{out}}{P_{in}}\right)^{\frac{k-1}{k}} \tag{29}$$

A similar relationship can be established between the pressure and volume:

$$\left(\frac{P_{out}}{P_{in}}\right) = \left(\frac{V_{in}}{V_{out}}\right)^{k} \tag{30}$$

Now, using the exit conditions of the isentropic device, the work to (compression) or from (expansion) in the device W_{actual} can be calculated using a first law analysis. The efficiencies can then be defined as either work-producing

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

efficiency ($\eta_{\text{work-producing}}$) or work-consuming efficiency ($\eta_{\text{work-consuming}}$), as defined below:

$$\eta_{\text{work-producing}} = \frac{W_{\text{isentropic}}}{W_{\text{actual}}} \tag{31}$$

$$\eta_{\text{work-consuming}} = \frac{W_{\text{actual}}}{W_{\text{isentropic}}} \tag{32}$$

For variable specific heat considerations, the relationship for specific heat and temperature must be determined to complete the integral of the temperature term as was discussed.

1.1.6 Compressible and incompressible flow

Different flows will occur, compressible and incompressible, depending on the forces and processes in the flow. For example, there are instances where the compressibility may be unity (ideal gas law is valid) but the flow may still be compressible (varying density). The definition of flow as compressible or incompressible must consider the *process* of the flow, not solely the type of fluid (gas or liquid) that is flowing (Balachandran, 2006). This relates to the consideration of the process and force transmission, which occurs essentially instantaneously for incompressible flow but takes some finite time for compressible flow.

One metric used to understand whether flow is compressible or incompressible is to determine the Mach number of the flow (Ma), which is defined as the ratio of the speed of the flow to the speed of sound. For gases, when this ratio is <0.3, the flow can be considered as incompressible, and when it is >0.3 the flow should be considered compressible.

Of more relevance to an engine, considering, for example, flow through a throttle or in turbochargers, is compressible and choked flow. For compressible flow, with a Mach number of 1, this yields conditions of choked flow, meaning the mass flow rate of the flow through an orifice or fixed area cannot increase further unless the upstream pressure is increased or the upstream temperature is reduced. Choked flow is encountered when the critical pressure ratio of static to stagnation pressure is 0.53 at a specific heat ratio of 1.4 for air.

2 THERMOCHEMISTRY

In an engine, fuel, which is typically a mixture of hydrocarbons, mixes with air to produce a combustible fuel–air mixture that is ignited by a plasma discharge (SI engines including gasoline) or through autoignition (CI engines including diesel). This process depends on the mixture composition of the charge gas, which includes residuals from the combustion of prior cycles, combustion chamber conditions, fuel properties, and so on. To characterize this process, an analysis of the composition of the charge gas, fuel, and their mixtures from the standpoint of thermochemistry is required.

2.1 Air and humidity standard

Air is composed of a number of gases, and the properties of a standard dry air are given in Table 1. In this table are the mole and mass fractions and the molar ratio based upon 1 mol of oxygen (O_2), which will be used in the thermochemistry balance equation with fuel. Mole fraction is defined as the ratio of the moles of the given species to the total moles, with mass fraction being the ratio of the mass of the given species to the total mass. Overall, there are 3.775 (3.728 + 0.045 + 0.002) moles of other gases per mole of oxygen, in 1 mol of air.

In most cases, the combustion air is not dry and contains water vapor in significant amounts. The quantity of water vapor is most often given by relative humidity (RH) or humidity ratio. RH is the partial pressure of water vapor (p_{vap}) in air to the saturation pressure of the vapor (p_{sat}) at the same temperature (T):

$$\text{RH} = \frac{p_{\text{vap}}(T)}{p_{\text{sat}}(T)} \tag{33}$$

The humidity ratio (ω) is the ratio of the mass of water vapor ($m_{\text{H}_2\text{O,Vap}}$) to mass of dry air ($m_{\text{Air,Dry}}$), which can be related to the ratio of the partial pressure of the water vapor to the partial pressure of the dry air ($p_{\text{Air,Dry}} = p - p_{\text{vap}}$) by the molecular weights (M).

$$\begin{aligned}\omega &= \frac{m_{\text{H}_2\text{O,Vap}}}{m_{\text{Air,Dry}}} = \frac{p_{\text{vap}}}{p - p_{\text{vap}}} \cdot \frac{M_{\text{H}_2\text{O}}}{M_{\text{Air,Dry}}} \\ &= \frac{M_{\text{H}_2\text{O}}}{M_{\text{Air,Dry}}} \cdot \frac{\text{N}_{\text{H}_2\text{O}}}{N_{\text{Air,Dry}}} = \frac{1}{1.608} \cdot \frac{\text{N}_{\text{H}_2\text{O}}}{N_{\text{Air,Dry}}}\end{aligned} \tag{34}$$

Table 1. Composition of dry air.

Gas	Molar mass	Volume (ppm)	Molar ratio	Mass (%)
N_2	28.013	780,740	3.728	75.51
O_2	31.998	209,430	1.000	23.14
Ar	39.948	9340	0.045	1.29
CO_2	44.010	390	0.002	0.06
Others[a]	19.700	100	0.000	0.01
Air	28.965	1,000,000	—	100.00

[a] Includes neon, helium, methane, krypton, hydrogen, and so on.
(Adapted from Moran and Shapiro (2008), updated to include current atmospheric carbon dioxide levels (National Oceanic & Atmospheric Administration, 2011).)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The molar humidity ratio is then $M_{\text{Air,Dry}}/M_{\text{H}_2\text{O}} \cdot \omega = 1.608\,\omega$, where 1.608 is the ratio of molecular weight of dry air and water. The number of moles of H_2O from humidity per mole of oxygen in air is then $1.608/y_{\text{O}_2,\text{Air,Dry}} = 7.677$ where $y_{\text{O}_2,\text{Air,Dry}} = 0.2094$. For our thermochemisty representation of humid air, we can then write air on the basis of one mole of oxygen as

$$\text{O}_2 + 3.728\,\text{N}_2 + 0.045\,\text{Ar} + 0.002\,\text{CO}_2 + 7.677\,\omega\,\text{H}_2\text{O} \tag{35}$$

2.2 Thermochemistry of fuel mixtures with air and residuals

For most fuels, the composition is comprised of carbon, hydrogen, oxygen, nitrogen, and sulfur, with trace amounts of other substances. Typical fuels such as gasoline and diesel consist of individual compounds that are unknown, but testing can provide atomic mass or mole fraction compositions of these fuels. Additionally, in some cases an average molecular weight can be determined such that the fuel can be represented by the molecular average formula $C_XH_YO_ZN_WS_V$. Sulfur and nitrogen levels are usually low, and for this analysis, they will be neglected. The ideal reaction of this fuel in air, including humidity, to combustion products for a lean ideal reaction is given by

$$\begin{aligned} C_X H_Y O_Z + \lambda R\,(&\text{O}_2 + 3.728\,\text{N}_2 + 0.045\,\text{Ar} \\ &+ 0.002\,\text{CO}_2 + 7.677\,\omega\,\text{H}_2\text{O}) \rightarrow X\,\text{CO}_2 \\ &+ (Y/2 + 7.677\lambda R\,\omega)\,\text{H}_2\text{O} + \lambda R(3.728\,\text{N}_2 \\ &+ 0.045\,\text{Ar} + 0.002\,\text{CO}_2) + (\lambda - 1)R\text{O}_2 \end{aligned} \tag{36a}$$

where λ is the excess air ratio ($\lambda = 1$ is the stoichiometric condition), and

$$R = X + \frac{Y}{4} - \frac{Z}{2} \tag{36b}$$

In this relationship, which is valid for $\lambda \geq 1$, the fuel $C_XH_YO_Z$ reacts with air to produce the ideal combustion products (CO_2 and H_2O).

The inverse of λ is the equivalence ratio Φ. Equivalence ratios >1 ($\lambda < 1$) signify rich combustion, meaning more fuel than required for complete combustion of air. Equivalence ratios <1 ($\lambda > 1$) define lean combustion, meaning excess air is present, or there is more air than needed for complete combustion of the fuel. A λ or equivalence ratio of 1 represents stoichiometric combustion, meaning the correct amount of fuel and air for complete combustion of all fuel. This corresponds to a stoichiometric fuel-to-air ratio (FAR) or stoichiometric air-to-fuel ratio (AFR), as tabulated in several texts, including Heywood (1988). With the stoichiometric values known, the excess air ratio or equivalence ratio can be determined based on the actual FAR or actual AFR as defined in Equation 37. The FAR and AFR are mass-based quantities, meaning they are the ratio of mass of fuel to mass of air, or vice versa.

$$\phi = \frac{1}{\lambda} = \frac{\text{FAR}_{\text{actual}}}{\text{FAR}_{\text{stoich}}} = \frac{\text{AFR}_{\text{stoich}}}{\text{AFR}_{\text{actual}}} \tag{37}$$

2.3 Enthalpies of formation

Fuels have different energy contents, which can influence combustion and emissions, as well as fuel economy. This energy content is represented through the heating value of the fuel; the larger the heating value, the more the energy available in the fuel for useful work, as will be discussed. To determine these energy contents, the thermodynamics of the intensive properties including chemical energy are required.

Enthalpy of formation $\overline{h}_{\text{f}}^{\circ}$ of a chemical is defined as the enthalpy increase from a reaction forming one mole of the given chemical, from its elements, for a standard state at the given temperature. As discussed, enthalpies require a definition of the reference state, with the most commonly used reference state being a temperature T_{ref} of 25°C (298.15 K) and pressure of 1 atmosphere (101.325 kPa). Elements at their reference state, which is the stable state of the element (e.g., O_2, N_2, H_2, He), are defined as having an enthalpy of formation of zero. These enthalpies of formation are tabulated or can be calculated with the available property data (Heywood, 1988; Moran and Shapiro, 2008, etc.). As an example application, enthalpies of formation can be used in the calculation of enthalpy of combustion (heating values).

Enthalpies of formation are used to define the enthalpy of a fluid at some defined condition. For the case of mixtures of ideal gases, their enthalpy can be calculated at the desired temperature, on either a mass or molar basis depending on the available enthalpy data. For the case of mole fraction x (as denoted by the overbar on the variables), the total mixture enthalpy is the weighted sum of the product of the mole fraction and enthalpy of each component species i at the desired mixture temperature, that is,

$$h = \sum_i x_i \bar{h}_i \tag{38}$$

Mole fraction is defined as the ratio of the number of moles of the species i to the total number of moles. To determine the molar-based enthalpy of each species, the enthalpy of formation and sensible enthalpy change $\Delta\overline{h}_{\text{s},i}(T)$, must be known (tabulated or functionally) to enable calculation of the enthalpy at the desired temperature, and is shown

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

below for a molar basis:

$$\bar{h}_i(T) = \bar{h}^{\circ}_{f,i}(T_{ref}) + \Delta\bar{h}_{s,i}(T) \quad (39)$$

The sensible enthalpy change is evaluated based on an enthalpy change from the defined reference temperature (e.g., 298.15 K) to the temperature of interest (T). These molar-based enthalpies are evaluated for each species of interest to enable the ideal gas mixture enthalpy to be calculated.

2.4 Heating values

The *heating value* or *heat of combustion* of the fuel provides a measure of the energy in the fuel, defined as the heat of reaction at either CP or constant volume (CV) at standard temperature (typically 298.15 K) for complete combustion of a unit mass of fuel (Heywood, 1988). That at CP is the most common heating value used in combustion; differences between heating values at CP and CV are small (Heywood, 1988).

Also of concern is whether the water in the products from combustion is in the liquid or gaseous state. If the heating value is defined using water in the liquid phase, this is defined as the *higher heating value* or *gross heating value*, Q_{HHV}. The *lower heating value* or *net heating value* (Q_{LHV}) defines the heating value when the water from combustion is in the vapor phase. These heating values are directly related, with the lower heating value more commonly used in combustion work. Heating values for fuels are tabulated (see Table 2 for the lower heating values of some typical fuels and hydrocarbons) and can be directly measured using calorimeters.

2.5 Maximum work

An IC engine can be treated as an open system (control volume) in which heat and work are exchanged with surroundings, and there is enthalpy flow of reactants and products into and out of the system. Hence, the first and second law of thermodynamics can be applied to the system to determine the *maximum useful work* that can be provided by the engine (Heywood, 1988).

Applying the first law of thermodynamics results in

$$\Delta Q - \Delta W_u = \Delta H \quad (40)$$

where ΔW_u is the usable work. The second law of thermodynamics tells us that

$$\frac{\Delta Q}{T_a} \leq \Delta S \quad (41)$$

As heat transfer occurs at atmospheric temperature (T_a), combining the two equations enables the definition of a maximum work relationship:

$$\Delta W_u \leq -(\Delta H - T_a \Delta S) \quad (42)$$

To achieve maximum work, the pressure and temperature of the reactants must reach the atmospheric values. For these conditions, the change in enthalpy and entropy can be calculated, which enables us to define the change in Gibbs free energy G at atmospheric temperature and pressure (T_a, P_a):

$$\Delta W_u \leq -(\Delta G)_{T_a,P_a} \quad (43)$$

The maximum work $\Delta W_{u,max}$ can then be defined as

$$\Delta W_{u,max} = -(\Delta G)_{T_a,P_a} \quad (44)$$

which is the difference in Gibbs free energy between the reactants and products at atmospheric pressure and temperature for complete combustion. This maximum work can be further related to other parameters such as availability conversion efficiency, the ratio of actual work delivered compared to the maximum work, and others. Refer to Heywood (1988) for details and further discussion. Also of note is that enthalpies and Gibbs free energies of combustion reactions for common hydrocarbons are very similar at the standard temperature, as shown in Table 2. As the Gibbs free energies are difficult to determine for typical hydrocarbon fuels, the heating value, which can be measured, can be used in the above equations for a close approximation.

Table 2. Enthalpies and Gibbs free energies of combustion reactions and lower heating values for typical fuels and hydrocarbons.

Hydrocarbon—combustion reaction	$\Delta\overline{h}^{\circ}_{298}$ (MJ/kmol) (H_2O in products is gas)	$\Delta\overline{g}^{\circ}_{298}$ (MJ/kmol)	LHV (MJ/kg)
Propane (C_3H_8)	−2044.0	−2074.1	46.4
Benzene (C_6H_6)	−3135.2	−3175.1	40.2
iso-Octane (C_8H_{18})	−5074.6	−5219.9	44.3
Gasoline	N/A	N/A	44.0
Ethanol	N/A	N/A	26.9
Diesel	N/A	N/A	42.5

(Modified from Heywood (1988).)

2.6 Equilibrium

In an IC engine, combustion does not yield the ideal results discussed above and requires the calculation of a

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto141
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

complex and detailed set of chemical reactions and associated kinetics of a large number of species. One simplifying assumption can be made that the products of combustion are in chemical equilibrium, meaning the products of combustion are shifting during expansion to maintain equilibrium. Chemical equilibrium can be determined by the first and second law of thermodynamics, leading to

$$(\Delta G)_{\mathrm{P,T}} = 0 \tag{45}$$

as a definition of equilibrium for a CP and temperature process. The Gibbs free energy change can then be related to chemical potential and moles of species, which is further related via the ideal gas law to define equilibrium constants. Refer to Heywood (1988) for derivation and examples.

This equilibrium will result in differing combustion product compositions as a function of equivalence ratio, temperature, and pressure based on species and temperature-dependent equilibrium constants. As the temperature increases, products begin to dissociate into other products at more significant levels, such as to OH, O, and H (Heywood, 1988). For lean combustion, N_2, CO_2, H_2O, and O_2 remain the major species, while for rich mixtures CO and H_2 increase rapidly. In addition to these species, products can also include unreacted or partially reacted hydrocarbons due to quenching and thermal formation of oxides of nitrogen. These species require additional nonequilibrium analyses.

3 SECOND LAW DISCUSSION

In order to determine the entropy change across a reacting system, the importance of which will be discussed in the next section, it is necessary to calculate the entropy of all constituents in the fuel, oxidizer, and reactants. This requires setting a common reference state for both the pressure and temperature. In general, the common reference pressure P_{ref} is taken to be atmospheric, while the common reference temperature is taken at absolute zero, where the entropy of a substance is also zero. For an individual species i, the molar entropy is determined by

$$\overline{s}_i(T_{\mathrm{m}}, P_i) = \overline{s_i^{\mathrm{o}}}(T_{\mathrm{m}}, P_{\mathrm{ref}}) - \frac{R_{\mathrm{u}} \ln(x_i P_{\mathrm{m}})}{P_{\mathrm{ref}}} \tag{46}$$

where m represents the mixture, the subscript "ref" represents the reference atmospheric condition, the superscript "o" represents the entropy measured with respect to absolute zero temperature, and x_i is the mole fraction of the constituent. In order to find the total entropy of a mixture, the entropy of each individual constituent is multiplied by its mole fraction, and then all values are summed. It should be noted that, for real gas effects, modifications would have to be made to each individual constituent. Cengel and Boles (2010) provide a correction for using entropy departure charts.

4 ENERGY/LOSS ANALYSIS

In order to determine losses of potential work in a system, it is necessary to perform a second law analysis using either entropy or exergy concepts. Performing an entropy balance across a reacting system yields the following:

$$\sum S_{\mathrm{r}} - \sum S_{\mathrm{p}} + S_{\mathrm{gen}} + \sum_k \frac{Q_k}{T_k} = \Delta S_{\mathrm{sys}} \tag{47}$$

where r represents the reactants, p the products, "gen" the entropy generation term, and "sys" the system entropy change term. If the process is proceeding at steady state, the right-hand side will go to zero. Solving for S_{gen} and relating it to the exergy destroyed enables the determination of the loss of potential work through the system.

5 SIMPLIFIED ENGINE CYCLES

Ideal simplified models can be used to approximate engine cycles that rely on the developed and previously discussed thermodynamic concepts. These models consist of idealizing processes to approximate real engines, including intake, compression, combustion, expansion, and exhaust. The standard, simplified, ideal gas engine cycles include constant-volume, constant-pressure, and limited-pressure cycles, based on how chemical energy conversion to sensible energy (combustion) is occurring. The overall cycle includes an adiabatic intake stroke, adiabatic and reversible (isentropic) compression stroke, followed by combustion, which can occur at *CV, CP*, or part CV and part CP (*limited pressure*, *LP*), with assumptions of adiabatic and complete combustion. The remainder of the cycle includes an expansion process (adiabatic and reversible—isentropic) and is followed by an adiabatic exhaust stroke.

Although these simplified engine cycle analyses are ideal, they can approximate actual engine combustion strategies including fast combustion at top dead center (infinitely fast combustion—CV, spark ignition or Otto cycle), slow and late combustion (CP, diesel cycle), or combustion strategies in between (limited-pressure cycle). Each of the strategies can be independently analyzed to characterize the cycle processes including efficiencies, indicated mean effective

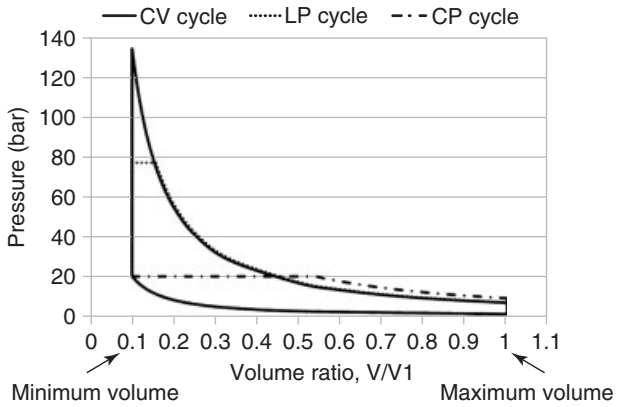

Figure 4. Constant volume, constant pressure, and limited pressure pressure–volume diagram for an ideal cycle analysis.

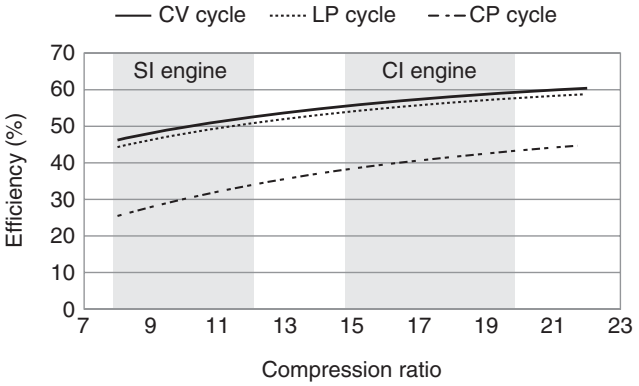

Figure 5. Constant volume, constant pressure, and limited pressure fuel-conversion efficiency as a function of compression ratio for an ideal cycle analysis.

pressure (IMEP), and values of maximum pressure ratios. The cycles will be summarized and efficiencies compared; however, full cycle derivations, which involve application of the first and second law of thermodynamics, as well as other combustion properties such as IMEP and maximum pressure ratios, are outside the current scope. Refer to Heywood (1988) or Stone (2002) for further details. The cycle assumes that the working fluid is an ideal gas with constant specific heats.

Shown in Figure 4 is a pressure–volume diagram for the three ideal cycles: CP, CV, and LP. These cycle diagrams are produced assuming that the engine is operating at a compression ratio of 10 (typical for SI engines), inlet pressure of 1 bar, and inlet temperature of 300 K. The engine is operating on gasoline, combusting in air, with a specific heat ratio of 1.3. The LP cycle assumes that 50% of the fuel is burnt at constant pressure, and 50% at CV.

The CV cycle, which has combustion occurring infinitely fast at CV, historically having been linked to SI engines, results in the largest peak pressure, as observed in Figure 4. The lowest peak pressure is observed with the constant pressure cycle, which has historically been associated with the diesel engine cycle, with combustion occurring at constant pressure, and hence the volume is allowed to expand to keep the pressure constant. Note that neither the CV nor the constant pressure cycle accurately represents current SI or CI diesel engines, but they represent the limits. The LP cycle, which most closely approximates an actual engine operating cycle, results in a peak pressure falling between these two values, as it combines a CV and constant pressure cycle. For this case, it is assumed that 50% of the fuel is burnt at constant pressure and 50% at CV; however, the split of fuel combustion between these stages can vary. As a larger fraction of the fuel is burnt at CV, the peak pressure will further increase, approaching the CV peak pressure. These different operating cycles also yield different fuel conversion efficiencies, as shown in Figure 5. Not only do the cycles yield different efficiencies at a set compression ratio but the compression ratio also directly influences the efficiency.

As the compression ratio is increased, the ideal fuel conversion efficiency increases, as shown. There are, however, limits, mechanically, on the maximum compression ratio based on increased pressures achieved and what the engine can physically withstand. Other limitations include engine knock, prevalent in SI engines, and NO*x* emissions. At a given compression ratio, the efficiency is largest for the CV cycle, followed by the LP, and finally the constant pressure cycle. Depending on the distribution of the fraction of fuel burnt at CV versus constant pressure for the LP cycle, the placement of the LP cycle with regard to efficiency between the CV and CP cycles changes.

It is typical in real engine operation that CI or diesel engines have a higher efficiency than SI engines. This is attributed in part to the differences in compression ratios, with diesels operating at higher compression ratios, typically in the 15–20 range, compared to gasoline engines in 8–12 range.

Alternative cycles are possible, such as the *Atkinson cycle* or *overexpanded cycle*, which involves an expansion stroke greater than the compression stroke. The advantages of this cycle are increases in work and in efficiency when compared to the standard CV cycle (Stone, 2002; Heywood, 1988). This engine operational strategy can be achieved with variable valve timing, and is prevalent in engines for hybrid electric vehicles. In addition to alternative cycles, modifications can be made in the analysis of the aforementioned cycles. For example, as opposed to an ideal

gas analysis, a fuel–air cycle can be considered, which has an unburned working fluid frozen in composition, and the burned gas mixture in equilibrium to provide a slightly improved approximation to actual engine cycles (Heywood, 1988). Actual engine cycles have lower efficiencies (about 80% less) compared to ideal cycles along with lower pressures. These differences can be attributed to heat transfer, the time required to burn the charge (noninstantaneous combustion), blow-down losses from the exhaust based on valve timing, gas flow and leakage into crevices in the combustion chamber, and incomplete combustion (Heywood, 1988).

In addition to these ideal cycle analysis, more complex cycle analysis can be applied using *one-zone* and *two-zone combustion modeling* to approximate realistically IC engine operating processes. To simplify, zero-dimensional combustion models are usually developed, which neglect engine flows and are classified into one-, two-, or multi-zone models. As the number of zones increases, the model complexity increases. In single-, or one-zone, models, the fluid (fuel, air, products) is a complete thermodynamic system and the first law of thermodynamics is applied to the system as a whole. For two-zone models, the engine fluid is treated in two states: a burned gas mixture (combustion products) and unburned gas mixture (fuel and air). Instead of just having one thermodynamic system, now there are two thermodynamic systems, with the first law applied to both zones. Additionally, there is energy and mass transfer between the two systems and the surroundings (e.g., the cylinder walls). Both models (one- and two-zone) enable the determination or calculation of in-cylinder pressure histories, energy release, or mass fraction burning rates, depending on known or assumed values including, for example, specific heat ratio, engine geometrical data, thermodynamic properties, and initial cylinder conditions of temperature. Greater detail on these types of models, including equation development, is provided in (see Pressure and Heat Release Analysis and Zero- and One-Dimensional Methodologies and Tools) and in Yeliana *et al*. (2008) and Yeliana (2010).

ENDNOTES

1. Two revolutions (rev) for a four-stroke engine. One rev for a two-stroke engine. This equates to n_R as utilized in Heywood (1988).
2. Molar concentration has units of moles or molecule per unit volume, the conversion factor being the Avogadro number.
3. Also referred to as the molar mass.

Exhaust Emissions

M. Matti Maricq

Ford Motor Company, Dearborn, MI, USA

1 INTRODUCTION

Engine exhaust emissions are increasingly under regulatory scrutiny and, therefore, an increasingly important activity in motor vehicle development. Under the Clean Air Act (most recently amended in 1990), the US Environmental Protection Agency (USEPA, 2011a) set National Ambient Air Quality Standards (NAAQS) for six "criteria" pollutants: O_3, CO, NO_2, SO_2, lead, and particulate matter (PM). Regions that experience more than an allowed number of annual exceedances in daily or hourly averages (ranging from 1 to 8 h) of any of these pollutants are designated as "nonattainment" and subject to developing State Implementation Plans aimed at bringing the region into attainment. Four of the criteria pollutants include undesired byproducts of combustion: CO and PM arise from rich combustion when insufficient air is present (see UHC and CO Formation and Models and Particulate Formation and Models). NO_x ($NO + NO_2$) is produced at combustion temperatures by reactions between nitrogen and oxygen (see NO_x Formation and Models). SO_2 forms from the oxidation of organic sulfur compounds present in fossil fuels. Lead emissions occurred in the past because of the use of tetraethyl lead as an antiknock agent in gasoline; however, this practice ceased in the United States in the 1970s and has been, or is being, phased out in the rest of the world as well. Ozone is not directly emitted by combustion sources; rather, its ambient levels depend intimately on the tropospheric concentrations of hydrocarbons (HCs) and NO_x, which are emitted in engine exhaust among other sources.

Motor vehicle emissions are regulated by the US Environmental Protection Agency (USEPA, 2011b), California Air Resources Board (CARB, 2011a), the European Union (UNECE, 2011), Japan, India, and a growing number of other countries. The "standard" pollutants include CO, HCs, NO_x, and PM, but this list is growing. Additional regulations are beginning to appear for compounds such as formaldehyde and ammonia and for particle number counting. Although not traditionally thought of as pollutants, CO_2, N_2O, and CH_4 are coming under regulation owing to their global warming potential (USEPA, 2011c). Emissions standards are predominantly written for room temperature and sea level conditions. However, additional standards cover vehicle operation at cold temperature and altitude.

Besides a growing list of species to monitor, the emissions standards are tightening. The US EPA and CARB are about to promulgate their Tier 3 and LEV III standards, and the European Union is beginning to address its Stage 7 limits. The standards are complex in that they can vary with vehicle weight, vehicle type (passenger vs commercial), engine technology (diesel vs gasoline), and so on. The standards are often comprised of a number of "bins" to allow vehicle manufacturers some flexibility, that is, if they certify vehicles in higher emissions bins, they must offset this by sales of lower emitting vehicles. Vehicles must be certified for a full useful life, which increases

Table 1. LEV II emission standards for light duty vehicles (<8500 lbs).

Category	120,000 miles/11 years				
	NMOG (g/mi)	CO (g/mi)	NO_x (g/mi)	PM (g/mi)	HCHO (g/mi)
LEV	0.090	4.2	0.07	0.01	0.018
ULEV	0.055	2.1	0.07	0.01	0.011
SULEV	0.010	1.0	0.02	0.01	0.004

to 150,000 miles under upcoming US regulations. Table 1 provides a simplified list of California's LEV II emissions standards. The categories low emitting vehicle (LEV), ultra low emitting vehicle (ULEV), and super ultra low emitting vehicle (SULEV) represent different emissions bins, where ULEV is the average required under LEV II and SULEV under LEV III.

Measuring emissions from modern vehicles, especially downstream of aftertreatment systems, poses a significant analytical challenge, as the species of interest, NO_x, HCs, PM, and so on, are typically present at parts per million (ppm) levels in a high temperature exhaust gas mixture comprised largely of CO_2 and water vapor, along with nitrogen and any uncombusted oxygen. Because high temperatures and water condensation can introduce substantial errors or damage-sensitive measurement equipment, correct sampling of the exhaust is at least as important as the measurements themselves. Regulatory methods stipulate measurement of the net pollutant emissions during a prescribed test or drive cycle (USEPA, 2011b; UNECE, 2011). According to regulations, the exhaust species are collected during the test, typically into Teflon bags, and measured afterwards. Engineering development, on the other hand, is better served by understanding the time-dependent history of each pollutant's emissions during the test or drive. Relating these two approaches to each other requires knowledge of the exhaust flow, which becomes an important auxiliary measurement.

The techniques to measure each species range from optical to electrical to gravimetric, and often multiple techniques exist. This chapter begins with the sampling methods used in emissions testing and then describes many of the typically used instruments. A number of new techniques are seeing increased application in emissions testing and two of these are treated in detail: Fourier transform infrared (FTIR) spectroscopy for gaseous emissions and real-time aerosol instrumentation to record PM emissions. The dynamometers employed to absorb the energy produced by engine operation and to mimic vehicle driving are also an important aspect of emissions testing. For descriptions of these devices and their use in engine testing, the reader is referred to Engine Performance.

2 SAMPLING ENGINE EXHAUST

2.1 Exhaust gas characteristics

Engine exhaust flow rate depends on displacement, speed, and load. It can vary from about 7 m^3/h (9 kg/h) at idle for a small 1.0-L automobile engine to 600 m^3/h (720 kg/h) for moderately high speed/load operation of a 6.5-L light-duty truck, and to higher rates for heavy-duty engines. The bulk composition of this exhaust is a consequence of combustion chemistry:

$$CH_{1.8} + 6.9\ \text{Air} \rightarrow CO_2 + 0.9\ H_2O + 5.45\ N_2 \quad (1)$$

Equation 1 applies to gasoline engines that operate at a stoichiometric air/fuel ratio so that little oxygen remains in the exhaust. $CH_{1.8}$ represents the average composition of petroleum-based fuels, predominantly a mixture of aliphatic and aromatic HCs. As a result, the exhaust is approximately 14% carbon dioxide and 12% water vapor by volume. The water fraction increases with the use of biofuels because of the oxygen in the fuel molecules. Combustion of E85 fuel (85% ethanol/15% gasoline), a highly oxygenated fuel blend, is described by

$$0.15\ CH_{1.8} + 0.85\ C_2H_5OH + 13.2\ \text{Air} \rightarrow 1.85\ CO_2 + 2.69\ H_2O + 10.4\ N_2 \quad (2)$$

Here, the water content in the exhaust climbs to 18%, whereas CO_2 falls to 12% by volume. On the other hand, water vapor and CO_2 fractions both decrease in diesel engine exhaust, which runs under lean conditions. At a typical diesel air/fuel ratio of 20 : 1, the water and CO_2 contents drop to about 9% and 10%, respectively.

The other major characteristic of engine exhaust is its temperature. As with flow, this depends on engine type, speed, and load. Typical gasoline engine-out exhaust varies in the range of 400–600°C and cools as it flows through the exhaust system. Diesel engines run somewhat cooler because of better thermal efficiency and higher air/fuel ratio, with exhaust temperatures normally between 200 and 400°C. However, for diesel vehicles equipped with particulate filters (diesel particulate filter, DPF), the exhaust temperature exceeds 600°C during active filter regeneration.

2.2 Raw sampling

There are two general strategies to sampling engine exhaust: (i) raw sampling and (ii) dilution sampling. Many commercially available emissions benches employ the former for

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

second-by-second emissions monitoring. Regulatory procedures for emissions certification, however, generally stipulate the second approach. There are advantages and disadvantages to each, as described in the following paragraphs.

The main advantage of raw sampling is that it preserves pollutant concentrations, a not inconsequential benefit under increasingly tighter regulatory standards. The primary disadvantage is the necessity to deal with hot humid samples, which can lead to losses, measurement interferences, and potentially, instrument damage. A straightforward approach is to employ heated transfer lines and detectors that prevent water condensation throughout the sampling and measurement processes, the so-called "wet" method. Heated lines offer the additional benefit of reducing losses during transport, such as losses of heavy HCs, ammonia, and PM by condensation and thermophoresis onto transfer line walls. Typical temperatures are 150°C for gasoline engine emissions measurements and 191°C for diesel measurements owing to their higher propensity for heavy HCs.

Raw sampling works well with methods such as flame ionization detection (FID) of HCs, as the detector operates at high temperature and is not sensitive to water vapor. However, it is less suitable in situations that are susceptible to interference from water vapor, for example, nondispersive infrared (NDIR) detection. This is a favored method for monitoring CO and CO_2; however, it has difficulty in distinguishing IR absorption by these compounds from that by water vapor. In such applications, one can "drop" out water by condensation leading to a "dry" measurement of emissions. However, it is important to correct the measured pollutant concentrations to account for the missing water, as this amounts to 9–18% of the exhaust, depending on fuel and engine types. The relationship between wet and dry concentrations of species x referenced to a common temperature (e.g., 25°C) is given by

$$c_{x\,\mathrm{wet}} = \frac{1 - \chi_{\mathrm{H_2O\,wet}}}{1 - \chi_{\mathrm{H_2O\,dry}}} c_{x\,\mathrm{dry}} \tag{3}$$

where $\chi_{\mathrm{H_2O\,wet}}$ and $\chi_{\mathrm{H_2O\,dry}}$ represent the mole fractions of water vapor in the exhaust and downstream of the condenser, respectively. Further details about wet and dry raw emissions calculations can be found in CFR 40 Part 89.412–89.418 (eCFR, 2011).

2.3 Dilution sampling

In contrast to the raw approach, dilution sampling cools the exhaust sample by mixing it with clean dry air or nitrogen (Hildemann, Cass, and Markowski, 1989). Heated lines are still required to avoid losses if there is any sample transport before dilution. Sufficient diluent is then mixed with the sample to ensure that it remains above the dew point at room temperature. Intermediate approaches are also possible where heated dilution air is used to cool an exhaust sample, but to a temperature higher than room temperature. This allows the use of lower dilution ratios and is therefore of interest when making very low level emissions measurements.

2.3.1 *Direct exhaust sampling*

There are a number of variations to dilution sampling. The simplest is to draw and dilute a constant volume of exhaust, as illustrated by the ejector pump system in Figure 1. The ejector pump is supplied with pressurized clean air or nitrogen at 2 atm overpressure, which expands past a nozzle creating a pressure drop that draws in exhaust through a short heated line. Heaters are used for the diluent and the first-stage diluter to avoid condensation and thermophoretic clogging by PM. A second stage (not shown) dilutes this mixture with air at room temperature to cool the sample without condensation. This method is relatively simple and

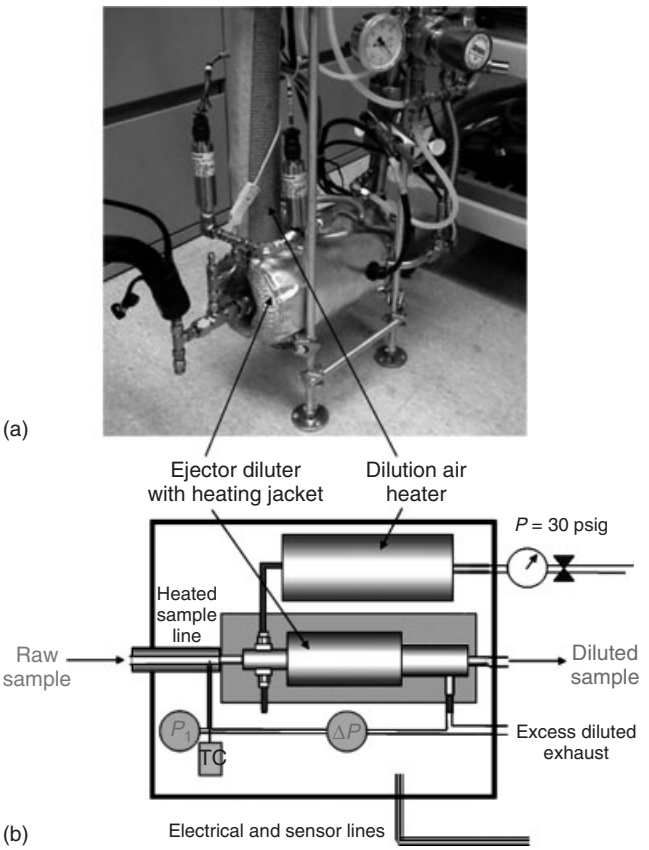

Figure 1. Dilution unit for direct tailpipe sampling. (a) Photo of an ejector pump diluter. (b) Schematic diagram of first stage of ejector pump dilution system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

can be made portable, as illustrated. It is particularly useful for engine-out measurements, where probe locations are often difficult to access and concentrations are relatively high; pre-DPF measurement of PM is an example.

2.3.2 Constant volume sampling

Constant volume sampling (CVS) takes a different tact, one usually applied to full exhaust flow. Figure 2 illustrates this approach for chassis dynamometer testing. Two variants are visible: (A) "remote mix tee" (RMT) and (B) dilution tunnel. The RMT connects to the vehicle tailpipe via a short, ∼1 m, stainless steel pipe. It is important to make this connection with metal and to avoid the use of silicone couplers or similar materials that can outgas HCs and shed particles leading to erroneous data. Temperature- and humidity-preconditioned dilution air (38 and −9°C dew point) enters the top of the RMT. However, the diluent flow is not kept constant; it rather varies and the total flow of exhaust plus diluent is kept constant. In the regulatory method, the diluted exhaust is then sampled into Teflon bags (marked "C" in Figure 2) to record integrated emissions over a drive cycle. The dilution air is simultaneously sampled into "ambient bags" to account for HCs, CO, and NO_x present in the dilution air.

The CVS approach draws diluent plus exhaust through a choked venturi, thereby creating a constant total flow. Consequently, the dilution ratio varies inversely with engine exhaust flow so that species concentrations in the CVS are proportional to the *fluxes* of emissions exiting the tailpipe. Raw sampling, in contrast, yields the *concentrations* of emissions in the exhaust. This is an important distinction because the CVS approach allows a simple calculation of test averaged emission rates directly from their CVS concentrations collected into Teflon bags,

$$\dot{M}_{x,\text{test}} = \frac{(\overline{C}_{x,\text{CVS}} \cdot V_{\text{CVS}} - \overline{C}_{x,\text{A}} \cdot V_{\text{A}})}{d} \tag{4}$$

where $\dot{M}_{x,\text{test}}$ is the test averaged mass emission rate, d is the distance traveled (in heavy duty testing, it is the energy utilized), $\overline{C}_{x,\text{CVS}}$ is the averaged mass concentration of species x in the sample bag, $\overline{C}_{x,\text{A}}$ is its concentration in the ambient bag, and V_{A} and V_{CVS} are the total volumes of diluent and exhaust plus diluent over the test. When $\overline{C}_{x,\text{CVS}} \gg \overline{C}_{x,\text{A}}$, the diluent volume can be approximated as $V_{\text{A}} = V_{\text{CVS}}\left(1 - \frac{1}{DF}\right)$, where DF is the average dilution factor. At very low emissions levels, *proportional ambient sampling* is used to improve the approximate ambient correction in Equation 4 (Silvis and Chase, 1999).

Dilution tunnels for PM measurement operate in the same manner, except that the engine exhaust must be transported to the upstream end of the tunnel where it mixes with dilution air. This transfer is conventionally done through a stainless steel hose that is insulated and heated to keep water from condensing and corrugated to allow flexibility to accommodate different size vehicles. The transfer hose in most facilities is many meters in length for logistical reasons, which presents a problem for low level emissions measurements because of storage/release artifacts. These arise from material deposited on the transfer hose walls in one test and then released by the exhaust heat of a subsequent vehicle test (Maricq *et al*., 1999). To minimize such artifacts, it is recommended to use an RMT approach also

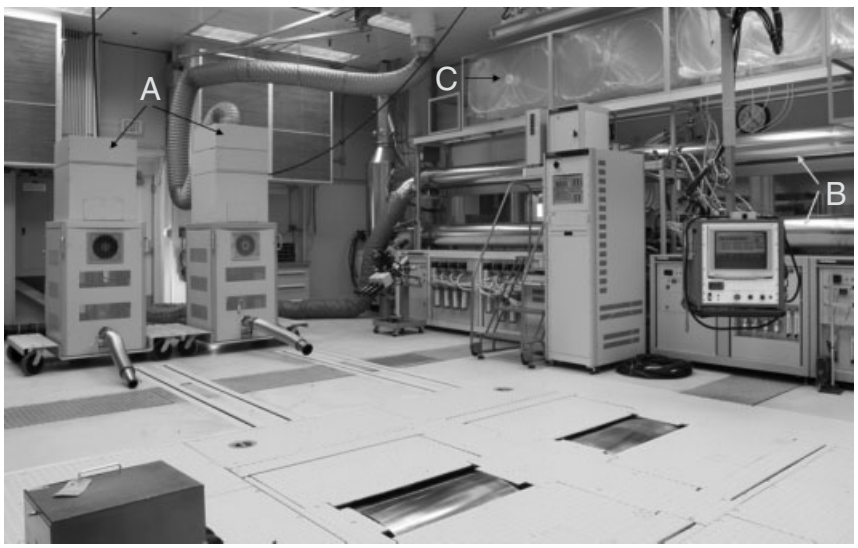

Figure 2. Chassis dynamometer test cell. "A" marks the remote mix "tees" for gasoline and diesel vehicles. "B" denotes the dilution tunnels that run along right-hand wall. And "C" shows the Teflon bags for integrated sampling.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

for dilution tunnel sampling; that is, dilute at the tailpipe with an RMT and deliver diluted exhaust to the tunnel.

As emissions levels continue to fall, it has become progressively more difficult to use the CVS approach as outlined earlier owing to the presence of pollutants in the dilution air. Attention is turning to a modification termed the *bag mini-diluter* (Guenther *et al*., 2000; Sun *et al*., 2005). In this approach, a small portion of the exhaust is sampled, diluted, and proportionally collected into Teflon bags. Proportional sampling implies that bag concentrations of HCs, CO, and NO_x are proportional to their emissions rates. Taking a small sample allows the use of "zero air" as a diluent, eliminating the need of a background correction as in Equation 4 for the ambient bag. A similar approach is feasible for PM measurement, but with the sample collected onto filters instead of into bags (Khalek *et al*., 2002).

2.4 Exhaust flow measurement

Exhaust flow is an important quantity in emissions measurement because it relates the mass per second of emissions exiting the tailpipe to their instantaneous mass concentrations,

$$M_x(t) = C_x(t)\, F_{\text{exh}}(t) \tag{5}$$

where x indicates HC, CO, NO_x, PM, or other species of interest and $F_{\text{exh}}(t)$ is the exhaust volume flow rate. There are two important considerations with respect to Equation 5: first, the concentration and flow measurements must be accurately aligned in time (<1 s) and second, the time response of the instruments recording species x concentration and exhaust flow rate must be comparable. A situation where this becomes problematic is the case of a long transfer hose because the delay time to the dilution tunnel then varies with exhaust flow rate.

Exhaust flow can be measured in a number of ways. Exhaust mass flow can be calculated from measured fuel and air intake rates based on conservation of mass, and the volume flow deduced from the stoichiometry of combustion. This method is often applied in engine dynamometer testing where fuel and air rates are recorded, but is less convenient in vehicle testing. A second approach is via CO_2 tracer. Combustion chemistry, for example, Equation 1, is used to relate CO_2 in the exhaust to the total flow including water vapor and remaining air. This method works well for gasoline engines where stoichiometry maintains a constant ratio between air and fuel. It becomes more problematic for diesel engines and gasoline engines with fuel shutoff, where the air and fuel rates vary independently. A third approach is followed in the CVS method. Here, a subsonic venturi is employed to record the diluent flow, and the difference between this and the constant total flow is equated to the vehicle exhaust flow. This method is preferred for vehicle testing, but requires some refinements for plug-in hybrid testing where the exhaust flow is near zero for extended times (Nevius and Rooney, 2010).

3 EMISSIONS MEASUREMENT METHODS

After emissions are sampled, raw or diluted, they are delivered to various instruments for concentration measurement. Multiple techniques exist for each species, but those used in the majority of emissions test cells include FID for HCs, chemiluminescent detection of NO_x, and NDIR absorption for CO and CO_2 (USEPA, 2011b; CARB, 2011b). Raw measurements require fast time response (1 or 0.1 Hz) and robustness against temperature and contamination. Dilute measurements need higher sensitivity but can trade off lower time resolution for regulatory applications.

3.1 Carbon monoxide and dioxide

Both CO and CO_2 exhibit strong absorptions of mid-infrared (IR) radiation owing to their molecular vibrations. Therefore, light penetrating a sample of these compounds experiences a decrease in intensity characterized by Beer's law,

$$I(\lambda) = I_0 \exp(-C_x \sigma_x(\lambda)\, L) \tag{6}$$

where C_x is the concentration of species x, $\sigma_x(\lambda)$ is its wavelength-dependent absorption cross section, and L is the path length through the sample cell. The optical cross section is a property of the molecule, but varies with pressure and temperature. These conditions and path length are fixed by instrument design, whereby concentration is calculated from light attenuation.

Figure 3 presents a schematic diagram of NDIR detection. Broadband IR radiation is produced by Globar, a small electrically heated SiC rod. The light is chopped

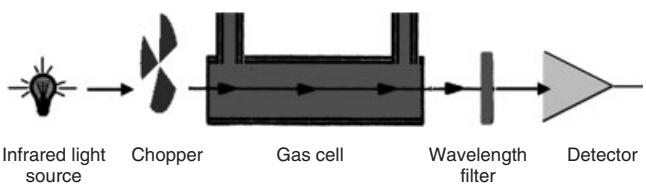

Figure 3. Schematic diagram of nondispersive infrared monitor. Various fixed wavelength filters are chosen to monitor CO, CO_2, N_2O, and other infrared active gases.

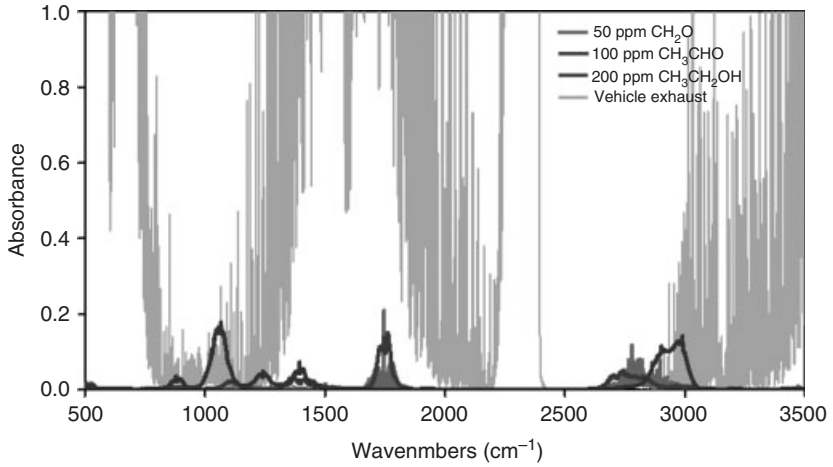

Figure 4. Infrared spectrum of a vehicle exhaust sample compared to reference spectra of ethanol, formaldehyde, and acetaldehyde, at concentrations expected for engine operation with ethanol-blended gasoline.

to take advantage of the lower electronic noise associated with AC detection. It passes through the sample cell and a wavelength-dependent filter and impinges on a pyroelectric or semiconductor detector. The wavelength-selective filter is chosen to optimize absorption by the compound of interest while minimizing interference from other compounds, CO_2, H_2O, and other emissions.

NDIR is generally limited to CO and CO_2 in vehicle emissions because of their relatively high concentrations and strong IR absorptions. Figure 4 illustrates why. It displays the IR spectra of formaldehyde, acetaldehyde, and ethanol at levels typical for gasoline engines using ethanol-blended fuels. Not only is IR absorption by these compounds swamped by CO_2 and water vapor, but they interfere with each other as well. In Section 4, we discuss the use of FTIR spectroscopy for emissions measurement, a dispersive method that provides substantially superior selectivity.

3.2 Hydrocarbons

Flame ionization provides a sensitive means to detect organic molecules (Sternberg, Gallaway, and Jones, 1962). The principle is illustrated in Figure 5. The sample is introduced into a hydrogen flame. Of the many high temperature reactions that occur as the material in the sample combusts, some produce ions and electrons (e.g., $CH + O \rightarrow CHO^+ + e^-$). These are collected in an electric field and recorded by a picoammeter.

The sensitivity of the FID to various organic compounds varies. For HCs, it acts similarly to a carbon counter; the relative response factor scales with carbon number, $RF = \alpha N_C$. As a result, HC concentrations are often expressed

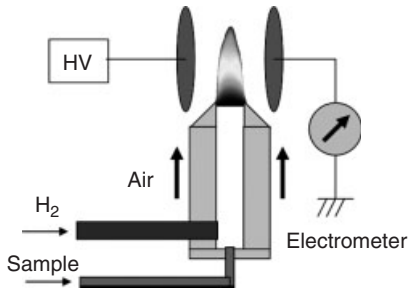

Figure 5. Schematic illustration of a flame ionization detector.

as parts per million carbon (ppmC), but sometimes they are reported as parts per million propane equivalent. At high concentrations, the FID can underestimate HC content as a result of the loss of signal due to ion recombination reactions. However, good design can achieve linearity over four orders of magnitude in concentration as well as millisecond time response (Cheng, Summers, and Collings, 1998).

Oxygenated compounds generally display a reduced FID response. FID response is negligible in the case of CO and CO_2, which is a benefit for engine exhaust applications, and also for carbonyl carbons in aldehydes, ketones, and esters. In the case of alcohols, the carbon with the OH group registers with a relative response of 40–75%, depending on the type of alcohol. For FID of specific organic compounds, such as in gas chromatography, it is possible to define effective carbon numbers (Scanion and Willis, 1985) and to calculate individual response factors from molecular structure and combustion enthalpies (Jorgensen, Picel, and Stamoudis, 1990; de Saint Laumer *et al.*, 2010). This does not apply to exhaust emissions measurements, which typically do not speciate HCs; thus,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

either additional measurements or empirical corrections are needed when testing with oxygenated fuels.

The presence of oxygen influences flame temperature and chemistry and, therefore, ion formation. Use of a hydrogen/helium mixture, usually 40/60, reduces the interference. It can be further compensated for through calibration. Spanning the FID against a known concentration of propane in nitrogen accounts for the lack of oxygen in gasoline vehicle exhaust, whereas for diesel emissions one can calibrate against propane in air.

Regulations call for measurement of non-methane hydrocarbons (NMHCs) and non-methane organic gases (NMOG). The former is accomplished by splitting the exhaust sample. Part is introduced directly into the FID to determine total HCs. The other portion first passes over a heated metal oxide catalyst that oxidizes the NMHCs, but not the relatively unreactive methane. The NMHC concentration is then found by subtraction. If oxygenated compounds are present, for example, gasoline engines run with ethanol/gasoline blends, they are underestimated by FID. For gasoline and low level blends (0–20%), the effect is small and can be accounted for by a correction factor, NMOG $= \alpha$ NHMC, where $\alpha = 1.03$ for gasoline and 1.1 for 10% ethanol.

3.3 Nitrogen oxides

3.3.1 Chemiluminescence analyzer

Chemiluminescence provides a very sensitive means to detect NO. It is based on the fact that when NO reacts with ozone to produce NO_2, a fraction of this product is electronically excited (indicated by the asterisk) (Clough and Thrush, 1967),

$$NO + O_3 \rightarrow NO_2 + O_2 \tag{7a}$$

$$\rightarrow NO_2{}^* + O_2 \tag{7b}$$

Some of these excited molecules are quenched by collisions with other molecules (Equation 8a); however, the rest emit light in the 600- to 3000-nm wavelength range (Equation 8b). To reduce possible interferences, the detected light is generally restricted with a filter to the 300- to 900-nm range.

$$NO_2{}^* + M \rightarrow NO_2 + M \tag{8a}$$

$$NO_2{}^* \rightarrow NO_2 + h\nu \tag{8b}$$

In practice, the linearity of chemiluminescent detection depends on a number of factors (Zabielski, Seery, and Dodge, 1984). First, the light intensity is a function of the production rate of $NO_2{}^*$ in Equation 7b. This is handled by using an excess of O_3 to create pseudo-first-order kinetic conditions, and using a capillary, critical orifice, or mass flow controller to regulate its flow rate. Second, the intensity of emitted light results from a competition between emission and quenching (Equations 8a and 8b) that depends on both the number density and chemical nature of the species present in the detector (Matthews, Sawyer, and Schefer, 1977). CO_2 and H_2O are more efficient quenchers than the N_2 and O_2 in air; therefore, an increasing presence of these in the exhaust sample can lead to underestimation of NO_x. These factors are mitigated by design and compensated for by calibration.

Other nitrogen compounds, NO_2 and NH_3, can also be monitored by chemiluminescence after first converting them to NO. It is possible to do this thermally (Sigsby *et al*., 1973), but usually a metal reactant is included to reduce the necessary operating temperature; for example,

$$3NO_2 + Mo \rightarrow 3NO + MoO_3 \tag{9}$$

Pretreatement of an exhaust sample via Equation 9 thus yields the NO_x concentration, whereas the NO_2 level is found by subtraction of the NO concentration measured without pretreatment. While ammonia can be measured by first oxidizing it to NO, its presence in engine exhaust interferes with the NO_x measurements. This interference can be eliminated by scrubbing NH_3 from the exhaust sample using filters treated with phosphoric acid (Shah *et al*., 2007).

3.3.2 Nondispersive UV

Recently, there has been an increased interest in nondispersive ultraviolet (UV) detection of NO_x owing to the inconvenience of chemiluminescence detectors for portable emissions measurement systems (PEMSs). The method follows the same principle as illustrated for NDIR in Figure 3, except for the use of a UV lamp and a detector. Both NO and NO_2 absorb in the UV, but NO has relatively sharp absorption lines. This allows it to be distinguished from NO_2 as well as from aromatic and unsaturated HCs that also exhibit UV absorption.

3.4 Particulate matter

3.4.1 Smoke meter

PM has traditionally been recorded by smoke meter in engine testing applications and gravimetrically in the regulatory method for vehicle exhaust measurement. The smoke

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

meter is a type of opacity meter that operates on the principle that soot decreases the transmission and reflection of light. It therefore measures the soot component of PM as opposed to the total PM. A filter-based smoke meter operates by drawing exhaust through a paper filter. As soot collects, it darkens the filter causing a reduction in its reflectivity. This reduction is converted into a smoke number (0–10 scale) by

$$SN = 10\left(1 - \frac{I}{I_{\text{clean}}}\right) \tag{10}$$

where I is the reflected light intensity from the blackened filter and I_{clean} is the reflected intensity from a clean filter. While this describes the basic principle, a variety of implementations exist and there are numerous conventions for defining *SN*. Converting *SN* to soot mass emissions is not straightforward as it depends on the nature of the soot, in particular, its optical properties. Further information on smoke number conventions and conversions is available from Homan (1985). Its slow time response and low sensitivity limits the use of the present-day smoke meter for steady-state engine-out measurements. However, its robustness against high soot levels makes the smoke meter a good choice in applications with high PM emissions.

3.4.2 *Gravimetric mass*

Regulatory methods stipulate a mass-based measurement of PM. The current practice is to direct the vehicle's exhaust (or engine's) into a CVS dilution tunnel, sample a fraction of the diluted exhaust through a filter (47 mm diameter, 2 μm pore size; Teflon membrane recommended over Teflon-coated glass fiber), and record the mass increase from the difference in pre and post-test filter weight. PM is a mixture of solid (soot and ash) and semivolatile materials (heavy HCs and sulfuric acid) that can vary depending on the engine, vehicle, and fuel. There is no calibration standard for PM; rather, the regulatory method operationally defines PM.

The lowering of US PM emissions standards in 2007 to 10 mg/mi for light-duty vehicles and 10 mg/hphr for heavy-duty engines, and an equivalent tightening of the mass standards in Europe and Japan, have necessitated substantial refinement of the gravimetric method. At these low emissions rates, less than 100 μg PM collects on the filter, which amounts to a few hundred parts per million change in filter weight. Regulations require the use of a 0.1-μg resolution balance to weigh the filters. At this sensitivity, temperature, humidity, air flow, ambient pressure, and static charge significantly impact balance performance. To reduce these impacts, weighing must be performed in a temperature- and humidity-controlled enclosure (e.g., $22.8 \pm 0.6^{\circ}$C, $50 \pm 1\%$ relative humidity, and $4\frac{1}{2}$ changes of HEPA-filtered low velocity air). The weighing is buoyancy corrected to account for any pre to post-test atmospheric pressure change. Moreover, the filters must be neutralized (using radioactive or corona bipolar ionizers) to reduce static charge, a particularly important step for Teflon filters (Chase *et al*., 2005).

As partitioning of semivolatile material between gas and particle phases depends on sampling conditions (temperature, dilution, ratio, and dilution rate), these are now specified in recent revisions to the regulatory PM method (USEPA, 2011b) in efforts to reduce PM measurement variability; for example, filter temperature is confined to $47 \pm 5^{\circ}$C. At the upcoming 3 mg/mi LEV III and Tier 3 standards, the sampling and weighing improvements remain inadequate. The amounts of PM collected are now so low that gaseous adsorption onto the filter media presents a sizable interference (Chase *et al*., 2004). This is illustrated in Figure 6 by post-DPF light-duty diesel exhaust PM recorded onto back-to-back Teflon filters. The primary and secondary filters show comparable weight gains, although they should differ by a factor of 100, as by design filter efficiency is >99%. Therefore, the secondary filter weight gain is attributed to gaseous adsorption. This implies a comparable gaseous adsorption onto the primary filter; thus, in Figure 6, the net PM in the exhaust is essentially zero. There are ongoing efforts to improve this situation, but applicability of the present gravimetric filter method becomes progressively more limited below 3 mg/mi (or 3 mg/hphr).

3.5 Greenhouse gas emissions

Owing to global warming concerns, greenhouse gas emissions from engines and vehicles have recently come under scrutiny (USEPA, 2011c). Compounds of significance to combustion engines include CO_2, CH_4, and N_2O. Water vapor is not included because its contribution to the greenhouse effect is already saturated. CO_2 and CH_4 are of interest for fuel economy and HC emissions reasons; therefore, their measurement is standard test cell procedure, as described earlier. N_2O is not produced during combustion; rather, it is a byproduct of incomplete NO_x reduction in catalyst aftertreatment systems. For model year 2012 and beyond, light-duty vehicle CH_4 and N_2O emissions will be capped at 0.030 and 0.010 g/mi, respectively (USEPA, 2011c).

There are a number of approaches to N_2O measurement, all variants based on the absorption of IR radiation. The standard method employs NDIR, as illustrated in Figure 3 and described earlier, for detection of CO and CO_2. This

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

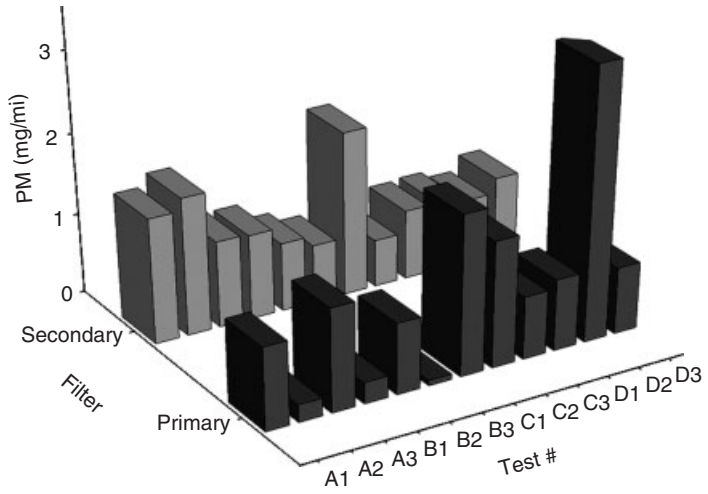

Figure 6. Demonstration of gaseous artifact at low level PM emissions. Back-to-back Teflon filters show comparable weight gains in post-DPF measurement of diesel PM emissions, even though filters are >99% efficient at collection PM.

method applies in principle to N_2O as well, but its exhaust concentrations are lower and spectral interferences are more problematic than for CO and CO_2. A version of this approach has recently been introduced, which uses photoacoustic detection. Absorption of a chopped IR beam by N_2O causes modulated heating of the exhaust sample, and this creates pressure waves that are detected by a microphone. This provides a sensitive means of detection, but it remains limited by the same spectral interferences as NDIR. Two better approaches, FTIR and laser spectroscopy, are described in Section 4.

4 ADVANCED METHODS OF EMISSIONS MEASUREMENT

The instruments described earlier have been improved and optimized for combustion applications over the years to where they are now standard equipment in emissions test cells. They are aimed at regulated emissions, whereas engine exhaust is, in reality, more complex. For research purposes, when developing new combustion concepts or aftertreatment systems, the ability to characterize the exhaust in more detail is valuable. This section describes some spectroscopic and aerosol tools that can provide this detail and are finding increased use in emissions testing.

4.1 Gaseous emissions

4.1.1 Fourier transform infrared spectroscopy

NDIR is a nondispersive optical technique that does not make full use of the wavelength-dependent nature of molecular absorption. In contrast, FTIR spectroscopy does; it records the entire mid-IR spectrum of radiation absorption, usually from 500 to 3500 cm^{-1} (inverse wavelength). Butler *et al.* (1981) first took advantage of this approach to measure engine emissions 30 years ago. Since then, there have been many instrumental improvements so that presently available spectrometers can sample raw exhaust and record emissions concentrations at 5 Hz time resolution.

A schematic diagram of FTIR operation is presented in Figure 7. It is similar to the NDIR approach, except that it replaces the fixed wavelength filter with a Michelson interferometer. IR radiation passes through the sample cell and is split into two beams: one reflects from a fixed mirror and the other from a movable mirror. When these beams are recombined, they interfere with each other in a way that depends on wavelength and path length difference.

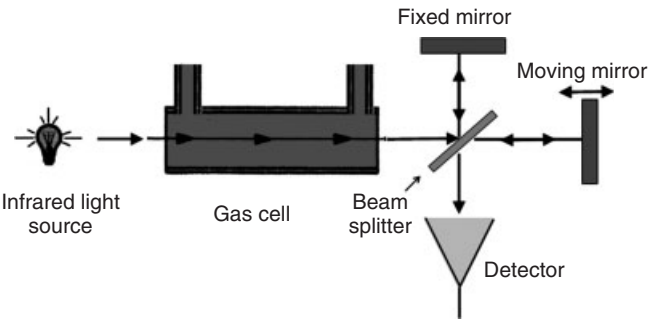

Figure 7. Schematic diagram of Fourier transform infrared spectrometer. Scanning the movable mirror generates an interferogram, the Fourier transform of which yields the infrared spectrum.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

This interference is recorded as a function of path length difference to yield an interferogram. Fourier transform of the interferogram gives the frequency spectrum of radiation transmitted through the cell, $I(\lambda)$. Comparing this spectrum with that of the empty cell, $I_0(\lambda)$, and using Beer's law, Equation 6, yields the IR absorbance of the sample, $A(\lambda) = \ln[I_0(\lambda)/I(\lambda)]$; an example is illustrated in Figure 4.

Atomic composition and bond strengths vary from one molecular species to another; thus, molecules exhibit characteristic vibrational frequencies that give each species its own IR "fingerprint." The idea then is to take the IR absorbance spectrum of an unknown mixture, such as an engine exhaust sample, and deconstruct it into a superposition of individual molecular fingerprints [i.e., their IR absorption cross sections $\sigma_i(\lambda)$],

$$A(\lambda, t) = L \sum_i C_i(t)\, \sigma_i(\lambda) \tag{11}$$

where L is the optical path length. An obvious benefit of this approach is the ability to determine from a single measurement the concentrations of a great number of exhaust constituents, $C_i(t)$. A second, less obvious, benefit is that the spectroscopic method does not need calibration or spanning. Because absorbance is determined as the ratio of two light intensities, neither the strength of the light source nor the sensitivity of the detector enters the calculation. In effect, the only "calibration" necessary is the wavelength-dependent IR cross section of each species, which is a property of the molecule and not the experimental apparatus.

The apparent simplicity of Equation 11 belies a number of technical details that must be carefully addressed to make reliable measurements by FTIR (Gierczak *et al.*, 1991). First, it is necessary to collect a library of reference spectra, $\sigma_i(\lambda)$, relevant to engine exhaust. This includes H_2O, CO_2, CO, NO, NO_2, N_2O, HNO_3, NH_3, SO_2, SO_3, H_2SO_4, H_2S, HCHO, CH_4, and a host of other organic compounds. The list depends on engine technology (diesel, gasoline, and two-stroke) and on fuel (gasoline, ethanol blends, diesel, biodiesel, and natural gas) because of differences in exhaust composition. Furthermore, the reference spectra of these molecules depend on temperature and pressure. Temperature affects the extent to which the molecules rotate, which changes the vibrational lineshapes. Pressure determines the rate of molecular collision which in turn causes line broadening. Therefore, the reference spectra must be recorded at the same temperature and pressure as used for the exhaust measurements.

Fitting the entire IR spectrum of an exhaust sample to the library of exhaust species is computationally intensive and it is difficult to ensure that the fitting procedure finds a global best fit instead of a local minimum. In practice, one selects a set of compounds to be measured and identifies for each compound a spectral region, or regions, where it can be best monitored with the least inference from other exhaust species, a process called *masking*. The choice of regions depends on engine technology and fuel; a region free from interferences in one case may not remain so in another. As an example, the regions near 1050 and 2800 cm^{-1} in Figure 4 can be used to monitor ethanol, formaldehyde, and acetaldehyde in the emissions from gasoline engines run with ethanol-blended fuels. Much in the art of FTIR emissions measurements lies in choosing these regions and recognizing anomalous results that contradict the choice when these occur. When this is done successfully, FTIR provides a powerful tool for engine exhaust analysis.

4.1.2 *Laser spectroscopy*

The advent of tunable IR lasers (Pb-salt and quantum cascade laser) opens up the possibility of highly selective detection of CO, CH_4, HCHO, NO, NO_2, N_2O, NH_3, and numerous other small molecules. These lasers have very high spectral resolution and sufficient sensitivity to allow operation of the sample cell at subambient pressure. Lower pressure reduces broadening of the IR absorption lines and enables identification of absorption features specific to one compound and free from interference by other exhaust species. Unlike the FTIR, these laser-based methods do not record a broad spectrum, so that multiple lasers, or lasers that can rapidly hop from one spectral line to another ($<$0.1 s), are needed for simultaneous detection of multiple pollutants.

4.2 Aerosol methods for PM

4.2.1 *PM characterization*

Mass measurement of PM, as required by regulations, represents a one-dimensional metric of what is a complex substance. PM is a heterogeneous material both in terms of its physical (solid and liquid) and chemical (soot, ash, sulfate, and organic) properties. The constituents of motor vehicle PM have various origins. Soot and ash form as byproducts during combustion. Sulfate is converted from SO_2 by oxidation in the catalytic converter, whereas HCs are mostly removed by the catalyst. Some remaining HCs and sulfate condense on the internally mixed soot and ash particles as they cool in the exhaust system. Further cooling as the exhaust exits the tailpipe and mixes in the atmosphere can lead to nucleation of new particles, often

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto142
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

promoted by the presence of sulfate (Keskinen and Rönkkö, 2010).

A variety of aerosol tools exist to interrogate the nature of exhaust PM. Particle size is the most common attribute examined. The definition of size is clear for spherical droplets, but not so straightforward for agglomerates such as soot. In this case, size is based on the concept of equivalent diameter; that is, if a particle follows the same behavior as a spherical particle of diameter d, then it is assigned that diameter. There are many possible choices for equivalent diameter, but two common ones are aerodynamic and mobility. Aerodynamic diameter, d_a, is a measure of a particle's ability to follow flow streamlines. This depends on both the particle's size and mass, and so is referenced to unit density spheres. Mobility diameter, d_m, relates to a particle's diffusion rate, and is mass independent. Aerodynamic size distributions can be measured using cascade impactors; the electrical low pressure impactor (ELPI) combines this with electrical detection to provide transient measurement capability (Marjamäki *et al*., 2000). The scanning mobility particle sizer (SMPS) represents a preeminent tool to record mobility equivalent size distributions. Particles are first brought to a well-defined bipolar Boltzmann charge distribution and then passed through a cylindrical electric field. Those within a narrow range of electrical mobility exit into a condensation particle counter (CPC). In this case, size distributions are recorded by scanning the electric field; therefore, this method applies to steady-state engine operation. Transient capability has been achieved by arranging the cylindrical electric field as a stack of rings and recording the currents that arise on each disk as particles segregated by the field deposit (Reavell, Hands, and Collings, 2002).

Size distribution measurements often show that combustion exhaust PM is bimodal. The mode of larger particles (accumulation mode) is associated with soot formed in the engine, perhaps with some condensed semivolatile material. It is lognormal in shape, with a geometric mean mobility diameter typically between 50 and 80 nm and a universal geometric standard deviation of 1.6–1.8. The smaller (nucleation) mode generally lies below 20 nm, but at high concentrations can appear at larger size owing to growth by coagulation. If the diluted exhaust sample is heated in a thermodenuder before size measurement, the nucleation mode disappears in the majority of cases, indicating that these particles are semivolatile (organic and sulfate).

In this method, particles are distinguished as soot plus condensed HCs versus nucleated organics plus sulfate. They can instead be analyzed for elemental carbon (EC) versus organic carbon (OC). To accomplish this, PM is collected onto quartz filters. But instead of weighing, the filters are thermally analyzed, first in an inert atmosphere to desorb organic material, and then in an oxygen atmosphere to oxidize soot (Chow *et al*., 2001). Both the desorbed organic material and soot are converted to CO_2 for NDIR detection, or further to CH_4 and recorded by FID.

Tandem measurements open a wealth of possibilities for deeper investigation into particle properties (Park *et al*., 2008). Examples include particle volatility and effective density. In each case, a differential mobility analyzer selects particles of a certain mobility diameter. Particle volatility can be examined by passing these through a heat pipe and remeasuring their size (Sakurai *et al*., 2003). In this way, one learns how the EC/OC composition varies with particle size. Particle effective density can be determined by taking the mobility diameter-selected particles and measuring their aerodynamic diameter (Maricq and Xu, 2004) or mass (Park *et al*., 2003). The effective density differs from the intrinsic material density in that it averages both the material and the voids that exist when one describes fractal-like particle morphologies in terms of equivalent spheres. For soot, it varies approximately as

$$\rho_e = \rho_0 \left(\frac{d_m}{d_0} \right)^{(D_f - 3)} \tag{12}$$

where $\rho_0 = \sim 1.8\ \mathrm{g/cm^3}$ is the soot intrinsic material density, $d_0 = \sim 20\ \mathrm{nm}$ is the primary particle diameter, and $D_f = \sim 2.3$ is the mobility fractal dimension (Maricq and Xu, 2004).

4.2.2 *Solid particle counting*

The European Union has recently introduced a solid particle number standard as a regulatory requirement in addition to particulate mass (UNECE, 2011). The main impetus for this was to enforce adoption of DPF technology to reduce soot emissions. It differs from the conventional PM mass regulation in two important ways: replacement of mass with a number metric and the stipulation of solid as opposed to total PM. The latter is by necessity because particle count is very sensitive to variations in nucleation mode particles from test to test and test site to test site. But it is a positive step, as this decision recognizes that all PM is not alike.

The solid particle counting method is illustrated in Figure 8 and described in the review by Giechaskiel *et al*. (2012). As with PM mass measurement, vehicle exhaust is directed into a dilution tunnel. A sample from the dilution tunnel is further diluted in a heated diluter and then passed through a heated residence chamber (~350°C), the volatile particle remover (VPR). Besides eliminating liquid particles, this also evaporates condensed semivolatile

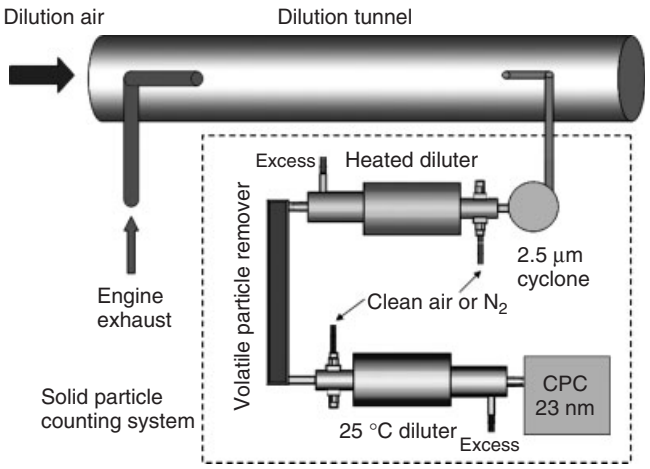

Figure 8. European Union PMP (Particle Measurement Program) method for solid particle counting.

material from soot particles, but this evaporation does not affect solid particle number. The sample is then cooled by dilution to room temperature. Gaseous concentrations at this point are too low for renucleation to occur, so a CPC registers solid particles.

This approach is very sensitive; it can record PM emissions at mass rates equivalent to <0.1 mg/mi. However, it requires significant care. The CPC needs to be calibrated against an electrometer to account for its size-dependent counting efficiency. Corrections must be made for size-dependent particle losses through the VPR. It is, however, not a unique means to record solid exhaust PM. The photoacoustic soot sensor (Schindler *et al.*, 2004) also records the solid PM component of engine exhaust PM. The principle is the same as for the detection of gases. Modulated light is absorbed by soot (but not by semivolatile droplets) and converted to heat, which generates pressure waves detected by a microphone. Interestingly, photoacoustic measurements of motor vehicle soot mass correlate well with solid particle counts (Kirchner, Vogt, and Maricq, 2010) owing to the limited variability in the mean sizes and widths of soot size distributions observed in motor vehicle exhaust.

5 CONCLUSIONS AND OUTLOOK FOR THE FUTURE

Owing to regulatory requirements and reasons of corporate stewardship, engine exhaust emissions have joined performance, fuel economy, and safety as a central attribute in engine and vehicle design. Over the years, the scope has broadened considerably. Emissions regulations now apply to light-duty vehicles, heavy-duty on-road vehicles, off-road machinery, locomotives, ships, aircraft, snow mobiles, and small engines such as those found in lawn mowers and weed whackers. The principle species of CO_2, CO, HCs, and NO_x have been joined by HCHO, NH_3, N_2O, particle number, and more generally by the list of compounds associated with air toxics. Heavy-duty engine testing has evolved to include transient operation in addition to the conventional steady-state test points. Light-duty testing has seen additions of aggressive driving cycles and air conditioner cycles. Test procedures have been evolving to keep pace with tightening emissions stringencies.

The basic methods used to measure the standard emissions have largely remained the same: NDIR for CO and CO_2, FID for HCs and CH_4, and chemiluminescence for NO_x. However, the sensitivity of these instruments has increased 100-fold. In addition, many new measurement methods have been developed. One is the use of FTIR to simultaneously measure a variety of exhaust gas emissions. Second is the use of highly selective and sensitive laser-based optical instruments to measure NO, NO_2, NH_3, N_2O, and a growing list of other compounds. Third is the introduction of instruments such as the Dekati Mass Monitor and photoacoustic soot sensor to measure second-by-second PM emissions. More important, but perhaps less appreciated, are the changes that have occurred in sampling. As emissions levels have fallen, more care has been required in the sampling and dilution processes. Proportional ambient sampling was introduced to better account for pollutants present in the dilution air. New filter handling and weigh room procedures were introduced to improve PM measurement capability. At even lower emissions levels, one will need to utilize bag mini-diluters or partial flow dilution to record accurate data.

The challenges in emissions measurement are not abating. Impending next generation LEV III and Tier 3 regulations in the United States and Stage VI and VII regulations in the European Union are adding additional challenges to efforts aimed at fuel economy and greenhouse gas improvements. As other countries in Asia-Pacific, South America, and elsewhere are adopting emissions regulations, discussions have begun on world harmonized test procedures. The desire to understand real-world emissions and ensure that regulated emissions levels are maintained under real-world conditions has driven the development of on-board PEMSs, so that emissions testing is no longer confined to test cells. These and other activities ensure that emissions measurement will remain a vibrant and important field for some time to come.

1 INTRODUCTION

Current and future combustion engine development targets a considerable reduction in fuel consumption and emissions to meet strict emission legislation despite steady or increasing customer comfort and performance demands. Additionally, reduced time to market is required despite increasing variations in customer demands and fuel qualities in worldwide markets. It can also be observed that the fuel consumption, or equivalently CO_2, has already been reduced significantly over the last decade (Figure 1).

In the European Union (EU), a vehicle-weight-dependent CO_2 emission limit of 130 g per km at a base vehicle weight of 1372 kg has been set for 2012 with increasing penalties until 95 € per g CO_2 per km. For 2020, the intention is to reduce this limit to 95 g per km (European Union, 2009a, b). A comparison of the limit for 2012 in the EU with the CO_2 emissions in the new European driving cycle (NEDC) for gasoline and gasoline hybrid passenger cars licensed in 2011 shows that only the best in class cars in the small and the lower middle sized segment meet the targets (Figure 2). For 2020, further fuel consumption reductions of >30% are necessary to fulfill the requirements. In the United States, a 12% fuel consumption reduction is required between 2012 and 2016 (Environmental Protection Agency and Department of Transportation, 2010), which follows a similar trend as Europe.

To achieve these limits, gasoline engines have made progress in efficiency through the introduction of technologies such as direct injection (DI) in combination with downsizing and turbo- or supercharging, variable valve trains, and a variety of additional measures to reduce friction losses such as electrification of accessories.

The high specific power of modern engines indicates the rising degree of downsizing (Figure 3). Without any additional measures, downsizing would lead to lower maximum power output contrary to customer's demands. Consequently, reasonable downsizing concepts provide high power density and correspondingly high specific power.

Higher power output can be achieved by either increased engine speed or higher load. While increased engine speed would lead to rising friction losses, current and future downsizing concepts use boosting or electrification to ensure the required reserve torque. The potential fuel benefits of highly boosted downsized engines compared to natural aspirated engines with equal power output amount to 10–30% (Golloch, 2005). The rising model share of boosted gasoline engines in Europe substantiates the boosting/downsizing trend (Figure 4). It can be assumed that this trend will be followed by the United States and other markets as well.

The higher the degree of downsizing, the higher is the negative effect of turbocharging on engine dynamics during transient operation (turbo lag, see Intake Boosting). Current engine development shows different ways to improve the transient response, as there are advanced charging technologies such as twin-scroll, two-stage turbocharging, or variable turbine geometries. Turbocharging in combination with variable valve timing (VVT) or lift can also improve the engine's transient behavior. Despite the higher costs, these technologies are already in use in all vehicle classes. Supercharging in combination with variable valve lift and DI enables scavenging and thereby an improved low-end torque (Figure 5). Current variable valve lift systems reach fuel consumption benefits of up to 10% by reducing throttling losses and controlling residual gas fraction. For engines with six or more cylinders, cylinder deactivation

can reduce fuel consumption by up to 18% in part load operation.

High supercharging leads to an increased propensity for preignition and irregular combustion (knocking). Owing to that, the degree of downsizing is limited. However, a high compression ratio (CR) is necessary for best efficiency. The adaption of DI on gasoline engines has helped lower the knock tendency and increase the CR by 1 to 1.5 units, thereby reducing the fuel consumption by up to 4% at part load operating points (Figure 6). The high CR of current gasoline engines indicates the rising share of DI (Figure 7).

Moreover, new concepts with variable CR promise further improvement regarding knock tendency and an increased fuel efficiency. Hereby, the investigations of variable CR focus especially on reducing complexity and costs while increasing usability and durability.

Another advantage of DI is the lean engine operation with stratified charge. Wall- or air-guided injection has already been used in series production vehicles since 1997. In 2006, spray-guided combustion systems with high pressure injection (200 bar) and multihole injector tips for fuel metering went into production, which improved stratification and thereby gaining fuel consumption benefits.

So far, lean engine operation is limited by reduced ignitability of the diluted air fuel mixture. Conventional ignition systems fail at local air fuel ratios higher than 22 ($\lambda > 1.5$). One solution to raise this limit and simultaneously decrease cyclic combustion variations is provided by a scavenged prechamber ignition or the corona ignition system. Contrary to the conventional local ignition, the spark corona ignition systems generate a significantly larger, intense plasma ignition source, which spreads throughout the combustion chamber.

For conventional stoichiometric-operated combustion engines, the three-way catalyst (see Gas Aftertreatment Systems) is the most commonly used for the simultaneous reduction of HC, CO, and NO_x. In lean engine operation, HC and CO are still converted by the three-way catalyst, whereas for the reduction of NO_x, additional aftertreatment technologies, such as SCR systems or NO_x storage catalysts (see Gas Aftertreatment Systems), have to be applied. With the upcoming legislation for exhaust emissions (EU6), the particulate number will be limited for DI gasoline engines. Current series production engines show that the first phase-in limit of 6×10^{12} # per km in 2015 can be achieved by optimized combustion systems. To meet the particle number limit of 6×10^{11} # per km starting 2018, DI engines might need a gasoline particulate filter (GPF) (European Union, 2011).

A further measure to reduce CO_2 and other emissions are alternative fuels using, for example, alcohol blending. Ethanol is most likely the short-term solution for gasoline engines. For 2020, the target for the overall use of renewable energies within the transportation sector is set to 10% in the European Directive 2009/28/EC.

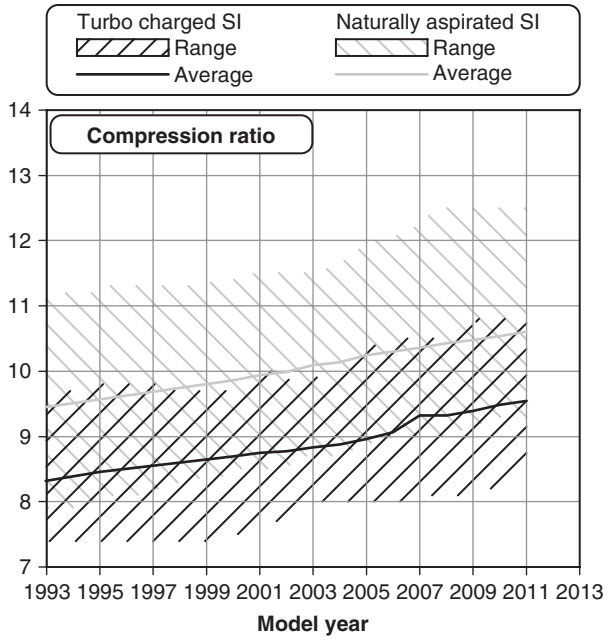

Figure 7. Trend compression ratio (FEV GmbH, 2011). (Reproduced by permission of FEV GmbH.)

In addition to these technologies, a further improvement in fuel consumption of up to 10% is possible through reduced friction losses (see Lubrication and Friction) and using advanced thermal management (see Engine Thermal Management). High potential to reduce friction losses is assigned to variable auxiliary drives such as variable oil or water pumps. The engine itself can be optimized regarding friction either by design or by material. Additionally, current research examines new coatings or fuel additives for further friction reductions.

The following example gives an impression of how a reasonable combination of the beneficial measures mentioned above can reduce CO_2 emissions and improve fuel efficiency. Assuming a 1.6-L I4 natural aspirating port fuel injection (PFI) engine with intake and exhaust cam phasing as a baseline (with relative CO_2 emissions defined as 100%), applying DI can already gain 2% CO_2 reduction (Figure 8). In combination with variable valve lift, a further 6.5% reduction is possible. Replacing this engine by a 1.0-L I3 boosted engine with equal performance gains a 12% fuel consumption benefit. Using additional measures such as external exhaust gas recirculation (EGR), variable CR, optimized thermal management, and friction reduction, a total CO_2 reduction of 27% can be achieved. Optimized automatic transmissions (see Engine/Transmission Matching) and hybridization (see Overview of Electric, Hybrid and Fuel Cell Vehicles) are necessary to achieve a reduction of >30% and meet the future emission targets mentioned above. As shown in Figure 8, measures to reduce CO_2 emissions come along with additional costs relative to the baseline, which have to be considered in the context of possible penalty payments for not meeting CO_2 fleet emissions.

2 DOWNSIZING AND DOWNSPEEDING

Currently, downsized gasoline engine concepts combined with boosting, gasoline DI, and VVT provide the major directions for meeting the desired fleet fuel economy targets. By increasing the engine load, downsized engines are operated with reduced specific fuel consumption. Thus, fuel efficiency can be improved by up to 15% for the "NEDC" (Weinowski *et al*., 2010). In addition to downsizing, lower piston velocities resulting from downspeeding lead to lower friction losses and thereby lower specific fuel consumption.

To maintain the power output equal to current natural aspirated engines, boosting technologies are applied to downsized engines (Alt *et al*., 2001; Brinkmann, Pingen, and Walder, 2003; Bormann *et al*., 2009). When the same power output is demanded, the engine load of the downsized engine is increased. Thus, the engine operation point is shifted to more efficient engine operating conditions. The de-throttling allowed by downsizing leads to reduced gas

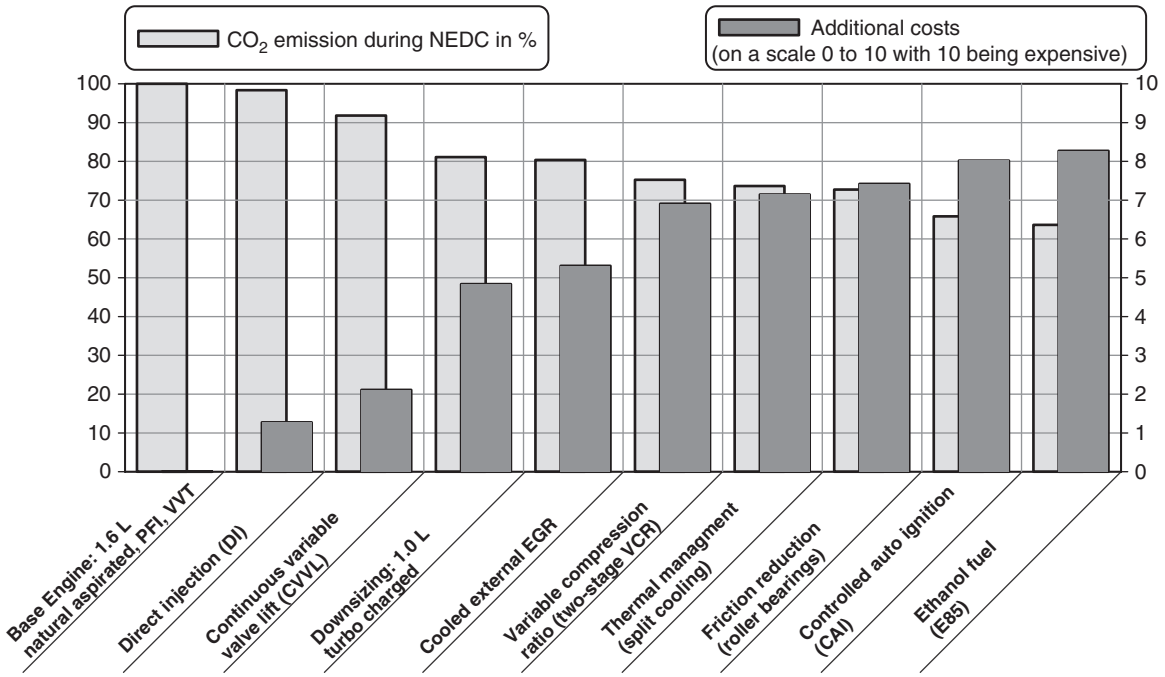

Figure 8. Measures to reduce CO_2 emissions contrary to additional costs.

exchange losses and reduced friction. Therefore, the overall engine efficiency is improved. The comparison of a conventional 1.4 L, NA engine, and a 0.7 L turbocharged engine, featuring gasoline DI and independent intake and exhaust cam phasing for NEDC is shown in Figure 9.

Downsized engine concepts demand a lower engine displacement, which can be achieved with a reduced number of cylinders. For the small vehicle class (800–1200 kg), the current state-of-the-art four-cylinder engine will be substituted in the future by three or even two cylinder engines, as shown in Figure 10.

Possible measures for a further displacement reduction are bore diameter and stroke. Decreasing the stroke alone is not preferred for downsized engine concepts, because it significantly determines the overall engine efficiency. Rather, an increased piston stroke is used, which results in a decreased surface to volume ratio. This in turn results in a more compact combustion chamber layout and thereby reduced heat losses to the wall (Gand, 1986; Bick, 1990). Furthermore, the elongated piston stroke enables an improved and intensified in-cylinder charge motion during intake stroke (Pischinger *et al*., 2001). Regarding the thermal load of internal combustion engines, small bore diameters are advantageous as well. Thus, the difference in wall temperature between the coolant and the combustion chamber and thereby the mechanical stresses due to thermal load is decreased. A smaller bore diameter also leads to reduced flame zones and thereby reduced burn delay and burn duration (Sterlepper, 1992). The losses due to incomplete combustion can also be diminished (Gand, 1986; Bick, 1990; Pischinger *et al*., 2001). While decreasing diameter has the above-mentioned benefits, challenges such as a rising oil dilution do arise when significantly reduced bore diameters below ~70 mm are considered for future downsizing engine concepts featuring gasoline DI.

The arrangement and the dimensions of gas exchange valves for downsized engines remains challenging. Particularly, the coolant capabilities of the water core and the positioning of spark plug and injector have to be considered within the overall combustion chamber layout. When using a standard central mounted spark plug, for example, intake and exhaust valve diameters can be increased by approximately 8% with a lateral injector positioning (Dünschede and Pischinger, 2010; Korte *et al*., 2011). However, the injector layout and targeting has to be addressed carefully to avoid excessive wall wetting. The injector position and the injector target of DI gasoline engines can help improve engine start-up and catalyst heating capabilities by allowing significantly retarded spark timings. The increased exhaust gas heat flux allows a fast and reliable catalyst light-off to fulfill future emission legislation. Furthermore, during engine part and full load at low engine speeds and during high speed engine operation, the injector layout has to support charge homogenization and stable injection patterns with reduced cyclic fluctuations in a short time span.

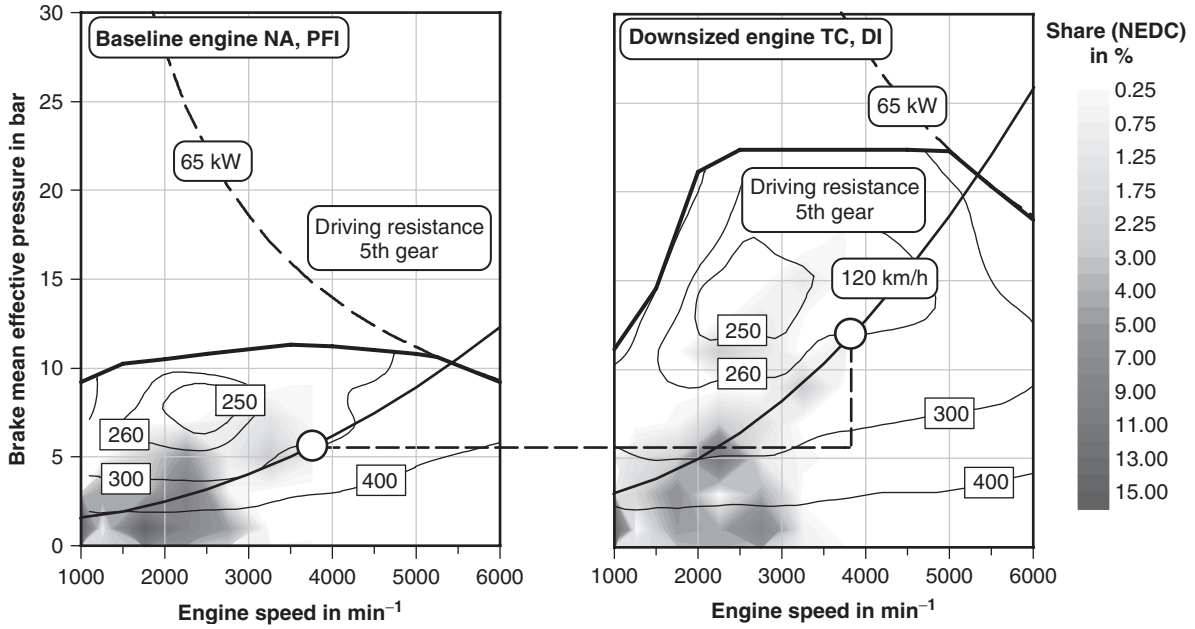

Figure 9. Load point shift for downsized engines.

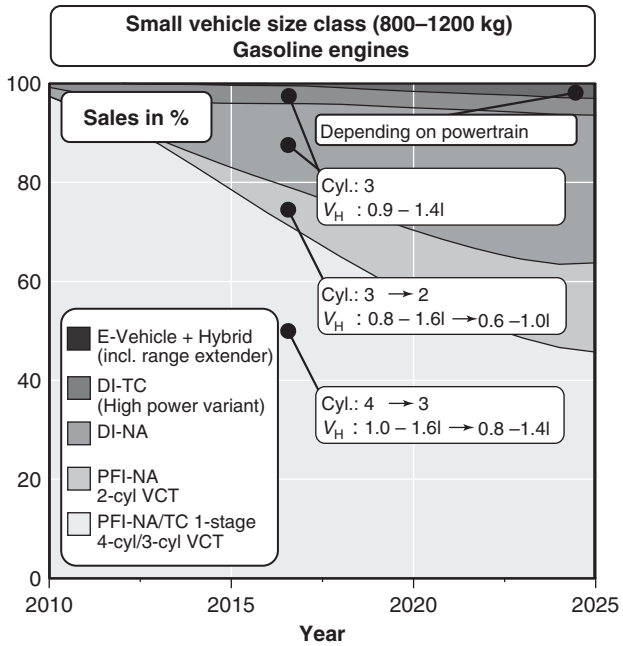

Figure 10. Roadmap engines for small vehicles, Europe.

Owing to the reduced engine displacement of the downsized engine compared to a natural aspirated engine with the same power output, the engines low-end torque is reduced. In addition, a boosted engine featuring an exhaust gas turbocharger has reduced transient response. Regarding a further increased market share for downsized engine concepts, improved low-end torque and enhanced transient response is mandatory to fulfill customer demands. The significantly increased boost pressure levels of downsized engines demand advanced boosting concepts to overcome these challenges. Thus, two-stage boosting of gasoline engines will become common for solving the current trade-off between acceptable low-end torque and demanded peak power output (Adomeit *et al*., 2010). Moreover, increased leakage and frictional losses of current turbochargers limits the available boosting technology for engine displacements below 1.0 L (Watson and Janota, 1982; Scharf *et al*., 2010). The combination of mechanical supercharging and exhaust gas turbocharging enables improved transient response of downsized engine concepts.

As a final note on downsized engines, they will be operated with increasing time spent at higher specific engine loads under real-world driving conditions. Accordingly, the risk of unwanted combustion events such as knocking or preignition rises. Knocking can be avoided by spark retard leading to higher exhaust temperatures. To stay within the specific temperature limit, fuel enrichment is necessary in terms of cooling. Alternative fuels using alcohol blending with increased heat of vaporization and knock resistance can help avoid fuel enrichment and maintain fuel efficiency.

3 BOOSTING

Turbocharger development focuses on enlarging the turbocharger operating range as well as increasing the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

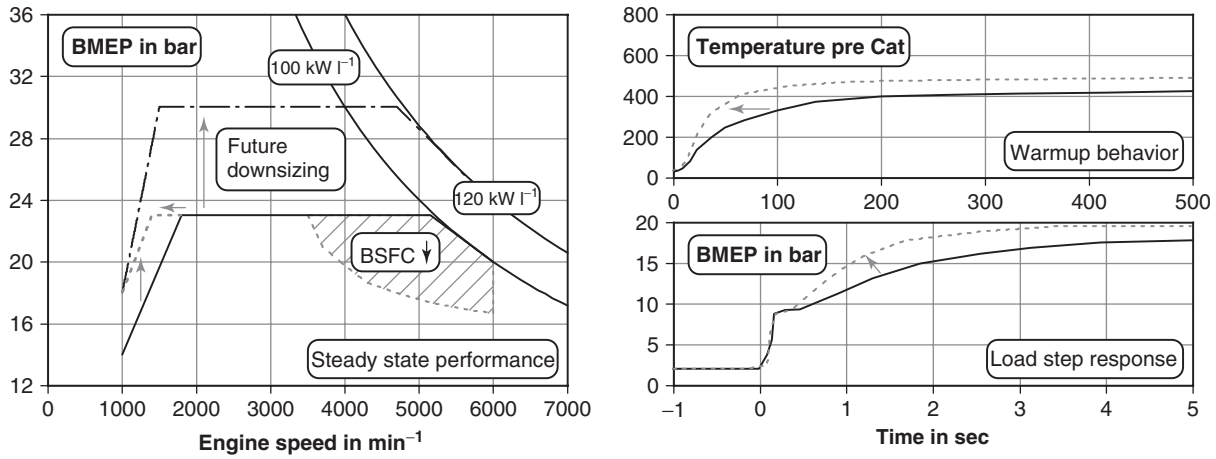

Figure 11. Boosting trends to improve steady-state and transient engine performance.

aerodynamic and mechanical turbocharger efficiency. All efforts have to be dedicated to benefiting the interaction of engine and turbocharger. Downsized engines have to comply with special requirements regarding performance and emissions, which are significantly affected by the boosting system. Figure 11 schematically illustrates the effect of boosting system optimization on engine performance in different operating domains. For a given specific power target, the aim is to improve stationary brake mean effective pressure (BMEP) at low speeds (low-end torque performance). If increased specific power is required, the level of BMEP has to be increased by enhancing boost pressure levels. At high speed and load, brake specific fuel consumption (BSFC) is to be optimized by extending the stoichiometric operating range and reducing the amount of enrichment. Improved warm-up behavior of exhaust manifold and turbine reduce the time to reach the catalyst light-off temperature, which significantly impacts cold-start emissions. The transient response of the engine-turbocharger system is determined by the ability to build up boost pressure after a load step and can be improved by using specific boosting technologies. Subsequently, the trends in boosting system technology to address the challenges associated with downsizing applications are presented. Details and fundamentals of turbocharging are discussed in Intake Boosting.

Single-stage compressors can already provide a sufficiently wide operating range for current engine concepts using a casing treatment such as ported shroud. However, single-stage operation is likely to exhibit limitations in terms of flow capacity and boost pressure demanded by future, enhanced downsizing. One possible solution for enlarging the compressor operating range is using two compressor wheels on one shaft driven by a single turbine. Here, the two wheels can either operate in parallel increasing the flow capacity or alternatively in a serial arrangement providing enhanced boost pressure. These arrangements can also contribute to improving the trade-off between operating range and transient response, because they usually feature reduced rotational inertia for a given flow and boost range.

Real multistage boosting systems offer even larger potential for increasing the specific power required for highly downsized engine concepts. A variety of different configurations exist, combining either two turbochargers or one turbocharger and one supercharger. Additional degrees of freedom arise from the thermodynamic coupling between the charging devices and the engine. A promising solution is based on exhaust port separation, which was made possible recently through application of variable exhaust valve control. The exhaust valves of each individual cylinder discharge into two separated manifolds and can thus act on different turbines. The two turbochargers can then be connected in a parallel-sequential arrangement or work in series-sequential mode. These systems yield a high degree of complexity regarding package design and control of the transition between single- and two-stage operation (Freisinger *et al*., 2010). Since the charging group represents a considerable heat sink, a key challenge is to minimize the thermal heat capacity of the charging group to ensure fast catalyst light-off and consequently comply with current and future emissions regulations (Schmuck-Soldan, Koenigstein, and Westin, 2011). Despite these drawbacks, two-stage charging systems allow a significant increase in SI engine low-end torque while enhancing the dynamic response at low engine speeds simultaneously. Furthermore, two-stage systems provide sufficient resources for the application of low pressure, high load EGR.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

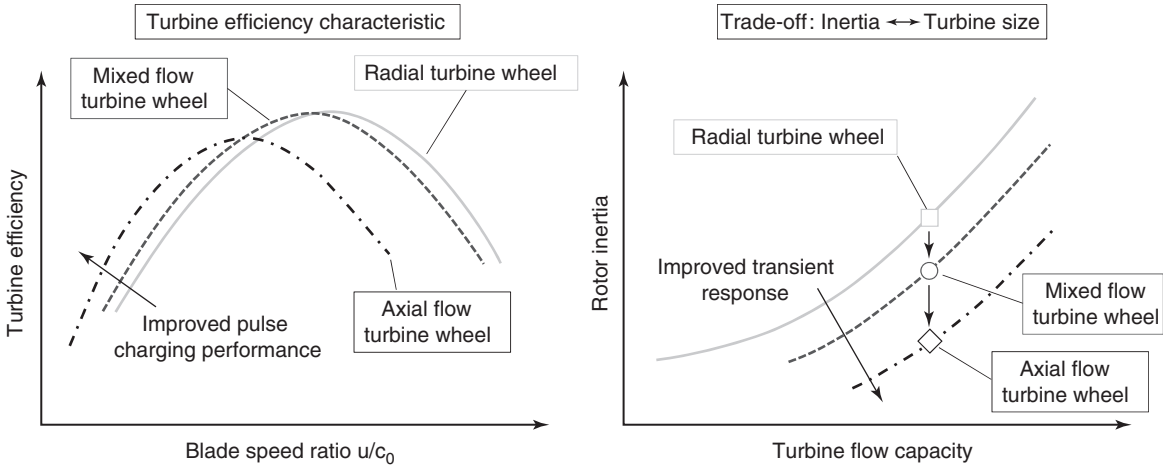

Figure 12. Comparison of radial, mixed flow, and axial turbine design characteristics.

The established design concept of automotive turbochargers consists of a radial turbine combined with a centrifugal compressor. On the turbine side, the radial design is widely accepted to be superior to the axial design for small turbine sizes employed in automotive applications, because axial turbines suffer more from rotor tip clearance losses. It has been suggested recently, however, that moving from radial to axial designs might be feasible. A less radical approach already commonly employed is the intermediate mixed flow turbine. The motivation for this consideration arises from the pulsating conditions present in the exhaust gas of an internal combustion engine. In order to extract as much energy from a pressure pulse as possible, a turbine has to be designed for high efficiency at high pressure ratios or low blade speed ratios (BSRs), respectively. Low BSR turbine efficiency benefits both transient and steady-state performance of the engine-turbocharger system. The only viable way to achieve this is shifting the efficiency peak to lower BSR. This, in turn, requires a nonzero inlet blade angle which can only be attained with a mixed flow or axial turbine design (Lotterman *et al*., 2011). It should be noted, however, that radial turbines offer higher peak efficiencies that are available over a wider BSR range. The swallowing capacity of the turbine increases when moving from a radial via a mixed flow until an axial design. That means a specified flow capacity can be achieved with a smaller dimensioned turbine and thus a reduced rotational inertia of the rotor (Rajoo and Martinez-Botas, 2008). The trade-off between the conflicting turbine performance requirements is schematically shown in Figure 12 for the different design options. Peak efficiency for the axial turbine is assumed to be marginally lower due to the stronger impact of tip clearance losses as mentioned before.

An alternative path in reducing the inertia without compromising efficiency is using alternative turbine wheel materials such as intermetallic titanium aluminide (γTiAl). Current state-of-the-art turbine wheel materials are Inconel for temperatures up to 950°C and MAR for temperatures up to 1050°C (Sonner *et al*., 2010). In comparison, γTiAl features significantly lower density, thereby reducing the rotational inertia of the rotor by approximately 30%. Increasing the temperature limit and ensuring long-term reliability at those temperatures contribute to the additional costs as well as the complicate manufacturing process (Lotterman *et al*., 2011; Sonner *et al*., 2010).

The degree of pulse charging is ever increasing in modern SI engines. In order to achieve optimum utilization of the kinetic energy and decoupling of the gas exchange of the individual cylinders, multi-scroll turbine housings have been developed. Scroll separation can be achieved by either a twin-scroll (twin-entry) or dual-volute (dual-entry) design. In current series application, the twin-scroll design is the preferred solution, because the dividing wall is more resistant and the wheel blades are less exposed to vibration excitation. Synergy effects may arise by combining scroll separation with variable geometry turbine (VGT) design (Sauerstein *et al*., 2009).

VGTs can be applied to SI engines in order to enhance the steady-state and dynamic torque build-up at low engine speeds. Additionally, efficiency benefits can emerge at wide open throttle compared to a conventional wastegate turbocharger as the complete exhaust gas enthalpy is utilized in the expansion process and not partially bypassed. Special emphasis has to be put on the control strategy of the VGT actuator during transient operation. Drawbacks

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto143
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in the transient performance might emerge, if scavenging gas exchange is not being enabled in the initial phase of the transient (Sonner *et al*., 2010; Neußer *et al*., 2011). A key challenge in applying a VGT to SI engines is the development of an actuating mechanism able to withstand the considerably higher exhaust gas temperatures compared to CI engines. Smooth operation of the actuating mechanism has to be ensured without increasing the gap between housing and moving parts too much, which is required due to the different thermal expansion of the materials (Breitbach *et al*., 2007). This can only be achieved by using expensive nickel-based alloys. Even so, the temperature resistance of current series application is limited to 980°C. Promising design concepts considered for series production involve a variable nozzle ring (Neußer *et al*., 2011) or a variable slider mechanism (Breitbach *et al*., 2007).

Instantaneous load management is crucial in today's SI engine operation, which requires fast and precise actuation of the wastegate valve. State of the art is the actuation by indirectly controlled pneumatic systems. Recently, electrical actuators were developed offering advantages in terms of dynamics. High closing forces make it possible to keep the wastegate completely closed under pulsating conditions. This reduces the leakage through the wastegate and thus improves the transient response of the engine (Schwerdel *et al*., 2009). Additionally, the wastegate can be opened completely in non-boosted operation. This reduces exhaust back pressure and enables faster catalyst light-off due to bypassing of the turbocharger acting as a heat sink (Hagelstein *et al*., 2009). A higher market penetration of electrical actuators can be expected with decreasing costs.

Several design attempts toward highly integrated exhaust systems have been made recently. The primary motivation is the reduction in expensive nickel-based alloys as turbine housing material for withstanding exhaust temperatures of 1050°C. One approach is to integrate the exhaust manifold into the cylinder head. This allows the cylinder-out gas temperatures to be increased without increasing the effective turbine inlet temperature, which is usually limited by the temperature resistance of the material (Bäumel *et al*., 2011). This eliminates the need for fuel enrichment in large areas of the operating map and results in a considerable benefit in high load fuel consumption due to stoichiometric operation. Furthermore, this concept yields improved cold-start behavior: First, engine warm-up is accelerated due to the added heat source which reduces parasitic friction losses. Second, faster catalyst light-off can be achieved due to a reduction in surface area of the exhaust duct (Ernst *et al*., 2011). The same advantages apply to water-cooled aluminum turbine housings. Synergy effects regarding package and cooling demand can be used when combining a water-cooled turbine housing with an integrated exhaust manifold. All water-cooled exhaust system designs act as a significant heat sink. The dissipated enthalpy potential directly affects engine performance under closed wastegate operation, because any loss in enthalpy cannot be compensated here. This aspect has to be considered as well as when designing the exhaust aftertreatment system (Prevedel *et al*., 2011).

A different approach to conventionally casted exhaust system components is using a sheet metal design for exhaust manifold as well as turbine housing. The insulating air gap between inner and outer sheet metal layer leads to lower heat rejection into the engine bay. Furthermore, this concept offers significantly lower thermal inertia, which improves the engine's transient response and catalyst light-off time without adding substantial production complexity (Björnsson, Johansson, and Kunde, 2010). It does not solve, however, the problem of fuel enrichment for component protection.

4 VARIABLE VALVE TRAINS

Within the last 30 years, variable valve lift systems have spread into almost every SI engine segment with increasing importance as a measure for reducing fuel consumption and optimizing performance, as well as efficiency. Those systems enable the variation of valve opening timing and valve lift depending on the operating point. The achievable improvement depends on the systems degree of variability. The following section provides an overview for variable valve lift systems seen in current production or development. They are divided into cam-actuated and direct-actuated systems.

Cam-actuated systems vary in timing, duration, and lift of the valve opening by adjusting the operating mechanism. Valve timing variation is realized by phasing the camshaft relative to the crankshaft. The first camshaft actuator was introduced in 1983 by Alfa Romeo. Besides two-position cam phasing, continuous cam phasing can be identified as state of the art (Schmidt *et al*., 1998). Continuous cam phasing can be realized with helical toothing moved by hydraulics or inverted use of the vane pump principle (Figure 13).

The first E-motor operated intake camshaft adjuster called the VVT-iE was implemented in the 4.6-L V8 32-V double overhead camshaft (DOHC) engine for Lexus 460. Today's production cam phasing systems enable phasing angles of until 80° crank angle (40° camshaft angle). Such a system applied to engines with DOHCs enables controlling size and position of the valve overlap.

There is also a possibility of using transmission elements (compensation elements) between the cam profile and

valve tappet. Switchable tappets or support elements allow the disconnection of individual valves. The alternating operation with two different cam profiles has also been realized in which the camshaft for each valve has two distinct cam lobes that actuate concentric surface areas of a switchable tappet. Therefore, a part and full load optimized valve lift can be realized, which mitigates the otherwise necessary compromise in valve timing and valve lift. An example for this technology is the VarioCam Plus (Eichler and Heiselbetz, 2001), which uses control bucket tappets combined with a camshaft phaser and is installed in various high performance engines produced by Porsche AG. Another example produced by Mitsubishi in series is the MIVEC engine, in which the switching mechanism is integrated in the rocker arm. This way, valve lifts for low and high engine speeds and a complete deactivation of individual valves for cylinder shut-off is realized. Honda produces a similar solution, which is used for various engines in series under the name of the VTEC system.

The Audi Valvelift System (AVS) first used in the 2.8-L V6 FSI engine switches between two valve lift curves. Sliding cam units with two different cam profiles are attached to the base camshaft on evolvent splines. The switching of the respective cam profiles in the base circle phase is made possible by the hydraulic actuated pins in combination with two switching grooves. The transfer to the valve via the roller cam followers and cam shaft bearings are basically adopted by the conventional valve train (Wurms *et al*., 2006). The AVS was also installed on the exhaust camshaft of the TFSI 2.0-L system to ensure

the firing order separation, which prevents the exhaust gas backflow into the suction at maximum valve overlaps.

In addition to the systems switching between two valve lift curves, there are other technologies that enable variable valve lift. UniAir is a hydraulic system that is used in several mass production vehicles by Alfa Romeo and Fiat. It is based on the principle of lost motion in which the cam lift is transmitted hydraulically to the valve so that the closing of the valve is triggered prematurely by redirecting the hydraulic pressure. As a result, the lift and closing time of the valve are decoupled from the cam profile. Hydraulic systems are used to dampen the motion of the valve as it approaches the valve seat.

To also change the valve lift continuously, mechanical valve controls were developed. Most of those concepts change the transmission ratio of the rocker arm via an eccentric shaft. In 2001, a fully variable valve control system was introduced to the market by BMW. This system enables an engine operation without throttle by continuously adjusting intake valve timing and lift. A similar system called Univalve was developed by enTec and is currently marketed by Kolbenschmidt Pierburg AG.

Since 2008, Toyota produces their variable valve timing system called the Valvematic. The system uses a special valve control lever (follower) for the continuous adjustment of the timing and the valve lift, which is arranged between the camshaft and conventional valve lever. An electronic actuator controls the valve lift and the valve opening duration. Additionally, a hydraulic variable cam phaser is used on both intake and exhaust. Latest investigations aim at an increased variability with lower complexity such as by the combination of a sliding cam unit with a full variable cam profile (Nitz *et al*., 2010).

Electromechanical valve actuators use electromagnets in combination with valve springs forming a spring/mass oscillator. The valve motion is mainly forced by spring forces and the electromagnets are used to initiate and support the opening and closing process. As a result, the necessary energy is reduced significantly compared to other electromagnetic valve controls. However, the energy demand using electromechanical valve control still has to be taken into account in comparison with conventional mechanical valve operation. Suggesting a generator efficiency of 80%, electromechanical systems have a part load energy demand comparable to current low friction valve trains (Salber, 1998). Again, the large design effort and difficulties in dynamic in-vehicle operation currently limits the use of electromechanical valve actuators. For future valve lift systems, it is most important to gain a high variability at low cost and design effort. Therefore, less complex mechanical or hydraulic solutions need to be developed.

5 POTENTIAL OF VARIABLE VALVE TRAINS

Variable valve trains enable improved fuel economy by the optimization of the gas exchange process. The cam layout and therefore the valve timing of standard, fixed valve trains reflect a compromise of acceptable engine stability at idle conditions for reduced engine operating speeds, improved part load fuel efficiency, and low emissions and enhanced volumetric efficiency at full load engine operation.

The valve timing for "intake valve closing" (IVC) has to maintain high levels of engine torque at low engine speeds and high peak power output at rated engine speed. During full load operation, maximum volumetric efficiency has to be maintained. Exhaust valve opening (EVO) has to consider the expansion work of the exhaust gases, whereas exhaust losses at high engine speeds and high engine loads have to be avoided. The trade-off between these contrasting requirements can be solved partially by the application of variable valve systems. By the application of variable valve timings, the opening and closing of valves can be adapted to the engine speed and load accordingly.

Further adaptation to a tailored gas exchange can be enabled by the application of a variable valve lift system. Variable valve lift systems can be classified by the valve timing, the valve opening period, and the valve lift. These functionalities can be combined to a fully variable valve lift (Unger, 2004; Haas and Rauch, 2010). The application of a fully variable valve train enables reduced gas exchange losses due to de-throttling of the intake air system.

The valve overlap is determined by the "intake valve opening" (IVO) and "exhaust valve closure" (EVC) and controls the amount of exhaust gas residuals. The recirculation of exhaust gas enables a partly de-throttled engine operation at part load engine operation. Thus, fuel efficiency can be improved and the level of raw emission for a stoichiometric-operated gasoline engine can be reduced. On the other hand, the combustion stability is deteriorated by the amount of recirculated exhaust gas, thus burn delay and burn duration increases. Misfire can occur and the HC emission level increases significantly (Tuttle, 1980, 1982; Hara, Nakajima and Nagumo, 1985; Wichart, 1987). The de-throttled engine operating range achieved by using exhaust gas recirculation can be enlarged by combustion systems featuring increased in-cylinder charge motion, which can enhance combustion stability and the amount of recirculated exhaust gas that can be used. (Wurms, 1994; Löbbert, 2006).

At increased engine speed and engine load, the fuel efficiency potential of de-throttling is reduced as the amount of throttling required for load control declines. However,

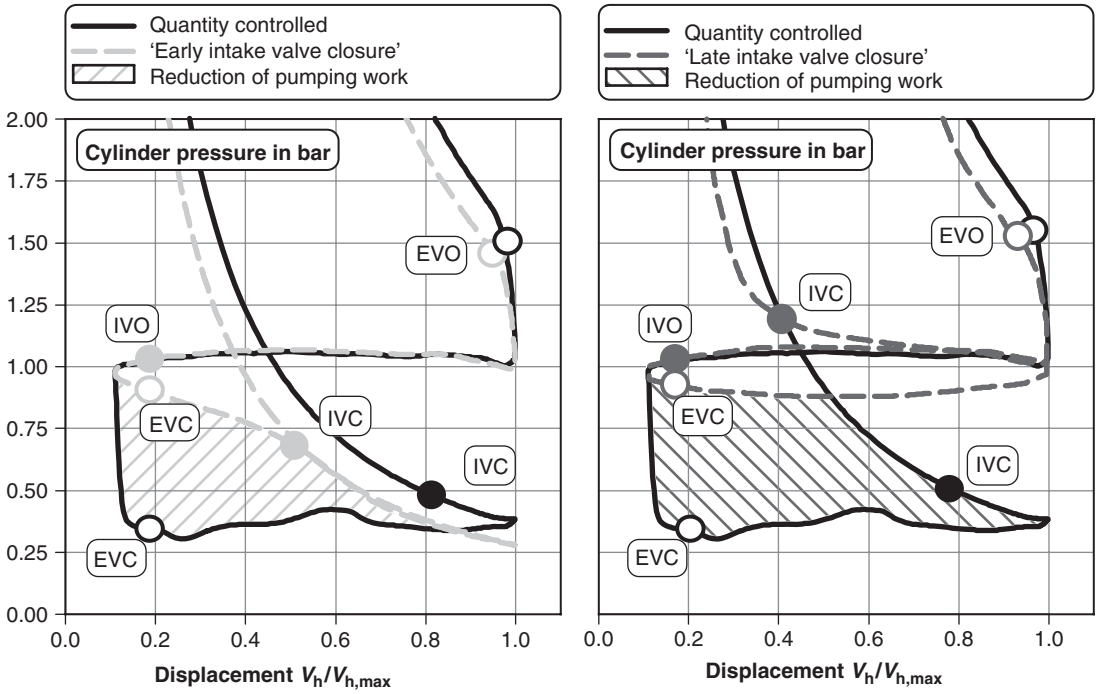

Figure 14. Load control by means of EIVC and LIVC for $n = 2000/\text{min}^{-1}$; IMEP = 2.8 bar.

further limitations arise related to increasing charge temperatures and knock sensitivity. Variable valve timing in the form of late intake valve closure (LIVC) can be used to reduce the effective CR. Owing to the upward moving piston stroke, a part of the cylinder charge is pushed back to the intake system. Thus, the final compression pressure and temperature decline. This reduces knock sensitivity and spark timing can be advanced, enabling improved engine efficiency. With early intake valve closure (EIVC), the gas exchange ends during the intake stroke before bottom dead center (BDC), as soon as the desired charge air mass is introduced. The cylinder charge is expanded after IVC and will be compressed afterward. The load control by EIVC or LIVC compared to conventional intake charge quantity control of internal combustion engines is shown in Figure 14.

When combustion and gross indicated efficiencies are constant, EIVC and LIVC can reduce gas exchange losses by approximately 35% for the engine operation point shown ($n = 2000/\text{min}^{-1}$, indicated mean effective pressure (IMEP) = 2.8 bar). During NEDC, a fuel consumption potential of approximately 8% was shown by the application of a fully variable valve train (Flierl *et al*., 2011).

The application of a switchable valve lift system enables adequate potential for future engine concepts, with reduced complexity compared to a fully variable valve lift system (Wurms *et al*., 2006; Luttermann, Schünemann, and Klauer, 2008). Different cam profiles for maximum torque, rated speed, and zero valve lift enable diversified potential. A reduced cam event length allows improved scavenging capabilities for current four-cylinder engines by the separation of the engine firing order (Budack *et al*., 2009). Furthermore, reduced valve lift combined with reduced event length can be used for de-throttled engine operation, using "EIVC" in a predefined engine operation area. The reduced valve lift can be combined with single or dual intake-port shrouding to intensify intake charge motion. Thus, combustion stability during low load engine operation can be improved and fuel efficiency in this engine operation area is enhanced (Gottschalk and Tschöke, 2000; Dilthey, 2004).

The cam profile and valve timing at rated speed enables lowered gas exchange losses at maximum cylinder charge with reduced residual gas content after gas exchange. Thus, charge temperature is reduced, knock sensitivity is lowered, and the spark timing can be advanced, thereby engine efficiency can be improved. The zero valve lift also enables cylinder deactivation which can be used to increase engine efficiency during low load engine operation (Indra, 2011; Middendorf *et al*., 2012).

Additional potential can be gained by different phasing of the intake valves. Different cam profiles on the intake side will lead to enhanced swirl motion. Thus, charge homogenization and residual gas tolerance can be improved, and

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

emissions and fuel consumption can be lowered (Wyatt *et al*., 2011).

The application of different valve timings/events enables the usage of the exhaust gas pulse for modulated boost concepts. The immediate exhaust gas pulse at EVO is used for pulse turbocharging, whereas the rest of the exhaust stroke is bypassed and not used for turbocharging. Thus, the gas exchange is improved due to the reduced gas exchange losses by lowered exhaust gas pressure (Wyatt *et al*., 2011; Ross and Zellbeck, 2010).

Further CO_2 and pollution emission legislation will be one of the main drivers for future engines. Valve train variability will play a dominant role in tailoring gas exchange of internal combustion engines to help meet these future demands.

6 SI FOR HYBRIDS

The development targets of the combustion engine in a conventional powertrain differ quite significantly from the requirements for hybrid powertrains. One main development focus for the conventional combustion engine is the improvement of the part load fuel consumption. This target can be achieved by different engine technologies, for example, downsizing, downspeeding, variable valve lift, and cylinder deactivation, as already discussed. Hybrid powertrains on the other hand offer the possibility to limit the operation range and avoid part load engine operation. This can be achieved by shifting the engine load point to higher engine loads or by substituting engine operation points with high fuel consumption at very low loads by electric driving (Figure 15). Thus, technologies that aim to achieve improved fuel consumption at low engine loads have a lower impact in hybrid powertrains.

Several investigations have been conducted to investigate the optimal layout of the combustion engines in hybrid powertrains. (Seibel and Pischinger, 2007; Balazs and Pischinger, 2011). These investigations are based on combinations of design of experiments, vehicle simulations, and numerical optimization methods.

Figure 16 displays the fuel consumption results for a parallel hybrid powertrain in several vehicle classes (Seibel and Pischinger, 2007). Additionally, the fuel consumption of a standard engine (naturally aspirated engine with variable valve timing) in conventional powertrains is shown.

Comparing the standard engine with VVT in a conventional and a hybrid powertrain, a fuel consumption benefit of 20–23% is achieved. With the turbocharged DISI engine, a fuel consumption benefit of 21–28% can be achieved compared to the standard engine with VVT in conventional vehicles. The fuel consumption benefit with hybridization

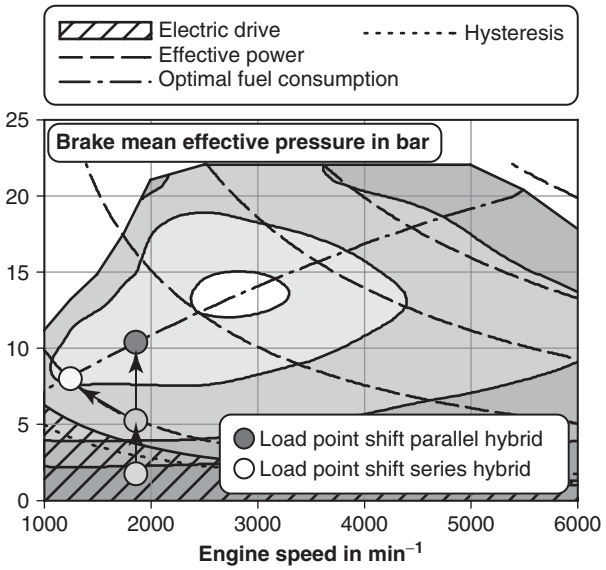

Figure 15. Engine operation range in hybrid powertrain.

increases with increasing vehicle and engine size. The same trend can be seen when comparing the fuel consumption differences of the different engine concepts within one vehicle class. For the compact class vehicle, the differences between the engine concepts are very small. However with increasing power to weight ratio in bigger vehicle classes, the fuel consumption benefits of advanced engine technologies, such as engine downsizing, increase significantly.

Typically, in larger vehicle classes, the ratio of engine power to vehicle weight increases significantly. Therefore, the engine is operated at lower loads. Shifting the engine load point to higher loads (by engine downsizing or hybridization) or substituting the engine operation at low loads by electric driving results in a bigger fuel consumption benefit.

In Figure 17, the CO_2 emissions of a hybrid vehicle with naturally aspirated engine, operating based on the Atkinson combustion process, and with a turbocharged DI engine are shown. The results were obtained from vehicle simulations performed by Balazs and Pischinger, 2011. The layout and scaling of the components in the parallel hybrid powertrain and the operation strategy have been optimized for five different driving cycles. This was done with equal vehicle performance targets, such as maximum vehicle speed, acceleration performance, elasticity, and gradeability.

The Atkinson engine represents a simple engine featuring an intake camshaft with long intake event (late IVC) and optimized engine friction. This results in low fuel consumption values but a low specific full load torque. In contrast to this, the turbocharged DI engine achieves 22-bar BMEP and 100 kW/L. The possibility of supporting the

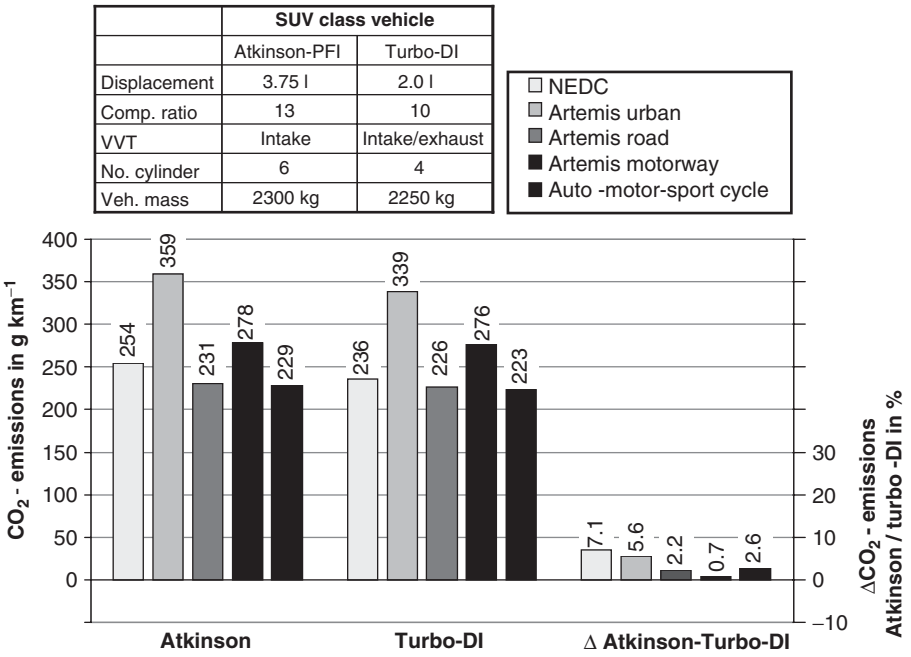

Figure 18. CO_2 emissions of a conventional vehicle with automatic dual clutch transmission in different driving cycles.

engine at low engine speeds by boosting with the electric machines enables a layout for high specific power rather than focusing on achieving a high low-end torque. The engine displacements have been adapted in order to achieve the same maximum power.

In Figure 17, it can be seen that the downsized engine has benefits when the engine is operated at low to medium engine loads (NEDC, Artemis Urban), whereas the Atkinson engine provides benefits at higher loads. Fuel consumption drawbacks at low engine speeds can be compensated by hybrid-specific features (electric driving, load point shift). In conventional powertrains, the benefit of the downsized engine increases (Figure 18).

In plug-in hybrid vehicles and electric vehicles, the electric motor is the prime mover. With increasing battery capacity and electric machine power, the electric driving range increases. This results in a lower time share of combustion engine operation. Figure 19 shows a typical strategy for a plug-in series hybrid vehicle. At the beginning of the driving cycle, the battery is fully charged. The vehicle is powered by the battery and the electric machine (charge depletion mode). After approximately 1500 s, the combustion engine begins operating when a certain vehicle speed is exceeded in order to power the electric traction motor and the battery. With this strategy, the state of charge (SOC) is maintained at 20% (charge sustaining mode). With increasing electric drive range, the importance of criteria for achieving low fuel consumption decreases, whereas the importance of criteria such as noise, vibrations, and harshness (NVH), packaging, and production cost increases.

In summary, the main development focus for combustion engines in electrified powertrains can be assumed as follows.

In the cost-sensitive small vehicle class, many vehicles will be equipped with simple combustion engines (e.g., naturally aspirated, port fuel injection) including limited technologies for engine improvement (e.g., friction reduction, Atkinson process)

In large vehicle classes, the diversity of different engine concepts will be higher for hybrid vehicles. Benefits by engine downsizing increase. In addition, combustion engines with cost-intensive technologies will be available in hybrid vehicles.

With increasing degree of electrification, the combustion engine will be simplified. In particular, for urban utilization, the share of electric drive increases and the combustion engine remains as a so-called "range extender" extending the electric drive range for long distances and exceptional cases. Criteria such as NVH and packaging gain importance while the impact of fuel consumption on the total energy consumption of the vehicle decreases.

6.1 Motivation and function of range extenders

Battery electric vehicles (BEVs) are facing drawbacks including short all electric ranges and the lack of heating

energy from the combustion engine. Today's batteries (Li-ion) still have low energy densities in combination with high costs; so, they are still not suitable for longer travelling distances. In order to overcome this drawback, range extenders can be used to produce electric energy when needed for longer distances. Hence, the batteries can be dimensioned even smaller, providing energy just for daily driving distances.

Furthermore, the lack of heating energy can be overcome if the range extender cooling circuit is linked to the vehicle's heat exchanger. It can be further improved if the exhaust gas enthalpy is recovered by an intercooler. At low ambient temperatures, instead of using electric energy from the battery to heat up the cabin, the range extender can be operated at an efficient operating point to provide the needed heating energy and simultaneously recharge the battery for an extended electric range.

The actual range extender integration strongly depends on the given vehicle category, which mainly defines requirements on development targets such as usability, driving performance, or convenience aspects (Fraidl, 2010). Since range extender modules (REMs) only operate when needed, start-up and response time or life expectancy become less critical specifications, whereas required space or NVH gain in importance. These new aligned requirements provide the opportunity to consider such potential technologies as external combustion or low-vibration space saving rotary piston. In Figure 20, important REM characteristics are compared for exemplary technologies.

As shown in Figure 21a, the range extender is driven as a serial hybrid. As a consequence, the range extender package has maximum freedom degrees. However, multiple energy conversions result in significant efficiency losses. The range extender in Figure 21b can be driven as serial or combined hybrid. By the use of a mechanical interface to the electric powertrain, its installation location is already fixed. The lower number of energy conversions results in higher efficiencies. In Figure 21c, the electric traction motor and the range extender are driving different axels. If the range extender should be usable also at low vehicle speeds (in case of low battery state of charge), a multistage gearbox is mandatory.

One of the major development targets for range extenders is a good NVH behavior. The excitations from the range extender onto the vehicle body can be distinguished between airborne sound and vibrations at the engine mount positions. Airborne sound is radiated by the engine surfaces

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto143
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

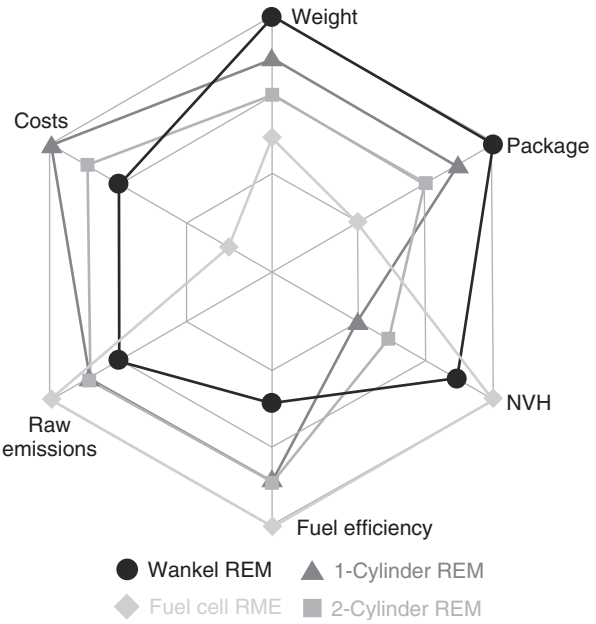

Figure 20. Comparison of the characteristics of different range extender modules.

and the intake and exhaust orifices (Genender, Speckens, and Schürmann, 2011).

Vibrations at the engine mount positions mainly result from free oscillating mass forces, which strongly depend on engine architecture. Without considering any mass balancing systems, to some extent two-cylinder engines, the inline three-cylinder engine, as well as the Wankel engine might be suitable concepts (Fraidl, 2010; Pischinger *et al*., 2011a; Warth *et al*., 2011).

The discontinuous combustion in multicylinder engines induces an oscillating torque with high amplitudes, especially at low engine speeds, and is most noticeable with a small number of cylinders connected to the crankshaft. The result is a rolling torque. Especially during start and stop, highly noticeable vibrations occur at the engine mounts. Intelligent layout of engine mounts or a special range extender layout for compensation of the rolling torque should be taken into account (Pischinger *et al*., 2011a).

Airborne sound of the intake and exhaust orifices is affected by the firing interval. High orifice sound levels are especially produced in engines with only a few cylinders (single cylinder, two-cylinder) and uneven firing intervals. The exhaust side with its until 20 dB higher pressure pulsations is more critical than the intake orifice (Genender, Speckens, and Schürmann, 2011). Therefore, high volumes and small runner diameters are needed to minimize the orifice sound. For a two-cylinder engine, intake and exhaust muffler volumes should be around 15 L.

For optimizing NVH, the operation strategy of the range extender offers another degree of freedom. Wind and road noise are the major interior noise components in an electric vehicle at higher driving speeds. However, during standstill and at low vehicle speeds, there is no significant masking noise such as wind and road noise. As a result, range extender operation is inappropriate under these conditions, unless absolutely necessary. In general, depending on the interior noise level of the electric vehicle, the range extender should not be used below vehicle speeds of 30 –50 km/h (Figure 22).

At higher vehicle speeds, the range extender speed should be linked to vehicle speed. Its load should vary with the driver's torque demand and its energy produced should directly be used for propulsion without buffering within the battery. At highway speed, the range extender can be driven steady at its rated power output point, because the driving noise is sufficient to mask the range extender interior noise.

Another key to successful market introduction are costs as the range extender technology is meant to enable reasonable priced electric vehicles. Naturally aspirated gasoline engines with port fuel injection deliver sufficient specific power output and allow exhaust gas aftertreatment systems to be kept simple and therefore cost-effective. Compared to DI combined with charging technologies, NVH behavior is also better. As efficiency and highly transient engine operation are minor targets, state-of-the-art technologies offering variable operation (e.g., cam phasing or variable

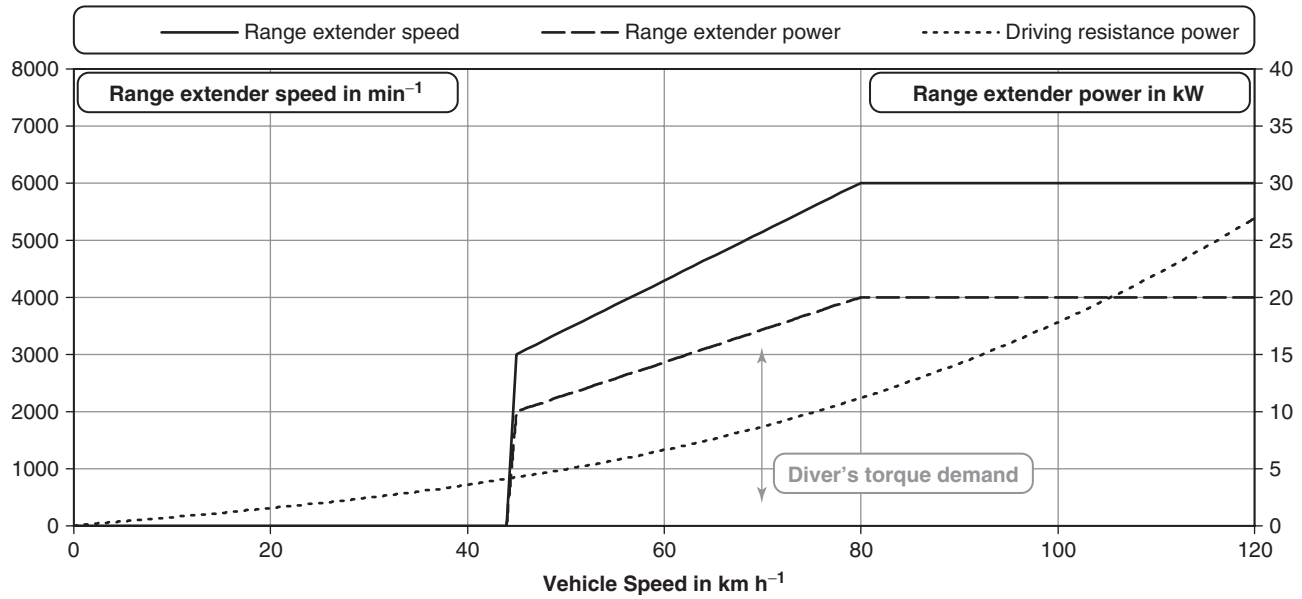

Figure 22. NVH optimized range extender operation strategy.

intake manifold) can be dropped. Moreover, a specific power output of 35–40 kW/L might already be sufficient, and a pushrod-driven OHV valve train with two valves per cylinder as well as rather low nominal engine speeds (≤4000 rpm) can be realized. Additionally, a high amount of carryover parts and geometries from existing engine families (bore diameter, bore pitch, engine architecture) enable integration into existing manufacturing processes.

7 ADVANCED COMBUSTION CONCEPTS

Compression ignition of gasoline under lean or dilute conditions has proven good potential to significantly cut down CO_2 emissions by up to 30% and reduce NO_x emissions by up to 99% in contrast to conventional throttled stoichiometric SI engine operation at part load. Gasoline compression ignition (GCI) has been implemented in various ways and referred to by various names in the literature (e.g., controlled autoignition (CAI), homogenous charge compression ignition (HCCI), etc.). The reduction in fuel consumption from GCI is mainly driven by the de-throttling of the intake system, the optimized charge properties due to the lean mixture, and the low temperature combustion and the comparatively quick combustion process. The distinct reduction in NO_x emissions due to the low temperature combustion (see NO_x Formation and Models and Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot) provides the fuel consumption benefits of stratified lean, spark-ignition combustion without the drawback of additional NO_x aftertreatment (see Emission Control Systems—Oxides of nitrogen, Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot, and Gas Aftertreatment Systems). Moreover, recent investigations are showing pathways to boosted, high load, low emission operation of advanced GCI strategies as discussed in Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot.

High amounts of trapped residuals from the previous combustion cycle help initiate the autoignition. The two most promising internal EGR strategies are exhaust port recirculation (EPR) and combustion chamber recirculation (CCR). EPR is characterized by a backflow of residuals from the exhaust port by opening the exhaust valve during the suction stroke, whereas CCR is characterized by an early exhaust closing and a short exhaust and intake event length (large negative valve overlap).

The autoignition process of hydrocarbons is controlled by chemical reaction kinetics and, according to Westbrook (2000), triggered by prompt decomposition of hydrogen peroxide (H_2O_2) into hydroxyl radicals (OH•) during the compression stroke at approximately 1000 K (see Fundamental Chemical Kinetics). Measures that can be taken to generate this temperature lead to earlier autoignition and vice versa. In general, GCI combustion can be influenced by:

- the global pressure and temperature in the combustion chamber (e.g., determined by the trapped amount of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

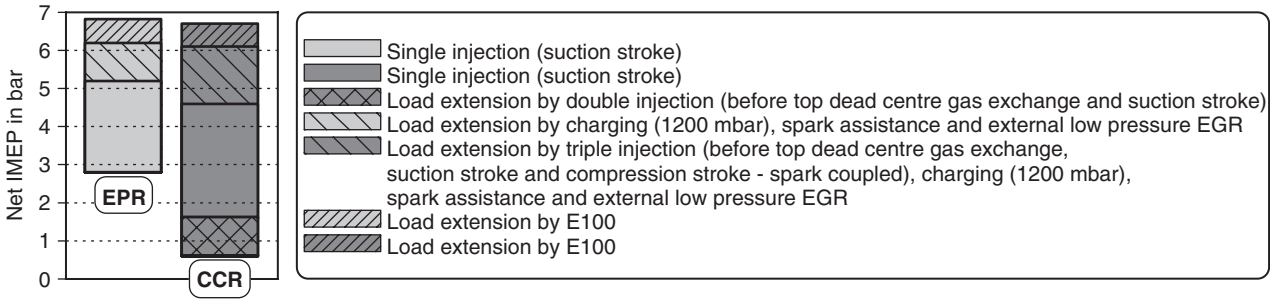

Figure 23. Strategies for load extension measured at a single cylinder engine with compression ratio of CR=12 at an engine speed of 2000/min^{-1}. Boundary conditions for GCI: a standard deviation of net IMEP of >0.15 bar, a maximal cylinder pressure gradient of <5 bar per °CA, or a relative air/fuel ratio <1.

residuals, the CR, or the thermodynamic conditions in the intake system),

- the local stratification of residuals, temperature as well as air/fuel ratio (e.g., depending on the calibrated injection strategy or the exhaust gas strategy used), and
- the fuel properties (e.g., primarily the autoignition characteristics, the enthalpy of vaporization, and the volatility).

Nevertheless, GCI currently reveals disadvantages such as a limited operation range. Toward low engine loads, the decreasing exhaust enthalpy leads to a deteriorated combustion and finally to misfiring. Toward higher engine loads, the maximum pressure gradient is significantly increasing.

Figure 23 illustrates possible strategies to enlarge the operational range starting from a single injection strategy during the suction stroke for both EPR and CCR. The early closing of the exhaust valves for CCR enables the possibility to inject a distinct fuel amount shortly before TDC gas exchange into a regime of compressed hot residuals that causes a major impact on combustion phasing. It leads—at sufficiently lean conditions and constant valve timings—to an advanced combustion, due to the partial conversion and particularly reformation of the fuel. This strategy can be used in combination with a spark-assisted operation to expand the load range significantly.

As the maximum load range is limited by a steeply increasing maximal pressure gradient, it is necessary to adopt strategies that slow down the reaction progress. This can be achieved by a further dilution through boosting or the usage of external EGR. In addition, the previously described injection before TDC gas exchange can be used to further lean out the mixture, as less residuals are necessary to achieve a certain combustion phasing.

To further extend the operational range toward low as well as high loads, it is possible to adopt a late third injection that is coupled to a supporting spark and leads to a stratified combustion in the vicinity of the spark plug. Moreover, the usage of alternative fuels such as ethanol with high RON/MON enables a further broadening of the maximum load range as the maximum pressure rise rate can be reduced by combustion duration extension.

As the NO_x emissions rise with increasing engine loads, it might be necessary to switch from lean to stoichiometric conditions at higher engine loads, in order to allow the usage of the three-way catalyst technology. Fully de-throttled operation can be maintained by using high amounts of external EGR.

8 VARIABLE COMPRESSION RATIO

The application of downsizing to reduce fuel consumption in context with boosting presents a disadvantage because of the higher knock sensitivity at higher engine loads. At a given boost level and fuel quality, this can only be compensated for by either spark retardation or adjustment of the CR. Despite the fact that the majority of the boosted engines in contrast to the naturally aspirated engines are equipped with direct fuel injection, today's boosted engines are designed for RON 95 gasoline with a CR of approximately 9.6. In comparison, naturally aspirated engines have a higher CR by 1–1.5 units.

While the lower CR at full load results in lower pressures and temperatures at the end of compression in concert with a beneficial location of the center of combustion offering improved efficiency, a higher CR at part load without knock limitation is always beneficial in terms of thermal efficiency and thus fuel consumption (Figure 24). The application of a variable CR mechanism lends itself to resolving this conflict.

Over the years, in order to achieve variable compression, a variety of different concepts have been published (Schwaderlapp *et al.*, 2001; Drangel and Bergsten, 2000).

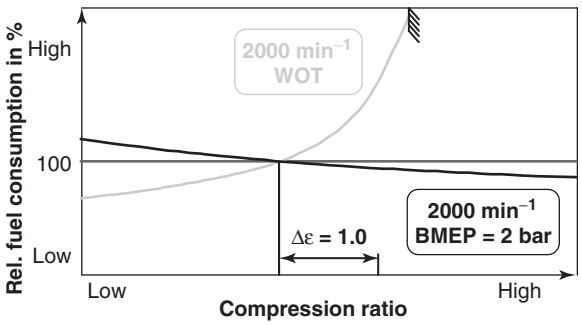

Figure 24. Fuel consumption depending on CR under part load and full load (WOT: wide open throttle) operation conditions.

Some of these concepts have already been realized in test vehicles (Pischinger *et al*., 2003). All of these systems entail a variation of the compression volume via a variable piston position at TDC. Figure 25 illustrates the classification of the systems according to type of TDC position variation mechanism.

The systems in the first group apply to unconventional cranktrains. There are different kinematic concepts of such multicomponent configurations using one moving pivot or support point. In general, the moving masses increase and more friction is added. However, as stated by Aoyama *et al*. (2006), an optimized kinematic design might result in an actual reduction of the friction.

The systems in the second group achieve the change in compression by varying the distance between the crankshaft and the cylinder head. The FEV system (Schwaderlapp *et al*., 2001) uses a crank in eccentric main bearings while the Saab system (Drangel and Bergsten, 2000) tilts the cylinder head relative to the crankcase. Both of these unconventional cranktrain systems that vary in the distance between the crankshaft and cylinder head require intense design modifications to existing engine architecture. The system can therefore only be applied to a new engine family.

The systems with variable kinematic lengths entail variable powertrain components that can be used instead of the conventional components and thus only require minor modifications in existing engine architectures. The FEV variable length connecting rod belongs to this group of VCR systems and has been continuously developed over the past years (Wittek, Tiemann, and Pischinger, 2009a, 2009b).

Investigations so far have shown that the fuel consumption improvement potential for a continuous CR adjustment over the European NEDC cycle is between 6% and 8% (Schwaderlapp *et al*., 2001; Pischinger *et al*., 2003). In this case, the CR can be optimized for each operating point. However, less complex approaches such as a two-stage VCR can result in close to the same fuel economy improvement. The fuel consumption improvement potential of a two-stage VCR system for a modern downsizing gasoline engine is between 5% and 7% depending on the driving profile and the degree of downsizing, as cycle simulations have shown (Weinowski *et al*., 2012). A two-stage VCR system has the following advantages: easily adaptable, low system complexity, and significantly lower cost. On the other hand, due to the knock limitation occurring now at part load caused by the optimized higher CR, the CR may need to be switched back to the lower value as designed for full load operation earlier.

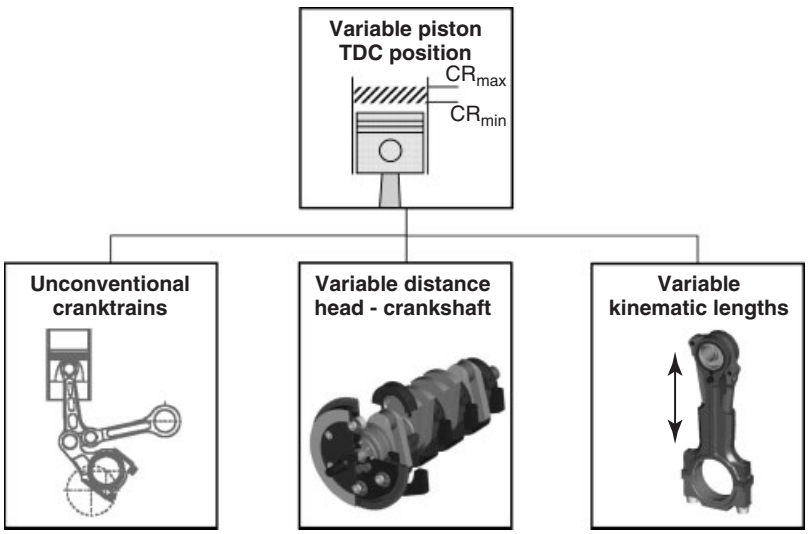

Figure 25. Classification of VCR systems with variable piston TDC position.

Furthermore, VCR systems can be used to exploit the benefit of higher octane rating of alternative fuels, such as CNG or ethanol, in bi-fuel or flex-fuel concepts. A fixed CR has to be designed according to the lowest expected octane rating, whereas VCR enables an efficient operation for different octane ratings. Thereby, VCR also allows compensating for worldwide gasoline octane rating fluctuation.

9 NOVEL ENGINE DESIGN

The ever increasing limitations of fuel consumption require a continuous improvement in engine efficiency, which is creating significant engine design challenges. The recent advanced developments of the combustion process and thermodynamics demand novel component designs, for example, variable valve timing and variable CR. Recent development trends show a tendency of increasing in-cylinder pressures and temperatures, which lead to greater mechanical and thermal loads on the engine parts. In addition, the market demands for lightweight designs and weight reduction increase even more the challenge for engine development. Current trends show several approaches to cope with these challenges.

One of the newest design trends targeting the reduction in friction forces on the cranktrain is the application of an offset between the crankshaft axis and the cylinder axis for inline engines. To achieve this reduction in the friction forces, the crankshaft has to be positioned away from the cylinder axis in a direction such that the piston arrives at TDC at a crankshaft angle $>0^\circ$. With this characteristic, the crank angle distance from TDC to BDC is also $>180^\circ$, resulting in an asymmetry of the cranktrain kinematics. Increasing the offset actually increases the friction forces during three of the four strokes of the engine cycle, as the side forces during these strokes are increased. Only during the power stroke is there a positive effect of the offset on the friction forces, as the overall distance between piston and crankshaft axis is larger than that in a conventional engine without an offset. This reduced friction during the power stroke increases the available torque on the crankshaft (Figure 26). A trade-off needs to be met between the reduced friction forces during the power stroke and the increased friction forces during the rest of the engine cycle, where usually the optimum offset is too large to be applied due to packaging constraints.

Another design trend is aimed at reducing moving and rotating masses in the engine, crankshaft, and camshafts by using hollow shaft designs. Special casting processes allow the production of hollow shafts. In addition, the application of assembled camshafts with hollow shafts has become a common approach to reduce masses in the valve train (Artur *et al*., 2010)

To avoid high thermal load on exhaust components such as the turbocharger turbine and the catalyst, latest engine designs employ integrated exhaust manifolds (Figure 27). The cylinder head and the exhaust manifold are realized as one aluminum cast part. In this configuration, the exhaust

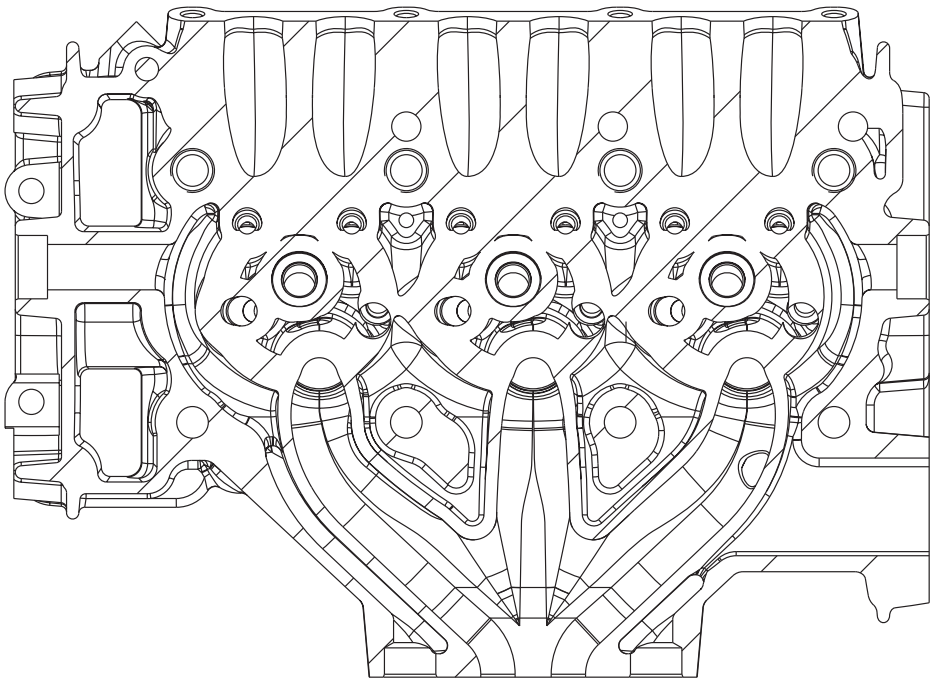

Figure 27. Cylinder head with integrated exhaust manifold (three-cylinder DI engine; three valves; exhaust: bottom).

ports can be cooled by the main water jacket of the cylinder head (Kirsch *et al*., 2011). As a consequence, the maximum temperature of the exhaust gas flow is reduced more rapidly, which reduces mixture enrichment requirements at full load operation. Furthermore, engine and catalyst warm-up can be achieved much faster, which results in further fuel consumption reductions (Ernst *et al*., 2011). Additionally, a beneficial outcome of the integrated exhaust manifold is the reduction of expensive heat-resistant Ni-alloys, which are used for conventional exhaust manifolds.

The reduction in internal friction is another major development target. Roller bearings show high potential for friction reduction. Plain bearings are still the prevalent type of bearings in the engine. Roller bearings in the cranktrain are yet to prove feasible for mass production applications. Nevertheless, roller bearings on assembled camshafts are already in use in current applications, bringing a further decrease in the friction forces on the valve train (Artur *et al*., 2010). Mass balance shafts with roller bearings have become as well state-of-the-art technology.

To achieve further improvements in fuel consumption, original equipment manufacturers (OEMs) are currently introducing engines with aluminum crankcases with spray-coated cylinder bore surfaces. This allows elimination of the cylinder liners, resulting in lighter engines as well as optimized water jackets between cylinder bores. Before honing the cylinder bore surface, with this process, a coating of a material which can be chosen according to the piston material is sprayed on a previously prepared cylinder bore surface. This has the advantage that an optimal material matching between piston and bore surface is achieved. With this optimal material matching, lower friction at the piston running surface is achieved as well as lower oil consumption (Pischinger, Ring, and Nijs, 2011b). Compared to other bore surface treatment processes, such as Nikasil, Alusil, and Lokasil, this process is cheaper, is easier to machine, has lower environmental impacts (compared to Nikasil), and better material matching is achieved.

Furthermore, the application of variable oil pumps shows high potential for the elimination of parasitic losses in the engine. In conventional oil pumps, oil flow and pressure rise with increasing engine speed. At high engine speeds, oil pressure and oil flow are higher than the required amounts. This results in unnecessary power consumption by the oil pump. With variable oil pumps, pressure or volumetric flow can be adjusted according to the engine demand, reducing parasitic power losses. There are several different concepts to achieve this, depending on the pump type.

Similar to the potential for reduction of parasitic losses through the application of variable oil pumps, comparable effects are achieved by the application of variable water pumps. However, the application of variable water pumps also allows an optimization of the thermal management, which leads to significant additional fuel savings.

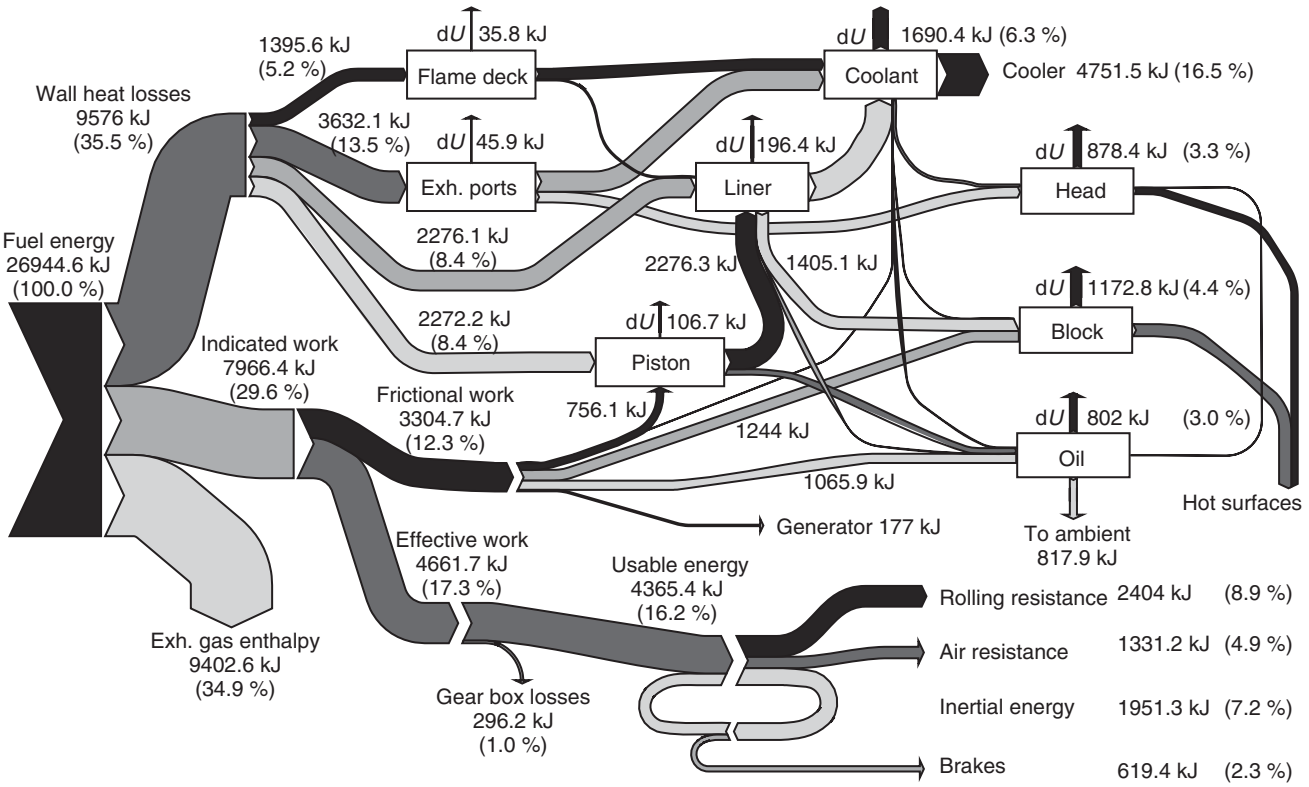

Figure 28. Exemplary cumulated energy distribution in NEDC.

10 THERMAL MANAGEMENT

Thermal management recently has moved more and more into the focus of new engine developments and makes up an important part of reaching lower fuel consumption rates. Figure 28 shows simulated cumulated energy flows of an upper middle class vehicle equipped with a four-cylinder 1.8-L gasoline engine when driving the NEDC. The diagram is a result of a thermal management simulation covering all relevant energy flows needed to describe a powertrain warm-up. Thermal inertias interact with heat inputs and outputs. The biggest heat source originates from the combustion process itself indicated as being wall heat losses which are input into thermal inertias close to the combustion chamber discretized as finite elements. Engine friction mainly is transferred into heat flowing into engine oil and engine structure and therewith has to be taken into account when simulating warm-up behavior.

The cumulated engine frictional work makes up a big portion of the fuel energy provided and thus yields the possibility for numerous fuel consumption improvements. Thermal management measures for reducing friction aim at a quick engine warm-up and at implementing advantageous engine operating conditions such as high system temperatures at low loads. The knowledge and manipulation of the heat distribution is the core business of thermal management. The effect of variable pumps for oil or coolant, different cooling concepts, artificial heat inputs, or any other variable parameter such as controllable piston cooling jets can be evaluated, as all relevant influences of any change in the system are covered.

As examples, thermal management analysis shows that the benefit of an electrical coolant pump strongly depends on its operating strategy, which should consider maximum allowable material temperatures in the cylinder head to guarantee structural strength and to avoid oil carbonization on the liner surface. In addition, split cooling concepts that separate the crankcase coolant jacket from the remaining cooling system to increase the liner temperature for lower piston friction show a measureable benefit in engine warm-up. Overall, depending on the operating strategy and system setup, benefits through split cooling, an electrical coolant pump, or a combination of both show advantages between 0.5% and 2% fuel consumption reduction in NEDC.

Stoichiometric Exhaust Emission Control

Joseph E. Kubsh

Manufacturers of Emission Controls Association, Arlington, VA, USA

1 INTRODUCTION

One of the most important technology bases that have emerged from the automotive industry in the past 50 years is the development, introduction, and continued evolution of automotive emission control technology. The centerpiece of this technology base is the three-way catalyst used on gasoline, stoichiometric, spark-ignited vehicles in all major world markets today. The name three-way catalyst was applied to catalytic controls that were capable of reducing all three criteria pollutants: carbon monoxide (CO), oxides of nitrogen (NO*x*), and volatile organic compounds (VOCs) within a narrow range of inlet exhaust gas compositions that corresponded to approximately the stoichiometric air/fuel ratio of the engine. Nowadays, more than 95% of the new gasoline automobiles sold around the world are equipped with catalytic converters that utilize three-way catalysts, adding to more than 750 million vehicles worldwide that have been equipped with catalysts since their first introduction in the United States in 1975.

Automotive catalytic emission controls were pioneered in the United States in response to public health concerns associated with elevated ambient ozone levels stemming, in part, from automotive tailpipe emissions of hydrocarbons (HCs) and oxides of nitrogen. These public health concerns were translated into emission control regulatory programs by both the US federal government and the state of California. On the federal level, the Clean Air Act Amendments of 1970 mandated significant reductions in automobile tailpipe emissions of CO, NO*x*, and VOCs starting in 1975. These federal standards led to the introduction of oxidation catalysts on automobiles starting with the 1975 model year to control CO and VOCs, and the use of three-way catalysts to control CO, NO*x*, and VOC tailpipe emissions starting in 1981. California, with severe smog problems in its large metropolitan areas, was provided with its own authority to set automobile emission standards and has typically led the US federal government and the world with the tightest standards requiring the best available emission control technology for automobiles.

1.1 Technology forcing exhaust emission regulations

Since the mid-1970s, US federal and California light-duty motor vehicle tailpipe emission regulations have been continually pushed to lower levels in response to air quality concerns. At the forefront of these new waves of regulatory programs aimed at significantly reducing emissions from light-duty vehicles are the US Environmental Protection Agency's (EPA) Tier 2 and the California Air Resource Board's (ARB) Low Emission Vehicle II (LEV II) programs. California acted first, adopting their LEV II program in the late 1998, followed by EPA finalizing the Tier 2 regulations in December 1999. Both the ARB LEV II regulations and the EPA Tier 2 regulations began their phase-in with the 2004 model year. In a parallel or slightly delayed time frame relative to these US initiatives, Europe (Euro 3 and Euro 4 regulations), Japan (Japan Low Emission Vehicle regulations), and Korea (Korea Low

ISBN: 978-0-470-97402-5

Emission Vehicle regulations) also established new, more severe light-duty emission regulations during the 1990s and established even more stringent light-duty vehicle emission standards in the 2000–2011 time frame (e.g., Euro 5 and Euro 6 regulations). Emission regulations for new vehicles based on the use of three-way catalyst technologies are now being implemented in almost every world market including large emerging markets in Brazil, India, and China. The introduction of catalytic converters in the United States and other world markets also required these countries to introduce unleaded gasoline as vehicle operation on leaded fuel results in dramatic deactivation of the active precious-metal-based catalytic materials (e.g., Pt, Pd, and Rh) present in three-way catalytic converters (TWCs).

All these current US light-duty vehicle emission programs require significant reductions in HC, CO, and NO*x* emissions relative to vehicle emission requirements associated with the regulations that precede each of these new emission programs (e.g., EPA's Tier 1 or California LEV I regulations). The LEV II regulations, for example, maintain tight HC emission levels established in the LEV I program (adopted in 1990; implementation began with the 1994 model year) but significantly reduce NO*x* emission requirements compared to LEV I requirements. The Tier 2 program draws from both the California LEV I and LEV II programs in significantly tightening both HC and NO*x* tailpipe emissions relative to Tier 1 regulations that were first implemented with the 1994 model year. An important input into each of these regulatory processes was the ability of emission control technologies to meet these increasingly tighter tailpipe emission standards in a cost-effective manner. The Manufacturers of Emission Controls Association (MECA) provided important technical inputs into the EPA Tier 2 and California LEV II rulemaking processes by completing a successful test program in the late 1990s that demonstrated that advanced three-way catalysts were capable of significantly reducing exhaust emissions from four different Tier 1-compliant passenger cars and trucks. Details of this test program were reported in a Society of Automotive Engineers (SAE) technical paper published in 1999 (Webb *et al*., 1999). Compared to precontrolled vehicles sold in the United States before 1975, today's Tier 2 and LEV II cars and trucks are meeting emission standards that require reductions of up to 98% with respect to VOCs, 96% for CO, and 98% for NO*x*. MECA completed a second light-duty gasoline vehicle test program in 2006 that demonstrated that advanced TWC systems allow even the heaviest light-duty gasoline trucks (e.g., SUVs and larger pickup trucks) to achieve very low exhaust emissions of HCs and NO*x*. Results of this test program are available in Anthony and Kubsh (2007).

Some additional details concerning the EPA Tier 2 and California LEV 2 emission regulations are provided here as each program includes the tightest light-duty emission certification categories currently in place in the world today. Full useful life tailpipe emission standards for the fully phased-in US EPA Tier 2 and California LEV II programs are summarized in Tables 1 and 2, respectively. Each of these programs provides auto manufacturers with several different certification categories to choose from for their light-duty vehicle fleet. In the case of EPA's Tier 2 program, auto manufacturers may select appropriate vehicle emission certification categories that allow their fleet of new vehicles to achieve a fleet average NO*x* emission limit of 0.07 g/mi (equivalent to a Tier 2, Bin 5 NO*x* fleet average). To comply with California's LEV II requirements, auto manufacturers must select appropriate vehicle emission certification categories that allow them to meet a declining annual fleet average NMOG standard that reached 0.035 g/mi NMOG for passenger cars and 0.043 g/mi NMOG for heavier, light-duty trucks in 2010.

Tailpipe emissions are measured on a chassis dynamometer using the US Federal Test Procedure (FTP, a vehicle speed vs time driving cycle). The concept of multiple certification categories was first introduced with California's LEV I program with Transitional Low Emission Vehicle (TLEV), Low Emission Vehicle (LEV), and Ultra-Low Emission Vehicle (ULEV) certification options that varied by vehicle weight class (e.g., passenger

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

car and light-duty truck weight classes). The EPA Tier 1 light-duty emission regulations also had weight class-specific emission regulations but only one set of emission standards for each gasoline vehicle weight class. The Tier 2/LEV II programs have several common features that are also significant changes from either Tier 1 or LEV I requirements: (i) fuel neutral requirements (emission standards are equivalent for gasoline and diesel-fueled vehicles); (ii) 120,000 mile full useful life durability; and (iii) a single set of standards that does not vary with light-duty vehicle weight class [up to 8500 lb. gross vehicle weight for all passenger cars and light-duty trucks and up to 10,000 lb. for medium-duty passenger vehicles (MDPVs)]. Treating passenger cars and light-duty trucks on an equivalent emission basis is an important focus for both the Tier 2 and LEV II programs. Both of these programs place a premium on cold-start emission performance and high emission system efficiencies with respect to NO*x* emissions.

Both EPA and California are in the process of proposing and finalizing a future set of light-duty vehicle emission standards that, once finalized, will further reduce US vehicle emission limits to a fleet average level consistent with California's current SULEV emission limit and EPA's Tier 2, Bin 2 emission limit by 2025. California's LEV III emission standards and EPA's Tier 3 emission standards are both expected to be finalized in 2013. A phased-in compliance schedule for California's LEV III emission limits begins in model year 2015, whereas EPA's Tier 3 program is expected to begin in model year 2017. In addition to tighter emission standards for HCs, CO, and NO*x*, the LEV III and Tier 3 proposals are also expected to tighten emission standards for particulates from future light-duty vehicles.

Reaching the tailpipe emission levels associated with today's Tier 2 and LEV II emission regulations, or future Tier 3 and LEV III emission limits on stoichiometric gasoline vehicles, requires a concerted systems approach that includes the use of advanced spark-ignited engines, advanced engine control strategies, clean fuels, clean lubricants, and advanced emission control technologies. Both ARB and EPA have included the clean fuel component in their LEV II and Tier 2 regulatory programs with respect to gasoline sulfur levels. ARB established a 30 ppm sulfur average for gasoline as a part of their California Phase II reformulated gasoline requirements. This sulfur level was further reduced to an average of 15 ppm sulfur starting in 2004 with the introduction of California Phase III reformulated gasoline regulations and was capped at 20 ppm starting in 2012. Similarly, the EPA included gasoline sulfur level regulations as an integral part of their Tier 2 regulatory package with the phase-in of 30 ppm average S levels started in 2005. EPA has proposed a 10 ppm gasoline sulfur average in conjunction with its Tier 3 light-duty vehicle emissions proposal. A recent publication by workers at Umicore (Ball, Clark, and Moser, 2011) showed that performance degradation of an advanced three-way catalyst system on a PZEV-class four-cylinder passenger car is still found of gasoline sulfur levels at 33 ppm. This publication shows that the lost catalyst performance observed at 33 ppm gasoline sulfur levels can be mitigated by either purging the catalysts of sulfur by operating the vehicle at higher speeds and loads or by reducing gasoline sulfur levels down to 3 ppm. Lubricant constituents such as phosphorus and inorganic elements such as Zn and Ca have also been shown to act as catalyst poisons or catalyst masking agents driving lubricant producers to optimize lubricant formulations to insure adequate engine lubrication characteristics with minimal impacts on catalyst performance and driving engine designers to minimize engine oil consumption characteristics of advanced engines. Clean fuels and lubricants are a necessary prerequisite for maintaining the high performance levels of the advanced engine and emission systems required for Tier 2/LEV II compliance, as well as future compliance with Tier 3/LEV III emission limits.

2 THREE-WAY CATALYTIC CONVERTERS

The TWC has been the primary emission control technology on light-duty gasoline stoichiometric vehicles since the early 1980s. The use of TWCs, in conjunction with oxygen sensor-based, closed-loop fuel delivery system, allows for simultaneous conversion of the three criteria pollutants, HCs, CO, and NO*x*, produced during the stoichiometrically calibrated air/fuel combustion process of an internal combustion, spark-ignited engine. Figures 1 and 2 depict a cut-away drawing and a cut-away photo of typical TWCs, one using a ceramic substrate and the other using a metallic substrate. The active catalytic materials are present as a thin coating of precious metals (e.g., Pt, Pd, and Rh) and oxide-based inorganic promoters and support materials on the internal walls of the honeycomb substrate. The substrate typically provides a large number of parallel flow channels to allow for sufficient contacting area between the exhaust gas and the active catalytic materials without creating excess pressure losses.

Catalytic materials are typically applied by contacting the substrate with a water-based slurry containing the active inorganic catalyst materials. The coated substrate is contained within an outer metal-based shell that facilitates connection of the converter to the vehicle's exhaust system through flanges or welds. The honeycomb-based

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

substrates are typically either ceramic or metal foil-based. Cordierite, a magnesium alumino-silicate compound, is the preferred ceramic substrate material because of its low coefficient of thermal expansion, good mechanical strength characteristics, and good coating adhesion properties. The ceramic substrate is formed as a single body using an extrusion process followed by high temperature firing. Metal-foil-based substrates are made from thin ferritic-based specialty stainless steel foils brazed together to form the parallel flow passages. The ferritic foil alloy provides good oxidation resistance in the exhaust environment, good mechanical strength, and an oxidized surface that promotes good adhesion of the catalytic coating to the foil. In the case of ceramic substrates, a special oxide fiber-based mounting material (typically referred to as a *mat*) is used between the substrate and the metal outer shell to hold the substrate in place, provide thermal insulation, and cushion the ceramic body against the shell. The outer metal shell or mantle is an integral part of the metal substrate production scheme, and no additional mounting materials are generally required. As shown in Figures 1 and 2, in some cases, the converter housing or "can" can be surrounded by a

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

second metal shell with an annular gap between these two metal shells. This type of arrangement provides additional heat insulation to the converter. The annular region between the two shells may be left as an air gap or filled with an insulating material such as an inorganic fiber-based material.

Although the primary components and function of a TWC have remained relatively constant during its more than 30 years of use on light-duty gasoline vehicles, each of the primary converter components (catalytic coating, substrate, and mounting materials) has gone through a continuous evolution and redesign process aimed at improving the overall performance of the converter while maintaining a competitive cost-effectiveness of the complete assembly. The performance-based catalytic converter re-engineering effort has had three main focuses: (i) wide application of close-coupled converters mounted near the exhaust manifold of engines for improved performance following a cold engine start; (ii) the development of thin-wall, high cell density substrates for improved contacting efficiency between the exhaust gas and the active catalyst and lowering the thermal mass of the converter; and (iii) the design of advanced, high performance TWCs for both close-coupled and underfloor converter applications that emphasize excellent thermal durability and efficient use of the precious metals platinum, palladium, and rhodium. Each of these three emission control technology platforms is discussed in more detailed in subsequent sections of this chapter.

Advanced TWC formulations often utilize multilayer architectures and/or axial placement of different catalyst materials along the length of the substrate that allow for the optimization of specific catalytic functions (e.g., improved light-off characteristics or improved overall efficiency for reducing HCs, CO, and/or NO*x*). These advanced catalysts also utilize a variety of advanced materials (in addition to the active precious metals) that promote the oxidation and reduction reactions associated with three-way catalysts and allow these catalysts to maintain activity in severe thermal exhaust environments. Catalyst substrate channel or cell densities as high as 1200 cells/in^2 have been used on production catalytic converters with 600 cells/in^2 substrates used in many late model vehicle applications. A similar re-engineering effort has occurred with other exhaust system components such as exhaust manifolds and exhaust pipes that complement improvements in catalytic converter technology. The focus of these manifold and other exhaust component improvements has been exhaust system thermal management and heat conservation through the use of low thermal mass, air-gap-insulated components, or other heat insulation strategies.

Current state-of-the-art, stoichiometric gasoline emission control systems are defined by SULEV (Super Ultra-low Emission Vehicle) or PZEV (Partial Zero Emission Vehicle) compliant light-duty vehicle sold in the US market. There are a number of recent references (Inoue and Mitsuishi, 2009; Matsuzono *et al*., 2008; Laurell, Dahlgren, and Vaisanen, 2007; Kidokoro *et al*., 2003; Oguma *et al*., 2003) that describe these systems that typically include combinations of close-coupled and underfloor converter systems that utilize high performance three-way catalysts displayed on high cell density substrates. These SULEV/PZEV systems utilize advanced cold-start calibration schemes including cold-start engine spark retard, higher cold-start idle speeds, and/or secondary air injection during the initial engine cold-start to accelerate the warm-up of the close-coupled converter within a few seconds after a cold engine start.

2.1 Close-coupled converters

Achieving high conversion efficiencies for both HC and NO*x* emissions during normal vehicle operation represented by the FTP driving cycle, for example, has focused attention on cold-start performance of catalytic converters for both US Tier 2 and LEV II light-duty applications. LEV I HC emission requirements introduced by California in 1994 provided the first regulatory driver that placed importance on cold-start emissions. Numerous studies published in the late 1980s and 1990s have discussed the high percentage of FTP driving cycle emissions associated with the early stages of vehicle operation following a cold engine start situation (Hughes and Witte, 2002; Pfalzgraf *et al*., 2001; Nishizawa *et al*., 2001; Brueck *et al*., 2001; Domesle *et al*., 2001; Williamson *et al*., 2000; Lafyatis *et al*., 2000; Holy *et al*., 2000; Moore *et al*. 1999; Webb *et al*., 1999; Ehmann *et al*., 1999; Takahashi *et al*., 1998; Kishi *et al*., 1998). This is especially true for 1990s vintage vehicles sold in the United States designed to comply with less severe Tier 1 emission standards. HC tailpipe emission profiles during FTP testing of Tier 1 vehicles are generally dominated by emissions emitted during the first 1–2 min of operation after the cold-start. This large fraction of cold-start emissions in Tier 1 vehicles stemmed from significant fuel enrichment used by auto manufacturers to facilitate engine start under cold conditions and significant delays in converter warm-up to catalyst operating temperatures required for high conversion efficiencies (e.g., 350°C or higher). Heat-up delays were usually associated with relatively long distances and the associated poor heat transfer between the converter location and the engine exhaust ports. NO*x* emission profiles also have a component related to cold-start operation but are generally distributed more uniformly through the FTP

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

driving cycle on Tier 1 certified vehicles because of NO*x* emission events associated with vehicle accelerations and decelerations.

To more effectively deal with cold-start emissions, converter volumes have been moved closer to the engine exhaust ports to minimize exhaust system heat losses and accelerate the heat-up of catalysts during the critical time following engine start. Converters located near the engine exhaust valves (e.g., at the exit of the exhaust manifold) are referred to as *close-coupled converters* (or sometimes light-off converters or preconverters). LEV I and ULEV I compliant light-duty vehicles introduced in the mid-1990s were the first significant applications of exhaust systems featuring close-coupled catalytic converters. In some applications (typically smaller displacement engines), a vehicle may have all or a large fraction of the required catalyst volume located close to the engine exhaust manifold. In other applications (typically larger displacement engines), the exhaust system will include smaller volume converters located close to the engine followed by a larger converter volume located further downstream in the exhaust in an underfloor location. In these multiple converter exhaust schemes, the size of the close-coupled converter is balanced between thermal mass (minimal catalyzed substrate mass for faster heat-up), diagnostic (adequate oxygen storage capacity), and durability considerations (sufficient volume to maintain required performance over extended mileage).

In larger engines, dual exhaust system configurations are often used with parallel systems for each cylinder bank (in the case of V-type engine designs) or groups of cylinders (in the case of in-line engine designs). These parallel systems may each incorporate close-coupled and underfloor converters or parallel close-coupled converters that lead into a y-pipe and a single underfloor converter. A schematic of an exhaust system layout featuring dual close-coupled converters flowing into a single underfloor converter is shown in Figure 3. Owing to their close orientation to the engine, the close-coupled converter(s) can reach temperatures required for high conversion efficiencies of HCs, CO, and NO*x* in 30 s or less following engine start, compared to heat-up times of 60 s or more associated with underfloor-only converter systems.

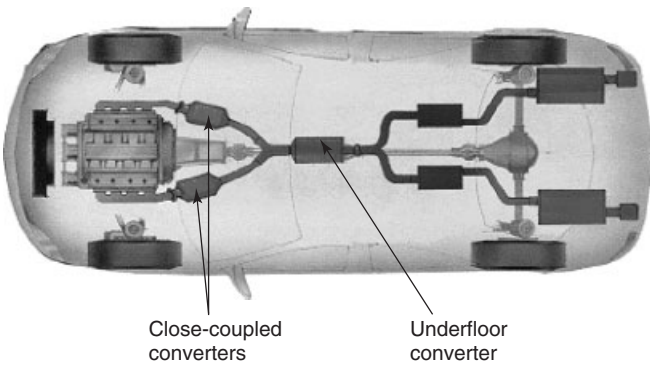

Figure 3. Exhaust system with close-coupled converters.

Fast dynamic converter heat-up, a requirement for low cold-start emissions, is also facilitated by advanced cold-start engine calibration strategies. These strategies include retardation of the engine spark, reduced idle speed, use of secondary air injection, and/or lean start strategies. Numerous examples of these cold-start strategies have been described in the literature (Inoue and Mitsuishi, 2009; Laurell, Dahlgren, and Vaisanen 2007; Kidokoro *et al*., 2003; Oguma *et al*., 2003; Matsuzono *et al*., 2003; Brueck *et al*., 2002) and are a key part of the systems approach required to achieve high conversion efficiencies for HC and NO*x* at the early stages following engine start. Each of these engine start-up strategies seeks to maximize conditions at the close-coupled converter that accelerate its heat-up following engine start (e.g., additional unburned fuel to combust over the catalyst, minimized total exhaust flow during initial engine idle, and slight excess of oxygen to combustibles in the exhaust to promote full oxidation at the catalyst).

Rapid converter heat-up also has placed greater emphasis on exhaust system thermal management. Efficient transfer of heat generated during the combustion process to the catalytic converter with minimal heat losses to the surrounding environment is facilitated by insulated exhaust manifolds and insulated exhaust pipes (Kidokoro *et al*., 2003; Oguma *et al*., 2003; Pfalzgraf *et al*., 2001; Webb *et al*., 1999). The preferred method of insulation is through the use of low thermal mass and air gap components. Insulated manifolds and pipes featuring dual wall construction separated by air gaps have been developed to improve light-duty vehicle cold-start and warm-start emission performances. These air gap components generally make use of a thin, low thermal mass, durable inner wall to facilitate fast heat-up characteristics. An air gap between the thinner inner wall and a thicker outer wall provides insulation to minimize heat losses between the engine and the converter(s). These air gap exhaust components provide significant reductions in converter heat-up during the FTP test protocol, which in turn provides significant reductions in cold-start and warm-start vehicle emissions.

Placement of catalytic converters closer to the engine results in dramatic reductions in cold-start emissions of all criteria pollutants (especially HC and CO emissions that are most associated with cold engine start conditions). The close-coupled converter environment also raises converter maximum operating temperatures relative to underfloor environments. This, in turn, has placed added

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

demands on the thermal durability of catalysts and other converter components used in these more severe close-coupled converter applications. In particular, fiber-based mounting materials and packaging assemblies used with ceramic substrates have been reengineered and optimized to meet these more severe thermomechanical environments, as well as the longer durability requirements associated with the Tier 2 and LEV II emission regulations. Similarly, metal substrate construction methods and brazing schemes have also been optimized for the high mechanical loads and high temperatures encountered in close-coupled applications. A discussion of high temperature catalyst designs is presented in a subsequent section of this chapter.

2.2 High cell density substrates

Tier 1 compliant vehicles generally relied on substrate designs that utilize straight flow channeled monoliths with square cross-sectional channel openings. Channel sizes that equate to 400 channels or cells per square inch of frontal area (designated as 400 cpsi) became an industry standard for many applications in the late 1980s and 1990s. In Tier 1 applications of ceramic substrate designs with 400 cpsi, ceramic substrate wall thickness was typically 0.0065 in or 6.5 mils, with some limited usage of 400 cpsi substrates with 8 mil walls. Limited applications of ceramic monoliths with triangular shaped cells were also used for Tier 1 applications with cell densities of 236 or 300 cpsi (wall thickness of 6.5–11.5 mils). Metal substrates were also introduced with channel densities of up to 400 cpsi but with thinner metal foil walls that were typically 50 μm (approximately 2 mils) in thickness. These standard metal substrate designs typically utilize sinusoidally corrugated metal foils layered between flat foils to produce parallel flow channels.

Interest in automotive emission systems with high conversion efficiencies and improved cold-start performance to meet more severe emission requirements, such as Tier 2/3 and LEV I/II/III standards, encouraged the development of a new generation of both ceramic and metallic substrate designs that offer significantly higher cell densities (more flow channels per cross-sectional area) and thinner walls separating flow channels. These two key substrate characteristics provide increased geometric surface area (GSA) per unit volume of monolith for efficient distribution of the active catalytic coating, relatively small flow channels (or more precisely, relatively small values for the channel hydraulic diameter) for good heat and mass transfer characteristics, and reduced substrate thermal mass for faster heat-up during emission critical cold-start events. Figure 4 provides a comparison of relative specific geometric areas and bulk densities of ceramic substrates with progressively higher cell densities and thinner wall thickness.

As discussed in the many references associated with these high cell density substrates, substrate GSA is an important physical property in heterogeneous catalysis associated with the effective mass transfer of reactants present in the exhaust stream of an engine (e.g., HCs, CO, NOx, H_2O, and O_2) to the solid surfaces that contain the active catalytic sites (references include Mueller-Haas *et al*., 2003; Hughes *et al*., 2003; Hughes and Witte, 2002; Leonhard *et al*., 2002; Brueck *et al*., 2002). Increasing this specific geometric area provides for more efficient contact between the reactants and the active catalytic sites and, in turn, a higher overall conversion efficiency of these reactants in a given volume of catalyzed monolith. Increasing cell density at a constant monolith wall thickness provides increased GSA but results in higher bulk density or thermal mass because of the resulting higher fraction of walls per given cross-sectional area (or, stated in another way, higher cell density at a constant wall thickness lowers the fraction of the frontal area open to the flow of exhaust gas). To compensate for this bulk density effect, substrate manufacturers have successfully developed high cell density products with significantly thinner walls than the "standard products" used primarily in Tier 1 applications. For example, ceramic

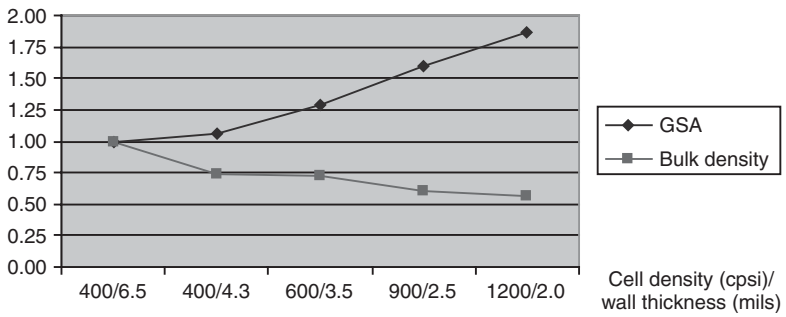

Figure 4. Relative geometric area and bulk density of ceramic substrates.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

substrates with 6.5 mil walls offered in "standard products" have been reduced to wall thickness in the range 1.5–3.5 mils in high cell density substrates. Similarly, metal substrates utilize 50 μm foils in "standard products" with high cell density products typically constructed with foil thickness ranging from 20 to 40 μm (approximately 0.8–1.6 mils). Thinning the monolith walls provides significant reductions in the thermal mass/bulk density of high cell density products. This low thermal mass characteristic enables catalyst-coated substrates to heat-up more quickly than heavier, "standard" wall thickness substrates. Fast dynamic heat-up of converters is key to achieving low tailpipe emissions during the critical cold-start and warm-start periods associated with normal driving operations and required to comply with Tier 2 and LEV II emission regulations. To further illustrate the properties and benefits associated with thin wall, high cell density substrates, results from three technical papers are briefly discussed later.

Hughes and Witte (2002) completed a comprehensive study of the impacts of high cell density substrates on light-duty vehicle emission performance in both the FTP and US06 test cycles. Their study made use of ceramic substrates covering a range of cell densities, including the "standard" ceramic substrate product with 400 cpsi/6.5 mil wall thickness, used in many Tier 1 applications, and high cell density, thin wall ceramic substrates such as 600 cpsi substrates with 3.5 and 4.5 mil wall thickness, and 900 cpsi substrates with 2.5 mil wall thickness. Table 3 summarizes ceramic substrates used in this study along with their accompanying properties including specific GSA and bulk density.

The performance of these substrates was investigated by catalyzing each substrate with an identical advanced Pd/Rh TWC (100 g/ft^3 total precious metal loading with Pd/Rh = 14/1; all substrates coated with a total coating weight of 140 g/L of substrate), aging the converters containing these catalyzed substrates using a Ford accelerated aging protocol, and performing triplicate FTP and US06 drive cycle tests on each aged converter. The Ford accelerated aging protocol was performed on an engine dynamometer and simulated approximately 50,000 miles of actual service life. FTP and US06 chassis dynamometer tests were run using a 2.0 L, four-cylinder, four-valve test vehicle with a single aged converter mounted at the exit of the exhaust manifold in a close-coupled location on the test vehicle. Catalyzed monolith volumes of both 1.0 L (50% of engine swept volume) and 0.5 L (25% of engine swept volume) were evaluated on the test vehicle using both drive cycles.

Figures 5 and 6 summarize NMHCs (non-methane hydrocarbons) and NO*x* average emission performance, respectively, of aged converters evaluated on the test vehicle during FTP evaluations as a function of substrate type (cell density and wall thickness). Emissions data are included in these figures for both the 1.0 L catalyzed volume and the 0.5 L catalyzed volume converters, appropriately weighted for each of the three phases of the FTP driving cycle [cold-start (Bag 1), hot transient (Bag 2), and hot-start (Bag

Table 3. Ceramic substrate properties for standard and high cell density products.

Cell density (cpsi)	400	400	600	600	900

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3)]. These data clearly show the significant decrease in both NMHC and NO*x* emissions that result from the use of high cell density/thin wall substrates relative to the base case 400 cpsi/6.5 mil wall standard. Lower emissions of NMHC and NO*x* are evident in each phase (or "bag") of the FTP drive cycle: cold-start phase (phase 1 or "bag" 1), warmed-up transient phase (phase 2 or "bag" 2), and warm-start phase (phase 3 or "bag" 3). These reduced tailpipe emissions stem from the higher GSA of these advanced substrates, the smaller hydraulic diameter of each coated channel, and the lower thermal mass of the higher cell density substrates. Thermal mass is proportional to the substrate bulk density values shown in Table 3 [thermal mass = (substrate bulk density) × (substrate volume) × (substrate-mass-specific heat capacity)].

Emission results presented by Aoki *et al*. (2002) also detail the performance of advanced high cell density ceramic substrates with respect to FTP NMHC emissions on a late model, four-cylinder test vehicle. This study evaluated engine-aged converters with equivalent volume (substrate dimensions of 106 mm diameter × 114 mm long) and equivalent precious metal loading (150 g/ft^3 advanced trimetal [Pt/Pd/Rh] catalyst) on a vehicle with a 2.3 L engine (vehicle calibrated for ULEV I performance with lean start strategy; converter inlet approximately 1.1 m downstream of the engine's exhaust valves). Converters were aged for 50 h using an accelerated engine aging protocol with a maximum catalyst temperature of 850°C. Aged converters with substrate cell densities from 300 to 1200 cpsi and varying wall thickness were evaluated on the test vehicle using the FTP drive cycle. Figure 7 compares the NMHC FTP emissions measured on the test vehicle for the various aged converters versus the specific GSA of the substrates evaluated by this program. In this figure, each ceramic substrate design is denoted by its cell density (cpsi) and wall thickness in mils (e.g., 600/3.5). The results show a strong relationship between NMHC emissions and substrate GSA with higher substrate GSA contributing to lower NMHC emissions in the FTP test cycle, a result consistent with the results shown in Figures 5 and 6. The results from Aoki *et al*. also show a relatively large benefit in emission performance for 600 cpsi substrates relative to 300 and 400 cpsi substrate designs. Smaller relative emission benefits were achieved in this study for additional increases in cell density beyond 600 cpsi (e.g., 900 and 1200 cpsi substrate designs). The relative magnitudes of the emission benefits shown in Figures 5–7 for different substrate cell density and wall thickness options will be impacted by the vehicle application environment including the number and location of catalysts in the exhaust system and the engine calibration strategy employed on the test vehicle. These optimization parameters again emphasize the overall systems design philosophy that needs to be employed to achieve the required emission performance with the most cost-effective system design.

Results presented by Marsh *et al*. (2001) show similar trends in reducing HC and NO*x* emissions with advanced high cell density metal substrates during FTP emission tests utilizing a 2.4 L, five-cylinder test vehicle. In this study, cell densities as high as 1600 cpsi were evaluated for their impacts on emissions performance. Physical properties for the metallic substrates evaluated in this study are summarized in Table 4, including values of the flow

Table 4. Metallic substrate properties for high cell density products.

Cell density (cpsi)	600	800	1000	1200	1600
Wall thickness (mils)	30	25	20	20	20
Hydraulic diameter (mm)	0.85	0.75	0.66	0.60	0.52
Geometric surface area (m^2/l)	3.77	4.32	4.88	5.36	6.08
Thermal mass (J/K)	689	681	641	680	750

channel hydraulic diameter. As in the study by Hughes and Witte (2002), converters were evaluated on the test vehicle using the same volumetric precious metal and total catalyst loading of an advanced TWC on each metallic substrate. Converters were located near the exit of the exhaust manifold on the five-cylinder engine. FTP HC and NO*x* emissions reported by Marsh *et al*. (2001) for these various high cell density metallic substrate-based catalysts are detailed in Figures 8 and 9, respectively. Similar to the results reported by Hughes and Witte (2002), FTP HC and NO*x* emissions were reduced in this study by utilizing higher cell density, thinner wall metal substrates. Improvements in HC emissions were most strongly impacted by the combined increase in cell density with thinner walls between channels as this substrate design strategy lowers thermal mass and increases geometric area (e.g., moving from 600 cpsi/30 μm wall to 1000 cpsi/20 μm wall), critical properties for maximizing converter heat-up and mass transfer characteristics during the HC intensive cold-start period. Further increases in cell density at constant wall thickness (e.g., 1000, 1200, and 1600 cpsi with 20 μm wall thickness) equate to higher thermal mass substrates with poorer heat-up characteristics during the cold-start phase of the FTP test cycle. The additional geometric area of these highest cell density designs helped to compensate for the higher thermal mass but no net benefit in cold-start HC performance was realized. NO*x* benefits were shown in each case as cell densities increased, largely because of more effective contacting efficiency between the exhaust gas constituents and the active catalyst coating present on the walls of the substrate. Somewhat higher pressure drop of these substrates with increasing cell density may also have contributed to some reductions in engine-out NO*x* levels in certain driving modes because of increased levels of internal exhaust gas recirculation (EGR) within the engine's combustion chambers.

Results like those shown in Figures 5–9 and many other studies aimed at understanding the impacts of advanced substrate properties such as cell density, hydraulic diameter, and thermal mass have allowed researchers and

design engineers to develop sophisticated mathematical models that accurately predict the performance of catalytic converters during vehicle operation including performance during the FTP test protocol (Lafyatis *et al*., 2000; Umehara *et al*., 2000; Becker *et al*., 2001; Marsh *et al*., 2001; Aoki *et al*., 2002; Leonhard *et al*., 2002). These models generally include mathematical descriptions of the heat and mass transfer processes that occur within catalytic converters. Becker *et al*. (2001) used a modeling approach to predict the emission performance of a variety of substrate types and designs. In their work, they report that the catalytic performance of these substrates could be strongly correlated with key substrate physical properties: higher catalytic efficiency was proportional to substrate GSA and inversely proportional to bulk density and substrate channel hydraulic diameter. Large GSA in combination with small channel diameters provide good heat and mass transfer characteristics, whereas low substrate bulk density results in fast dynamic converter heat-up properties. In addition to cell density and wall thickness modifications, metal substrates have been developed and put into production that incorporate structural elements that help to promote turbulence within flow channels that promotes enhanced contacting efficiencies between the gas-phase reactants and the active catalyst components that are coated on the substrate channel surfaces.

The production of high cell density ceramic and metallic substrates is subject to the many quality system requirements of the auto industry. These advanced substrates are manufactured with precise specifications on all key fabrication parameters, resulting in only small variations in the key performance-related physical properties such as bulk density, cell density, and wall thickness. For example, ceramic monolith wall thickness typically varies by ±0.5 mils or less for nominal wall thickness in the range 2–4 mil. Similarly, metal foil thickness in metal substrates varies by ±0.2–0.3 μm for foils in the range 20–50 μm. Cell densities in ceramic substrates are controlled by the precision die used in the extrusion process and process controls associated with the extrusion and firing operations. Cell densities in metal substrates are controlled by tight specifications on the process used to produce corrugated foils, as well as process controls on other key production operations. As an example, cell densities in metal substrates vary by ±5% for high cell density substrates ranging from 600 to 1600 cpsi. Modifications to traditional canning operations and mounting materials have also been developed for high cell density, thin wall ceramic substrates to ensure a mechanically robust, durable converter package. Similarly, high cell density, thin wall metal substrates have reengineered brazing strategies and matrix/mantle connection methods to maintain required mechanical durability for all light-duty vehicle applications.

2.3 Advanced three-way catalysts

Three-way catalysts have traditionally relied on highly dispersed precious metals (Pt, Pd, and Rh) supported on high surface area aluminum oxide with the addition of a variety of base metal oxide promoters and oxygen storage materials to provide the simultaneous HC and CO oxidation and NO*x* reduction behavior required in automotive emission control applications. Oxygen storage and release behavior of TWCs is an important functionality required to maintain acceptable performance during air/fuel perturbations that occur as a result of the closed-loop air/fuel feedback control algorithm associated with oxygen sensors. Cerium oxide-based materials contained in TWC formulations have been the primary source of this oxygen storage behavior. Catalyst performance criteria associated with meeting the low emission requirements of Tier 2 or LEV II applications include maintaining high conversion efficiencies for all three criteria pollutants during all phases of vehicle operation (e.g., start phases, accelerations, decelerations, and cruise conditions) for extended operational lifetimes (i.e., 120,000 mile durability). These demands for high conversion efficiencies and extended durability have evolved TWC formulations and design strategies significantly in recent 15 years.

The interest in cold-start performance discussed with close-coupled converters previously puts emphasis on TWC light-off characteristics, especially with respect to HCs (Light-off generally refers to the catalyst temperature required to achieve significant conversion activity with respect to the pollutants of interest.). Pd-based TWCs (e.g., Pd-only, Pd/Rh, or Pt/Pd/Rh trimetallic catalyst formulations) became the preferred choice for close-coupled applications because of the inherent good HC light-off performance of Pd relative to Pt or Rh (Waltner *et al*., 1998; Nagashima *et al*., 2000; Williamson *et al*., 2000; Williamson *et al*., 2001; Ohmoto *et al*., 2002; Truex *et al*., 2002). Close-coupled applications also place a premium on catalyst thermal stability/durability as these close-coupled converters expose catalyst materials to significantly higher operating temperatures than temperatures associated with converters located in cooler, underfloor locations. This thermal durability requirement also placed attention on Pd-based close-coupled TWCs because of Pd's superior thermal stability compared to other precious metals. The thermal stability of other catalytic materials used in TWC formulations was equally important in meeting the demands of close-coupled catalysts. This need resulted in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the concerted development of new catalyst materials such as stabilized aluminas (a support material for precious metals), stabilized cerias and zirconias (both are catalytic promoters and oxygen storage materials), and the development of more stable precious metal impregnation strategies that helped to push maximum catalyst operating temperatures from 800°C to over 1000°C over recent 15 years. The longer durability requirements of Tier 2 and LEV II emission regulations, as well as the inclusion of heavier light-duty trucks with their relatively higher exhaust temperatures compared to passenger cars, contributed to this focus on improving TWC thermal stability.

TWCs with high conversion efficiencies and extended durability with respect to NO*x* (HCs and CO, as well) are additional important criteria of Tier 2 and LEV II emission systems. The need for high performance and extended durability catalysts influenced all aspects of catalyst design and the selection of materials used as supports, promoters, and oxygen storage materials. Enhancements in oxygen storage materials, in particular, have been a key element in pushing catalyst performance in advanced TWC formulations. New families of ceria-zirconia materials have been developed that provide higher capacities of thermally stable oxygen storage and release functionalities to TWCs (references include: Hirasawa *et al*., 2009; Rohart *et al*., 2007; Kanazawa *et al*., 2003; Truex *et al*., 2002; Schmidt *et al*., 2001; Williamson *et al*., 2001; Williamson *et al*., 2000). Synergies between these new ceria-zirconia materials and the catalytically active precious metals have led to improvements in intrinsic catalyst light-off characteristics, broader three-way operating windows with respect to the simultaneous oxidation and reduction reactions as a function of inlet air/fuel ratio, and more highly dispersed and thermally stable precious metal activity. Figure 10 provides an example of TWC performance improvements with respect

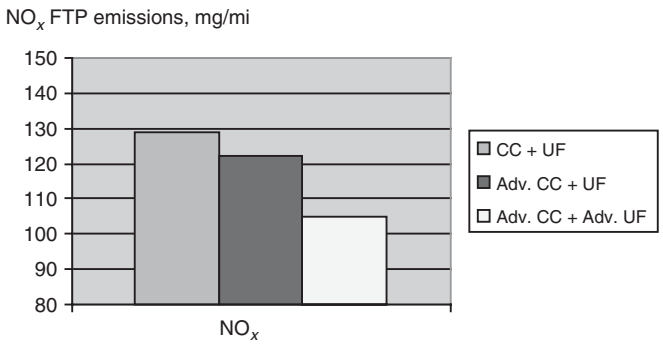

Figure 10. Impact of advanced catalyst formulations on NO*x* FTP emissions from a 5.3 L, V8 test vehicle equipped with close-coupled (50 g/ft^3 Pd-only)+ underfloor converters (30 g/ft^3 Pt/Rh = 3/1). (See Williamson *et al*. (2001) for details.)

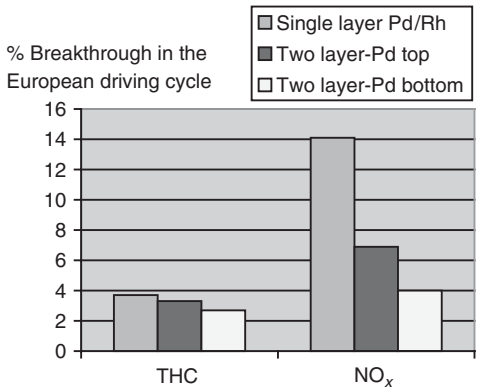

Figure 11. Impact of catalyst coating architecture (single layer vs double layer) on total hydrocarbon (THC) and NO*x* performance of a Pd/Rh three-way catalyst (100 g/ft^3 total precious metal loading with Pd/Rh = 5/1; 100 h aged catalyst on a 1.8 L, 4-cylinder test vehicle. (See Lindner *et al*. (1996) for details.)

to NO*x* emissions stemming from the use of new materials such as advanced ceria-zirconia-based oxygen storage materials (Williamson *et al*., 2001).

New catalyst design strategies have also been developed to better tailor precious metal performance in advanced catalysts. A primary example of these tailored design strategies is the development of multilayer catalyst coating architectures in which preferred precious metal functionalities and oxygen storage performance can be segregated to maximize performance and minimize unwanted negative interactions that may result by co-mingling certain catalyst materials (Punke *et al*., 1995; Lindner *et al*., 1996; Nagashima *et al*., 2000, Schmidt *et al*., 2001; Williamson *et al*., 2001; Ohmoto *et al*., 2002; Schmidt *et al*., 2002; Ball *et al*., 2005; Aoki *et al*., 2009; Aoki *et al*., 2011). For example, undesirable alloying of precious metals due to high temperature sintering phenomenon can be minimized by segregating precious metals in unique chemical layers in a multilayer coating format. An example of the performance improvements achieved by new multilayer catalyst architectures is shown in Figure 11 (Lindner *et al*., 1996). These advanced catalyst materials and catalyst design strategies have cascaded through all TWC formulations (precious metal types including Pd-only, Pd/Rh, Pt/Rh, and trimetal) and applications (close-coupled and underfloor converters) to deliver cost-effective high performance and durable catalysts required to meet the needs of Tier 2 and LEV II light-duty applications.

The need to reduce cold-start HC emissions for Tier 2/LEV II and future Tier 3/LEV III applications has also resulted in the development of HC adsorber functions that can be added to three-way catalyst formulations or stand-alone HC adsorbers that are integrated into the exhaust

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto146
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

system of light-duty vehicles that utilize three-way catalysts. HC adsorbers have seen only limited commercial applications on a few selected models of SULEV or PZEV-compliant vehicles thus far. In these applications, materials that can adsorb typical exhaust HCs at ambient temperatures and then desorb the HCs at elevated temperatures are used to capture HC emissions during the cold-start phase of the emissions test cycle. When the HCs are desorbed later in the cycle, as the adsorber materials reaches its HC desorption temperature(s), the desorbed HCs can be oxidized by available three-way catalysts (assuming that the catalyst has reached a temperature that facilitates HC oxidation). Synthetic zeolites have been the HC adsorber material of choice for automotive applications. In some cases, the adsorber can utilize a mixture of zeolites in order to broaden the HC capturing efficiency of the adsorber relative to the range of HCs that are associated with automotive exhaust gas. Zeolite properties such as silica/alumina ratio, crystal structure, the presence and composition of exchanged cations, and zeolite pore size have been shown to impact the specific adsorption capacity and desorption properties of a zeolite relative to the HC species present in the exhaust (Mukai *et al*., 2004; Kanazawa and Sakurai, 2001; Goralski *et al*., 2000). A key design property for maximizing the impact of an HC adsorber on cold-start HC emissions is the overlap of the desorption temperature with the onset of catalyst HC oxidation activity over the whole regulated durability time frame of the emissions system (e.g., 120,000 or 150,000 miles).

A zeolite adsorber layer has been added to commercial three-way catalyst formulations that are displayed in underfloor converters to reduce cold-start HC emissions (Inoue and Mitsuishi, 2009; Lupescu *et al*., 2009; Oguma *et al*., 2003; Ballinger and Andersen, 2002). In this configuration, the ceramic or metallic monolith is coated with successive layers of the zeolite-based adsorber material and the three-way catalyst formulation to form an integrated, multifunctional converter. In another commercial application (Inoue *et al*., 2000), the underfloor HC adsorber material is physically separated from the underfloor three-way catalyst and an exhaust valving arrangement is used to first direct the bulk of the cold exhaust through the adsorber-containing monolith. Once the close-coupled three-way converter has reached catalyst light-off temperatures, the exhaust valve is opened to allow flow through the underfloor three-way converter. As this converter warms-up, heat is transferred to the adsorber function (located in an outer annulus of the underfloor converter) and HCs are desorbed and directed into the underfloor converter for conversion via a catalyzed HC oxidation reaction.

To achieve the full performance benefits of these advanced catalyst/advanced substrate combinations for Tier 2 and LEV II applications, it has also been necessary to develop improved engine operating algorithms that more closely match inlet catalyst conditions with the optimal operating window of the catalyst in order to maximize catalyst efficiency for all three criteria pollutants. The discussion on close-coupled converters included the development of cold-start engine operating strategies that accelerate converter heat-up during the crucial cold-start process. Similarly with respect to NO*x* emissions, tighter air/fuel control strategies during all modes of vehicle operation (especially high NO*x* emission modes associated with vehicle accelerations and decelerations) have been developed to achieve the low NO*x* emission requirements of the Tier 2 and LEV II programs. Precise air/fuel control strategies balance the relative concentration of oxidants and reductants in the exhaust stream within the catalyst's preferred operating window under highly dynamic vehicle operations. Similarly, vehicle calibrators can make use of EGR strategies to minimize engine-out NO*x* levels during some vehicle operating modes and maximize emission system performance. These EGR calibration strategies may involve either internal EGR calibrations through changes in exhaust valve lift or timing characteristics or external EGR calibrations through changes in the duty cycle of an external EGR valve during certain portions of a given driving cycle. The interplay and optimization of engine controls and emission control technology is a necessary part of the overall systems approach and integration required in meeting Tier 2/LEV II low NOx emission goals on light-duty vehicles.

New high performance TWCs have also required the development of new precision substrate coating processes and equipment capable of producing and placing complex coating formulations on the interior walls of ceramic and metallic substrates (both standard and advanced high cell density substrates) in high volume production. These advanced catalyst formulations have also been tailored to be compatible with advanced high cell density substrates (Lafyatis *et al*., 2000; Williamson *et al*., 2000; Domesle *et al*., 2001; Williamson *et al*., 2001; Schmidt *et al*., 2002; Hughes *et al*., 2003). For example, the volume-based catalyst loading on a high cell density substrate must be balanced to provide required performance and durability characteristics without adversely affecting the overall thermal mass (and the resulting dynamic heat-up) and pressure drop characteristics of the coated substrate. Similar to substrate manufacturing processes, catalyst manufacturing processes must also be operated within the rigorous automotive industry quality control requirements. Catalyst formulation and coating specifications on all materials (precious metals, support materials, oxygen storage materials, etc.) minimize physical and chemical variations between production parts and production lots of a given catalyst type.

2.4 Gasoline particulate filters

The emerging interest and growing number of regulatory programs associated with reducing greenhouse gas emissions from motor vehicles (and improving vehicle fuel economy) has put significant attention on developing and commercializing gasoline direct injection (GDI) technology. This gasoline engine platform has combustion characteristics that parallel diesel engines that use direct fuel injection strategies and provides lower fuel consumption compared to port injected gasoline engines that have been the dominant stoichiometric, gasoline engine technology on light-duty vehicles for more than a decade. Compared to port fuel injected gasoline engines, the initial wave of commercial GDI engines introduced in the 2005–2011 time frame has been shown to produce higher levels of particulates under typical emission test cycle conditions (e.g., the US EPA FTP cycle). Future US and European light-duty emission standards (e.g., LEV III, Tier 3, Euro 6) are expected to lower PM emission requirements for some or all classes of gasoline vehicles. As a result of this interest in lower PM emission levels, emission control technology developers and auto manufacturers have begun to assess the feasibility of using gasoline particulate filters (GPFs) on future GDI engines. A number of recent references (Chan *et al.*, 2013; Eakle, Zahn, and Weber, 2010; Mikulic *et al.*, 2010; Saito *et al.*, 2011) are available that describe the development and performance of first-generation GPFs on GDI vehicles. The filter technology base is drawn from the large experience base with diesel particulate filters (DPFs). The filter substrates are high efficiency, wall-flow type filters made of ceramic materials that are essentially identical to wall-flow filters that have been used commercially on light-duty and heavy-duty diesel engines since 1999 (see Exhaust Emission Control Considerations for Diesel Engines on particulate emission control technologies for more information on wall-flow particulate filters). In these recent references, GPFs have been evaluated on GDI vehicles with and without a three-way catalyst coating present on the wall-flow ceramic filter. Similar to DPFs, the wall porosity of the GPFs can be adjusted to modify the pressure drop and catalyst coating capacity of the filter. Similar to DPFs, wall-flow GPFs are capable of large reductions (>90%) of particulate emissions across a very broad range in particle size. Vehicle and engine manufacturers are also evaluating improved fuel injection strategies and other improvements to engine combustion technologies as a way of reducing particulate emissions from GDI engines. The topic of particulate emission from GDI engines is expected to grow in interest in the coming decade as more work is done to understand the health impacts of ultrafine particulates.

Spark Ignition Combustion

Ulrich Spicher

Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

1 BASICS AND MAJOR FEATURES

Spark ignition (SI) engines for passenger cars in the market today work exclusively according to the four-stroke principle. The four strokes of one engine cycle inside the combustion chamber of the SI engine take place during two crankshaft revolutions and are shown in Figure 1 (Bosch, 2003).

During the first stroke (intake stroke), the intake valves, directly controlled by the intake camshaft profile, are open. Owing to the downward motion of the piston, the air–fuel mixture (external mixture preparation) is drawn into the cylinder through the valves. The second stroke (compression stroke) is characterized by the upward motion of the piston and the compression of the unburned gas mixture of air and fuel. During this second stroke and also during the third stroke (expansion stroke), the intake valves are closed. At the end of the compression stroke, the premixed homogeneous air–fuel mixture is ignited by the spark plug. The combustion process propagates outward from the spark plug and combustion continues until the entire air–fuel mixture is consumed during the expansion stroke, which is characterized by the downward motion of the piston. Owing to the combustion, both the gas temperature and the gas pressure inside the combustion chamber (cylinder) increase significantly, which drives the piston down and imparts a downward force on the crankshaft via the connecting rod. At the crankshaft, this force is converted into engine torque. After the end of the combustion, the exhaust gas expands until the exhaust valves open at the end of the expansion stroke; this is controlled by the exhaust camshaft profile. During the fourth stroke (exhaust stroke), the exhaust valves are open and the piston moves upward, pushing the exhaust gas out of the combustion chamber via the open exhaust valves into the exhaust system. The exhaust gas can reach temperatures of higher than 1000°C at full-load operation.

SI engines are traditionally characterized by a premixed and nearly homogeneous mixture of fuel and air, which is ignited by a spark plug located in the cylinder head. The homogeneous mixture can be prepared by one of two different methods of fuel delivery, either via external mixture preparation in the intake system or via internal mixture formation with fuel injection directly into the cylinder.

1.1 External mixture formation

External mixture formation is employed in the majority of SI engines. A more or less homogeneous mixture consisting of air and fuel vapor is generated before it enters the cylinder. Such systems typically make use of low pressure fuel injection into the intake port close to the intake valves, as shown in Figure 2.

The main advantage of this so-called port fuel injection (PFI) is the longer duration available for vaporization and

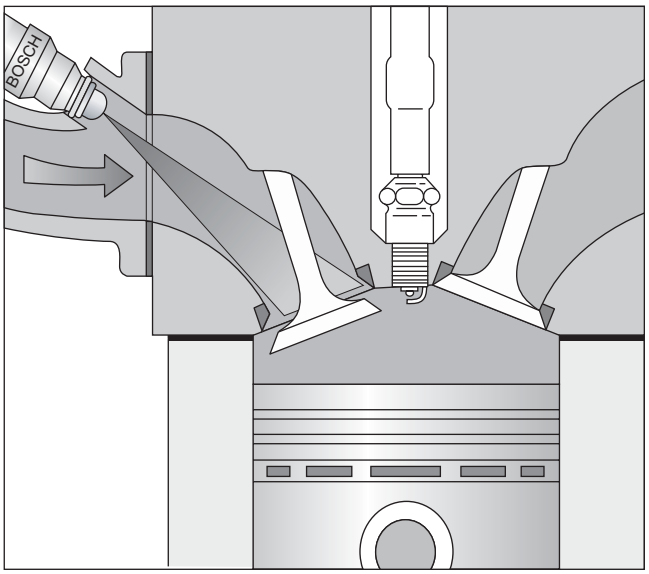

Figure 2. Port fuel injection (PFI) into the intake manifold close to the intake valve.

mixing of the fuel with the intake air during both the intake and the compression strokes until the ignition takes place. The mixture homogeneity is normally sufficient for ignition and combustion. One of the main difficulties is the condensation of fuel on the intake manifold walls during cold start operation, which can lead to an insufficient mixture process and incomplete combustion. This results in high levels of unburned hydrocarbons (UHC) and carbon monoxide (CO) emissions in the exhaust. To avoid these problems, intake manifold injection and special injection strategies (multiple injections) have been developed. The fuel is targeted such that it is injected directly behind the intake valve and partially toward the open intake valve and into the cylinder. In this case, time is sufficient to homogenize the mixture during intake and compression.

1.2 Internal mixture formation

Since Mitsubishi presented the first direct injection spark ignition (DISI) engine with stratified operation in 1995, the development of these engines has made significant progress. Owing to the direct injection of the fuel into the combustion chamber, the mixture formation occurs in the cylinder of the engine. To achieve this direct fuel injection, two different arrangements of the injector and the spark plug have been introduced in the development of DISI engines: the wide spacing arrangement and the narrow spacing arrangement (Figure 3). These arrangements are also often referred to as the *wall-guided and spray-guided arrangements*, respectively. They both can be used to create either homogeneous or stratified mixtures in the cylinder.

With a wide spacing arrangement, the injector is typically located between the intake valves. The fuel is injected downward toward the piston and is then directed by the shape of the piston and/or by the in-cylinder flow to the centrally mounted spark plug. As a result of this relatively long mixture formation process, an optimal mixture stratification cannot be achieved. In addition, wall wetting on the

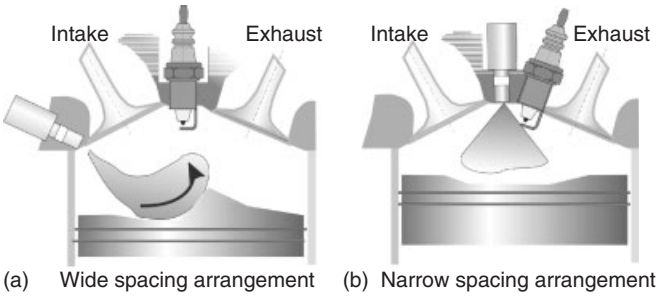

Figure 3. (a,b) DISI with different arrangement of spark plug and injector.

piston surface occurs, which leads to significantly increased UHC emissions.

In concepts with a narrow spacing between the injector and the spark plug, both the injector and the spark plug are located centrally in the cylinder head between the intake valves and the exhaust valves. A primary reason for this configuration is to realize a stratification of the air–fuel mixture during part-load operation of the engine enabling higher fuel efficiency due to overall lean air-fuel mixture. In this case, an extremely rapid vaporization of the liquid fuel is necessary to create an ignitable mixture that reaches the spark plug in a very short time, thus allowing minimum spark advance for best or minimum advance for best torque (MBT). Under optimal conditions, any contact between liquid fuel and the combustion chamber walls should be avoided. At full-load operation, the centrally located fuel injector proves to be very effective for producing a homogeneous charge. Because it is possible to generate a highly stratified air–fuel mixture at part load, an overall very lean mixture can be realized, too. This means that there is more than enough air in the cylinder to allow all of the fuel to burn completely.

Owing to the narrow spacing arrangement and close temporal coupling of fuel injection and spark advance, both mixture formation and stratification are expected to be incomplete at the time of ignition and during the early combustion phase. A further problem caused by this configuration is coking of the injector nozzle, which influences the spray characteristics in a way that can lead to misfiring. Manufacturing tolerances of nozzles, especially those involving nozzle hole geometry, directly affect the spray characteristics and therefore the combustion, too. Furthermore, deterioration of the durability of the spark plug has been observed due to high thermal stress. Another drawback of lean operation is the necessary use of more complicated and expensive NO_x aftertreatment systems in the exhaust to meet emission regulations. As a result of these difficulties, very few SI engines with direct injection and stratified lean mixture preparation are currently in production. However, to achieve a significant reduction in fuel consumption in future SI engines, it is expected that the share of DISI engines with lean combustion and mixture stratification will increase in the future. This requires further development of the injection system, including the fuel pump, the fuel rail, and the fuel injector, which will enable improved and extremely rapid mixture preparation near the end of the compression.

1.3 Operation modes with direct injection

In principle, direct injection in SI engines can be implemented using two different operating modes: homogeneous charge and stratified charge, shown in Figure 4.

In the higher load range, fuel is injected during the intake stroke, thus giving the injected fuel adequate time to mix with the air and form a homogeneous mixture before the start of ignition (Figure 4a). This operation mode shares some similarities with PFI in terms of injection timing and mixture homogeneity. Achieving wide open throttle (WOT) operation at lower load, which would require a lean homogeneous mixture in the combustion chamber, is not possible as the mixture present at the spark plug might be leaner than the lean ignition limit for lighter loads. During part-load operation, the advantages of WOT operation can be realized via operation with charge stratification. Injection is staged to ensure that an ignitable combustible mixture is always present near the spark plug at the time of ignition by creating a stratified air–fuel mixture in the combustion chamber through appropriate mixture preparation processes.

The advantages of operation with stratification of air–fuel mixture can be demonstrated by analyzing the losses during the gas exchange process (Figure 5).

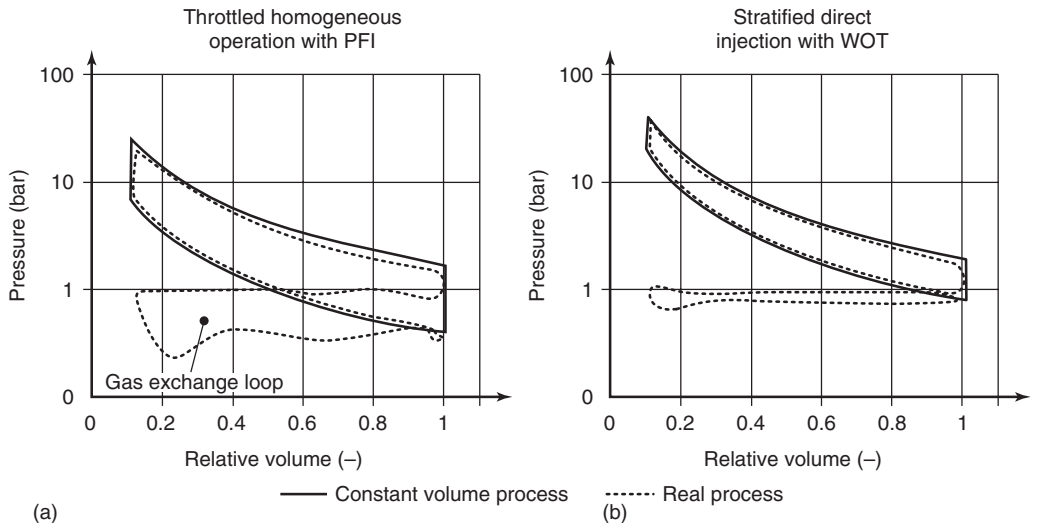

Figure 5. (a,b) Comparison of homogeneous throttled PFI and WOT stratified DISI working cycles at part load (equal engine speed and load). (Reproduced from Lückert *et al*., 2004. With permission from Aachen Colloquium Automobile and Engine Technology, Lückert *et al*., Daimler AG.)

WOT operation with DISI and a stratified charge effectively reduces the pumping losses normally associated with part-load operation of an SI engine. These pumping losses are represented by the area of the gas exchange loop in the $p-V$ diagram. With stratified operation and WOT, this area is significantly smaller than in the case of throttled operation with a homogeneous mixture and PFI. In addition, wall heat losses at stratified operation can be reduced during combustion if the stratified air–fuel mixture and eventual high temperature combustion products are insulated from the wall as much as possible by inducted fresh air and/or residual gas that remain in the cylinder. Overall, the reduced pumping losses will lead to improved engine thermal efficiency.

Stratified operation of a DISI engine is ideally implemented with a WOT. The load is then regulated solely by the quantity of injected fuel, as is the case in a diesel engine. During this process, the fuel is injected directly into the cylinder during the compression stroke shortly before ignition occurs. An ignitable mixture cloud forms in the center of the combustion chamber, surrounded by air that is not required for combustion. This stratification and the layer of insulating air reduce the heat losses through the combustion chamber walls that occur during subsequent combustion. Therefore, the engine is indeed operating with a globally lean mixture, whereby large air–fuel ratio gradients are present in the combustion chamber.

Figure 6 shows the range of the different operation modes for DISI engines in the engine operating map in terms of λ (where λ is defined as the ratio of actual air–fuel ratio to stoichiometric air–fuel ratio). In the low part-load range and the low speed range, the engine should be run with WOT and a stratified air–fuel mixture. This typically requires optimization of the in-cylinder flow and a specially adapted exhaust gas recirculation strategy to improve mixture formation and reduce the formation of nitrogen oxides (NO_x) during combustion. In the mid-load range (labeled $\lambda > 1$), a homogeneous lean air–fuel mixture, which is still within the ignition limit, should be used to avoid an abrupt change from homogeneous mixture formation to stratified mixture formation and vice versa. In the upper load and speed range, homogeneous mixture preparation with an air–fuel ratio of $\lambda = 1$ for operation with three-way catalyst or rich operation ($\lambda < 1$) for cooling at full load is necessary.

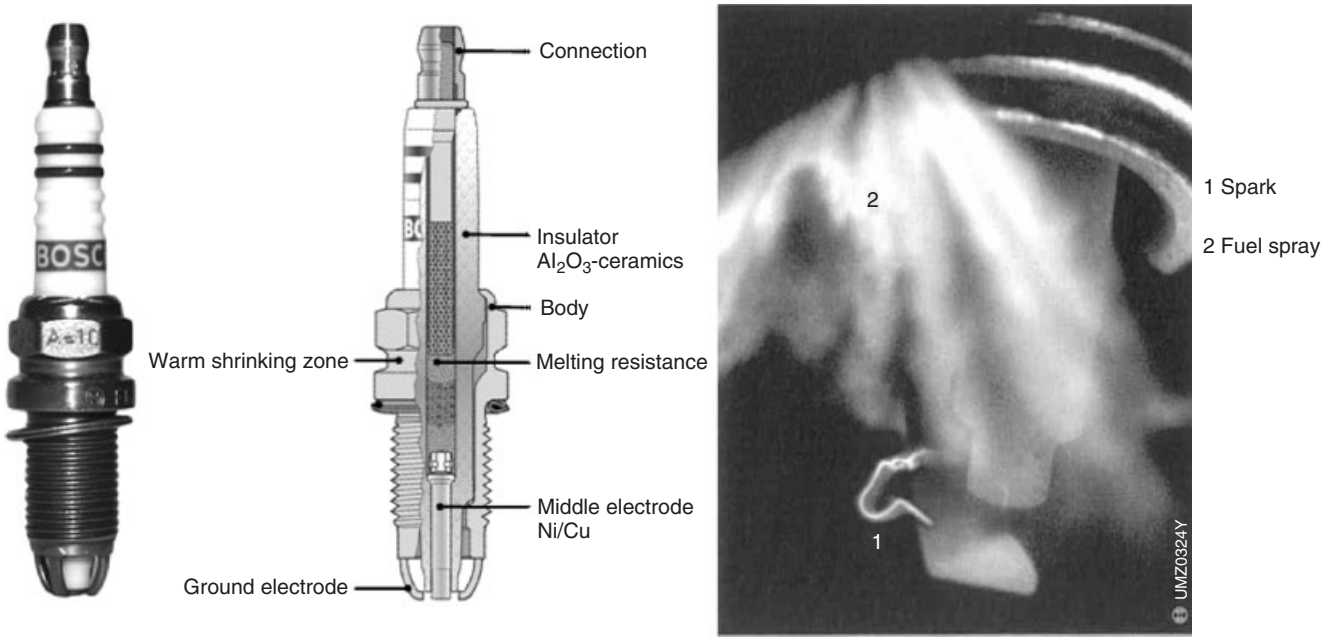

Figure 7. Spark plug and image of spark and liquid fuel spray for a DISI system with a narrow injector and spark plug arrangement. (Reproduced from Bosch, 2003. With kind permission of Springer Science+Business Media.)

2 IGNITION AND COMBUSTION

To initiate combustion, an electric ignition spark is provided by a spark plug. The air–fuel ratio λ around the spark plug must be within the ignition limits, between 0.6 (rich mixture) and 1.5 (lean mixture) for petrol (gasoline) fuel, in order for the mixture to be reliably ignited. The energy required for ignition is provided by an ignition system and supplied to the spark plug of the appropriate cylinder at the required spark advance. A spark plug and an ignition spark are shown in Figure 7 for a DISI system with a narrow injector and spark plug arrangement.

The spark is generated by an arc discharge between the middle and the ground electrodes. The spark plug is subjected to high thermal stress because of cyclical thermal loading with heating by combustion temperatures of up to 3000 K followed by cooling with fresh air–fuel mixture or even liquid fuel from the injection. In addition, the spark plug has to seal the combustion chamber at the maximum cylinder pressures, which can be more than 100 bar at full-load operation.

Ignition timing is an important variable for controlling the combustion of SI engines. It influences engine performance, fuel consumption, and exhaust gas emissions. It takes up to approximately 2 ms from the time of ignition until the time of maximum combustion rate. Therefore, spark advance must be set according to engine speed, engine load, and air–fuel ratio for the current operating conditions. For high combustion efficiency, it is necessary that approximately 50% of the fuel is consumed shortly after top dead center (TDC). In this way, an approximation to the ideal constant volume combustion is achievable.

Independent of the combustion system, which means independent of both fuel injection and mixture formation, spark advance is ideally adjusted to its minimum for best torque (MBT). However, at full load, SI engines are normally restricted in power output because of the occurrence of knocking. Therefore, MBT spark advance cannot safely be achieved. Figure 8 shows the comparison

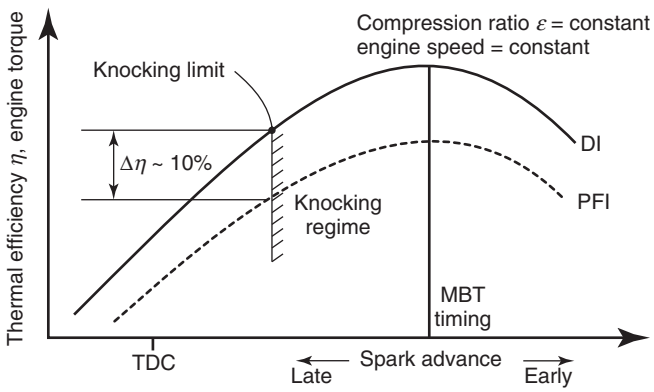

Figure 8. Thermal efficiency and engine torque versus spark advance.

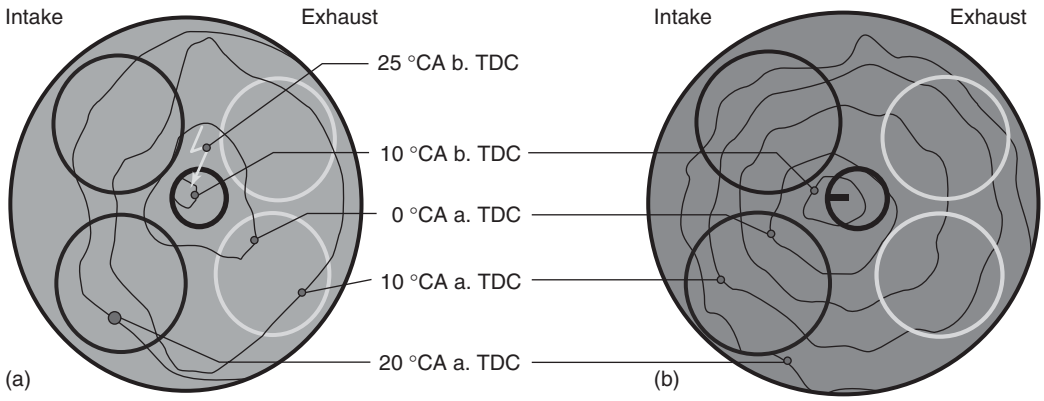

Figure 9. Flame propagation for nonknocking combustion [production engine (a); optimized configuration (b)]. Each contour represents the flame front location at the given °CA before (b) or after (a) TDC.

of engine torque as well as engine efficiency versus spark advance for an engine either with PFI or with direct injection (DISI). Engine speed is the same and constant for both injection strategies.

The flexibility of modern direct injection systems, combined with the charge cooling provided by the accompanying vaporization process inside the cylinder result in a higher volumetric efficiency and improved knocking behavior, which enables an improvement of power output of up to 10% (van Basshuysen *et al*., 2004).

After ignition has been initiated, propagation of the flame front (combustion zone) through the combustion chamber starts. If unrestricted by the combustion chamber walls (piston, cylinder liner, and cylinder head), the flame front would propagate approximately spherically. However, the flame front is distorted by the shape of the combustion chamber and the in-cylinder flow behavior. In addition, the temperature distribution in the combustion chamber as well as the temperatures of the combustion chamber walls and the homogeneity of the air–fuel mixture during combustion influence the contour of the flame front during its propagation. Figure 9a depicts the flame propagation of an individual combustion cycle, measured with the optical fiber technique (Spicher and Krebs, 1990) in one cylinder of a six-cylinder four-valve production engine at WOT operation. The engine speed was 5500 rpm with a spark advance of 25 crank angle degrees (CAD = °CA) before top dead center (BTDC), which represents the knock-limited spark timing.

The flame front (isolines) reaches the areas around the exhaust valves at TDC and has engulfed most of the combustion chamber at 20 CAD after TDC. By varying the in-cylinder flow, redesigning the piston crown and combustion chamber walls, and repositioning the spark plug, combustion can be optimized to produce uniform and approximately spherical flame propagation as shown in Figure 9b. As a result of these modifications, both torque and power output are increased by approximately 3% over the entire full load and speed range when compared to the production engine.

Variance in the processes involved with ignition, mixture composition, and flow turbulences cause statistical fluctuations in successive working cycles. These fluctuations essentially arise from irregularities during the first phase of the combustion sequence (inflammation phase) and invoke characteristic differences in the pressure traces of individual combustion cycles. These manifest themselves as variations in peak pressure values, crank angles of peak pressures, and indicated mean effective pressures (IMEP) (Figure 10). The variations in maximum pressure can be as high as 20% or more, depending on the operating point (load, engine speed, and air–fuel ratio). In addition, the cycle-to-cycle variations can influence the amount of UHC emissions and nitrogen oxide emissions as well as fluctuations in

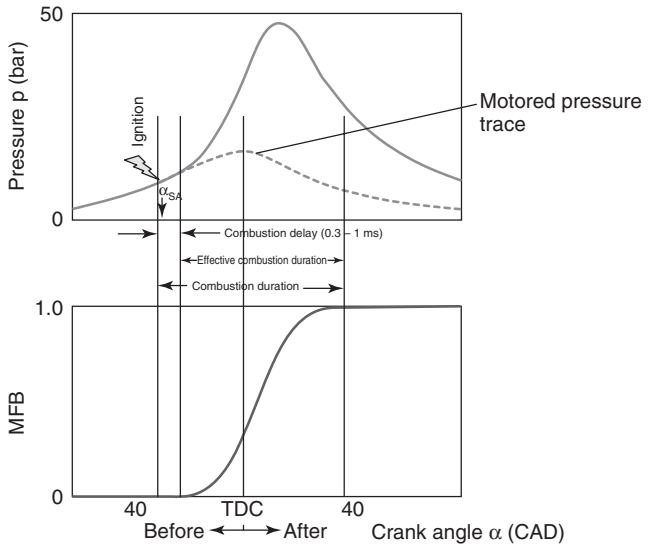

Figure 11. Pressure trace and mass fraction burned (MFB) function.

crankshaft rotational speed, which may be apparent as irregular engine operation.

Combustion behavior can be described by the mass fraction burned (MFB) function, which is calculated from the measured pressure trace using a thermodynamic two-zone model as well as an appropriate heat transfer model (see Pressure and Heat Release Analysis and Zero- and One-Dimensional Methodologies and Tools for related thermodynamic model discussions). The MFB curve has a value of between 0 and 1 (Figure 11).

After ignition, it normally takes a certain time until a measurable difference between the motored (without combustion) and the fired cylinder pressure traces is observed. This time duration of 0.3–1 ms is defined as "combustion delay" and corresponds to an MFB of approximately 2–5%. The total combustion duration from ignition time (MFB = 0) to the end of combustion (MFB = 1) is defined as "combustion duration." It is well known from experience in engine research and development that with homogeneous mixture formation, the point of 50% MFB (MFB50) should be in the range between 6 and 10 CAD after top dead center (ATDC) for maximum thermal efficiency. This means spark advance α_{SA} should be adjusted to achieve such combustion behavior.

A comparison between homogeneous operation with PFI and stratified operation is shown in Figure 12 for an engine speed of 2000 rpm and an IMEP = 3 bar. It is apparent from the p–V diagram on the left that the cylinder pressure at the end of compression is significantly higher for WOT, stratified operation; this is due to the higher pressure at the start of compression. The location of 50% MFB is at its thermodynamic optimum of eight CAD ATDC for the homogeneous operating point, as can be seen in Figure 12b.

The MFB curve for stratified operation indicates a rapid increase in the initial burning rate and a very slow burnout; this results from the mixture stratification. Near the spark plug, air–fuel ratios are rich or stoichiometric, which results in not only high flame speeds and thus rapid rates of combustion but also potentially high particulate emissions. However, the outermost portions of the air–fuel mixture have had a longer time to mix with the combustion air and become lean. These leaner mixture compositions burn much more slowly and are responsible for the long combustion duration observed for the stratified case. These longer combustion durations represent larger deviations from the thermodynamic optimal constant volume process and can lead to increased UHC emissions. To minimize

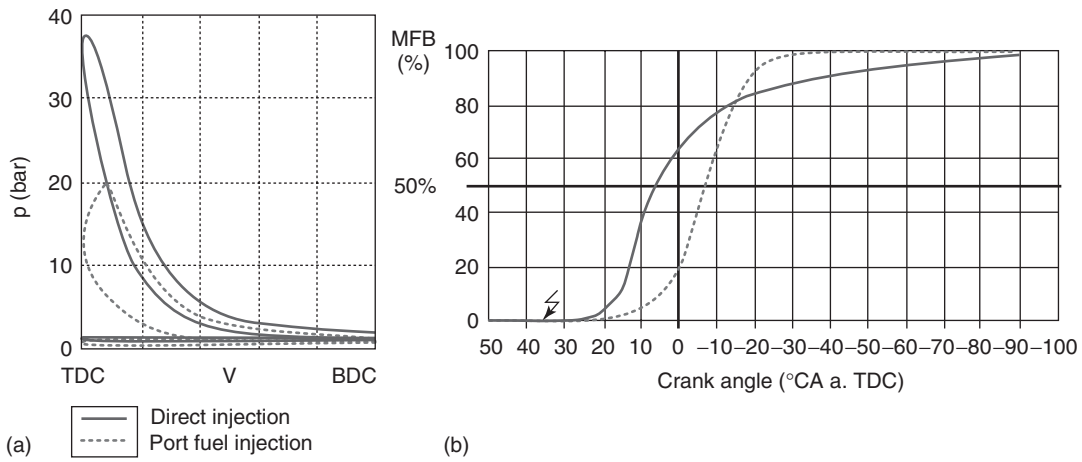

Figure 12. (a,b) Pressure–volume (p–V) diagrams and MFB functions for PFI and DI.

these pollutant emissions, both the fuel injection and the SI are advanced to ensure that the combustion is as complete as possible at the time of exhaust valve opening. As a result of this early combustion phasing, the point of 50% MFB occurs much earlier than its thermodynamic optimum. The goal of current and future DISI research and development is the mitigation of these problems through optimized mixture formation and stratified combustion processes.

3 SI AND ADVANCED DISI COMBUSTION SYSTEMS

Until the late 1970s, carburetors were the most widely used means of mixture formation. Increasingly, stringent demands for accurate air–fuel ratios led to the introduction and dominance of PFI systems in recent decades. However, with the introduction of the first gasoline direct injection (GDI) engine with stratified operation in 1995, together with the increasing emphasis on reducing fuel consumption, an increasing number of systems with direct injection can be found on the market.

3.1 SI port fuel injection

In combination with catalytic converter technology for aftertreatment of exhaust gases, the use of PFI has displaced carburetors since the mid-1980s (and since the 1970s in California). This trend was driven by the advantages of injection into the intake port in terms of fuel economy, performance, and reduced emissions. This is due to the fact that PFI allows for very accurate metering of fuel to match the range of operating conditions of SI engines.

In SI engines with external mixture formation, the fuel is injected either into the intake manifold (single injection) or into the intake port inside the cylinder head (multipoint injection) (Figure 13). Depending on the induced airflow and intake air mass, detected by an airflow meter in the intake manifold, the proper amount of fuel is injected. In the case of multipoint injection, the total fuel amount is divided among the cylinders. The injectors are responsible for the injection into the port of each cylinder; they inject the fuel over certain injection durations. Both injection timing and injection duration depend on the engine operating conditions and the flow of intake air. The data for injection, ignition, and all other necessary information for engine operation are stored in the engine control unit (ECU), which is responsible for adapting engine operating parameters to fit the desired operating conditions.

3.1.1 Variable valve train (VVT)

One effective method to reduce pumping losses and control the load in an SI engine is to vary the intake valve timing in combination with variable valve lifts. An example of a real world implementation of this concept is shown in Figure 14. On early closing of the intake valve during the intake stroke, the piston continues its downward motion and expands the cylinder contents. In this way, the intake throttle can be completely opened and the intake valve

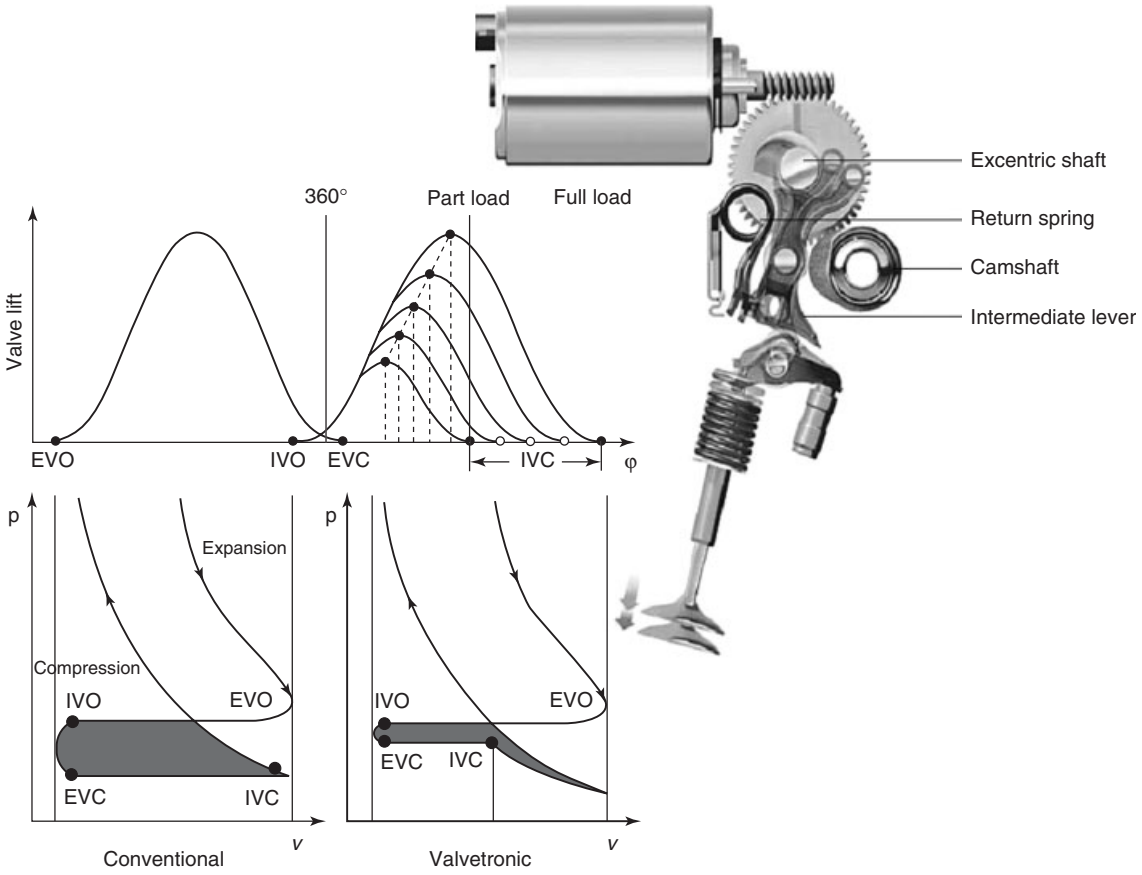

Figure 14. Variable valve train system and early intake valve closing. (Reproduced from Klüting *et al*., 2001. With kind permission of Springer Science+Business Media.)

closing time determines how much air or mixture is drawn into the cylinder. The intake pressure is higher and the duration of the intake process is shorter, so the pumping loop is significantly smaller than for the throttled SI engine (represented by the left diagram in Figure 14). The gas in the cylinder is heated by the warm cylinder walls, so the pressure at a given cylinder volume is slightly higher during the compression stroke than it was during the expansion (Figure 14). The use of this variable valve train (VVT) system can improve fuel economy by up to 10%. This is a result of the lower pumping losses, which is indicated by the smaller shaded area in the lower right plot relative to the lower left plot in Figure 14, as well as the better formation process of the air–fuel mixture because of the higher speed of the intake flow, which is produced by the smaller valve opening area with smaller valve lifts.

3.2 Advanced direct injection (DISI)

The first modern SI engine with direct injection (GDI) was introduced in 1995 in the Japanese market and in improved form in 1997 in the European market. This first generation of stratified charge engines operate according to the wall-guided combustion system with a wide spacing between the injector and the spark plug (Figure 3). The fuel spray is generally guided toward the spark plug by both the bowl-shaped piston crown on the intake side of the combustion chamber and the reverse tumble flow generated by the design of the intake port. The vaporization process and the mixture transportation to the spark plug are influenced by the interaction between the injection spray, the in-cylinder flow, and the piston shape.

In 2000, the first engine with fuel stratified direct injection (FSI) was released onto the European market (a 1.4-L four-cylinder, FSI engine by Volkswagen for the Lupo). As a result of direct injection, the engine's maximum power output could be increased from 74 to 77 kW. The piston was shaped with a bowl on the intake side. A tumble flow was created by a tumble system in the intake ports. The spark plug was centrally located between the intake and the exhaust valves. Owing to the cooling effect of the vaporized fuel, the compression ratio could be increased from 10.5 : 1

to 12 : 1. However, all current FSI engines are operated with homogeneous mixtures for all engine operation conditions and use of the stratified charge operation is completely avoided, as it is the case with all turbocharged TSI engines until now. The reason for that is the lack of sulfur-free fuel in the worldwide market, which is necessary for suitable aftertreatment systems for lean combustion.

All DISI engines are equipped with common rail injection systems, which have been in production for diesel engines since the beginning of the 1990s; this technology makes modern DISI engines possible. Figure 15 shows a typical common rail system used in a four-cylinder engine for homogeneous mixture formation with a wide spacing between the spark plugs and the injectors. The common rail injection system offers high flexibility to adapt the injection to the engine operating point.

Fuel pressure generation and injection are decoupled in this system. The fuel system of the injection unit consists of a low pressure section (a low pressure pump in the fuel tank) to transport the fuel to the high pressure pump, which supplies the rail with fuel at a pressure of between 100 and 200 bar. The injectors are connected to the rail and thus to a relatively stable source of pressurized fuel. At injection time, the fuel is injected into the combustion chamber as dictated by the ECU for various engine operating conditions (common rail injection systems are also discussed in Trends—Compression Ignition).

Three different types of nozzles are traditionally used for fuel injectors with GDI. The nozzles can be differentiated from one another by the means in which they open and close and the spray patterns that they produce. Figure 16 shows the design of these nozzles as well as their corresponding spray patterns.

The swirl nozzle exhibits very good atomization and high spray flexibility. It also has a relatively low sensitivity to contamination as well as mechanical and thermal interferences. It is relatively affordable because it is produced in large quantities. The fuel spray is cone shaped with spray angles that are influenced by both the fuel pressure and the cylinder pressure. This is a major disadvantage when a stratified mixture is desired, especially with a narrow spacing of the injector and spark plug. Hence, such nozzles are currently favored only for DISI engines operating with purely homogeneous mixtures.

Compared to the swirl nozzle, the outward opening A-nozzle has the distinct advantage of being able to produce a uniform hollow-cone spray. In addition, the spray angle of the A-nozzle is hardly affected by the backpressure. Using this injector type in conjunction with a piezo-actuator, multiple injections during one cycle are possible. Furthermore, the precise control of fuel mass, droplet size, and the shape of the fuel spray makes the piezo-actuated injection system superior to the conventional solenoid-actuated system. With narrow spark plug-injector spacing, the spark plug can be positioned in the recirculation area and also at the boundary of the fuel jet produced by the A-nozzle. The A-nozzle is an attractive choice for lean combustion with stratified mixture preparation because of the stability of its spray profile. The piezo-actuator's capability of multiple fuel injections can be used to improve mixture formation and thus the combustion process. The inflammation and burnout characteristics can be stabilized by optimizing the fuel injection times in relation to the time of ignition.

Owing to the high costs of piezo-actuated injectors, solenoid injectors with multihole nozzles, which are well known from diesel engines, have been introduced in the market in recent years. Sharply defined injection jets are a characteristic of the multihole nozzle. Because of the inadequate atomization quality of the multihole nozzle, it is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto147
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

only possible to establish a partially homogeneous mixture in the combustion chamber with the injection jet shape, even when using a variety of configurations. Enriched mixture zones containing excess fuel are directly adjacent to lean mixture zones containing insufficient fuel. Consequently, once an injection jet is ignited—the origin of ignition is determined by the position of the spark plug—the flame front in the combustion chamber does not progress uniformly. Rather, it spreads at varying speeds: the flame front accelerates in enriched zones of individual injection jets but slows down in lean zones between the injection jets. The number of nozzle holes significantly influences the operation characteristics of the engine. To avoid this behavior as well as to create a sufficiently homogeneous mixture, an in-cylinder flow with high turbulence is necessary for good mixture formation. A multihole pattern that results in effective fuel distribution and constant flame spread between the various injection jets produces the best engine operating characteristics. The lean burn capability can be improved by increasing the number of holes and also reducing the individual hole sizes. However, the number of holes is currently limited because of an increasing tendency toward coking. The spray penetrates further with multihole nozzles than with A-nozzles. This can lead to excessive wetting of the piston as well as the cylinder liner during retarded fuel injection operations, thus increasing hydrocarbon and soot emissions.

In order to increase the efficiency of SI engines, it is desirable to operate the engine at higher loads, where pumping losses and hence the brake-specific fuel consumption (BSFC) are lower. This can be accomplished by making the engine smaller, either by reducing the displacement volume or by reducing the number of cylinders; this concept is referred to as *downsizing*. However, in order to meet customers' expectations of increased power and dynamic response, downsizing is very often combined with boosted operation. In 2005, the first downsized engine (four-cylinder, 1.4-L TSI) with boosting was introduced in the market. This engine is equipped with direct injection with multihole injectors, variable tumble flaps, an intake cam phaser, a supercharger, and a turbocharger. The fuel injector is located in the cylinder head below the intake ports and the spark plug is located in the center of the cylinder head between the intake and exhaust valves. Owing to this wide spacing arrangement of injector and spark plug, the mixture formation is homogeneous for the entire engine operating range. Figure 17 shows a schematic of the arrangement of the supercharger (compressor) and the turbocharger of this engine.

The compressor is belt driven by the crankshaft and the amount of boost is adjusted by a special control valve in the intake system. At an engine speed of 2500 rpm, the compressor is disconnected from the crankshaft by a magnetic clutch and the control valve is fully opened.

The charge cooling provided by the vaporizing fuel improves the volumetric efficiency of the engine and decreases its propensity to knock. This allowed the designers to increase the compression ratio of the engine to 10.0 : 1, thus increasing the thermal efficiency. A specially designed piston bowl and the injector design help prevent the injected fuel from wetting the cylinder walls and aids in directing the fuel injected in the compression stroke toward the spark plug during the catalyst heating phase of cold start operation. Injection pressures of up to 150 bar are necessary for the wide range of engine speeds and loads required of this engine. The intake cam phaser and the tumble flaps are used to optimize volumetric efficiency and in-cylinder flow over the entire range of engine operating conditions. The supercharger is used to boost intake pressure at low engine speeds and high loads and increases the available exhaust enthalpy (Figure 18). This significantly improves the dynamic response of the turbocharger, which is used to boost the engine at higher engine speeds. Special materials are used in the design of the turbocharger so that exhaust temperatures of 1050°C are possible, so mixture enrichment for the purpose of cooling at high loads is minimized.

The engine has a peak torque of 240 Nm that is available from 1750 to 4500 rpm, which is a significant contribution in a car that accelerates faster than its predecessors with a fuel consumption improvement of nearly 20%. The fuel consumption during the New European Driving Cycle (NEDC) of the Golf TSI car powered by this engine (125 kW) was 7.2 Le/100 km or 30 mpg. The current engine is equipped with only a turbocharger, which not only results in a reduced power output of 118 kW but also has reduced fuel consumption in the NEDC of 6 L/100 km or 36 mpg.

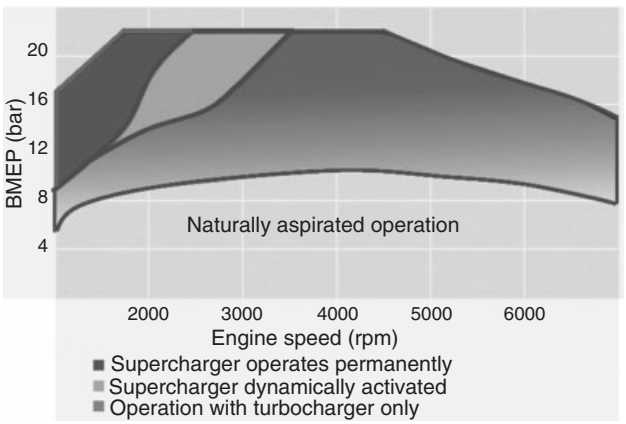

Figure 18. Boosted operation of the 1.4-L TSI. (Reproduced with permission from Middendorf *et al.*, 2005. © RWTH Aachen University.)

One new technology is the use of twin-scroll turbochargers. The latest engine to be outfitted with this technology is a four-cylinder 1.6-L engine, which is additionally equipped with fully variable valve lift, intake and exhaust cam phasers, and direct injection, [8]. The charge cooling provided by direct injection makes a compression ratio of 10.5 : 1 possible. In order to significantly reduce pumping losses at part load, the engine is operated at nearly WOT. The continuously variable valve lift and an early intake valve closing are used to control the amount of air that enters the cylinder and, for a homogeneous charge at part load, the load. The valve lifts and timings are also used to increase the residual gas fraction in the cylinder and to generate desirable in-cylinder flow, which improves the combustion characteristics at part load. At higher loads, the in-cylinder flow is created by tumble ducts and the load is controlled by the boost pressure. The twin-scroll turbocharger provides a much improved dynamic response compared to the single-scroll turbocharger.

This technology results in engine torque characteristics that are similar to those of a diesel engine. The maximum engine torque of 250 Nm is available from 1500 up to 4800 rpm (Figure 19). This engine has a displacement volume

20% smaller than its predecessor and a 30% greater torque output, and the fuel economy is improved by 5% (Schopp *et al*., 2011).

In 2006, the first spray-guided direct injection engine (3.5-L V6 engine) with stratified operation was introduced in the European market (Altenschmidt *et al*., 2011). The fuel injector is an outward opening piezo-actuated A-nozzle and is located together with the spark plug centrally in the four-valve cylinder head (Figure 20). The fuel is injected with fuel pressures of up to 200 bar. Without this arrangement, mixture stratification and combustion for production applications would not be possible. The special characteristics of the piezo-injector, including high nozzle capacity, small spray fluctuations, and the ability to precisely inject the smallest quantities of fuel, made it possible to use special injection strategies for stratified and lean operation.

Figure 21 shows the spray dispersion for an injection at the end of compression. The fuel injection enables a combustible mixture to be positioned at the spark plug in a way that reliable ignition occurs. The spray characteristic forms the basis not only for robust and reliable stratified operation but also for operating modes with critical ignition conditions.

To extend the range of both mixture stratification and lean combustion of a DISI engine in the engine operation map, a special mixture formation strategy was developed, which is shown in Figure 22.

Depending on the engine speed and load, the engine is operated in the most favorable mode of with a homogeneous stoichiometric mixture, a combination homogeneous lean/stratified mixture, or a purely stratified mixture. The corresponding injection strategies are shown as circles with gray-shaded sections representing the injection events. The individual injections take place either during the intake stroke (shown at the right side of the circles) or during the compression stroke (shown at the left side of the circles) to achieve the desired mixture stratification. The best injection strategy with up to three different injections is used for each mode. The ignition timing is adjusted together with the injection strategy to optimize operating behavior. With a triple injection, spark timing typically occurs between the second and third injections.

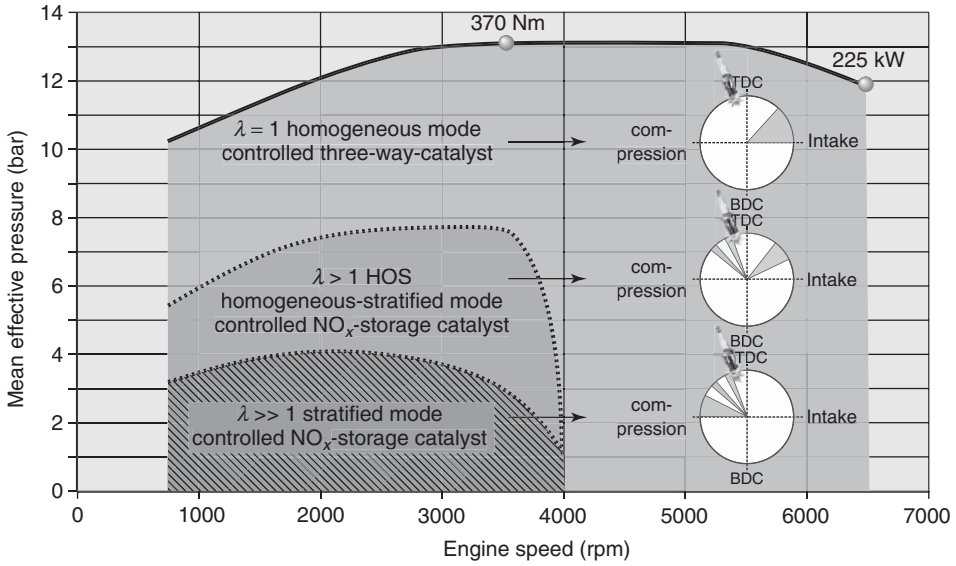

Figure 22. Operating modes in the entire engine map (Altenschmidt *et al*., 2011). (Reproduced by permission of Daimler AG.)

the outer regions of the combustion chamber are surrounded by almost pure air. In homogeneous stratified mode, a homogeneous lean mixture of air and fuel is created with an early fuel injection and is present in the entire combustion chamber. In addition to this lean mixture, a small and stratified charge is induced directly at the spark plug by late-fuel injection during the compression stroke. This predominantly homogeneous distribution is particularly favorable under high load conditions. While the air–fuel mixture can become overly rich in stratified mode, which increases fuel consumption and emissions, these disadvantages are not evident in the homogeneous stratified mode. Using this operating mode, fuel consumption can be further reduced with increasing load (Figure 23).

It can be seen that considerable benefits are achieved for stratified operation up to a brake mean effective pressure (BMEP) of approximately 4 bar. With further increases, BSFC does not continue to improve but actually increases slightly. Fuel consumption with homogeneous stratified mode is more favorable than in stratified mode at a load higher than BMEP = 4.5 bar. Between BMEP of 4.5 and 7 bar, the engine operates in the homogeneous stratified mode. With increased loads of more than 7 bar, the electronic control unit (ECU) switches automatically to the pure homogeneous mode without stratification.

When examining the energy losses for a PFI engine, a PFI engine with VVT, a DISI engine with a wide spacing arrangement, and a DISI engine with a narrow spacing arrangement, the individual losses can be characterized (Figure 24). The energy required to drive the high pressure pump in a DISI engine increases the auxiliary energy demand, and the friction in a DISI engine is slightly higher than for the PFI engine. The degree of dethrottling and therefore the amount of pumping work is at a minimum for a VVT system and for the narrow spacing arrangement. The higher combustion chamber temperatures for the PFI engine tend to increase heat losses, but the lower in-cylinder mass and pressures tend to offset this, so the heat exchange losses do not vary significantly among the various concepts.

Incomplete combustion due to over lean regions of the combustion chamber results in a higher amount of energy loss for the DISI engines. The products of the extremely lean mixtures found in the DISI engines have thermodynamic characteristics superior to those of a stoichiometric mixture found in the PFI engine and the VVT engine, so useful work is more effectively extracted from the expanding combustion products. The higher compression ratio of the narrow spacing DISI engine leads to increased work output and therefore less energy lost to exhaust heat.

4 KNOCKING COMBUSTION

Both the thermal efficiency and the power output can be improved by increasing the compression ratio of SI engines. However, for high specific engine loads, achieved for example by boosting or downsizing SI engines, the increased compression ratio can lead to engine knocking and therewith to severe engine damage. The investigation of engine knocking has been a major research topic since the invention of the SI engine and requires the highest instrumentation accuracy for the analysis of measurement

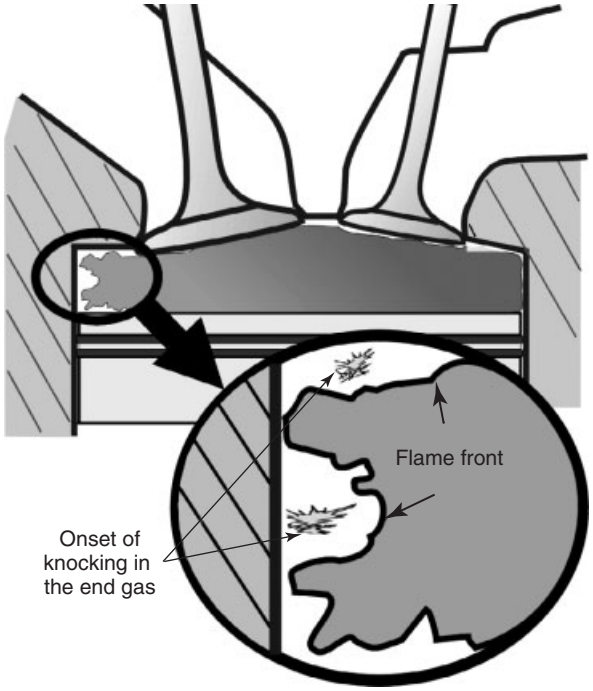

Figure 26. Autoignition in end-gas "hot spots."

results, because the location, the onset, and the intensity of the knocking event must be exactly determined. At present, it is well known that knocking combustion is a result of an autoignition in the region of unburned air–fuel mixture in front of the propagating flame front during the late phase of normal combustion. Many investigations during the past three decades with different optical measurement techniques have confirmed this behavior. Figure 25 represents knocking combustion in the end-gas region, detected by high speed Schlieren cinematography in a single-cylinder engine (Spicher, Kröger and Ganser, 1991). The intensity of knocking during this combustion cycle has been defined as an intermediate level with a zero-to-peak amplitude of 11 bar in pressure oscillations, created by knocking. The first picture (number 26) was taken at 191.85 crank angle degrees (CAD) after bottom dead center (ABDC) or 11.85 CAD ATDC. At this time, only the flame front of the nonknocking combustion can be seen. In picture 34, the first chemical reactions of autoignition are detected. From this autoignition location, a so-called reaction front propagates quickly through the end-gas region from picture 37–44, which seems to press the original flame front back slightly (pictures 46–56).

The pressure and temperature increase in the combustion chamber during spark-ignited flame propagation can lead to critical thermodynamic conditions, thus causing this autoignition either in the end-gas region or in end-gas pockets, shown schematically in Figure 26. These pockets are formed because of a turbulent flame front close to the combustion chamber walls in the last phase of flame propagation.

Some of these pockets with short ignition delays due to nonuniformities in temperature and concentration, the so-called hot spots, are able to autoignite. Their location is strongly dependent on the local temperature–time history in the end gas. For this reason, the phenomenon of regular engine knocking can be detected shortly after the SI and generally occurs in a reproducible manner.

The knock amplitude after a self-ignition depends on the chemical reaction rate. At high reaction rates within the hot spots, pressure compensation by expansion into the surrounding areas is not possible. Pressure waves propagate through the combustion chamber causing mechanical vibrations (knocking) when they reflect on the cylinder walls. The differences of knocking intensity and frequencies result from fluctuations of the end-gas boundary conditions.

Owing to the local autoignition in the end-gas region during the late combustion, pressure waves are induced. The amplitude of the pressure waves depends on the pressure, temperature, mixture composition, and the volume of the pockets in the end gas where autoignition occurs (Rothe *et al*., 2006). The pressure waves propagate through the combustion chamber and are reflected at the combustion chamber walls. The characteristic pressure oscillations can be recognized in the pressure trace shown in

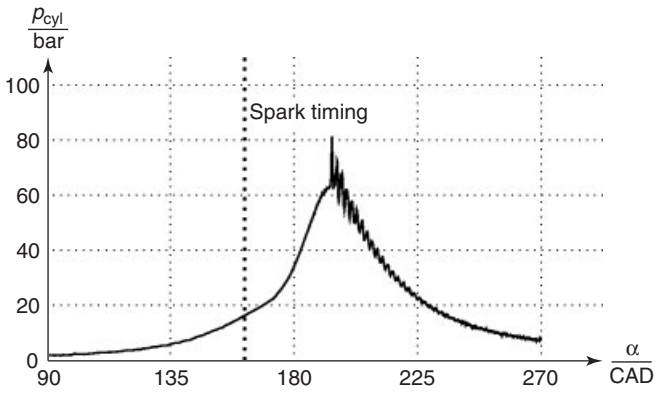

Figure 27. Pressure trace of knocking combustion.

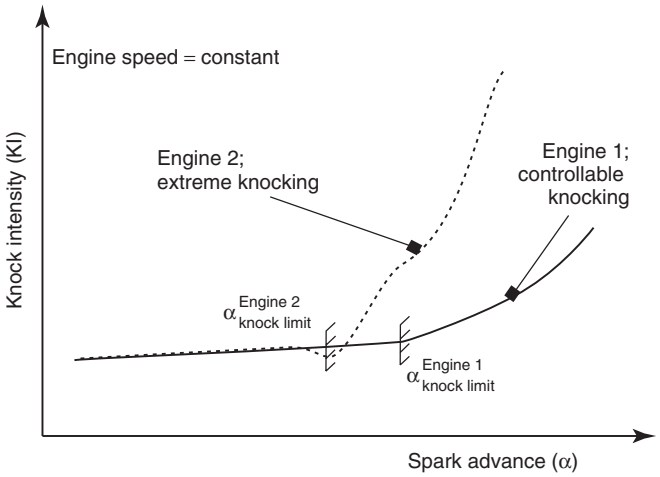

Figure 28. Knock intensity versus spark advance for two engines.

Figure 27. The resulting structural vibrations are responsible for the characteristic knocking sound that gave this phenomenon its name. The pressure wave interferes with the thermal boundary layer at the combustion chamber walls, which leads to locally elevated heat transfer rates. In conjunction with the increased mechanical loading due to the high pressure gradients and vibrations, this can cause severe engine damage. To avoid this, piezoelectric sensors using the inertia of a seismic mass to detect structure-borne sound induced by knock are employed in modern engines to operate them close to the knock limit. This is possible because of the knock limit being rather well defined as a function of ignition timing. The effect is well reproducible and thus controllable. If knock is detected, the spark timing is retarded, which decreases the risk of knock in the subsequent cycles at the cost of thermal efficiency.

In some engines, a more extreme type of knocking combustion can be observed. This phenomenon is referred to as *super-knock*, *megaknock*, or *extreme knock*. It is characterized by pressure amplitudes that are significantly higher than in the case of normal knock. In addition, super-knock occurs stochastically so that it is not controllable in the same manner as normal knock. Figure 28 shows the knock intensity versus spark advance for two different engines (Spicher and Krebs, 1990). While engine 1 shows a slight increase in knock intensity with spark advance, engine 2 shows a steep increase in knock intensity with spark advance. That means engine 1 can be easily controlled by the knock control system. After a certain spark advance when knock intensity exceeds the threshold of knock limit, spark advance is retarded by the knock controller. For engine 2, the knock intensity increases too fast and the threshold of knock limit is exceeded directly after spark advance of knock limit. This behavior leads to extreme knocking combustion, which hardly can be controlled by the knock control system due to its stochastic occurrence nature.

Figure 29 shows the knock characteristics of an engine at two different operating points. Both diagrams show a variation of spark timing. Beginning at 1.6 CAD after knock limit α_{KL}, ignition is advanced in four steps until 1.6 CAD before knock limit.

At 3000 rpm, knock amplitudes Δp increase nearly linearly with spark advance. Therefore, at this operating point, the knock control described earlier works as intended. However, at 5000 rpm, extreme knock events exhibiting significantly higher amplitudes occur stochastically, which cannot be controlled by a knock control unit. Besides these differences, the progress of extreme knock is very similar to that of normal knock.

Figure 30 shows the pressure trace, the flame signal detected with an optical fiber, and the location of knock onset for a combustion cycle with extreme knocking. It can be seen from the pressure trace that the maximum amplitude in knocking pressure oscillation is nearly 70 bar. Knock onset occurs close to the cylinder liner wall at the left intake valve. The reason for that is the structure of the in-cylinder flow generated by the design of the intake manifolds. While the right intake manifold creates a swirl flow, the left intake manifold is designed for high volumetric efficiency. Owing to these two different flow conditions, a weak flow movement with enrichment in air–fuel ratio occurs at the location of knock onset. The CAD difference between the steep increase between oscillations in flame signal and oscillations in pressure trace is 1.2 CAD. On the basis of the engine speed and the distance between the location of the optical fiber and the pressure trace, the speed of the knocking combustion front

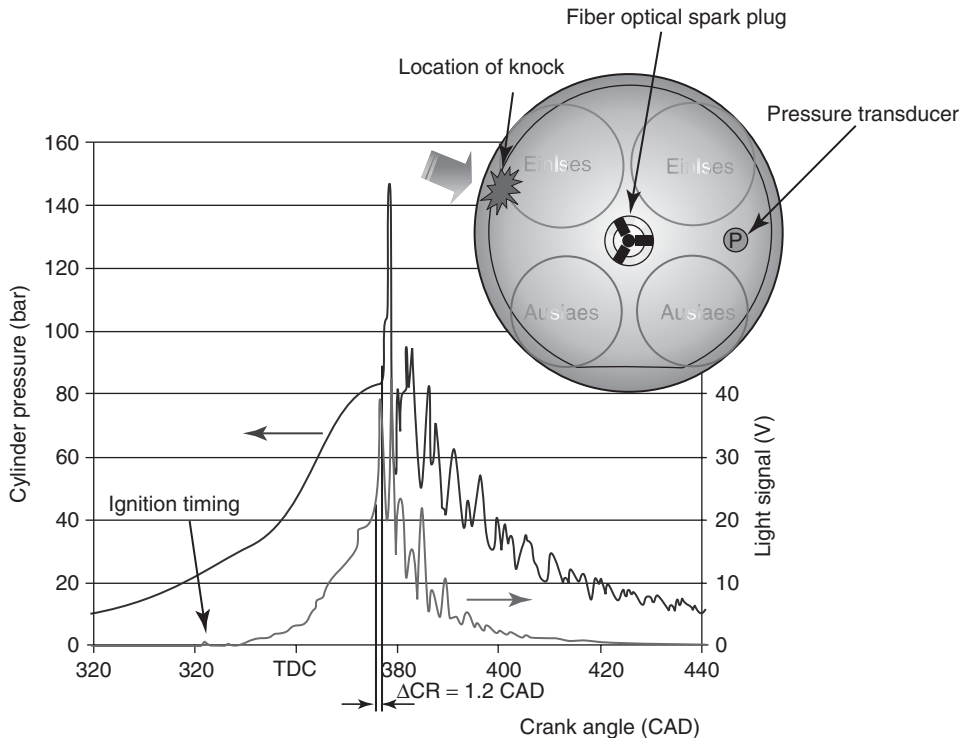

Figure 30. Extreme knocking combustion for a DISI engine.

can be estimated to approximately 1150 m/s, which can be supersonic speed.

Knock as well as extreme knock causes an elevated heat transfer to the walls. Consequently, parts of the combustion chamber can be heated up significantly. This can promote earlier autoignition in the end gas, which results in even stronger knocking and thus further heating. This effect, referred to as *surface ignition*, can be self-preserving or even self-amplifying (Figure 31). The diagram shows the pressure traces of four subsequent engine cycles with

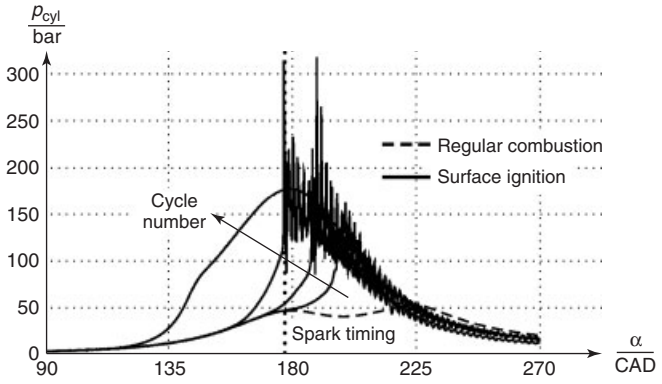

Figure 31. Pressure traces of consecutive cycles after a surface ignition.

surface ignition, and, as a reference, one of a regular combustion event at the same operating point.

It is seen in the figure that in the first cycle with surface ignition combustion starts considerably earlier than in the cycle with regular combustion. The first pressure rise is observable almost simultaneously with spark timing. Owing to this early onset, combustion progresses into very severe knock. In the next two cycles, autoignition timing moves forward because of the heated combustion chamber. In the last cycle plotted in this diagram, combustion starts at an extremely early stage of compression so that the complete cylinder charge is consumed before autoignition can occur in the end gas. Consequently, there is no knock observable in this cycle. However, because of the burned gas being compressed, peak pressure and temperature are much higher than in the case of regular combustion, which can cause immediate engine breakdown. Surface ignition is extremely dangerous but can be avoided reliably by proper dimensioning of the cooling system and the right choice of spark plug.

During recent years, with the appearance of highly supercharged downsizing engines, a new combustion phenomenon has been observed in these engines, especially in full-load operation at low engine speed. This phenomenon, referred to as *premature ignition* or *preignition*, shows some similarities to extreme knock as well as to surface ignition. As in the case of surface ignition, combustion obviously starts before the spark plug fires. However, the phenomenon acts neither self-preserving nor self-amplifying. Instead, preignition occurs stochastically, just like extreme knock. All three phenomena have in common that they are characterized by very high knock amplitudes. Figure 32 shows pressure traces for cycles with preignition and regular combustion at the same operating point.

Owing to the enormous knock amplitudes, preignition is considered one of the most important issues in the development of downsized engines. However as it is the newest and thus least explored of the described phenomena, there is still very little research about it (Palaveev and Spicher, 2010; Dahnz and Spicher, 2010).

Knocking is significantly influenced by the operating conditions, fuel, and the shape of the combustion chamber. In principle, the knocking tendency of an engine increases under the following boundary conditions:

- high pressure and high temperature in the unburned remainder of the air–fuel mixture;
- proximity to the stoichiometric air–fuel ratio ($\lambda = 1$);
- fuel with a low octane number; and
- high compression due to a high compression ratio and/or boosting of the premixed air–fuel mixture.

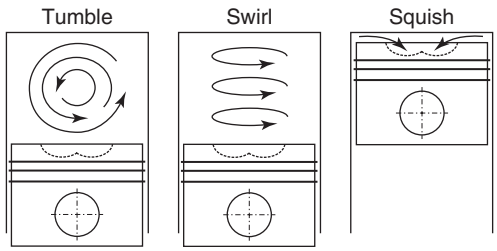

Figure 33. In-cylinder tumble (rotation around a horizontally oriented axis), swirl (rotation around the cylinder axis), and squish flow.

The combustion chamber design can have a considerable influence on combustion and knocking. Combustion chambers with low knocking tendencies (knock-resistant combustion chambers) must meet the following basic requirements:

- Short flame paths: compact combustion chamber, centrally positioned spark plug
- Avoidance of hot spots at the end of the flame path: spark plugs close to the exhaust valve
- High flow velocities: tumble and/or swirl movement and/or squish flow (Figure 33)

5 POLLUTANT FORMATION

The fuels used in SI engines typically consist of hydrocarbons. The combustion of these fuels is the oxidation of these hydrocarbons with the oxygen contained in the intake air. When a hydrocarbon molecule is completely burned, it ideally produces only carbon dioxide (CO_2) and water (H_2O). The following chemical reaction describes generally the conversion of hydrocarbon fuels such as petrol:

$$C_xH_y + \left(x + \frac{y}{4}\right) O_2 \Rightarrow x\,CO_2 + \frac{y}{2} H_2O$$

Owing to incomplete combustion processes, the exhaust gas also contains the following pollutants:

- carbon monoxide (CO);
- unburned hydrocarbons (UHC);
- nitrogen oxides (NO_x);
- particulates including soot, mainly in engines with direct fuel injection; and
- aldehydes (H-C-O compounds), predominantly in engines with pure ethanol or ethanol blends as fuel.

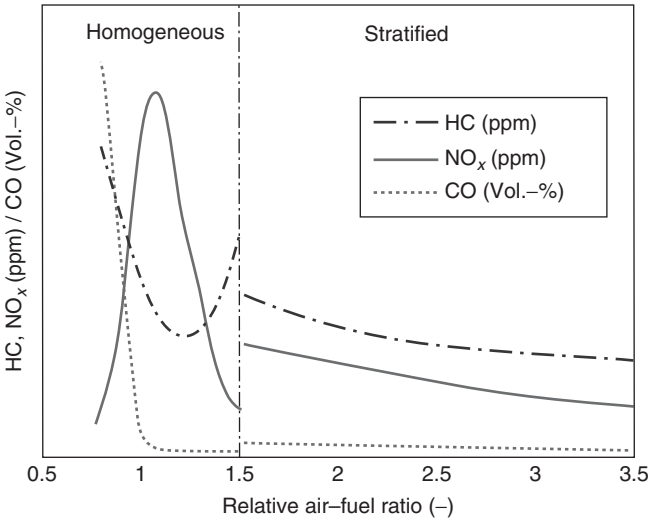

Figure 34. Emissions concentration with homogeneous (PFI and DISI) and stratified (DISI) mixture formation.

With the exception of nitrogen oxides, the various pollutant components are primarily determined by the fuel and its additives. The emission level is significantly determined by the engine operating characteristics. Figure 34 shows the fundamental dependence of pollutant concentrations for CO, NO_x, and UHC (HC) on the air–fuel ratio for an SI engine with PFI as well as with DISI. For an air–fuel ratio between $\lambda = 0.8$ and 1.5, the engine can be operated with homogeneous mixture. The resulting curves of pollutant concentrations therefore match those of an engine with either PFI or DISI. Stratified charge operation for air–fuel ratios greater than 1.5 produces the illustrated characteristics of UHC, nitrogen oxide, and carbon monoxide emissions.

In air-deficient, fuel-rich zones ($\lambda < 1$), carbon monoxide is a product of incomplete combustion. In the range of $\lambda \approx 1$ and with lean combustion ($\lambda > 1$), CO formation essentially results from any inhomogeneous mixture distribution resulting in some rich mixtures or delayed combustion in which the chemical reaction does not reach completion because the temperature of the reacting gases has become too low during expansion and the dissociation of CO_2 into CO and O_2 during combustion.

In addition to CO emissions, incomplete combustion in air-deficient zones leads to the emission of UHCs. UHC emissions also form in combustion chamber regions that have not completely been penetrated by the flame, such as boundary layers near combustion chamber walls where the flame is extinguished by cooling (quench effects) or crevices (e.g., ring land crevices) into which the flame cannot penetrate. Besides these UHC emissions resulting

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto147
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

from quench effects, UHC emissions result from crevice volumes, deposits, and desorption from the oil film on the combustion chamber surfaces. During expansion and expulsion in the exhaust manifold, the UHCs formed by various methods are mixed with the hot exhaust gas and oxidized by after-reactions. Both high temperatures and the presence of oxygen are important agents for these after-reactions. The after-reactions are one reason for the minimum level of UHC emissions observed in the presence of only a slight air surplus. An extremely high air surplus during combustion will cause flame quenching that strongly increases the level of UHC and CO concentrations. The combustion temperatures for these very lean conditions are not high enough to maintain flame propagation in the cooler zones of the combustion chamber. The fundamentals of UHC and CO emissions are also discussed in more detail in UHC and CO Formation and Models.

Nitrogen oxide emissions (NO_x) are a combination of the nitrogen monoxide NO (approximately 90%), nitrogen dioxide NO_2 (approximately 9%), and nitrous oxide N_2O (approximately 1%). The maximum combustion temperature and the duration of its effects are the most decisive influences on the NO_x concentration, especially the concentration of NO. While the combustion temperature peaks in the engine are encountered at an air–fuel ratio of $\lambda \approx 0.95$, the maximum NO_x concentration occurs in the lean range between $\lambda \approx 1.05$ and 1.1. This is due to not only the high temperatures but also the availability of oxygen in the burned mixture. NO_x Formation and Models discusses NO_x formation fundamentals in more detail.

First SI direct injection engines with stratified mixture preparation were designed with wide spacing arrangement of fuel injector and spark plug. For injection of the fuel solenoid, actuated injectors and swirl nozzles were used. The fuel pressure for injection was in the range 80–120 bar. The wall-guided strategy with significant wall wetting fuel on the piston surface results in relatively high emissions of both UHCs and soot particles, especially at higher load as well as during cold start and engine warm-up. Owing to these difficulties with particulate emissions, most of the automobile companies changed to pure homogeneous mixture preparation in the entire engine operating range. In addition, to exploit the advantages of direct injection, boosting was introduced in combination with this change in mixture formation. At present, only one automaker is still running SI engines with stratified operation, whereby the injector is centrally mounted in the cylinder head close to the spark plug (spray-guided or narrow arrangement). Instead of solenoid-actuated fuel injectors, these engines are equipped with piezo-actuated injectors and outward opening nozzles (A-nozzle), which allow very flexible multi-injection strategies. Owing to this flexibility of injection timing and numbers of injection pulses, the particulate emissions can be kept to an extremely low level during engine operation over test cycles and also during real world driving (Altenschmidt *et al*., 2011). In addition, during cold start and catalyst heating, a centrally mounted hollow-cone injector (A-nozzle) and multipulse injection strategies with short injection pulses just before ignition timing allows engine operation with low particulate number emissions ($<10^5$ p/cm^3) while keeping the cyclic variations of combustion on a sufficient low level (Piock *et al*., 2011).

Another main parameter to reduce particulate emissions is to increase injection pressures. At present, the fuel pressure with gasoline is limited to 200 bar because of the lack of lubrication from gasoline inside the high pressure fuel pump. Investigations with significantly higher fuel pressures up to 1000 bar have shown that particulate emissions can be kept to an extremely low level during both real world operation and cold start (Buri *et al*., 2009) (Schumann, Kubach and Spicher, 2012). Concluding from research work up to now, with the right injection system and the right injection strategy, an adequate mixture formation at homogeneous and stratified operations can be created, which allows keeping emissions of particulate mass and particulate number significantly below the most stringent emission regulations.

1 INTRODUCTION

Automotive diesel engine applications can be found worldwide because of their low fuel consumption and high level of robustness. With the continuous introduction of stringent emissions regulations, fuel economy targets (the United States), and CO_2 regulations in Europe, the United States and many other countries, the diesel engine development undergoes a permanent change to adapt to its new boundary conditions. Applying new materials, machining/manufacturing processes, design methods, fuel injection systems, aftertreatment components, control algorithms, sensors, and so on, the diesel engine is set to maintain its status as the most efficient automotive powerplant worldwide. This chapter will identify and highlight the corresponding topics relevant to the development of state-of-the-art automotive diesel engines and explain the associated background.

2 HISTORIC REVIEW

2.1 Rudolf Diesel

Rudolf Diesel was born in Paris, France in 1858, as the second of three children of Theodor and Elise Diesel. His parents were immigrants from Bavaria, then living in Paris. At the age of 14, he stated his strong interest to become an engineer. After concluding his basic education in 1873 superior, he joined the newly founded industrial school of Augsburg and finished his classes as the best in 1875. Only 2 years later, he received a merit scholarship from the Royal Bavarian Polytechnic of Munich. He graduated in January 1880 with highest academic honors and returned to Paris, where he supported his former professor Carl v. Linde with the building of a new, modern refrigeration plant.

In early 1890, he moved from Paris to Berlin with his family considering management of Linde's R&D department. Initially, he worked in the area of steam processes, but his own research aimed for better fuel utilization. Owing to an accident, he had to stay a couple of months in a hospital, followed by continuous problems regarding general health. In 1887, he published a treatise entitled "Theory and Design of a Rational Heat-Engine to Replace the Steam Engine and Combustion Engines Known Today." Finally, in 1897, he built the first working model of his engine. On September 29, 1913, he entered in Antwerp on board of a ship targeting England. He seemed in good spirits, but was, after he had gone to his cabin, never seen again. The exact circumstances of his death, however, were never clarified up to now.

2.2 Advantages of diesel engines versus gasoline engines

The primary dominating benefit of the diesel engine versus its gasoline counterpart is found in the higher efficiency of the underlying reference cycle, namely the constant-pressure process for the diesel combustion and the constant-volume process for the gasoline combustion. It features theoretically a difference in the utilized compression ratio by the factor of 2 in favor for the diesel engine, offering higher internal combustion efficiencies. In addition, the engine is operated typically with air excess, which describes an additional source of higher fuel efficiency. Furthermore, the load control via delivered fuel quantity, the so-called control of mixture quality, concludes in another advantage against the load control via charge mass, the so-called control of mixture quantity. On the basis of these fundamentals, diesel engines offer overall efficiencies between 55% for large diesel engines (two-stroke for marine or genset applications) and 42% for small, high speed passenger car applications, whereas gasoline engines reach a maximum of 35–37%.

The corresponding internal efficiency differs even more, but because the higher utilized combustion pressures of diesel engines require a more rigid layout of the engine architecture, higher mechanical losses in terms of friction have to be considered, so that the effective numbers are slightly closer to each other.

2.3 Initial challenges

As a student of Professor Carl v. Linde at the University in Munich, Germany, R. Diesel studied the topic of calorific machines. Realizing that the steam engines as the predominant power source at that time were highly inefficient, he focused on the idea of turning the most efficient thermodynamic cycle, the Carnot cycle, into reality. The first fully functional diesel engine with a bore of 250 mm and a stroke of 400 mm delivered about 20 hp at 175 rpm. However, the development of the diesel engine was overshadowed by many challenges. Continuously reducing his expectation of a compression pressure from about 250 bar down to approximately 30 bar to ensure ignition of the induced fuel quickly became an issue. This level of gas compression was rather exceptional at that time. Further challenges were the cooling of the engine. As it was initially uncooled, it allowed only for short periods of operation at a time and thus delayed the development process severely. The application of a liquid cooling system drastically improved the situation and helped to accelerate the development. Another significant issue was the fueling. The introduction of fuel into the high pressure and temperature environment inside the cylinder became a huge problem. In addition, also the precise timing and metering of the fuel quantity turned into an obstacle that was very difficult and time consuming to overcome. As high pressure injection pumps and injection nozzles were not available yet, Rudolf Diesel decided to apply an air-assisted fuel injection design that allowed him to induce the fuel into the combustion chamber. However, despite his realization that the Carnot cycle was not the best cycle to represent his idea, he continued to make further improvements. These improvements led ultimately to the first diesel engine-powered truck in 1927 and the first passenger car in 1936. The main reason for the long development period were not only related to combustion system but also based on the lack of appropriate machinery to manufacture fuel injection pumps and injection nozzles at their relatively small size in larger quantities and at very low tolerances. Precision and lowest possible production tolerances while maintaining a high level of robustness still remain as some of the biggest challenges in diesel engine development even today.

2.4 Passenger car examples

The Mercedes-Benz 260 D in the W 138 series was the world's first series-production diesel passenger car. Seventy-five years ago, in February 1936, 50 years after the invention of the petrol-powered automobile by Carl Benz, Mercedes-Benz presented this revolutionary vehicle at the International Motorcycle and Automobile Exhibition in Berlin.

Its 2.6-L OM 138 four-cylinder engine with the Mercedes-Benz prechamber system and a Bosch injection pump produced 33 kW (45 hp) @ 3200 rpm, and was installed in the chassis of the petrol-powered Mercedes-Benz 200 with a long wheelbase. The Bosch four-plunger injection pump allowed engine speeds of up to 3000 rpm and ensured rapid fuel delivery.

Two years before, in November 1934, after experimenting with various diesel engines in Mercedes-Benz passenger cars, the engineers opted for a modified version of the well-proven six-cylinder in-line engine from the commercial vehicle sector. The result was a four-cylinder unit with a displacement of 2.6 L (bore $\times$ stroke was 90×100 mm). The new engine utilized the base engine's comparably smooth prechamber combustion process. The technical specifications featured OHV (Over-Head Valve) and a five-bearing crankshaft.

Series production of the model 260 D commenced at the end of 1935, and the world's first regular production diesel car was premiered in February 1936 at the International Motorcycle and Automobile Exhibition in Berlin. At an

average diesel fuel consumption of 9.5 L, a tank filling was initially sufficient for 400 km, and this increased to not <500 km or more after a model upgrade in 1937. This was not without significance considering the relative scarcity of filling stations at the time.

Even in 1936, the diesel engine in the model 260 D delivered impressive fuel economy: average consumption was slightly above 9 L of diesel per 100 km, considerably bettering the 13 L consumed by the petrol-powered model 200. Moreover, diesel fuel cost only 17 pfennigs per liter for holders of a passenger transport license in 1936: at the time, that was less than half the normal cost of petrol. Taxi drivers in particular immediately opted for this car, which was available in a spacious Pullman version with six seats right from the start.

A new momentum in the development of passenger car diesel brought PSA and VW (Volkswagen). The French OEM (original equipment manufacturer) engineered in 1968 for the first time a diesel engine transversely in a small compact car and VW followed 1976 by following the same approach in the Golf model. Mercedes-Benz implemented a year later for the first time a turbocharged diesel engine in a passenger car. The 300 SD should cut, with its 125 hp I-5 engine, the fuel consumption of Daimler models in the United States.

New developments such as four-valve technology, turbocharging, and intercooling supported the generation of the formerly sluggish aggregate to a more powerful propulsion unit. In the 1980s and 1990s, vehicles such as the VW Golf TD with 51 kW/70 hp allowed enjoying the attractive driving practice with a fuel consumption of 7 L/100 km.

The final breakthrough was achieved by the transition of the direct injection principle from large bore and heavy-duty engines to smaller displacements with higher rated power speeds. In 1988, the 1.9 L Fiat Croma TD with 68 kW/92 hp @ 4200 rpm was the first car that entered the market with this new technology. At about the same time, Ford released a similar engine concept in the light-commercial vehicle segment with 2.5 L displacement. Two years later, Audi introduced with the 2.5 L TDI (turbocharged direct injection) the first direct injection engine of a German manufacturer on the market. The introduced I-5 aggregate delivered initially 88 kW/120 hp. A little later, VW 1.9 L TDI's followed with 66 kW/90 hp and 81 kW/110 hp in various VW and Audi models.

2.5 Diesel combustion system

The diesel combustion system is usually defined by the interaction of the fuel injection sprays considering their corresponding orientation and the piston bowl. In practice, distinction is made between two main combustion system types. These are (a) the indirect-injected (IDI) and (b) the direct-injected (DI) systems as shown in Figure 1.

IDI applications distinguish further between the so-called prechamber and swirl chamber applications. In both cases, the entire combustion chamber is being divided into the main combustion chamber and a smaller separate chamber while both are connected via a smaller port opening. The distribution, shape, and orientation of the corresponding chamber volumes, their surface areas, the length and diameter of the port connecting the two chambers, and the location, orientation, and type of injection nozzle located in

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the smaller chamber and the associated injection pressure (and injection rate shape) have a significant impact on the combustion efficiency of an IDI diesel engine. The airflow and the air velocity present in the small chamber support the combustion process. The volume of the pre or swirl chamber represents usually 25–60% of the entire combustion chamber volume and also houses the injection (pintle) nozzle, which injects fuel in form of a single injection jet at pressures between 200 and 300 bar. The surface temperatures in both the pre and the swirl chambers are high and, therefore, allow for a reduced ignition delay. After fuel injection has occurred, the combustion starts (supported by a glow plug in case of the swirl chamber) rather smooth because of the lack of oxygen (rich) inside these chambers and continues as the hot combustion gases and the remaining unburnt fuel propagates into the main chamber because of thermal expansion allowing the remaining fuel to be oxidized. One major benefit of the IDI combustion system is that the high surface temperatures and the consequential short ignition delay result into a smooth combustion and thus low noise level while being also more tolerant regarding fuel quality (cetane number) fluctuations. Furthermore, the injection pressure is on a relatively low level and thus does not require a high level of work to be generated, while the pump and nozzles are not exposed to excessive mechanical loadings. In addition, these systems allow for wider engine speed ranges and are less prone to nozzle coking because of the self-cleaning function of the pintle nozzle. However, the design requires detailed attention because of the very high thermal load at the exit of the pre/swirl chamber and the area of the piston, which is directly exposed to the hot expanding gas coming from the chamber. Both systems exhibit fairly high geometric compression ratios in the order of 19–22 and lend themselves to come close to a stoichiometric combustion because of the intensive air–fuel mixture formation inside the chamber.

The DI combustion system, which is the predominant process used in the industry nowadays, features only one main combustion chamber. The combustion chamber is defined by the bowl machined in the top of the piston and the fire deck of the cylinder head while a centrally located and preferably vertically oriented injector provides fuel for combustion via evenly spread out injection holes located in the nozzle tip. The mixture preparation, and thus ensuring ignition, is heavily influenced by the charge air motion inside the cylinder and the injection pressure available. Specially designed intake ports allow for a certain swirl level inside each cylinder promoting the ignition and combustion of the fuel injected. Over time, the swirl levels have continuously decreased because of the airflow losses associated to the generation of the swirl resulting ultimately in lower flow coefficients and thus cylinder filling. In that context, distinction is made between swirl and tangential intake ports, which are engineered to provide the desired swirl level at maximum air delivery. Owing to a continuous increase in fuel injection pressure levels from approximately 1350 bar at the beginning to now over 2000 bar, the injection system is able to support the required air–fuel mixture preparation and, therefore, allows for higher cylinder charge filling and ultimately higher engine power output. In parallel to that development, the amount of nozzle holes has increased from approximately 5 up to 8–9 for state-of-the-art high speed direct-injected (HSDI) diesel engines resulting in not only a more efficient combustion process but also lower engine-out emission levels. Usual compression ratios also have declined over time because of increasing fuel injection pressure and have come down from approximately 19–16. This also increases the sensitivity level regarding fuel quality (mainly cetane number) and its impact on engine startability at lower (cold) ambient temperatures and avoiding white smoke formation. Owing to the more compact combustion chamber and avoiding the throttle losses between the main and pre/swirlchambers as well as the heat losses, the DI technology provides a fuel consumption benefit of approximately 5–10% over the IDI technology while exhibiting higher in-cylinder peak pressures (up to 200 bar) and pressure gradients. However, with the ability for multiple injections and precise metering of small injection (pilot) quantities, the noise level of modern DI engines is close to the former IDI engines.

As a result, the state-of-the-art turbocharged and highly efficient and clean HSDI diesel engines have become the prime power source for diesel automotive applications.

2.6 Modern DI and turbo technology

The DI diesel engine always represented the most efficient internal combustion engine used in mobile applications. However, besides the aspect of superior fuel efficiency, also other parameters are relevant for homologation and market acceptance. Consequently, out of continuously strengthened emission standards, the improvement of the emission behavior of diesel engines depicted always the driver for enhanced or new technologies, especially regarding PM and NO_x emissions, as the legal norms were reduced regularly. In addition, the customer-related attributes such as performance and noise, vibration, and harshness (NVH) raised the need for upgraded capabilities of the engine and its main subsystems. With respect to an on-going engineering of the combustion process to meet increasing demands, base engine architecture and main subsystem (e.g., turbocharger and fuel injection system) specifications were part of numerous iterations of improvement and

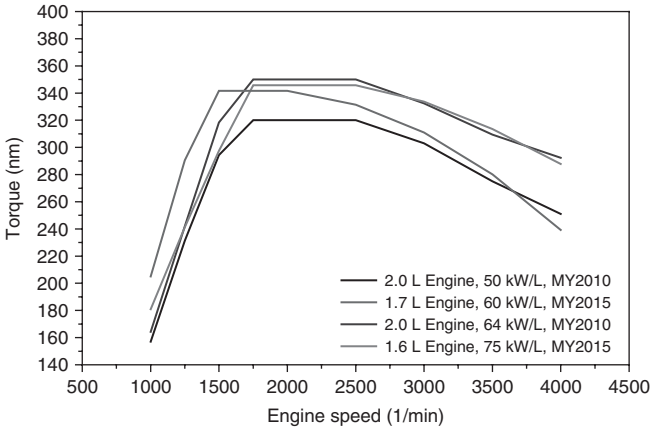

Figure 3. Turbocharger technology as the driver for engine downsizing. (Reproduced by permission of FEV Inc.)

refinement. On the basis of general design aspects such as increased peak firing pressure capability and central, perpendicular installation of injectors, mostly in combination with four-valve technology, a continuous adaptation of the combustion system parameters such as compression ratio and bowl geometry, charge motion, and spray pattern was performed (Figure 2).

A fundamental element in the success story of small HSDI diesel engines represents the charging system. In order to raise the power density and the specific torque, numerous improvements on the turbocharger specifications were realized. Beginning with increased efficiencies for conventional wastegate (WG) turbochargers over to refined VNT (variable nozzle turbocharger) technology to two-stage charging systems, a large bandwidth of charging devices for all engine sizes is meanwhile available to support the actual needs of all kinds of developments. The process of technology upgrade for the elementary diesel technology is continued to support actual trends such as downsizing or other advanced tendencies, as Figure 3 indicates. Furthermore, advanced turbocharger specifications are also assisting in improving part-load engine-out emission performance.

The second important factor for realization of the recent market success is given by the high pressure fuel injection system. Especially in balancing the demands from emission performance, fuel efficiency, and acoustic appearance of a diesel engine, actual common-rail technology delivered a superior contribution. With continuously rising pressure levels up to actually 2000 bar and in conjunction with modern piezo-control, an extremely capable and reliable fuel injection was developed, representing currently the forefront regarding system performance and accuracy (Figure 4).

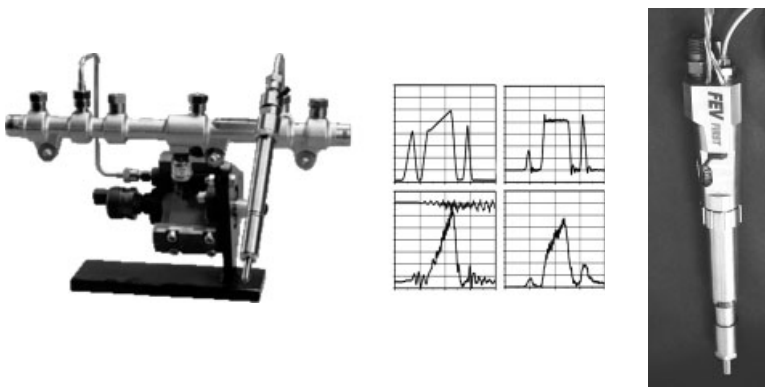

Figure 4. Advanced prototype high pressure common-rail system (FEV FIRST—flexible injection rate shaping tool). (Reproduced by permission of FEV Inc.)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Owing to the on-going tightening of the legal and market demands, engineering activities are continued in all areas of DI diesel technology.

3 CURRENT AND FUTURE TECHNOLOGIES

3.1 Current and future emissions legislations (EU/US/JP/BRIC)

The currently valid emission regulation is still related to local and national standards as shown in Figure 5.

In the United States, still exists a tendency toward further minimization of engine-out pollutants, concentrating on lowering PM, NO_x, and HC emissions. Despite the fact that already today's Tier 2 Bin 5 emission limits display the most severe emission norm in the world, a further step of tightening is planned with the introduction of the new LEV 3 (low emission vehicle) legislation with its implementation to be completed by 2025. In Europe, with the actual main market for passenger car diesel engines at an average market penetration of ~50%, a reverse trend is actually seen. While having established already reasonable low emission standards with EU-6 in 2014, a higher focus is actually placed on reduction of greenhouse gases (GHG). Besides a further moderate strengthening of emissions, strict legal demands are formulated for CO_2 emission behavior, as shown in Figure 6. The Japanese emission regulation (JP Post New Long Term, JP PNLT) is strongly related to domestic conditions and remains regarding complexity between European and US standards.

The emerging countries such as China, India, Brazil, and Russia follow, in most cases, the European regulation with a slight temporal delay and small adaptations to local conditions.

For all countries, it is valid that starting with stringent emissions standards such as EURO-5/-6, US Tier 2 Bin 5, or JP PNLT, adequate norms for appropriate fuel quality, especially regarding sulfur content, have to be enacted.

3.2 Design and materials

Since its inception, the combustion engine, independent of gasoline or diesel as its main representatives, has evolved significantly not only in its design but also with respect to the materials used; starting with cast iron (CI) over steel to more advanced materials such as aluminum alloys up to more exotic materials such as titanium and magnesium, as they are primarily used in racing applications. In the following, the main attributes of these materials in context of engine component design will be discussed.

3.2.1 Cylinder block

Being exposed to a variety of mass and gas forces, torsionals, and engine mounting forces, the cylinder block (crankcase) represents one of the main engine components. Housing the cranktrain (crankshaft, rods, and pistons), as

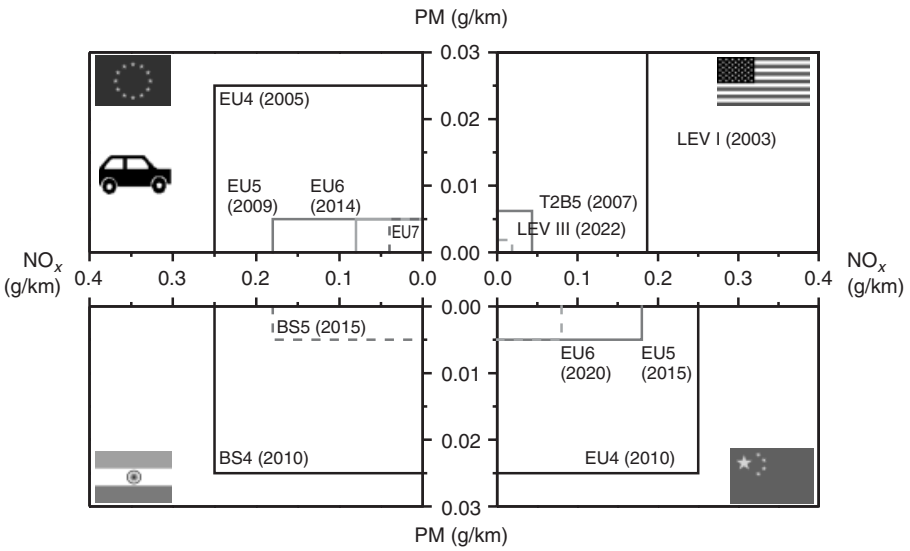

Figure 5. Actual emission regulation in selected major markets and prognosis. (Reproduced by permission of FEV Inc.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto148
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

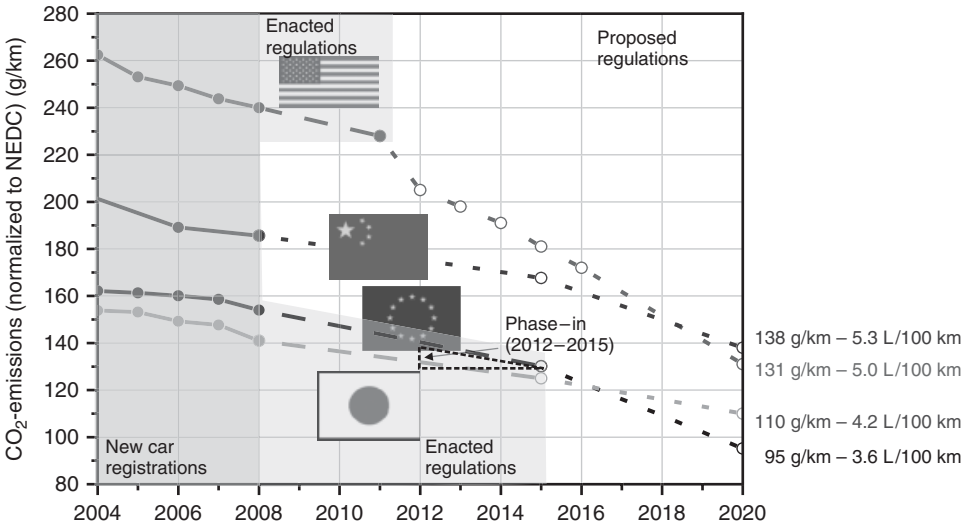

Figure 6. Current global CO_2 regulation in major markets and outlook. (Reproduced by permission of FEV Inc.)

well as coolant, oil, and a variety of accessories as well as interfacing with the cylinder head, oil pan, and transmission, it requires a thoughtful design. As a long-time standard material, CI meanwhile has been surpassed by a variety of different aluminum alloys for gasoline and diesel engine cylinder blocks. Owing to the significantly lower weight, higher heat conductivity, and machining properties, aluminum has become a competitor to CI as the prime block material. Despite its higher price and lower strength, this tendency is continuing even for diesel engines. In order to be able to compete with CI though, design decisions such as open versus closed deck design and deep skirt versus bedplate (girdle) design to stiffen up the block are of significant importance.

Usually, distinction is made between CI and aluminum liners. For CI liners, further distinction is made between pressed-in or slip-fit liners (either dry or wet) and cast-in liners. For aluminum blocks, distinction is made between all-aluminum configurations, depicting either an over-eutectic aluminum alloy or a special liner coating and inserted aluminum liners (slip-fit or cast-in). Owing to cost and durability reasons, the most used configuration in the market is represented by the cast-in CI liner in aluminum blocks.

In addition, the implementation of additional ribs to minimize deformation during operation, as well as for noise reasons, is a must for current production applications.

One additional alternative is represented by compacted graphite iron (CGI). Representing a hybrid between aluminum and CI by depicting good strength at a lower density compared to CI, it has been used for some automotive production applications, where emphasis was placed on lightweight and high specific power. However, owing to difficulties in machining this specific material, high cost has precluded CGI from becoming a standard material. For automotive diesel engines, considering the current threshold of 180 bar in-cylinder peak pressure, one can expect to reach and potentially exceed the 200 bar mark within the next years because of the continuous demand for increased specific power and torque. Using state-of-the-art tools to analytically optimize and validate the structural integrity of an engine block, the main target in the future will be to lower weight while simultaneously increase strength and stiffness.

3.2.2 *Cylinder head*

Similar to the cylinder block, aluminum has become the standard cylinder head material for gasoline and diesel engines. Only for diesel engine designs exploiting peak pressures exceeding 180 bar, the application of alternative materials such as CI or CGI become an option. While CGI owing to its machining challenges and its material price has become an expensive alternative though, other smart designs using aluminum with an intermediate deck design have potential to comply with future demands.

While the four-valve cross-flow liquid-cooled design has become a standard in the automotive industry for most diesel powertrains, some exceptions using two or three valves can be found as well. Considering further downsizing resulting in smaller bore diameters, some two-valve concepts bear a lot of potential for highly efficient combustion systems at low cost. In addition, with decreasing bore diameters, the accommodation of valves, injectors,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and glow plugs for automotive diesel applications becomes more and more challenging from a thermal and mechanical perspective.

3.2.3 Cranktrain

The cranktrain, consisting of the crankshaft, connecting rods, and pistons, is exposed to gas and mass forces, as well as torsionals in case of the crankshaft. Crankshafts for higher specific power engines are usually forged to ensure high strength and stiffness, whereas cast crankshafts at a lower cost are less robust. Compact design with highest possible pin overlaps in Vee engines and shortest possible cylinder-to-cylinder distance for inline engines are highly desired. To reduce friction, the main and connecting rod bearings need to be minimized in width and diameter to just satisfy all criteria relevant to achieve full engine life.

Similar to crankshafts, connecting rods are also either forged or cast depicting the same trade-off regarding strength, stiffness, and cost. To reduce complexity regarding the machining of the big end, sintered metal connecting rods with fractured bearing caps have been successfully introduced over the past decade. This process eliminates the machining of that part of the components and assures perfect alignment of the rod with the cap because of the individual cracking characteristics. The pistons, for basically all automotive diesel applications, are actually aluminum based because of its excellent heat transfer properties. To cope with the high thermal and mechanical stresses, a steel carrier for the top steel compression ring is incorporated in the top section of the piston while oil jets improve cooling on the bottom side of the piston for higher specific power applications. Anodizing around the rim of the piston bowl helps to mitigate the potential for cracking while being exposed to temperatures up to 350°C. The application of low friction coatings on the skirt of the piston helps to reduce the overall engine friction level, with the piston group being a significant contributor. Latest developments offered some fuel-saving potential with advanced steel piston design, which are currently introduced in first applications.

3.2.4 Valvetrain

The majority of automotive diesel engines employ dual overhead camshaft (DOHC) four-valve applications, while the application of belt versus chain as a driving mechanism is highly depending on the manufacturers' preference. Owing to high cost, gear-driven valvetrains represent an exception for automotive applications. To minimize friction, in most cases, (roller) finger followers or buckets are applied. To reduce maintenance cost, hydraulic valve lash adjusters are incorporated either into the cylinder head or directly into the bucket itself. Ensuring low seating velocities in favor of low NVH requires optimized camshaft profiles considering the kinematics of the entire valvetrain and the components involved. To further optimize the combustion system, variable valve lift on the intake side and potentially cam phasing on the exhaust side to improve catalyst light-off, technologies well known from gasoline engines, will find their application more and more in modern diesel engines. The design, material, and manufacturing of the camshaft depends on the application. While the cast camshafts represent the conventional designs, build camshafts using steel tubing and lobes attached via press fit are a lightweight solution that is found more and more.

3.3 Fuel injection system

In the challenging competition of all alternatives in the late 1990s, ultimately the common-rail injection emerged as the final winner. The dominating merits of this innovation, where the fuel is stored at high pressure in one (for Vee-type engines in two) common supply rail ("common rail") for all cylinders of an engine arrangement, were:

- largely speed-independent injection pressure;
- multiinjection capability at constant nominal injection pressure.

As a function of time, with growing demands from market and legislation, enhanced capabilities and increased functionalities regarding

- higher injection pressure,
- accurate metering, especially concerning small quantities,
- fast opening and closing behaviors,
- increased number of injections,
- short dwell times,
- raised hydraulic efficiency,
- repeatability, and
- long-term stability.

were requested.

Actual premium systems are piezo-controlled and operate with injection pressures of 2000 bar. Future development trends aim at a maximum injection pressure of 2500 bar in the coming years, eventually going to higher values up to approximately 3000 bar at the end of the next decade. In the high volume market, the advantages of the solenoid-controlled layout dominate because of cost and significantly improved, competitive performance values compared to the piezo-controlled injectors.

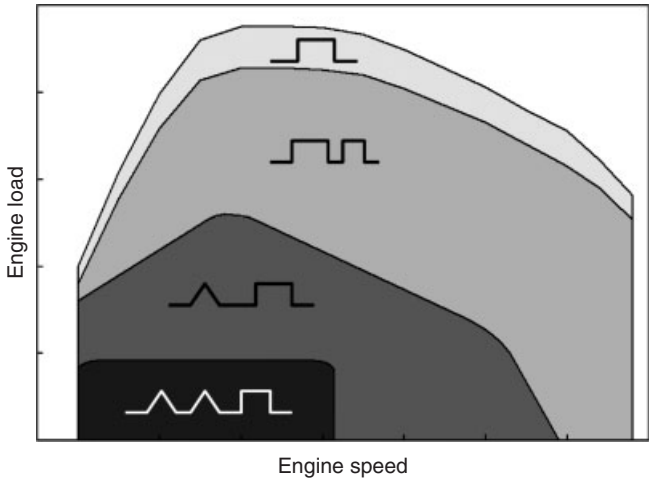

Figure 7. Representative injection characteristics for adsorption mode as function of engine load and speed. (Reproduced by permission of FEV Inc.)

According to the individual needs at various operating points and depending on operational modes such as cold start, warm-up, or regeneration strategies, different injection characteristics are preferred as function of engine speed and load, as shown in Figure 7.

3.4 Combustion system

The selection and optimization of the combustion system represent the heart of modern diesel engines, as all relevant factors such as performance, efficiency, emissions, noise, and reliability strongly depend on the characteristics of the incorporated combustion system. The main objective of the combustion system definition is given by the proper matching of charge motion, spray pattern, and combustion chamber geometry under all operating conditions.

By the proper matching of fuel injection (injection pressure, number of sprays, and spray hole diameter), charge conditions (motion and density), and piston bowl geometry, all fundamental elements of diesel combustion regarding fuel atomization, mixture formation, air utilization, flame propagation, and fuel burn-off are described.

Owing to the needs of continuous emission minimization, significant development effort was performed to lower engine-out emission levels. Main technologies and contributors in the evolution and adaptation of the combustion to today's needs were:

- smaller spray hole orifices in conjunction with increased injection pressure;
- higher number of spray holes and refined spray hole geometries (Figure 8) (e.g., hydro-erosive and conical spray holes → k-factor[1]);
- utilization of multiinjection strategies;
- rate shaping functionalities;
- higher boosting levels due to improved charging systems;
- optimized port geometries regarding flow and swirl characteristics;
- lowered compression ratios and optimized bowl geometries (reduced parasitic volumes, increased ratio of bowl volume to compression volume → higher k-factor[2]);
- EGR (exhaust gas recirculation) (noncooled/cooled HP-EGR; noncooled/cooled LP-EGR);
- valvetrain variabilities.

Owing to conflicting requirements in the entire operational map, for example, between cold start/light load and full load with respect to ignition conditions, best balanced compromises have to be worked out. Owing to limited capabilities of previous fuel injection systems, former engine variants required higher compression ratios to ensure appropriate cold start behavior and good mixture formation. With improved performance and enlarged functionalities of today's common-rail systems, a substantial reduction of compression ratios to values of minimal 14.5 : 1 is achieved in production, resulting in higher degrees of mixture homogenization and controllable peak firing pressures. The trend to lower compression ratios enabled new bowl geometries, which featured better ratios between bowl volume in relation to compression volume, described in the k-factor*. Besides the continuously increasing injection pressures of advanced high pressure fuel injection systems reaching 2500 bar in the near future, also further merits in the hydraulic system technology were introduced. In order to support improved mixture preparation, the number of spray holes raised from five in the early years of DI diesel engines to seven or eight for the majority of engines; meanwhile, even 10 are found in mass production. Furthermore, the introduction of conical spray holes, specified by the k-factor** index, resulted in a significant improvement of spray penetration and fuel atomization. The demand for minimized engine-out NO_x emissions increased EGR rates, which can be recirculated in the ways, upstream of the turbine as high pressure EGR, downstream of the turbine and diesel particulate filter (DPF) as low pressure EGR, or as internal EGR via variable valve timing. The tendency toward higher ratings in conjunction with raised low-end torques affected the design of valvetrain functionalities similar to the needs concerning variable charge motion. Furthermore, the requirement of

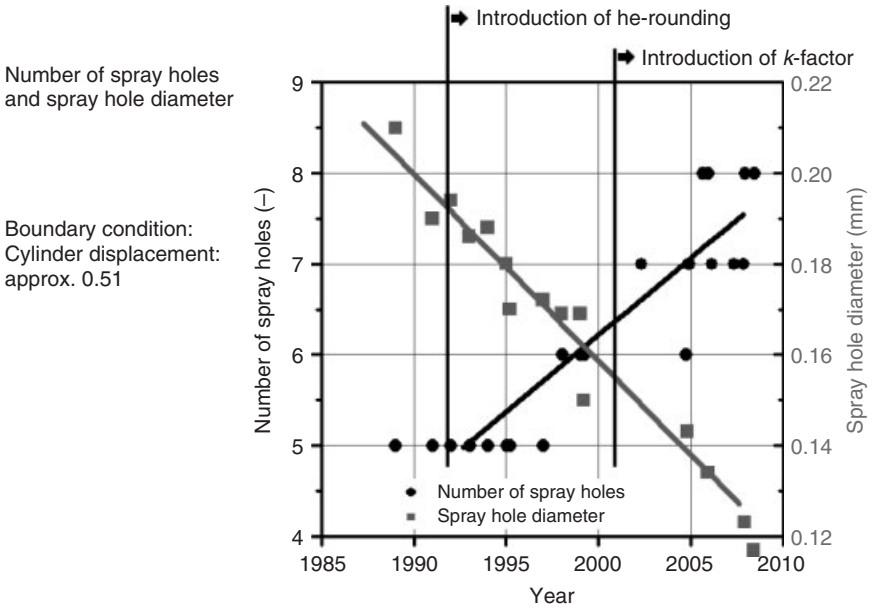

Figure 8. Evolution of spray hole number and spray hole diameter. (Reproduced by permission of FEV Inc.)

adequate temperature levels for good conversion efficiencies of the aftertreatment devices caused additional pressure on increasing valvetrain variabilities. Consequently, various technical solutions concerning valvetrain functionalities are actually launched in the market, at the time being mostly focused on one parameter at a given engine. More powerful, combined solutions are expected soon.

While driving the combustion system to the limits, stabilization measures for production scattering and ambient disturbance have to be implemented. A very powerful technology is represented by the glow plug-integrated pressure sensor. An online sensing of the pressure inside of the combustion chamber with post-processing and automatic correction of the combustion phasing ensures combustion stability with low gaseous emissions (HC and CO) and high efficiency. A further benefit is applied in the field of varying fuel qualities, where the glow plug sensor can adapt the injection scheme according to the corresponding cetane number.

3.5 Air management system

With the introduction of turbochargers, the operating range and power output of the diesel engine could be expanded significantly. Meanwhile, modern turbochargers allowing for precise boost pressure control via either WG or variable turbine geometry (VTG) are standard. To enhance further the engine performance, a two-stage sequential turbocharging has been introduced into the marketplace. These systems, employing different combinations of WG, VGT (variable geometry turbocharger), or fixed geometry turbochargers, enable very high low end torque while providing high power output making the automotive diesel engine very competitive with state-of-the-art gasoline engines. However, such a system requires refined controls and calibration to realize its true benefits. For Vee engines, twin turbo arrangements (one per cylinder bank) are also thinkable—potentially, even with a third larger turbocharger in series allowing for high power output bypassing both high pressure twin turbos.

Owing to continuously more stringent NO_x emissions regulations, high pressure EGR has become a standard feature in all automotive modern diesel engines. Routing a part of the exhaust upstream the turbine back to the intake system also influences the choice of turbine and compressor because of changes in exhaust and airflow across the corresponding impellers. To address most stringent NO_x emission targets such as Tier 2/LEV 2 in the United States, combined high and low pressure EGR systems have been developed and placed into production. In that case, where the high pressure EGR system remains unchanged, an additional low pressure system is added. This low pressure system reroutes exhaust from after the DPF to the inlet of the compressor of the turbocharger as shown in Figure 9.

To minimize thermal throttling in both cases, the exhaust is being routed through an EGR cooler, which is usually cooled by the engine coolant. As a result, the volumetric flow of the EGR is reduced and ultimately, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto148
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

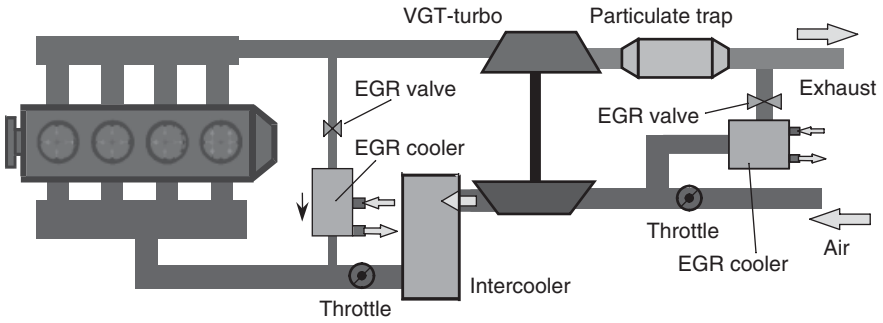

Figure 9. High and low pressure EGR system concepts. (Reproduced by permission of FEV Inc.)

cylinder charge and the amount of oxygen available for the combustion of the fuel increased. As the emissions need to be met over the expected (full useful) lifetime of the vehicle, the minimum cooling power of the EGR cooler has to be maintained. Challenges such as cooler fouling because of condensation of hydrocarbons forming a hard, nonremovable layer on the inside of the cooler leading to increased EGR temperatures are being addressed by the design of the cooler, materials used, cleaning strategies, and bypass operation of the cooler during operating regimes exhibiting higher HC emissions (e.g., cold start and DPF regenerations).

The amount of EGR recirculated is controlled via an EGR valve, which, in most cases, is a poppet-type valve. Control of boost pressure and EGR, which influence each other, has evolved over time. Meanwhile, multivariable controllers (multiple input—multiple output: MIMO) are being applied to accurately control boost and EGR within the entire operating map. Further challenges are primarily related to transient control optimization.

3.6 Exhaust system (DOC, DPF, LNT, SCR, and so on)

In order to meet the increasing demands in emission control, already in the early 1990s, the DOC (diesel oxidation catalyst) or a two-way catalyst was introduced. As the diesel engine typically operates with air excess, only oxidation processes regarding HC and CO can be supported. Main purpose of the initial usage of the DOC was given by the reduction of PM mass because of oxidation of wet elements on the PM, namely accumulated HCs.

In 2005, the installation of DPFs was renewed in Europe by PSA according to Euro-4 norms, after unsatisfactory previous experience in the United Sates with older technologies. Despite the fact that most OEMs targeted Euro-4 compliance without the usage of DPF technology, the overwhelming public response forced all OEMs to follow this direction. While PSA favored a fuel-borne assisted DPF regeneration with lowered temperature levels for soot burn off, all other OEMs concentrated on realizations without additional fluid on board of the vehicle. With enacting the Euro-5 norm and the US Tier 2 standards, the wall-flow DPF technology became mandatory for all applications. In order to improve the emission behavior of in-field vehicles, retrofit systems on the base of open DPF technologies were launched based on fiscal incentives. Depending on base combustion system performance and package boundaries, some companies installed a special fuel injector in the exhaust line to lower the risk of in-cylinder after injection regarding fuel-in-oil consequences and oil dilution. As a function of time, new substrate materials were introduced owing to cost, performance, and robustness aspects. Main substrate types are SiC, AlTi, and cordierite.

With the implementation of wall-flow DPF devices, the tailpipe PM emission level reached levels below ambient air qualities and even future particle number limits can be ensured, so that future emission legislations focused on NO_x emissions. Despite a massive improvement on in-cylinder NO_x-reducing technologies such as amplified EGR rates and homogenized low temperature combustion, future applications require highly sophisticated $DeNO_x$ aftertreatment technology to meet upcoming emission regulations. While SCR (selective catalytic reduction) technology is clearly the selected path for heavy-duty diesel engines, the light-duty diesel engines use two different systems. Besides the SCR technology, the lean NO_x trap (LNT) or NO_x storage catalyst (NSC) also offers substantial benefits regarding individual parameters in the global assessment matrix. The SCR technology is based on a continuous NO_x conversion process in the exhaust line, while applying ammonia derived from an aqueous urea solution once appropriate temperature levels have been realized. In contrast to that, the LNT performs in a discontinuous way. The working principle of the LNT is based on

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto148
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a certain adsorption phase, followed by a frequent regeneration phase. The challenge is given by the realization of the regeneration conditions, where the engine has to be operated under rich conditions (relative A/F ratio <1) and the fast transition from normal lean to rich operation and back to lean operation again. Typical intervals are factors of >25 between lean and rich operations. Further challenges are found in the sensitivity of LNT technology regarding sulfur coming from the fuel and oil in the engine. Owing to the pronounced accumulation of sulfur in the LNT, frequent desulfation events have to take place in order to maintain NO_x conversion efficiency. For reliable release of sulfur out of the LNT, quite high temperatures in conjunction with enriched exhaust composition have to be achieved. Therefore, typically, desulfation phases are combined with DPF regeneration events; because, during that phase, elevated thermal boundary conditions are present in the exhaust system.

3.7 Controls and sensors

All of today's automotive diesel engine control systems are torque based, meaning that a torque request indicated by pedal position is turned into a fuel injection quantity, providing that requested torque independent of varying accessory drive loadings caused by, for example, increased alternator current demand and air conditioning. The amount of calibratable parameters for an entire automotive diesel vehicle including the powertrain and transmission can be up to 30,000 parameters, with continuously increasing tendency. To appropriately populate (calibrate) all of these parameters within a reasonable timeframe, satisfying targets in terms of performance, emissions, drivability, fuel consumption, NVH, and so on, very detailed procedures, highly sophisticated tools, and calibration experience are required.

To ease the calibration effort and improve the quality of the calibration and thus engine operation, a variety of sensors have been developed and introduced into production. Cam and crank sensors to determine engine speed and actual position of each cylinder relative to each other, also on an absolute basis, are crucial. Temperature and pressure measurements for boost conditions in the intake manifold are also standard. Sensors related to the aftertreatment systems have also evolved over time. There, temperature, lambda, NO_x, and differential pressure sensors for DPF loading monitoring are standard. For common-rail injection systems, pressure sensors are used to control the rail (injection) pressure in a closed-loop manner compared to commanded rail pressure as calibrated in the rail pressure map. Other sensors monitoring parameters such as coolant temperature for thermostat control and in-cylinder combustion pressures for fuel injection parameter optimization based on, for example, fuel quality variations are also used. Future sensor developments include ammonia (NH_3) sensors to monitor the ammonia break-through downstream the SCR catalyst optimizing the urea injection quantities injected into the exhaust as well as radio frequency (RF) sensor technology to more accurately determine the loading level of a DPF compared to a differential pressure sensor.

To reduce cost and hardware complexity, the development of the so-called virtual sensors has become more and more a part of the engine control system and the associated sensor infrastructure. Using the output of several sensors, another sensor can be modeled virtually providing important information. This becomes especially attractive for sensors that are expensive, difficult to manufacture, have a critical lifetime, or are even suspect to undesired cross-sensitivities. To continuously improve engine operation especially under highly transient conditions, such fast reacting virtual sensors can significantly improve the outcome.

All of these sensors also play an important role regarding on-board diagnostics (OBD), which is a regulatory certification requirement demanding continuous diagnosis of all relevant sensors to ensure proper engine operation (functional monitors) and all subsystems potentially affecting emissions (threshold monitors).

3.8 Fuels and alternative fuels/biofuels

Owing to the continuous decline in fossil fuel reserves, it is mandatory to develop meaningful alternatives to the conventional diesel fuel currently available. On the basis of significant fluctuations of some of the relevant diesel fuel properties such as cetane number and sulfur concentration, each of the relevant world markets have established their own fuel standard/norm that they adhere to. Nevertheless, the desire to develop and market alternative fuels and biofuels has resulted in a variety of products, which to some extent have been introduced while the majority is still under development.

Biodiesel, often also referred to as *FAME* (*fatty acid methyl ester*), using rapeseed (RME, rape methyl ester) or soybeans (SME, soy methyl ester) as a feedstock has become a common fuel for blending in the European Union or the United States, respectively. Representing a share of up to 20% (B20) allows reducing the use of fossil-based fuels. However, as for conventional diesel fuel, the introduction of tight biodiesel fuel standards (e.g., ASTM D6751) to ensure adequate quality is critical, as engine components, mostly fuel injection system related,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto148
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

can potentially be damaged. For most engine applications, significant reductions of CO, HC, and particulate matter have been observed while NO_x at the same time have been increasing slightly yet almost linearly as a function of biodiesel concentration.

In order to not use feedstock, which compete with foods consumed by humans, another group of the so-called second-generation biofuels have been established. These fuels use feedstocks that have no direct impact on food cost or availability. One particular example is algae-based fuels. As a part of the production process, algae are grown in a controlled environment feeding off gases such as CO_2 and SO_x under direct sunlight. As a result, while producing the algae, which can then be processed into biofuel, this technology helps to reduce the overall carbon footprint. Research continues to improve the process in terms of algal growth and the associated fuel processing.

Another process utilizes natural gas to develop diesel-like fuel as a part of the gas-to-liquid (GTL). This fuel exhibits significant advantages over conventional diesel fuel, as it has a higher net heat of combustion, practically no sulfur content, very low aromatics, and a drastically higher cetane number. At this point, only cost and production volume prevent a deeper penetration into the market while blending with conventional diesel-like fuels with biodiesel also represents a meaningful approach. Similar attempts are made focusing on biomass-to-liquid (BTL) and coal-to-liquid (CTL).

Other opportunities exist with feedstocks such as jatropha oil, palm oil, canola oil, and other plant or animal-based fats. In addition, some studies are also investigating the use of supplemental fuels such as ethanol, which is already used in gasoline fuels in concentrations of up to 85% (E85). Promising features such as improved in-cylinder cooling resulting in lower NO_x emissions and eventually allowing for even higher engine loads have caused interest despite the need for a separate fuel and injection system.

Beyond biofuels, artificial or the so-called tailor-made fuels from biomass (e.g., 2-methyltetrahydrofurane) exhibiting similar results compared to common diesel fuels are also subject to laboratory investigations worldwide. While promising fuels have already been identified, the cost to produce them in the required quantities is still exceeding the limits making a short- or even mid-term introduction not feasible.

3.9 Noise, vibration, and harshness

The noise level of a combustion engine can be broken down into a variety of different categories as depicted in Figure 10. According to this flowchart, each individual category can be optimized for lowest possible noise levels focusing on the parameters influencing it.

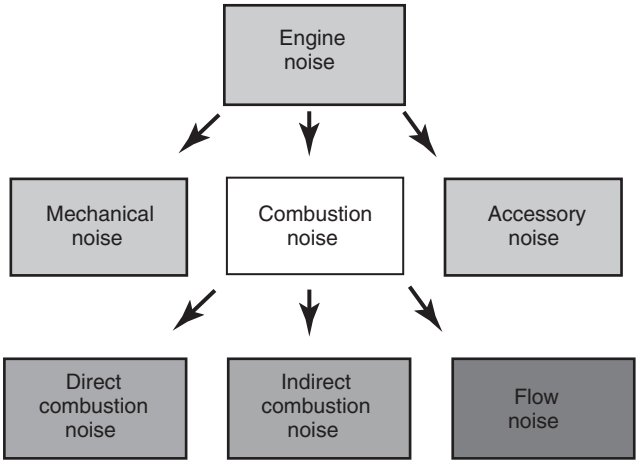

Figure 10. Engine noise categories. (Reproduced by permission of FEV Inc.)

While direct combustion noise contains the total excitation (force and impact) by gas force and all other forces inside the engine, which have a similar course versus time (allowing for a certain cylinder pressure gradient correlation), the indirect combustion noise contains the total excitation by rotary and piston normal forces, which have a different course versus time compared to gas force (e.g., piston slap, crankshaft torsion, and cyclic speed fluctuations caused noise such as gear rattle noise). The flow noise is excited by air mass flow and it is radiated by the intake and exhaust systems.

For a diesel engine, part load noise increase is typically caused by direct combustion noise. The indirect combustion noise and flow noise are increasing with load, caused by the increase of air mass flow and peak pressures. The increase of boost and thus in-cylinder charge pressure typically increases indirect combustion noise because of higher peak pressures, but decreases direct combustion noise based on increasing combustion chamber pressure and temperature level, reduced ignition delay, and pressure gradient.

With the introduction of EGR, the combustion noise can be reduced significantly because of a higher inert gas fraction inside the combustion chamber leading to a reduced premixed charge during the ignition period. The application of EGR in combination with modern fuel injection systems, which allow for one or even more subsequent small pilot injection quantities, results in an even shorter ignition delay leading to an even further reduced direct combustion noise level close to gasoline engine noise levels under warm operating conditions.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto148
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Further means to reduce noise are reduced moving masses, bearing and piston clearances, stiff cranktrain and engine block/cylinder head architecture (ladder frame or bedplate design), engine downspeeding (reduced maximum engine speed), short ignition delay (soft initiation of combustion), lower valve-seating velocities, noise insulation (via seals or gaskets), and potential encapsulation.

In addition to that, optimizations regarding the intake and exhaust system noise levels attribute to the overall beneficial noise level of a state-of-the-art automotive diesel engine.

3.10 Thermal management

Thermal engine management has become one of the most critical engine management items. Avoiding overheating of the most vulnerable and thus critical engine components such as pistons, cylinder head, valves, and turbochargers mitigating excessive thermal stresses and ultimately engine failure has become a routine. Applying piston oil cooling jets, providing sufficient cooling flow at appropriate temperatures in combination with optimized material selections usually result in thermally very robust engine architectures.

Other challenges, however, are represented by the reduction of exhaust gas temperatures because of increased use of EGR and continuous improvement of thermal efficiency and, therefore, reduced exhaust gas heat losses. In combination with that, vehicle certification cycles such as the FTP-75 (federal test procedure) or NEDC (new European driving cycle) also promote rather low exhaust gas temperatures because of the low vehicle velocities and idle phases especially at the beginning of the test cycles leading to low engine speed and loads. Despite the improvement of catalytic light-off temperatures down to approximately 180–200°C, catalyst heating by increasing the exhaust gas enthalpy during the cold start period of the corresponding certification cycles is required to efficiently reduce CO, HC, and NO_x emissions early on in the test cycle. This catalyst heating is usually achieved by fuel injection timing retardation and can be further complemented by advanced exhaust cam phasing as far as available. Intelligent thermal management also includes taking advantage of the thermal inertia of some of the aftertreatment system components, which can vary drastically based on the difference in size, cell density, porosity, material, and their location within the exhaust system. Monitoring the relevant temperatures of the DOC, LNT/SCR catalyst, and the DPF helps reduce the additional fuel quantities required to achieve the necessary conversion rates of the regulated exhaust constituents.

In addition to that, fast heat-up of the engine coolant and oil is desired as well to help increase exhaust gas temperatures and lower fuel consumption. In that context, applications of technologies such as split cooling and electric coolant pumps are beneficial.

ENDNOTES

1. Nozzle *k*-Factor: (inner diameter−outer diameter)/10 with both diameters (μm).
2. Combustion chamber *k*-factor: (bowl volume*)/compression volume—*bowl volume = compression−parasitic volume.

Cooling Systems

Stephen F. Bowyer, Haralabos Triantafyllidis, and Mark E. Case
FEV Inc., Auburn Hills, MI, USA

1 INTRODUCTION

Heat release from the combustion process will have negative effects on component durability, engine performance, and the combustion process if the engine is not properly cooled. Modern automotive cooling systems have been developed to address several of these issues during the vehicles operation. The following sections outline durability, performance, and emissions characteristics of automotive engines that are addressed by the engine cooling system.

1.1 Mechanical durability

1.1.1 Low cycle fatigue

Combustion gas temperatures inside modern combustion engines significantly degrade the mechanical strength of the components while simultaneously imparting a thermal strain on the components and assemblies. Yielding of the material under high compressive strain caused by thermal stresses can cause catastrophic engine failures by low cycle fatigue. Thermal yielding while in operation and subsequent cooling after engine shutdown imparts significant tensile strain loads in the combustion face of the cylinder head. Each time the engine is heated, further yielding occurs, and, over time, the resultant stresses can become significant enough to cause a crack to form in the base material of the cylinder head.

1.1.2 Thermal distortion

High component temperatures can create sealing issues throughout the engine because of the thermal strains of the components. Combustion gas sealing at the bore interface to the piston is highly dependent on the thermal distortions in the cylinder block. One countermeasure to bore distortion is increased piston ring tension to ensure sufficient contact pressure with the bore wall. This countermeasure, however, is not ideal as increased friction and increased fuel consumption will be observed. A more productive countermeasure is improving the cooling system to provide a more round cylinder bore during operation.

Another critical combustion seal is the valve to the valve seat that is also heavily influenced by the roundness of the valve seat as well as the true position of the valve seat with respect to the projected centerline of the valve guide. Misaligned or out-of-round valve seats are typically caused by poor or inconsistent cooling within the cylinder head.

In addition to the combustion seals already discussed, the engine contains lubrication, cooling, and crankcase gas seals throughout the engine that are affected by the distortion of various engine components. For example, the cylinder head gasket interface typically transfers pressurized oil, low pressure return oil, coolant, and ventilation gases between the cylinder block and the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto149
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

cylinder head. Thermal distortion to either of these components can compromise the head gasket's ability to seal the passages resulting in warranty claims and customer dissatisfaction.

1.1.3 Lubrication

The heat from the combustion process is also transferred through the engine components to the lubrication system. Failure to keep the engine's lubricant temperature to an acceptable level will cause a degradation of the lubricant and cause the lubricant to coke or sludge. This will, in turn, lead to further catastrophic failures of moving parts within the engine as the ability of the lubricant to reduce friction and remove heat will be compromised.

1.2 Combustion gas temperatures

As the fresh air charge travels through the engine for the next combustion process, it absorbs heat as it makes its way through the inlet duct, cylinder head, and into the cylinder. The heat absorbed raises the temperature of the final charge and reduces the density of the air captured in the cylinder. This, in turn, reduces the volumetric efficiency of the engine, thereby reducing the engine's power density.

For gasoline engines, a second detriment is the reduced knock margin because of the increased charge temperatures or hot surfaces in the combustion chamber that can serve as knock initiation points. Several countermeasures are possible, such as retarding spark, enrichment, or throttling the engine but all have a negative effect on engine efficiency and should be avoided, as much as possible, by minimizing the heat transferred into the fresh air charge.

For diesel engines, high in-cylinder temperatures contribute to the formation of NO*x* emissions that can be difficult and expensive to manage with aftertreatment systems. Keeping components that make up the combustion chamber cool reduces NO*x* emissions and allows for smaller, less costly, and more efficient exhaust aftertreatment systems.

2 ENERGY BALANCE

Energy from the fuel consumed by the engine can be split into several categories and is highly load and speed dependent with the main categories being shaft power, exhaust heat, heat rejected to the cooling system, and miscellaneous other losses including radiation and remaining chemical energy from incomplete combustion.

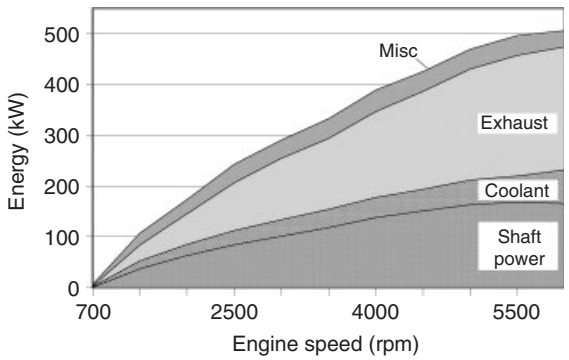

Figure 1. Energy diagram for a turbocharged direct injected gasoline engine at full load. (Reproduced by permission of FEV Inc.)

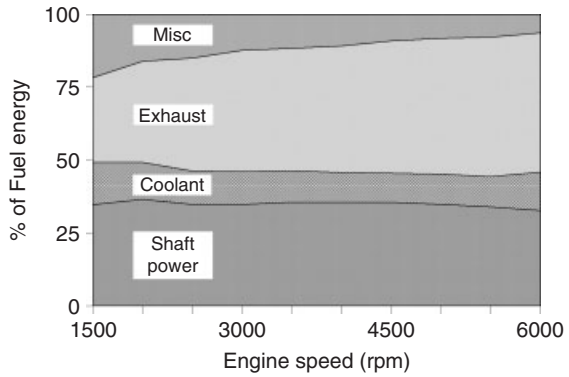

Figure 2. Energy split for a turbocharged direct injected gasoline engine at full load. (Reproduced by permission of FEV Inc.)

Figures 1 and 2 show the heat rejection graphs from a turbocharged direct injection gasoline engine at full load. Here, we can see that the heat rejected to the cooling system is varied within a tight band between 10% and 15% of fuel energy.

Figure 3 shows the heat transferred to the cooling system over various engine speeds and loads. Generally, the heat rejected to the coolant increases as engine power and engine speed increases. Looking only at the low engine speed points (2000 rpm), we see that the heat transferred to the coolant becomes larger as more loading is applied to the engine. Conversely, we see the opposite effect at the high end of the speed range (6000 rpm) and no definable trend for the mid-speed point (4000 rpm). The differences in heat rejection trends for the charted speed ranges are caused by differing boundary conditions. At low speeds, the engine is operated with a near stoichiometric air/fuel ratio for all load cases. As engine speed is increased to the 4000 rpm speed point, the engine is again operated at a near

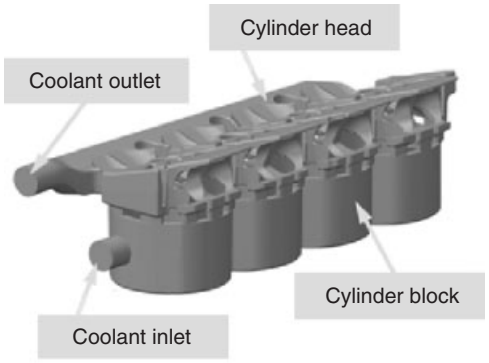

Figure 4. Example liquid cooling jacket. (Reproduced by permission of FEV Inc.)

stoichiometric air/fuel ratio during low loads but enrichment to limit exhaust gas temperatures begins to occur at higher loads causing a reduction in the amount of heat rejected to the coolant. At 6000 rpm, enrichment begins at even lower loads and increases further as engine loading is increased explaining the negative slope shown in Figure 3.

3 FUNDAMENTALS OF COOLING SYSTEMS

3.1 Types of cooling systems

3.1.1 Air cooled

The simplest cooling system available for internal combustion engines is air cooling. In these systems, either vehicle motion or a cooling fan blows ambient air over the engine to provide engine cooling. Cooling is aided by fins that are cast into the cylinder head, cylinder block, and other external components. These systems were used in some early automotive applications because of the systems simplicity and low cost. While this type of cooling system is inexpensive, it is no longer used in automotive applications in developed and emerging markets because of its inability to reject enough heat and also direct cooling to key problem areas in modern, high power density engines. As such, this section is largely devoted to liquid cooling systems.

3.1.2 Liquid cooled

Water- or liquid-based cooling systems have become standard for virtually all automotive markets. Liquid systems operate by pumping a liquid coolant through cast-in passages of the engine that form a jacket around the combustion chamber and cylinder liner (Figure 4). This liquid absorbs heat as it passes through the engine and then exits the engine to a heat exchanger typically mounted at the front of the vehicle where the heat is rejected to the atmosphere.

Keeping the center of the combustion chamber cool is the greatest challenge for the engine's cooling. While the air-cooled system must first transfer the heat from the center of the chamber to the outside surface where it can be rejected to atmosphere, the engineer has the ability to target the cooling of a liquid system to the critical areas that need the most heat transfer. It is for this reason that liquid cooling systems have become standard in modern automotive applications.

3.2 Common liquid cooling schematic

Countless engine cooling systems can be imagined and vary in cooling effectiveness, efficiency, and cost. Vehicle application, thermostat placement, expansion tank style, cabin heating requirement, and the number of external devices requiring cooling can make cooling system layouts differ significantly from one vehicle to another. A reference schematic is shown in Figure 5. This particular cooling system has multiple external devices that require cooling including the center housing of a turbocharger, an engine oil cooler, and an EGR (exhaust gas recirculation) cooler. A two-stage thermostat and pressurized expansion tank are also included in the system. It is clear that this is neither the simplest form of cooling system with the additional add-ons nor as complicated as some systems that incorporate strategies to speed cold start performance. Examples of these systems are discussed in later sections.

Developing the balance of the individual branches of the system requires several iterations of 1D flow analysis.

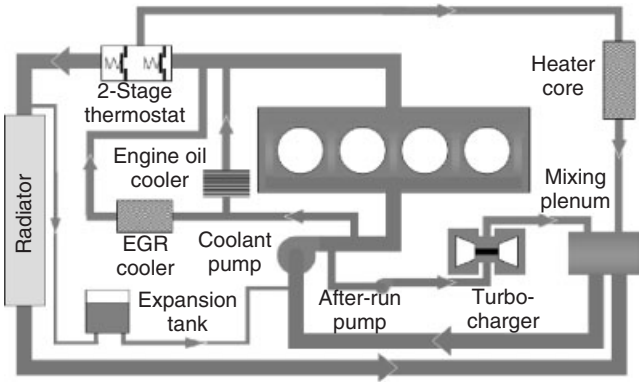

Figure 5. Common cooling system layout for a turbocharged automotive engine. (Reproduced by permission of FEV Inc.)

Table 1. Sample flow rate requirements for common cooling system components on a 175-kW turbocharged four-cylinder.

Component	Requirement (L/min)
Engine	170
Heater core	21
Oil cooler	19
Expansion tank (pressurized)	8
Turbocharger	8
Radiator	120

Careful selection of hoses, pipes, and orifices are selected to provide appropriate flow rates to the components within the system under different boundary conditions. In some cases, pump sizing may be dependent on meeting flow requirements to certain devices such as heater cores rather than cooling requirements for the engine. Table 1 shows some sample flow rates for given components in a typical cooling system.

4 LIQUID COOLING SYSTEM COMPONENTS

4.1 Coolant

Plain water has excellent cooling properties and can be used as an engine coolant. However, there are several significant issues associated with its use that prevent it from being used directly as an engine coolant. The largest issue is that water will freeze near 0°C and can cause severe damage to the engine, radiator, and piping as the frozen water expands. Another significant issue is that water boils near 100°C, whereas the coolant side of the chamber surface frequently ranges in temperature from 120 to 125°C with short-term excursions to 130 or 140°C. Plain water, even under pressure, in contact with surface temperatures this high will begin rapid boiling and the local heat transfer coefficient will be dramatically reduced.

Ethylene glycol is the primary constituent in virtually all automotive coolants. It is an alcohol that, when diluted 50% with water, significantly increases the boiling temperature and simultaneously reduces the freezing temperature of water.

In addition to the ethylene glycol, corrosion resistant additives are mixed with the coolant to protect the internal passages of the cooling system. Three of the most popular additives are based on using silicates, organic acid technology (OAT), or hybrids of the prior two (HOAT, hybrid organic acid technology).

Silicate-based cooling systems were the most popular options for automotive applications and can be identified by their green pigment. The silicates offer great corrosion and pitting protection to metal engine parts. However, the protection is limited to 2 years at which time the silicates can start to fall out of the mixture and begin to build up in the internal passages of the cooling system. This can eventually lead to blocked passages and an ineffective cooling system. The silicates are also abrasive and can limit the longevity of coolant pump seals.

To address the limited change intervals of the silicate-based cooling systems, most major automotive companies have moved to either OAT or HOAT coolant for their factory coolant fill. OAT coolants typically will use carboxylate, sebacate, and 2-EHA as corrosion inhibitors and can be distinguished by their orange pigment. The biggest advantage of the OAT coolants is that there are no silicates to drop out and build up. Thus, a longer service life of the coolant, up to 5 years, can be expected.

HOAT coolant is basically an OAT with benzoate as an inhibitor and a small amount of silicate added in order to obtain the superior corrosion benefits silicate combined with the extended life of the OAT coolant.

4.2 Coolant pump

4.2.1 Mechanical pumps

Most coolant pumps are mechanically driven from either the front accessory drive or the timing drive system. Virtually, all mechanical pumps are centrifugal style with variations in impeller designs and impeller materials used. The most simple and cost effective are simple stamped steel impellers. Pump efficiency can improve significantly with the addition of backing and top plates as shown in Figure 6. These plates are used to seal off the front and back sides of

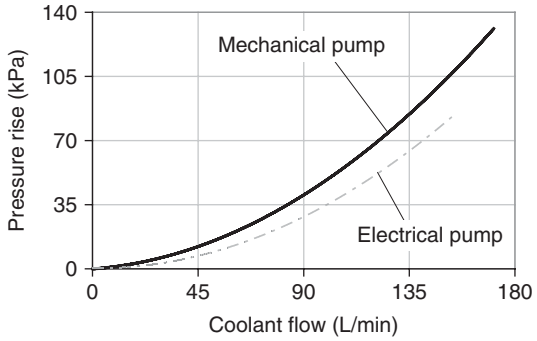

Figure 7. Comparison between mechanical coolant pump for a typical four-cylinder gasoline engine and a 400 W electrical coolant pumps for an automotive application. (Reproduced by permission of FEV Inc.)

the impeller blades to reduce leakage from one blade to the next as the pump rotates. These plates can be either welded to a steel impeller or, more commonly, integrated into a one-piece plastic impeller. Although less effective, some pumps will use only backing plates to improve efficiency. It is important to note that many manufacturers opt for impellers without backing plates and take a penalty in efficiency in order to reduce the hydraulic work at higher speeds when additional coolant flow is not required.

The housing for mechanical pumps can be made from either plastic or aluminum. However, owing to the accessory drive loads and support for appropriately sized bearings, aluminum is the most common housing material. Accessory drive loads and the location of the water pump within the accessory drive must be considered when sizing the bearing for the water pump.

4.2.2 *Electrical pumps*

The traditional mechanical coolant pump is tied to engine speed and not cooling requirement of the engine. As such, the pump is sized for a worst vehicle operating condition, which is a low speed full load, low airflow, high ambient condition. Thus, the pump is sized for a condition is rarely encountered (less than 5% of vehicle operation), the majority of the time the pump is oversized for the cooling needs of the system. This results in unnecessary parasitic losses and reduced fuel efficiency. In addition, as the mechanical pump is tied to engine operation, it continues to operate during cold start where no coolant flow is necessary resulting in longer warm-up times, increased engine emissions, increased engine friction, and reduced fuel efficiency.

Electric pumps can provide peak cooling when needed but less cooling when it is not due to decoupling cooling flow and engine speed. For hybrid vehicles and engines equipped with stop/start capability, the decoupling of the coolant pump and engine speed also offer better cooling and continued cabin heater performance during temporary engine shutdowns. Finally, with engine downsizing becoming more popular as a means to reduced fuel consumption, electric pumps are becoming more popular. As engine downsizing usually involves replacing a higher displacement naturally aspirated engine with a smaller displacement, turbocharged engine, the electric pump can circulate coolant after engine shutdown resulting in increased turbocharger durability and eliminating the need for a separate after-run pump. Table 2 shows some of the benefits of electrical versus mechanical pumps.

The greatest limitation to the market penetration of electric pumps is the significant cost increase over that of a mechanical pump. However, the cost is a function of the size of the pump, which is directly related to the peak flow capacity, or, more accurately, the size of the electric motor. Reduction in the pressure drop throughout the cooling system can help reduce the electrical pump size and ultimately the cost of the pump. Electric pumps for automotive applications are typically sized at about 400 W. Figure 7 compares a 400 W electric pump to a typical mechanical unit. As can be seen in the chart, the electric pump is not capable of meeting the same flow rate as the mechanical pump at a given pressure. As such, significant effort must be placed on reducing the cooling system pressure drop during the development of the engine.

4.2.3 *Clutched and hybrid pumps*

A third option is a mechanical pump with either a clutched pulley or a small electric motor. Clutched pumps offer the ability to disconnect the pump from the engine using a vacuum or electrically operated clutch. The pump pulley is allowed to free spin to reduce parasitic losses and speed cold start warm-up while re-engaging to drive the pump

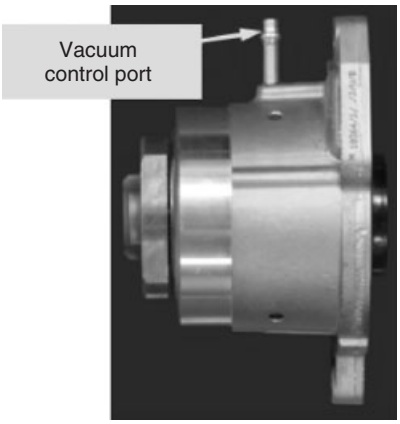

Figure 8. Example of a vacuum-clutched coolant pump. (Reproduced by permission of FEV Inc.)

when engine cooling is required. An example of a clutched coolant pump is shown in Figure 8.

Hybrid pumps are similar clutched pumps with the addition of a small electric motor capable of spinning the pump for low flow rates. These hybrid pumps, while more expensive than mechanical pumps, not only offer the ability to flow the amount of coolant required for the given engine load but also switch to mechanical operation for high load operations such as towing. At maximum output, mechanical drive efficiency is better than the combined efficiency of an electric pump, which must have its drive power created by an alternator.

4.3 Thermostat

On most engines, the coolant temperature is regulated by the thermostat. In its basic form, a thermostat is a spring-loaded valve used to regulate coolant flow through the vehicle radiator. When the coolant is cold, the thermostat remains closed. As the coolant heats up, wax inside the capsule begins to melt and expand forcing the valve open gradually beginning at a prespecified temperature. As the engine cools, the thermostat then begins to close again. Changes to the thermostat's geometry and blend of wax can be used to calibrate the opening temperature of the valve. In addition, the location of the thermostat is an important factor in the behavior of the overall cooling system. These locations and effects are discussed in the following sections.

In order to speed engine warm-up, some engines use a double valve arrangement. On start-up, the secondary valve opens first that allows the engine coolant to circulate freely through the engine but without flowing through the vehicle's radiator. As the coolant circulates through the engine, the temperature of the coolant continues to rise and the main valve begins to open diverting coolant to the radiator. Figure 9 shows an example of a double valve mechanical thermostat.

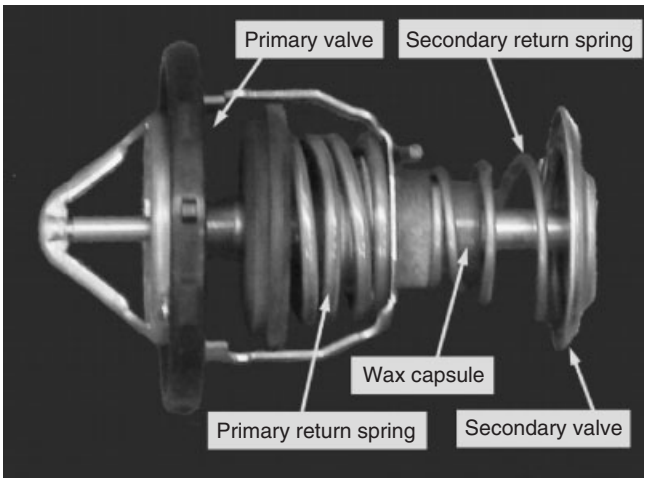

Figure 9. Mechanical thermostat. (Reproduced by permission of FEV Inc.)

4.3.1 *Inlet/outlet t-stat*

Thermostats are generally placed on the inlet or outlet to the engine. Both configurations have their benefits and disadvantages, and placement is typically driven by the preferences of each OEM.

Outlet thermostats were traditionally the most common configuration. When the coolant heats up and thermostat opens, cold coolant begins to flow through the engine until it reaches the thermostat. This rush of cold coolant causes the thermostat to close and the cycle begins over again. The series of thermal shocks imparted on the engine components during engine warm-up is the main reason that some automobile manufacturers have chosen to move to inlet thermostats.

Conversely, when an inlet thermostat starts to open only a small amount of cold coolant is allowed into the engine but, because it is located on the inlet side, the valve begins to close quickly until the engine heats up the new coolant and the valve opens again. Inlet placed thermostats are not without their own issues, though. The large pressure drop across the valve just before the inlet pump can negatively influence pump efficiency as well as create cavitation issues in the pump.

4.3.2 *Mapped thermostat*

To obtain more control over the coolant temperature of the cooling system, some thermostats have become electrified.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto149
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

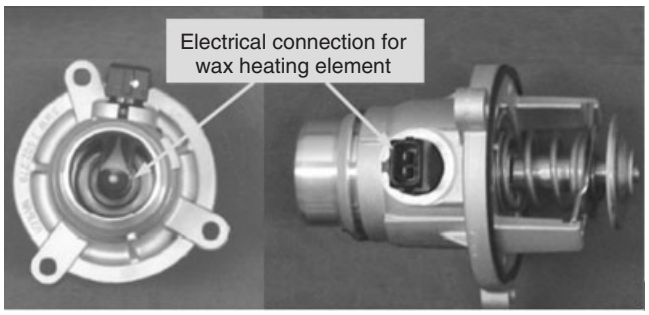

Figure 10. Electric (mapped) thermostat. (Reproduced by permission of FEV Inc.)

The basic function of an electrically assisted thermostat is unchanged in that the valve is opened by expanding the wax within the capsule. However, the opening coolant temperature is set 10–15°C higher than traditional, mechanical only thermostats. This allows the coolant to maintain a higher temperature during part load operation that reduces engine friction through higher oil temperatures and lower viscosity while also improving thermal efficiency by reducing heat transfer into the coolant. During full load operation, a small electric heater within the thermostat is used to increase the temperature of the wax and open the valve further and faster, thereby reducing the overall operating temperature of the coolant and response time of the thermostat to protect the engine structural components and provide better knock margin for gasoline engines at full load. It is worth noting that the electric heater alone cannot open the thermostat when the coolant is below a certain temperature. However, the electric heater does extend the opening temperature range and response time of the thermostat. Figure 10 shows an example of a thermostat with electric assist.

4.3.3 Electric valve

As most OEMs are starting to realize the effects a well-controlled cooling system can have on fuel economy, electric valves are being introduced in the automotive industry as they provide a number of advantages over both traditional and electric thermostats. The two main advantages are precise control of the coolant temperature and much faster response. As these valves can go from fully closed to fully open in about one second, the operating coolant temperature can be set to much higher temperatures than traditional systems reducing engine friction and improving thermal efficiency much like electrical thermostats. However, due to the much faster response, electric valves offer the highest overall engine thermal efficiency improvement as they allow for engine operation very close to the knock limit for gasoline engines. The operation of the valve is controlled by the engine's ECU that can consider ambient air temperature, throttle position, air/fuel ratio, and coolant temperature to determine the best position of the valve. With mechanical systems, the only signal used to determine valve position is the temperature of the coolant at the thermostat. However, with the electric valve, temperature measurements can be made anywhere in the cooling system and the ECU can control the valve. This allows the valve to be positioned at the outlet of the engine to eliminate the pressure drop directly before the coolant pump, whereas the temperature signal can come from the entrance to the engine, thereby eliminating the thermal cycling effect of an outlet thermostat.

4.4 Expansion tank

As the engine coolant increases in temperature, it begins to expand and pressure is built up in the cooling system. This increase in pressure is advantageous in that it increases the boiling point for the coolant reducing the chances for overheating. However, if excessive pressure builds up within the system, permanent damage can be done to engine components and seals. Therefore, a spring-loaded pressure relief valve is placed in the system fill cap, which allows excess coolant and vapor to exit the system and reduce system pressure. There are two main system strategies used to manage this effect as described in the following sections.

4.4.1 Unpressurized

In an unpressurized system, a simple overflow reservoir is used to capture the excess coolant during operation. In this configuration, the system fill cap is generally located at the radiator with a hose that runs from the radiator, downstream of the pressure relief valve, to the expansion tank. As excess coolant bleeds off of the system, it is caught in this reservoir, which remains at atmospheric pressure. As the system cools, the vacuum within the cooling system pulls the excess coolant back into the radiator.

4.4.2 Pressurized

Pressurized reservoirs, sometimes referred to as *hot bottles*, are inherently more expensive but offer some additional advantages. With pressurized reservoirs, a small amount of flow is diverted into the expansion tank. There, the flow velocity is relatively low because of the large volume and low flow rate. This semiquiescent chamber allows for small vapor bubbles to settle out of the coolant before being reintroduced into the system ensuring better cooling properties

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto149
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

for the coolant in the engine. The action of removing the vapor bubbles from the coolant is called *deaeration* and is extremely important as very small amounts of vapor can have a detrimental effect on the ability of the coolant to transfer heat.

In addition, some turbocharger applications can be set up to cool the turbocharger after shutdown with the aid of a pressurized expansion tank. This process, known as *thermal siphoning*, is described in more detail in the following section.

4.5 Cooling fan

A cooling fan is used to pull additional air through the vehicles radiator beyond that which is provided through either natural convection or ram air forced through the radiator due to vehicle speed. There are two basic drive methods used for cooling fans, electric and mechanical.

4.5.1 Electric

Most passenger car applications are equipped with thermostatically controlled electric cooling fan(s) for improved vehicle fuel economy and also facilitate transverse mounting of the powertrain. These fans operate only when the radiator temperature exceeds a predetermined limit; fan speed may be continuously controlled as a function of the coolant temperature. The conversion of mechanical energy to electrical energy through the belt to alternator and then back to mechanical work at the electric fan is inherently inefficient. However, despite this inefficiency, electric fans offer superior parasitic loss advantages to most mechanically driven fans because they are decoupled from engine speed and their operation can be controlled based on cooling requirement. This enables the fans to be turned off during low heat rejection load points, cold start, or when available ram air across the radiator is sufficient for engine cooling.

4.5.2 Mechanical

For $^1/_2$- and 1-ton truck applications, the cooling demand may be too high during towing conditions for reasonably sized electric fans. As such, mechanical fans are still commonly used to cover the peak cooling requirements, which are more likely to be a steady-state condition than on a passenger car.

To mitigate the parasitic losses during low loads, mechanical fans are equipped with a thermostatically controlled viscous clutch. This clutch allows the fan to spin at a slower speed than the engine during cold conditions. As the radiator warms up, air surrounding the clutch warms up as well and a thermal spring located on the front of the clutch begins to open a valve within the clutch at around 70–80°C. This valve allows more coupling fluid to be released and brings the fan speed closer to that of the engine.

4.5.3 Hydraulic

Although unusual, there have been applications of hydraulic cooling fans for light-duty vehicles. In one application, the hydraulic power steering pump provides the hydraulic fluid to drive the cooling fan motor. The hydraulic fan motor speed is electronically controlled to match the cooling demands.

4.6 Radiators

The heat absorbed by the coolant as it passes through the engine is released to atmosphere at the radiator. While the operating principle of common automotive radiators has remained unchanged from the early years of the automobile, the construction and materials have changed over time. Modern radiators are constructed using an aluminum core, tube and fins, and composite end tanks, whereas prior art utilized a copper core and brass tanks.

The layout of the automotive radiator has improved from early designs as the industry has converted from vertical or down flow to horizontal or cross flow. This change allows the radiator cap to be placed at the low pressure side of the radiator, beneficial during prolonged high speed operation where the high pressure side of the radiator may exceed the vent pressure of the cap. In addition, moving the tanks to the sides creates more heat transfer area low in the vehicle, where the majority of the ram air used for cooling is available, and also facilitates a lower, more aerodynamic hood line.

The amount of cooling air that travels through the vehicles grill in order to cool the radiator has a significant effect on the vehicles aerodynamics. With increasing concern regarding fuel consumption, active aerodynamic devices are starting to be adopted by some automotive manufacturers. One such device are grill shutters, which allow air to travel through the vehicles grill and provide cooling to the radiator when required but can close off the opening in the grill when additional cooling is not needed. Another device used to reduce aerodynamic drag is a hood extractor, which allows for the air passing through the front fascia to be extracted. This device in addition to aerodynamic benefits offers cooling benefits as it increases the velocity of the air traveling through the radiator, which in turn increases the heat transfer capacity of the radiator.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto149
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

4.7 Oil cooler

For high power density engines and vehicles that will spend large amounts of time under high load, oil temperature can become a concern. To mitigate the risk of oil coking, an oil cooler is frequently used to transfer heat from the oil to the cooling system or directly to ambient air. These oil coolers, with the appropriate control strategy, can also be used to speed the heat-up of the engine oil and reduce oil viscosity during start-up.

4.8 EGR cooler

EGR is commonly used on diesel engines as a method to reduce the in-cylinder creation of NO*x* emissions, whereas some gasoline engines also use EGR as a method of reducing engine knock at high load. However, both of these strategies require the exhaust gases to be cooled before inducted into the engine. As such, EGR coolers are frequently used and plumbed into the engine's cooling system. Depending on the amount of EGR used by the engine, these coolers can account for a significant portion of the engine's cooling requirement. While this requires an increase in the capacity of the cooling system, it can also be beneficial by accelerating coolant warm-up that reduces engine friction and fuel consumption.

4.9 Heater core

The vehicle passenger compartment heater core circuit must be considered when sizing the engines cooling pump. Many customer complaints regarding the cooling system are based on poor heater performance during either warm-up or operation. The fundamental flaw with poor performing systems can be directly related to coolant flow through the heater core. This phenomenon is exaggerated during idle. A simple but not desirable countermeasure is to increase idle speed, which has negative effects on fuel consumption. In some cases, pump sizing can be dictated by the minimum coolant flow rate required to provide adequate cabin heating. Larger vehicles with multiple heater cores are particularly susceptible to this condition. As such, it is extremely important to properly design the heater core circuit to reduce overall pressure drop.

5 ENGINE COOLING

5.1 Cooling jacket design

There are several flow strategies used for the cooling passages within the engine. While there are many configurations not covered here, three of the most commonly used strategies are described in the sections later.

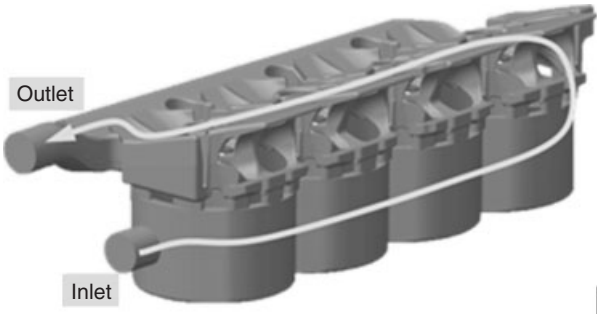

Figure 11. U-flow cooling diagram. (Reproduced by permission of FEV Inc.)

5.1.1 U-flow

The most common cooling system is the U-flow, or sometimes referred to as *axial-flow*, configuration. In this configuration, coolant enters the cylinder block at one end of the engine. The coolant then flows through the cylinder block and then flows up into the cylinder head once it reaches the other end of the block. Once in the cylinder head, the coolant flows back toward the same end of the engine where the coolant entered the block. An illustration of the U-flow cooling jacket is shown in Figure 11. This cooling system, even though more susceptible to thermal bore distortion, is the simplest to design and develop. However, with increasing power densities and ever-increasing fuel consumption targets, other, more advanced cooling strategies are becoming more common.

5.1.2 Split cooling

Split cooling systems are similar to the U-flow configuration in how they flow through the cylinder block and head. However, in this strategy, coolant enters the head and block at the same end of the engine, flow in parallel, and exit at the other end. There is no communication between the head and block as shown in Figure 12. This enables the head and block temperature to be metered by separate thermostats and be controlled to different temperatures. The benefit of this strategy is that the cylinder head can be held at a temperature cool enough to avoid any mechanical failures, whereas the block, which has significantly less heat loading and few delicate features, can be kept at a higher temperature. The higher temperature cylinder block keeps the engine oil temperature higher and viscosity lower, thereby reducing engine friction. This system requires

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

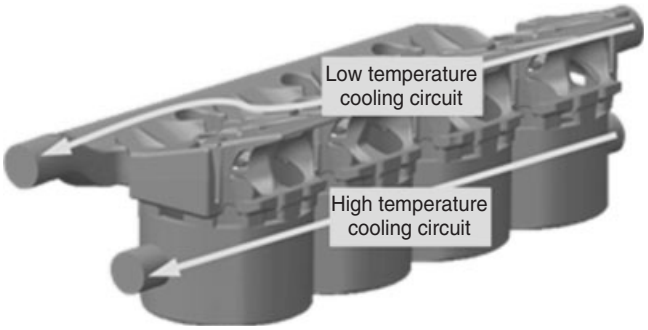

Figure 12. Split cooling diagram. (Reproduced by permission of FEV Inc.)

additional external plumbing and an additional thermostat in comparison to the U-flow design.

5.1.3 Cross flow

The most common cooling jacket design for high power density engines is the cross-flow design that gets its name from the flow path of the coolant across the cylinder head from the exhaust side to the intake side of the jacket. Coolant can enter the engine block from the side or end of the block and then circulates to the opposite side. There, it flows up into the cylinder head, across the cylinder head, and collects on the opposite side. Once there, the coolant must be routed to a location where it can exit the engine. An illustration of the cross-flow cooling jacket is shown in Figure 13.

This cooling system has the best cooling capability because coolant can be directed to specific, high heat flux regions of the cylinder head such as the small bridge between the two exhaust valves in a four-valve-per-cylinder engine. If designed correctly, the cross-flow design can also offer the lowest pressure drop of the three major options. However, development of this system requires more effort and multiple loops of three-dimensional cooling simulation to verify that the flow is balanced across all cylinders, the critical areas receive a proper amount of flow, and that there are no stagnant volumes in the block or head.

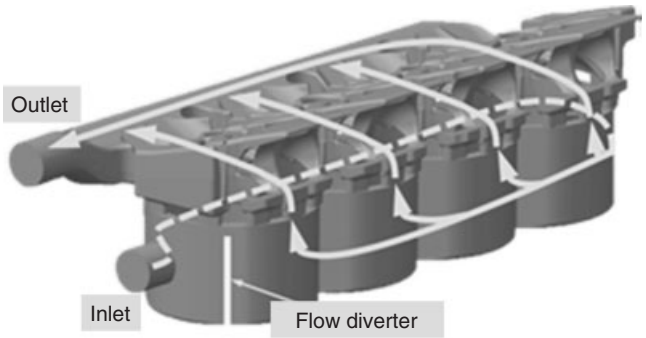

Figure 13. Cross-flow cooling diagram. (Reproduced by permission of FEV Inc.)

One challenge with this strategy is getting uniform cooling flow through the block without stagnation points while simultaneously and providing uniform coolant flow into the cylinder head. A flow diverter can be inserted in the cylinder block that forces the majority of the flow to take the long path through the cylinder block while allowing a small portion of the flow to take a shorter circuit strictly to help balance the cylinder head. The cylinder head gasket is used to meter the coolant between the cylinder block and head. The location and size of the holes can be tuned to provide cooling where it is required in the head and also balance the cylinders.

The coolant entry point and flow distribution in a cross-flow configuration can play a significant role in the uniform cooling of the block. If designed properly, thermal bore distortion can be minimized and coolant temperature difference between block entry and exit points can be increased. This temperature difference increase allows for a reduction in coolant flow, which leads to a water pump downsizing and thus better fuel efficiency because of the reduction in parasitic losses.

5.2 Cylinder head

The cylinder head has the highest heat load in the combustion system and features several delicate, thin bridges between the various valves, spark or glow plugs, and fuel injectors. The cylinder head cooling jacket must be designed to target the highest heat flux areas within the cylinder head. The primary concerns in this respect are the small bridges between the two exhaust valves (for four-valve-per-cylinder engines) and the bridges between the exhaust valves and spark plug or fuel injector as shown in Figure 14. These bridges are highly susceptible to low cycle fatigue and must be kept cool to limit the reduction in material strength and also reduce the thermal growth that causes compressive stress at high load. As such, directing coolant to these critical areas is a primary concern for design engineers. An example flow path for a cooling jacket designed to provide key coolant flow rates to these areas is shown in Figure 15.

Beyond cooling the valve bridges, the chamber is generally receives a sufficient amount of cooling as long as the coolant flow is not stagnant and stays close to the floor of the water jacket.

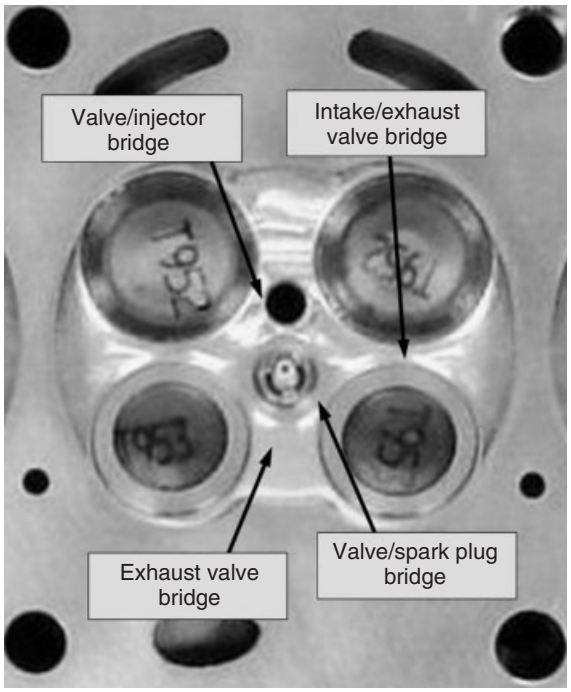

Figure 14. Key bridges in the combustion face of a cylinder head. (Reproduced by permission of FEV Inc.)

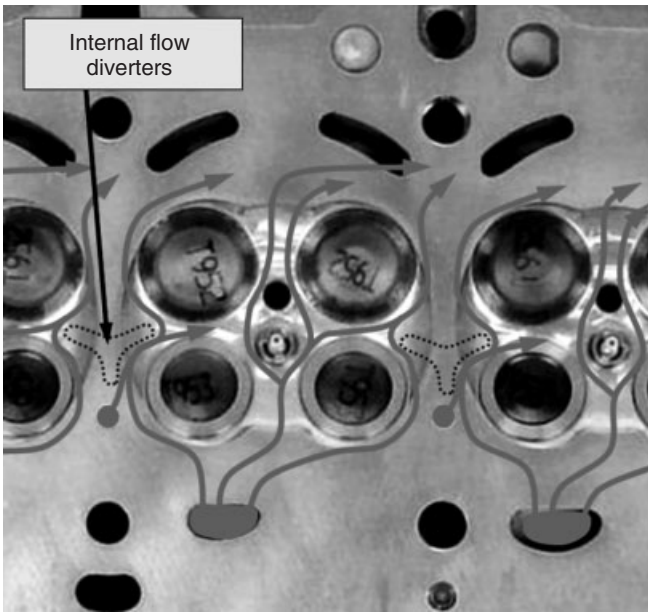

Figure 15. Example cylinder head cooling cross-flow pattern designed to cool all key areas. (Reproduced by permission of FEV Inc.)

5.2.1 Degassing

The cylinder head cooling jacket must be able to purge gas during system filling and vent coolant vapor that may be created during operation. The ceiling of the cooling jacket is largely determined by the oil cavity above it, which has its own requirements including oil drain paths. Regardless, it is important that the cooling jacket maintain its ability to properly vent. It is acceptable, however, to have some localized, slightly negative slopes in the ceiling as these will vent as the engine motion shakes the gas past the trap.

5.2.2 Head gasket

The cylinder head gasket plays a key role in the cooling system. It acts as a metering plate between the cylinder block and head. This enables the engineer to specify the amount of coolant required into each cylinder head core print. The head gasket can also create the highest pressure drop in the engine. As such, the metering passages should be as large as possible while still providing the proper direction for the cooling. Small passages that allow for gas and vapor must be used to transfer gases from the high side of the cylinder block into the cylinder head jacket and eventually out of the engine.

5.2.3 Valvetrain

Cooling the valvetrain must be considered when designing the cylinder head cooling jacket. A significant amount of heat is transferred through the valve head into the cooling jacket through the valve seats. It is critical that the coolant has a moderate flow velocity around the valve seat. Failure to properly cool the valve seats can lead to distorted seat rings and/or valve-to-valve seat adhesion.

Cooling the valve guides, specifically for the exhaust valve, is also critical for the engines durability. Moderate cooling velocity in the jacket surrounding the exhaust valve is required to dissipate the heat released by the valve and prevent galling of the guide. Thermal distortion in the cylinder head between the valve guide and the valve seat can create a misalignment between the projected valve guide centerline and the centerline of the valve seat. Steep temperature gradients within the head can lead to this condition causing high edge loads on the valve and seat and small clearances at the seat when the valve is closed. Both conditions can lead to poor combustion sealing and ultimately failure of the engine.

5.2.4 Two-piece cooling jacket cores

Most automotive diesel engines and some high power density gasoline engines utilize two water jacket cores in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto149
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the cylinder head. The primary reason for the additional core is to create an intermediate deck that helps to support the combustion chamber under high cylinder pressure. It is important, though, that the cooling flow pattern be designed properly to keep good cooling characteristics across the combustion chamber.

5.3 Cylinder block

Thermal loading in the cylinder block is significantly lower than in the cylinder head. This is largely due to the very small portion of the cylinder being in direct contact with the combustion gases for the full power and exhaust strokes and the large contact area of the cylinder liner with the cooling system. General cooling jacket design targets should be to cover the top piston ring at top dead center and follow the piston down for at least 80% of the stroke. In applications where high load operation can be expected for extended periods of time, such as towing conditions for light-duty trucks, a cooling jacket that covers 100% of the piston ring travel should be considered.

The main durability concern is at the top of the cylinder liner between adjacent bores. This area is in direct contact with combustion gases for the entire combustion and exhaust strokes with exception of when the piston is at top dead center. Heat is transferred into this small interbore bridge from two cylinders giving it less time to dissipate heat by comparison to other areas about the circumference. The problem is compounded in most aluminum block applications where the cylinder walls are joined together in a Siamese arrangement. While this arrangement allows for a tighter bore spacing and smaller package, there is typically no way to cast in cooling passages between the bores.

Several strategies have been used by the automotive manufacturers to minimize the effect of Siamese bores. Thinner bore walls in the interbore area can be used to drive the coolant toward the pinch point as much as possible. From there, the engine relies on the superior heat transfer characteristics of aluminum to transfer the heat to the coolant.

However, high power density engines typically require better interbore cooling than can be achieved with the directed cooling approach outlined earlier. Instead, various machining operations can be considered to improve cooling in this region. Saw cuts separating the bores at the top 20–30 mm allow coolant to pass from one side of the block to the other has been used frequently. While effective, the two commonly encountered issues with this method are the loss of structural integrity at the top of the liner and the low flow rate generated by the relatively small difference in pressure between the two sides of the block.

Cross drilling from one side of the block to the other is another common practice and can offer a structural advantage to saw cuts as the connection between the top of the cylinder bores is not completely removed. In comparison to saw cuts, which can be made quickly with large diameter circular saw blades plunged into the block, cross drills require very small diameter drills to be used over relatively large distances. The diameter to length ratio creates a high risk of the drill bit wandering and contacting the iron liner. Several variations have been used to try to mitigate this effect. The use of a stepped drill allows for a larger diameter to be used for a portion of the span that creates a stiffer tool that is less prone to walking. Another method is to use the same stepped drill but drill from both sides of the block. These drills effectively form a V configuration and provide the lowest tolerance option for cross drilling.

One final variation of interbore is cross drilling through the block into the cylinder head. This configuration gives the best flow rate of the three most common options, because the pressure difference between the cylinder block and the head is used to develop a consistent flow rate. Examples of all three configurations are shown in Figure 16.

The amount of coolant volume is critical for cabin heating and engine friction attributes of the engine. Large volumes of coolant create a large thermal mass that takes a significant amount of time to bring up to temperature. During this time, passengers go without the ability to heat the cabin of the vehicle while cold oil creates higher engine friction leading to poor fuel economy. As such, it is important that the volume of the cooling jacket be minimized in order to reduce the thermal mass as much as possible. With high pressure die-cast cylinder blocks, the coolant volume is fixed primarily by the engine's stroke and the depth of the cooling jacket. Given the standards for die designs, some manufacturers have opted to install plastic inserts in the block cooling jacket to displace coolant volume and improve cold start conditions. An example of such an insert is shown in Figure 17.

5.3.1 Degassing

One critical parameter that should not be overlooked when developing the water jacket in the cylinder block is the ability to purge air and coolant vapor. Small holes in the head gasket on the high side of the water jacket must be used to transfer gas from the block water jacket to the cylinder head. The hole sizes in the gasket to support degassing of the cylinder block are typically driven by the smallest hole that the head gasket manufacturer can make with reasonable tool life (Figure 18).

5.4 Piston

Automotive pistons are not cooled by the cooling system directly beyond their heat release to the bore wall. The heat transfer from the piston to the block liner is mainly through the piston rings and a function of the area, materials, and physical connections between rings, piston, and liner. However, it is important to note that piston cooling jets are required for high power density engines in order to cool the piston crown and ring pack. Piston cooling jets are mounted at the bottom of the cylinder and direct a stream of oil onto the bottom side of the piston or into a small, cored annulus cast into the piston crown. Heat from the piston is transferred to the oil where it is then removed from the oil by the cooling system at the oil cooler.

5.5 Turbocharger

Virtually, all automotive turbochargers have a center housing cooled by the engine cooling system. Failure to provide adequate cooling will lead to seizure of the turboshaft and failure of the assembly. General cooling is relatively easy to accomplish as the flow rates required are relatively low, commonly 8 L/min. However, the challenge for the cooling system is typically in the hot-soak condition. Once the engine is shut down, heat in the turbocharger continues to flow into the cooling system. The coolant then vaporizes and, if not replaced with fresh coolant, temperatures in the center bearing increase rapidly and may damage the shaft and bearings as well as engine oil itself whose lubricating properties are degraded when the temperature exceeds its functional limits.

5.5.1 After-run pump

The most robust solution to the hot-soak condition is an after-run pump. Here, a small electric pump is placed in the turbocharger's cooling loop. Once the engine is shut down, the pump continues to circulate coolant through the turbocharger, providing fresh coolant and pushing out any vapor.

After-run pumps offer a second advantage. Once the engine is shut down, the pump can also be used to circulate coolant through the heater core. This feature would allow the occupant the ability to stay warm for a period of time with the engine shutoff.

5.5.2 *Thermal siphon*

Thermal siphoning can be a low cost alternative to after-run pumps but is not possible in all applications. The thermal siphoning concept utilizes natural convection in a closed-loop circuit to provide coolant flow to the turbocharger. On shutdown, coolant in the turbocharger is heated and becomes more buoyant than the cooler coolant in the loop. As such, cooler coolant is pushed into the turbocharger as natural convection forces the hotter coolant to rise in the system. For the system to function, the hot coolant must be allowed to rise continuously on its route to the expansion tank, which means that a low mounted turbocharger is required. Any negative slope in the path between the turbocharger and the reservoir will prevent the convection process from completing the circuit. It is also important to point out that the system must be closed loop. This requires that the system incorporate a pressurized expansion tank. A simplified representation of the circuit is shown in Figure 19.

5.6 Charge air cooler

While not part of the traditional engine cooling system, charge air coolers are critical to engine performance in boosted applications. Two types of charge air cooling systems are commonly employed and described later.

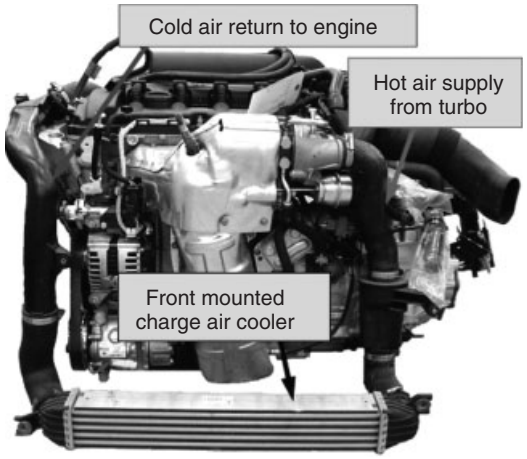

Figure 20. Engine assembly with air-to-air charge air cooler mounted at the front of the vehicle. (Reproduced by permission of FEV Inc.)

5.6.1 *Air-to-air*

Air-to-air charge air coolers are the most common charge air coolers for boosted applications. Once air exits the compressor, it is plumbed to a heat exchanger that is typically located in front of the radiator. As the air passes through the charge air cooler, heat is rejected to a cross flow of ambient air that is forced through the cooler by the vehicle's motion (Figure 20).

This is a relatively simple system with the greatest challenge being fitting an appropriately size heat exchanger in the vehicle and in a location that allows enough ram air to properly cool. The other challenge is the design of the long and complex charge air pipes that navigate through the engine compartment to the heat exchanger and back to the intake while being flexible enough to account for engine roll and thermal growth.

5.6.2 *Liquid-to-air*

Liquid-to-air charge air coolers utilize liquid coolant, typically the same formulation as the engine coolant, to remove heat from the charge air. The liquid cooling circuit is separate from the engine's main cooling circuit in order to keep the temperature of the coolant as close to ambient as possible. The charge air heat exchanger can be placed anywhere between the compressor and the cylinder head. Most often, it is integrated as a plug-in module into the intake manifold. The ability to cool the air in the manifold makes it a popular option for Roots style superchargers. These systems are also becoming more popular options for turbocharged applications for the reasons outlined later. To properly integrate the charge air cooler into the intake, it is

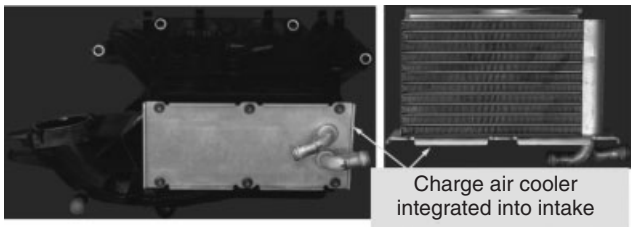

Figure 21. Example of a liquid-to-air charge air cooler with the heat exchanger integrated into the intake manifold. (Reproduced by permission of FEV Inc.)

critical that the engineering team develop the intake manifold to properly distribute air across the exchanger to realize an efficient system. An example of a charge air cooler integrated into an intake manifold is shown in Figure 21.

The cooling loop includes the charge air cooler, low temperature radiator, coolant pump, and associated cooling lines. The low temperature radiator is located in front of the engine's cooling module to have access to the coolest air possible. The coolant pump is typically between 50 and 100 W. Owing to the price difference between the available cooling pumps, significant effort should be made to minimize pressure drops through the entire system in order to minimize the size of the electric pump. A cooling loop schematic is shown in Figure 22. Note that while the system is separated from the engine cooling circuit, they can share a common expansion tank allowing a single coolant fill point for the vehicle plant and end customer.

The liquid-to-air system has several advantages over the air-to-air system. Throttle response is enhanced because of the reduced compressed air volume. The lack of large diameter piping traveling from the compressor to the front of the vehicle and back allows for a compact package with minimal volume. The thermal mass of liquid coolant is also an advantage for drive cycles that frequently operate in boosted mode. In contrast, an air-to-air cooler, with lower thermal mass, heats up quickly and loses effectiveness, resulting in reduced engine power.

6 ADVANCED COOLING SYSTEMS

6.1 System effects on transient cycles (cold start strategies)

The cooling system effectively removes excess heat from the engine during operation. Unfortunately, the same characteristics that make an effective cooling system also inhibit quick warm-up of the combustion chamber and lubrication system. Traditionally, minimizing the coolant volume in the head and block cooling jackets would suffice. However, with ever-increasing emissions and fuel economy constraints, more effort has been put into cooling system layouts to speed catalyst light-off and improve engine friction during cold start.

There are several system layouts and strategies that can be imagined. One example is shown in Figure 23. In this particular layout, the engine is equipped with an EGR cooler in the cooling circuit. During cold start operation, coolant is allowed to flow through the EGR cooler to speed the heating of the coolant. The hot coolant is then diverted to flow through a transmission fluid heat exchanger and engine oil cooler. Heat is transferred to the transmission fluid and engine oil in order to quickly reduce the viscosity of the fluids and subsequently reduce the frictional losses of the engine. One concern with this strategy is time to catalyst light-off. Care must be taken with respect to how much heat is extracted from the exhaust in front of the catalyst and its effect on time to light-off.

6.2 Effects of hybrid and start/stop operation

One of the benefits of having a liquid cooling system is that the waste heat captured by the cooling system can be used to heat the cabin. If the engine is shut down, the coolant flow through the heater core stops and, during prolonged shutdown, cabin temperatures can drop. A supplemental coolant pump that allows continuous circulation of hot engine coolant through the heater core or an additional electric heater is required for acceptable heater performance in these applications.

During engine shutdown, metal temperatures within the engine increase significantly as heat is further transferred into a stagnant cooling jacket. Under normal engine
