
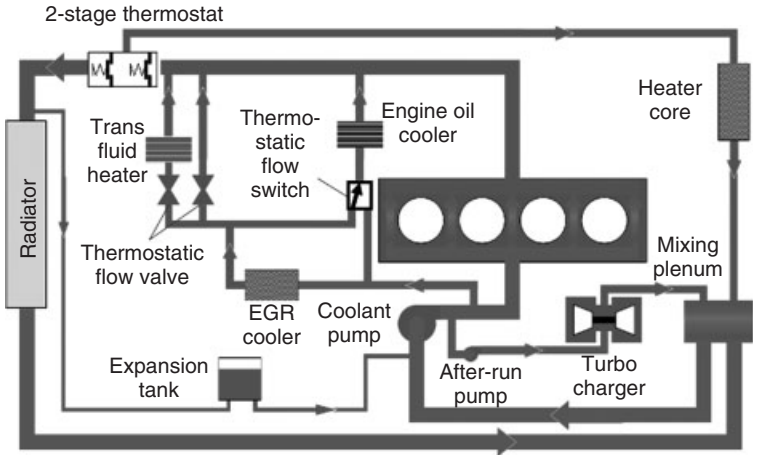

Figure 23. Example cooling circuit utilizing an EGR cooler to speed cold start heating cycles. (Reproduced by permission of FEV Inc.)

operation, these effects can be managed. However, when start/stop operation (engine shutdown during prolonged idle to reduce fuel consumption) is added, the number of cycles dramatically increases through the life of the engine. An electric pump that can be operated while the engine is shut down should be considered for some applications where high power density and start-stop operation are combined. With this configuration, the pump can continue to circulate cool engine coolant through the engine to limit peak hot-soak temperatures.

1 INTRODUCTION

Diesel engines are used in wide variety of applications such as passenger cars, trucks, locomotives, and marine and power generator applications. Most diesel engines carry fuel injection systems that manage the engine speed and power through controlled fuel injection. Over the past decades, increasing demands on fuel economy, emissions, and performance forced the automotive segment into tremendous improvements in diesel fuel injection system operation in terms of both design and precision. With the introduction of electronics to manage the complex control needs, they have improved the efficiency of fuel injection while making way for flexible fuel injection management such as multiple injections to achieve the comfort and efficiency needs. Section 1.1 reviews the development trends and discusses the state-of-the-art fuel injection system.

1.1 Diesel fuel injection systems

As shown in Figure 1, the diesel fuel injection systems are categorized into three main segments such as pump line nozzle, unit injector type, and common rail fuel injection systems.

In Section 1.1.1, a brief overview of the pump-line-nozzle and unit injector-type fueling systems is discussed followed by the discussion of state-of-the-art common rail fuel systems and advanced electronic diesel control (EDC) system working principles.

1.1.1 Pump-line nozzle

Pump-line-nozzle, consists of three major components to handle the fuel delivery. The pump manages both fuel delivery pressure and quantity using specially machined plungers. The nozzles inside the nozzle holder assembly are preloaded with spring, such that their opening for fuel injection depends on the fuel pressure generated by the pump, thus the pump influences the start of fuel delivery. The high pressure lines connect the pump and the nozzle holder. Shown in Figure 2 is a review of the each type of pump-line-nozzle type of injection system (Robert Bosch GmbH, 2000).

Although the principle of fuel injection remains common between the three categories, the specialization in pump design differentiates them in their operation. The in-line pump consists of a plunger and an element pair for every nozzle holder mounted in-line, where each plunger element pair is spring loaded on a cam, which develops pumping action. All the plunger and the element assemblies are connected by a single control rod, which uses a rack and pinion method to control the position of the plunger's helix with respect to the fuel relief port on the barrel/element side. The position of the helix defines the effective stroke of the plunger for fuel delivery; maximum stroke defines the highest quantity to achieve the full power. The control rod is operated by a governor, which adjusts the control

rod position to refine the fueling command to meet the idling and safeguard the engine against over-speeding by opening the helix early to cutoff the fuel. The unit pump is a miniature version of the in-line pump, where the pump element for every injector is separated and mounted directly on the engine; the unit pump is operated by a cam on the engine.

The distributor pump has a unique design, where the pump has one plunger with multiple grooves equivalent to the number of injectors connected; the plunger is operated by a single circular cam. A sleeve on the plunger the fuel relief port is controlled by governors that define the fuel quantity. The plunger moves both radially and axially, the axial movement creates pressure, whereas the radial movement creates injection distribution to each nozzle holder. This feature of distribution of high pressure fuel to each injector line by single plunger element coined its name as distributor pump.

As shown in Figure 3, the nozzle holder assembly is the other important part of the pump-line-nozzle fuel injection system. It consists of a nozzle body that is micromachined to carry fuel delivery holes, a needle that is spring loaded to open and close the fuel path to nozzle holes, and a nozzle holder body that houses high pressure fuel and leakage paths. The high pressure fuel enters the injector body through a filtered fuel path into the nozzle body, which houses the needle. When the pressure inside the fuel chamber increases, it lifts the needle against the spring force and opens the nozzle holes to make way for the fuel to inject.

1.1.2 Unit injector

Shown in Figure 4 is a working principle of a unit injector system. The high pressure pump and injector are assembled together in a single housing; the pump is operated by a rocker arm together with a cam on the engine. During the suction stroke, the pump chamber is filled via the open solenoid valve, and during the compression, the solenoid closes to create high pressure and injection. The injection cutoff is regulated by the opening of the solenoid.

1.1.3 Common rail fuel injection system

The key factors of a diesel engine fuel system are shown in Figure 5 (Mahr, 2002). Over the past few decades, the demands placed on diesel engines to operate at low noise and reduced harmful emissions level resulted in the introduction of common rail fuel injection systems. The most known feature of the common rail fuel system is the decoupled rate of injection/fuel injection pressure and start of injection compared to any of its predecessors in diesel fuel injection.

The advantages of a common rail fuel injection system along with advanced electronic control systems paved the way to address the diesel engines efficient combustion demands such as multiple injections, high pressure fuel injection, and broad range for start of fuel injection. Figure 6 shows the common rail fuel injection system hardware components (Robert Bosch GmbH, 1998): the common rail fuel system consists of high pressure fuel pump, common rail fuel reservoir, high pressure fuel lines, and injectors. The constantly available fuel supply enables the highest flexibility regarding injection timing for multiple injection events per cycle. Furthermore, the injection pressure can be adjusted nearly independent from engine speed and load. The electronic control unit (ECU)

is integrated around the fuel system and engine to ensure controlled operation. The state-of-the-art EDC fuel management by a common rail fuel injection system continues to evolve and expand the horizon of engine management to vehicle management and addresses stringent emissions and fuel economy demands.

Figure 7 shows a schematic diagram of an electronically controlled common rail system for engine management (Robert Bosch GmbH, 1998). The sensors covering both, the engine and the common rail system, send signals to the ECU, whereas the actuators covering both, the engine and the common rail fuel system, receive signals from the ECU. The fuel management portion comprises low and high pressure circuits. The low pressure circuit comprises the fuel tank, fuel filter, presupply pump, and fuel-connecting lines. The components of the high pressure circuit are high pressure pump, fuel accumulator (rail), fuel injectors, and high pressure fuel lines.

The responsibility of the low pressure fuel circuit is to deliver a sufficient volume of fuel to the high pressure circuit and to return the excess fuel from the high pressure circuit back to the fuel tank.

The high pressure fuel circuit has to maintain the fuel in the common rail at desired pressure at all times, which is crucial for fuel delivery and precise control through full engine operation.

The high pressure pump, as shown in Figure 8, is made up of three plungers operated by an eccentric shaft (Robert Bosch GmbH, 1998). For the first-generation common rail system, the fuel pressure is controlled by a rail pressure control valve (PCV). The fuel flow is defined by the pump displacement and the pump speed. The high pressure fuel flow, which is not required by the engine, is spilled by the rail PCV into the low pressure circuit. This kind of rail pressure control has a poor efficiency and generated high fuel temperatures in the fuel return line. Later versions of common rail pumps (shown in Figure 9) are quantity controlled by a metering unit, which delivers only the required amount of high pressure fuel into the rail. A high pressure fuel line connects the pump to the common rail.

Figure 9 shows a later version of a common rail pump, which is designed for future increased rail pressures of up to 2400 bar (Leonhard *et al*., 2008). The high pressure leakage along the plunger is reduced by using a much longer plunger guide. The flat tappet of the older pump version has been replaced by a roller tappet for better lubrication. Furthermore, the speed range of the pump displayed in Figure 9 is larger. This common rail pump is typically driven at crankshaft speed, which improves lubrication.

The fuel accumulator, which is also known as the *common rail*, is shown in Figure 10 (Robert Bosch GmbH, 1998). The common rail consists of a fuel accumulator with high pressure connections, pressure sensor, PCV, and fuel

return connector. The common rail is made of high grade materials; therefore, it can withstand high fuel pressures under all conditions. The pressure sensor provides feedback to the ECU for closed-loop pressure control, whereas the PCV is a pressure regulator on the common rail for pressure management. Usually, both metering unit on the high pressure pump and the PCV are used together to achieve the desired pressure. The metering unit is used for increasing the pressure commands, whereas the PCV is used for decreasing it. However, the logics share the appropriate responsibility with each other to meet the dynamics of pressure management. As the common rail name states, all fuel injectors are connected to a common rail having

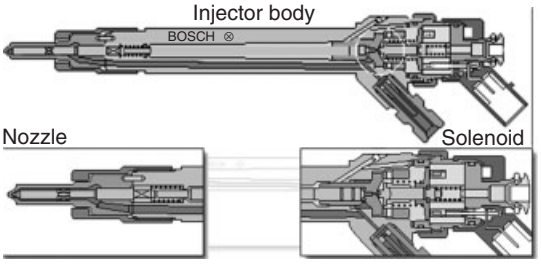

Figure 11. Injector cross section (first and second generations). (Reproduced by permission of Robert Bosch GmbH.)

high pressure fuel available for injection. This enables the fuel injection system to operate all of the injectors at the same precise fuel pressure, which results in a more uniform fuel management among all cylinders. This aspect of the common rail fuel system allows it to provide uniform fuel injection rate control to all cylinders over the entire engine operation range.

Such a hardware design change from all the previous fuel injection equipment enabled smooth engine operation, better drivability, dynamic response, and low emissions and fuel consumption. In addition to achieving high pressure and stable pressure management through the entire engine operation range, one of the most advanced parts of common rail fuel injection system is the fuel injector. Figure 11 shows the three main components of a common rail fuel injector (Robert Bosch GmbH, 1998). The injector body, which is the outer shell of the injector, also carries fuel paths for high pressure supply and low pressure return. The design and construction of the injector body is very robust and machined precisely to meet the packaging needs on the engine and cooling of the injector components by diesel fuel.

The solenoid is electrically operated by the ECU; a high current opens and closes the solenoid valve to actuate the injection. The solenoid valve in turn opens and closes the pressure relief orifice inside the injector body to alter the pressure above the nozzle needle. The nozzle, as shown in Figure 11, comprises a nozzle body, which has fuel injection holes, and a needle that defaults to the closed position by the control rod. On the top of the control rod and at the seat side of the needle, there is a pressure chamber used to move the needle to allow fuel injection. As stated earlier, when the solenoid is operated, it relieves the fuel pressure in the control chamber at the control rod, whereas the lower chamber of the needle pressure remains at the same pressure as the high pressure common rail. This pressure difference across the needle and the control rod moves the needle up, thus opening the fuel holes inside the nozzle body, which allow the fuel to spray into the

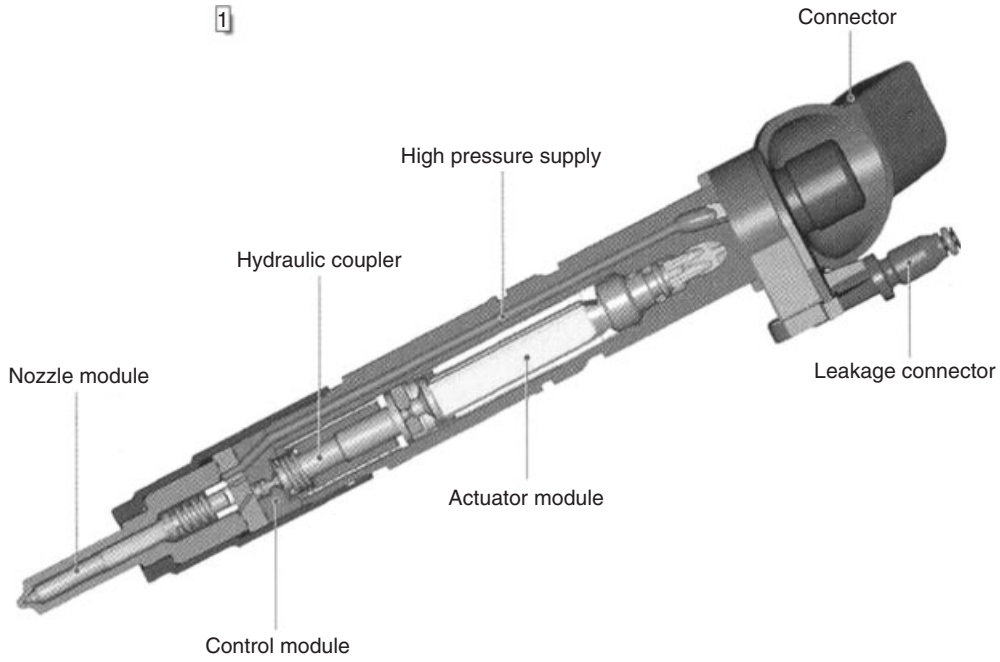

Figure 12. Common rail injector with piezoelectric actuator (Mattes, Boecking, and Kampmann, 2004). (Reproduced by permission of Robert Bosch GmbH.)

combustion chamber. When the solenoid valve closes, it prevents the fuel relief from the control chamber. The increasing pressure on the top end of the control piston, with a slightly larger diameter than the nozzle needle along with the spring force, closes the needle to stop the fuel injection. The drawbacks of this injector are the permanent high pressure leakages around the needle shaft and the control piston. Furthermore, the large combined mass of the moving parts reduces the opening and closing velocities of the nozzle needle.

The third-generation injector, as shown in Figure 12 (Mattes, Boecking, and Kampmann, 2004), uses a piezoelectric actuator. The servo-control chamber is located on the rear side of the nozzle needle. This means that there are no static leakages as with the injector type discussed and shown in Figure 11. Furthermore, the moving mass is significantly reduced, which enables faster needle opening and closing velocities. The smaller needle mass reduces the nozzle seat load, which offers the higher needle dynamic. The piezoelectric actuator provides higher forces and shorter response time between start of energizing and start of injection, which allows for higher fuel metering accuracy.

The nozzle module is shown in more in detail in Figure 13a. The spring presses the sleeve against the top plate and separates the control chamber on the rear side of the nozzle needle from the high pressure area. The needle guide is located in the nozzle shaft region and thereby, closer to the nozzle seat.

The desired injection rate is displayed in Figure 13b (Busch, 2004). A relatively low injection rate should be reached during ignition delay, in order to reduce noise and NO_x emissions. After the start of combustion, a strong increase in the injection rate is important to achieve short injection duration and a fast combustion. At the end of the injection, a fast decrease in the injection rate is important.

The integrated electrical and hydraulic systems designed in the state-of-the-art common rail diesel injector allow for multiple injections in each combustion phase. This is one of the key features of the common rail system designed to address performance, emissions, and NVH (noise, vibration, and harshness) needs as shown in Figure 14 (Mahr, 2002). The early small injections are called *pilot injection*. Pilot injection helps minimize the ignition lag for the main injection, while minimizing the heat-release rates that reduce combustion noise and lower NO_x formation. The main injection is targeted to meet the torque and power demands, whereas postinjections close—coupled to main injection help minimize the particulates by late combustion cycle oxidation. The late post-injection is used for providing fuel into the exhaust to create an exothermic reaction across a DOC (diesel oxidation catalyst) for DPF (diesel particulate filter) regeneration or any exhaust gas treatment device that requires high temperatures to operate.

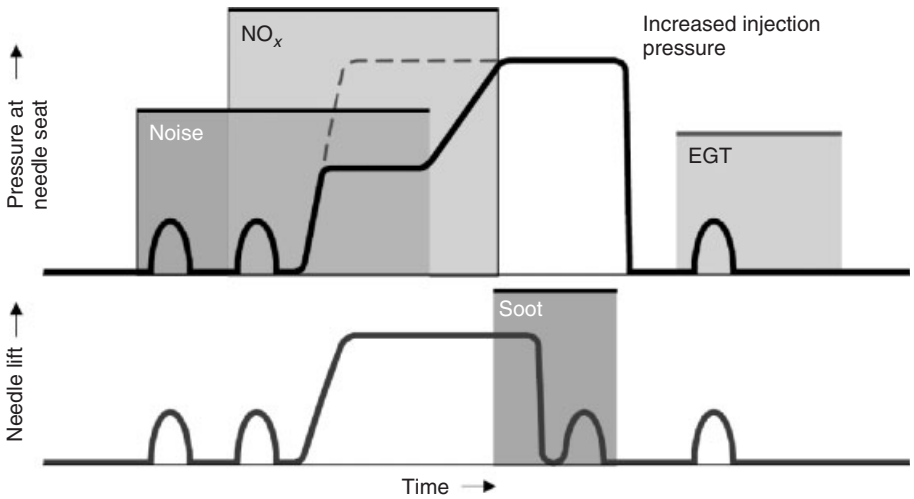

Figure 14. Desire for multiple injection and injector. (Reproduced from Mahr, 2002. With kind permission from Springer Science+Business Media.)

The nozzle is a very important part of the injector designed to meet the emissions, performance and NVH requirements of the combustion process. As shown in Figure 15 (Mahr, 2002), the nozzle geometry has evolved to address some of the diesel fuel injection needs. The needle seat, where the needle rests, has been found to influence combustion noise and fuel leakage. The sac volume, which is the dead volume between needle seat and nozzle hole, influences the hydrocarbon (HC) emissions by allowing fuel to reach the combustion chamber during the exhaust stroke. The nozzle hole geometry was developed to address unique emissions and fuel delivery efficiency needs.

The valve covered orifice (VCO) nozzles were introduced for cam-driven injection systems such as distributor injection pumps. In comparison to the mini sac hole nozzle, the VCO nozzle has a very low parasitic volume below the needle seat, which reduces HC emission. In combination with a common rail injector, which is working with lower opening and closing velocities, the VCO nozzle shows an

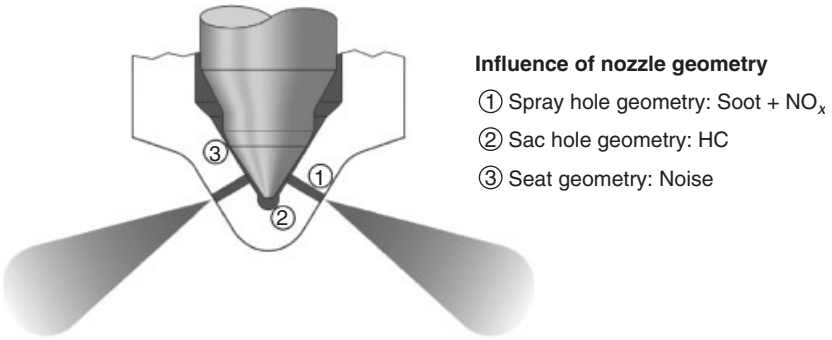

Figure 15. VCO nozzle geometry. (Reproduced from Mahr, 2002. With kind permission from Springer Science+Business Media.)

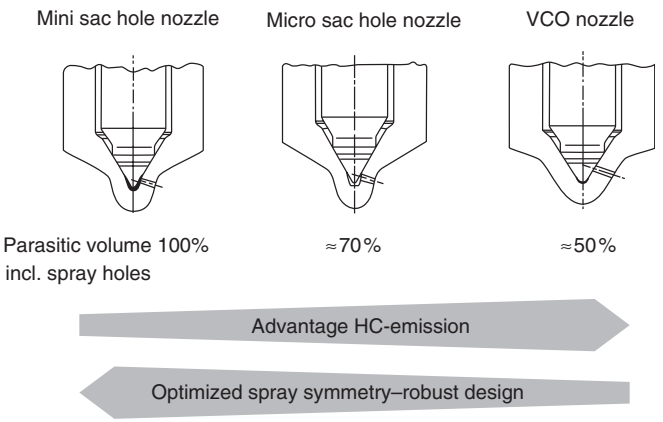

Figure 16. Influence of the nozzle design on spray pattern and HC-emission (Potz *et al*., 2002). (Reproduced by permission of Robert Bosch GmbH.)

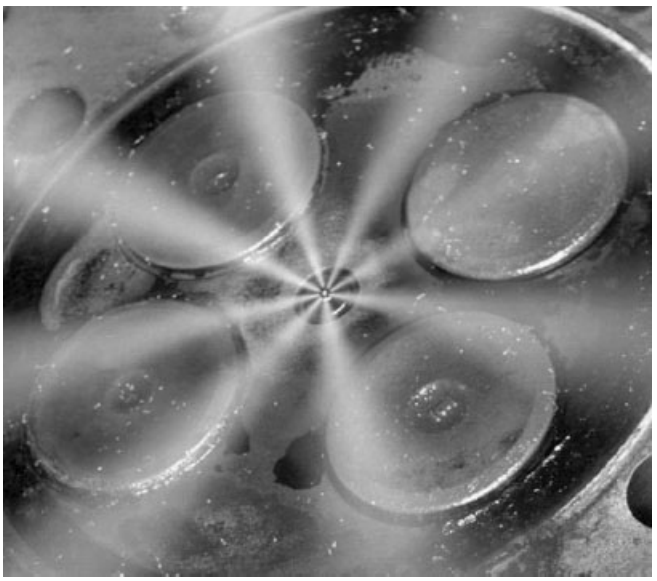

Figure 17. Fuel spray by an eight-hole nozzle inside the combustion chamber. (Reproduced by permission of FEV. Inc.)

asymmetric spray pattern because the needle tip is not always concentric with the nozzle seat. For this reason, the so-called micro sac hole nozzle has been developed, which provides a symmetric spray pattern with a compromise in the parasitic volume. Figure 16 shows examples of various nozzle types (Potz *et al*., 2002).

The state-of-the-art nozzles have anywhere between six and eight holes with a diameter in the range 0.1–0.15 mm for passenger car engines. The diameter of the nozzle holes depends on the minimum-to-maximum fuel injection quantity necessary to meet the power requirement with the given number of holes. However, improvements in nozzle hole geometry have resulted in much smaller holes with improved hydraulic properties that enhance the combustion process while minimizing emissions. Smaller spray hole sizes are possible, yet are difficult to manufacture for series production and are at greater risk of nozzle coking. The spray pattern of a modern eight-hole nozzle mounted in the cylinder head is shown in Figure 17. The fuel is injected at ambient conditions.

Figure 18 shows some examples of new nozzle designs (Mahr, 2002). Hydro-erosive rounding of the spray hole entrance allows a more stable static flow rate by reducing the run-in effect. Furthermore, the tolerances can be reduced because the process of hydro-erosive rounding can be stopped when the target flow rate is reached. The *k*-factor is a measure of conical hole; conical holes were developed to reduce the cavitation phenomena in the spray hole and hence to improve the spray penetration especially when using reduced spray hole diameters. Better spray quality helps improve fuel and air mixture allowing for reduction in particulate matter, which forms during rich combustion phases. The spray distribution among the nozzle holes is

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

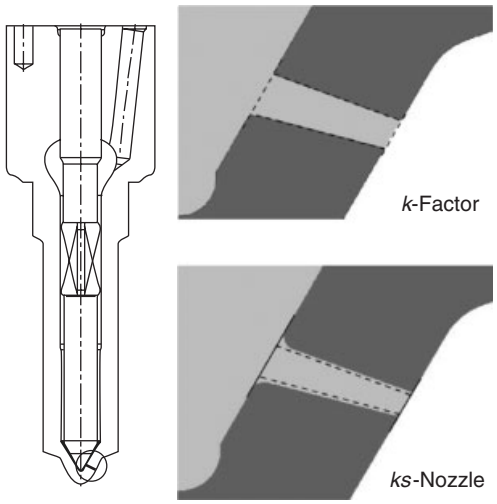

Figure 18. Nozzle hole profile. (Reproduced from Mahr, 2002. With kind permission from Springer Science+Business Media.)

extremely important to address improved air–fuel mixture distribution as well as improved combustion.

The *ks*-nozzles represent an improved conical profile combined with an optimized hydro-erosive grinding, in order to achieve highest discharge coefficients combined with highest spray penetration for optimized air–fuel mixture preparation by avoiding cavitation effects. On the other hand, eliminating spray hole cavitations causes a drawback in terms of deposit formation at the spray hole wall, which may end up in an engine power loss of 5% or even more. To reduce deposit formation in the spray hole, fuel contaminants such as zinc (Zn), sodium (Na), or potassium (K) must be avoided. A Zn concentration of 0.5 mg/kg in the fuel is already critical in terms of engine power loss. For this reason, engine oil-lubricated fuel systems in combination with flow-optimized nozzles may cause a loss of power because of Zn additives in the lube oil.

Continuous development of advanced electronic fuel management, improved fuel injection components, and precision manufacturing enabled more precise fuel management. As shown in Figure 19, the ECU now holds some of the most complex algorithms to improve the fuel delivery and durability (Busch, 2004). Algorithms such as injector quantity adjustment (IQA) are is used to adapt energizing time (ET) of the solenoid for each injector based on the tolerance difference with respect to nominal component at all fuel delivery ranges, allowing for more uniform fuel delivery among all injectors. Fuel balance control (FBC) works on minimizing the torque fluctuations between cylinders and each combustion stroke to make the engine run smoothly. Similarly, pressure wave correction (PWC) is used to adapt for hydraulic wave impact on fuel delivery. There are a variety of algorithms and intrusive tests developed over time to meet the NVH, efficiency, durability, and performance of the fuel injection system.

2 ELECTRONIC DIESEL CONTROL SYSTEM

EDC systems were blended into the mechanically actuated fuel injection systems and introduced to the market during the 1980s. These mild electronic control systems started to address the need for precise and more flexible

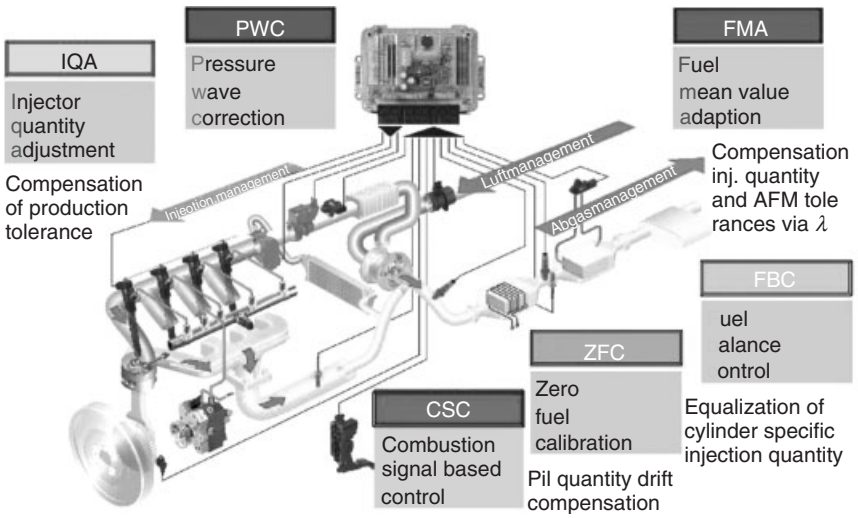

Figure 19. Fuel delivery corrections. (Busch, 2004. Reproduced by permission of Robert Bosch GmbH.)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

fuel injection. Further on the control system, application widened the scope to full engine and vehicle management systems. The present state-of-the-art diesel engine control system manages a wide spectrum of propulsion management ranging from engine, aftertreatment, driver demand, safety, and comfort. In this section, a brief overview of electronic diesel fuel injection systems is discussed.

2.1 Technical overview of electronic control

Over the past decades, a demand for more fuel-efficient engines with low emissions (such as NO_x, HC, CO, and PM) combined with higher power and torque output to enhance drivability has played a crucial role in bringing electronic control systems into engine management. Electronic control of a diesel engine allows precise and differentiated modulation of fuel injection allowing for control over the engine operation to meet the demands placed on it. As shown in Figure 20, the electronic control system comprises sensors, actuators, and ECU (Robert Bosch GmbH, 1998).

1. The sensors provide the ECU with the operating conditions of the engine such as engine speed and angular position with respect to top-dead center (TDC), amount of airflow, coolant temperature, oil temperature, and exhaust gas condition.
2. The ECU processes the information received from sensors and desired value calculation modules within the ECU through a systematic mathematical calculation sequence (control algorithm). The output of these algorithms results in electrical signals to actuators to develop necessary reactions or controls.
3. The actuators convert the electrical signals into physical reactions. If the ECU commands to open a valve by means of an electrical duty cycle, the actuator in this case, the injector solenoid valve moves the needle in the direction commanded by ECU to inject fuel as desired to meet the torque demands.

2.2 Signal acquisition and processing

Sensors and actuators play an interfacial role between the physical operating systems, in this case, an engine and ECU. The sensors provide the state of the system in the form of an electrical signal. There are several types of sensors used on the engine to determine its state of operation; few are discussed in this section. Shown in Figure 21 is a schematic diagram of signal handling by the ECU (Robert Bosch GmbH, 2004). The electrical signals from sensors are processed inside the signal conditioning unit of the ECU where further signal is transferred to a microcontroller for processing the values inside a logic defined by a software strategy. The ECU's decisions are sent out through driver stages to actuators.

Analog signals: These are voltage-based signals such as temperature sensors, boost pressure sensors, and battery voltage. These assume a voltage range and are processed to physical values inside the signal conditioning unit; further, the values are converted into the digital format for the ECU to process them through the logical algorithms.

Digital signals: These signals assume high [1] or low [0] state, sensors such as switches or digital signal generators,

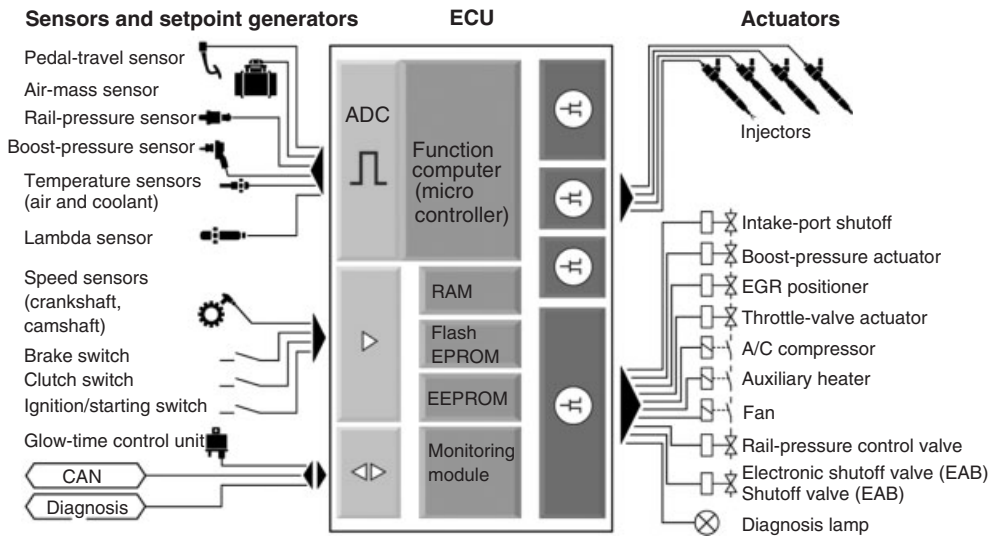

Figure 20. Electronic control system modules. (Reproduced by permission of Robert Bosch GmbH.)

DOI: 10.1002/9781118354179.auto150
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

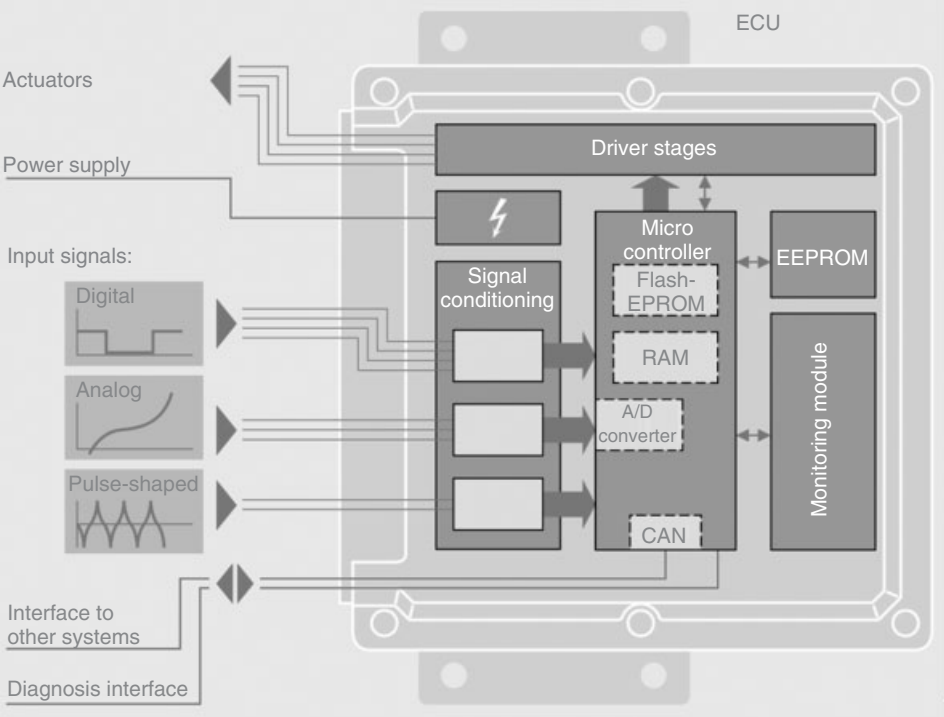

Figure 21. Signal processing inside ECU. (Reproduced from Robert Bosch GmbH, 2004. © John Wiley & Sons.)

such as Hall effect sensors picking up rotational speed will be processed inside the ECU directly.

Pulsed signals: These are inductive sensors such as variable reluctance speed sensors. These signals need processing inside the ECU to convert them into digital signals and then into a physical representation before being processed inside the ECU.

Signal conditioning: Inside the ECU, protective circuitries are used to limit and regulate the sensor voltage range. Filtering techniques are applied and the superimposed interference signals are removed before processing. Sometimes, the signals are amplified to meet the microcontrollers, working range of 0–5 V. For advanced sensor technology such as microelectromechanical systems (MEMS) sensors, the signal conditioning can be performed at the sensor level to reduce the burden on the ECU processing power.

Signal processing: The ECU performs signal processing to execute the tasks necessary to manage engine operation. The open- and closed-loop sequences along with the associated algorithms are performed inside the ECU upon receiving the sensor signals to take appropriate actions. The microcontroller is the ECU's central control unit and operates all ECU functions. The microcontroller consists of RAM (random access memory), ROM (read only memory), central processing unit (CPU), Quartz timer, serial interfaces, and peripheral interfaces. The CPU accesses the software that is stored in EEPROM (electrically erasable programmable read only memory), which defines the sequence of activities that the microcontroller should execute. The working software is downloaded to flash-EEPROM to process the signals received. The computation needs memory space to execute the algorithms. This is done by storing and retrieving the data from RAM.

The output signals from the microcontroller trigger the driver stages, which further handle the actuator signals. The driver stages can handle various types of actuators; pulse-width modulation (PWM) is one of the most used methods for controlling valves such as EGR (exhaust gas recirculation), intake air mass control throttle, and boost pressure modulation by waste gating on turbochargers. Advancements in actuators carrying unique ECUs are capable of processing the commands from the ECU directly. The output signals can be either a PWM signal or a CAN (controller area network) signal, further driving the high power circuitry involving motors for actuation. The CAN network is used to communicate with other peripheral ECUs.

With increasing safety and performance demands, the ECU itself has undergone a revolution. The ECUs should operate in real time, which means that the ECU should perform and respond in conjunction to physical processes

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto150
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

outside the ECU that demands high computational power to execute complex algorithms. Advancements in multilayer printed circuits, surface-mounted devices eliminating loose wires, and application-specific integrated circuits help make the ECU more compact, versatile, and robust. The ECU should withstand severe electromagnetic radiations to work under any severe conditions without failure. The construction technology of the ECU must meet the stringent demands of electromagnetic compatibility (EMC) tests and be able to withstand severe magnetic radiation, vibrations, and environmental conditions.

As outlined in Section 2.2, the ECU uses various closed- and open-loop logics along with complex algorithms to define the output actions. Thus, it is important to understand the concept of closed and open loops. Section 2.3 will discuss the basic idea behind closed- and open-loop control theories.

2.3 Concept of open- and closed-loop controls

Both open- and closed-loop controls are applied in EDC for engine management. The application is defined by the need and purpose of the control area. To describe these control systems, a simple example of room temperature control is considered for discussion.

As shown in Figure 22, the room temperature control can be managed by adjusting the valve that controls the airflow through a heat exchanger. In the open-loop control case, the position of the air control valve is reached using a characteristic curve, which is a function of set point. A characteristic curve is stored in the ECU, which determines the unique value for every desired room temperature set point. No adjustment to the control valve is made to compensate the variations in the room temperature with respect to the set point.

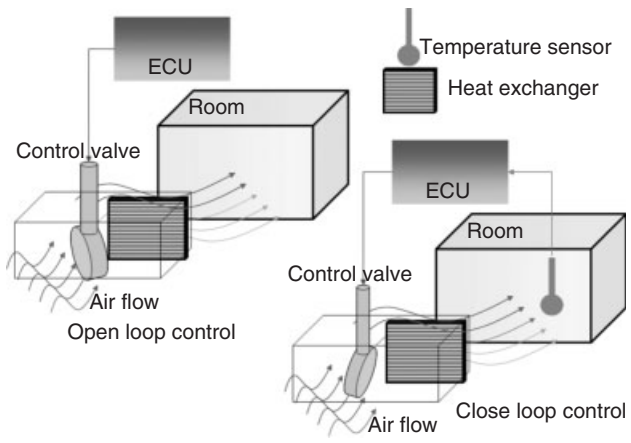

Figure 22. Open- and closed-loop examples for room temperature control. (Reproduced by permission of FEV. Inc.)

In the closed-loop control case shown in Figure 22, the ECU compares the set point with measured room temperature to determine the deviation between the desired and the measured temperatures.

This deviation is used to finely adjust the control valve to either open further or close to meet the set point request. The closed-loop control system allows for minimizing the error in maintaining the room temperature at the set point.

For more dynamic systems, a combination of predefined values from the open-loop control and deviation-based fine adjustment from the closed-loop system is used to provide faster response times.

The EDC system carries several such control system combinations to address air and fuel management during steady-state and transient engine operations.

2.4 Driver demand to fueling command

An engine is the main source of energy for propulsion in a vehicle; thus, the engine management is the center for safety, comfort, and performance. Figure 23 shows an example of a common rail system integrated into the vehicle, with the ECU to manage the fuel and air around the engine for efficient operation (Robert Bosch GmbH, 1998).

However, the rapid integration of electronics in every portion of the vehicle system such as transmission, braking, and body has opened up the doors for control system integration as shown in Figure 24. For vehicle management, multiple on-board ECUs are combined with an engine ECU that is used as the main controller for the power management. The engine ECU has to make significant interventions and satisfy demands received from various parts of the vehicle to ensure that engine power is managed. The demands of the driver need to be satisfied with consideration given to vehicle safety and drivability.

As shown in Figure 25, the accelerator pedal signal from driver demand passes through several signal interventions and conditioning before being converted to an equivalent fueling command. The interventions to the driver demand come from the other various control units on the vehicle such as the transmission controller. For example, the transmission controller is demanding torque reduction during gear change, whereas the traction control unit is demanding torque optimization to prevent wheel spin along with the electronic stability control asking for torque variation and split among the wheels to prevent the vehicle from going out of control. These interventions usually limit the driver-demanded torque. Driver demands are the

highest of all torques; accessory load requests add on top of the driver demand to compensate for accessory power needs such as AC and alternator. However, the final torque request is limited against engine protection before being converted to fueling command. The engine protection algorithm inside the ECU limits the maximum fueling to protect the engine against maximum cylinder pressure. There are also engine performance-based torque limitations such as smoke limitations, which are dynamic and transient, based on the amount of air available at anytime in the combustion chamber.

Electronic control systems led to more efficient engine and vehicle management from energy efficiency to safety and performance, leading a way to integrate the state-of-the-art control systems.

Figure 26 shows vehicle operation control unit demands for a certain power output from the engine to overcome losses and meet driver demands. The driver is the closed-loop control element of engine torque; the driver decides how much power he or she needs at any given time. The driver demand results in speed and torque to operate the engine at desired power levels. The speed and torque

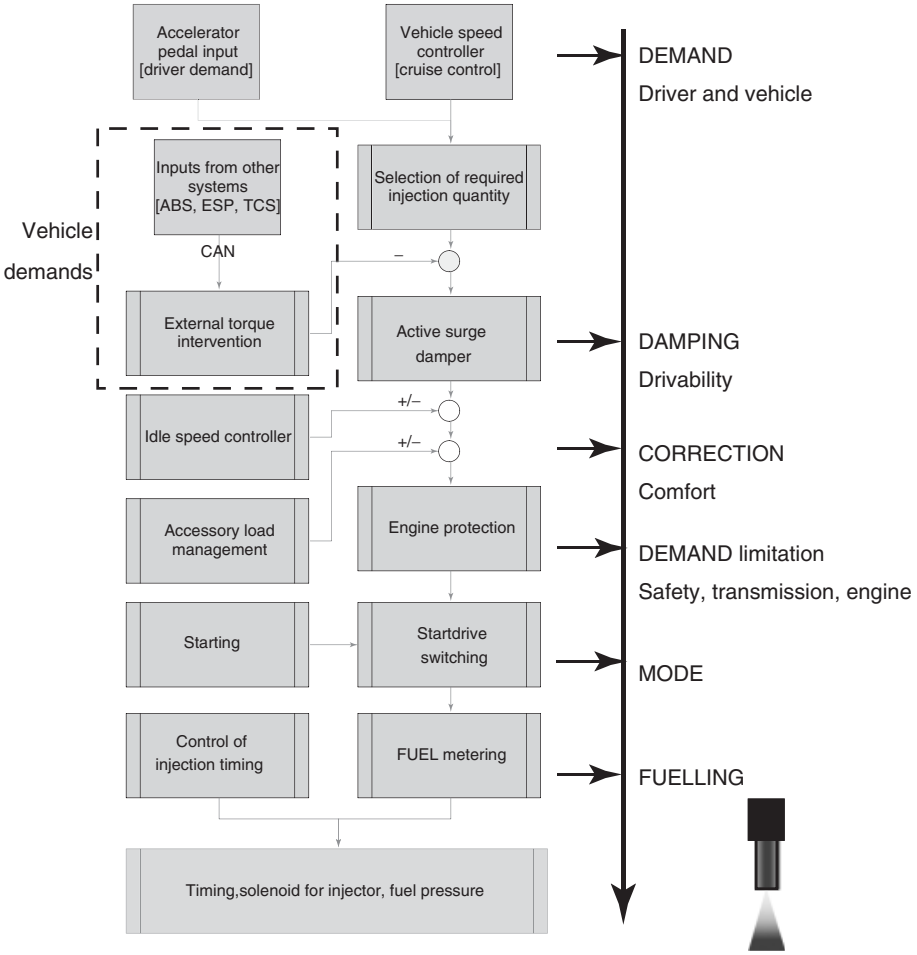

Figure 25. Fuel quantity calculation. (Reproduced by permission of Robert Bosch GmbH.)

defines the operating point of an engine, and the operating point further defines the desired air and fuel injection characteristics required to maintain engine operation at optimum performance.

In case of the diesel engine, the engine torque is defined by the fuel quantity; depending on the power requirement, the engine speed will be adapted to the defined fuel quantity. As shown in Figure 27, the diesel fuel injection is a very complex hydraulic process. Although the mass of fuel injected matters inside the combustion chamber for the energy to generate sufficient power, the fuel injection handling is done on volume basis. The fuel injection quantity is influenced by various parameters such as fuel pressure, fuel temperature, density, viscosity, nozzle hole profile or discharge coefficient, and the duration of nozzle opening. The nozzle opening time for fuel injection is defined in microseconds and is known as (*ET*). ET is a function of fuel pressure and desired fuel quantity defined in a map.

As outlined earlier, the operating point that is defined by engine speed and fuel quantity desired is used to define the rail pressure set point for further closed-loop control. This operating point also includes the injection timing, that is, when to open and close the injector to deliver fuel into the combustion chamber with respect to TDC. An example of driver demand to fuel quantity handling in a common rail fuel injection system is shown in Figure 28 (Robert Bosch GmbH, 1998).

Maps are three-dimentional matrices; the *X*-axis usually carries engine speed, whereas the *Y*-axis carries fuel quantity command required for a desired torque. The *Z*-axis carries the corresponding values for the set point determination, which defines the characteristic of a map. In the example shown in Figure 29, the maps define the set point for the start of injection in crank angle degrees with respect to TDC, which further sets the open-loop energizing system to operate the solenoid on the injector. However, rail pressure set point is first compared to the rail pressure sensors

Drive Cycles

Mark E. Case and Dean Tomazic
FEV Inc., Auburn Hills, MI, USA

1 INTRODUCTION

Starting in the late 1940s, research in the causes of air pollution accelerated, led by California in a world effort. Emissions of pollutants from light-duty vehicles were directly associated with poor ambient air quality in the Los Angeles basin. Government agencies began researching the causes for smog forming pollutants, and also vehicle test facilities, and simultaneously what might represent typical driving conditions of a vehicle in real-world conditions that could be simulated.

From this research, different approaches to representing the vehicle driving condition were made. In the United States, driving cycles were developed to represent the actual vehicle operation in traffic on public roads primarily in California. Traces of vehicle speed were recorded over time in city and highway driving environments. In Europe and Japan, typical operating modes were identified, and driving cycles were created to provide a representation of these typical modes. In either case, the goal is identical: represents the operating conditions of the powertrain in terms of vehicle speed along a time trace and provide a representative set of conditions under which the emissions and fuel economy of the vehicle could be measured against regulatory limits.

Development began on a test facility that could provide the capability to measure output of emissions and consumption of fuel from a vehicle in a controlled environment. To provide the capability to exercise a vehicle powertrain in a static facility in a way that is representative of actual use, it was desirable to make the ability to repeatedly operate the vehicle in an environment that simulates the operation of a vehicle on a road, but in a facility where instrumentation can be conveniently and permanently located. Standard measurements of gaseous emissions including carbon monoxide (CO), carbon dioxide (CO_2), unburned hydrocarbons (generically HCs), and oxides of nitrogen (NO_x) are made using an emissions bench that collects and samples the gases from the tailpipe of the vehicle. Because consumption of HC fuels produces CO_2 in proportion to the quantity of fuel consumed, the rate of fuel consumption, or inversely fuel efficiency, could also be measured.

Theoretically, the driving cycle and test facility provides also a repeatable standardized test that can be replicated and controlled.

The major driving cycles from the United States, Europe, and Japan were all standardized and written into each country's regulations for exhaust emissions and fuel economy. All three major regulatory regimes—the United States, Europe, and Japan—have modified or introduced supplementary driving cycles that are designed to create a more complete emissions relevant operating region under regulatory limits and monitoring. In the United States, these incremental cycles do not replace the first cycle but expand

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

ISBN: 978-0-470-97402-5

the coverage of the operating map under legal control. The expanded coverage can be a wider vehicle operating range (e.g., aggressive driving) or ambient weather conditions (e.g., cold or hot climate).

The test facilities established for measurement of emissions and fuel economy have become essentially a world industry standard. In each major market, with individual drive cycles, the facility is usually capable of testing all cycles from all major regulatory regimes. In some cases, the regulated emissions constituents are different; for example, California regulates non-methane organic gases (NMOGs), whereas earlier US federal measurements were total hydrocarbons (THCs), and current limits are in non-methane hydrocarbons (NMHCs). The key components of an emissions/fuel economy test facility include the room with ambient condition control, chassis dynamometer that applies resistance representative of the load required to move the vehicle, and the emissions system that samples and quantitatively measures the gaseous emissions from the tailpipe, inferring fuel consumed by sampling CO_2 emissions. In this chapter, regulatory limits for the passenger car classification of light-duty vehicles are provided.

Because the driving cycle is intended to provide representative load conditions to the powertrain, there is a process to follow that establishes chassis dynamometer coefficients that adequately simulate the driving resistance in each specific vehicle. A reduction in the driving load generally reduces emissions of CO_2 and improves fuel economy.

Vehicle manufacturers are required to estimate the durability of the emissions control system of a vehicle. The degradation in emissions over vehicle usage is estimated and must be enacted and accounted for on typical emissions test results that are conducted on new or lightly used vehicles. It is implied that each vehicle must meet the regulated limit for each constituent for the entire useful life of the vehicle, and forms of demonstration of compliance from vehicles in consumer use are enacted in the major regulatory markets.

2 STANDARD DRIVE CYCLES AND REGULATORY LIMITS

2.1 The United States

In the United States, the original driving cycles developed for emissions and fuel economy were created by the Environmental Protection Agency (EPA) to represent driving in city and suburban driving conditions mainly in Los Angeles. Since the late 1970s, the standard emissions and fuel economy cycle applied toward emissions and fuel economy testing has been the Federal Test Procedure

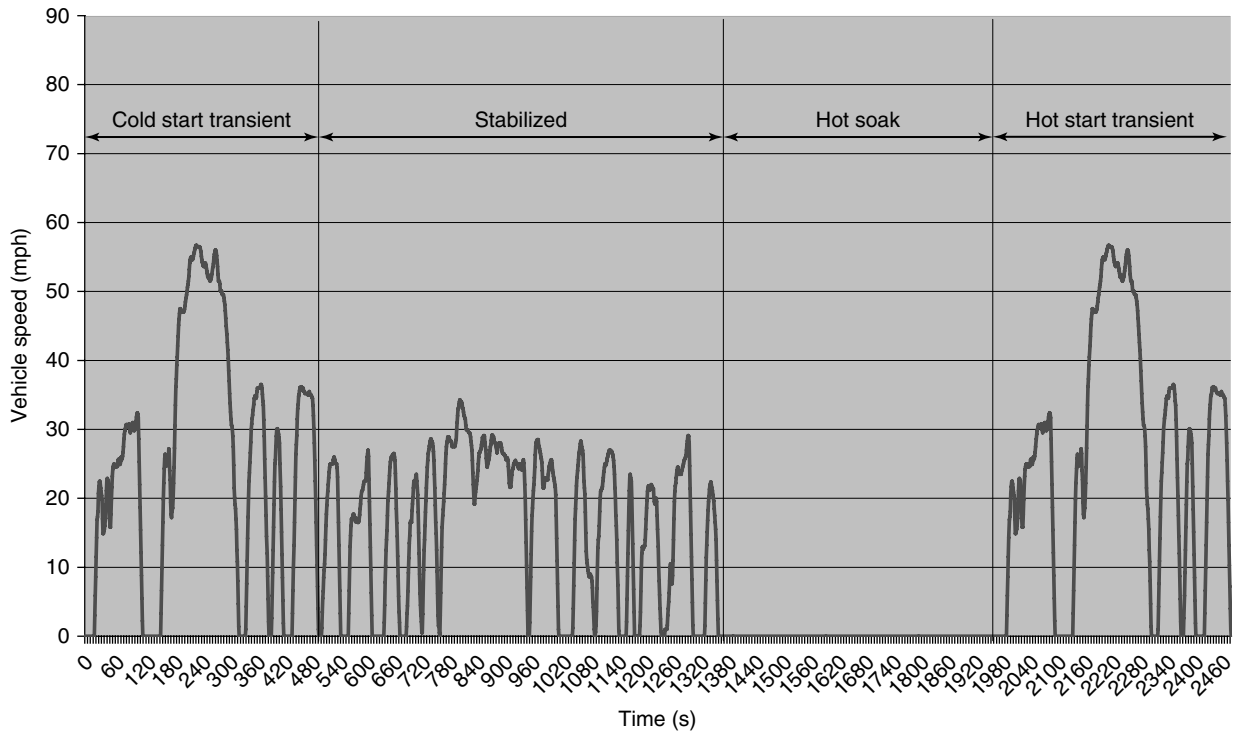

Figure 1. FTP-75 cycle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto151
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

FTP-75 cycle, also referred to as *EPA-III*. Shownn its entirety in Figure 1, this cycle was the exclusive cycle required to certify tail-pipe emissions from a passenger car or light truck for the US market until 1994 and still represents the primary emissions and part of the fuel economy regulatory cycle in 2013.

The FTP-75 cycle is intended to present a typical driving trip from cold start, followed by a shutdown and 10-min-long soak period, a hot restart, and additional short driving cycle. In total, the FTP-75 cycle represents a driving distance of 11.04 miles in two sections, a duration of 1874 s, at an average speed of 21.2 miles/h.

The FTP-75 cycle is made up of an initial cold start after a prescribed soak time and city driving cycle that is 505 s long. Without a stop, the cycle continues with a stop-and-go driving portion followed by engine shutdown. After a 10-min hot soak, the driving cycle is repeated with both first and second phases after a hot start. In actual testing, the second stop-and-go cycle is not repeated because the completion of the cycle in the first half is not expected to change, as both phases are conducted after the vehicle has reached operating temperature. Shown in Table 1, weighting factors representing this double counting of the stabilized stop-and-go phase, and accounting for the difference in distance traveled for each phase, have been developed and have been in use from the inception of the cycle.

Table 1. FTP-75 weighting factors.

Portion of Cycle	Name	Distance (miles)	Time (s)	Weighting Factor
Phase 1	Cold start transient	3.6	505	0.43
Phase 2	Stabilized stop-and-go	3.9	864	1.0
Phase 3	Hot start transient	3.6	505	0.57

Emissions regulations are generally written in an allowed emissions constituent in mass, which is measured or sampled over the entire driving cycle, and then divided by the distance traveled. In US regulations, the units are in grams of constituent per mile traveled. The regulated maximum integrated emissions for HC, NO_x, and CO emissions constituents are shown from the original regulation limits through 2001 in Table 2. There was an early version of the FTP-75 cycle called *FTP-72* for some early model years. The FTP-72 cycle only differs from the FTP-75 cycle in the lack of the hot start portion of the cycle. An estimate of emissions from a typical passenger car is made before 1968, and the limits before 1975 were set on the early FTP-72 driving cycle. In later years, more emissions constituents including particulate matter (PM) and formaldehyde have been added to regulation, but the test cycle remains unchanged. Originally, California and the United States required that emissions measured from the tailpipe of the vehicle should be guaranteed by the vehicle manufacturer for 50,000 miles, a value that was termed the useful life of the vehicle. Limits of emissions constituents were promulgated at 50,000 miles useful life and extended to 100,000 miles beginning in 1994. Beginning with this model year, emissions limits were published and required to be met at 50,000 miles intermediate life and 100,000 miles full useful life.

A companion to the FTP-75 cycle is the highway fuel economy (HWFE) cycle, which is representative of highway driving in the US market. This driving cycle is conducted immediately following the FTP-75 cycle without engine shutdown. If not conducted immediately, a warm-up cycle is required. The HWFE cycle, shown completely in Figure 2, represents 10.2 miles of driving with maximum vehicle speed of 57 miles per hour, a typical highway vehicle speed in the 1970s when the cycle was created, and

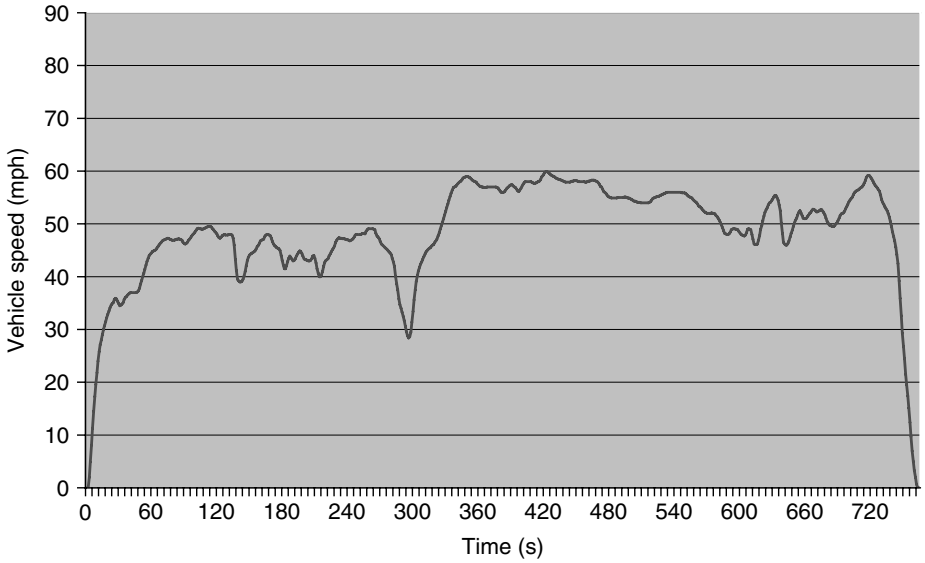

Figure 2. Highway Fuel Economy (HWFE) cycle.

the national speed limit in the United States was 55 miles per hour. In US federal regulations, the HWFE cycle was considered exclusively as part of a fuel economy regulation, not for tail-pipe emissions regulations.

Together, the FTP-75 and HWFE cycles are published for light-duty vehicles as city and highway ratings on the window sticker of new vehicles and combined for a single fuel economy cycle number. The combination of FTP-75 (city) and HWFE (highway) results in the combined fuel economy that is regulated by the US Department of Transportation under Corporate Average Fuel Economy (CAFE) limits. Equation 1 shows the calculation of combined fuel economy with 55% city cycle (FTP-75) and 45% highway cycle (HWFE), which is then applied as a single number to CAFE limits.

$$\text{Combined F.E. (MPG)} = \frac{1}{(0.55/\text{FTP-75 MPG}) + (0.45/\text{HWFE MPG})} \quad (1)$$

Using Equation 1, example fuel economy measured on the FTP-75 (city) and HWFE (highway) cycles results in a combined fuel economy level shown:

FTP city: 27.74 MPG
FTP highway: 40.14 MPG
FTP combined: 32.22 MPG

Originally developed for the 1975 model year, but subsequently delayed in implementation until 1978, the CAFE rules targeted an increase in the average fuel economy of a light-duty passenger car in the United States by 50% by 1985 from the typical level of 1973. These requirements were phased in as a response to the oil shortages of the early 1970s, which caused significant economic disruption in the United States and around the world. The target of 27.5 MPG fleet average for passenger cars was delayed but finally achieved in 1990 calendar year. There were no changes to this requirement for passenger cars and small increases for light trucks between 1990 and 2010, after which new increases were again mandated. Figure 3 shows the CAFE requirement history for passenger cars and light trucks sold in the US market. Fleet average requirements for passenger cars and light trucks are published from 1978 until 2016 model years, with proposed requirements from 2017 until 2025 model years also included. Beginning with 2011, these regulations established a new basis for fuel economy targets based on the vehicle footprint, which is defined as the vehicle wheelbase multiplied by vehicle track width.

The regulated CAFE limits for fuel economy are still based on the original formulation of combined fuel economy, which has led to the new terminology of *unadjusted* fuel economy (raw FTP-75 and HWFE values). Vehicle manufacturers are required to publish *adjusted* fuel economy values which are calculated using a different formula. Phased in beginning with the 2008 model year, the new five-cycle fuel economy values are calculated using Equations 2 and 3.

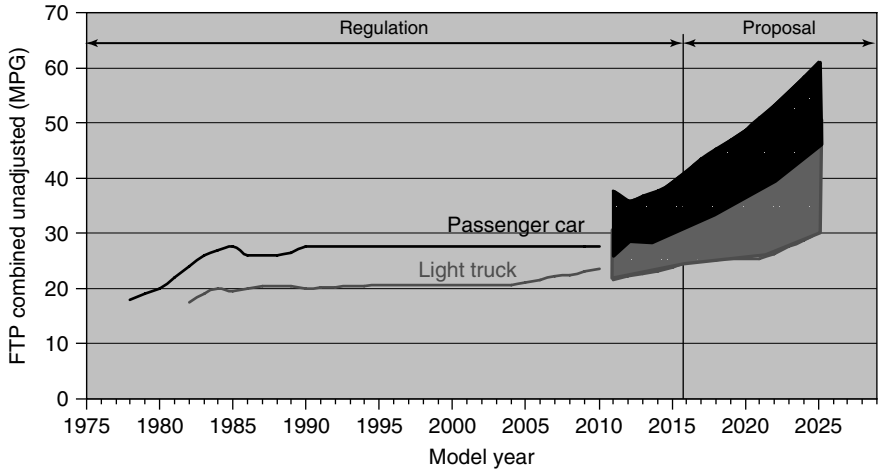

Figure 3. US Corporate Average Fuel Economy (CAFE) requirements.

$$\text{City FE} = 0.89\frac{1}{\text{Start FC} + \text{Running FC}}$$

$$\text{Start FC} = 0.33\frac{(0.76 \times \text{Start Fuel}_{75} + 0.24 \times \text{Start Fuel}_{20})}{3.5}$$

$$\text{Running FC} = 0.70\left(\frac{0.48}{\text{Bag2}_{75}\text{FE}} + \frac{0.41}{\text{Bag3}_{75}\text{FE}} + \frac{0.11}{\text{US06City FE}}\right) + 0.30\left(\frac{0.5}{\text{Bag2}_{20}\text{FE}} + \frac{0.5}{\text{Bag2}_{20}\text{FE}}\right) + 0.133 \times 1.083 \times (\text{A/CFC})$$

$$\text{MPG Based City FE Label Value} = \frac{1}{\left(0.002549 + \frac{1.2259}{\text{FTP FE}}\right)} \tag{2}$$

$$\text{Highway FE} = 0.89\frac{1}{\text{Start FC} + \text{Running FC}}$$

$$\text{Start FC (gallons per mile)} = 0.330\left[\frac{(0.76 \times \text{StartFuel}_{75} + 0.24 \times \text{StartFuel}_{20})}{60}\right]$$

$$\text{Running FC} = (1.012)\left(\frac{0.79}{\text{US06 Highway FE}} + \frac{0.21}{\text{HFET FE}}\right) + 0.133 \times 0.377 \times \text{A/C FC}$$

$$\text{MPG Based Highway FE Label Value} = \frac{1}{\left(0.000308 + \frac{1.4030}{\text{HFET FE}}\right)} \tag{3}$$

The new *adjusted* values are required for publication on the window sticker of new vehicles sold in the United States, and only these values can be used in advertising. An example window sticker is shown in Figure 4.

Beginning with a phase-in starting in the 2004 model year, the United States Environmental Protection Agency (US EPA) federal requirements were substantially updated to a new regulatory regime called *Tier 2*. First, reduced tailpipe emissions regulatory limits were imposed, still using the FTP-75 cycle, and the full useful life of a vehicle was extended to 120,000 miles. The new limits are published as bins allowing the manufacturer the discretion to develop vehicles meeting different emissions standards in the same model year. In addition, a fleet average NO_x standard was

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto151
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

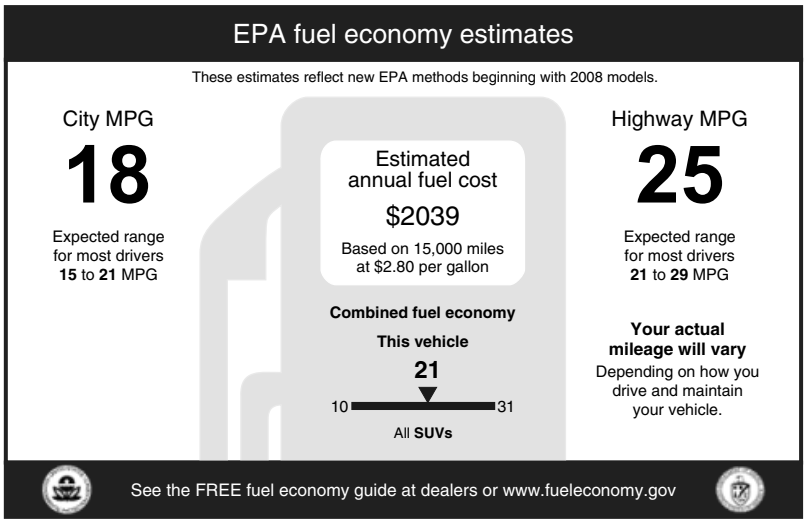

Figure 4. Required US fuel economy window sticker from the 2008 model year.

adopted that all vehicles in the manufacturer's sales for that model year must achieve, and there are caps to the NO_x emissions limit that effectively cancel the least stringent bins 9–11 by the 2007 model year. The more stringent bins no longer have 50,000 miles intermediate requirements. The individual bins and their limits are documented in Table 3.

As part of the Tier 2 emissions program, EPA enacted fleet average HC and NO_x emissions limits to be phased in over several years. By the 2007 model year for passenger cars and the 2009 model year for all light trucks, NO_x emissions must average less than 0.07 g/miles (bin 5). In addition, by the 2013 model year, fleet average HC emissions must average less than 0.3 g/miles; the test for fleet average HC emissions is the FTP-75 test conducted at ambient temperature of 20°F (−7°C).

Because the combination of FTP-75 emissions cycle and HWFE cycle has been the legal requirement for over 35 years for both emissions and fuel economy regulations in the United States, and because the EPA and California have been collecting data from all vehicles certified for their respective markets over that time period, the history of fuel economy and emissions measurements is both telling and valuable. US fleet average fuel economy for passenger cars and light trucks 1978 through 2011 is shown in Figure 5.

Because in early years of the regulatory process, there was no fleet average requirement and therefore no collection of the documented average emissions from a vehicle during this time period, a collected assessment of the average emissions from vehicles is not readily available. Therefore, as an illustration, the regulatory limits in the three major emissions constituents in grams/miles on the FTP-75 cycle from unregulated to the most recent Tier 2 (bin 5) level are plotted in Figure 6. The regulatory limits represent a

reduction in tail-pipe emissions from a typical unregulated light-duty vehicle of 95% (CO), 99% (HC), and 98% (NO_x).

With phase-in beginning with the 2001 model year, two additional driving cycles were added to the certification regime for the US market. These cycles, termed *Supplemental Federal Test Procedure* (*SFTP*), have the goal of expanding the operating region of driving to be more representative of faster and more aggressive driving conditions and operation with the air conditioning in the vehicle operating.

The first cycle was designed to cover the operating regime typical of more aggressive driving styles. Because the original FTP-75 cycle is a relatively lightly load cycle with moderate accelerations, the new US06 cycle was designed to monitor operation in areas that had previously been outside the regulated cycles. The US06 cycle, shown in Figure 7, represents 10 min of driving with vehicle speed up to 80 MPH.

A second supplemental cycle called *SC03* was designed to test vehicle operating in hot ambient environmental conditions with the passenger compartment air conditioning system operating at maximum. The air conditioning system can present a significant load on the engine and therefore significantly change the emissions and fuel economy performance levels. The new SC03 cycle, shown in Figure 8, also represents 10 min of driving, at ambient

temperature of 95°F, with simulated solar load applied to the vehicle; the air conditioning system is set to maximum.

US federal limits for SFTP cycle performance for the Tier 2 4000 miles condition are documented in Table 4. Regulatory limits for California and later US federal requirements have been adjusted.

The US federal and California have created a complex set of regulations depending on the vehicle size and use. For US regulatory purposes generally, passenger cars are used primarily for the purpose of transporting people, whereas light- and medium-duty trucks are used primarily for transporting material or for use off paved roads. Emissions limits for passenger car legislated values are quoted throughout this chapter. However, there are multiple additional categories of vehicles including light-duty trucks and medium-duty passenger vehicles (i.e., buses) that have to meet somewhat less stringent requirements on an emissions mass per mile traveled basis. In the United States, there is a somewhat arbitrary line between light-duty vehicle (light truck and passenger car) and medium/heavy-duty truck with gross vehicle weight (GVW) of greater than 8500 pounds. The definition of GVW is the total weight of the vehicle including maximum payload stated by the manufacturer.

2.1.1 California

Because California faced severe local issues related to smog and ambient pollution related to geography with increased population and passenger car use, it was the first jurisdiction in the world to enact specific emissions control requirements. In 1961, the first regulations for positive crankcase ventilation (PCV) were required for new light-duty vehicles sold in California. Limits for HC and CO tail-pipe emissions were enacted in 1966. The first standard for NO_x from passenger cars was implemented by California in 1971. Although not entirely related to the regulation of automobile emissions, there is documented improvement in ambient air quality over the time period during which passenger car tail-pipe emissions were reduced, even though the population and number of light-duty vehicles increased.

California is the only state in the United States allowed to develop and promulgate emissions standards that are unique from the federal standards, although other states are allowed to adopt California standards.

Table 5 documents the early California emissions limits, although the 1960s limits conducted on a different driving cycle without comparable emissions sampling standards are excluded; before 1975, an early variant called the *FTP-72 cycle* was applied. The California definition of full useful life of a vehicle was extended to 100,000 miles for the 1980 model year, 14 years in advance of US federal regulations.

With phase-in beginning in the 1994 model year, California introduced a new emissions regime called the *Low Emissions Vehicle* (*LEV-1*) program. New categories of vehicles were created to provide automotive manufacturers the flexibility to certify vehicles in different categories.

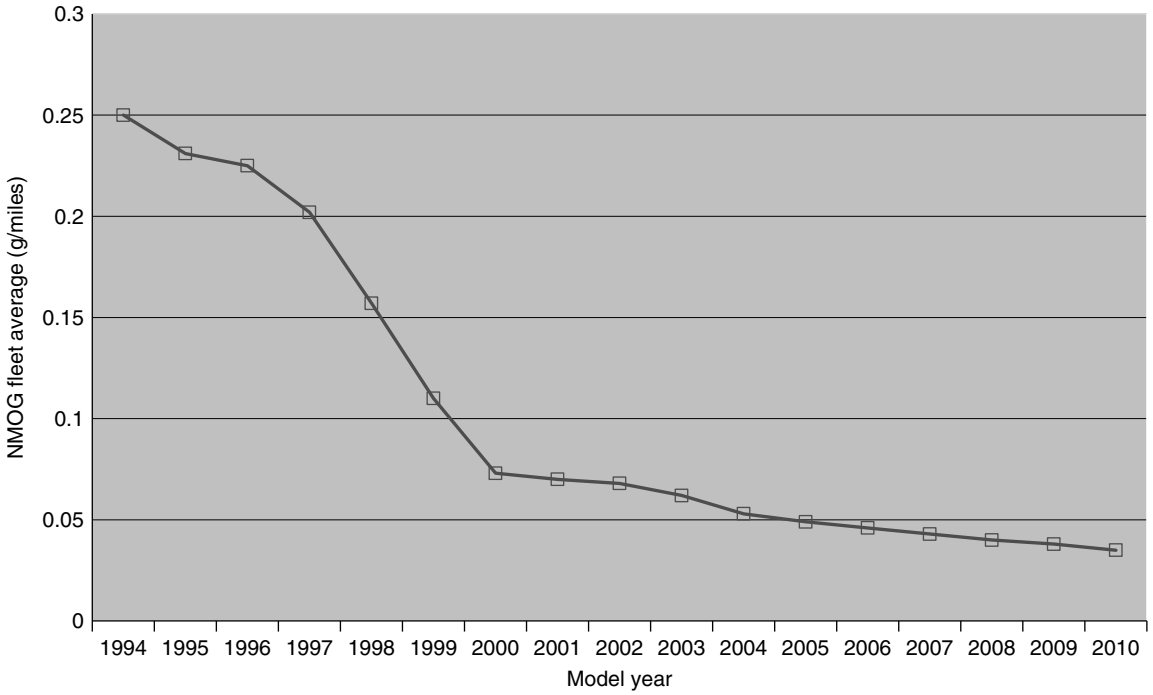

Figure 9. California fleet average hydrocarbon (NMOG) emissions limit.

A fleet-average HC emission rule was established, with targets for each calendar year progressively lower. This fleet-average HC emissions, or more correctly NMOGs, requirement is shown beginning with the 1994 model year in Figure 9. In addition, the new federally developed SFTP cycles were added to the regulation; supplemental emissions limits to be met on each cycle for each constituent were also mandated. New categories of vehicles called *transitional low emission vehicle* (*TLEV*), *LEV*, and *ultra low emission vehicle* (*ULEV*) were created. The full useful life requirement for vehicles was increased to 120,000 miles. The California LEV-1 limits for passenger cars are summarized in Table 6.

With phase-in beginning in the 2004 model year, California introduced a new emissions regime called *LEV-2* program. Another new category of vehicle was created to another even lower category level, termed the *super ultra low emissions vehicle* (*SULEV*). Fleet-average HC emissions levels were extended until the 2010 model year. The California fleet-average NMOG emissions level for both LEV-1 and LEV-2 regulatory periods from 1994 to 2010 is shown in Figure 8. Table 7 summarizes the passenger car LEV-2 emissions requirements.

With phase-in anticipated in the 2014 model year, California has *proposed* and implemented an extension of the LEV-1 and LEV-2 to the revised LEV-3 program. New categories of vehicles were added to the existing levels. Summed fleet-average HC and NO_x emissions levels were extended until the 2022 model year. Table 8 summarizes the passenger car LEV-3 emissions requirements.

2.1.2 *Inspection and maintenance*

To comply with federal clean air requirements, some states and municipalities require regular emissions measurements to confirm adequate emissions are maintained in use by a

vehicle owner. For this monitoring program, an inspection cycle called *IM-240* was developed. The IM-240 cycle is similar to the first 240 s of the FTP-75 cycle. Figure 10 shows the IM-240 cycle.

Tail-pipe emissions limits from vehicles tested on the IM-240 cycle are established independently by each jurisdiction depending on the ambient air quality of the region and plan for achieving national air quality standards and depending on the model year of the vehicle being tested. Such a test is performed as a part of vehicle registration typically once every 2 years. In 2011, IM-240 testing is performed in only a few cities whose ambient air quality does not meet standards established by the EPA. In 2011, US states, cities, and municipalities that require tail-pipe emissions inspection and maintenance sampling are listed in Table 9.

Table 9. US municipalities with inspection maintenance requirements.

State	Emissions Inspection Requirements (at License Application)
Alaska	Anchorage municipality only; CO emissions only
Arizona	Phoenix and Tucson areas only
California	All vehicles from outside state, and all vehicles in Los Angeles, San Francisco, San Diego, and Sacramento metropolitan areas
Colorado	Denver and Boulder municipal areas and Northern range areas only
Connecticut	All vehicles
District of Columbia	All vehicles
Delaware	All vehicles
Georgia	Atlanta municipal area only
Idaho	Boise (Ada County) municipal area only
Illinois	Chicago and St. Louis municipal areas only
Indiana	Lake and Porter Counties only
Louisiana	Baton Rouge municipal area only; visual and OBD inspection only
Maine	Portland municipal area (Cumberland County) only
Maryland	All vehicles; idle test and OBD inspection only
Massachusetts	All vehicles
Missouri	St. Louis municipal area only
Nevada	Clark County (Las Vegas) and Washoe County (Reno) only; idle test and OBD inspection only
New Hampshire	All vehicles; OBD inspection only
New Jersey	All vehicles
New Mexico	Bernalillo County (Albuquerque municipal area) only
New York	All vehicles; OBD, gas cap, and visual inspection only
North Carolina	48 (of 100) counties; OBD inspection only
Ohio	Cleveland/Akron municipal area only
Oregon	Portland and Medford-Ashland municipal areas only
Pennsylvania	Pittsburgh, Philadelphia, and select counties only
Rhode Island	All vehicles
Tennessee	Memphis and Nashville municipal areas only
Texas	Dallas-Ft. Worth, Houston, Austin, and El Paso municipal areas only
Utah	Salt Lake City—Ogden municipal area only
Vermont	All vehicles; OBD test only
Virginia	District of Columbia municipal area
Washington	Seattle municipal area (five counties) only
Wisconsin	Milwaukee and suburban Chicago municipal areas only

The use of this type of program is typically applied to urban areas whose ambient air quality exceeds the national and state requirements set by the EPA and CARB. Such a program can support the implementation plan for a local community to improve ambient air quality in the impacted "nonattainment" areas.

Canadian provinces of British Columbia and southern Ontario also require vehicle emissions testing at regular intervals.

2.2 Europe

The European Union introduced vehicle emissions limits beginning with the 1992 calendar year for all member states. Before this year, some countries implemented early regulations beginning in the late 1960s, but implementation timing varied by country. For the original European-wide regulation, the MVEG-A driving cycle was defined as were the EURO-1 category of emissions limits. As in the United States and California, the emissions limits were defined as a mass of emissions produced over a distance traveled on the complete driving cycle. In the original regulation, measurement of gaseous emissions started 40 s after the engine start allowing a brief unregulated warm-up period. Beginning with EURO-3 limits for the 2002 model year, the cycle was modified to become the current MVEG-B cycle officially called the *New European Driving Cycle* (*NEDC*). Shown completely in Figure 11, the NEDC is made up two parts. The first part is made up of four replicates of a short urban driving cycle with vehicle speeds up to 50 km/h. The second part is a representation of highway driving made up of acceleration and higher vehicle speed up to 120 km/h. The complete NEDC is made up of both sections with total distance traveled of just over 11 km in 1180 s. For reporting fuel economy, the cycle is typically separated into urban (city) and extra-urban (highway) portions, but the emissions test and limits are conducted on the entire cycle.

From 1993 through today, the emissions limits for the European Union are shown in Table 10. The European regulations have recognized a difference between gasoline and diesel engines, and the limits are different for the engine type for all years up to EURO-6 level in the 2015 model year for new vehicles.

European regulators have required measurement and reporting of fuel consumed on the standard emissions cycle as the beginning of its inception. However, European-wide requirement to meet fuel economy standards, CO_2 emissions limits, was phased in beginning in 2012. Individual member states have implemented different forms of tax

incentives or penalties. Fuel consumption and CO_2 emissions are measured using the same equipment and driving cycle.

There are in addition different limits for vehicles whose primary use is not for personal transportation. Light-duty commercial vehicles are regulated according to the same driving cycle and testing protocol, but the individual constituent limits are somewhat higher depending on the inertia class and test weight of the vehicle.

A new set of three driving cycles has been proposed by European regulators potentially for future emissions standards. The new Common ARTEMIS Driving Cycles (CADC) are developed under the European ARTEMIS project (ARTEMIS, Assessment and Reliability of Transport Emissions Models and Inventory Systems). The three cycles are defined for urban, rural road, and motorway, with maximum speed variants in the motorway segment of 130 or 150 km/h. Currently, the ARTEMIS Cycle, which is shown completely in Figure 12, is not used for emissions regulatory purposes.

2.2.1 *Inspection and maintenance*

The European Union requires vehicle inspections to be completed on light-duty vehicles, but emissions' testing is not included in the European wide inspection requirement. Some countries require emissions testing regularly as part of their vehicle inspection requirements. Germany, Spain, France, the Netherlands, and the United Kingdom have some form of emissions inspection on vehicles.

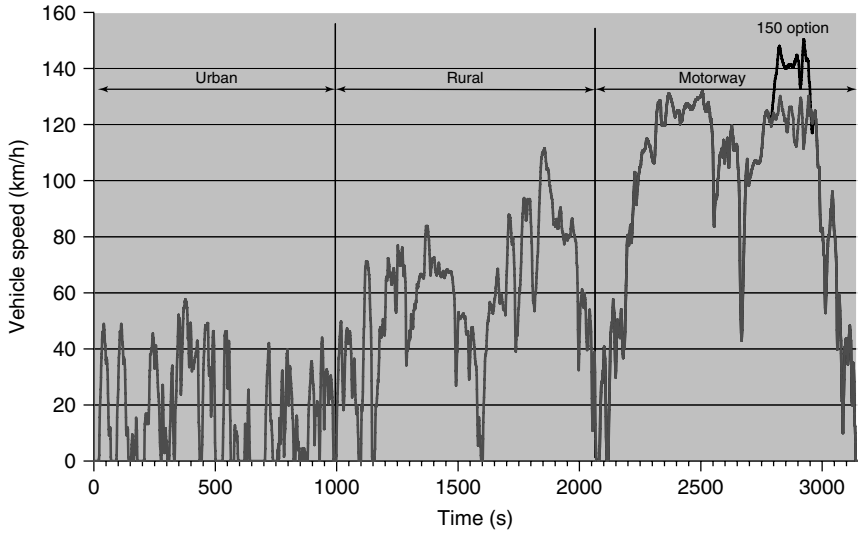

Figure 12. ARTEMIS Drive Cycle.

2.3 Japan

Beginning with the 1975 model year, Japan initiated a vehicle emissions program with a unique drive cycle more representative of driving in the Japanese market. Like the US and European regulations, the main emissions limits were established as a total mass of emissions constituent divided by the total distance traveled. The first Japanese driving cycle that regulated emissions from a warm vehicle was called the *10–15 mode cycle* is shown in Figure 13. A companion cycle called the *11 mode cycle* was also established for regulation of cold start emissions; on the 11 mode cycle, the regulated limits were in units of grams of pollutant per test, unlike most other cycles whose regulatory limits are stated on a distance traveled basis.

With phase-in beginning for the 2008 model year, the Japanese government implemented a new driving cycle to replace both existing cycles with a new test more representative of actual vehicle driving. Like the FTP-75 cycle, the new JC08 cycle shown in Figure 14 is representative of actual vehicle driving conditions on a public road.

Japanese emissions standards for passenger cars were first enforced for the 1975 model year for HC and CO

emissions, and 1978 for NO_x emissions. The standards were reduced for the 2001 model year. Emissions requirements with these early cycles are summarized in Table 11.

Together with the implementation of the new JC08 emissions cycle, much more stringent emissions limits (Table 12) were also phased in.

2.3.1 *Inspection and maintenance*

The Japanese government requires vehicle inspections to be completed on light-duty vehicles after 3 years of service and every 2 years thereafter, which includes emissions test requirements. The periodic inspection known as *Shaken* is

quite expensive. The emissions test is conducted at idle and only HC and CO emissions are measured.

2.4 Other

Most other countries with light-duty vehicle emissions standards base those requirements on a European, US, or Japanese standards, or even a combination. India has implemented a variation on the European emissions cycle called the *Modified India Driving Cycle*, which is essentially identical to the NEDC with the exception of maximum vehicle speed on extra-urban portion reduced from 120 to 90 km/h. Mexico currently (2011) allows either US standards from 1994 or EURO-4 levels from 2005.

3 VEHICLE TESTING PROCESS AND MEASUREMENTS

3.1 Representation of vehicle load

To represent correctly the powertrain operating regime, the chassis dynamometer should apply a resistance to motion that is consistent with the load required to move the vehicle forward on the road. There are industry standard processes for calculating the road load and applying it to the chassis dynamometer. Two categories of load are required to correctly represent this resistance. First, based on vehicle mass, a mass inertia is applied to resist vehicle acceleration. Second, as a function of the rolling resistance to motion, a quadratic resistance function that represents the increase in load as a function of vehicle speed is applied. Expressed as a quadratic equation, the coefficients are generally correlated with resistance to motion, rolling friction, and aerodynamic resistance.

To develop a set of dynamometer values that represent the actual vehicle on a road, a standard coast down test of a vehicle on a test track is performed. The vehicle test is conducted on a flat straight track in which the vehicle is coasted from high speed to low speed. The rate of deceleration is measured; effectively, the vehicle speed is measured over time and deceleration rate is calculated as a change in velocity over a time interval. Once the vehicle rate of deceleration without motive input from the powertrain is measured, the resistive force equation is calculated. When a vehicle is tested in a closed facility, the dynamometer resistance is calibrated to the actual road test, so that when a vehicle is coasted from high to low speed, the deceleration rate is comparable.

3.2 Deterioration factors

Because the exhaust emissions of a vehicle tend to increase with usage over the life of a vehicle, European and US regulatory regimes require a prediction of the deterioration is used to guarantee that the vehicle will produce emissions under the required limits over their entire useful life. The deterioration factor can be directly measured from a vehicle as it accumulates mileage. The US EPA has, for example, developed a standard cycle to exercise a vehicle over the full useful life. During the accumulation of mileage, emissions are measured on the regulated cycle. Linear regression is applied to calculate the exact deterioration of each emissions constituent from the new condition to the end of the required useful life. The US EPA Standard Road Cycle (US EPA SRC) used for demonstration of emissions durability is shown in Figure 15.

To conduct such a test to develop the emissions capability and deterioration for a life of a vehicle, this test cycle should be repeated until the limit mileage on the vehicle is obtained, typically 100,000–150,000 miles.

Because the catalytic converter in the exhaust is effectively responsible for the vast majority of the emissions control capability of a modern vehicle, the US EPA also allows a bench procedure for emissions deterioration. The catalyst assembly is aged using a bench on a cycle that is calculated to represent the deterioration experienced over the useful life of the vehicle. Aged exhaust components are prepared using bench methods. The test vehicle is tested with new and aged components for determination of the deterioration factor. According to US EPA regulations, the catalyst temperature profile and number of durability hours the exhaust system is exposed to is a function of the instrumented measurement of temperature the catalyst is exposed to over the Standard Road Cycle (SRC).

The US EPA allows manufacturers the flexibility to modify the process for determining the deterioration of emissions and durability depending on proprietary development processes and test cycles that are not part of the EPA standard process. To use a nonstandard cycle, the manufacturer must demonstrate the process and typically provide documentation of historical performance of vehicles in customer use.

In the European regulatory environment, standard assigned deterioration factors are permitted. The assigned deterioration factors are written into the regulation and available for all manufacturers. Assigned factors for each emissions constituent for the current series of regulations from EURO-1 to EURO-6 are tabulated in Table 13.

In both European and US markets, the manufacturer must warrant that vehicles in customer use must, when maintained according to the manufacturer's recommendations,

perform within the regulated emissions limit to which they are certified to when new for the useful life of the vehicle. Theoretically and in practice, the regulating agencies have the authority to mandate recalls of vehicles when a model does not demonstrate emissions compliance and durability.

3.3 Emissions and fuel economy measurement system

Gaseous emissions from the tailpipe of a vehicle are collected in a constant volume sampling (CVS) emissions bench. A CVS system collects a sample of exhaust from a mixing tunnel in which the complete vehicle exhaust is mixed with air. Samples of diluted exhaust emissions are collected in bags and processed after completion of the test. The mass of the various constituents is calculated by direct measurement of the mass in the sample bag and calculation of the ratio between sample mass flow and tunnel flow. Several different types of measurement devices are employed for measurement of each constituent.

3.3.1 Emissions/fuel economy gaseous emissions

Gaseous emissions in the form of HCs, CO, CO_2, and NO_x are measured normally from the gaseous tail-pipe emissions from a vehicle. On an emissions chassis dynamometer facility, the standard method dilutes the exhaust sample in filtered air with a constant total volume flow rate at all operating conditions. Because the exhaust flow rate varies as a function of operating condition, the relative dilution of the exhaust varies also during testing. A small sample is continuously drawn from the diluted exhaust to a polytetrafluoroethylene (PTFE) (Teflon®) bag over the entire duration of the test phase. Similarly, a sample of the dilution air without exhaust is continuously drawn and sampled for comparison to the measured from the tailpipe of the vehicle. Because any constituents in the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto151
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ambient air are also collected in the emissions sample, the offset due to ambient is subtracted from the emissions samples.

By drawing a gaseous sample of emissions for a complete cycle and measuring and calculating the integrated total mass of each constituent for a cycle or portion of a cycle, this standard method provides no indication of the rate of emissions production as a function of the driving condition during the time domain of the cycle.

3.3.2 *Hydrocarbon emissions*

HC emissions are most often measured using a flame ionization detector, or FID. In principle, an FID measures the number of carbon–hydrogen bonds in a gas sample. A flame of hydrogen and oxygen is created. The HC sample is introduced through the flame, creating ions. An electric potential between the flame tip and the cathode is created, and the measured electric potential is proportional to the number of carbon–hydrogen bonds and therefore the HC concentration.

3.3.3 *Oxides of nitrogen*

NO_x, normally NO, but also NO_2 and N_2O, are measured using primarily chemiluminescence technology. First, the NO and NO_2 are typically converted into exclusively NO for measurement. NO is typically generated during high temperature combustion in an internal combustion engine, but when released into the low temperature atmosphere, NO is slowly converted to NO_2 at a relatively slow time constant. Therefore, for measurement, NO_2 is typically first converted to NO. In a chemiluminescence detector, NO and ozone (O_3) react to produce light, whose intensity is measured with a detector. The concentration of NO is proportional to the light intensity.

3.3.4 *Carbon monoxide and carbon dioxide*

CO and CO_2 are typically measured using an instrument that applies the principle of NDIR nondispersive infrared detector. Gas molecules of components such as CO and CO_2 interact with infrared radiation in specific wavelengths for each compound. An infrared radiation source is applied to a sample and the infrared absorption can be measured using a detector proportionally to the amount of the compound in the sample. Because the different compounds absorb infrared radiation sensitive to different wavelengths, a sampling system with multiple detection wavelengths can be used for both CO and CO_2 measurements.

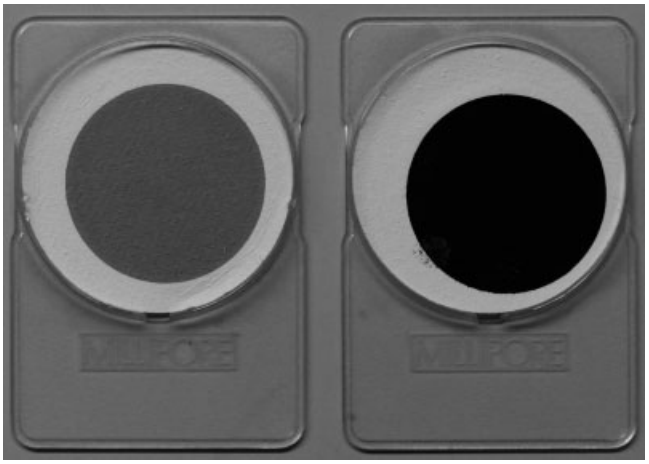

Figure 16. Two filters with deposited diesel engine exhaust particulate.

3.3.5 *Particulate emissions*

A special class of emissions measurements is required for vehicles powered especially by diesel engines. The particulate matter (PM) from the exhaust is sampled in a facility that dilutes and cools the exhaust. The mass of particulate is defined as the mass collected on a filter once the exhaust sample has been diluted and cooled in ambient air. The actual measurement properties of the filter are mandated in the regulations. The total mass of particulate that can be collected from the exhaust of an internal combustion engine is made up of several different sources including black carbonaceous compounds, heavy HCs that condense when cooled, sulfates, and water.

Two samples of particulate matter (PM) collected from the exhaust of a small industrial diesel engine are shown in Figure 16. The total mass of particulate collected on each filter sample is similar, but clearly the character of the particulate is significantly different. The lighter colored sample is measured at light-load conditions and is dominated by heavy HCs from fuel and lubricating oil and sulfates combined with water. The darker colored sample is measured at full-load conditions and is predominately made up of black carbon agglomerates.

By regulation, the mass of particle deposited on the filter, corrected for the ratio of sample compared to that of the total exhaust flow, is the definition of PM.

3.4 Example measurements and calculations

The following sequence of measurements is used as an example measurement of vehicle on the major components of the process for emissions and fuel economy. Some test

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

measurements are from a European process, and some are from the US process, but either illustrates a similar process.

3.4.1 Coast-down test

A test vehicle representative of the class of vehicle to be certified must perform a coast-down test on a test track. The results of the coast-down test are applied to the chassis dynamometer test facility to appropriately represent the driving load the vehicle experiences in the test cell. Depending on the manufacturer's preference, a single variant of a vehicle class may be tested; this vehicle should represent the vehicle with the maximum weight and highest rolling resistance of all vehicles represented by the class. A manufacturer may also choose to test each major powertrain or inertia class variant so that each version is tested with the lowest possible road load for that vehicle model.

The test vehicle is prepared for testing. The actual test is conducted on a straight and level track of suitable length. The vehicle is accelerated past the maximum speed of the driving cycles to which it will be evaluated—120 km/h on the NEDC. The test driver then places the transmission in neutral and the vehicle coasts from high to low vehicle speed. The time between each speed interval is measured and tabulated as shown in Table 14.

For such a test to be considered valid, typically several replicates of the test must be conducted with small variation between each sample, and the average interval times are used for further calculation. Test conditions and the facility definition are written. In most cases, it is to the advantage of the automaker to achieve the lowest resistive force and therefore reduce the relative motive power the powertrain must exert to move the vehicle in a simulated environment. Therefore, the vehicle preparation and ambient conditions are very often selected carefully. The test results must be corrected for the standard ambient conditions of the nominal chassis dynamometer test.

Table 14. Exemplary vehicle coast down test result.

Velocity (km/h)	Time Interval (s)	Force (N)
120	5.30	1069
110	6.00	944
100	6.87	825
90	7.82	725
80	8.99	630
70	10.41	544
60	11.88	477
50	13.68	414
40	15.59	364
30	17.33	327
20	19.73	287

The rate of change of vehicle speed is calculated across the intervals to determine an average acceleration rate over each 10 km/h increment.

With a documented vehicle mass, the resistive force applied to the vehicle by aerodynamic drag, rolling resistance, and rolling friction is calculated using the simple calculation of Equation 4:

$$\text{Force} = \text{Mass} \times \text{Acceleration} \tag{4}$$

Using the average acceleration from the coast-down intervals that represent a change in vehicle velocity over a measured time interval, the average force over this interval is calculated.

The resistive force applied by the chassis dynamometer should be representative of the force applied on a road. The force equation is simply represented by a quadratic equation of force as a function of vehicle speed, typically fit with a least squares regression calculation. Using the same coast-down measurements from Table 14, the quadratic coefficients can be calculated. In the United States the A, B, and C coefficients for this quadratic equation are also tabulated and available to the public. Figure 17 illustrates the resistance curve calculated from the measured coast-down times from Table 14, and the calculated A, B, and C coefficients for the quadratic equation associated with that curve. In practice, the quadratic terms are associated with functionality of a vehicle that these terms in some ways represent. Coefficient A, the square term, is associated with aerodynamics as this term is a squared function of velocity of the vehicle. Coefficient B, the linear term, is associated with rolling resistance. Coefficient C, the offset term, is associated with the constant force needed to move the vehicle from rest—mainly a force associated with tire rolling friction. The quadratic equation representing this resistive force curve is also shown with A, B, and C coefficients.

$$\text{A Coefficient: } 0.0549 \ (\text{N}/(\text{km/h})^2)$$

$$\text{B Coefficient: } 0.3443 \ (\text{N}/(\text{km/h}))$$

$$\text{C Coefficient: } 270.25 \ (\text{N})$$

3.4.2 Chassis dynamometer setup and vehicle preparation

When a vehicle is first to be tested on a chassis dynamometer facility, the initial setup must be performed to match the road load from the coast-down test. The

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto151
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

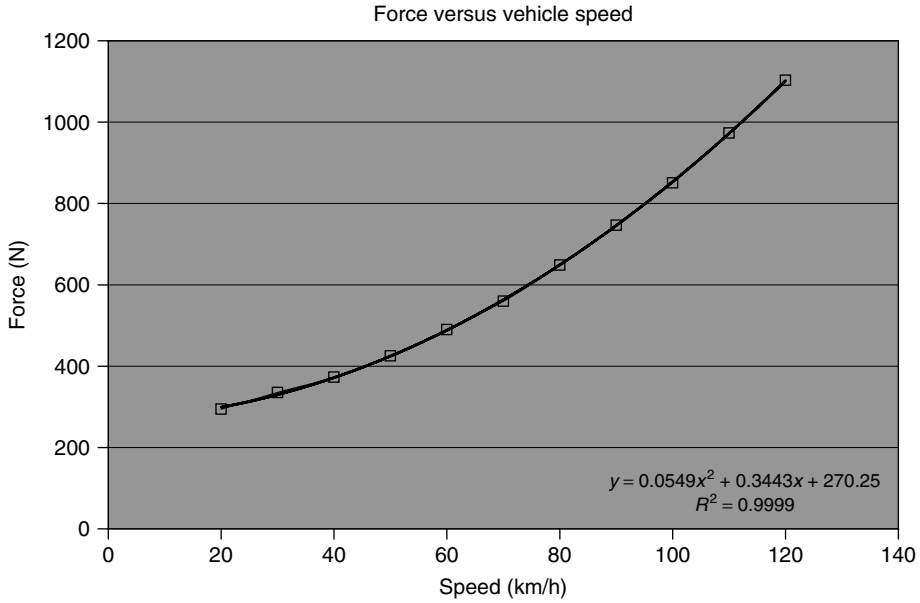

Figure 17. Resistive force and quadratic equation calculated from coast-down test.

quadratic coefficients are used initially. The measured coast-down time intervals when the test vehicle is decelerated from high speed to low speed are also considered. The chassis dynamometer facility does not ideally represent the vehicle on-road conditions, so in some ways the idealized environment of the facility is modified so that it represents as closely as possible the same resistance to motion a vehicle would experience on road driving. Once the chassis dynamometer matches the coast-down times, actual driving cycle testing can begin.

A test vehicle may be prepared with instrumentation for testing, or in some cases, the unmodified vehicle is provided for testing. A known fuel with measured properties including number of carbon atoms must be used for accurate results, because the measurement of CO_2 emissions is made directly, and fuel consumed during the test is inferred from these measurements. For either US FTP or European NEDC testing, a vehicle must be tested first on a known cycle and then soaked for a prescribed period of time at specified humidity and temperature. Before a driving cycle begins, the vehicle is rolled on the facility and fixed to the floor; the drive wheels are placed in contact with the dynamometer roller. The tail-pipe exhaust is captured by the emissions sampling system. An external cooling fan supplies cooled air to the vehicle cooling system to maintain standard conditions for the powertrain; in newer facilities, a cooling fan is controlled proportionally to the vehicle speed on the driving cycle. Ambient conditions must be maintained during the soak period before a test and also during the entire test phase.

Some incremental new driving requirements require testing the vehicle after soaking and/or while operating at different ambient conditions. In these cases, the room of the test facility must have the capability of controlling the ambient conditions. Effectively, this requires a test facility that must be able to soak vehicle for normal ambient temperatures of 20°C, for cold ambient temperatures of −7°C, and at elevated temperatures of 35°C for US SFTP requirements.

3.4.3 Test performance

The driver starts the engine and follows the instructions provided in a monitor outside the vehicle. The key instruction to follow is a vehicle speed trace in kilometer/hour that the vehicle should follow. The vehicle speed trace is prescribed in the NEDC as shown in Figure 10.

The driver is evaluated whether the prescribed driving trace is met with the actual driving cycle performed during the test using a regression analysis. If the actual driving is not close enough to the prescribed cycle, the results are invalid. Figures 18 and 19 show the actual vehicle speed measured during the completion of an NEDC, overlaid with the prescribed cycle on the complete cycle, and for a short segment. Generally, the vehicle speed must be within a tolerance of the target, and the average deviation over the complete cycle must also be within a specified tolerance.

For maximum repeatability, automated "robot" drivers have been developed and are in use in some facilities. Such

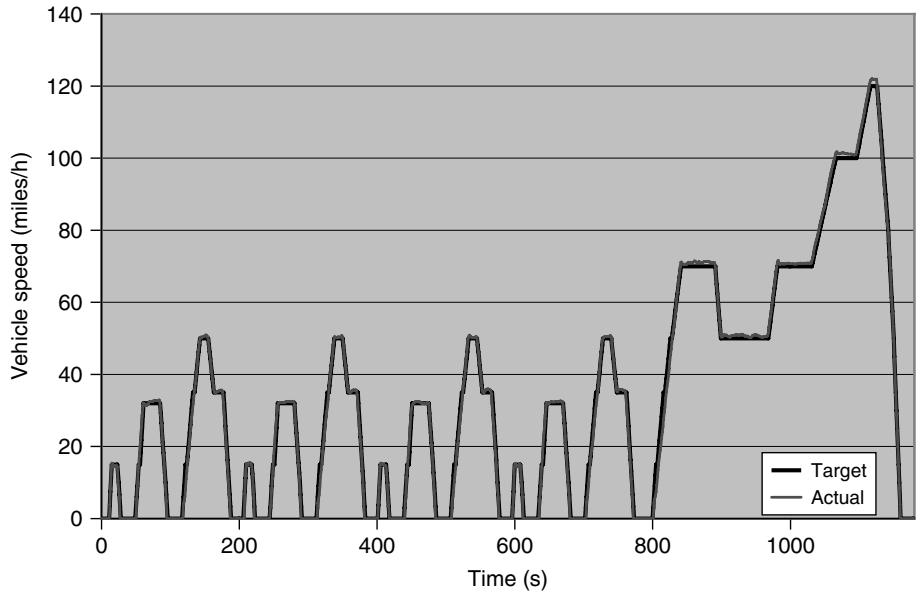

Figure 18. Target and actual vehicle speed on complete NEDC.

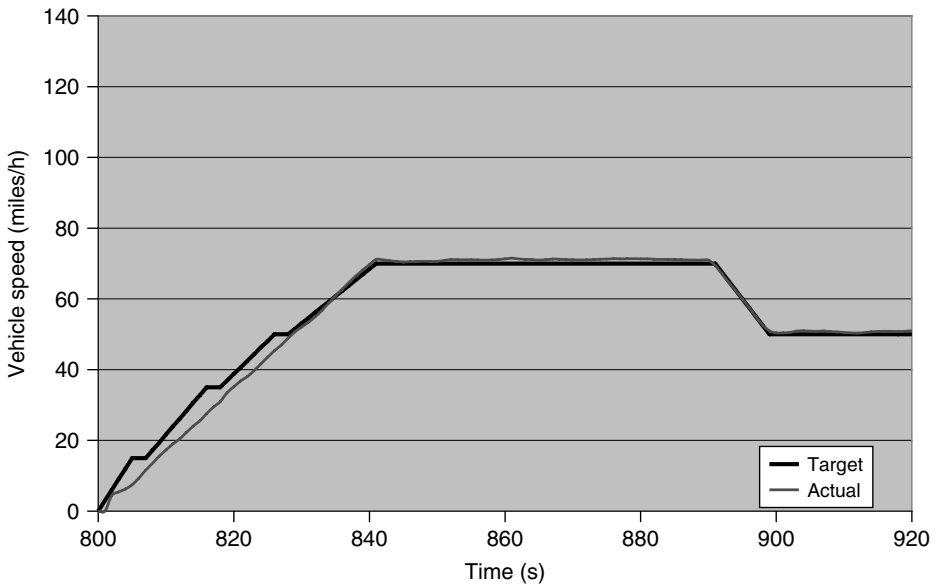

Figure 19. Target and actual vehicle speed on complete NEDC—detail.

automated drivers improve test to test repeatability and can remove some variation in results attributed to the driver.

3.4.4 Emissions postprocessing and cycle calculation

Once the vehicle completes the driving cycle, the engine is turned off and emissions sampling equipment stopped. Measurements of the regulated emissions are entirely post-processed from the emissions constituents that are collected in Teflon sampling bags. On the NEDC, two bags are required: one for the urban portion and other one for the extra-urban portion. The concentration of each emissions constituent captured during the driving cycle is measured by direct measurement of each constituent and the concentration. The total amount in grams of each constituent is

divided by the distance traveled for that phase or totaled for the complete driving cycle. Because the complete vehicle exhaust flow is too large and bulky to efficiently store and hold, only a small portion of the total exhaust flow is diverted to the emissions sampling system.

An exemplary table of emissions and fuel economy measurements from a vehicle test conducted on the FTP-75 cycle is given in Table 15.

In the regulated emissions constituents and levels, only the final bag results that are the integrated total emissions values are required. Such a test is the only accepted method used for the regulatory bodies. However, for engineering, it is invaluable to know at what event in a driving cycle the emissions rates are highest or lowest and, in addition, the aftertreatment system efficiency. For these product development requirements, emissions measured in a vehicle facility typically include also emissions sampled instantaneously and often both before and after the aftertreatment system to calculate the effectiveness. Table 16 shows emissions collected instantaneously during the completion of an FTP-75 test. In this case, the emissions before and after the catalytic converter are also measured that allows calculation of conversion efficiency. With this information, the attribution of performance to specific operating points in the cycle can be performed.

These modal emissions results are useful for product development, but are not performed according to the regulations and are not exactly identical to the prior integrated values. For example, the fuel economy estimate from this method is about 10% lower than that measured using the CVS method. It should be clear from the amount of information available that such a method greatly increases the use for a developer. For example, the conversion efficiency of the catalyst and allocation of emissions to the individual operating conditions are only available from modal measurements.

Unlike other emissions constituents, diesel particulate emissions are sampled separately from other gaseous emissions and continuously throughout the cycle. A sample of the exhaust is routed to a dilution tunnel in which it is mixed with ambient air. A portion of the diluted and cooled sample is drawn through a filter. The amount of mass deposited on the filter is defined as the mass of particulate. In most light-duty automotive facilities, only a portion of the complete exhaust is introduced into the dilution tunnel. Then only a portion of the diluted sample is routed through the filter for measurement. The ratio of the total vehicle exhaust flow rate to the sample flow rate and then the ratio of the tunnel flow to the probe flow rate must be continuously calculated or controlled.

4 VEHICLE TESTING FACILITIES

Several different types of facilities have been developed for automotive product development in a static location.

4.1 Emissions chassis dynamometer

For measurement of emissions and fuel economy according to the procedures required by the major regulatory regimes,

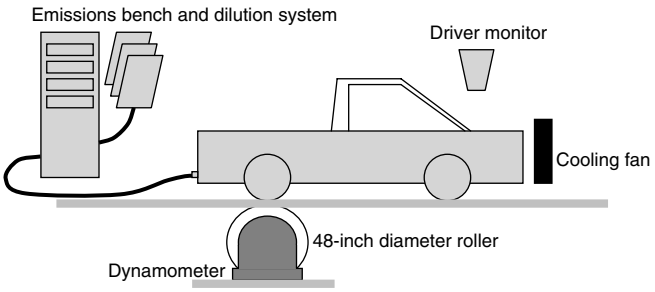

Figure 20. Emissions chassis dynamometer facility.

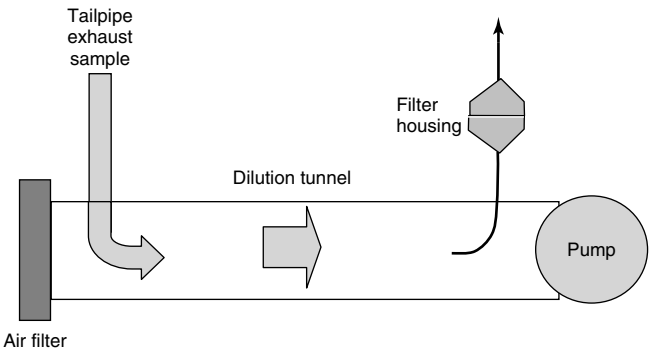

Figure 21. Particulate emissions dilution tunnel.

the emissions chassis dynamometer facility must consist of the major components shown in Figure 20. First, the facility must have rooms that control temperature and humidity in which the vehicle is soaked before testing. The capability to control temperature and humidity in the actual room in which testing is conducted must also be provided. Often, a facility with multiple test cells has attached a soak room in which multiple vehicles are soaked in preparation for testing.

The chassis dynamometer itself consists of a large drum on which the tires of the drive axle of the test vehicle sit. The drum is both restrained and in some cases driven by an electric dynamometer controlled by microprocessor-based system. The emissions from the vehicle tailpipe are collected by a duct attached to and sealed to the tip of the exhaust of the vehicle. The complete vehicle exhaust sample is routed to a dilution tunnel and mixed with sample air, which is pumped through at fixed flow rate. The sample air is controlled for temperature and pressure and humidity in regulated tolerance range. For facilities that are located where the ambient air contains significant levels of CO or HCs, the sample air can first be treated with filtration or catalyst technology to reduce the ambient levels introduced with the dilution air. A small sample of the diluted exhaust is drawn into a set of bags and stored for processing after the test is completed. If modal emissions are also measured, an additional sample probe is placed in the dilution tunnel for additional measurements, and a second set of emissions analyzers that can measure at higher sampling speed is required (Figure 21).

4.2 Environmental chassis dynamometer

An environmental facility is similar to the facility used for emissions measurement, with the addition of ambient environmental conditions. For emissions requirements, the ambient temperature range for testing must be extended to a temperature of -7°C (20°F) for both European and US requirements. Also for US requirements, an ambient temperature range must be extended to ambient temperatures of 95°F (35°C).

For evaluation of the performance of a powertrain at conditions that are outside the normal range, but still experienced by customers, an environmental facility may also be specified for continuous operation at cold or hot ambient temperature, high altitude, testing, and various humidity levels.

4.3 Evaporative emissions test facility

Emissions of volatile organic compounds (HCs) that are not from the tailpipe of running engine but from liquid fuel evaporating from the vehicle are also regulated in United States and California. The facility for measuring this category of emissions is called a *sealed housing for evaporative determination* (*SHED*). Such a facility is used to capture the HCs that are emitted by a vehicle from fuel evaporating from the fuel system components and fuel tank when the vehicle is running or not running. In the United States, the emissions of fuel vapor during the fuel tank refueling process are also monitored and limited. Typically, the mass emissions of HCs are limited during an extended test period under which the vehicle is tested, soaked at high temperature, or refueled. The low speed New York City Cycle, shown in Figure 22, which was developed in similar time frame to the FTP-72 cycle is employed for some parts of evaporative emissions testing for US requirements.

Recently, hybrid vehicles with potential for energy storage and energy recovery have required additional standards to represent the state of charge applied at the beginning, and how much that available energy can be depleted and included in the cycle calculations for emissions and fuel economy.

Fuel Economy Optimization

Stephen F. Bowyer, Dean Tomazic, and Gary W. Rogers

FEV, Inc., Auburn Hills, MI, USA

1 INTRODUCTION

The efficiency of a thermomechanical system is defined as the ratio of the mechanical work done versus the amount of fuel energy input per unit time. As applied to the automotive engine, the chemical energy in the fuel is converted into heat, which is in turn converted into the mechanical work extracted from the crankshaft. The fuel efficiency (fuel quantity/distance traveled) and fuel economy (distance/fuel quantity) of the vehicle are related to the vehicles mass and other dynamic parameters associated with the vehicle being propelled such as aerodynamic and rolling resistances. To achieve the lowest possible fuel consumption, while maintaining high customer satisfaction, in a given vehicle powered by an internal combustion engine, parameters such as mechanical design, fluid dynamics (gas exchange), combustion cycle, exhaust emissions, torque, electronic controls, noise and vibration, and torque versus speed must be optimized. In some cases, higher vehicle performance must be sacrificed to achieve government-regulated fuel economy and exhaust emission standards. This chapter outlines the influences major components and subsystems have on thermodynamic energy conversion and the mechanical losses that limit total system efficiency and identifies advancements being developed to optimize fuel economy.

2 OVERVIEW OF FUTURE FUEL ECONOMY REGULATIONS

The United States recently enacted legislation requiring automotive manufacturers meet tough new Corporate Average Fuel Economy (CAFE) standards. These new standards will score a vehicle's fuel economy with respect to the size of the vehicle's footprint. The new CAFE standard will require the manufacturers to sell vehicles in order to obtain a fleet average of approximately 54.5 mpg by 2025 or receive heavy fines. There are some variances to this target as the CAFE targets are adjusted by the types of vehicles the manufacturer sells and, therefore, typical footprint of the vehicles. By comparison, the former CAFE standard was 27.5 mpg for passenger cars.

The European Union (EU) has already converted largely to more fuel-efficient vehicles because of the fuel taxes levied within the region. Further, EU regulations under discussion stipulate that manufacturers must limit their European fleet average CO_2 emissions to 130 g/km by 2012. Ongoing negotiation may push future CO_2 levels below the 100 g/km level by 2020.

The regulations in place and in discussion in developed economies and the fuel costs in developing countries are putting new pressure on automotive manufacturers. As

such, many of the fuel-saving technologies outlined in this chapter are under research, being developed, and beginning to be implemented in future engine programs faster than ever before.

3 OVERVIEW OF INTERNAL COMBUSTION ENGINE EFFICIENCY

Internal combustion engines have been the primary source of mobile power for more than a century. Two combustion cycles, spark ignition (gasoline or alcohol) and compression ignition (CI) (diesel), have dominated the automotive industry since its inception for their excellent power density and load flexibility. However, there are significant inefficiencies inherent with both cycles and differences in efficiencies between the two resulting from the way load is controlled.

Most modern automotive gasoline engines operate at approximately 36% overall engine efficiency, whereas diesel engines are capable of just over 40%. The largest share of wasted energy for both cycles escapes the engine through the exhaust. The loss of 25–45% of the fuel's chemical energy through the exhaust is a result of the difficulty in extracting energy from high temperature but low pressure gas. The remaining losses include heat transfer to the cooling system, internal friction of the engine, and unburned fuel. An example of the energy split from a turbocharged, direct-injected gasoline engine is shown in Figure 1 illustrating the distribution of fuel energy for a high power density engine.

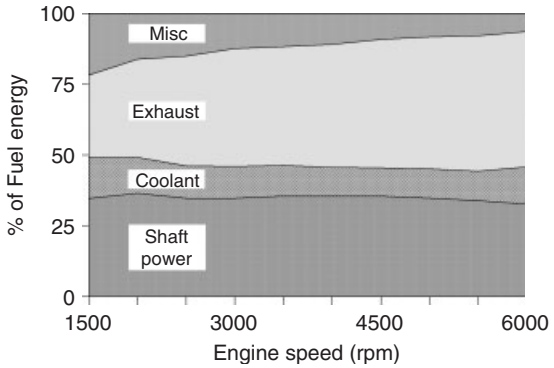

Figure 1. Energy split for a turbocharged, direct-injected gasoline engine at full load. (Reproduced by permission of FEV Inc.)

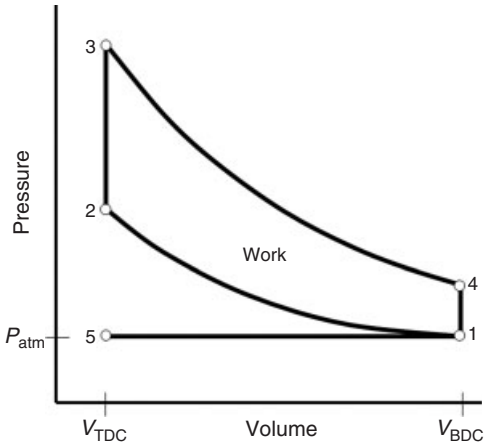

Figure 2. P–V diagram for an ideal Otto cycle. (Reproduced by permission of FEV Inc.)

3.1 Spark-ignited engines

Spark-ignited (SI) engines operate using the Otto cycle, a theoretical constant volume combustion process as shown in Figure 2. In this process, fresh charge is pulled into the cylinder as the piston expands the volume in the chamber from points 5 to 1. From there, the air/fuel mixture in the cylinder undergoes adiabatic compression from points 1 to 2. Heat is added to the cylinder through combustion at such a rapid rate that it occurs at a constant volume condition as shown from points 2 to 3. From point 3, the gas undergoes adiabatic expansion to point 4 before being exhausted to atmosphere where the conditions in the cylinder return to their starting point at point 1. The work output of the engine is defined by the area bounded by points 1–4.

The efficiency of this cycle is determined by the compression ratio. Equation 1 defines this relationship.

$$\eta_{th,v} = 1 - \frac{1}{r_v^{\gamma-1}} \qquad (1)$$

where γ = ideal gas constant and r_v = compression ratio.

In practice, several aspects of the P–V diagram vary from that in Figure 2. The charge is compressed nearly adiabatically from points 1 to 2 but there is some heat transfer between the gas and the surrounding chamber. While combustion duration is very short for modern engines, typically over 30–50° crank angle, it is not a constant volume process. As such, the combustion must be initiated before top dead center (TDC) and continues for several crank degrees beyond TDC giving a rounded-off appearance between points 2 and 3. Expansion of the combustion gas is not purely adiabatic, as a small amount of heat is transferred to the components making up the combustion chamber. The exhaust valve opens before the piston reaches bottom dead center (BDC) in order to provide time for the combustion pressure to be relieved before the piston begins the exhaust stroke on its way to point 5. Finally, flow losses through the induction system and intake valve

cause a negative depression above the piston relative to the pressure in the crankcase. This pumping loop of negative work reduces the available output of the engine. An overlay of P–V diagrams for an ideal and actual cycle is shown in Figure 3.

For SI engines, load demand by the driver is varied through the use of a throttle blade, which meters the amount of air allowed into the engine. Throttling of the incoming air charge reduces engine output by reducing the amount of fresh charge allowed into the engine that is desired. In addition, though, the amount of work required for the pumping loop is increased, as manifold pressure is reduced further below atmospheric pressure. All of these modifications to the cycle cause the real efficiency of an SI engine to deviate from the efficiency calculated from Equation 1. The most significant of these losses are created by the negative work from the pumping loop. Reduction in the amount of work required for load metering is the major focus for improvement in gasoline engines.

3.2 Compression ignition engines

CI engines operate using the Diesel cycle, a theoretical constant pressure combustion process as shown in Figure 4. In this process, fresh charge is pulled into the cylinder, as the piston expands the volume in the chamber from points 5 to 1. From there, the air in the cylinder undergoes adiabatic compression from points 1 to 2. Heat is added to the cylinder through the combustion of fuel. The fuel is sprayed into the chamber at a rate such that the pressure in the cylinder remains constant from points 2 to 3. From point 3, the gas undergoes adiabatic expansion to point 4 before being exhausted to atmosphere, where the conditions in the cylinder return to their starting point at point 1. The work output of the engine is defined by the area bounded by points 1–4.

The efficiency of this cycle is determined by the compression ratio and an inverse of the cutoff ratio. The cutoff ratio is defined by the distance the piston travels while heat is being added to the chamber divided by the total stroke. Thus, for a given stroke, a short heating time and long post-expansion provide the best efficiency. Equation 2 defines this relationship.

$$\eta_{\text{Diesel}} = 1 - \frac{1}{(\gamma \times r_v^{\gamma-1}) \times \left[\dfrac{(r_c^{\gamma} - 1)}{(r_c - 1)}\right]} \tag{2}$$

where γ = ideal gas constant, r_v = compression ratio, and r_c = cutoff ratio.

As with the SI engine cycle, real-world diesel P–V diagrams vary from ideal. As with the SI engine, both compression and expansion strokes are not quite isentropic, as heat is transferred between the combustion chamber and gas during these processes. Multiple fuel-injection events before TDC are frequently used to mitigate noise. Fuel delivery at this point does not match a pure constant pressure system, which also contributes to the deviation between points 2 and 3. Like the SI engine, the diesel engine requires that the exhaust valve opens early in order to allow for blowdown before the piston begins the exhaust

stroke causing a deviation at point 4. Pushing the exhaust gas out of the cylinder and pulling fresh air into the cylinder creates a pumping loop caused by the flow losses through the valves as the piston moves to and from point 5. Deviations from the ideal cycle can be seen in Figure 5.

Load in a diesel engine is managed by the amount of fuel injected into the combustion chamber. This provides a positive advantage relative to the SI engine cycle at part load. By comparison, the diesel-pumping loop actually decreases at part load because of the reduced port velocities during low boost conditions. Diesel exhaust, however, cannot be cleaned with a simple three-way catalyst (TWC) as the SI engine is. The significant oxides of nitrogen (NO_x) and particulate emissions created by the diesel engine require significant aftertreatment systems, which add cost and reduce the efficiency of the diesel engine. The efficiency losses are caused by increasing the effort to pump exhaust gases through the exhaust system and occasional exhaust system regeneration process, which burns additional fuel to clean particulate filters and NO_x traps.

4 GENERAL FUEL EFFICIENCY ENABLERS

4.1 Reduction in parasitic losses

4.1.1 Friction

Reduction in engine friction helps improve fuel consumption by reducing the work that is consumed by the various sliding motions within the engine. An example of an engine's friction contribution by subsystem is shown in Figure 6.

4.1.1.1 Piston and ringpack. As can be seen in Figure 6, the piston and ringpack are the largest contributors to the engine's overall friction. Several enablers are used to reduce friction in this assembly but the most effective are reductions in pretension of the piston rings. In order to achieve the greatest reduction in piston ring tension, great effort must be put into minimizing cylinder bore distortion. Typically, the most challenging order of distortion is related to the number of cylinder head fasteners used per cylinder. In most automotive applications, fourth-order distortion is then most prominent and should be reduced below 5 μm in order for reduced ring pack tensions to be considered. If bore distortion can be managed, significant reductions in oil control ring tensions can be achieved.

Another option to reduce piston group friction is to offset the crankshaft by somewhere between 0 and 20 mm in the direction of major thrust as illustrated in Figure 7. This puts the connecting rod in a more vertical orientation during high cylinder pressures, thus reducing the side force of the piston on the cylinder bore. However, the friction is increased during the compression stroke. During high load conditions, the increased compression stroke friction is offset by the reduction in friction during the power stroke providing a net friction reduction. At low loads, however, the friction improvement during the power stroke friction may not fully compensate the increase in the compression stroke, potentially leading to a net increase in friction. As such, engines that will see high load for most of their operation, such as hybrid applications, range-extending engines, and extreme downsize applications, will see the most benefit for offset crankshafts. Thus, it is important to

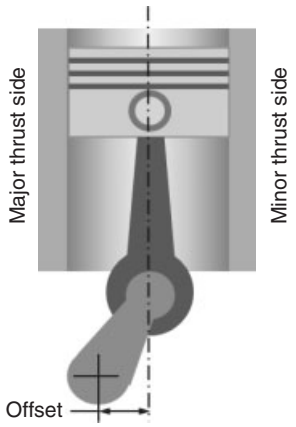

Figure 7. Illustration of crankshaft offset. (Reproduced by permission of FEV Inc.)

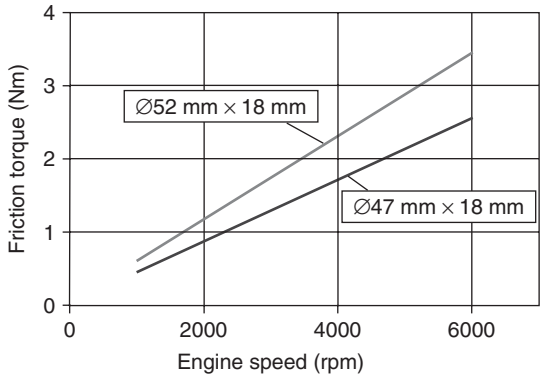

Figure 8. Friction comparison of different bearing sizes. (Reproduced by permission of FEV Inc.)

know the intended drive cycle of the engine to determine the magnitude of offset and benefit of doing so.

4.1.1.2 Dynamic seals. New dynamic seals on the market have the ability to reduce friction of rear main and front main seals. These seals, with more compliant lip designs and lower friction coefficient materials, have the ability to reduce seal friction by 30–70% compared to conventional polytetrafluoroethylene (PTFE) (Teflon®) seals. Reducing the speed of the shaft in contact with the seal contacts by reducing shaft diameters can also have measurable benefits. Great effort should be made during the design phase to minimize shaft diameters riding on dynamic seals and thereby reducing the frictional drag caused by the seals.

4.1.1.3 Bearings. Reductions in the sizes of various engine bearings throughout the engine can provide a measurable reduction in engine friction. Figure 8 illustrates a comparison of a main bearing that is 52 × 18 mm (diameter × width) to one that is reduced to 47 × 18 mm. Here, a reduction in driving torque of 0.3 Nm at 2000 rpm for a typical four-cylinder engine with five main bearings can be seen. At rated engine speeds, an additional half of a kilowatt is consumed by the friction of the larger bearing.

There have been many investigations into utilization of roller bearings in place of various plain journal bearings throughout the engine; however, these have not been implemented in production engines because of various durability issues, cost relative to plain bearings, and relatively small frictional improvement at most engine speeds. Owing to the efficiency at high speeds for plain bearings, it is anticipated that plain bearings will remain the dominant bearing for the foreseeable future. The valvetrain, however, which rotates at half of the engine's speed may see some roller bearings used, particularly in the highly loaded front journal. Camshaft tappets, finger followers, and rocker arms have already seen significant penetration of roller use in order to improve valvetrain friction and allow the use of more aggressive valve events.

4.1.1.4 Advanced coatings. Several coatings throughout the engine have been evaluated for improved friction behavior. The most common coating used in the engine for improved friction and scuff resistance is a molybdenum disulfide coating, which is screen printed onto the piston skirt. Another coating that is receiving a lot of attention for its improved friction characteristic is diamond-like carbon (DLC). DLC is a coating that is formed and leaves a very hard and smooth surface on the part providing a very low friction coefficient. Several engines now employ DLC coating on surfaces that slide with only splash oil lubrication such as gudgeon pins and valvetrain parts.

4.1.1.5 Advanced lubricants. Advanced lubricants can also help improve an engine's frictional losses. Synthetic engine lubricants can provide improved friction features while simultaneously improving temperature capability. Friction is not the only requirement for these advanced engine lubricants, as features such as engine sensor compatibility and soot loading are also important and must be considered.

4.1.2 Accessories

Engine accessories can create a significant drag on the engine as shown in the friction strip measurements in Figure 6. Many of these components impart a load on the engine even when they are not in use. The parasitic

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

losses associated with conventional accessory drives, in combination with advanced fuel economy enablers such as start/stop and full hybrid powertrains, have driven significant changes to accessory drives.

Power steering pumps are one of the most common components to be removed from the accessory drive in conventional powertrain configurations. Conventional pumps bypass the fluid when the driver does not demand power-assisted steering. Although it is not pumping the fluid to a high pressure during this standby mode, hydraulic work is being conducted with no benefit to the driver. Electric power-assisted steering (EPAS) and electro-hydraulic power steering (EHPS) are replacing accessory drive power steering units. The power-assist feature is provided by an electric motor or hydraulic pressure generated by an electric pump. In either system, the electric motor operates only when commanded by the driver, thus eliminating the standby losses of a pump in the accessory drive.

AC compressors are also starting to be removed from the accessory drive and converted to electrical operation. Conventional compressors have a clutched pulley that eliminates all but the bearing friction within the compressor. Although converting mechanical energy from the crank to electrical energy through the alternator and then back to mechanical energy of the compressor is inefficient, it is necessary to enable other fuel-saving technologies such as stop/start (engine shutdown during prolonged idle to reduce fuel consumption) and full hybrid powertrains.

Some manufacturers have started using electrical coolant pumps to better match cooling demand to cooling supply. Conventional pumps provide coolant flow based on engine speed because of the direct couple to the engines' crankshaft. This means that a cooling system sized to provide cooling power at high load is oversized during low load conditions. An electric pump's speed is decoupled from the engine and has the ability to match the engine's cooling requirements independently, thereby eliminating the excess hydraulic work performed by a mechanical pump.

4.1.3 *Thermal management*

Advanced cooling systems can be employed to reduce engine friction and improve fuel economy. These systems include computer-controlled thermostats or electric cooling pumps to meter the coolant flow through the engine. This enables engine calibrators to allow the engine to run hotter during low load, which keeps engine oil hotter and less viscous while also allowing the engine to receive more cooling during high demand to protect the durability of the engine's structural components.

There are several configurations that can be used in an advanced cooling system to speed up the heating of engine and transmission fluids. These strategies can be particularly effective if the engine is equipped with an exhaust gas recirculation (EGR) cooler. In such a configuration, coolant is first circulated through the EGR cooler to absorb heat from the exhaust gas and then routed through the oil cooler where heat is then transferred to the oil. The reduced viscosity of hot oil reduces the friction of the engine during cold start operation and improves fuel consumption during this cycle.

4.1.4 *Idle*

The fuel an engine consumes while idling at a stop light is wasted, as the intent is strictly to keep the engine in standby mode. Start/stop strategies are now being implemented to reduce the fuel consumed during idle. The engine automatically turns off when the vehicle is stopped and then automatically restarts when the driver presses the accelerator pedal. Start/stop systems require a more robust starter motor and may require one-way clutches in the system, such as at the flywheel and alternator, to manage various inertias in the engine system.

4.1.5 *Lubrication system*

Similar to the cooling pump, the lubrication pump is sized for one or two key load conditions but is tied to the engine's speed. As such, the lubrication pump provides an oversupply of oil through much of the engine speed range. The lubrication pump is also sized for operation at maximum operating temperatures and maximum design tolerances (e.g., bearing clearance), which also implies that at normal operating temperature with normal tolerances, the pump capacity is larger than required. Two-stage and variable displacement lubrication pumps are sometimes employed to limit these losses. Two-stage pumps have two sets of pump elements in the pump body with the high capacity pump being used at low speeds and the low capacity pump being used at high speeds.

Variable displacement pumps are vane-type pumps, which use oil pressure to vary the eccentricity of the pump. These pumps automatically adjust to the lubrication flow rate required and are tuned by sizing a spring that determines the maximum oil pressure achieved by the pump. While vane-type pumps are inherently inefficient because of the size of the leak paths within the pump, these pumps can offer a significant overall improvement to the engines fuel economy.

4.2 Cycle efficiency

4.2.1 Atkinson cycle

A modified version of the cycle invented by James Atkinson has been developed in recent years. In this cycle, the intake valve is either held open longer or closed before BDC, such that fresh charge that is trapped in the cylinder is reduced by pushing some portion of the charge back into the inlet tract before the valve closes or reducing the charge pulled into the cylinder by cutting the intake event short thereby making the expansion stroke significantly longer than the effective compression stroke. This extended expansion stroke reclaims some of the lost work when the cylinder pressure is released to the exhaust system during the blowdown process. The effective compression ratio in this cycle is significantly lower than the geometric compression ratio because of the shortened compression stroke after the intake valve is closed. As such, the geometric compression ratio must be increased in order to mitigate the inefficiency caused by a lower compression ratio.

The reduced effective displacement of the engine needs to be mitigated to keep the power density at an acceptable level. Most applications using the Atkinson cycle are hybrids, which use the electric motor to augment the engine's power. It is possible, though, that application of variable valve timing in conjunction with a variable compression ratio system would be able to convert an Atkinson cycle engine with high geometric compression and late valve timing to a conventional Otto cycle combustion system for high load operation.

4.2.2 Miller cycle

Ralph Miller developed the Miller cycle to mitigate the power loss associated with the Atkinson cycle. In this cycle, a supercharger is used to boost the engine to power density levels of a conventional Otto cycle. The additional benefit that is realized with compressing the charge air outside of the cylinder is that the heat generated from the compression of the gas can be removed before it is ingested in the engine. As such, a higher cylinder pressure can be achieved at the conclusion of the compression stroke without the risk of knock in SI engines or increased NO_x production in CI engines.

4.3 Waste gas energy

The majority of lost energy from an internal combustion engine is the high temperature exhaust gas as shown in Figure 1. There are several strategies to recover some of the energy lost to the exhaust, the most common of which is turbocharging. The expansion of exhaust gas through a turbocharger spins a turbine wheel, which is attached to a compressor wheel that compresses the incoming intake charge. Turbochargers do increase the pumping work of the engine; therefore, they do not improve fuel economy by themselves but their ability to enable downsizing of the engine and higher thermal efficiencies because of higher in-cylinder peak pressures can provide a significant improvement in overall fuel efficiency.

Turbo-compounding operates under the same process as the turbocharger in the way it extracts energy from the exhaust. However, the shaft is not connected to a compressor wheel but is instead mechanically connected to the output shaft of the engine or, in some cases, can be connected to an electrical generator or hydraulic pump. For the systems realized to date, the friction of the system creates a drag on the engine at low loads but offers net positive work output at high loads. A beneficial turbo-compounding system has not been realized to date for automotive applications because of this effect but it has been found to be beneficial in heavy-duty trucking applications because of their duty cycle with extended high load operation.

4.4 Engine mass

Reduction in engine mass does not improve the specific fuel consumption of the engine but can play a role in the total fuel economy of the vehicle. Particular attention should be paid to the largest powertrain in the vehicle. Mass reductions for the heaviest powertrain in a particular vehicle will allow reductions to the vehicle structure, suspension, and braking systems, which compound the benefits that the engine can achieve on its own.

Downsizing the engine's displacement can have beneficial mass reductions as well depending on the level of downsizing. In particular, if the largest engine available in a vehicle can be reduced from a V8 to a V6 or a V6 to an I-4, the maximum powertrain mass that must be accounted for in a vehicle can be reduced and the vehicle mass reductions discussed earlier can be realized.

When considering mass reduction, materials are always the first consideration. Lightweight materials such as magnesium, composite plastics, and aluminum have seen significant penetration in modern automotive applications. Beyond this, several hybrid cylinder block and head construction concepts have been considered with some market penetration in recent years. These hybrid structures utilize a lightweight material for most of the component while using other materials for their strength or wear properties. Audi and BMW both have cylinder blocks in production that utilize an aluminum structure at the core of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

component but with a lightweight magnesium casing that encloses the engine structure for extreme weight reduction.

Mass reductions of components within the engine can make secondary mass reductions possible. In particular, piston and connecting rod mass reductions can reduce crankshaft mass because of reduced balance mass requirements. In addition, reduced reciprocating and rotating mass forces allow for reduced cylinder block structure, especially in high speed gasoline applications.

4.5 Hybrid strategies

Engines that are used in hybrid applications or as range extenders for electric vehicles are not required to have the same range of flexibility as those used in a conventional powertrain. This enables the powertrain to be tuned for a very narrow speed and load band. Valve events, intake and exhaust tuning, coolant pump sizing, and lubrication pump sizing can be optimized for fuel economy when the engineer is not concerned with the extreme or obscure load conditions required from conventional powertrains.

5 SI ENGINE-SPECIFIC ENABLERS

5.1 Throttling losses

SI gasoline engines exhibit several losses resulting in lower engine efficiency. The majority of the losses are based on throttling of the intake charge because of the quantitative engine load control principle. Load control through throttling of the intake charge leads to high pumping losses and a nonoptimized in-cylinder combustion process.

5.1.1 Exhaust gas recirculation

EGR as a means to reduce engine-out NO_x emissions on diesel engines was already introduced decades ago. Increasing the inert gas (CO_2) content with high specific heat capacity inside the cylinder, it results in lower in-cylinder peak temperatures and thus reduced NO_x emissions. Although a common technology for all automotive diesel engines exists nowadays, its application on gasoline engines has been limited. However, EGR can be used in SI engines to displace fresh air/fuel charge and allow for reductions in throttling losses and consequently result in reductions in fuel consumption. It can be assumed that, in combination with further future tightening of emissions legislation such as EU6 and LEV III, it will be utilized more and more on upcoming applications. In addition to exhibiting beneficial behavior at part-load conditions, EGR also shows significant advantages during high load conditions by mitigating knocking while simultaneously reducing fuel consumption due to drastically reduced enrichment requirement.

EGR can be introduced back into the cylinder either internally or externally. Internal EGR is achieved by holding both intake and exhaust valves open simultaneously, known as *valve overlap*, during gas exchange near TDC. For fixed valve timing, the amount of EGR induced is mostly a function of engine speed and load. However, as most modern gasoline engines are equipped with individually controllable exhaust and intake cam phasers, the overlap can be freely adjusted as a function of operating conditions allowing for the desired amount of EGR. Greater reductions in throttling losses are seen, as more EGR is drawn back into the cylinder. However, the amount of EGR that the engine is capable of operating with is limited. Each engine will reach a level of EGR dilution at which misfiring becomes prevalent, a condition that needs to be avoided under all circumstances. Generally, high rates of charge motion can increase an engine's EGR tolerance and the amount of throttling losses that can be mitigated using this method.

External EGR can be achieved taking advantage of the positive pressure differential between the exhaust and the intake systems. Connecting the exhaust with the intake using a pipe and an EGR valve to meter the amount of EGR is common. Depending on the application, an additional EGR cooler can be installed to reduce the EGR-diluted intake charge temperature. This countermeasure reduces the thermal throttling caused by heating and expanding the intake gas and thus maximizes performance.

5.1.2 Downsizing

As SI engines exhibit the biggest efficiency losses during part-load operation and most engines are operated under low part-load conditions for a large portion of their entire operating regime, one approach is to reduce engine displacement to raise engine load and thus improve engine efficiency. However, for a naturally aspirated (NA) engine, that would result in lower engine power and torque, which is unacceptable. Therefore, supercharging or turbocharging to make up for that loss in performance is applied. This process is called *downsizing*, where the engine displacement is reduced, in some cases, by approximately 50%, compared to a NA engine while increasing or at least maintaining engine performance of the NA engine. Appropriate downsizing, also often referred to as *rightsizing*, can result in fuel consumption reductions approaching 15–20% depending on the applicable drive cycle.

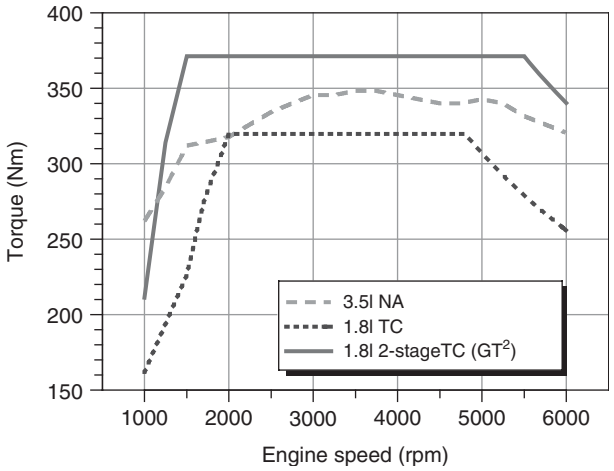

Figure 9. Performance comparison of a large naturally aspirated engine to that of two smaller turbocharged engines. (Reproduced by permission of FEV Inc.)

Meanwhile, turbocharged, direct-injected (DI) engines are able to achieve brake mean effective pressure (BMEP) levels above 20 bar currently with levels approaching 30 bar in the near future. This allows replacing 3-L class six-cylinder NA engines with 2-L class four-cylinder engines. To further optimize the entire full-load curve, two-stage turbocharging systems with intercooling are under development. These engines can provide excellent transient response behavior, high low-end torque and high rated power and torque over a wide range of engine speed for superior vehicle performance. In the near future, state-of-the-art two-stage turbocharged intercooled engines will be capable of specific power ratings of 100–120 kW/L and specific torque ratings of 180–200 Nm/L. Figure 9 depicts a downsizing example starting with a 3.5-L NA V6 engine compared to a 1.8-L engine with a single turbocharger and two-stage turbocharging.

Combinations of supercharger and turbocharger are possible and have already successfully been introduced into the market. This combination can provide superior transient response at low engine speeds because of the direct drive of the supercharger and may prove to be a good combination for large vehicles with downsized engines.

5.1.3 Lean burn concepts

5.1.3.1 Gasoline. In contrast to the conventional stoichiometric operating mode of the gasoline engine, the application of a lean-burn concept offers additional gains in engine efficiency because of de-throttling of the engine and increased peak pressures offering improved cycle efficiency. In general, distinction is made between lean-burn homogenous and stratified engines. While lean burn, in general, indicates an over-stoichiometric ($\lambda > 1$) engine operation resulting in excess oxygen in the exhaust, the stratified combustion system employs a local enrichment around the spark plug at ignition, whereas the homogenous lean-burn engine is using a globally constant in-cylinder $\lambda > 1$. The homogenous lean-burn engine can use either port fuel injection (PFI) or a direct injection (side or central DI) system. The stratified system, however, can only be realized using a centrally located injector close to the spark plug that develops a locally rich air–fuel ratio for ignition while the remaining charge throughout the remainder of the cylinder is significantly leaner.

Despite the significant efficiency advantage of a lean-burn concept, the change in emissions treatment is substantial, as the standard TWC commonly used to treat gasoline engine emissions cannot be applied. Although the engine-out hydrocarbon (HC) and carbon monoxide (CO) emissions are lower based on the excess oxygen in the exhaust, the amount of NO_x is increased. In addition, a typical three-way exhaust catalyst is relatively efficient at oxidizing HC and CO emissions with lean mixtures, whereas the NO_x reduction efficiency is nearly zero when operating lean. Therefore, for stratified engines, a separate NO_x reduction aftertreatment device is essential. Over the past years, two systems, the selective catalytic reduction (SCR) system using urea as a reductant and the lean NO_x trap (LNT), also often referred to as *NO_x absorber catalyst* (*NAC*), have been developed and successfully applied. Both systems have already been successfully used in diesel engines, whereas the LNT has been used in some lean-burn gasoline production engines.

Although the emissions can be reduced to the required legislated levels, the issues of increased cost and overall efficiency gain are subject to further refinements, as the LNT needs to be kept at operating temperature (above "light-off") to ensure proper reduction of the NO_x. This requires the engine management system to artificially raise exhaust gas temperature by inducing inefficiencies such as spark retardation or early exhaust cam phasing. This effect is more pronounced with lower base exhaust gas temperature levels. Therefore, catalyst heating is required more often for less-aggressive drive cycles, diminishing the advantage of the lean-burn concept. In addition, the LNT technology requires extremely low fuel sulfur content, as fuel sulfur in form of sulfates occupies the receptive catalyst sites in the LNT; therefore, rendering it useless over time. As a result, desulfation is required to remove the sulfur from the LNT during a rich and high exhaust gas temperature operating period. Again, this operating point utilizes fuel energy to clean the LNT further reducing the efficiency

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the concept. Reduced sulfur fuel may provide a future solution for lean-burn concepts.

Much like current diesel engines, SCR systems might find their way into the market place for gasoline engines as well. However, it is not known if the requirement of the driver to periodically refill the reductant tank with separate fluid will achieve widespread market acceptance in all markets.

Although it is desired to operate the engine as lean as possible for efficiency reasons and the side effect that with increasing excess air, beyond λ of 1.2, the NO_x engine-out emissions start to decline drastically, misfiring begins to limit the capabilities of the combustion system as the lean threshold is approached. Increased charge motion and higher ignition energy can help push the threshold but engine operation above relative air–fuel ratios of 1.5 remains challenging.

Another combustion system modification required because of lean engine operation is related to the ignition system. Owing to the increased in-cylinder gas pressure levels (especially in case of turbo- and supercharged engines), the energy level at the spark plug is higher to ensure proper spark and thus combustion initiation. This necessitates a different, high energy system and special spark plug materials (e.g., iridium electrodes) to minimize electrode erosion because of the increased spark energy.

5.1.3.2 Compressed natural gas. Compressed natural gas (CNG) due to its global availability in large quantities and its excellent fuel properties for SI engines represents a beneficial alternative to gasoline. Especially, owing to its high knock resistance and the superior mixture formation, CNG is gaining importance. CNG is also a very suitable fuel for lean-burn concepts. As most CNG automotive applications use port injection systems, only homogenous lean-burn concepts can be found in the market place. However, it can be expected that future DI CNG injectors will also allow for stratified lean-burn configurations further pushing the lean operating limit and overall engine efficiency.

5.1.4 Cylinder deactivation

Reducing the number of active cylinders when an engine is at part load allows for the remaining cylinders to provide the same amount of power, but at a reduced level of throttle. Deactivation of the cylinders is accomplished in both overhead cam and pushrod engines by allowing lost motion in the valvetrain. Either collapsing finger followers for overhead camshaft engines (OHC) or collapsing tappets in overhead valve engines (OHVs) are activated and deactivated with pressurized engine oil to control the actuation of the valves. Controlling cylinder usage by means of valvetrain actuation allows for the deactivation of the cylinders without the pumping losses that would remain if deactivation were to be enabled simply by fuel cutoff.

Considerations for engine balance tend to lead to deactivation of half of the total engine cylinder count. As such, the load requested from the engine must be less than half of the total engine output and some additional coverage to allow for seamless transition from deactivated to fully operational cylinder counts in order for the engine to operate with deactivated cylinders. Engine vibration at idle with cylinders deactivated typically exceeds the comfort level of most customers in developed markets. Thus, full engine operation is typically required at idle, which further limits the utilization range of cylinder deactivation. As the operating window is narrowed by these considerations, the effectiveness of cylinder deactivation on engines with smaller cylinder count becomes smaller making cylinder deactivation a better option on V8 and V6 engines than on I-4 configurations.

5.1.5 Fully variable valve lift and duration

A significant amount of development effort has been invested in the development of fully variable inlet valve lift and duration known as *variable valve lift* (*VVL*). There are electromechanical, hydraulic, kinematic, and pneumatic systems being developed or on the market. There are several advantages to having real time control over intake valve motion. In a conventional, mechanical camshaft valvetrain, inlet valve lift and duration are fixed by the profile of the camshaft. This profile is a compromise between the desired events at high and low engine speeds and high and low engine loads. At high engine speeds and loads, it is desired to keep the intake valve open longer and at higher lift for more complete cylinder filling. This is contrary to the short duration and low lifts desired at idle.

With some fully VVL systems, the intake valve movement is not limited to a single event per combustion cycle. Instead, a second lift event can be included to increase in-cylinder turbulence and enhance fuel mixing and combustion speed or increase the amount of internal EGR.

Another use of VVL is to reduce or eliminate the intake air throttle and reduce the throttling losses of the engine. As discussed in Section 3.1, work is performed by the piston at low loads, as it pulls intake charge through the open inlet valve. The difference in pressure between the throttled intake manifold and positive crankcase pressure generates the pumping loop shown in Figure 3. The piston conducts the work throughout the intake stroke. With a VVL system, the valve can be opened for a short duration at the beginning of the intake stroke allowing the pumping loop to resemble

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the engine at full load. Once the appropriate amount of mass is induced, the intake valve is closed and the piston begins to perform negative work, as it expands the gas during the final travel to BDC. As such, the average cylinder pressure throughout the intake stroke is higher than during for a conventionally throttled engine.

5.2 Combustion efficiency

5.2.1 Compression ratio

As shown in Equation 1, the maximum potential efficiency of an SI engine is limited by the compression ratio. Therefore, it is important to maximize the effective compression ratio of the engine in order to achieve the highest possible engine efficiency. This section outlines some key parameters to consider when attempting to maximize an engine's compression ratio.

5.2.1.1 Combustion chamber design. Besides some three-valve and five-valve exceptions, the majority of current gasoline engines are four-valve engines with a central spark plug in a pent-roof type combustion chamber arrangement. With two intake valves on one side and two exhaust valves on the other side, a thermal gradient across the cylinder head is inevitable. Therefore, in order to maximize the compression ratio of the engine, cooling of the combustion chamber must be considered during the design phase of the engine to avoid hot spots in the combustion chamber and mitigate knocking.

The central spark plug location is also beneficial for maximizing the engine's compression ratio. The central location allows for basically identical flame propagation distance in each direction fostering a stable combustion. As the flame travels through the combustion chamber, the charge mixture that is farthest from the spark plug, known as *end gas*, absorbs heat from the combustion process and is exposed to higher pressure in the combustion chamber. As this gas absorbs heat and is compressed, it becomes more susceptible to self-ignition. Shortening the time it takes for the flame front to reach the end gas reduces this risk and allows the compression ratio to be increased relative to noncentralized spark plug engines. Regardless of plug location, it is of utmost importance to provide sufficient cooling to the spark plug to avoid overheating of the plug and providing a preignition source.

5.2.1.2 Exhaust system. Besides the combustion chamber geometry, the intake and exhaust port geometries play an important role. Focusing on scavenging of the combustion chamber, some newer integrated exhaust manifold designs combine the cylinder head and exhaust manifold and provide reduced resistance in the exhaust port. By doing so, reduced levels of residual gas are retained in the cylinder during full-load operation thereby reducing the overall charge temperatures and risk of engine knocking.

Another option for the exhaust system is to utilize long primary exhaust runners. Long runners allow for the cylinder exhaust process to occur without interference from pressure waves of the adjacent cylinder. The high pressure waves from an adjacent cylinder beginning the exhaust blowdown process can force hot exhaust gas back into a cylinder that is trapped by a closing exhaust valve. This process increases the charge temperature for the next combustion cycle requiring a lower compression ratio.

5.2.1.3 Intake system. On the intake side, the port geometry is crucial in terms of charge motion generation allowing for stable combustion over the entire engine operating map. Designing the port for optimized tumble motion and high in-cylinder flow velocities, resulting in fast combustion and high EGR tolerance while in combination with the piston top design preserving the charge motion until ignition occurs, is the prime focus of each combustion system development effort. The increased combustion speeds created by high charge motion reduce the amount of time available for end gas heating and allow for higher compression ratios.

5.2.1.4 Variable compression ratio systems. The engine's compression ratio is an important parameter defining the efficiency, performance, NVH behavior, and engine-out emissions. While under cold start and part-load operations, a high compression ratio is desired. However, high compression ratios limit the full-load performance, as it promotes knocking at higher loads requiring enrichment of the air–fuel ratio ($\lambda < 0.9$) and ultimately leading to severe efficiency losses. Therefore, the compression ratio for each application needs to be selected very carefully because of these compromises.

As the compression ratio always represents the best acceptable compromise between efficiency and performance, it is even worse considering flex-fuel applications such as E85 or CNG. In that case, despite the fact that a much higher compression ratio could be employed delivering much higher engine efficiencies, the engine will be operated at the same low compression ratio as designed for operation with gasoline only. Thus, a conventional fixed compression ratio engine cannot take advantage of the significantly lower knock sensitivity of E85 or CNG.

Considering upcoming CO_2 emission limits worldwide and fuel consumption regulations, one major technology considered for future applications are mechanisms capable of varying the engine's compression ratio. This technology,

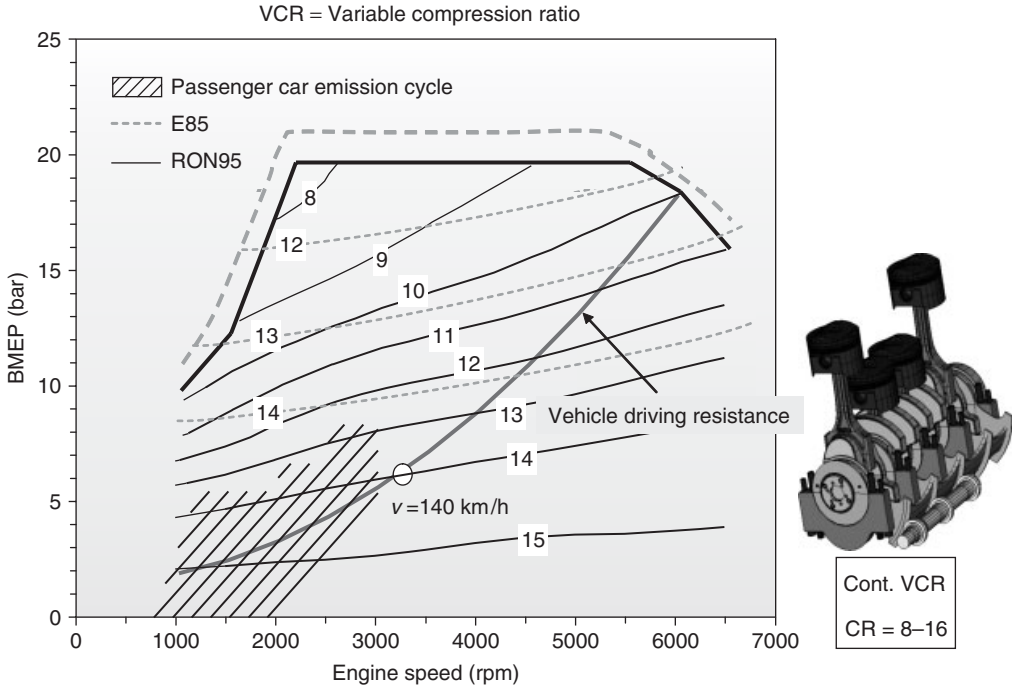

Figure 10. Ideal compression ratio based on engine load and speed illustrating the benefits of a variable compression ratio mechanism. (Reproduced by permission of FEV Inc.)

in combination with downsizing, allows for fuel consumption reductions up to 25% compared to a NA engine configuration of identical performance. In addition, it offers improvements to cold start behavior, cold start emissions, reduced or eliminated enrichment during high load, and more optimal operation on alternative fuels. An illustration of a VCR system and associated capability is shown in Figure 10.

In addition, by dynamically optimizing the compression ratio during engine operation, the EGR tolerance and thus emissions and fuel consumption can be further improved during part- and full-load conditions.

5.2.1.5 In-cylinder temperatures. Advanced cooling system technologies such as electrified thermostats and electric water pumps offer further potential for reduction of fuel consumption. By allowing the cylinder liner to run hotter during part-load operation, but increasing cooling capacity during high load conditions, it is possible to increase the compression ratio beyond that of a fixed, mechanical cooling system.

Another possibility to mitigate knocking and increase the engine's compression ratio is spray bore liner technology. Here, the cast iron liners used in most aluminum cylinder blocks are removed and replaced with a thin coating that provides better heat transfer between the in-cylinder gases and the cooling jacket. This ultimately reduces the heat-up of the fresh intake charge during the intake stroke and also improves heat removal during the compression stroke. Both effects assist in mitigating knock and allow for increased compression ratios.

5.2.1.6 Fuels. The fuel used in an SI engine is probably the easiest method for achieving higher compression ratios. Higher octane-rated fuels are less prone to autoignition and can tolerate higher temperatures associated with higher compression ratios. The issue, however, is market acceptance of purchasing higher cost fuels for the vehicle. Therefore, countermeasures must be made to protect the engine should an insufficient octane fuel be used by the end consumer. In case the octane rating of the fuel is insufficient, modern engines are equipped with a knock sensor as a part of the engine management system that will retard spark timing to mitigate knocking.

6 CI ENGINE-SPECIFIC ENABLERS

In comparison to the gasoline engine, the diesel engine due to its lean operating mode, higher compression ratio, and the unthrottled operation has major advantages making it the most efficient combustion engine available on the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

market. On the basis of these advantages, it can be found in applications ranging from small passenger cars up to large bore engines for ships, power generation, and other industrial applications. However, in contrast to gasoline engines, cleaning the exhaust of a diesel engine is significantly more challenging. Thus, the majority of the effort in diesel engines is the development of the combustion system to produce fewer engine-out emissions and the development of aftertreatment systems that minimize their impact on engine efficiency.

6.1 Efficiency

6.1.1 Combustion system

Each combustion system applied in a certain market must be engineered to comply with the corresponding regulatory agencies. Differences in fuel properties such as biodiesel and sulfur content and cetane number can have a huge impact on how a combustion system is configured and optimized. Therefore, implementation of an in-cylinder pressure sensor in combination with a glow plug can improve the adjustment to different fuel properties and thus help optimize the efficiency of the engine. Diesel fuel sulfur content is low in Western Europe and North America (<10 ppm in both cases), whereas other markets, especially in developing countries, exhibit significantly higher sulfur concentrations requiring hardware and calibration changes. Meeting future, more stringent, emission standards will require ultra-low sulfur diesel (ULSD) fuel worldwide in order to not jeopardize the sulfur-sensitive exhaust aftertreatment systems. In contrast to sulfur content, the cetane numbers between Europe and North America are very different. With the European norm EN590 requiring a cetane number of at least 51, the US market 2D fuel requirement is between 40 and 50 according to the EPA (Environmental Protection Agency). In addition, California requires a range between 47 and 55. In order to avoid excessive white smoke emissions (unburned HCs) during engine start and simultaneously improve cold start capability, the compression ratio as a part of the combustion system must be chosen very carefully. While a high compression ratio is desired for good starting behavior defined by low emissions, fast start-up, and low noise, the compression ratio is desired to be lower at higher loads and speeds to limit pressure and production of NO_x emissions.

6.1.1.1 Compression ratio. Although a higher compression ratio is usually beneficial with respect to engine efficiency, it results in high in-cylinder peak pressures and undesired high NO_x formation at higher engine speeds and loads, especially for high output downsized engines. Therefore, the right compromise, considering all aspects in terms of performance, emissions, fuel consumption, NVH, and fuel properties, is crucial. Current development efforts are also looking at variable compression ratio mechanisms, which allow for the optimal compression ratio to be selected as a function of engine speed and load. With such a mechanism in place, all the trade-offs described earlier could be eliminated.

6.1.1.2 Intake system. Minimizing the pressure loss in the intake system in order to maximize the air throughput, it is desired to provide the highest amount of air to fully oxidize (combust) the fuel injected on a per-cycle basis and minimize pumping work. However, the charge motion generated in the intake port is as important as the quantity of air provided. The design of the usually separated intake ports in case of a four-valve engine configuration is usually split into a swirl port and a filling port to achieve the best compromise. Charge motion is required to assure sufficient mixing inside the cylinder before and during combustion to optimize combustion efficiency and minimize emissions. The overall swirl level has been slightly reduced over the past years, as the higher injection pressures available in modern diesel fuel systems promote improved mixture preparation. Lower required swirl levels allow for higher flow ports that improve volumetric efficiency and power density and reduce pumping losses in comparison to more restrictive high swirl ports.

To further enhance the charge motion with minimal flow penalty is to incorporate an offset chamfer at the intake valve seat. This offset chamfer, often referred to as a *swirl chamfer*, promotes swirl at low valve lifts during the initial opening and especially closing of the intake valve. This has proven to be a very effective measure to improve mixture preparation, combustion, and thus fuel efficiency. In combination with a VVL system, this approach can result in not only significantly improved combustion efficiency but also lower emissions.

6.1.1.3 Fuel spray and piston crown. The piston crown geometry and injector spray pattern have a major influence on the combustion efficiency and emissions performance of the engine. The interaction between the fuel spray and the combustion bowl in the piston need to be developed simultaneously to achieve the best possible combination. Such systems are typically developed analytically during the early stages of engine development but test hardware must be used to confirm the final selections.

6.1.1.4 Exhaust system. To further improve the overall efficiency, the backpressure generated by the typical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto152
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

exhaust components such as piping and muffler in combination with the required aftertreatment components such as diesel particulate filter (DPF) and LNT or SCR needs to be minimized to avoid unnecessary pumping work.

6.1.2 *Aftertreatment system effects*

Meeting regulated emission standards worldwide has become a challenging task for automotive diesel engines because of the lean operating mode and the particulate matter (PM) contained in the exhaust emitted. However, the applied aftertreatment system technology can require additional engine operation modes, increase the total backpressure of the exhaust system, and require additional fuel injection events. All can increase the total amount of fuel consumed.

With the initial introduction of diesel oxidation catalysts (DOCs) in combination with DPFs in the European and the US markets exhibiting PM filtration efficiencies of 95% and higher, the PM emissions can be contained within the regulated limits. Further reductions can be expected to be achieved based on continuous improvements in DPF technology related to parameters such as materials (ceramic vs metal based), porosity, and pore size. As the backpressure and subsequently also the fuel consumption increase due to PM trapped in the DPF, the ECU will enforce periodic filter regeneration. During that process, the engine management system demands a secondary injection inside the cylinder later in the expansion cycle. By generating an exotherm across the DOC to provide a sufficiently high exhaust gas temperature level to oxidize the PM trapped in the DPF, the backpressure will (in case of a successful regeneration) return back to the original value. Depending on the regeneration strategy, the entire exhaust system layout in terms of heat losses (insulation) and location, potential catalytic coating inside the DPF, the consistency of the trapped PM, and the potential use of a fuel-borne catalyst to reduce the soot ignition temperature define the loss in efficiency due to the regeneration. Current development efforts continuously improve the efficiency of the DPF system focusing on areas such as active and passive thermal managements as well as DPF materials and substrates. Further losses that need to be accounted for are based on potential oil dilution caused by the late (post) in-cylinder injection to provide sufficient HC molecules needed to generate the exotherm across the DPF. On the basis of the nozzle layout, the rail pressure applied, and the injection timing, it is of utmost importance to minimize oil dilution to the highest possible extent.

In addition to the PM emissions, the stringent NO_x emissions pose another challenge to vehicle manufacturers. In order to meet these limits, two different systems have been established in the marketplace, SCR catalyst and LNT. Requiring a reductant in the form of liquid urea, which is injected into the exhaust stream upstream of the SCR catalyst, this system can achieve NO_x conversion ratios well above 90%. However, a separate tank system aboard is required to provide the urea in its demanded quantities. By comparison, the LNT system does not rely on another liquid but utilizes the diesel fuel already aboard to regenerate the LNT by temporarily enriching the exhaust. With the LNT directly using diesel fuel to regenerate, the LNT system exhibits a loss in efficiency. In comparison, the SCR catalyst uses a separate fluid to allow meeting the NO_x standards and does not require additional fuel heating for regeneration. In both cases, the efficiency is reduced because of the increased backpressure caused by the flow-through catalyst substrate and the fuel/reductant necessary to reduce NO_x to required levels. Owing to the overall stringent NO_x emission targets, a further advanced beginning of injection (BOI) to gain efficiency can unfortunately not be realized as BOI retardation (resulting in deteriorated efficiency), application of EGR, and NOX aftertreatment means must be combined in order to achieve NO_x tailpipe emission levels that are safely below the mandated limits.

EV Auxiliaries

Gang Jin and Yuefeng Liao

BAIC Motor Technology Center, Beijing, China

1 INTRODUCTION

In a conventional vehicle equipped with an internal combustion (IC) engine, power generated by the engine is transferred to the various auxiliary systems through different mechanisms. As shown in Figure 1, the high power consumption, continuous operation devices such as alternator, hydraulic power-assisted steering (HPAS) pump, air conditioning (AC) compressor, and engine coolant pump are directly driven by the auxiliary belt off the engine crank shaft. The alternator converts the kinetic energy into electricity that powers various electrical loads and charges the 12V onboard battery. The vacuum incurred by the engine intake system[1] provides the assisted brake force through the brake booster. Finally, a portion of the residue thermal energy from the combustion process is transferred to the HVAC heating core through the engine coolant circulation system and heats up the passenger compartment.

For electric vehicles (EVs), the energy source is changed from liquid fuel to rechargeable battery and the power generating device from the IC engine to the electric motor. As the energy density of the battery is significantly lower than that of the liquid fuel, major design changes must be made in order to maximize the energy utilization efficiency to achieve commercially viable driving range and operation cost. The design shall also observe the current state of the art that (i) the electric motor has much higher energy conversion efficiency (around 85–95%) than that of the IC engine (around 20–30%); (ii) the transfer of energy, including routing and buffering, can be more efficiently conducted via the electrical path than the mechanical links (belts, hydraulic, or pneumatic circuits); and (iii) the precision control of the actuation dynamics, for example, power on demand and fast transient that help to conserve energy, can be more easily achieved by dedicated electrical actuators than direct mechanical links.

A typical architecture of the EV auxiliary system is shown in Figure 2. The traction battery pack provides the main source of energy to the auxiliary system in the form of high voltage electricity (typically 200–400 V). The high voltage is a prerequisite for driving efficiency of the traction motor and other high power consumption devices (typically over 1000 W) such as the AC compressor and the PTC (positive temperature coefficient) heater of the HVAC system.[2] The direct current to direct current (DCDC) converter converts the high voltage electricity to 12 V that powers the conventional electric power net. This enables the carryover of vast electric components designed for the conventional vehicles, for example, lighting, infotainment, and power convenience that typically consume less than 100 W of power and can be safely powered by the 12 V net. For devices that consume a few hundred watts of electric power,

	Power brake	A few percentage	
Body	Power convenience	A few percentage	Depending on use
	Lighting and infotainment	Up to 10%	

for example, engine cooling fan, HVAC blower, EPAS (electric power-assisted steering) motor, and brake booster vacuum pump, EV adaptation offers the opportunities to move these devices to the high voltage power net for better energy efficiency (Shiraki *et al*., 2012). This, however, is still largely under research investigation because of high voltage safety concerns and the currently achievable cost versus performance balance.

This chapter presents an overview of the EV auxiliaries with a focus on subsystems or components that are unique or have major changes over the conventional vehicles, namely the DCDC converter, the HVAC system, and the electric-driven vacuum booster and EPAS motors. As these devices consume (or conduct) a few hundred to a few thousands Watts of power, their impact to the EV driving range can be significant. An estimate is provided in Table 1. The theme of the system design shall then be centered on energy efficiency subjected to safety and cost constraints that align with the design of the total EV. This should be apparent from the subsequent discussions.

2 DCDC CONVERTER

The EV has a 12 V auxiliary battery to operate the lights, radio, and other equipments. The 12 V battery in a gasoline-powered vehicle is recharged with an alternator driven by the engine. In an EV, the auxiliary battery is recharged with the use of a DCDC converter with power from the high voltage battery pack. The conversion efficiency of today's state-of-the-art DCDC converter is above 90% with an output power rating typically around a few thousands Watts. This compares to about 70% for the alternator in a conventional vehicle with the same power rating. Considering the additional power loss to generate the kinetic energy to drive the alternator, the packaging constraint, and the additional weight of the alternator, it is apparent that the DCDC converter is a more efficient solution to power the 12 V net directly from the traction power net.

2.1 Typical DCDC converter topologies

Over the past few decades, many topologies have been developed for DCDC converters to suit the special needs of different applications (Gu, Lu and Qian, 2004). For EVs, the DCDC converter must satisfy a few baseline requirements. First, it must provide galvanic isolation from the high voltage source to the low voltage output for safety concerns. Second, it must have high conversion efficiency of at least 80% and preferably above 90% over a wide operation load range. Third, it must meet the stringent environmental, EMC, and reliability requirement for automotive applications.

The most commonly used DCDC converters for EV applications have the basic configuration as shown in Figure 3. After passing the high voltage filter to suppress high frequency noise, the DC current is converted to AC current by means of a switching circuits typically operating at tens to hundreds of kilohertz. This AC signal is down converted from high voltage to low voltage by a transformer with an $n:1$ ratio between the primary and the secondary windings. The down converted AC signal is then rectified and passed through the low voltage filter to feed the low voltage load. With proper design, the output voltage can be precisely controlled by the duty cycle of the switching circuits for a wide range of input voltage and output load. The transformer provides the required galvanic isolation between the high voltage input and the low voltage output. The power density and the conversion efficiency largely depend on the circuit design for the DCAC inverter and the ACDC rectifier and the selection of switching components and the transformer.

Depending largely on the design of the DCAC inverting circuits, different topologies for the DCDC converter have been proposed. Here, two types of topologies that have seen most applications in EV DCDC designs are briefly introduced. Figure 4 shows the configuration and key operation waveform of a *single end forward* DCDC converter.

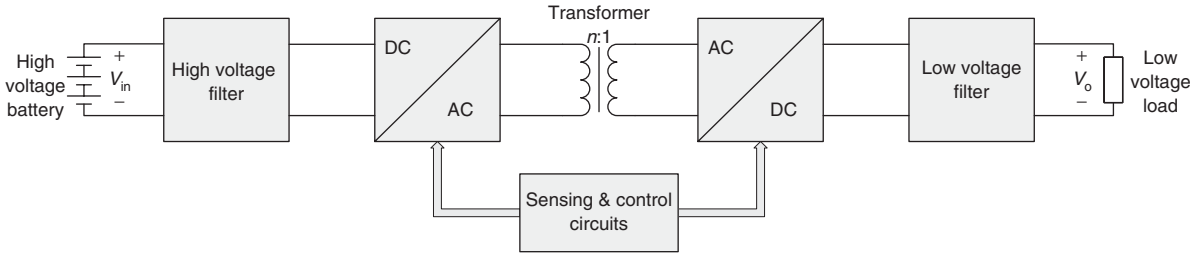

Figure 3. Basic DCDC converter configuration.

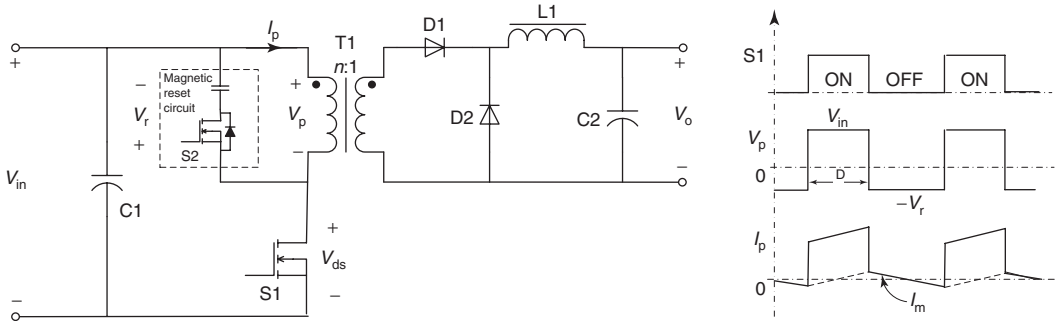

Figure 4. Single-ended active clamp forward DCDC converter.

In this type of converters, only one main switch S1 is employed on the primary side of the transformer. When the switch S1 is turned on, the transformer primary winding is connected to the input voltage V_{in} and energy is transferred from the input source to the output load through the transformer. When the switch S1 turns off, the transformer primary winding is connected to a magnetic reset circuit that applies a negative voltage $-V_r$ to the primary winding and resets the magnetizing current I_m. There are different ways to design the magnetizing reset circuits, for example, by an auxiliary winding or by an active clamping circuits as shown in the figure. In the latter design, the switch S2 turns on and off out of phase with S1 to provide a recirculation path for the magnetizing current. As the transformer primary winding is alternatively applied with V_{in} with duration of DT, and with $-V_r$ with duration of $(1-D)T$, where D represents the duty cycle and T the switching period, the following equation must be true in order to maintain a balanced current in the primary winding when the DCDC operates in stationary mode

$$V_{in}DT = V_r(1-D)T \tag{1}$$

This leads to

$$V_r = V_{in}\frac{D}{1-D} \tag{2}$$

It can be seen that when the duty cycle D approaches one, the clamping voltage V_r could be very large compared to V_{in}. For this reason, the main switch S1 must be designed with a sufficiently high blocking voltage ($>V_{in}+V_r$) for this type of topology or the control duty cycle D must be limited. As no power is transferred to the secondary side of the transformer when S1 is open and the current recirculates through S2, the power output of this type of converter is limited (typically up to a few kilowatts).

Now on the secondary winding side of the transformer, when the main switch S1 turns on, the diode D1 becomes positively biased and conducts the current through the low frequency passing filter circuit to the load. When S1 turns off, D1 becomes negatively biased and blocks the current in the secondary winding. As a result, D2 turns on to provide the recirculation path for the inductor L1 current. During stationary operation, the inductor L1 must maintain a balanced current flow that implies that

$$\left(\frac{V_{in}}{n} - V_o\right)DT = V_o(1-D)T \tag{3}$$

This gives to

$$V_o = \frac{V_{in}}{n}D \tag{4}$$

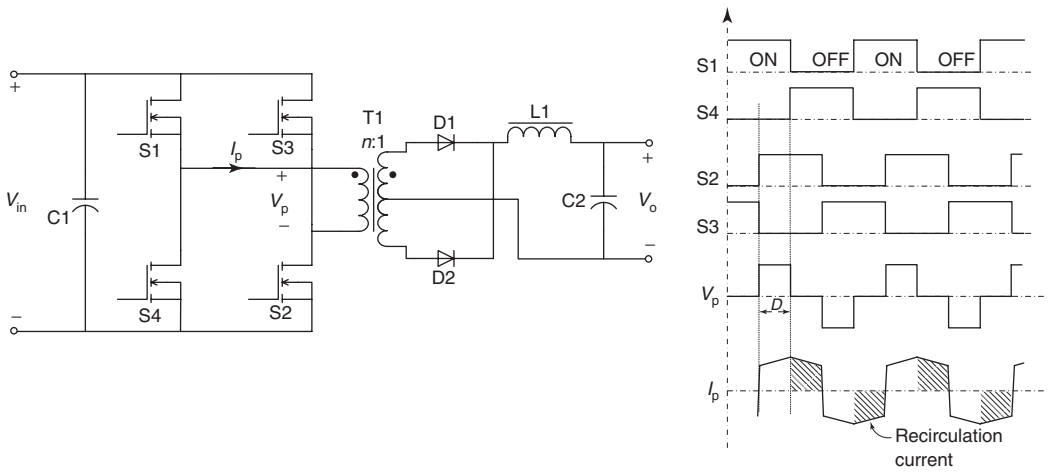

Figure 5. Phase-shifted full-bridge DCDC converter.

Thus, the output voltage can be changed by linearly adjusting duty cycle D based on the input voltage V_{in} and the primary over secondary winding ratio n.

For increased power output, the DCDC converter can be designed with a full bridge topology on the primary side inverting circuits.[3] The commonly used *phase shift full bridge* topology is shown in Figure 5. In this configuration, the primary winding is connected to the center point of the two half bridges formed by S1–S4 and S3–S2 respectively. When the transformer operates in the stationary state, there are four primary modes of operation: (1) when S1 and S2 are turned on, the primary winding is connected to the power input V_{in} and the primary current I_p is positively charged up; (2) when S1 turns off and S4 turns on, the primary winding is shorted (both sides connected to ground) and the primary current recirculates; (3) when S2 turns off and S3 turns on, the primary winding is *reversely* connected to power input V_{in} and the primary current I_p is negatively charged up; and (4) when S4 turns off and S1 turns on, the primary winding is shorted (both sides connected to power input) and the primary current recirculates. It should be noted that the minimum required blocking voltage for the four main switches is V_{in}, which is lower than that of the single-ended forward DCDC converter.

On the secondary winding side, the reflected current flows through diode D1 to the load during mode (1) and mode (2) and through diode D2 during mode (3) and mode (4). However, only during mode (1) and (3), power is transferred from the power input to the load, and thus the combined duration of mode (1) and (3) over the total switching period (all four modes) defines the effective duty cycle D. The input to output voltage map can be similarly derived as that of the single-ended forward DCDC converter; in fact, it takes the same form as that of Equation 4.

It is noteworthy that there are multiple ways to improve the efficiency of the DCDC converters by optimizing the circuit design on either side of the transformer. On the primary side, the most widely used technique is the so-called *zero voltage switching* (ZVS) where the main switches are turned on and off when the voltage across it passes through zero. This minimizes the switching loss and the electromagnetic emission, which is essential for high switching frequency operation. On the secondary side, low impedance active switches, for example, power MOSFET, can replace the passive diodes that turn on and off in synchronous with the main switches on the primary side to rectify the output current. This *active synchronous rectification* is especially effective when the regulated output voltage is relatively low compared to that of the diode voltage drop. Both techniques have seen wide applications in EV DCDC converter designs.

2.2 Key DCDC converter design parameters

To select a proper DCDC converter for an EV application, its key design parameters must be carefully examined. In this section, we review the parameter design based on a real-world application. The Beijing® E-150 is a pure electric compact sedan launched in 2012. The DCDC converter selected for this vehicle is a Dilong® DZEH2000S9 series product designed especially for EV applications. As shown in Figure 6, the DCDC converter is packaged in the engine compartment along with the traction motor, the inverter, the ACDC charger, and other auxiliary systems.

Refer to Table 2 for a list of the DCDC converter's key parameters and specifications. The first group of parameters

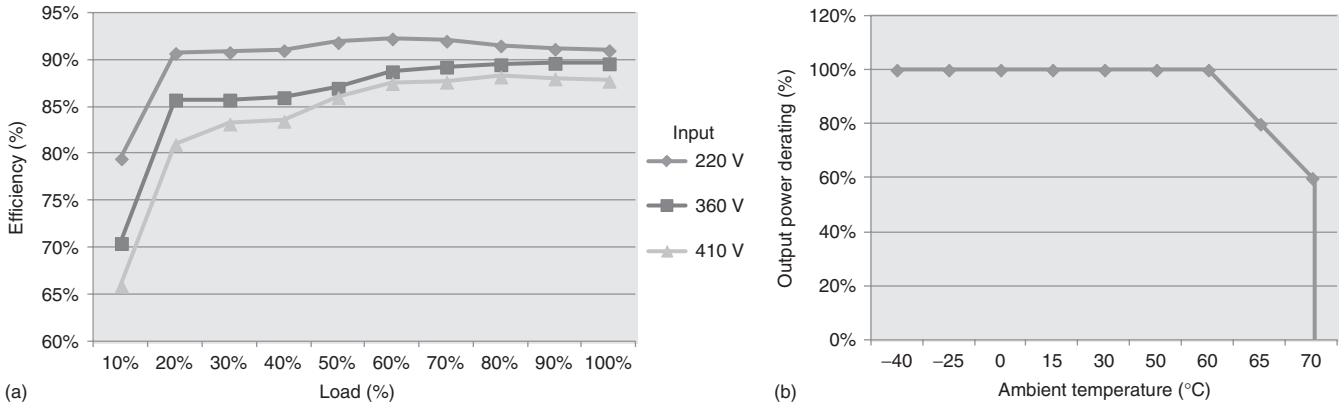

Figure 7. (a,b) DCDC converter efficiency and output power derating.

specifies its electrical performance. It supports a wide input voltage range from the traction battery (from 220 to 410 V) to ensure maximum achievable driving range. The output is precisely regulated at 14 V to feed the conventional low voltage power net. The rated output power is 2000 W with an efficiency rating around 90% under high load conditions. To achieve the aforementioned design performance (wide input voltage range, high output power, and high conversion efficiency), it employs the phase-shifted full-bridge topology as introduced in the previous section with ZVS technology. It should be noted that to ensure robust and reliable operation, the output power must be properly derated based on ambient temperature (Figure 7b). The ambient temperature directly aggravates the operation temperature of the heat-generating devices within the DCDC converter and hence under high ambient temperature condition, the output power shall be properly reduced to limit the internal rise of temperature. Furthermore, the conversion efficiency highly depends on input voltage and output power loading conditions (Figure 7a). With the increase of the input voltage and the decrease of the output power, the conversion efficiency can be significantly reduced.[4]

The DCDC converter must also be protected from inadvertent conditions such as abnormal input/output voltages and an internal temperature exceeding the range of safe operation. In addition, the input, output, and the DCDC converter enclosure must be electrically isolated for operation safety. This is measured by the leakage current when a high voltage potential is applied between input and output of the converter and by the insulation resistance.

Finally, the DCDC converter must be designed to operate properly in the environment where it is packaged inside the vehicle and the environment where the vehicle will be operated. This relates not only to the ambient temperature as mentioned earlier but also to the electromagnetic interferences,[5] mechanical loading (e.g., vibration and shock), foreign material ingression (e.g., water, dust, and chemicals), and other environmental conditions.[6] For under hood installation, a minimum ingression protection rating of IP66[7] is required. With a sealed enclosure, the DCDC converter is cooled by nature air convection. This limits its heat transfer efficiency and hence requires large area of heat sinks (Figure 6). Liquid cooling can be designed but with the added complexity of coolant circuit construction.

2.3 DCDC converter design trend

To meet the stringent requirements for EV applications, the design of DCDC converters continuously evolves. This includes the invention of new topologies to achieve multiple design objectives, for example, wide range of input voltage, minimum voltage stress on the switches, high effective switching duty cycle, and soft switching for the main switches to achieve maximum conversion efficiencies for a wide range of operation conditions (Zhang, Huang and Gu, 2002). Innovative products are engineered and commercialized that have unique internal architect to enable new features and functions, for example, multiple voltage outputs for multiple power nets, and bidirectional conversion for fuel cell EV (Su and Peng, 2005). In addition, to maximize the volume efficiency and simplify the high voltage wiring harness design, the DCDC converter and other power electronics, for example, the traction motor control inverter and the onboard household charger, are increasingly integrated together in an EV application. For example, the VW Golf EV boasts an integrated traction motor control inverter with DCDC converter installed in the engine compartment. The Mitsubishi i-MiEV has an integrated onboard charger with DCDC converter. The Beijing E-150 is also fitted with an integrated power module of onboard charger and the DCDC converter (Figure 8). The

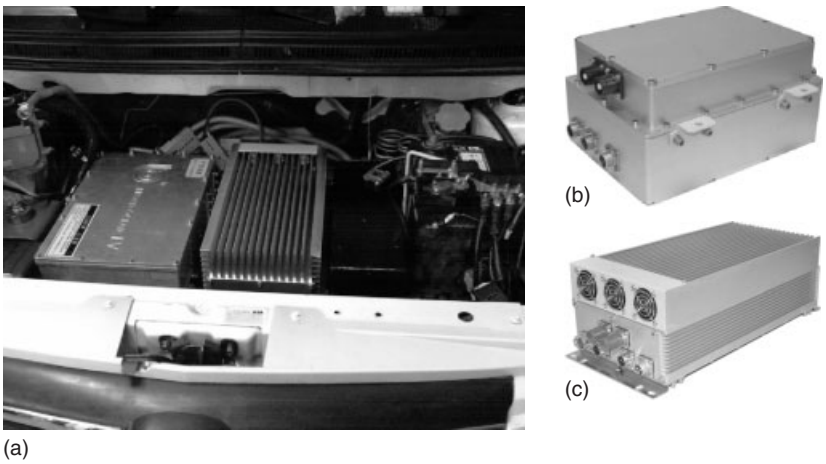

Figure 8. (a–c) DCDC converter with onboard charger for Beijing E-150 pure electric sedan.

product from Shinry® Technologies Corporation contains a 3.3-KW charger and a 1.5-KW DCDC converter in one housing (Figure 8a dimensions 430 × 220 × 148 mm) with nature air convection cooling. The series of products also support liquid cooling (Figure 8b, with dimensions 280 × 234 × 150 mm) and forced air cooling (Figure 8c, 485 × 200 × 146 mm) mechanisms for different EV applications. The liquid-cooled version requires significantly less packaging space compared to that of the nature or forced air convection versions. It also has a better protection for foreign object ingression with an IP rating of IP67. The topology for this DCDC converter is the single-ended active clamp forward type.

3 HVAC SYSTEM

The move toward battery-powered EVs poses several challenges when it comes to the heating, ventilation, and air conditioning (HVAC) system design. Safety regulations require all vehicles to have adequate heating and defrosting capacities. The heater/defroster system is easily operated in a conventional gasoline-powered vehicle using the waste heat from the engine combustion process. The EV is powered by an electric motor running on batteries that produces much less heat due to its high efficiency (roughly 90% for electric motors compared to 30% for IC engines). A dedicated heat source is often required to supplement the waste heat scavenged from the energy conversion devices (e.g., the traction motor, the traction battery, the DCAC inverter, and the DCDC converter) on the EV.

The AC system on a conventional vehicle consumes significant amount of power (around 15%) in very hot weather with the AC compressor being the largest power consumption device (around 50%) in the system. This will have a major impact to the driving range when the system is refitted in an EV. The first design change is to directly drive the AC compressor from the traction battery with a dedicated inverter often integrated within the motor assembly. This not only improves motor efficiency but also enables the compressor to produce externally controllable variable displacement that helps to improve system level performance.

Both the auxiliary heater and the electric AC compressor can cause significant reduction to the EV driving range (around 30%) in extreme weather and their design is crucial to the success of the initial conversion from conventional to EVs. Along with that, innovative concepts are being developed for EV applications to further minimize energy usage by HVAC system while maintaining a safe and comfortable driving environment. There are also unique requirements to properly condition the EV powertrain system for optimal performance and long-term reliability. All of the above forms an integral part of the HVAC system and its design is reviewed in this section.

3.1 The AC subsystem

The fundamental working principle of all AC systems is the same that constitutes the four basic processes in physics (compression, condensation, expansion, and evaporation) accomplished in four major mechanical components of the system (compressor, condenser, expansion valve, and evaporator) interconnected with tubes filled with the AC refrigerant (typically R134a). The compressor compresses cool, low pressure refrigerant gas, causing it to become hot, high pressure gas. This hot gas runs through the condenser where heat is extracted by (forced) convection of

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

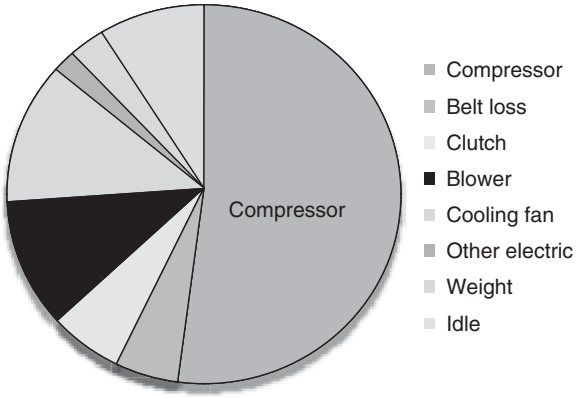

Figure 9. Energy usage in conventional AC system with fixed displacement compressor.

lower temperature ambient air and it condenses into liquid. The pressurized refrigerant flows through the expansion valve, which is basically a constricted orifice that reduces pressure of the liquid refrigerant so that it can expand and partially vaporize. The low pressure liquid/vapor mixture runs through the evaporator and completely vaporizes. During this process, heat is absorbed from the ambient air that is forced through the evaporator by the blower. The circulated low temperature air then cools down the passenger compartment. The cool, low pressure refrigerant gas is again compressed by the compressor and recirculates in the AC system.

The heart of the AC system is the AC compressor. It consumes the highest amount of power in the conventional AC system driven off the engine auxiliary belt (Figure 9). For this reason, significant effort has been devoted to the design and control of the compressor to maximize AC system efficiency. One of the most common improvements is to use an externally controlled variable displacement compressor.

In a conventional vehicle, the fixed displacement AC compressor is turned on and off based on several real-time parameters, among them are (i) the subjective request from the operator, (ii) the evaporator temperature, (iii) the compressed refrigerant pressure, (iv) the interior and exterior temperatures, and (v) the key engine operation status. As the turn-on transition of the compressor requires significantly more power than steady operation, this mode of control is less efficient compared to the variable displacement control (Figure 10). Another advantage of using variable displacement compressor is the ability to precisely control the surface temperature of the evaporator to keep it in the optimal region (typically between 2°C and 5°C). In Figure 11a, the evaporator temperature fluctuates without displacement control. This is compared to Figure 11b where the evaporator temperature remains constant with displacement control. Studies have shown that systems with externally controlled compressor can improve COP by 25% and fuel consumption by 30% in both city and highway drive modes.

The compressor suitable for EVs must have controllable rotary speed (variable cooling capacity), similar to the stepless variable frequency control of home AC. This corresponds to the externally controlled variable displacement compressor in a conventional vehicle but is driven by a dedicated inverter (that converts the high voltage DC to high voltage AC with variable frequency and amplitude) instead of the auxiliary belt. Owing to the difference in the driving mechanism, it can achieve higher efficiency, lower vibration and noise, and more accurate control (Hendricks, 2003). The electric compressor adjusts the cooling capacity in real time by changing the rotary speed and keeps the evaporator surface temperature at the desired level. Most commonly used control algorithm takes on the popular proportional, integrative, and derivative (PID) form with adjustment based on the large time delay of temperature change. Optimal control of the compressor to minimize energy usage is the core of the AC system design for EVs.

In the following, an industry-leading design, the Nanjing Aotecar® ATC-E26A electric compressor, is introduced to

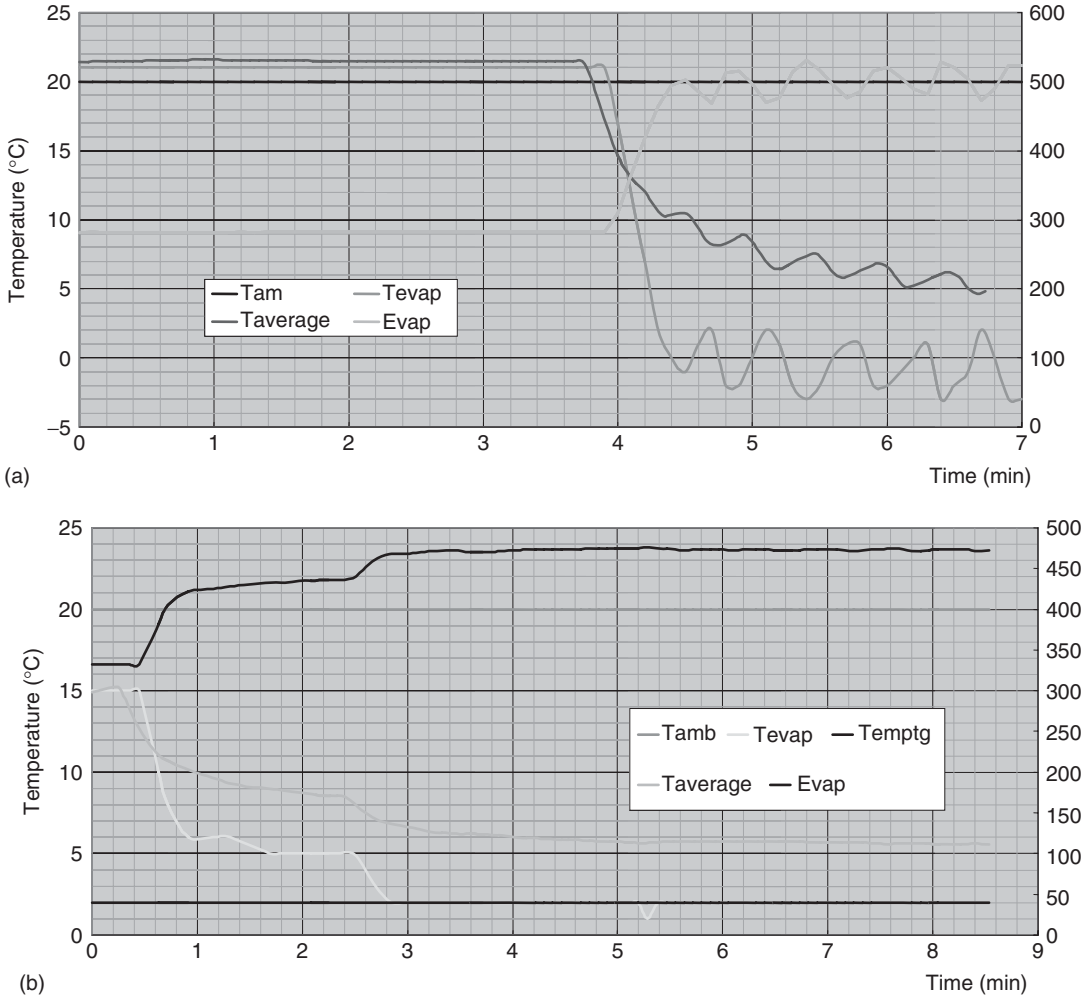

Figure 11. (a,b) Performance comparison between fixed and variable displacement compressor.

illustrate the key features and performance measures of an electric compressor. This device has been successfully integrated into the production Beijing E-150 pure EVs. Refer to Figure 12 for the internal structure of the assembly and Figure 13 for its external appearance and key performance curves. This device has the following main features and its key parameters are listed in Table 3.

(a) One piece design with integrated compressor, motor, and onboard inverter. The motor is directly cooled by the low temperature, low pressure-inhaled refrigerant. The inverter is cooled by its heat sink pressed against the cooler part of the compressor shell (close to the intake port).

(b) Under voltage protection. To protect the battery and the compressor motor, the inverter will automatically shut off the output when the power supply voltage is too low (less than 260 ± 5 V). The inverter will automatically reset if the supply voltage returns to normal (higher than 275 ± 5 V).

(c) Over current protection. When the input or the output current is too high, the inverter will automatically shut off the output to protect the inverter and the compressor motor.

(d) Variable speed control. Set the compressor rotary speed using a 400-Hz 12 V PWM signal by linearly adjusting the duty cycle (0–100% duty cycle corresponds to 1000–6500 RPM). The speed can also be controlled through a CAN interface.

3.2 The heating and defrosting subsystem

While IC engines generate a lot of waste heat, making it easy to warm the passenger compartment and clear the front windscreen frost in cold weather, EVs produce very

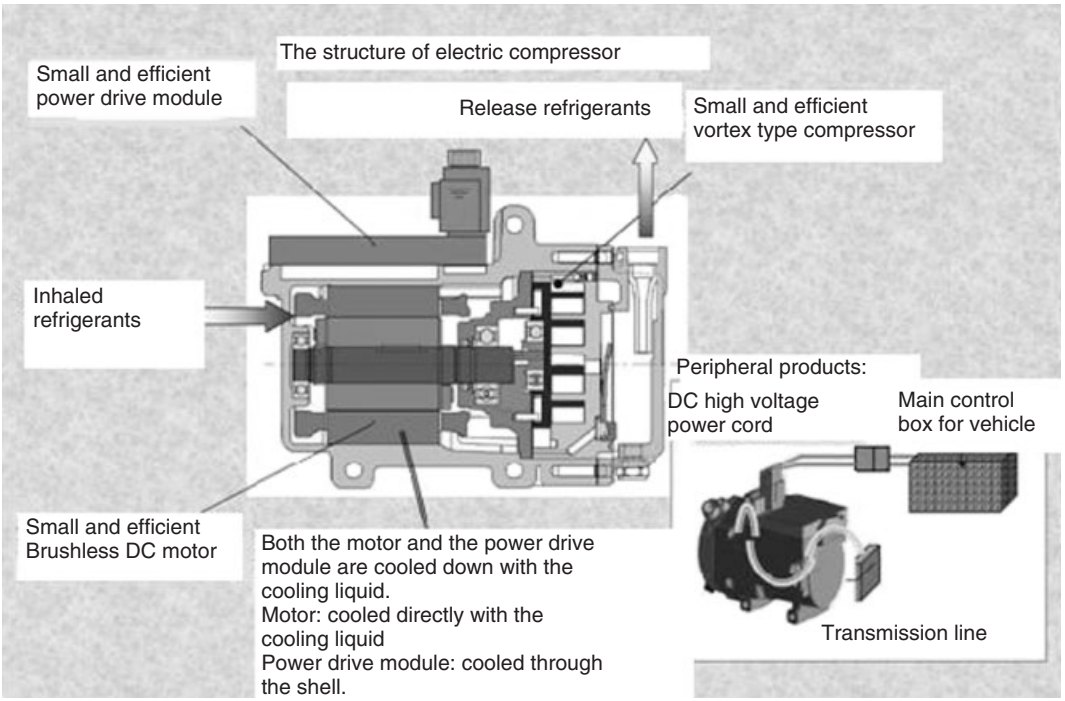

Figure 12. Electric AC compressor internal construction.

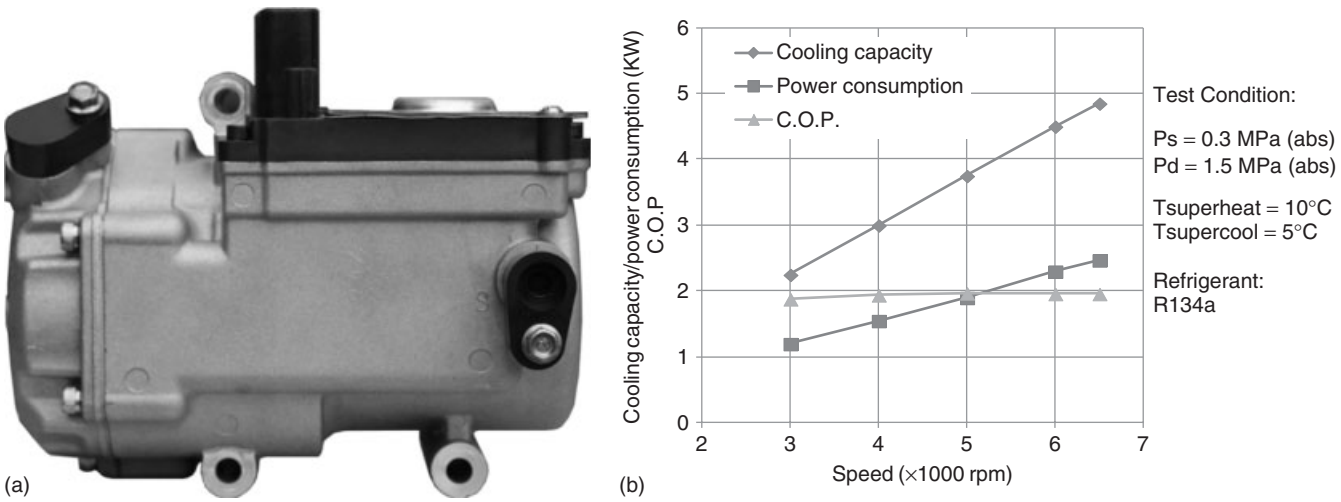

Figure 13. (a,b) Electric AC compressor with performance plot.

little excess heat. Furthermore, owing to material insulation constraints and semiconductor thermal characteristics, the electric motor and drive systems operates at a much lower temperature compared to the IC engine system. The IC engine operates optimally when the coolant temperature is around 90°C (normal operation range 85–100°C for gasoline engine and 80–90°C for diesel engine). For the traction motor, it is 60°C. As a result, it is often necessary to have additional (dedicated) heat sources in an EV.[8]

There are two main types of heater available on the market: the fuel burning heater and the PTC electric heater. Heaters using liquid fuel (e.g., gasoline, diesel, or ethanol) do not use electricity from the battery pack and will have no impact to the driving range of an EV. However, the emissions from the exhaust have a negative effect on the environment and open flame burning requires adequate protective measures for fire safety. The PTC electric heater uses a special type of ceramic that has positive thermal

coefficient of resistance (i.e., resistance increases upon heating). This class of ceramics (often barium titanate and lead titanate composites) has a highly nonlinear thermal response such that it becomes extremely resistant above a composition-dependent threshold temperature. The rise in resistance is experienced within a fairly small temperature window of a few degrees centigrade. This attribute of the PTC results in a heating element that self-regulates to a preset temperature and automatically varies its wattage in order to maintain that preset temperature. The behavior causes the material to act as its own thermostat.

Compared to the fuel heater, the PTC heater has fast heating response times and plateau once the predefined reference temperature is reached. Because of these characteristics, it is possible to directly replace the conventional heater core by a PTC heater with a preset temperature threshold (i.e., the Curie temperature point) below the highest rated temperature of the surrounding plastic enclosures.[9] Currently, for this type of application, the rated power is limited between 2 and 3 KW for the PTC heater. This power level can meet the general requirements for heating and defrosting but is not ideal under low temperature (e.g., below −10°C) or for large vehicles. To increase the heating capacity, a PTC coolant heater with a higher power rating (greater than 4 KW) is often installed. Another added benefit of the coolant heating system is that the heated coolant can be used to warm up the traction battery pack to ensure optimal performance during start-up at low temperature. However, this type of system does require more packaging space for the added coolant circuits and will consume more electric energy.

The Changchun Chengde® air heating PTC that is installed in the production Beijing E-150 pure EVs is shown in Figure 14 with its temperature—resistance characteristic curve. The key product parameters are given in Table 4.

3.3 EV HVAC system design trend

In the initial effort to convert a conventional vehicle to an EV, the emphasis has been on minimizing the component change to achieve viable system cost and reliable operation. For the HVAC system, the basic approach is to replace the belt-driven compressor with an electric compressor and to add a supplemental heating source to satisfy regulation and comfort requirements. Owing to the large power consumption of the two devices, the control mechanisms will have

Maximum start-up current	13 A	Ambient temperature: $25 \pm 1^{\circ}$C Applied voltage: 384 ± 1 V DC
Cold resistance	80–300 Ω	Soaked in $25 \pm 1^{\circ}$C ambient temperature for 30 min

to be adapted as well. This involves, for example, (i) adding direct control of the heating element (just like the AC activation switch in a conventional vehicle) for customer to consciously control the energy consumption (and hence driving range), (ii) dynamic regulation of the surface temperature of the heater core, and (iii) dynamic adjustment of the compressor cooling capacity for maximum level of system efficiency based on vehicle and environmental conditions.[10]

In addition, new concepts are being developed to further improve system level performance. One approach is to localize heating and cooling only to the driver and occupied passenger locations instead of the whole cabin (Weissler, 2012). It involves redesigning the HVAC air distribution system (e.g., the HVAC case, the temperature/mode control doors, and the air ducts) to direct airflow to the spots where the customer is most sensitive, for example, the ankle, the chest, and the face. By selectively enhancing airflow, and together with the use of climatically controlled seats, the objective is to make the driver and passenger feel more comfortable without actually increasing the heating or cooling output. A second approach is to precondition the passenger compartment before the trip while the vehicle is being charged from an external power supply. New thermal energy storage systems are being developed that have volumetric energy density greater than that of electrical batteries with charging and discharging achieved via solid-state converters (Green Car Congress, 2011). Thanks to the recent advances in the Telematics technology, the whole process can be conveniently automated or remotely controlled by the customer. Yet, the fundamental improvement of the heating performance comes with the incorporation of a heat pump system. The COP of the PTC-based system is below 1.0 (typically 0.95). The COP of a heat pump system can reach over 2.3. This is demonstrated by the Delphi Unitary HPAC (heat pump air conditioner) System (Kowsky *et al.*, 2012). In addition to improved heating efficiency, the system also has the potential to

integrate powertrain components (e.g., the traction battery, inverter, and motor) cooling with the HVAC system for optimal vehicle level performance.

4 ELECTRIC VACUUM BOOSTER SYSTEMS

The vast majority of vehicles are equipped with vacuum servo brake system to provide assistance to the driver by reducing the braking effort. The vacuum source of the vacuum booster system for vehicles with normally aspired IC engines is from the engine intake manifold. The vacuum negative pressure could reach 0.05–0.07 MPa. For pure electric or fuel cell vehicles refitted from the traditional vehicle, the vacuum source is lost because of the removal of the engine assembly. The braking force generated solely by the human cannot meet the requirement of the servo brake system. A common solution is to restructure the booster system by adding an electric vacuum pump that can provide sufficient vacuum pressure to the brake booster system. The basic configuration of an electric vacuum booster brake system is shown in Figure 15. It consists of the electric vacuum pump, the vacuum tank, and the real-time controller. The mechanical structures of vacuum pumps used for brake servo systems include the rotary vane (with oil lubrication or dry type) and the diaphragm type. This will be discussed in the following sections.

4.1 Rotary vane pump with function of alarming

The production Beijing E-150 pure EVs are equipped with the rotary vane type vacuum pump as shown in Figure 16.[11] The structure diagram of electric vacuum booster brake system is displayed in Figure 17.

The rotary vane pump is mainly composed of the stator, rotor, rotary vane, upper cover plate, lower cover plate, springs and other parts. The rotor is eccentrically mounted inside of the stator cavity with spring loaded sliding rotary vanes. When the rotor is driven by the electric motor, the rotary vanes slide out of the rotor and are pressed against the inner lining of the stator due to the centrifugal force.

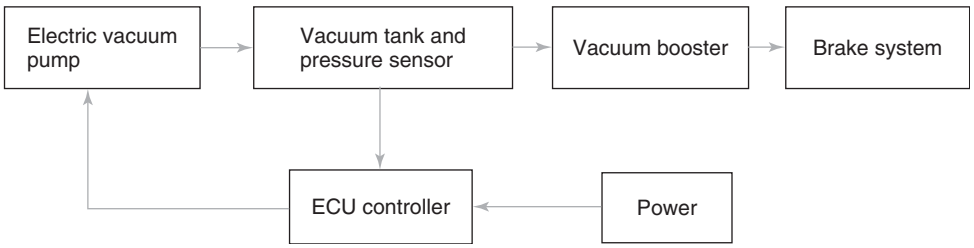

Figure 15. Schematic diagram of electric vacuum booster brake system.

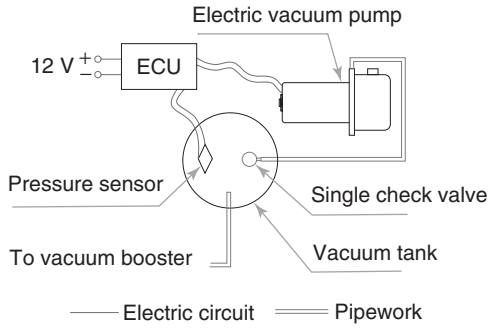

Figure 17. Structure diagram of electric vacuum booster brake system.

This creates the vane chambers that do the pumping work as follows. On the intake side of the pump, the vane chambers are increasing in volume. These increasing volume vane chambers are filled with air forced in by the inlet pressure. The inlet pressure is actually the pressure from the system being pumped which is the vacuum booster tank in this application. On the discharge side of the pump, the vane chambers are decreasing in volume, forcing air out of the pump into the atmosphere. With fixed inlet pressure, the pump drives out the same volume of air with each rotation.

A pressure sensor measures the pressure of the vacuum tank. A simple strategy of threshold comparison with hysteresis control is implemented with the following functions.

(a) *Prestart Self-Checking*. Implement the self-check function after vehicle start to detect system failure and activate the alarm.
(b) *Start*. The vacuum pump starts to work when the measured tank pressure reaches threshold P_a.
(c) *Pressurization*. When the pressure reaches threshold P_b, the vacuum pump continues to increase the degree of vacuum for an adjustable delay time of 5–20 s.
(d) *Stop*. When the pressure reaches threshold P_c, the vacuum pump stops working immediately.
(e) *Alarm*. When the pressure reaches threshold P_d, the alarm is activated.

The primary performance criteria of a vacuum pump include the vacuum level that can be produced, the rate of air removal, and the required input power. Other parameters include the temperature effect, the noise level, and the service life. These are listed in Table 5.

Table 5. Specifications of the rotary vane electric vacuum pump assembly.

Parameters	Specifications
Rated voltage	12 V
Antileak tightness	At -66.7 ± 5 KPa vacuum level, the pressure loss shall be less than 0.3 KPa during a period of 15 s
Maximum suction	≥ -85 KPa
Operating current	≤ 15 A
Noise	≤ 75 dB(A)
Operation temperature	-30°C to 100°C
Corrosion resistance	No more than 2 diameter corrosion per 100 cm^2
Pumping capacity	With test volume of 2 L, time for pressure initiation is: 1. From atmosphere pressure to -50 kPa: less than 4 s 2. From atmosphere pressure to -70 kPa: less than 7 s 3. From -40 to -70 kPa: less than 4 s
Service life	Activation cycles: 1. Normal temperature: minimum 200 K cycles 2. Low temperature (-30°C): minimum 50 K cycles 3. High temperature (100°C): minimum 50 K cycles

4.2 Auxiliary dry rotary vane pump

The vacuum pump introduced in the previous section requires oil lubrication. The oil-lubricated types have distinct advantages if proper maintenance is provided. They can usually provide higher vacuums because the lubricant acts as a sealant between moving parts. In addition, they usually last longer than oil-less units in normal service because of their cooler operation and less susceptibility to corrosion from condensed water vapor. Yet, oil-less pumps are preferred for the brake booster application on the basis of avoiding the cost and time of regularly maintaining the oil fillings. This is particularly important when the pump is to be mounted in an inaccessible location. The dry rotary vane pump presented in this section is one type of oil-less vacuum pump that uses specialized rotary vanes to eliminate the need of the lubricating oil. The diaphragm pumps introduced in the next section are also designed to be oil-less.

The auxiliary dry rotary vane pump with its internal structure displayed is shown in Figure 18. The internal structure, operation principle, and control strategies between the oil-less and the oil-lubricated pumps are quite similar, which will not be detailed again here. The major technical features of the dry pump are listed below:

- Graphite rotary vane structure;
- Good sealing performance;
- Maintenance-free, without oil refilling;

(a) (b)

Figure 18. (a,b) Auxiliary dry rotary pump outline.

Table 6. Technical parameters of auxiliary dry rotary vane pump.

Parameters	Specifications
Rated voltage	12 V
Operation voltage	6–16 V
Rated current	10 A
Starting current	≤60 A
Operation temperature	−40°C to 120°C
Noise	≤75 db(A)
Performance	With test volume of 3.2 L, time for pressure initiation is: 1. From atmosphere pressure to −50 kPa: less than 5.5 s 2. From atmosphere pressure to −70 kPa: less than 12 s
Service life	≥300 K Cycles

- High pumping speed with shorter vacuum restoration time
- Compact and light weight
- Wide operating temperature range: −40°C to 120°C.

The technical parameters are listed in Table 6.

Table 7. Main technical parameters of diaphragm pump.

Parameters	Specifications
Rated voltage	13 V
Average current consumption (13 V; room temperature; after run-in)	<15 A
Operation temperature	−40°C to 110°C 120°C for limited time
Maximum degree of vacuum (13 V; room temperature; after run-in)	Great than 86% of ambient pressure
Noise level (13 V; room temperature; after run-in)	<60 dB(A)
Motor speed	≈3300 rpm
Pumping capacity (13 V; room temperature; after run-in)	With 5I Booster, time for pressure initiation is: 1. From atmosphere pressure to −50 kPa: less than 3.5s 2. From atmosphere pressure to −70 kPa: less than 6.5 s
Maximum working load (>80 h, 90°C)	100%
Service life	>1200h >1.2 *M* Cycles
Product weight	<2.6 kg

4.3 Diaphragm vacuum pump

A production diaphragm pump for EV applications is shown in Figure 19.[12] Its internal structure is revealed in Figure 20. The diaphragm pump creates vacuum by flexing of a diaphragm inside a closed chamber. The reciprocating action of the diaphragm is driven by an electric motor. The check valves on either side of the chamber ensure single direction of airflow. Diaphragm pumps have good suction lift characteristics and handle well with impurities in the air. The flow rate primarily depends on the effective working diameter of the diaphragm, its stroke length, and the motor speed. Diaphragm pumps also have good dry running characteristics and can be very power efficient. The detailed technical parameters for the pictured product are listed in Table 7.

5 ELECTRIC POWER STEERING SYSTEMS

Currently, almost all production EV models are equipped with electric power steering (EPS), also refereed to as electric power assisted steering (EPAS), systems of different types. As in conventional IC engine vehicles, EPS systems are categorized into the column-assist type (C-EPS), the pinion-assist type (P-EPS), and the rack-assist type (R-EPS), according to the location of the booster actuation. However, unlike in conventional vehicles, electro-hydraulic power steering (EHPS) systems are seldom used in EV's because of the need for a separate power source.

The EPS system is in general composed of a torque sensor, an electronic control unit, a power amplifier module, an electric motor, and a reduction gear mechanism. The electronic control unit calculates the required steering assist torque according to the torque sensor output and controls the rotation of the electric motor through the power amplifier module. The motor output drives the conventional steering rack and pinion mechanism after the reduction mechanism to produce the corresponding assist steering torque. The electronic control unit also communicates with other vehicle subsystems through onboard network to further enhance steering control accuracy and comfort and to optimize fault diagnosis. The EPS system must meet the reliability requirements and electromagnetic compatibility requirements of an automotive electronic system.

Note that the design of EPS systems in EVs follows the same basic principles of that in conventional IC engine vehicles. Therefore, interested readers are recommended to reference the related materials as provided in New Electrical Power Steering Systems for more details. For the remainder of this section, two production EPS systems, both from Zhuzhou Elite Tech Corporation, are briefly presented. The first is the column-assist type EPS as shown in Figure 21 with technical parameters in Table 8. The second is the pinion-assist type EPS as shown in Figure 22 with technical parameters in Table 9. These systems have been fitted to the Beijing E-150 pure EVs.

Figure 21. Production C-EPS system. (Reproduced with permission from Zhuzhou Elite Tech Corporation.)

Table 8. Technical parameters of the C-EPS system.

Devices	Parameters	Specifications
Controller	Supply voltage	10–16 V
	Maximum operating current	35 A
Motor	Rated voltage	12 V
	Rated power	200 W
	Maximum operating current	35 A
	Maximum output torque	2 Nm
Sensors	Supply voltage	3.3 V
	Main torque voltage	0.66–2.64 V
	Assist torque voltage	0.66–2.64 V
	Medium voltage between main and assist torques	1.65 V
Column assembly	Maximum steering wheel output torque—manual	7 Nm
	Reduction ratio	16.50
	Maximum steering wheel output torque—assisted	40 Nm

Figure 22. Production P-EPS system. (Reproduced with permission from Zhuzhou Elite Tech Corporation.)

Table 9. Technical parameters of the P-EPS system.

Parameters	Specifications
Angle ratio of steering gear	44.15 mm/rev
Angle of gear and rack shaft	20°
Center distance between pinion and rack	16.5 mm
Rack displacement	±71.5 mm
Rack width	24 mm
Number of pinion	8
Module of pinion	1.75
Pitch radius of pinion	7.724 mm
Rated current of EPS motor	52 A
Rated output torque of EPS motor	2.36 Nm
Rated power of EPS motor	360 W
Reduction ratio between worm and gear	1 : 18

6 SUMMARY

This chapter serves as an introduction of the auxiliary systems for EVs. These systems complement the main power house of the EV (namely the traction battery, the traction motor, and the vehicle central control unit) and help create a safe and comfortable driving environment. The systems covered in this discussion include the DCDC converter that powers the conventional 12 V low voltage net, the HVAC system that is essential for driving comfort and hence safety, the electric vacuum booster system for assisted power braking, and the EPS system that increasingly becomes an integral part of the total vehicle dynamic control systems. It shall be clear from the presentation that the theme of the design is energy efficiency, which coincides with that of the total EV. Yet, the drive for sustainable mobility shall also take advantages from technologies in other fields. The particular one worth mentioning is the technologies for connectivity that intimately link between the vehicle, the customer, a (typically cloud-based) back-end server, and from there, an integrated supporting infrastructure. Together, they provide the foundation for the success of EVs.

ACKNOWLEDGMENT

The authors would like to acknowledge the support from their colleagues including but not limited to Dr. W. Gao, Dr. L. Gu, Mr. H. Zhou, Dr. Y. Wei, Dr. R. Wu, Dr. G. Huang, and Dr. A. Cooprider. The authors appreciate the guidance that the associate editor Prof. C.C. Chan had kindly offered to the team.

ENDNOTES

1. For naturally aspired engines. For turbo charged engines, a dedicated vacuum pump may be required.
2. This can be seen from the equation $P_{\text{Loss}} = I_{\text{Load}}^2 \times R_{\text{Conductor}} = (P_{\text{Load}}/U_{\text{Load}})^2 \times R_{\text{Conductor}}$ that with given load power P_{Load} and conductor resistance $R_{\text{Conductor}}$,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto153
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the power loss in the conductor P_{Loss} is inversely proportional to the square of the voltage across the load U_{Load}.

3. Another approach is to have multiple windings on the primary side that turn on in sequence to (continuously) inject current to the secondary winding side. Thus, the effective duty cycle is multiplied without jeopardizing the maximum blocking voltage of the main switch. This is the so-called *multi phase* DCDC converter that has additional benefits such as (i) the heat generating components (the winding and the main switch) are spread out so that the power density of the device can be increased and (ii) if one primary winding circuit fails, the device can still operate with reduced power.
4. At higher operating temperature, the conversion efficiency can also be reduced because of higher conduction loss in the transformer (copper loss) and the main switching semiconductors.
5. Electromagnetic compatibility (EMC) is defined as the ability of an equipment or system to function satisfactorily in its electromagnetic environment without introducing intolerable electromagnetic disturbances to other devices in that environment. Much of the existing methods to address EMC of motor drives (primarily conducted and radiated emissions) are based on "legacy" low voltage components and systems. The high voltage (typically 200–400 V) and high current (hundreds of amperes peak demand) in EV propulsion systems will require new analysis approaches, test methods, and effective use of simulation/modeling. The standards are also under development by various governmental agencies and industrial institutions. The reader may refer to the publications from EC, ISO, IEC, SAE, and other issuing bodies for the latest status.
6. For example, when operating at high altitude with reduced air pressure, the cooling capacity has to be derated compared to that of sea level. A rule-of-thumb formula for the derating factor is given as $1\frac{h}{17{,}500}$, where h is the height over sea level in meters.
7. Under IEC529 designation, the first digit "6" implies "dust tight," or no ingress of dust (at a partial vacuum of 20 mbar inside the enclosure); the second digit "6" implies "powerful water jets," which means water projected in powerful jets against the enclosure from any direction shall have no harmful effects.
8. It should be noted that for vehicles equipped with highly efficient small diesel engines, it is also often necessary to have a dedicated heat source such as the fuel burning heater or the PTC electric heater that are discussed in this section for sufficient heating in very cold weather.
9. Owing to its relatively high surface temperature, care shall be taken when packaging the PTC heater to ensure safety of operation. This includes keeping plastics, sponge, and other temperature-sensitive components at safe clearance to the heating element and adequate ventilation.
10. It should be noted that the aforementioned technologies are not unique to electric vehicles but have seen applications in (high end) conventional vehicles for better fuel efficiency.
11. The internal structural diagram of the rotary vane vacuum pump as displayed in Figure 16 is based on Wikipedia, http://en.wikipedia.org, article on Rotary vane pump, March 2013.
12. The internal structural diagram of the diaphragm vacuum pump as displayed in Figure 19 is based on Wikipedia, http://en.wikipedia.org, article on Diaphragm vane pump, March 2013.

Steel Processing: Formability of Steel Sheets and Tailor-Welded Blanks for Automotive Applications

Kaushik Bandyopadhyay and Sushanta K. Panda

IIT Kharagpur, Kharagpur, India

1 INTRODUCTION

The intrinsic ability of metals and alloys to be worked into various shapes without removing materials forms the basis for manufacturing operations known as *metal forming* or *plastic deformation processes*. Metal forming processes can be broadly classified into two types as bulk forming processes and sheet metal-forming processes. In sheet metal forming, the *working material* often referred to as *blank* has a lower dimension in one direction compared to other two directions. The complete discussion on steel processing including iron making, primary and secondary steel making, hot rolling, cold rolling, extrusion, forging, joining, machining, coating, and heat treatment is very complex and time consuming, and hence, beyond the scope of this chapter. However, the various aspects of sheet steel processing are discussed. In sheet metal processing, plastic deformation is imposed in the blank by punch and die tooling assembly to achieve a required three-dimensional shape. Tensile stress plays a major role during deformation. Commonly used sheet metal-forming processes are bending, deep drawing, ironing, and stretch forming (Figure 1).

In sheet bending, the desired bent or curved shape is given to the sheet material by deforming about the bending axis with little or no change in surface area. Mostly, sheet bending operations are U-bending, air bending, arc bending, and V-bending process. In bending, inner side of the sheet metal across the thickness is compressed and outer side is stretched. Through successive bending, complex form can be achieved. Sheet metal is drawn into desired flat end hollow cylinder or box shape with the help of flat bottom punch and dies in deep drawing process. A blank holder is used to prevent wrinkling in the flange portion of the cup. In deep drawing, the thickness of the cup wall is not constant. It is minimum near the cup bottom and maximum at the top of the cup. Ironing is the process in which a cup height is increased at the expense of wall thickness, making the wall thickness more uniform. This can be achieved by forcing the cylindrical cup through an ironing die in which the punch–die clearance is smaller than the metal thickness. Ironing may be done along with deep drawing or after deep drawing as a separate step. In stretch forming, blank is clamped rigidly by jaws along the edges and stretched over a punch or die block. Generally, the punch has a spherical or convex shape. In stretching, mainly tensile stress plays the major role to deform the sheet. Complex autobody stamping requires a combination of stretching and drawing with which bending and unbending are associated (Mellor, 1981).

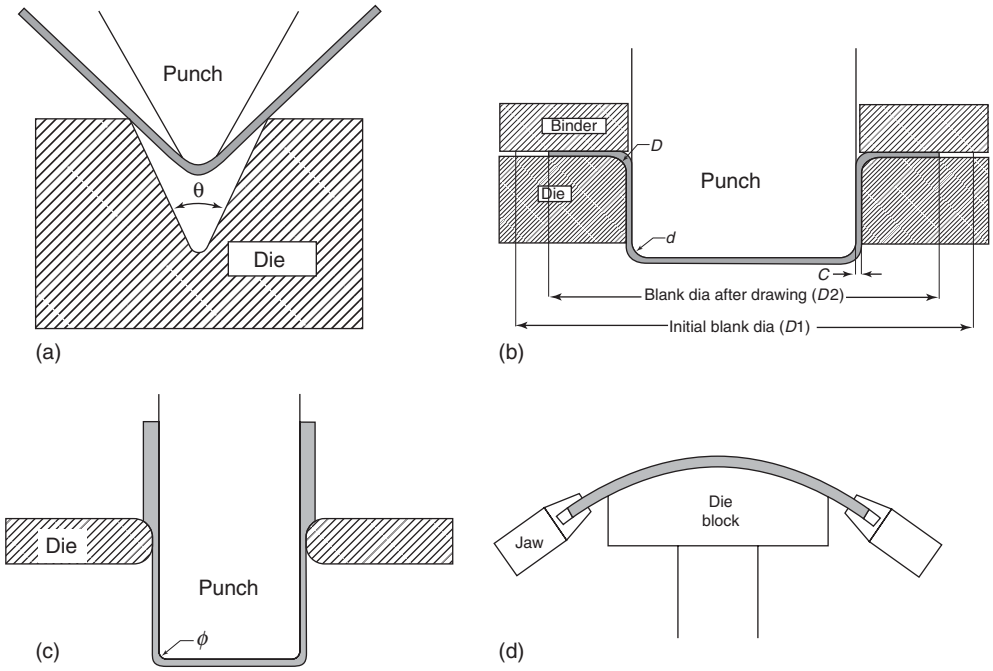

Figure 1. Schematic diagrams of some basic sheet forming processes: (a) bending, (b) deep drawing, (c) ironing, and (d) stretch forming.

The ability of a sheet metal to be worked into different shapes without flow localization under complex conditions of loading and deformation is called *formability*. Flow localization is an unstable flow where the deformation is confined to one zone of the sheet metal. This is also referred to as *onset of necking*, which leads to fracture on further deformation. When a stamping tears during forming, the tear is a visible indication that metal has been worked beyond its prevailing forming limit. Whether or not a particular sheet of metal can be formed without failure depends on many factors such as material properties, surface conditions, blank size and shape, lubrication, press speed, blank holder pressure, and punch and die design. Because of this, source of flow localization problem is difficult to pinpoint and quantify. Hence, formability is an attribute that has no precise, universal meaning. Because of multitude of materials, stamping designs, and press conditions, there are no standard valid rules for improving the formability of a stamping through changes in tool design or process parameters (Mellor, 1981; Rao and Sing, 2000).

1.1 Materials for automotive manufacturer

Typical automotive steel grades include low strength steels such as interstitial free (IF), drawing quality (DQ), extra deep drawing (EDD) steel, and conventional high strength steel such as high strength low alloy (HSLA). These low carbon steel sheets have long been the work horse material in automotive manufacturing and consumer industries because it can be stamped into inexpensive, complex stamping at a very high production rate (Panda, 2007). However, the driving force for the increased use of recently developed advanced high strength steel (AHSS) has been their superior strength and enhanced formability compared to HSLA. In addition, these steels have excellent crash energy absorbing behavior. The various types of commercial available AHSSs are dual phase (DP), transformation-induced plasticity (TRIP), complex phase (CP), twinning-induced plasticity (TWIP), and martensitic steel (MS). These AHSSs are primarily steels with a microstructure containing a phase other than ferrite, pearlite, for instance, martensite, bainite, austenite, and/or retained austenite in quantities sufficient to produce favorable mechanical properties. Application of AHSS in automotive body structures, for example, motor compartment rail, bumper, B-pillar, and door panel, can significantly increase the crashworthiness of the vehicle with reduction in weight (Advanced High Strength Steel Application Guidelines, 2009). It was reported by Worldsteel Association[1] that replacement of conventional steels by AHSS for the car body or the body in white (BIW) resulted in 17–25% weight savings. Weight saving has a remarkable influence on a vehicle's efficiency, with researches showing that 1% reduction in a vehicle weight can result in

0.6–1% reduction in fuel consumption (Hrayashi, 1996). The chemical composition with carbon equivalent (CE) using Yurioka formula (Yurioka and Kasuya, 1995) and the mechanical properties of some automotive grade steel sheets are enlisted in Tables 1 and 2 for reference. The influence of these properties on forming behavior is discussed in various sections of this chapter where ever necessary.

1.2 Tailor-welded blank

Automakers are constantly searching for innovative means of reducing vehicle weight and manufacturing costs in order to meet ever-restricting fuel economy standards while remaining economically competitive. A promising opportunity to meet these seemingly conflicting requirements is through the use of tailor-welded blanks (TWBs). TWBs are blanks where multiple sheet metals of different shapes and thickness are welded together before forming into a three-dimensional component. Thus, the blanks can be tailored for a particular application, including not only sheets of different shape and thickness but also sheets of different quality, and with or without coatings on one or both surfaces. This trend of welding and forming of sheet metal pieces allows significant flexibility in product design, structural stiffness and crash behavior (crashworthiness), formability, and use of different materials in one component (Auto Steel Partnership, 1995; Wang *et al*., 1995). This method is becoming increasingly important, particularly in the automotive industry. Because each welded piece can have a different thickness (as guided by design considerations such as stiffness), grade of sheet metal, coating, or other characteristics, these blanks possess the needed characteristics in the desired locations of the formed part. As a result, productivity is increased, the need for subsequent spot welding of the product (e.g., a car body) is reduced or eliminated, and dimensional control is improved. TWBs offer several other notable benefits including decreased part weight, reduced manufacturing costs, increased environmental friendliness, and improved dimensional consistency (Lokka, 1997). In order to take advantage of these benefits, however, designers need to access the formability of TWBs early in the design process. Hence, researchers have worked on various aspects on formability of TWBs (Kinsey, Liu, and Cao, 2000; Chan and Chan, 2003; Kinsey, Viswanathan, and Cao, 2001; Waddell, Jacken, and Wallach, 1998). Currently, TWBs are used for manufacturing auto body parts such as front door inner, rear door inner, floor pan, A-pillar, center pillar (B-pillar), and body side frames (Pallet and Lark, 2001). The application of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

AHSS in TWB has the potential to significantly reduce part weight and improve product performance.

1.3 Hot stamping and coating

In the context of continuously increasing demands for reduced vehicle weight with improved crashworthiness qualities, a brief note about the hot press forming (HPF) or hot stamping technology is mentioned to produce AHSS parts for automobile application. Recently, different hot stamped parts find their applications in various chassis components: door beams, bumpers, pillars, roof rails, rocker rails, and tunnels. Hot stamping has two main variants: direct HPF and indirect HPF. In direct HPF, the blanks are heated to achieve full austenization (i.e., 900–950°C), and subsequently, they are press formed and quenched. However, the cold preformed parts are first austenized and then these parts are calibrated and quenched in the press during indirect HPF. After quenching, full martensitic transformation is obtained in the material resulted increase in the strength of the component (Fan, Kim, and De Cooman, 2009). This process can be exploited to tailoring properties of the blanks. It can be achieved by changing the cooling rate below the critical rate to avoid martensite formation in some parts or heating the blank below AC_3 temperature, which results incomplete austenization. Different techniques such as introducing segmented tools having different thermal conductivity at different zone, differentiating temperature of different region of die by heating, local heating of the blank, and so on (Karbasian and Tekkaya, 2010).

Coating using molten zinc by electroplating, spraying, and hot dip galvanizing is used for protection against corrosion in a wide variety of low carbon steel finished products. Under atmospheric conditions with high moisture content or condensation on the metal surface, zinc hydroxide forms, and this film reacts with carbon dioxide to form insoluble zinc carbonate that shields zinc from the outside environment. Thus, zinc carbonate is very protective and is responsible for the excellent corrosion resistance of zinc in the atmosphere (Porter, 1991). In addition, the zinc layer provides cathodic or sacrificial protection to the substrate steel under extreme corrosive environment as it is more electronegative than steel. Research shows that by annealing the hot dip galvanized coatings to produce galvannealed coatings, the corrosion rate can be substantially decreased (Zhang, 2000). This is due to the presence of various Fe–Zn intermetallic phases. Unfortunately, the great difference in linear thermal expansion coefficient between steel and Fe–Zn phases lead to development of large residual stresses at high heat input, and this may result detrimental cracks in coating. Mainly, coating of Al–Si layer is applied by researchers in direct HPF to prevent the formation of scale during hot forming. Recently, lots of research work is ongoing in the selection of various oxidation preventive oils, metallic, inorganic, and organic coatings with coolants for hot stamping applications (Karbasian and Tekkaya, 2010; Naderi *et al*., 2011).

2 DEEP DRAWING OF ANISOTROPIC STEEL SHEET

Deep drawing process is widely used in automotive industries for forming complicated sheet metal parts, for example, automotive body parts, fuel tank, and flash light at a very high production rate. This process is also popular for assessing formability of sheet metals in terms of limiting drawing ratio (LDR). In deep drawing operation, different regions of the half drawn cup is subjected to different states of stresses as shown in Figure 2. The flange region of the cup experiences a radial tensile stress and tangential (hoop) compressive stress resulting reduction in circumference of the blank while being pulled into the die cavity. The cup flange buckles when the tangential compressive stress reaches a critical value and wrinkling defects appear due to lateral deflection. However, the development of lateral deflection of flange is suppressed by application of compressive blank holding force. The cup wall is held tightly over the punch, whereas the drawing force is transmitted into the cup. Hence, the cup wall region is experiencing tensile longitudinal and hoop stress. The drawing punch force is limited to the maximum tensile load that can be carried by the cup wall and this in turn limits the depth of drawn cup with a tearing mark. The cup bottom experiences a minor biaxial tensile stress as this region is resting on the flat face of the punch from the beginning of deep drawing.

2.1 Anisotropy in sheet steel-Lankford parameter

The mechanical properties are not uniform in all direction of cold-rolled steel sheets because of preferred crystallographic orientation of grains (texture of polycrystalline). The anisotropic behavior of sheet metal is quantified in terms of Lankford parameter, often referred as *R*-value and it is defined as Equation 1.

$$R = \frac{\varepsilon_2}{\varepsilon_3} \tag{1}$$

where ε_2 and ε_3 are the true strains in width and thickness directions, respectively. As the thickness strain is difficult

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

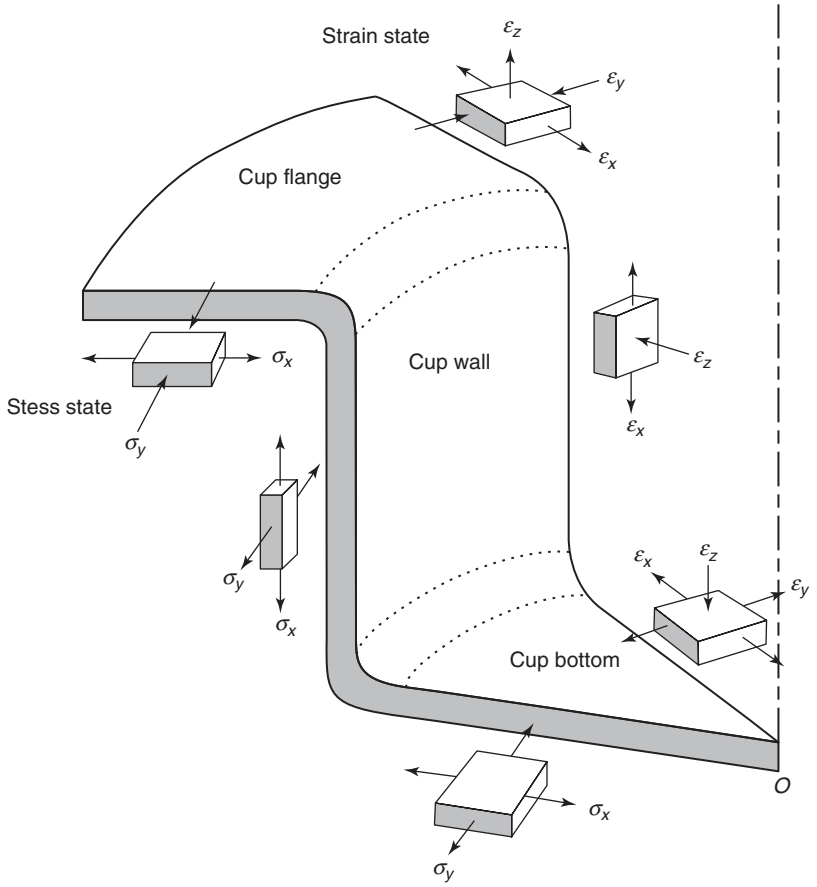

Figure 2. State of stress and strain at different regions of a deep drawn cup.

to measure, the volume constancy condition is invoked and the Lankford parameter can be calculated as Equation 2,

$$R = \frac{\varepsilon_2}{-(\varepsilon_1 + \varepsilon_2)} \tag{2}$$

where ε_1 is the true strain in length direction. Typically, R-value is measured from tensile specimens machined parallel, perpendicular, and at 45° to the rolling direction (RD). The R-value of the rolled steel sheet in these directions being represented by R_0, R_{90}, and R_{45} respectively. The average normal anisotropy coefficient is calculated as Equation 3.

$$\overline{R} = \frac{R_0 + 2R_{45} + R_{90}}{4} \tag{3}$$

Sheet metals with high $\overline{R}$-value have a low thickness strain compared to the strain in width direction. Hence, these sheets have a high resistance against thinning and are therefore said to have a good drawability. Another description of anisotropy is the variation of the R-value in the plane of the sheet, referred as *planar anisotropy* and it is defined as Equation 4.

$$\Delta R = \frac{R_0 - 2R_{45} + R_{90}}{2} \tag{4}$$

If $\Delta R = 0$, then the sheet metal is exhibiting planar isotropy, that is, same properties in all directions within the plane of the sheet. However, most of the sheet metals are planar anisotropic and exhibit different resistance while drawing into the die cavity in different direction. This leads to a wavy profile on the top edge of the completely drawn cup, which is referred as *earring*. These ears are usually removed through trimming operation after deep drawing and leads to lots of scrap materials. Hence, earring is a highly undesired phenomenon in deep drawing and referred as a *defect*.

2.2 Limiting drawing ratio (LDR)

Wrinkling, earring, and tearing are most common defects observed in deep drawn products and are shown in Figure 3.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

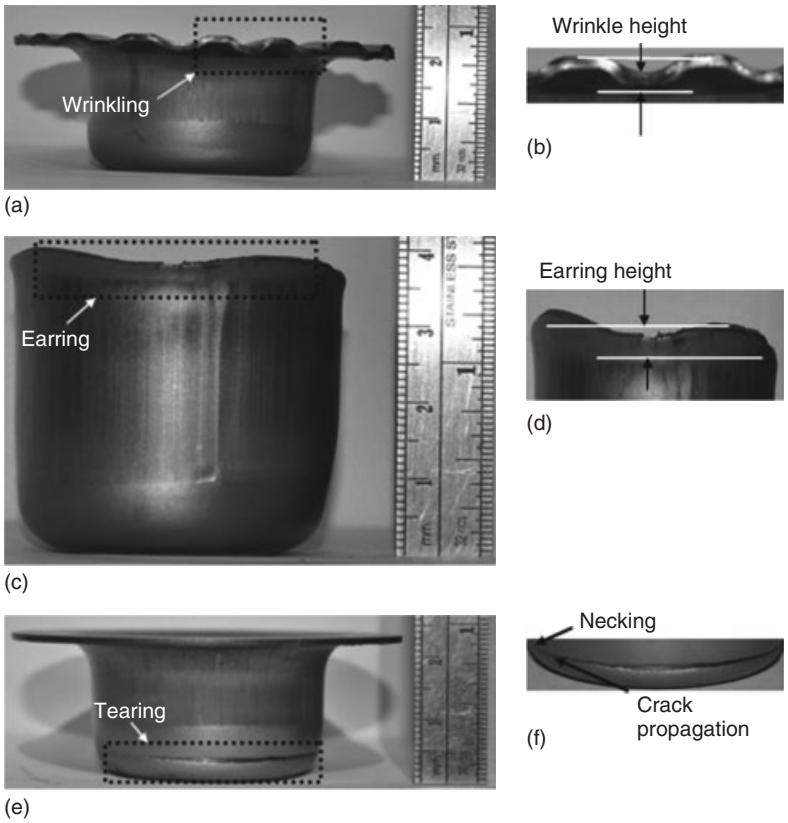

Figure 3. Deep drawing defects: (a) wrinkling, (b) wrinkling height, (c) earring, (d) earring height, (e) tearing, and (f) necking and crack propagation.

Two commonly found surface defects in deformed low carbon steel components are stretcher strain and orange peel. The stretcher strain is flame like pattern of depression on the surface, and it is associated with nonuniform deformation because of Lüder's band formation at yielding. This defect can be avoided by temper rolling. However, the stretcher strain will reappear because of strain aging during storage. Orange peel is a pronounced surface roughening in the deformed component made of steel metal of relatively larger grain size. This problem can be avoided using sheet metal with finer grain size so that deformation of individual grain is difficult to distinguish in bare eye (Hosford and Caddell, 2007). In deep drawing process, drawing ratio (DR) is defined as ratio of the initial blank diameter to the punch diameter. Formability in deep drawing is evaluated in terms of LDR, and it is the maximum DR that may be successfully drawn without wrinkling and tearing. The LDR depends on various tool design parameters, process parameters, and material parameters as listed in Table 3 in a very complex manner. Because of multitude of materials,

Table 3. Various factors influencing formability of sheet metal.

Design Parameters	Process Parameters	Material Parameters
Punch corner radius	Blank holding force	Sheet thickness
Die corner radius	Friction and lubrication	Grain size
Punch–die clearance	Mode of deformation	Material properties
	• In-plane (flat punch)	• Anisotropy (R-value)
	• Out-of-plane (domed punch)	• Strain hardening exponent (n-value)
		• Strain rate sensitive index (m-value)
Drawbead design and location	Punch speed	Inclusions and defects
	Strain path

stamping design, and press condition, there is no single analytical formula to predict LDR and defects.

Nonmetallic inclusions have significant influence on fatigue and impact strength apart from deep drawing behavior of steel sheets. Generally, some inclusions entrapped into the molten steel accidentally and others generate in the process of separation from steel when their solubility in the metal exceeds. A study of the fracture surface of IFHS steel specimen reveals the presence of sulfide inclusion (MnS) in the dimples. The crack initiates at the inclusion interface because of difference in plastic deformation, and the crack grows to generate microvoids. The accumulation of these voids leads to material separation as shown in Figure 4. Inclusions of sulfide such as MnS elongate during hot rolling, and these are also responsible for anisotropy in steel resulting different mechanical properties [YS (yield strength), UTS (ultimate tensile strength), *n*-value, and elongation] in different direction with respect to RD (Paul and Ray, 1997). Similarly, the presence of brittle Fe–Zn intermetallic phases at zinc–steel interface in the coated IF steel sheets appears to have a more dominant role in reducing the formability in stretch forming than the beneficial effect of reduced friction at the punch–sheet interface (Gupta and Ravi Kumar, 2006).

2.3 Numerical prediction of deep drawing behavior

Finite-element (FE)-based models of sheet forming processes are now capable of understanding the complex deformation mechanisms and giving outstanding improvements in economy of manufacture and product quality. Accuracy of this numerical modeling technique depends largely on the use of a constitutive material model that describes the deformation behavior, boundary conditions, and failure criteria.

2.3.1 *Theoretical background on finite element method*

In FEM (finite element method), the deformable sheet metal is discretized into number of shell or solid elements of volume, ve, and surface area, se, which are interconnected at nodes. The governing equation over the total deformation region consisting of ne-number of elements can be expressed in matrix form as Equation.

$$\sum_{i=1}^{\mathrm{ne}}\left[\int_{\mathrm{ve}}\left(B^{\mathrm{T}}E_{\mathrm{p}}B\,\widehat{u}+N^{\mathrm{T}}\rho N\ddot{u}\right)\mathrm{d}v - \int_{\mathrm{ve}}N^{\mathrm{T}}\mathbf{f}\,\mathrm{d}v-\oint_{\mathrm{se}}N^{\mathrm{T}}\mathbf{t}\bullet\mathrm{d}s\right]_i=0 \tag{5}$$

where B is the strain displacement matrix relating $\varepsilon_{ij} = B\,\widehat{u}$, E_{p} the constitutive matrix representing elastic–plastic modulus of the material, N the matrix of shape function for interpolating displacement inside element from the nodal displacement vector as $u = N\,\widehat{u}$, ρ the density of the material, $\ddot{u}_i$ acceleration of the body, and $\mathbf{f}$ and $\mathbf{t}$ the vectors representing body force and traction force, respectively. The Gauss quadrature technique is mostly applied for numerical integration for each element and the governing equation can be reduced to the following form (Equation 6) after assembling for all the elements.

$$[m]\{\ddot{u}\}+[c]\{\dot{u}\}+[k]\{u\}=\{F\} \tag{6}$$

where the global mass matrix $[m]=\sum_{i=1}^{\mathrm{ne}}\int_{\mathrm{ve}}N^{\mathrm{T}}\rho N\,\mathrm{d}v$, global stiffness matrix $[k]=\sum_{i=1}^{\mathrm{ne}}\int_{\mathrm{ve}}B^{\mathrm{T}}CB\,\mathrm{d}v$, the force vector $\{F\}=\sum_{i=1}^{\mathrm{ne}}\left(\int_{\mathrm{ve}}N^{\mathrm{T}}\mathbf{f}\,\mathrm{d}v+\oint_{\mathrm{se}}N^{\mathrm{T}}\mathbf{t}\bullet\mathrm{d}s\right)_i$, and the damping matrix is approximately selected in sheet metal forming as $[C]^t=\alpha[m]^t$ and is added to the system. The

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

above-mentioned equilibrium equation is solved at a time step, t, during the sheet forming to obtain the nodal displacement vector at next incremental time, $t+\Delta t$ using central difference scheme as shown by the following two Equations 7 and 8. This procedure is referred as *explicit method*.

$$\{X\}^t = \{\mathbf{F}\}^t - \left[[k]^t - 2\frac{[m]^t}{\Delta t^2}\right]\{u\}^t - \left[\frac{1}{\Delta t^2} - \frac{\alpha}{2\Delta t}\right][m]^t\{u\}^{t-\Delta t} \quad (7)$$

$$\left[\frac{1}{\Delta t^2} + \frac{\alpha}{2\Delta t}\right][m]^t\{u\}^{t+\Delta t} = \{X\}^t \quad (8)$$

However, the explicit method is only conditionally stable with a time increment less than critical value governed by Courant criterion $\Delta t_{\text{critical}} = \left(L_{\min}/\sqrt{E/\rho}\right)$, where $L_{\min}$ is the smallest element size, E the Young's modulus, and ρ the density of the sheet metal (Reddy, 2005; Worswick, 2002).

2.3.2 *Material models for sheet forming*

Material models for sheet metal forming processes that are used in FE simulations are the concept of yield surface, the flow rule, and the hardening rule. The convex yield surface is defined as a function, $f(\sigma_{ij}) = 0$, which encloses the elastic region in the stress space. If the stress state in the deforming body lies on the yield surface, then the material will start to yield. For a small change in stress state directing outside the yield surface, the plastic strain increment is governed by normality rule as Equation 9.

$$d\varepsilon_{ij} = d\lambda\frac{\partial f}{\partial \sigma_{ij}} \quad (9)$$

where $d\lambda$ is an arbitrary constant.

This rule also shows the direction of the plastic flow as shown in Figure 5. During sheet metal forming, the flow strength increases on plastic strain in most of the metal. In the FE analysis, this work hardening or strain hardening description should be incorporated mathematically. There are various phenomenological models and Hollomon's power law hardening expression commonly used for steel sheets is shown in Equation 10.

$$\overline{\sigma} = K\varepsilon^{-n} \quad (10)$$

where K and n are the strength coefficient and strain hardening exponent, respectively.

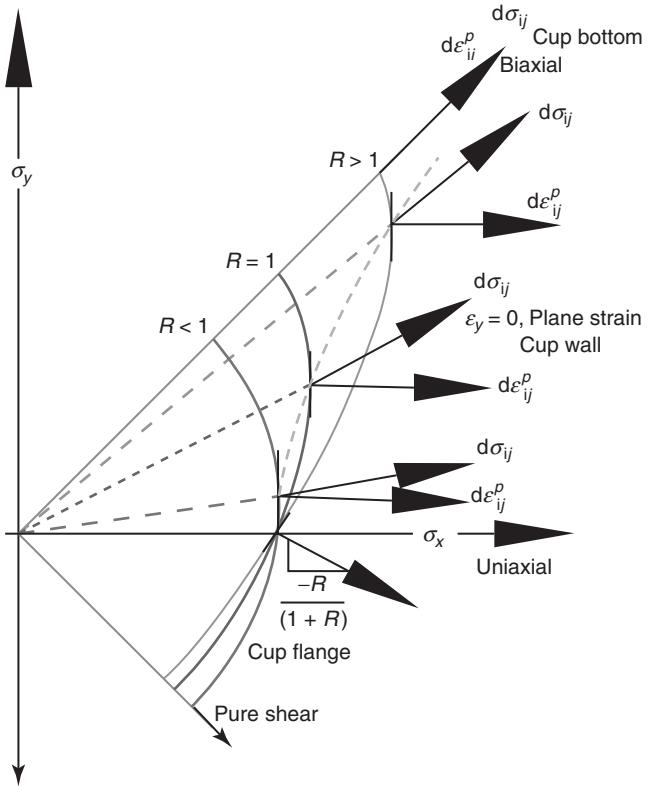

Figure 5. Schematic yield loci for Hill's and von-Mises's yield criterion with stress state of deep drawn cup.

The various yield criteria used extensively in numerical modeling of sheet metal forming are von-Mises, Hill's 48, Hosford, and Barlat89.

2.3.2.1 von-Mises yield function. The von-Mises yield criterion is one of the most widely accepted yield functions for isotropic materials. In sheet metal forming, plane stress condition along thickness direction (z-direction) is assumed while neglecting stresses in the plane of the sheet. The von-Mises yield functions for the plane stress condition is expressed as shown in Equation 11.

$$f = ({\sigma_x}^2 + {\sigma_y}^2 - \sigma_x\sigma_y) + 3{\sigma_{xy}}^2 - \sigma^{-2} = 0 \quad (11)$$

where σ_x and σ_y are the normal stresses, σ_{xy} shear stress, and $\overline{\sigma}$ is the effective stress of material. When $\overline{\sigma}$ reaches yield stress material starts to yield. The yield function is shown in graphical as in Figure 5.

2.3.2.2 Hill's 48 yield function. The most commonly used yield criterion for anisotropic sheet materials is the classical Hill's criterion proposed in 1948 (Hill, 1948), often referred as *Hill's 48*. It is expressed by a quadratic

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

function as Equation 12 for a plane stress condition,

$$2f = H(\sigma_x - \sigma_y)^2 + G{\sigma_x}^2 + F{\sigma_y}^2 + 2N{\sigma_{xy}}^2 - 1 = 0 \quad (12)$$

The relation between Hill's material anisotropy parameters H, G, F, and N can be expressed in terms of Lankford parameters R_0, R_{45}, R_{90} applying flow rule in the Hill's yield function as Equation 13.

$$\frac{H}{G} = R_0 \quad \frac{H}{F} = R_{90} \quad \frac{N}{F+G} - \frac{1}{2} = R_{45} \quad (13)$$

The Hill's 48 yield function can be further expressed as Equation 14.

$$2f = \frac{R_0R_{90}(\sigma_x-\sigma_y)^2+R_{90}{\sigma_x}^2+R_0{\sigma_y}^2 +(R_0+R_{90})(2R_{45}+1){\sigma_{xy}}^2}{R_{90}(1+R_0)\sigma^{-2}} = 1 \quad (14)$$

The effect of normal anisotropy on the yield locus is shown in Figure 5.

2.3.2.3 Hosford yield function. Hosford proposed a nonquadratic yield function as shown in Equation 15 (Hosford, 1985).

$$f = \frac{1}{\{R_{90}(1+R_0)\}^{\frac{1}{a}}} \times [R_{90}|\sigma_x|^a + R_0|\sigma_y|^a + R_0R_{90}|\sigma_x - \sigma_y|^a]^{\frac{1}{a}} - \overline{\sigma} = 0 \quad (15)$$

It can be observed that the yield surface depends on the exponent a as shown in Figure 6. An important drawback of this criterion is caused by the lack of shear stress.

2.3.2.4 Barlat yield function. Barlat and Lian (1989) proposed a nonquadratic yield function, often referred as *Barlat89*, which would accurately predict both normal and planar anisotropic behavior of materials. Under conditions of plane stress, it has the nonquadratic form as shown in Equation 16.

$$a|K_1 + K_2|^M + a|K_1 - K_2|^M + c|2K_2|^M = 2\overline{\sigma}^M \quad (16)$$

where the parameters K_1 and K_2 are defined as Equation 17.

$$K_1 = \frac{\sigma_x + h\sigma_y}{2} K_2 = \sqrt{\left\{\frac{\sigma_x - h\sigma_y}{2}\right\} + p^2{\sigma^2}_{xy}} \quad (17)$$

where σ_x and $\sigma_y$are the normal components of stress in an arbitrary set of orthogonal directions and σ_{xy} represents the shear stress. On the basis of crystalline plasticity considerations for face-centered cubic (FCC) materials,

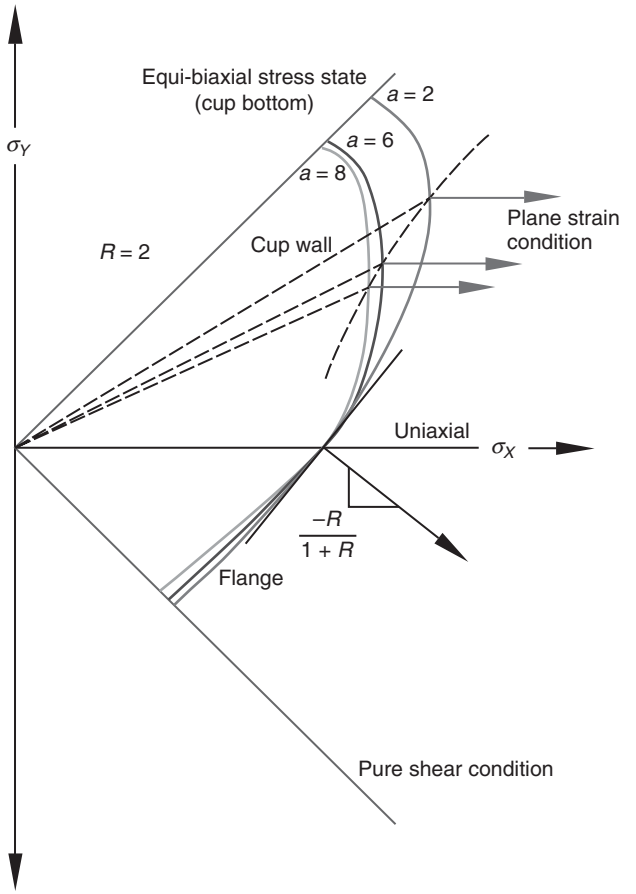

Figure 6. Schematic yield loci for Hosford's yield criterion with stress state of deep drawn cup.

Barlat determined that a value of $M = 8$ is appropriate, whereas for body-centered cubic (BCC) materials, a value of $M = 6$ is appropriate based on crystalline plasticity calculations. The material parameters, a, c, h, and p, can be determined using the Lankford coefficients, R_0, R_{45}, and R_{90}, with the help of Equations 18 and 19.

$$a = 2 - c = 2 - 2\sqrt{\left(\frac{R_0}{1+R_0}\right)\left(\frac{R_{90}}{1+R_{90}}\right)} \quad (18)$$

$$h = \sqrt{\left(\frac{R_0}{1+R_0}\right)\left(\frac{1+R_{90}}{R_{90}}\right)} \quad (19)$$

Figure 7 shows schematic drawing of Barlat's yield criterion along with the effect of M.

2.3.3 *Failure criteria- forming limit diagram*

Failures of sheet metal occur by strong local thinning/necking after diffuse necking. The deformation is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

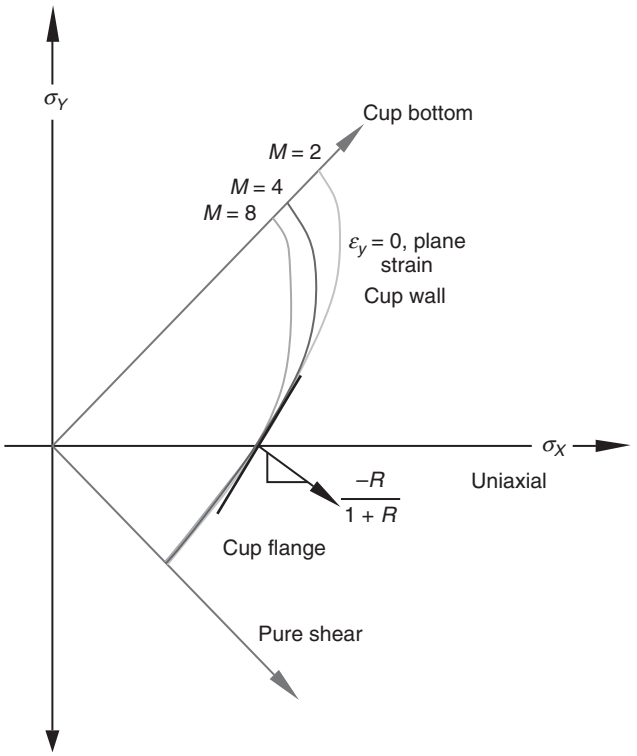

Figure 7. Schematic yield loci for Barlat's yield criterion with stress state of deep drawn cup.

confined to the localized necking region without further contraction of width of specimen and this region leads to tearing of sheet metal on further deformation. This localized necking is a visible indication that the sheet metal has been worked beyond its prevailing limit. Whether or not a particular sheet metal can be formed without failure depends on many factors such as material properties, surface conditions, blank size and shape, lubrication, press speed, blank holder pressure, and punch and die design. Because of this, source of flow localization problem is difficult to pinpoint and quantify. In the past a few decades, the technique of analyzing failures in sheet metal stampings through the use of circle grids and forming limit diagrams (FLDs) has gained considerable importance. The forming limits, determined by elaborate laboratory experiments, are typically represented in terms of limiting principal strains, known as the *FLD*. The diagram was first constructed by Keeler and Goodwin, following the concept of Keeler and Backofen (1963). The FLD represents the onset of localized (visible) necking over all possible combinations of strains in the plane of a sheet. Figure 8 shows the "Keeler–Goodwin" curve that characterizes the forming limits of a 1 mm thick low carbon steel sheet. This diagram describes the combinations of major and minor principal surface strains at which a highly localized zone of thinning or necking becomes visible on the surface of the sheet metals. The shaded area represents the scatter of results between strain combinations that are safe and those which cause failure. The lowest surface strain occurs at plane strain tension. The detailed procedure for determination of the FLD has been explained in several publications (Hecker, 1975; Hiam and Lee, 1978). After the initial work of Keeler and Goodwin, a large number of investigations (Ghosh and Hecker, 1975; Coubrough, Matlock, and Van Tyne, 1993; Talyan, Wagoner, and Lee, 1998) were carried out for experimental determination of FLDs of various materials such as deep DQ steel, EDD quality steel, HSLA steel, and stainless steel. Many theoretical models have been proposed to predict FLDs of sheet metals. Marciniak and Kuczynski (1967) developed a theoretical model for predicting the FLD based on the assumption of existence of an initial nonhomogeneity of the material in the form of a groove. This model was formulated for sheet metals subjected to biaxial tension, when the ratio of principal stresses lies in the range 0.5–1.0. This model was extended by Sowerby and Duncan (1971) to cover all cases of biaxial tension. Many more theoretical models were subsequently formulated based on the M–K model to predict the FLDs (Tadros and Mellor, 1975; Korhonen, 1978; Lu and Lee, 1987; Barlat and Lian 1989). The effects of strain hardening exponent (n), strain rate exponent (m), and strain ratio on FLD were analyzed by some researchers (Marciniak, Kuczynski, and Pokora, 1973; Graf and Hosford, 1990). Some approaches that are not based M–K hypothesis have also been proposed to predict limit strains (Jones and Gillis, 1984; Choi, Gillis, and Jones, 1989; Pishbin and Gillis, 1992). However, there has always been some deviation in the theoretically predicted FLDs from the experimental curves because of a variety of reasons.

To analyze sheet metal forming, Chow, Jie, and Hu (2003) determine the forming limit by applying Hosford nonquadratic yield criterion and the concepts of plasticity theory on Storen–Rice vortex theory (Storen and Rice, 1975). The details of the formulation of this theoretical FLD damage model are published elsewhere (Chow, Jie, and Hu, 2003). This damage model was also applied successfully in prediction of FLD of TWBs. In FLD, the limiting curve intersects the Y-axis (major strain axis or the plane strain line) by an intercept called FLD_0. Despite all the recent enhancements of the computational models, they are not able to give very accurate predictions of the limit strains in all the cases encountered in practical applications (different materials, thickness, forming rates, temperatures, strain paths, etc.). Owing to this fact, the commercial finite element codes still make use of experimental FLDs or

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

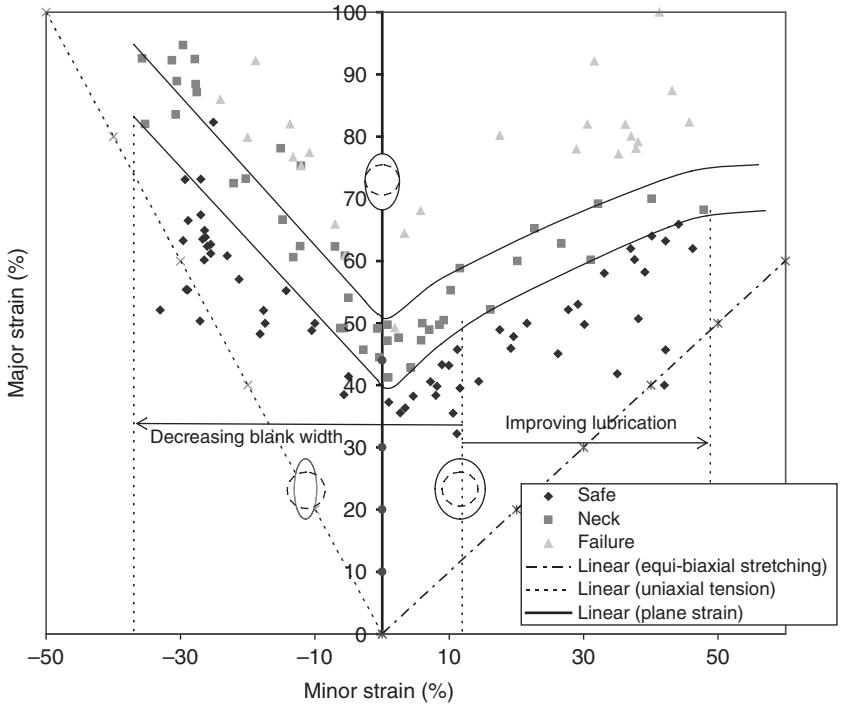

Figure 8. Forming limit diagram of a low carbon steel sheet showing different strain paths.

calculated FLDs with simple semiempirical models. Keeler and Brazier (1977) proposed an empirical relationship for calculating the limit strains corresponding to plane strain, FLD_0, using thickness and n-value of the sheet material. Equations 20, 21, and 22 are listed (all strain in the equation is true strain).

$$\mathrm{FLD}_0^{\mathrm{True}} = \ln\left[1 + (0.233 + 0.413t)\,\frac{n}{t}\right] \tag{20}$$

$$\varepsilon_1 = \mathrm{FLD}_0^{\mathrm{True}} - \varepsilon_{2,} \text{ while } \varepsilon_2 < 0 \tag{21}$$

$$\varepsilon_1 = \ln\left[0.6\left(\exp\left(\varepsilon_2\right) - 1\right) + \exp\left(\mathrm{FLC}_0^{\mathrm{True}}\right)\right] \tag{22}$$

where t is sheet thickness in inches and n strain hardening coefficient of the sheet.

Comparison of experimental and theoretical FLDs for HSLA, DP980, and DP600 steel sheets is shown in Figure 9. Experimental limit strains of HSLA sheet are close enough to Keeler–Brazier FLC; however, limit strains of DP980 and DP600 are matching well with the strains predicted by Storen–Rice vortex theory using Hosford yield criterion for $a = 6$ and 4, respectively. The near plane strain conditions show difference as much as 16%, but they are close to experimental strains in other regions. It can also be observed that yield criteria do not affect the forming limits in the tension–compression region, but it has remarkable influence in the tension–tension region of FLC. Moreover, as the order of Hosford yield criterion increases, the predicted limit strains decreases in the tension–tension region (right-hand side) of FLC. Suitable theoratical model of FLD has to be incorporated as a damage model in FEM. The calculated major and minor strain data points at each step of the deformation are superimposed on the FLD curve. The cup failure takes place at the cup depth when the strain state falls above the FLD while evaluating the formability.

2.3.4 *Prediction of limiting drawing ratio and earring*

In circular cup deep drawing, the method of determining LDR is well established. However, the LDR while drawing of noncircular parts can be calculated indirectly by replacing the punch and blank area by circles of equal size and calculating their respective equivalent diameter (Equation 23).

$$D_{\mathrm{p}} = 2\sqrt{\left(\frac{A_{\mathrm{P}}}{\pi}\right)}$$

$$D_{\mathrm{o\,max}} = 2\sqrt{\left(\frac{A\mathrm{o}}{\pi}\right)} \tag{23}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

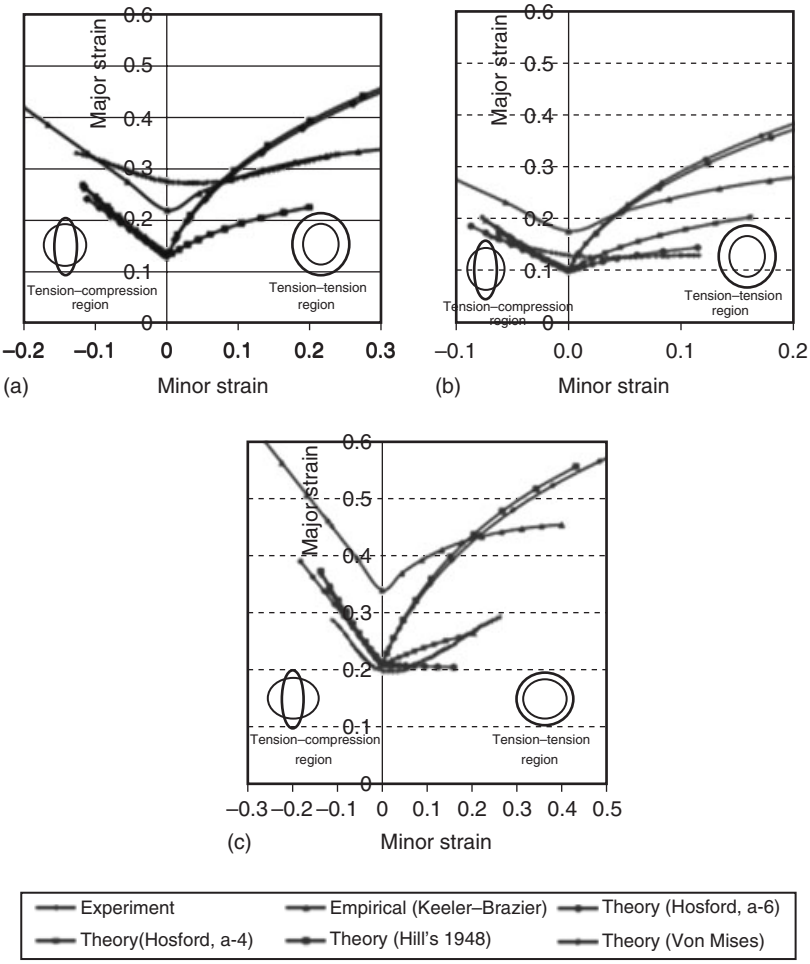

Figure 9. Comparison of experimental and theoretical forming limit curves: (a) HSLA, (b) DP980, and (c) DP600.

The DR can be calculated as for circular components by Equation 24.

$$\mathrm{DR} = \left(\frac{D_{\mathrm{o\,max}}}{D_{\mathrm{p}}}\right) \tag{24}$$

The LDR can be determined by two commonly used analytical relations namely Whiteley's (1960) and Leu's (1997) formula. Whiteley proposed the Equation 25 to predict LDR.

$$\mathrm{LDR} = \mathrm{e}^{\mathrm{f}\sqrt{(1+\overline{R})}/2} \tag{25}$$

According to this formula, the LDR increases with increasing $\overline{R}$ value. The formula proposed by Leu (Equation 26) considers the effect of both n and $\overline{R}$ value.

$$\mathrm{LDR} = \sqrt{\{\mathrm{e}^{2\mathrm{f}\,\mathrm{e}^{-n}\sqrt{(1+\overline{R})/2}}\} + \{\mathrm{e}^{2n}\sqrt{((1+\overline{R})/2)}\}} \tag{26}$$

The theoretical LDR from both the methods was calculated on the assumption that the drawing efficiency (f) is 0.9. The LDR obtained from FE simulations using Hill's, von-Mises's, and Barlat's yield criterion and analytical relationships was compared with the experimental results as shown in Figure 10. The LDR predicted by Barlat's yield criterion is very close to experimental LDR in both cylindrical and square box drawing cases (2.3% and 0.9% deviation). Whiteley's formula over predicted the LDR for both cases. However, Leu's formula over predicted the LDR in case of cylindrical cup and under predicted the LDR of square cup. These analytical relations do not consider design parameters and blank geometry and hence LDR predictions deviate from experimental results. The von-Mises's yield criterion, which is an isotropic yield criterion, does not consider the influence of normal anisotropy parameter while evaluating LDR. For both cases, Hill's yield criterion predicted higher LDR than experiment as the cup wall strength increased during cup drawing following plane strain deformation path. The increase in cup wall strength during plane strain deformation is predicted to be higher by

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto155
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

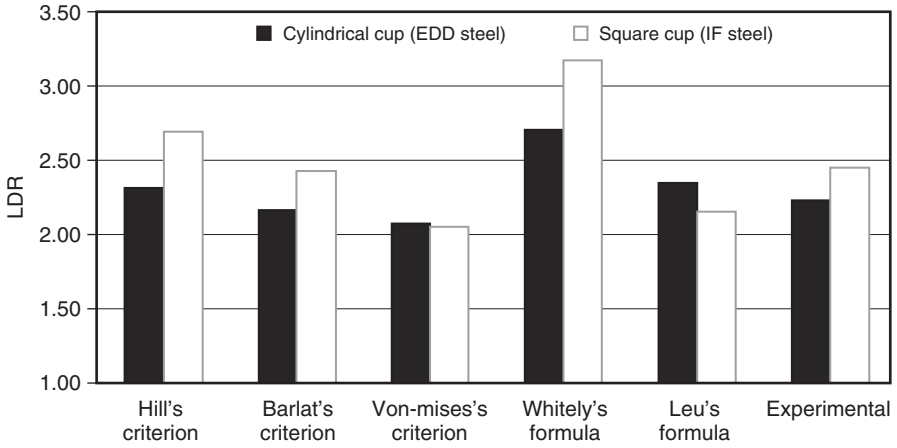

Figure 10. Comparison of LDR obtained through different methods for cylindrical cup drawing (EDD steel) and square cup (IF steel).

Hill's criterion and hence higher LDR is predicted than the Barlat's yield criterion (Barlat and Lian, 1989).

The EDD and IF steels both have high normal anisotropy $\overline{R}$ and planar anisotropy ΔR values, so significant earring was observed in the drawn cups. It can be seen that four ears have formed in case of cylindrical cup, at 0° and 90° to the RD because the ΔR-value of this material is positive. In FE-simulated cups, ears were formed in case of Barlat's and Hill's yield criteria because these criteria incorporated both normal and planar anisotropy. However, earring was not observed in case of von-Mises's yield criterion, which is an isotropic yield criterion (Figure 11). The cup is divided into angles with respect to RD to determine the cup height and the earring profile obtained for cylindrical cup from the FE simulations using Hill's and Barlat's yield criterion was compared with the experimental profile (Kishore and Ravi Kumar, 2002) as shown in Figure 12. The cup height of the experimentally drawn cup was nonuniform because of eccentricity in placing the blank holder on the blank and because of lack of exact centering of the blank. The cup height predicted by the FE simulations at points of ear formation is lower as compared to the actual cup height at ears. However, it is very difficult to point out the yield criterion that is predicting the ear profile in a better manner. Hence, the percentage ear height with respect to minimum cup height was determined and compared as shown in Figure 13. It was observed that the Hill's yield criterion predicted the ear profile more accurately. It was calculated that the maximum percentage ear height was 14.22% in the experiment and 14.27% in the FE-simulated cup using Hill's yield criterion, respectively. However, the maximum percentage ear height was 6.83% for the cup drawn using Barlat's yield criterion. Four ears have formed in case of square cup at the four corners representing 45° and 135° to the RD. The blank material available on die opening offers less resistance at side edge compared to diagonal direction as more material is available to deform in diagonal direction. The square cup obtained from the FE simulations using the three yield criteria has predicted earring in the cups. It is observed from the Figure 11 that square cup is having ears in spite of using von-Mises's yield criterion in FE simulations. Similar to the cylindrical cup drawing case percentage ear height with respect to minimum cup height has been determined for all the three cases and compared. It is observed that FE simulations are predicting similar ear height (as well as percentage ear height) with both Barlat's and Hill's yield criterion (Figure 14). Hence, it can be concluded that the geometry of tooling is mainly responsible for ear formation in square cups.

Numerical simulation was extensively studied incorporating different die radius, punch corner radius, and coefficient of friction between tooling for various steel sheet materials such as EDD, IF, HSLA, DP, DQ, and DDQ. It was observed that LDR increased with increase in punch corner radius and die corner radius, but the increase was more significant in case of die corner radius. The LDR decreased linearly with increase in friction. The LDR varied significantly with $\overline{R}$-value but strain hardening exponent had a negligible influence.

2.3.5 *Modification of blank shape to minimize earring*

Earring is highly undesirable as it adds on an additional processing step "trimming" and also metal representing ear will undergo deformation that demands extra load and work. One case study of modification of initial circular blank shape (blank diameter 82 mm) is studied in this

section. The modified X- and Y-coordinates were done as per the Equations 27 and 28.

$$\text{Modified X-coordinate} = R - \beta\Delta r_1 \tag{27}$$

$$\text{Modified } Y\text{-coordinate} = R - \beta\Delta r_2 \tag{28}$$

where R is the initial radius of the circular blank, $\Delta r_1 = R_0 - R_{45}$ and $\Delta r_2 = R_{90} - R_{45}$.

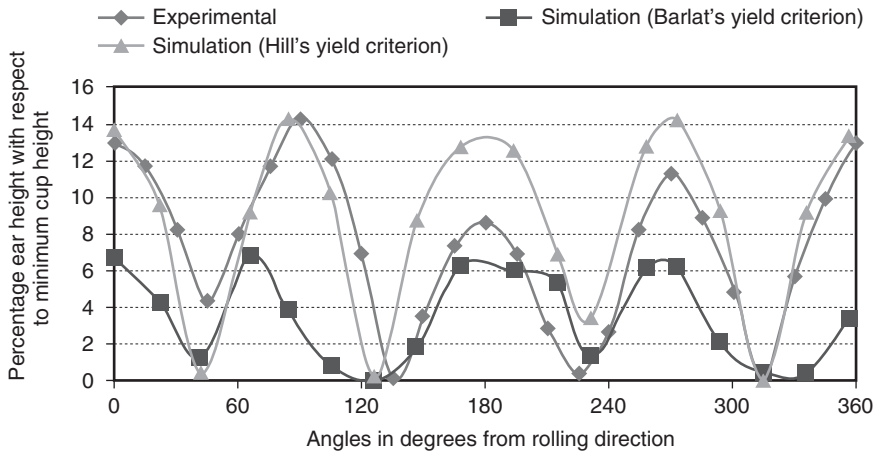

Figure 13. Comparison of percentage ear height above the minimum cup height based on experiment and yield criteria.

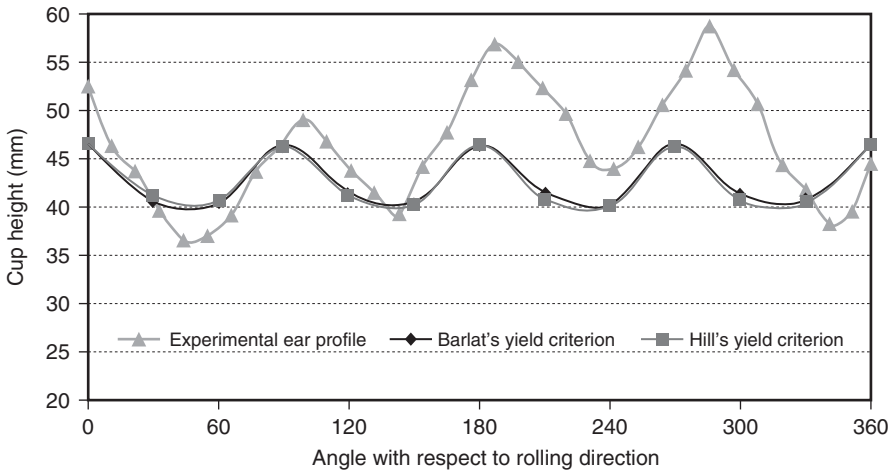

Figure 14. Comparison of cup height for a DR of 2.127 (108 mm blank diameter).

The detailed procedure was described elsewhere (Kishore and Ravi Kumar, 2002). Figure 15 shows the initial blank shape and modified shape of the initial blank using different $\beta = 3$, 6, and 8 values. Figure 16 shows the top view of the simulated cup at the stage when the ear touches the die corner radius. It was observed at this stage that the ear height in case of modified blanks was less than the initial circular blank shape. The completely drawn cups without and with modification are shown in Figure 17. It can be observed from figures that the ear height is decreasing in the case of modified blank after they have been completely drawn. The cup height reduced by 22.37% in the case of modified blank 1, 62.86% in modified blank 2, and 51.23% in the case of modified blank 3 as compared to initial circular blank. Comparison of cup height of conventional circular blank and modified blank shape is shown in Figure 18. The percentage ear height was determined in the case of initial circular blank and modified blank using approach 2 (Figure 19). It shows that use of modified blanks instead of circular blank while drawing cylindrical cups can save material during trimming operation. It was found from deep drawing experiments of circular and modified blank that the maximum load required to deform decrease by 7.0% because of the elimination of ears. It leads to less power consumption during deformation of modified blank that may increase cost effectiveness of the process. There are various theoretical techniques to estimate the load and power consumptions in deep drawing processes such as slab analysis (Hosford and Caddell, 2007), FEM (Worswick, 2002), upper bound technique (Agrawal, Reddy, and Dixit, 2008), and slip line field theory (Hosford and Caddell, 2007). However,

the details of these techniques are not within the scope of this chapter. To completely eliminate the waviness at the cup top need further optimization of the blank shape. This method of blank modification can be extended to other initial blank shapes for minimizing earring and wastage of scrap during automotive component stamping.

After finalizing the two-dimensional arbitrary shape to minimize the earring, the required shape has to be blanked

out from the coil to reduce the amount of scrap. Owing to rapid development of CAD/CAM technologies, soft computing expert systems and optimization techniques, efficient methods of blank layout, or nesting from the strip or coil can be planned using progressive dies (Prasad, 1994; Ghatrehnaby and Arezoo, 2009). It was reported that approximately 30–50% of sheet materials procured is wasted as scrap. Proper utilization of the materials purchased is required to decrease the cost of the part produced, as only material cost shares 70% of the total cost (Ghatrehnaby and Arezoo, 2009). However, the factors to be considered in nesting to minimize the scrap are crystallographic orientation in the sheet (i.e., directionality of properties), direction of the burr, type of stock (strip or coil), type of press (mechanical or hydraulic), die cost, and size, shape, and thickness of the blank. TWB technology is also a best practice to reduce scrap production as the scraps can be utilized by welding and forming components for different applications.

2.3.6 *Deep drawing through tractrix die*

While deep drawing through conventional die using blank holder, the blank is bent through 90° as it passes over the die entry radius and then has to unbend as it straightened out to form cylindrical wall. This bending and unbending considerably exhaust ductility of the metal during deep drawing. Hence, contoured die was proposed by various researchers (Al-Makky and Woo, 1980; Narayanasamy and Sowerby, 1995) to increase the DR while eliminating the blank holder. The deep drawing can be possible in a single action press reducing the cost of the equipments and toolings. The die is referred as *tractrix die* if the die contour profile is a tractrix profile as shown in Figure 20a. The tractrix profile satisfying Equation 29 ensures only blank edge contact between blank and die during cup drawing reducing the frictional force. Bending occurs around the punch corner without any unbending action during deep drawing through tractrix die and hence a bigger cup can be drawn. It is found in practice that the exact tractrix die contour is difficult to fabricate, which will always give edge contact. Hence, modified tractrix die profile with a conical surface was proposed as shown in Figure 20b. It was observed that a sheet metal having very low normal anisotropy parameter, $R = 0.8$ had an LDR of 1.73 in

conventional deep drawing, and the LDR was increased to 2.36 in tractrix die. The cross section of the maximum cups drawn by conventional die and tractrix die is shown in Figure 20d and c. The comparison of thickness profile obtained from experiment and numerical simulation is shown in Figure 21. However, it was observed that the sheet thickness and clearance plays a role for successful drawn cup. The drawn cup usually fails due to wrinkling and fracture. The safe working zone for a 75 mm circular cup drawing is shown in Figure 22. It can be very well

3 FORMABILITY OF TAILOR-WELDED BLANK

3.1 Tailor-welded blank fabrication-laser welding

The various fusion and solid-state welding techniques adopted for fabrication of TWBs are tungsten inert gas (TIG), metal inert gas (MIG), electron beam welding (EBW), laser beam welding (LBW), and friction stir welding (FSW). Among these processes, laser welding of steel sheets is frequently used by the industries because of narrow weld and HAZ (heat-affected zone) width with higher penetration. The different lasers adapted for welding processes are CO_2 laser, YAG (yttrium aluminum garnet) laser, diode laser, and fiber laser. Laser spot size in YAG laser and fiber laser is in micrometer level and hence is capable of producing very narrow weld width. Weld quality should be good and free of imperfection/defects as it may significantly affect postweld forming process. Some common welding defects are lack of fusion (due to misalignment of beam), lack of penetration (due to insufficient energy density of the laser source), concavity (due to

Table 4. Weld width and maximum weld hardness in different laser-welded sheet metals.

Welded Blanks	Power (kW)	Scan Speed (mm min^{-1})	Weld Width (mm)	Maximum Weld Hardness (VHN)
IF–IF(both 1.0 mm)	1.8	6000	0.49	187
IFHS–IFHS (both 0.7 mm)	1.5	6000	0.62	227
HSLA–HSLA (both 1.0 mm)	1.8	6000	0.68	349
IF–IFHS (1.0 mm	1.6	6000	0.62	173
IF1.0–HSLA1.0	1.8	6000	0.72	352
DP980–DP980	1.8	1000	1.50	452
DP600–DP600	1.8	1000	1.25	398

lack of filling material in the weld zone), undercut (due to high surface tension of weld pool), porosity (due to evolution of absorbed gas from molten metal), and misalignment of the sheet metals to be welded. TWBs with above weld defects fail in the weld region during sheet-forming processes leading to drastic decrease in formability. Weld quality in TWBs is generally tested by visual inspection, observing weld macrostructure, microhardness test, tensile test of transverse weld specimen, and Erichsen cupping test. Successful fiber laser welding parameters for fabrication of TWBs are given in Table 4 for various automotive steel sheet grades. The weld width and hardness depends on laser power, scan speed, and the sheet material. The influence of sheet material chemistry in terms of CE on average weld hardness and relative formability is shown in Figure 23. The relative formability is calculated in terms of ratio between the Erichsen cup height of the laser-welded blank and corresponding parent metal. It can be observed that increase in CE from 0.002 to 0.41 in steel sheets decreases the Erichsen cup height of laser-welded blanks to 57% of that of parent metal. Hence, influence of weld zone in formability is significant at higher steel chemistry because of increase in weld hardness.

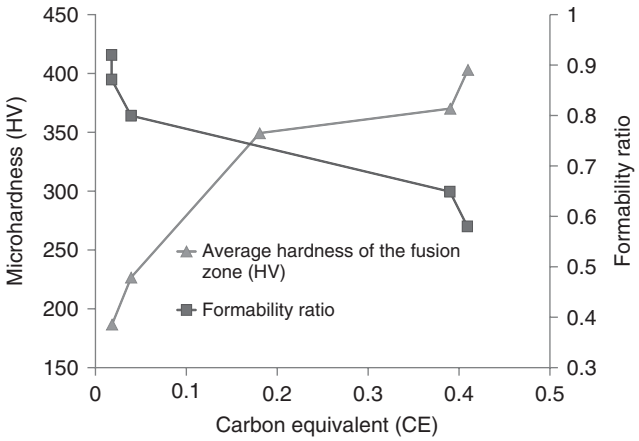

Figure 23. Dependence of hardness of the fusion zone and the relative formability of the LWBs on carbon equivalent.

The weld macrostructure and microhardness profile across the weld for DP980 and DP600 laser-welded specimen are shown in Figures 24 and 25. There are various observations those can be made for these weld. The first is that the weld fusion zone (FZ) is narrow and has excellent penetration into both the sides of sheet metal. The hardness (Figure 24) is observed to decrease in the outer HAZ region compared to parent DP980 metal and this is referred as *soft zone* (*SZ*). The peak temperature experienced by this region is below the AC_1 temperature, and hence, austenitization transformation is not possible in this region. However, tempering of preexisting martensite occurred during laser welding and 25% reduction of hardness was observed in this region. The SZ was not observed in the DP600 steel (Figure 25). However, hardness gradually increases toward the HAZ closer to the FZ. This inner HAZ region has experienced recrystallization and maximum hardness was recorded near the boundary of HAZ and FZ. FZ and inner HAZ are referred as *hard zone* (*HZ*). The presence of SZ is responsible for decrease in ductility and strength of DP980 laser-welded sheet because of strain localization and premature failure of the DP980 laser-welded specimen. This observation is clearly shown in Figures 26 and 27. The weld HZ and SZ significantly affect the formability. The influence of weld zone on formability can be characterized by standard Erichsen cup test. It was observed that DP600 laser-welded blanks showed lower cup height than that of parent metal because of reduced ductility of the hard weld zone and 39% reduction in cup height was observed for DP980 laser-welded blanks because of strain localization in the SZ during deformation. Hence, the presence of SZ is detrimental in forming of welded DP steels. However, TWB sample of IF–IFHS and IF–HSLA failure occurred in the weaker or thinner side justifying good quality weld (Figure 28). The fracture location depends on difference in properties and thickness, but the latter plays more critical role. The nonuniform deformation leads to decrease in ductility of the TWBs as shown in Figure 29.

3.2 Deep drawing behavior of tailor-welded blank

Cylindrical flange drawing operation was carried out by a 36 mm punch and the cup height just at the start of necking for 80 mm circular blank was considered as the measure of deep drawability. The drawn cups of the parent metals and welded blanks are shown in Figure 30. The IF steel has higher drawability with a cup height of 22.25 mm compared to 13.33 mm of HSLA sheet. This is due to higher resistance to thinning of IF steel as it has a higher anisotropy parameter (*R*-value) compared to that of HSLA. The reduction in cup depth in all the similar laser-welded blanks compared to the respective parent metals is about

5–7%. This is due to negligible influence of a very narrow weld zone on the drawability of the selected laser-welded sheets, and similar observation was also during uniaxial transverse tensile testing.

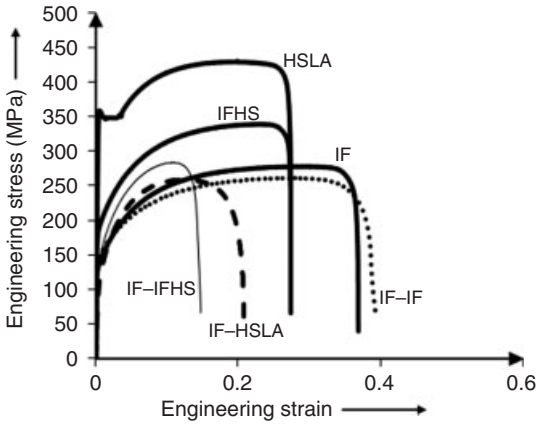

Figure 29. Engineering stress–strain curves of parent metals, IF–IF similar welded specimen and TWBs.

3.2.1 Drawability and failure location of TWBs

Figure 30c shows comparison of failure locations in the drawn TWBs. In the IF–IFHS TWB with thickness ratio of 1.43, the cup depth was found to be 19.45 mm, which was more than the cup depth of the thinner parent metal

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

IFHS (18.25 mm) but lower than the thicker counterpart IF (22.5 mm). In the IF–HSLA TWB having strength ratio 1.56, the cup depth was found to be 14.20 mm, which is higher than the cup depth of HSLA parent metal (13.33 mm) but very much lower compared to IF parent metal. Hence, drawability depends on the material combination in TWBs. IF–IFHS TWB was found to have necking in the thinner IFHS side. However, in IF–HSLA TWB, necking was found to be initiating at the stronger HSLA side, which deviates from the fracture location in tensile testing (Figure 28). This is due to lower anisotropy parameter, *R*-value of HSLA, and hence it offers less resistance to thinning during deep drawing of IF–HSLA TWB leading to failure in HSLA side. Simulation results were found to agree very well with experimental cup height and failure location.

3.2.2 *Weld line movement and thickness distribution*

Weldline was found to move toward stronger or thicker side at the center of the drawn TWB cups. A maximum weldline movement of 2.57 mm was observed toward HSLA side at the cup center because of resistance from stronger side while drawing IF–HSLA TWB into the die cavity. In addition, the weldline moved by 4.02 mm in opposite direction, that is, toward the IF (weaker side) at the outer most cup flange. However, very negligible weld movement was observed in IF–IFHS TWB compared to IF–HSLA TWB. Figure 31 shows the comparison of weldline profile

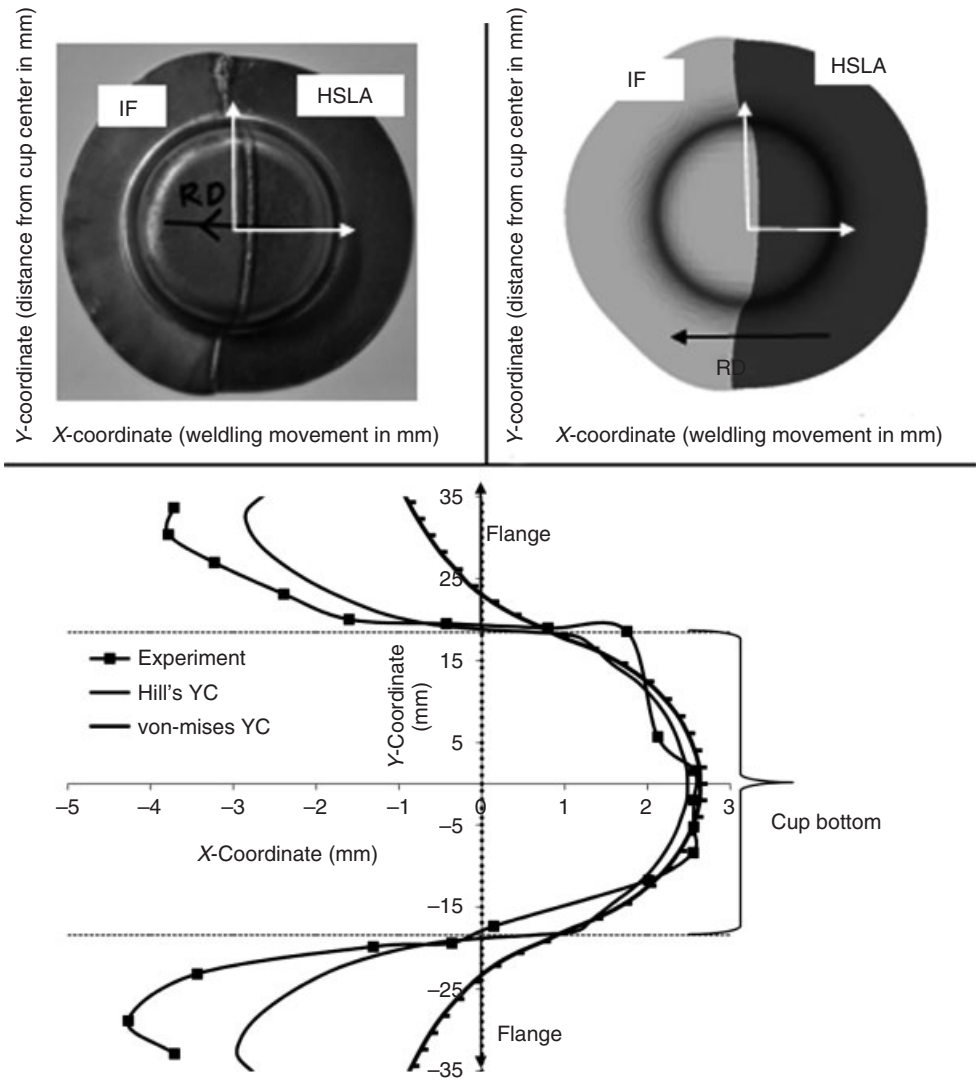

Figure 31. Comparison of experimental and numerical weldline movement in deep drawn IF–HSLA TWB cups.

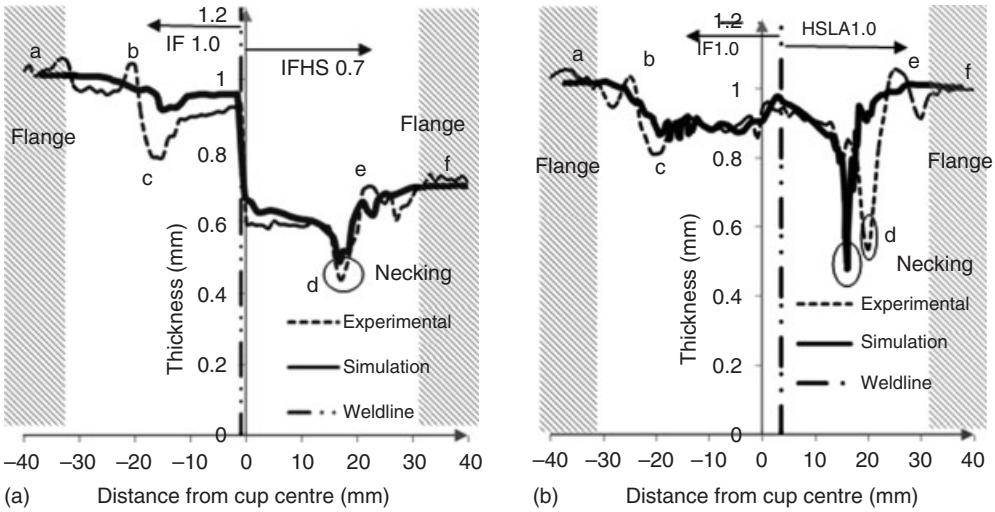

Figure 32. Thickness distribution in deep drawn cups across the weld in TWBs: (a) IF–IFHS TWB and (b) IF–HSLA TWB.

after deformation in the experiment and simulation for IF–HSLA TWB. The comparison of thickness distribution along RD (i.e., across the weldline) of both the TWBs is shown in Figure 32. It was observed that maximum thinning took place in the cup corner corresponding to the punch corner (at location-d). Minor thickening was also observed at the flange. In the IF–IFHS TWB, reduction in thickness was observed on the flat portion of the cup, although necking occurred in the thinner IFHS side corresponding at the cup corner, indicated by location-d. In IF–HSLA TWB, reduction in thickness on the flat portion of the cup was negligible and necking occurred at the cup corner region in HSLA side (location-d). These results revealed the influence of thickness ratio and *R*-value in thinning during deep drawing of TWBs.

4 CONCLUSIONS

Formability study is an important aspect of stamping lightweight automotive body components from various alternative sheet steels and TWBs. It was observed that forming behavior of the sheet metal is significantly influenced by various design, material, and process parameters. This chapter provides insights into various formability measures through laboratory scale experiments and FE-based CAE (computer-aided engineering) techniques. This chapter also highlighted prediction of earring, necking, and wrinkling during steel sheet deformation. Large reduction in formability of two AHSS laser-welded steel sheets, for example, DP980 and DP600, was observed because of hard weld zone and soft outer HAZ. The reduction in cup depth of all laser-welded IF, IFHS, and HSLA is negligible because of narrow weld zone without any soft outer HAZ. Hence, the presence of SZ was detrimental in forming of welded DP steels. The presence of SZ and various defects in weld zone of laser-welded blanks can be characterized by macro- and microstructures with microharness testing before forming. Fracture took place in thinner IFHS side of IF–IFHS thickness combination TWB and material with lower anisotropy HSLA of IF–HSLA material combination TWB. Weld line movement was observed toward HSLA in the cup bottom and toward the IF side in the flange leading to nonuniform deformation of TWBs indicated by thickness distribution. Hence, formability, weldline movement, and failure location in TWBs were influenced by additional parameters such as difference in thickness, difference in properties, and difference in weld zone properties.

1 PROCESSING OF POLYMERS

High volume automotive part production requires a range of polymer processing methods because of the diversity of parts required. Besides standard molding processes, several other special forming methods are available.

The following focuses on automotive-relevant molding and forming processes such as injection molding, which is used broadly for both nonstructural and structural parts; extrusion of semifinished products; thermoforming of larger parts; and foaming of lightweight parts.

This chapter provides an overview of the most significant processes. Furthermore, some new and innovative process examples will be presented. This section focuses on thermoplastic material processes. Thermoset composite materials that are mainly processed by compression molding will be presented (see Processing of Polymeric Composites) (Figure 1).

2 INJECTION MOLDING

Injection molding is the dominate processing method used to produce plastic parts in high volume. It has fast cycle times and produces finished parts directly from raw materials. Molded parts are normally made to net shape and require little to no post finishing. Although thermoplastic materials are primarily used for injection molding, thermosets and elastomers can also be used.

In addition to simple mass-produced components, complex shapes can be automatically produced in a single operation. Injection molding is ideal for weight reduction, cost savings, and provides design flexibility to adjust form factor to fit space constraints.

2.1 Thermoplastic injection molding

Thermoplastic injection molding is the foundation for all other injection processes, and it is the most common plastic processing method. Piston type injection molding was introduced by the end of the 1950s. These machines melted polymer pellets in a heated cylinder and injected them using a piston.

At present, single screw injection molding is the most common method in which granular plastics are fed from

Figure 1. Environmentally friendly polymer materials in automobile manufacturing. (Reproduced with permission from Daimler © Daimler AG.)

a hopper into a reciprocating screw inside in a heated barrel in order to plasticize and shear the material into a relatively homogeneous melt. The melt collects at the front of the tip of the retreating screw. In the so-called injection phase, the screw is set back by hydraulic or mechanical force under pressure to axially feed (auger acts as a piston) the molten polymer into the cavity. The melt is injected at high pressure (usually 500–2000 bar) through a nonreturn valve on the injection nozzle and flows through a gate into the mold cavity. Following the high pressure injection, a lower packing pressure is applied until the material in the gate has solidified. Parts manufactured by injection molding have tolerances up to 1/100 mm or even better in special applications.

The two main sections of an injection molding machine are:

- The injection unit that processes and injects the molten polymer under high pressure into the mold.
- The clamping unit that holds the tool and provides an opening and closing function.

A three-zone screw is used for most thermoplastic processing. First, the feed zone is where the plastic pellets are gravity fed from a hopper into the barrel. Next, the compression zone is where the plastic is plasticized and compacted (degassed). Finally, there is the discharge zone, also known as *metering*, where the material is homogenized and finally injected through a nonreturn valve in front of the screw. Owing to increasing back pressure in the cylinder front, the screw moves axially backward. The nonreturn valve prevents the injection melt from flowing back into the screw. This arrangement allows the screw to function as an injection piston (Figure 2).

Typical process values for thermoplastic injection molding are

- mold temperature: 30–120°C, usually 50–80°C;
- melt temperature: 200–320°C;
- feed pressure: 0–50 bar;
- injection pressure: 200–1500 bar;
- packing pressure: 50–70% of injection pressure (Figure 3).

2.2 Elastomer injection molding

The primary difference between injection molding of elastomers and injection molding of thermoplastics is the

temperature distribution inside the machine. In order to process elastomers, the cylinder around the screw is maintained uniformly at about 80°C using a water jacket to prevent premature vulcanization before the material being injected into the mold. In addition, the elastomer powders are fed by a special ribbon-shaped auger that generate little shear to the plasticized composition.

One additional consideration when molding elastomers is the material's low viscosity state, almost in a liquid form before injection. This process also requires more attention to the design of the tool surface; otherwise, the elastomer injection process is similar to thermoplastic injection molding.

Hoses, seals, and dampeners are typical elastomer molding applications. Elastomers are often used as a functional element when combined with other plastic or metal materials.

2.3 Thermoset injection molding

Injection molding thermosets is similar to the elastomer molding process. Thermoset materials harden at relatively low temperatures. Once cured, no additional processing is possible. The viscosity decreases with increasing temperature and increases during the chemical cross-linking phase. Therefore, the material has a narrow "process window" for optimal flow behavior. To avoid premature initiation of the chemical cross-linking, processing temperatures must be carefully controlled.

The injection unit mixes the chemical units (usually part A and part B) through the screw, which is shorter and has deeper cuts compared to that used for thermoplastic pellets. The compression in the thermoset screw is low because of the low viscosity of the uncross-linked materials. The molds require high surface quality and additional measures for reduced flash formation are necessary. The mold is heated to the curing temperature, which is commonly between 150 and 250°C for thermoset materials. Once 80% of the material has been cross-linked, the material has sufficient strength to be demolded. On demolding, the part will still be relatively hot and will continue to cross-link until a full cure is achieved. Injection molded thermoset components are often used in applications requiring higher temperature and chemical resistance than common thermoplastic materials. They also have high mechanical strength and dimensional stability, especially when reinforced with fibers. These applications are often found in automotive, rail, and aerospace industries.

Plastic processing associated with fiber reinforcement will be described in more detail in Processing of Polymeric Composites.

2.4 Special processes

In addition to traditional injection molding methods, there are a number of advanced injection molding processes (Table 1). The following table lists some processes, which are relevant for the automotive industry.

Table 1. Classification and types of special injection molding methods.

Classification	Variants
Multicomponent injection molding	Sandwich/coinjection Composite molding Multicolor molding Interval injection molding
Fluid and gas-assisted injection molding	Gas-assisted molding HELGA process Water injection technology (WIT) Structural foam molding (w/chemical expanding agent) MuCell process (w/physical expanding agent)
Low pressures injection molding	Cascade injection Compression injection Gas back-pressure technology
Insert molding techniques	Back injection (General) In-mold labeling In-mold decoration Insert moulding Back compression
Injection molding processes to join multiple components	Overmoulding technology Insert molding Hybrid technology In-mold assembly
Lost core processes	Lost core technology Multishell technology
Other special procedures	Injection molding with core pullers for undercuts (liquid silicone rubber) Injection Powder injection molding CD injection molding Cleanroom technology Combined compound/injection molding

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Owing to the large number of process varieties used for injection molding applications, the following describes a few relevant special procedures for the automotive industry as an example.

2.4.1 *Multi-component injection molding*

Multicomponent injection molding refers to the use of several polymers to produce high quality plastic parts, when different material properties or appearences are needed. Plastics with different colors and/or physical characteristics are combined within a single mold. The polymers can be injected at the same time or sequentially. They can be injected next to, opposed to, or one into the other. Multicomponent sandwich injection molding can be used for recycled materials by injecting them between virgin plastics to achieve a class A surface quality.

A typical example for multicolored injection molded parts are automotive tail lights made out of PMMA (polymethyl methacrylate) (Figure 4).

Multicomponent injection molding is used to produce cost-effective parts with a higher degree of functionality. The chemical compatibility of the materials must be ensured, as it has a strong influence on the adhesion between the injected components.

However, there is another advanced multi-injection molding process, which takes advantage of materials without chemical compatiblity. This process is sometimes called *inmold assembly* because the parts are injected next to, or into each other, and they can be easily disassembled because of low adhesion between the incompatible materials. Good examples are injection molded polymer screws or figurines with movable arms and legs, which are produced in a single tool. Multicomponent injection may also be used for products within daily use, such as packaging, electrical appliances, or for technical products such as rubber bearings, rollers, gaskets, dampers of various types, and housings within molded seals.

Figure 4. Injection molded tail light from Mercedes-Benz CLA. (Reproduced with permission from Daimler © Daimler AG.)

2.4.2 *Gas-assisted molding*

The principle of gas-assisted molding is to inject the polymer first, followed by injecting an inert gas (usually nitrogen) into the polymer core at approximately 100–200 bar. This process is especially used to produce lightweight parts by hollowing out thick sections. Lightweight parts with a well-defined shape and smooth outer skin can be produced economically with gas-assisted injection. The shrinkage of the part during the cooling process is reduced because of the internal gas pressure. In addition, this method allows for the molding of parts that would either be too difficult or impossible to mold using standard injection molding. The molding process is equivalent to injection molding, but costs are higher as there is additional equipment needed for gas injection.

Depending on the part design, the following are advantages of gas-assisted molding over standard injection molding:

- Design flexibility with respect to different wall thickness within one part
- High rigidity due to large, closed cross sections
- Low warpage and uniform shrinkage
- Reduced sink marks on large parts
- Weight savings of up to 50%
- Shorter cycle times compared to thick walled or solid parts.

2.4.3 *MuCell process*

MuCell is the name given to a special injection molding method developed by the company Trexel, which uses a microcellular foaming process. MuCell is a physical foaming process utilizing nitrogen in a supercritical state (supercritical fluid, SCF) as a blowing agent to generate micrometer- sized voids in thin-walled plastic parts. The SCF is introduced during the metering of the plastic melt. The foaming process begins when the melt is injected into the mold cavity. Compared to traditional injection molding, cycle times are reduced up to 40%. The process offers 50–75% improvement for key quality issues associated with injection molded parts such as flatness, warpage, and removal of sink marks. The process also contributes to

Figure 5. MuCell valve cover. (Reproduced with permission from Trexel GmbH. © Trexel GmbH.)

weight savings on the order of 20%. For example, a valve cover produced by this method is lighter, has improved flatness, and requires 30% smaller machine size (350 tons instead of 500 tons for compact parts), which contributes to faster cycle times (Figure 5).

3 EXTRUSION

The key element of an extrusion line is the extruder (Figure 6). The most common machines are single-screw and twin-screw extruders. Single-screw extruders are characterized by simple constructions and are mainly used for plastification. The shaping of the melt to semifinished parts such as plates, slides, profiles, or coatings is realized by an extrusion die and the downstream equipment.

Twin-screw extruders with co- and counter-rotating screws are mainly used for polymer compounding, which includes coloring, degassing, and treating of the polymer melts. The co-rotating extrusion is suitable for economic compounding of plastics with very different characteristics and the counter-rotating twin-screw extruder is mainly used for the extrusion of PVC (polyvinyl chloride).

Beside the automotive industry where extrusion is mainly used for wiring harnesses and profiles, extruded products can be found in many industries such as building, packaging, furniture, and aerospace.

Furthermore, there are numerous special extrusion designs, such as the ring extruder (12 screws rotate around a fixed core), planetary extruder (satellite screws rotating around the main screw), Ram extruder (for the production of profiles of PTFE (polytetrafluoroethylene) and UHMW-PE (ultra high molecular weight polyethylene), Kneader- (includes a set of counter rotating kneading blades and a discharge screw), and pin extruder (with pins for additional shear flow).

In addition to the extruder, the complete extrusion line consists of a temperature-controlled heated die along with a cooling/shaping mold followed by a puller (caterpillar), and a cutting unit (saw). A collection table then collects the extruded and cut materials. All these elements are called the *extrusion line*.

Alternatively, an extruder can be used to custom compound plastic pellets. The starting polymers and additives are mixed in the extruder and then pelletized. The convention is to extrude strands, which are then cut and cooled in a water bath. The plastic strands are extruded through a perforated plate directly into a water tank. A rotating blade is used to cut the strands to a designated length as they exit the die. The compounded pellets produced by this process can be further processed in subsequent injection or compression processes.

Figure 7. Exdruded elastomer door sealing of a Freightlinier-Cascadia. (Reproduced with permission from Daimler © Daimler AG.)

3.1 Extrusion of profiles

For tube and profile extrusions, the extruded material is maintained after leaving the shaping tool and is sized to specific dimensions as it is drawn through a cooled calibration tube. Often, it is necessary to apply vacuum between the material and the calibration tube during the cooling process. The material is then sequentially grabbed and pulled from the calibration tube using a crawler, which is moved by chains. The speed of the crawler largely determines the extrusion line speed (Figure 7).

Combining different plastics is often required to produce technical products. Multilayer structured products (up to 9 layers) can be produced by a coextrusion process. For this process, each molding material is plasticized in an independent extruder and introduced into the extrusion die together. With this method, different materials can be optimally homogenized and bonded.

Another important extrusion application in the automotive industries is sheet or film extrusion. A foil is extruded via a flat die and goes through calendering process or a tube is extruded, which is inflated, cut, and flattened (blown film extrusion). Coextrusion is also used for sheet production. For decorative parts, these films are later vacuum or thermo formed and connected to a injection molded part with soft polyurethane (PUR) foam (e.g., instrument panels).

3.2 Extrusion blow molding

In addition to pellet compounding, extrusion or injection molding is increasingly being used to create preforms for blow molded parts. A tubular preform can be created by extrusion with a volume from a few liters to greater than 10,000 L. By combining this method with a blow molding tool, it is possible to create lightweight, hollow-bodied components with three-dimensional surfaces.

The procedure for creating a blow molded part from a plastic extruded preform is as follows:

- Extrude a plastic tube directly into an open, two-part blow mold.
- Close blow mold containing the molten tube.
- Cut the extruded tube across the top surface of the blow mold.
- Insert blow mandrel into the blow mold and introduce compressed air into the cavity of the preform (molten plastic tube).
- Preform is inflated to final part dimensions by taking the contour of the mold surface.
- Cool, open, and eject finished plastic article from blow mold.

Material flash (excess plastic) that is commonly created by the mold pinch at the top and bottom of the part is often removed by a secondary operation automatically and can be recycled. Fasteners, or other functional components may be inserted into the blow mold before molding (Figure 8).

A typical automotive part produced using extrusion blow molding process is a lightweight, plastic fuel tank (PFT). This process offers possibilities to manufacture lightweight tanks with complex geometries and has been established as a successful alternative to tanks made from steel or aluminum. The PFT is generally produced by extrusion of a tubular preform of HDPE (high density polyethylene), which is pinched by the blow molding tool and inflated with air or nitrogen as described earlier. While the first automotive fuel tanks had comparatively simple geometries, they are now complex shapes such as a saddle tank (Figure 5). Since around 1994, the PFTs contain barrier layers to reduce diffusion of volatiles. (Karsch, 2001; Klee, Karsch, and Kempen 2000). PFTs are produced using both the coextrusion and the blow-molding operations. In 1994, Chrysler introduced the first PFTs utilizing a six-layer coextrusion material. At present, this is the most used method (Figure 9).

Increasingly, three-dimensional curved and bellowed tubes are produced using the extrusion/blow molding

process. In the example shown below, a robot is used to place the extruded tube along the mold contour. After insertion, the mold closes and the tube is inflated by compressed air (Figure 10). The advantage of this method lies in the produced part's material uniformity and net shape. No reworking of the article edges is required. The part is lightweight because of uniform wall thickness. Furthermore, this method considerably reduces amount of flash, which minimizes scrap material (Geiger).

Coextrusion can also be used for a range of applications requiring a combination of different plastic materials to address performance requirements. Air intake hoses, manifolds, axle boots, and shock absorbers are a few examples. A further development is sequential coextrusion. The individual components (hard or soft component) can be extruded into various storage heads, alternately released sequentially, and then blow molded.

Blow molding can also be combined with injection molding to reduce part weight and cost. Through a combination of these production processes, the cost of a charged air pipe can be reduced by about 25% over an aluminum component. Inside the blow mold, functional elements are simultaneously injection molded onto the blow molded part. For this example, fixing lugs will be attached to the blow molded tube by injection molding. Immediately after the extrusion is blown and before cooling, plastic tabs are injection molded on to the plastic tube creating a single functional part. The securely attached tabs can withstand a pressure up to 2.8 bar at 230°C. The part is 30% lighter than the aluminum tube.

High melt strength polyolefines (HMSPE) and high melt strength polypropylene (HMSPP) are the most common plastics for extrusion blow molding, but other thermoplastic materials used today include

- ABS (antilock brake system): panels, extenders, and exterior components;
- PVC, PET: transparent and round handle bar;
- PA: hydraulic reservoir and air intake in the engine compartment;
- PC: transparent transport container; and
- TPE (thermoplastic elastomer): substitution of elastomer components.

4 THERMOFORMING

Thermoforming is a forming process by which a plurality of different process steps allows the manufacture of a dimensionally stable plastic part. Essentially, a thermoplastic sheet is placed into a frame which is exposed to heat to soften the material. The material is then transferred over a single cavity mold and vacuum is applied. The vacuum draws the sheet to the mold surface forming the part. The material cools and the part is removed from the mold. Cooling can be accelerated by applying chilled air. The orientation of the molecular chains is frozen in their extended position during the cooling prosses.

Almost all amorphous and semicrystalline thermoplastics are suitable for thermoforming. This method can be used to produce large surface area technical parts and is widely used in packaging. A range of sheet thicknesses (0.05–16 mm) can be used. Foamed sheets can even be up to 60 mm thickness. Parts can be made from PC, PMMA, PA, and ABS semifinished sheets as well as fiber-reinforced composites and self-reinforced materials. In the automotive sector, thermoformed parts are often made from elastomers and thermoplastic polyolefins. The window for the thermoforming temperature is (Table 2):

- above the glass transition temperature for amorphous thermolasitc materials and
- below the crystalline melting temperature for semicrystalline thermoplastic materials.

The thermoforming process typically uses only one tool surface. This means that only one-contouring surface is possible. An advantage is that only one half mold needs to be designed, machined, and purchased. The process works well for parts with medium to large surfaces.

Interior and exterior hoods and panels, especially for commercial, construction, and agricultural vehicles

(Figure 11) are examples of thermoformed parts in the automotive business. Moreover, fenders and bumpers have been produced using this method including fiber-reinforced polymers and sandwich panel materials. Other vehicle components are manufactured by vacuum forming, including painted films, which are subsequently

Figure 12. Mercedes Benz Atego thermoformed rear wall interior trim. (Reproduced with permission from Daimler © Daimler AG.)

back-injected, or fuel tanks, which consist of two thermoformed parts welded together (Figure 12).

In addition to numerous packaging applications, thermoforming is increasingly being used as an alternative to injection molding, in particular, for small to medium sized production runs. For example, panels for machines and material handling devices are produced via thermoforming. Engineered components are usually made from positive–negative vacuum forming, mainly produced through automation (Figure 13).

In the first stage, the thermoplastic sheet is brought to the appropriate forming temperature. (i) By preblowing, the film is prestretched (ii) in order to achieve a uniform wall thickness distribution. Thereafter, the tool (iii) and an applied vacuum pull the film into the desired final shape (iv). After cooling, the plastic can be removed from the mold (without the risk of deforming).

The thermoforming process is usually in competition with injection molding. Thermoforming is advantageous over injection molding for the following cases:

- High component weight (up to 125 kg)
- Large surface area parts (up to 4 m)
- Low cost for low volume production (cost-effective tooling)
- Low cost for design change and color change
- Homogeneous multilayer composite parts.

The disadvantages compared to injection molding are as follows:

- Few design options (large undercuts are not possible)
- Precise temperature control required
- The use of semifinished goods does not allow for plastic formulation.

Low cost tooling enables quick part restyling and facelifts, which are desirable for the automotive industry. Furthermore, deep drawing methods offer high potential for lightweight construction.

Twin-sheet thermoforming is a new variation that can be used to produce car air ducts. They are manufactured in sophisticated 3D geometries from PE (polyethylene) foam sheets and offer very lightweight and flexible properties as well as heat insulation for the surrounding components . For twin-sheet thermoforming, the process steps are heating, forming, and cutting at the same station. Two heated PE sheets are supported between the two half molds and are then formed and welded together simultaneously during the twin-sheet forming process. The final hollow body part is stamped directly in the tool. Compared to extrusion blow molding, polypropylene (PP)-air ducts made by the twin-sheet thermoforming method offers a 65% weight reduction.

5 ROTATIONAL MOLDING

Rotational molding is a well-known plastic processing method used for over 50 years. It is suitable to produce large volume, hollow-bodied parts in small quantities. Initially, only simple part geometries could be produced. Currently, there are numerous plastic resin materials tailored for the rotational molding process. Technically sophisticated and weight-optimized parts with complex shapes such as shaped fuel tanks, body parts, air intake ducts, and canoes can be made.

A rotational molding technique is also an effective process to produce decorative interior skins from PVC and TPE thermoplastic polymer powder.

In rotational molding, powder or liquid material is placed into the tool, which then rotates multiauxiliary in a heated chamber. The rotational motion provides a uniform distribution of the plastic material on the mold wall. The mold is then transferred to a cooling station, and the part is removed.

In the first step, the tool is filled with a measured quantity of powdery polymer or liquid raw material. Next, the tool is placed onto a two-axis rotational arm to insure complete distribution of the plastic materials along the wall surface. The tool is then moved into the heating chamber, whereas the tool is rotating allowing for the material to heat and melt gradually, or polymerize. Depending on the component, plastic, or process control, several heating stations may be required. Once uniform distribution of the material is completed, the tool moves to a cooling station. During cooling, rotation is maintained to prevent draining of the material or sagging of the part walls. The tool can be cooled by cold air, water spray, or direct immersion in a water bath. After sufficient cooling, the mold goes to the loading and unloading station. Here, the part is removed. Finally, the tool is refilled and the production cycle starts again.

Common powdered plastics used in this process include PE, PP, PC, PA, fluorpoylymere (PVDF and PFA), and EVA. Tanks, housings for machinery, transport and security containers, leisure, and water sports equipments such as kayaks, furniture, and toys are typical examples for rotational molded parts.

Advantages of rotation molding:

- "Pressure-free" manufacturing with uniform cavity pressure
- Low cost tooling
- Hollow body parts with a wide size range (from few ml up to several cubic meters)
- Economical for small batches
- Very low shear forces—parts with low internal stresses
- Thin-walled structures based on maximum part size possible
- Load inserts or labels possible.

Disadvantages of rotation molding:

- Long cycle time (about 10–30 min) compared to blow molding, thermoforming, and injection molding
- Raw materials must be preground
- Long residence time of the materials at high temperatures (good stabilization is required)
- Heating and cooling in one unit per tool
- High energy consumption
- Intrinsic heat-up and cool-down time.

A process variant is slush molding, which is used for sintering polymer powder into molded skins. The method can produce decorative skins with a constant surface quality, for example, for foils for dashboards. Especially in areas with tight radius, the surface grain will be of better quality compared with thermoformed skins. Furthermore, the production of continuous multicolored skins is possible.

6 PRESSING

Pressing methods are mainly used for the production of components made of fiber-reinforced plastics. For manufacturing these components, mechanical or hydraulic presses and two-or multipart tools are used. In order to shorten the cycle time, the materials are often preheated outside of the tool using radio frequency, microwave, infrared, or convection heating. Alternatively, pressing can be a means to mold parts from extrusion, which is connected upstream of the pressing process. For example, the extrusion machine is utilized to meter a predefined melt that

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

can be compressed to the final shape. Recent developments also use one or more twin-screw extruders in which the extrudate can be automatically handled and inserted into the press tool (see Processing of Polymeric Composites). In addition, high bending strength panels can be produced with this process, by inserting comingled continuous fiber textiles (glass/themoplast fibers) into the press, functioning as outer layers around the extruded core.

7 FOAMING

Polymer foams can achieve weight reductions of up to 98%, compared to their solid counterparts. The foaming process uses chemical or physical blowing agents to expand the material. In principle, all plastics, thermoplastics, thermosets, and elastomers polymers can be expanded. Plastic foams share a common manufacturing process such that the material at the beginning of the foaming process is in a malleable, fluid state, and then foamed and solidified into a foam structure. The main plastics converted to foams are PURs and the thermoplastic polymers such as PS (polystyrene), PE, PP, and PVC.

7.1 Extrusion foaming

Extrusion foaming is the simplest and most economical foaming method for thermoplastic materials. A conventional extruder is utilized to plasticize the polymer and uniformly mix and disperse a blowing agent into the melt. The mixture is dispensed through a cooling die to shape the foam to desired geometry and foam density. Typically, semifinished products such as profiles, sheets, and films are made with a foam core. These parts are often used directly for acoustic, mechanical, and thermal insulation or damping (pipe insulation and packaging).

There are a diverse range of automotive applications that use foam-extruded parts (sun visors, soft skin, door panels, and engine enclosures).

7.2 Particle foams

7.2.1 Extruded foam particles (EPS and EPP)

Particle foam can be produced in a special foam extrusion process. A physical blowing agent is injected into the melt and uniformly mixed and dispersed. Temperarure and pressure are controlled to allow nucleation to occur within the melt but not actual expansion. The material is pushed through channels forming long strands and expands during a sudden pressure drop as the material exits the die. The expanding material is cut by rotating knives into approximate spherical particals, which are cooled in a water bath.

7.2.2 Production of EPP foam particles in the autoclave process

The autoclave process is currently the most widely used method to produce foam particles, especially EPP (expanded polypropylene). In an autoclave, PP microgranules are suspended in a solution containing an inert gas and an expanding agent such as propane or butane. The mixture is stirred while heated and the propellant accumulates in the PP particles through diffusion. When the desired blowing agent content is reached, a valve is opened to release the particles into a lower pressure chamber. In the lower pressure environment, the impregnated propellant expands rapidly creating foamed beads. The cells do not collapse because the melted polymer freezes instaneously during the pressure drop.

7.2.3 Expansion of polystyrene (EPS)

EPS beads (expanded polystyrene) are also initially produced from microgranules. Styrene is polymerized in a suspension polymerization process in the presence of pentane, whereby the propellant gas becomes dissolved in the reacted product. Foaming the EPS microgranules occurs in a pressure vessel with steam. Pentane with a boiling point of just 35°C is evaporated and the granules inflate into foam beads. Approximately 50% of the blowing agent still remains in the foam particles and is used in a later process for further expansion. The produced foam beads must be processed into parts within approximately 1 week after the pre-expansion process.

7.2.4 Molding components from particle foam materials

For EPS molding, steam is used as an energy source, which heats and melts the surface of foamed particles in a shaping tool. Steam is evenly injected through a porous aluminum tool that is placed inside a steam chamber (Figure 14).

The EPS and EPP methods to mold foamed articles are quite similar, although the mechanism is different. During the EPS molding process, the EPS beads still contain a blowing agent. In the case of EPP, they do not. For EPS, the particles expand through the evaporation of the blowing agent. As the foam particles expand, they create internal pressure in the mold cavity, allowing the particles to fuse together to form a part. EPP, on the other hand, is injected with higher backpressure into the mold. The EPP

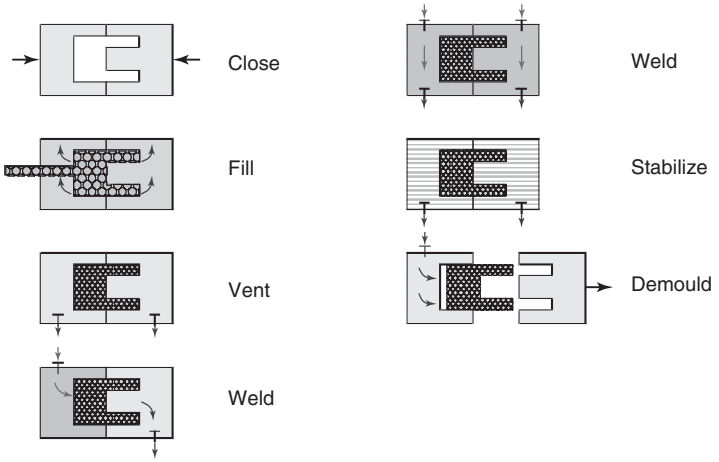

Figure 14. Schematic cycle sequence of moldings made from EPP and EPS.

Figure 15. Bumper with EPP inserts. (Reproduced with permission from Ruch Novaplast © Ruch Novaplast.)

particles expand as the mold is depressurized and then steam is injected to fuse the particles together. Subsequent to the molding process, the parts must be annealed to reach the final geometry and smooth the part surface. This is necessary for the removal of residual moisture contained in the cells, resulting from the steaming process. Six to eight hours are common anealing cycles at approximately 80°C.

EPS is mainly used for packaging and thermal insulation in the construction industry. EPP is currently applicable in the field of reusable transport packaging and increasingly in the automotive sector. For example, tool boxes, side impact protection, and head and knee cushions are made out of this material. Moreover, the majority of the car bumpers are equipped with EPP inserts. The market for EPP is constantly growing because of the lightweight properties

Figure 16. Polypropylene monomaterial composite with TPO skin. (Reproduced with permission from Taracell.)

and the good energy absorption. Compared with EPS, EPP offers higher mechanical flexibility and higher temperature resistance (Figure 15).

Typical applications for EPP in combination with other materials are EPP sun visors with injection molded frames and headrests using an EPP reinforcement structure in conjunction with a surface out of PUR foam.

A simple and cost-effective method for producing decorative and lightweight shaped parts can be achieved by combining a TPO skin (thermoplastic olefin based on PP) with EPP. This is a new, economical way of producing fully recyclable, decorative parts such as sun visors, pillars, and door trims (Figure 16).

8 POLYURETHANE PROCESSES

PUR is one of the most divese polymers existing in a thermoplastic or thermoset form and widely used in the automotive area. Accordingly, there are multiple production processes for PUR.

Figure 17. Instrument panel. (Reproduced with permission from Daimler © Daimler AG.)

High strength PUR parts are made in low pressure or high pressure machines, in which the liquid components of polyisocyanate and polyol that may include additives and fillers, are mixed, and then form a reaction mixture. This process is known as the *reaction injection molding* (*RIM*) method. In principle, this method is used to make structural parts (porous core with virtually cell-free surface layers) and parts with predetermined, homogeneous density. The reactive mixture can be combined with fibers to increase the molded part strength. This is called *reinforced reaction injection molding* (*RRIM*). With additional continuous fiber reinforcement layers in the tool, the process is called *structural reaction injection molding* (*S-RIM*) or *structural reinforced reaction injection molding* (*SRRIM*).

PURs are also used as elastomers [mainly themoplastic polyurethane (TPU)] or as lightweight, flexible foams. The most important applications of PURs are in the furniture and upholstery industry, construction, and the automotive industry. Lightweight components are relevant for automotive applications, such as steering wheels, dashboards, seats, interior trim parts, and damping elements. Similar components are found in rail vehicles and aviation (Figure 17).

9 SUMMARY

Polymers are becoming more important in the auotmotive engineering society, as they are highly versatile, lightweight, and offer greater flexiblity for part design and component integration, compared with metals. This chapter only highlights some major polymer processes and applications that are being used by the industry. There are many more applications and developments in the polymer field, such as decorative exterior polymer films and polymer adhesives, which are increasingly playing an important role to simplify the assembly process. The field of polymer science continues to evolve rapidly and will offer new applications in the near future.

1 CLASSIFICATION OF INTERNAL COMBUSTION ENGINES

Internal combustion engines (ICEs) are mechanical devices that thermodynamically convert the chemical internal energy of a fuel into mechanical work. This is accomplished by allowing the fuel to chemically react in the confinement of the cylinder, during which the chemical internal energy is converted into sensible internal energy. The transformation of the chemical internal energy into sensible internal energy is manifested by an increased temperature and pressure in the cylinder, which can then be expanded to extract mechanical work. Therefore, the chemical energy, which is contained in the fuel, is transformed into "thermal" energy, which is subsequently used to produce mechanical work.

Principally, the conversion process that produces mechanical work from combustion should be distinguished between the case of continuous-flow machines, for example, gas turbines or jet engines, and reciprocating engines. In continuous-flow machines, work is achieved using the kinetic energy of the working fluid. In reciprocating engines, for example, reciprocating ICEs, rotary engines, and steam and Stirling engines, the working chamber has rigid walls, with at least one movable wall (usually this is the piston). Owing to the volume change, combined with a varying gas pressure within the working chamber, power output is obtained.

Further differentiation of reciprocating engines could be made by considering external (steam and Stirling engines) and ICEs (reciprocating piston and rotary engines). In external combustion engines, the combustion process occurs outside the work producing chamber, whereas in ICEs, combustion takes place intermittently inside the work producing chamber, that is, the cylinder. In external combustion engines, energy transfer takes place by heat transfer processes from the combustion chamber to the working fluid (which is not the products of combustion in the external combustion chamber), which limits the viability of external combustion engines for mobile transportation systems because the timescales of the energy transfer are far too long. One advantage of internal combustion is that response times to load changes are extremely short. This makes the ICEs the preferred design for mobile transportation, which is characterized by frequent transient and dynamic change of torque requests. Maximum pressures and temperatures arise only for short times, and thus, thermal and mechanical stresses on the power unit are limited. Moreover, power density is high. However, one problem for ICEs is the short time available for the fuel–air mixture generation, needed to completely oxidize

the fuel–air mixture. This can lead to decreased efficiencies because of imperfect and incomplete combustion. In addition, combustion is always accompanied by formation of unwanted pollutants in (locally) high temperature and inhomogeneous (rich or lean) mixtures.

2 ENGINE OPERATING CYCLES

2.1 Design of reciprocating engines

Nearly all ICEs are of the reciprocating piston type, where the piston moves back and forth in a cylinder. Power is transferred from the piston by a connecting rod into the crankshaft, as shown in Figure 1. Owing to the rotation of the crankshaft, a cyclic movement of the piston takes place. At the top-dead-center (TDC) and bottom-dead-center (BDC) positions, the piston comes to rest and the corresponding volumes of the working chamber have minimum and maximum values, respectively. The minimum volume is called the *clearance volume* V_c, whereas the swept volume by the piston (the maximum minus the minimum volume) is called the *displacement volume* V_d.

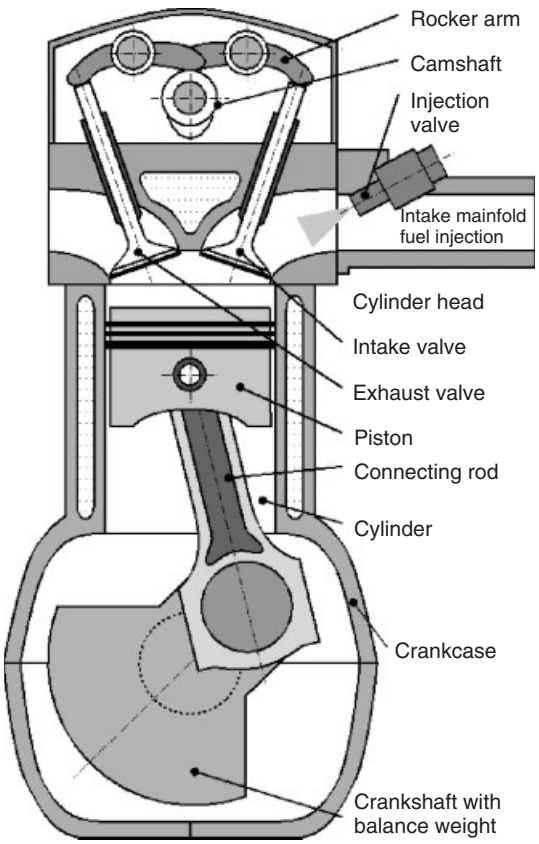

Figure 1. Cross-sectional drawing of a reciprocating engine.

2.2 Definitions and classifications

Figure 2 summarizes the classification of ICEs. It can be seen that the whole engine consists of many aspects involving interdisciplinary fields of activity.

2.2.1 Classification for process management and mixture generation

2.2.1.1 Spark-ignited engine. The spark-ignited (SI) engine or the "Otto engine" is one of the dominant engines on the road today. The notation "Otto engine" refers to the inventor of the so-called four-stroke cycle process management (see later), Nikolaus Otto ((Sass, 1962); (Goldbeck, 1976)). It is an ICE with an open circuit of the working fluid for both reciprocating piston and rotary engines. Mixture preparation of fuel and air takes place as early as possible in order to get a well-mixed homogeneous mixture, which is compressed in the working chamber. It should be noted that the compression must be limited, to ensure that no autoignition due to the increased temperature occurs. At the time of maximum compression, which is near TDC, which is at the lowest volume, ignition is initiated by a spark plug (externally supplied ignition) and the air–fuel charge can be burned. (SI engine combustion system details are discussed in Spark Ignition Combustion.)

SI engines can further be differentiated into Otto engines operated with liquid or gaseous fuels. The fuel can be either delivered to the intake manifold (the fresh air inlet system) using a carburetor or an injection system or it can be injected directly into the cylinder. The mixture can be rich (excess fuel), stoichiometric, or lean (excess air). In case of a globally lean mixture, the charge can be stratified by a late injection in the compression portion of the cycle.

2.2.1.1.1 Gasoline-fueled engines. More than 95% of all SI engines worldwide are fueled with liquid gasoline of different qualities. With a mixture preparation in the intake system, the fuel typically evaporates completely before it enters the working chamber. This is true for part load condition where the manifold pressure is lower than the atmospheric pressure. For full load and especially turbo- or super-charged conditions, a significant part of the fuel enters the working chamber in liquid form, and the evaporation as well as the mixing process with the fresh air for creating a homogeneous fuel–air mixture takes places during the induction and compression stroke.

2.2.1.1.2 Gaseous-fueled engines. In this case, the fuel is gaseous under atmospheric conditions. The mixture generation takes place upstream of or within the working chamber.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

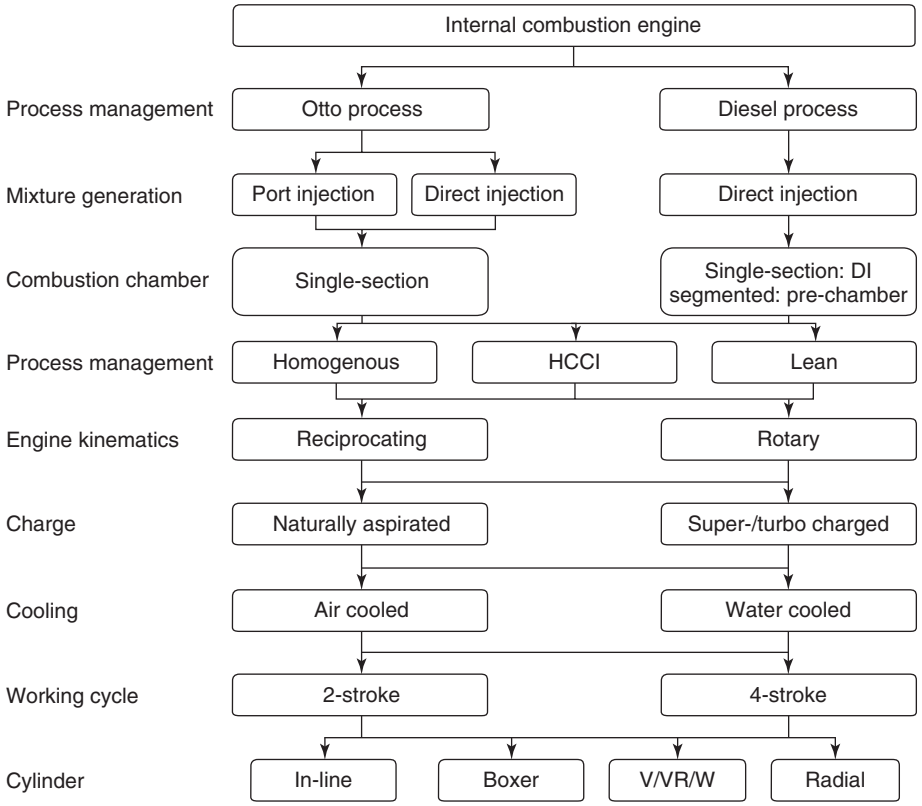

Figure 2. Main classification definitions in internal combustion engines.

Most gaseous-fuel engines are modified gasoline-fueled engines, thanks to the similar behavior of the different fuel types from a combustion perspective. Two options are more commonly used: liquid petroleum gas (mainly propane and butane, LPG) and methane-containing gas (e.g., natural gas and biogas, CNG and LNG), which is compressed and stored (i.e., to be transportable in acceptable volumes) in liquid or gaseous form (under high pressure, 200 bar, in the latter case) in special tanks. Engines using hydrogen as a fuel have been the subject of scientific studies for many years but do not have any significance in today's market for lack of infrastructure.

2.2.1.1.3 Otto engines having a carburetor. Liquid fuel is mixed with air in a carburetor before the mixture enters the working chamber. This is an old technology and will not be discussed in detail.

2.2.1.1.4 Injection Otto engines. Liquid fuel is injected directly into the air inlet system before the mixture enters the working chamber or directly into the cylinder, as can be seen in Figures 3 and 4.

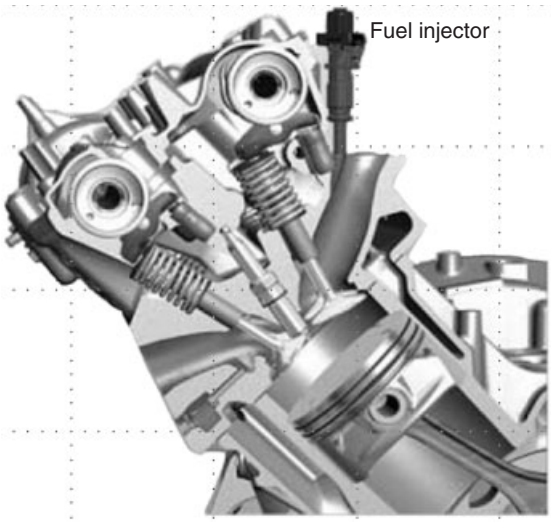

Figure 3. Otto engine with port injection. (Reproduced by permission of Daimler AG.)

2.2.1.1.5 Lean-burn engines. In lean-burn engines, globally very lean air/fuel ratios (AFRs) are used ($1.3 < \lambda < 1.7$, where λ is a characteristic property describing the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

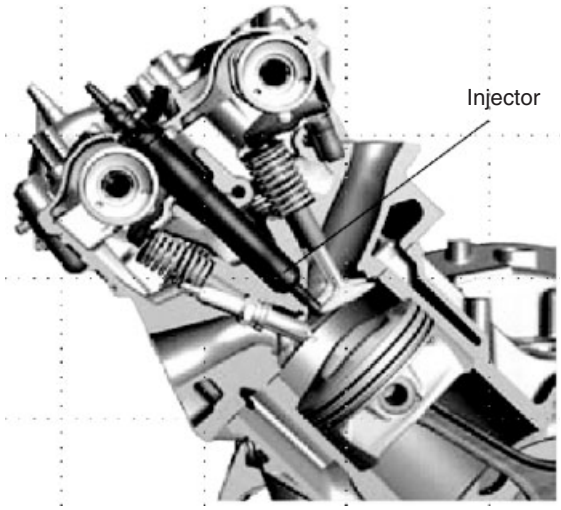

Figure 4. Direct injection Otto engine. (Reproduced by permission of Daimler AG.)

fuel to air ratio. For the definition of λ, refer to Section 3.2). Special attention is needed in order to ensure ignition of the lean mixture. Therefore, special design of mixture preparation, air-inlet and inlet manifold, combustion chamber, and ignition system is needed. One problem is that the very efficient exhaust gas after-treatment system known as the three-way catalyst, and used in stoichiometric mixture conventional Otto engines, cannot be used because of the lean AFR, which results in the presence of a significant quantity of oxygen in the exhaust stream. Additional and more complex exhaust gas after-treatment systems are necessary for the chemical reduction of nitrogen oxides in oxygen-rich exhaust gases from lean-burn engines.

2.2.1.1.6 Stratified-charge engines. In this case, an inhomogeneous mixture of fuel and air is desired. The mixture is ignited by the spark plug within a fuel rich zone (rich = excess of fuel). The hot gases of the rich combustion process get mixed with the mixture of lean areas (lean = excess of air), and thus, lean combustion takes place. Usually, direct injection (DI) of the fuel into the combustion chamber is used to achieve charge stratification. The globally lean fuel–air mixture leads to higher efficiencies and to lower fuel consumption. However, although engine-out-emissions can be reduced, additional exhaust after-treatment systems are necessary for the chemical reduction of nitrogen oxides in oxygen-rich exhaust gases, as mentioned earlier for lean-burn engines.

2.2.1.2 Compression ignition engine. Compression ignition (CI) engines include the most prevalent CI engine on the road today, the Diesel engine, as well as new CI engine technologies being researched, such as homogeneous charge compression ignition (HCCI) engines. The notation "Diesel engine" refers to Rudolf Diesel, the inventor of a combustion method initiated by autoignition in reciprocating engines ((Sass, 1962); (Diesel, 1892); (Diesel, 1913); (Diesel, 1893)). The Diesel engine is also an ICE having an open working fluid circuit. In contrast to Otto engines, the combustion chamber is filled only with air during compression. Therefore, the compression ratio can be much higher. During compression, the air temperature increases. Near the end of compression, which is near the TDC position of the piston and minimum volume in the cylinder, the fuel is injected. The fuel evaporates in the preheated air, mixes with the air, gets ignited by autoignition, and finally gets oxidized. (Diesel engine combustion system details along with advanced, low temperature Diesel combustion strategies currently being research are discussed in Diesel and Diesel LTC Combustion.)

Diesel engines further can be classified as Diesel engines using air injection (not in use anymore and not discussed further), with prechambers (divided chamber), and using DI.

2.2.1.2.1 Diesel engines with prechamber. The liquid fuel is injected into a small-volume prechamber, which is connected via a small passage to the main combustion chamber. During compression, airflow is introduced in the prechamber from the main chamber. When fuel is injected near TDC into the prechamber, mixing and autoignition (or glow-plug-assisted ignition) occur rapidly because of fluid motion, followed by a rich combustion. After the combustion starts, the reacting mixture blows down the passage into the main combustion chamber where an overall lean combustion takes place to complete the combustion process. Figure 5 depicts a Diesel engine having a swirl prechamber. Because of the generally lower efficiency of prechamber engines, owing to heat losses to the passage walls, these engines are not widely used anymore.

2.2.1.2.2 Direct injection Diesel engines. In a DI engine, liquid fuel is injected directly into the combustion chamber near TDC. High pressure injection systems are used to support fast mixture generation. The commonly used common-rail injector technology allows more than one injection event per operating cycle in order to optimize the combustion processes to reduce noise and pollutant emissions (e.g., pre-, main-, and postinjection). Nearly all Diesel engines are equipped with a DI system today (Figure 6).

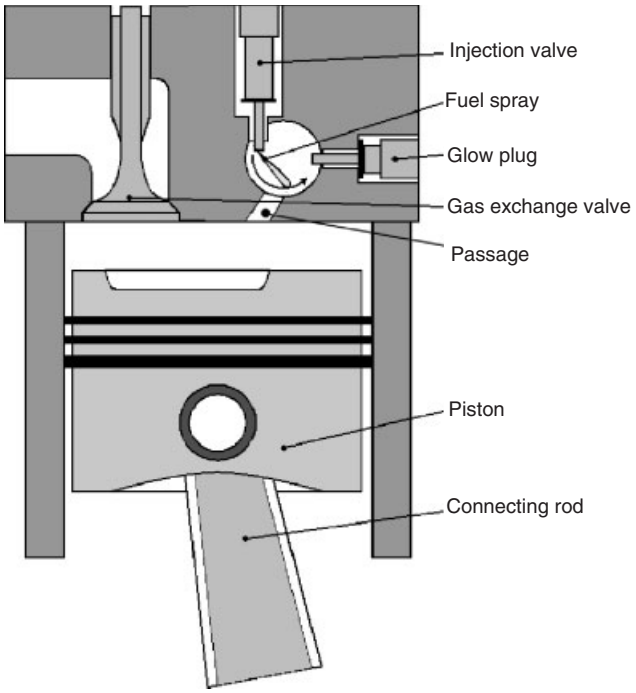

Figure 5. Cross-sectional drawing of a Diesel engine having a swirl prechamber.

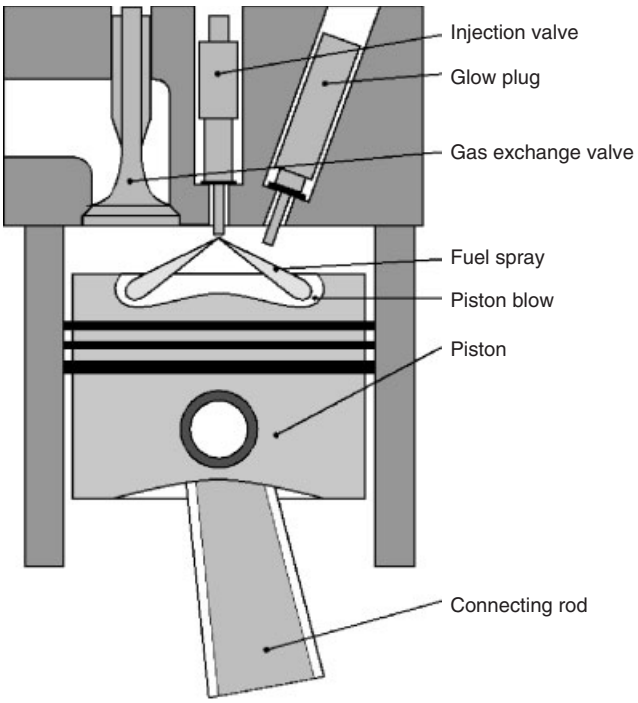

Figure 6. Cross-sectional drawing of a direct injection Diesel engine.

2.2.1.2.3 Homogeneous charge compression ignition engines. Creating a homogeneous mixture of fuel and air is usually not a big problem, especially with gasoline, because of its relative low evaporation temperatures. On the other hand, a controlled self-ignition of the homogeneous mixture close to the TDC position of the piston marking the end of the compression stroke is not easily realizable, because the ignition process mainly depends on very complex kinetic issues. Owing to high knock resistance (high RON numbers), gasoline needs very high temperatures—above 1100 K—for self-ignition at realistic engine speeds. This can be realized, for instance, by retention of hot burned gas in the cylinder from the previous combustion event. This retention process can be controlled, for example, by a variable valve actuation system. The benefits of the HCCI strategy are very low NO_x emissions and a better indicated efficiency due to very lean or dilute operating conditions leading to low combustion temperatures, very short combustion duration, and lower throttling losses. The drawbacks are the need for complex control, and higher combustion rates that lead to significant combustion generated noise. The high combustion rates and noise limit this combustion mode, in a highly premixed form, to part-load conditions and moderate engine speeds. However, test bench results suggest that compression ignition of stratified mixtures, coupled with EGR, can allow control of combustion rates and noise, especially at low and high load conditions. Practical application of this technology continues to be a subject of current research. (Advanced CI combustion strategies such as HCCI are discussed in detail in Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot.)

2.2.2 *Classification of intake condition*

2.2.2.1 Naturally aspirated engine. Naturally aspirated engines induct air from the surrounding and discharge the exhaust gases into the surrounding.

2.2.2.2 Super- and turbocharged engines. In super- or turbocharged engines, the fresh air in the air intake system is compressed by external devices, for example, by a turbo- or supercharger. Thus, the density of the intake gas is increased, resulting in more fresh gas entering the cylinder and increased power and torque from the engine. There are two well-established methods for compressing the intake air, exhaust gas turbochargers and mechanical superchargers, with turbochargers being used more commonly in series production. In addition, two- or more-staged charging combinations of series of turbochargers and compressors can be used.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

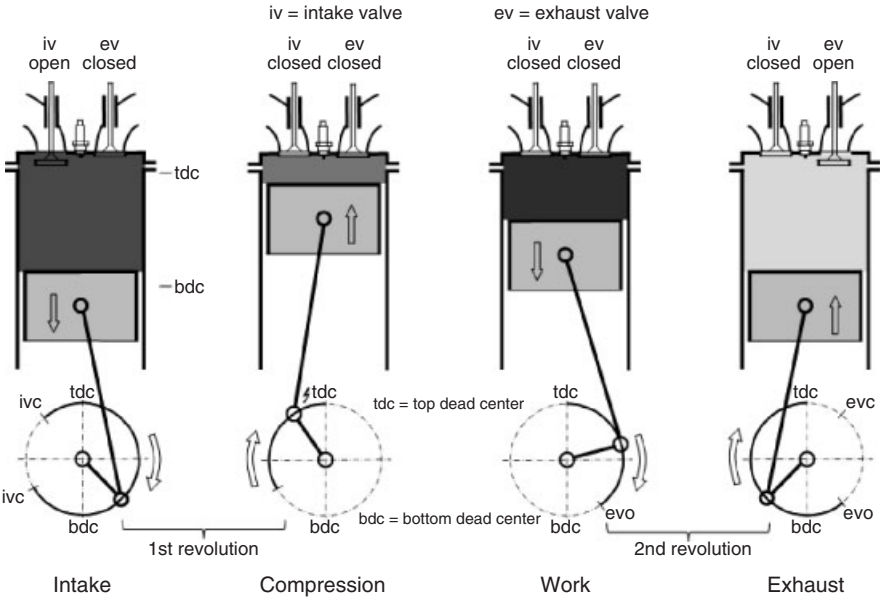

Figure 7. Four-stroke operating cycle (schematically).

2.2.3 *Classification of working cycle*

2.2.3.1 Four-stroke engine. Most of the engines (reciprocating and rotary) operate with the so-called four-stroke cycle, that is, for one complete working cycle, four strokes (piston movements), corresponding to two revolutions of the crankshaft, are necessary. Both Otto- and Diesel engines can use this cycle, which is shown in Figure 7. The four different strokes are as follows.

2.2.3.1.1 Intake stroke. Piston movement from the TDC to the BDC position with intake valves open. This draws fresh gas into the cylinder (fuel–air mixture for Otto and air for Diesel engines).

2.2.3.1.2 Compression stroke. Piston movement from the BDC to the TDC position with all valves closed. The gas inside the cylinder is compressed to a small volume compared to the volume at BDC position. During compression, the gas pressure and the temperature increase. Near the end of the compression stroke, combustion is initiated. In Otto engines, ignition takes place at the spark plug, and in Diesel engines, injection of the fuel and subsequently evaporation and autoignition occurs. When combustion starts, cylinder pressure increases rapidly.

2.2.3.1.3 Power stroke. Piston movement from the TDC to the BDC position with all valves closed. The movement starts at high pressure and temperature gas, which pushes the piston down because of the gas force onto the piston, rotating the crankshaft. The gas inside the cylinder rapidly cools down when volume is increased.

2.2.3.1.4 Exhaust stroke. Piston movement from the BDC to the TDC position with exhaust valves open (EVO). This causes the burnt gases to exit the cylinder.

In real engines, the valve opening and closing times are not precisely at the TDC and BDC positions but short times earlier or later. The four strokes are also visible in pV diagrams, where p is the pressure in the cylinder and V is the cylinder volume at any time. In Figure 8, an example for an Otto engine pV diagram at full load is shown.

2.2.3.2 Rotary engine (Wankel engine). The notation Wankel engine refers to its inventor Felix Wankel (Huf, 1961). Wankel engines work with the four-stroke principle, that is, the working chamber is opened and closed two times, whereas in two-stroke engines (see later) only once.

In contrast to reciprocating piston engines, no valves for the gas exchange are needed. The gas exchange process, similar to two-stroke engines, is realized by simple ports. For a schematic illustration of a Wankel engine, see Figure 9.

Advantages of rotary engines are their compact design, the smooth and low vibration performance, and the high rotational speeds. Problematic are the sealing of the combustion chamber, the nonoptimal design of the combustion chamber (from a combustion perspective), and the high one-sided thermal stresses (e.g., no cooling of the spark plug by inflowing fresh gas).

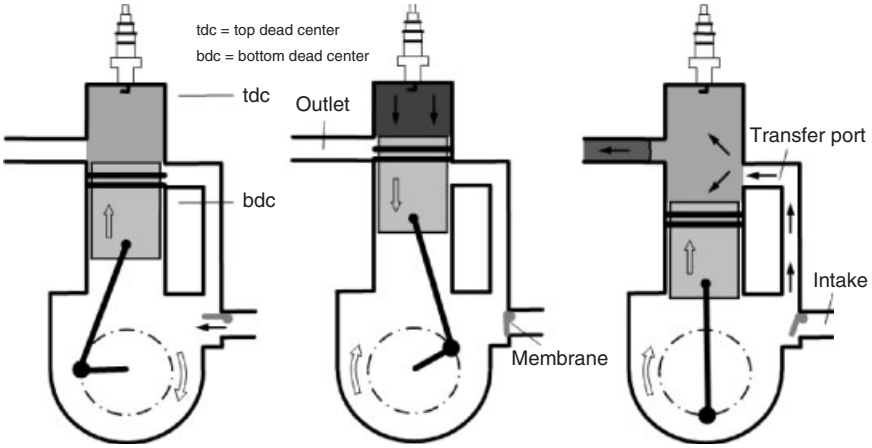

Figure 10. Two-stroke operating cycle (schematically).

2.2.3.3 Two-stroke engine. Only one rotation of the crankshaft is necessary for one power cycle in a two-stroke engine. The gas exchange mostly is managed by simple ports in the liner of the cylinder, which are opened and closed by the reciprocating motion of the piston. In Figure 10, a simple configuration for a two-stroke engine is shown. The two strokes are discussed in the following sections.

2.2.3.3.1 Compression stroke. Piston movement from around the BDC to the TDC position with inlet and exhaust ports closing at the beginning of the stroke. The gas mixture above the piston is compressed. Below the piston, the crankcase volume pressure drops below atmospheric pressure, until at a certain position, the piston opens the crankcase membrane and fresh gas can enter the volume below the piston.

2.2.3.3.2 Power stroke. Piston movement from the TDC to the BDC position with inlet and exhaust ports closed at the beginning. Ignition by spark plug occurs above the piston around the TDC position and rapid combustion takes place. The piston is pushed downward causing a rotation of the crankshaft. In the volume below the piston, the gas mixture is compressed and near the end of the stroke, the *transition from power to compression stroke* starts.

2.2.3.3.3 Transition from power to compression stroke. Exhaust ports open first, initiating the exhaust of burnt gases, followed by opening of the intake ports initiating induction of fresh compressed gas from the crankcase (or from an external supercharger), a process called *scavenging*.

In Figure 11, a corresponding *pV* diagram for a two-stroke cycle is shown. Because power is produced every stroke, these engines can have roughly twice the power

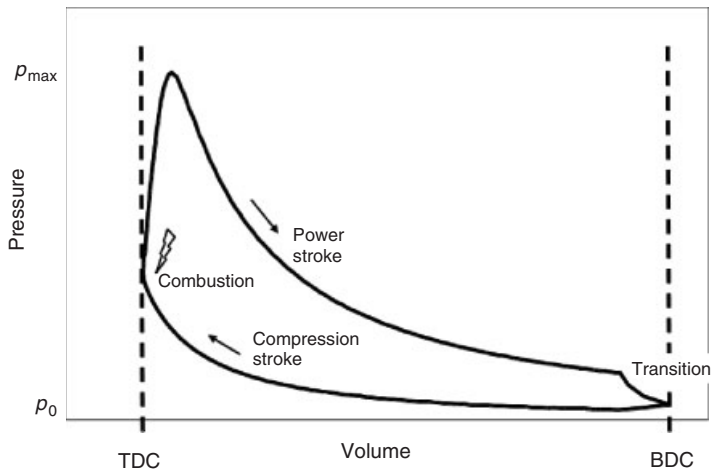

Figure 11. *pV* diagram of an Otto two-stroke cycle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159

density of comparable four-stroke engines but have significant challenges with exhaust emission control. It should be stated that the remarks given are simplified and illustrative. It is also possible to realize the two-stroke cycle with a valved engine and mechanically driven auxiliary boosting system (Blair, 1990).

3 CHARACTERISTIC PROPERTIES

In this chapter, important properties are given, which are helpful to characterize engines. It is important to note differences in the subscripts, which are used to relate the meaning of the reference parameter to different variables (e.g., distinguish between the displacement of a single cylinder, V_d, and the displacement of the whole engine-all cylinders, V_D). For further reading, refer also to basic textbooks such as Refs ((Heywood, 1988); (Taylor, 1985a), (Taylor, 1985b); (Obert, 1973); (Taylor & Taylor, 1961)).

Nearly all important properties can be introduced by investigation of a single relation for engine power. This will be the guide throughout this chapter.

3.1 Compression ratio

The ratio between maximum and minimum volume per cylinder is denoted as compression ratio r_c. The maximum volume is the sum of the displacement volume V_d per cylinder and clearance volume V_c per cylinder at TDC. The minimum volume corresponds to the clearance volume. The compression ratio r_c then can be expressed as

$$r_c = \frac{\max V}{\min V} = \frac{V_d + V_c}{V_c} \tag{1}$$

Diesel engines usually are operated at high compression ratios to ensure autoignition of the mixture. Conversely, Otto engines have lower compression ratio, because unwanted uncontrolled autoignition, leading to shock waves inside the cylinder (engine knock), has to be avoided. Knock is favored at high pressures and temperatures. For typical numbers for r_c, refer to Table 1.

3.2 Power, work, and torque

The main important properties of ICEs are the actual power measured at the exit of the crankshaft, the brake power P_b [in units (W = Nm/s = J/s)], which is the usable power delivered. The brake power is related to torque T [in units (Nm)] and the angular or crankshaft rotational speed N [in units (1/s)] by

$$P_b = 2\pi \cdot N \cdot T \tag{2}$$

The torque, the work per unit of revolution, is given by the following expression

$$T = \frac{W_b}{n_R} \tag{3}$$

where $n_R = 2$ for four-stroke and $n_R = 1$ for two-stroke engines and W_b [in units (J)] is the brake work, respectively. The brake power relationship to brake work is therefore given by

$$P_b = 2\pi \frac{N}{n_R} \cdot W_b \tag{4}$$

The brake work can be expressed by the product of the input energy of the fuel mass ($m_f \cdot Q_{LHV}$) and the brake fuel energy conversion efficiency η_b

$$W_b = \eta_b \cdot m_f \cdot Q_{LHV} \tag{5}$$

with m_f being the input fuel mass [all masses are in units (kg)] and Q_{LHV} the fuel lower heating value [corresponding to the chemical energy stored in the fuel, in units (J/kg)].

Table 1. Typical values for compression ratio r_c, peak brake mean effective pressure *bmep*, peak mean piston speed S_p, peak-specific brake power related to either piston area $P_b/n_c A_p$ or displacement volume P_b/V_D, minimum specific fuel consumption sfc_b, and peak brake efficiency η_b for different engine types.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

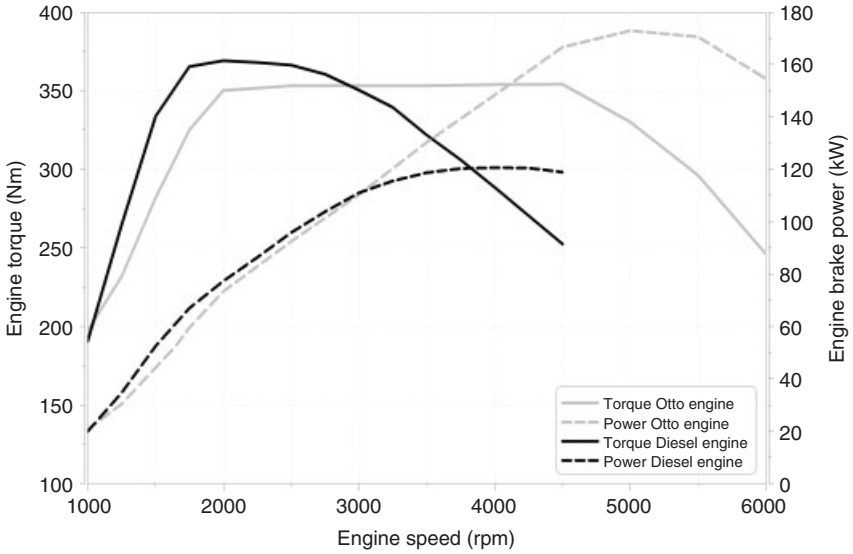

Figure 12. Typical curves for torque and power as a function of engine speed for both, an Otto engine (light gray curves) and a Diesel engine (black curves) of similar power and displacement volume, $V_D = 2\,\mathrm{L}$.

In Figure 12, an example for an Otto engine and a Diesel engine for brake power and torque versus angular speed is given. One recognizes the maximum values for both properties, occurring at different speeds. This is due to concurring processes depending on engine speed. At high speed, friction losses are high and the induction of a full charge of air into the cylinder becomes problematic, whereas at low speeds, heat losses are significant. In Table 1, typical values for the specific brake power for different engine types are given.

3.2.1 Air/fuel ratio

Introducing the AFR with the input air mass given by m_a

$$\mathrm{AFR} = \frac{m_a}{m_f} \tag{6}$$

the ratio of actual AFR to the stoichiometric $\mathrm{AFR_{st}}$ for a given mixture can be defined as

$$\lambda = \frac{\mathrm{AFR}}{\mathrm{AFR_{st}}} = \frac{m_a}{m_f \cdot \mathrm{AFR_{st}}} \tag{7}$$

and the equivalence ratio ϕ as

$$\phi = \frac{1}{\lambda} \tag{8}$$

These expressions relate the actual fuel mass m_f and air mass m_a to stoichiometric requirements. Stoichiometric conditions are when, theoretically, all the carbon and hydrogen bounds in the fuel molecules react completely with the O_2 in the air to convert all the fuel and O_2 into CO_2 and H_2O molecules. Typical numbers for λ for the different engine types are given in Table 2.

Table 2. Typical values for the air/fuel ratio as expressed by λ for different engine types.

Diesel engines	1.1	$< \lambda <$	6 . . . 10
Otto engines	0.7	$< \lambda <$	1.5
Otto engines ($\lambda = 1$ controlled)	0.99	$< \lambda <$	1.01
Stratified-charge Otto engines	1.2	$< \lambda <$	5

Then by substitution of Equation 7 into Equation 5 for the brake work, it follows that

$$W_b = \eta_b \cdot \frac{m_a}{\lambda \cdot \mathrm{AFR_{st}}} \cdot Q_{LHV} \tag{9}$$

3.2.2 Trapping efficiency

The trapping efficiency η_t denotes a relation between the intake air or the fresh gas mixture and the displacement of the engine. The notion trapping efficiency originally was used as a two-stroke engine metric. However, as in super- and turbocharged DI spark-ignition engines scavenging is also present, this efficiency is also commonly employed in four-stroke engines (Schmid *et al.*, 2011). The basic definition of the trapping efficiency η_t is given by

$$\eta_t = \frac{m}{m_A} = \frac{m}{n_c \cdot V_d \cdot \rho_A} \tag{10}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

with m being the charge mass in the cylinder (fresh gas per working cycle), m_A and ρ_A the ambient load mass and load density, respectively, n_c the number of cylinders, and V_d the displacement per cylinder.

For air inducting engines, such as Diesel or DI Otto engines, the load mass corresponds to the air mass in the cylinder

$$m = m_a \qquad \rho_A = \rho_a \tag{11}$$

whereas for engines inducing fuel/air mixtures, such as typical Otto engines, m and ρ_A are

$$m = m_a + m_f = m_a \left(1 + \frac{1}{\lambda \cdot \mathrm{AFR_{st}}}\right)$$
$$\rho_A = \rho_a \left(1 + \frac{1}{\lambda \cdot \mathrm{AFR_{st}}}\right) \tag{12}$$

Then it follows from Equations 9–12 that the brake work in both cases is

$$W_b = \eta_b \cdot \frac{\eta_t \cdot \rho_a}{\lambda \cdot \mathrm{AFR_{st}}} \cdot n_c \cdot V_d \cdot Q_{LHV} \tag{13}$$

For naturally aspirated engines, the air density ρ_a is approximated by atmospheric values. For turbocharged engines, values for pressures and temperatures are assumed to be equal to the corresponding values after the compressor or after the charge air cooler, as appropriate.

3.2.3 Charging efficiency

The charging efficiency η_{ch} denotes a measure of the cylinder fresh charge trapped mass m_c at the position when intake valve closes (IVCs). Similar to for m in Equations 11 and 12, it makes a difference between engines inducing air (Diesel engines) or fuel–air mixtures (Otto engines). Its definition reads

$$\eta_{ch} = \frac{m_c}{m_A} = \frac{m_c}{n_c \cdot V_d \cdot \rho_A} \tag{14}$$

3.2.4 Scavenging ratio

The scavenging ratio is a nondimensional characteristic property, which accounts for excess flow losses into the exhaust system during gas exchange. It is defined as

$$\eta_s = \frac{\eta_{ch}}{\eta_t} = \frac{m_c}{m} \leq 1 \tag{15}$$

The scavenging ratio is smaller than one when during exhaust valve opening times inducted fresh gas can exit the cylinder into the exhaust system. This is typical for piston-ported two-stroke engines.

3.3 Efficiency

3.3.1 Brake efficiency

Efficiency is defined as the ratio between work delivered and intake energy. In ICEs, the brake efficiency η_b describes the ratio of brake power output, for example, at the crank shaft, over the chemically energy contained in the fuel used during the combustion process

$$\eta_b = \frac{W_b}{Q_{in}} = \frac{W_b}{m_f \cdot Q_{LHV}} \tag{16}$$

3.3.2 Indicated efficiency

The indicated efficiency η_i of an ICE is defined as

$$\eta_i = \frac{W_i}{Q_{in}} = \frac{W_i}{m_f \cdot Q_{LHV}} \tag{17}$$

where the indicated work W_i corresponds to the integration over the full work cycle in the pV diagram (Figures 8 and 11) and represents the work that has been transferred to the piston face.

$$W_i = \oint_{\mathrm{cycle}} p\,\mathrm{d}V \tag{18}$$

For four-stroke engines, the integration is necessary for two crankshaft rotations, whereas for two-stroke engines, it only takes one revolution.

3.3.3 Gross indicated efficiency

For two- or four-stroke engines, if the pV integration is performed from BDC of the compression stroke to BDC of the expansion stroke (Figures 8 and 11), the result is the gross indicated work, W_{ig}, with the corresponding indicated gross efficiency η_{ig} being defined as

$$\eta_{ig} = \frac{W_{ig}}{Q_{in}} = \frac{W_{ig}}{m_f \cdot Q_{LHV}} \tag{19}$$

For the determination of W_{ig}, compression is assumed to start at BDC and expansion at TDC, regardless of differing opening times for the EVO and closing times for the IVC relative to BDC. This integral over the power cycle includes unused (lost) expansion work ΔW_E (calculated as the area of an extrapolated expansion pressure curve from EVO to BDC and the real pressure curve from EVO to BDC) and unused (lost) compression work ΔW_C (calculated as the area between the real pressure curve between BDC and IVC and an extrapolated pressure curve from IVC to BDC), illustrated in Figures 13 and 14 and discussed

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

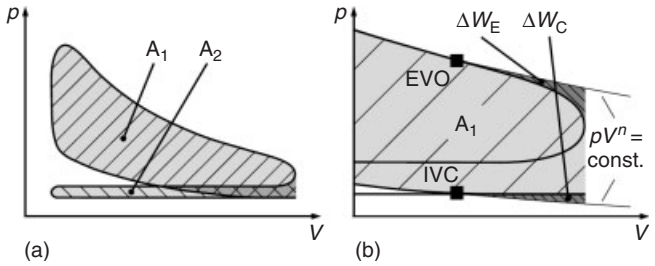

Figure 13. (a) pV diagram of a full four-stroke cycle. (b) Details explaining losses in work due to real start of compression and exhaust exit due to variable valve opening and closing times.

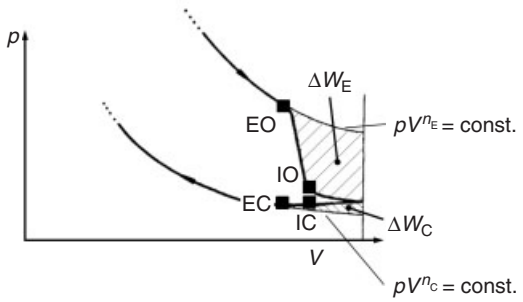

Figure 14. Details explaining losses in work due to real start of compression and exhaust exit due to variable valve opening and closing times in two-stroke engines.

additionally in Section 4.1. This definition is used in order to avoid dependencies of efficiencies on variable valve timing, which is a very common feature in today's ICEs. This dependency is considered with the gas exchange or pumping efficiency, which is discussed in Section 3.3.4.

3.3.4 *Pumping efficiency*

The pumping efficiency η_p is related to the work needed to do the gas exchange, called *pumping work* W_p. It covers the work needed to do the exhaust and intake strokes in four-stroke engines (Figure 8) and is determined by conducting a pV integration from BDC to BDC over the exhaust and intake strokes that include ΔW_E and ΔW_C explained in the last chapter. Thanks to this definition, which is valid also for any kind of variable valve timing, the integration is carried out from BDC to BDC. In two-stroke engines, W_p is solely the losses during compression, ΔW_C, and expansion, ΔW_E (Figure 14).

Pumping work is an energy loss mechanism to be minimized. The relationships between the pumping work and W_i and W_{ig} and the pumping efficiency and η_i and η_{ig} are given by

$$W_p = W_i - W_{ig} \qquad \eta_p = \frac{\eta_i}{\eta_{ig}} = \frac{W_i}{W_{ig}} = 1 + \frac{W_p}{W_{ig}} \tag{20}$$

3.3.5 *Fuel conversion and combustion efficiency*

Combustion efficiency describes the effects of incomplete and/or imperfect combustion. Incomplete combustion means that there are combustible components left in the exhaust gas, such as CO or H_2 present, for example, when chemical equilibrium is reached or when unburnt fuel remains in the exhaust for fuel-rich conditions. Imperfect combustion on the other hand describes nonequilibrium effects, such as local or global extinction of a flame, which leads to HC emissions and additional CO emissions. Usually, complete (or perfect) combustion never takes place.

Imperfect combustion is described by the fuel conversion efficiency η_f

$$\eta_f = \frac{Q_{in} - (Q_{HC} + Q_{CO})}{Q_{in}} = \frac{Q_f}{Q_{in}} \tag{21}$$

with Q_{HC} and Q_{CO} being the unreleased energy because of the presence of "additional" HC and CO emissions from imperfect combustion processes.

The HC and CO emissions due to incomplete combustion, for example, from rich combustion, are accounted for by the combustion efficiency term η_c. The fuel energy released during incomplete combustion is denoted by Q_c, and η_c is defined as the ratio of Q_c to the maximum possible energy release less that lost due to imperfect combustion, $Q_f = Q_{in} - (Q_{HC} + Q_{CO})$.

$$\eta_c = \frac{Q_c}{Q_f} \tag{22}$$

The losses due to incomplete and imperfect combustion could easily be measured (and/or calculated) and thus could easily be accounted for in the calculation of efficiency (Weberbauer *et al.*, 2005).

Using the assumptions, given in Vogt (Vogt, 1975), η_c can easily be determined from the AFR λ

$$\eta_c = 1.3373 \cdot \min(1, \lambda) - 0.3373 \tag{23}$$

or in a little more detailed form as given in Grill *et al.* (2007) by

$$\eta_c = 1 - \frac{Q_0}{Q_{LHV}} \cdot (0.415 \cdot L_{st} + 1) \cdot (1 - \min(1, \lambda))$$
$$Q_0 = 8.11 \text{ [MJ/kg]} \tag{24}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where $L_{st} = m_{a,st}/m_f$ describing the air mass needed for stoichiometric combustion.

3.3.6 Thermal efficiency and quality grade

Thermal efficiency, η_{th} (often also η_v), denotes the maximum possible gross indicated efficiency of the related ideal constant volume or constant pressure cycle for a given compression ratio. Therefore, it denotes the efficiency maximum, which for real cycles is never reached

$$\eta_{th} = \frac{W_c}{Q_c} = 1 - \frac{1}{r_c^{\gamma-1}} \tag{25}$$

with W_c being the maximum possible high pressure work of the related ideal constant pressure or volume cycle and $\gamma = c_p/c_v$ the adiabatic exponent given as the ratio of specific heat capacities at constant pressure and constant volume (which is assumed to be constant in the ideal process analysis). The thermal efficiency relates to the maximum releasable fuel energy, Q_c.

Thermal efficiency, fuel conversion efficiency, combustion efficiency, and gross indicated efficiency are related together by the definition of a combustion quality grade, η_g

$$\frac{\eta_{ig}}{\eta_{th}} = \eta_f \cdot \eta_c \cdot \frac{W_{ig}}{W_c} = \eta_f \cdot \eta_c \cdot \eta_g \tag{26}$$

The term η_g describes how much ignition timing, burn duration, the shape of the heat release rate, wall heat losses, leakage, and nonconstant gas properties influence efficiency.

3.3.7 Mechanical efficiency

Brake and indicated efficiency are related together by the mechanical efficiency η_m. η_m includes all losses in work between W_i and W_b, defined as W_f

$$W_f = W_i - W_b \tag{27}$$

Besides friction losses from the engine, W_f includes work that is needed to drive accessories, such as pumps, fans, and superchargers, as well as churning losses in the oil circuit or ventilation losses in the crank case. The mechanical efficiency reads

$$\eta_m = \frac{\eta_b}{\eta_i} = \frac{W_b}{W_i} = 1 - \frac{W_f}{W_i} \tag{28}$$

The overall system effectiveness could then be expressed as

$$\eta_b = \eta_m \cdot \eta_i = \eta_m \cdot \eta_p \cdot \eta_{ig} = \eta_m \cdot \eta_p \cdot \eta_f \cdot \eta_c \cdot \eta_g \cdot \eta_{th} \tag{29}$$

and brake power can be finally computed to be

$$P_b = 2\pi \cdot \eta_m \cdot \eta_p \cdot \eta_f \cdot \eta_c \cdot \eta_g \cdot \eta_{th} \cdot \eta_t \cdot \frac{\rho_a}{\lambda \cdot AFR_{st}} \cdot n_c \cdot V_d \cdot Q_{LHV} \cdot \frac{N}{n_R} \tag{30}$$

which is a general description of power output from ICEs.

Nearly all possibilities for increasing power can be derived from Equation 30. To increase power output of an ICE, the most effective measures are as follows:

- Increase in number of cylinders n_c or increase the piston displacement V_d
- Increase of intake air density ρ_a, for example, by turbocharging
- Increase of rotational speed N
- Increase of trapping efficiency η_t, for example, by an increase of charge by a vibration tube
- Increase of thermal efficiency η_{th} by increasing the compression ratio r_c
- Increase of mechanical efficiency η_m by reducing friction losses
- Reducing gas exchange work, increasing η_p
- Optimization of quality grade η_g.

4 SPECIFIC METRICS

One primary measure of ICEs is the piston displacement of a single cylinder V_d or of the whole multicylinder engine V_D. The piston displacement often is used to define specific metrics, which are commonly used to compare different engines.

4.1 Mean effective pressure

Definition of the brake, indicated, and friction mean effective pressures are

$$\text{imep} = \frac{W_i}{V_d} = \frac{1}{V_d}\oint_{\text{cycle}} p \cdot dV \qquad \text{bmep} = \frac{W_b}{V_d}$$
$$\text{fmep} = \text{imep} - \text{bmep} \tag{31}$$

Within the friction mean pressure fmep, not only losses due to friction inside the engines are included but also power needed for additional ancillary units. Measuring fmep is a

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

complicated task, especially in turbocharged engines when mean pressures are high (<20 bar). Therefore, usually it is determined directly from the difference between imep and bmep. Typical values of bmep for different engines are given in Table 1.

In four-stroke engines, splitting the imep into a high pressure (gross indicated mean effective pressure) imep_g and a gas exchange part (pumping mean effective pressure) pmep is useful.

$$\text{imep}_g = \frac{W_{ig}}{V_d} = \frac{1}{V_d} \cdot \left[\left(\int_{BC}^{BC} p \cdot dV \right) + \Delta W_C + \Delta W_E \right]$$

$$\text{pmep} = \text{imep} - \text{imep}_g \tag{32}$$

ΔW_C denotes the work difference between real start of compression, when inlet valve closes, and the compression of an ideal cycle process starting at BDC. ΔW_E denotes the difference between a real exhaust exit, when the EVOs, and the ideal process followed by expansion at BDC (for details, see Figure 13).

For two-stroke engines, the mean pressure for the gas exchange process is directly determined from the losses during compression, ΔW_C, and expansion, ΔW_E (for details see Figure 14)

$$\text{pmep}_{2\text{-stroke}} = \text{imep} - \text{imep}_g = \left[-\frac{1}{V_d} \left(\Delta W_C + \Delta W_E \right) \right] \Big|_{2\text{-stroke}} \tag{33}$$

4.2 Specific fuel consumption

Instead of efficiency, often the specific fuel consumption *sfc* is used. The brake and indicated specific fuel consumptions sfc_b and sfc_i in units of (g [kWh]$^{-1}$) are

$$\text{sfc}_b = \frac{m_f \cdot N}{n_R \cdot P_b} = \frac{1}{\eta_b \cdot Q_{LHV}}$$
$$\text{sfc}_i = \frac{m_f \cdot N}{n_R \cdot P_i} = \frac{1}{\eta_i \cdot Q_{LHV}} \tag{34}$$

using the following relations between power and efficiency

$$\eta_b = \frac{P_b}{\dot{m}_F \cdot Q_{LHV}} \qquad \eta_i = \frac{P_i}{\dot{m}_F \cdot Q_{LHV}}$$
$$\text{and} \qquad \dot{m}_F = \frac{m_f \cdot N}{n_R} \tag{35}$$

The indicated specific fuel consumption especially is used in single-cylinder engine research in order to estimate differences in combustion or gas exchange, in particular at low loads when unwanted changes of mechanical efficiency show big effects. Typical values for the specific fuel consumption for different engine types are given in Table 1.

4.3 Mean piston speed

The averaged piston speed is among others of importance for estimating the life of an engine. Sports car engines operate at mean piston speeds >20 ms^{-1}, whereas large

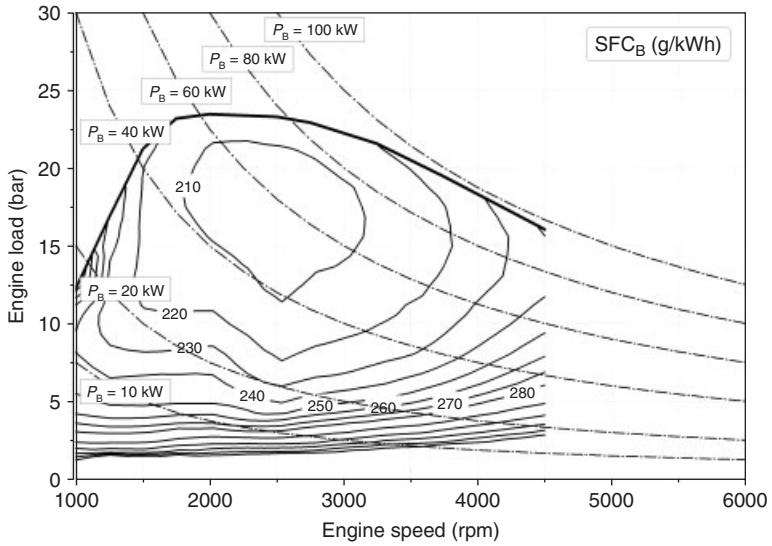

Figure 15. Typical characteristic map of specific fuel consumption and brake power for a Diesel engine (V_D = 2 L). The isocurves denote either constant brake-specific fuel consumption (solid curves) or constant brake power (dashed-dotted curves).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto159
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

engines with long life times are operated below $10\,\mathrm{ms}^{-1}$. The piston speed also exerts strong influence on the in-cylinder fluid mechanics, which affects in-cylinder mixing processes and combustion rate. The averaged piston speed is defined as

$$\overline{S}_\mathrm{p} = 2 \cdot L \cdot N \tag{36}$$

where L being the stroke and N the rotational speed of the engine. Typical values for the mean piston velocity for different engine types are given in Table 1.

4.4 Engine characteristic maps

Engine characteristic maps describe a three-dimensional behavior of ICEs. Mainly engine-specific properties are plotted over rotational speed and engine load, with load being characterized by the torque T or brake mean pressure *bmep*. This allows a general description of the engine over the whole operating range. In Figures 15–17, characteristic maps of fuel consumption for a Diesel engine and two Otto engines (naturally aspirated and turbo charged) are shown.

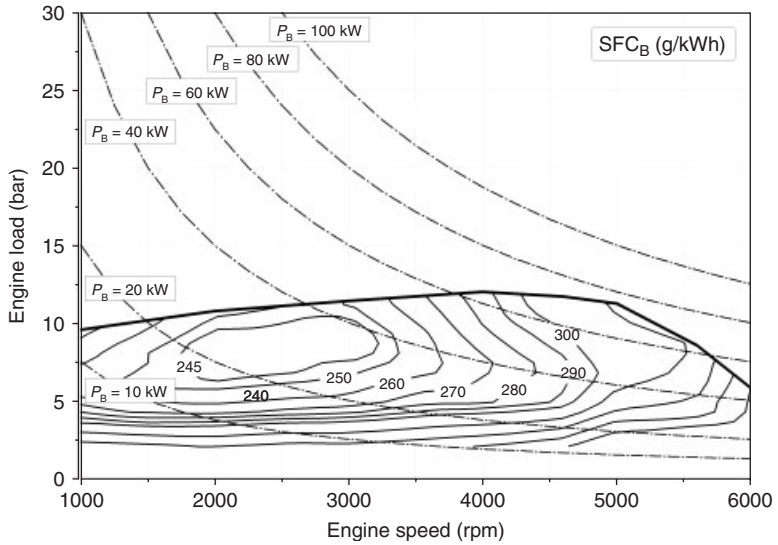

Figure 16. Typical characteristic map of specific fuel consumption and brake power for a naturally aspired Otto engine ($V_\mathrm{D} = 2\,\mathrm{L}$). The isocurves denote either constant brake-specific fuel consumption (solid curves) or constant brake power (dashed-dotted curves).

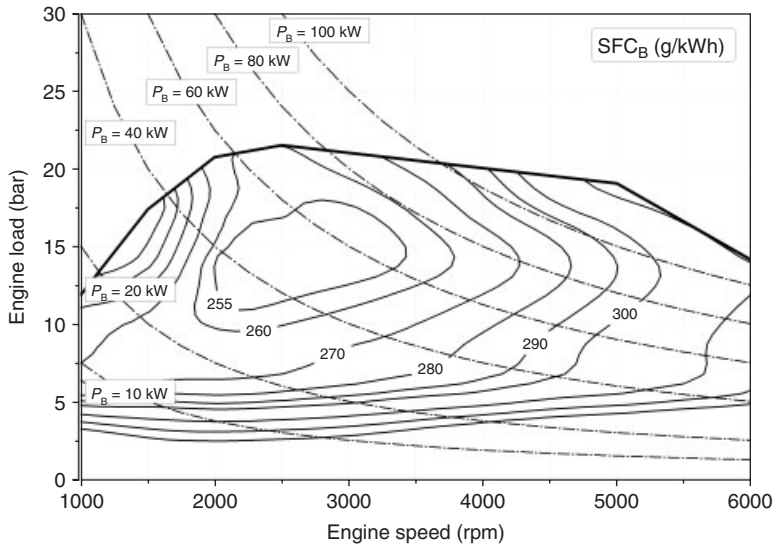

Figure 17. Typical characteristic map of specific fuel consumption and brake power for a turbocharged Otto engine ($V_\mathrm{D} = 2\,\mathrm{L}$). The isocurves denote either constant brake-specific fuel consumption (solid curves) or constant brake power (dashed-dotted curves).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

All engines have similar power and a displacement volume of 2 l. In the graphs, isocurves are plotted for constant specific fuel consumption and constant brake power. From these characteristic maps, the minimum fuel consumption can be obtained for a requested power.

Elastomeric Components for Noise and Vibration Isolation and Control in the Automotive Industry

Xiao-Ang Liu and Wen-Bin Shangguan

South China University of Technology, Guangzhou, China

1 INTRODUCTION

Elastomeric isolators are widely used in industries to reduce noise and vibration. To use isolators effectively, the development engineer must design the isolators to satisfy multiple objectives, which typically include packaging restrictions, environmental criteria, motion control, load requirements, and minimum fatigue life, in addition to vibration isolation performance. An understanding of elastomeric material properties and the methods used to characterize elastomeric component behavior is necessary to achieve desired performance. In addition, the processing and preparation of rubber components and molding methods for elastomeric components are essential knowledge. Typical isolator used in automotive applications, including powertrain mounts, suspension bushings, shock-absorber bushings, flexible couplings, body and subframe mounts, and mass dampers are discussed in this chapter.

2 STIFFNESS AND DAMPING MEASUREMENTS

A rubber isolator is usually simplified as three sets of elastic and damping elements in three perpendicular axes. The performances of a mount are evaluated by static and dynamic performances. The static property of a mount is the force versus displacement relations in the three perpendicular directions. The dynamic performances of a mount are usually evaluated with dynamic stiffness and loss angle (DSLA). A static force versus displacement relation is measured under quasi-static loading conditions, and the typical rates are between 10 and 25 mm per minute. In measuring DSLA of a mount, a preload corresponding to a part of the weight the isolator supported is applied firstly to one end of the mount, then a sinusoidal displacement excitation, $x(t) = X_0 \sin(\omega_0 t)$, is applied through the hydraulic actuator. The reaction force at another end of the mount, $F_T(t) = F_0 \sin(\omega_0 t + \phi)$, and the excitation displacement are acquisized at one time. The complex stiffness of the mount at $\omega = \omega_0$ is defined as, see Shangguan and Lu (2004a, b)

$$K^*(j\omega_0) = F[F_{\mathrm{T}}(t)]/F[x(t)]|_{\omega=\omega_0} = K_{\mathrm{s}} + jK_{\mathrm{l}} = K_{\mathrm{s}} + j\omega D \quad (1)$$

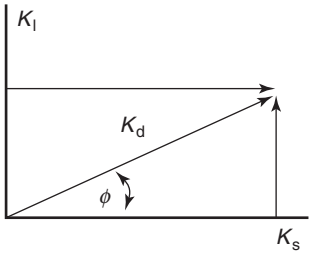

Figure 1. Phasor diagram for complex stiffness.

where F represents the Fourier transformations, K_s is the storage stiffness, K_l the loss stiffness, and D the damping coefficient. The dynamic stiffness, k_d, loss angle, ϕ, and damping coefficient, D, of a mount are calculated from

$$K_d = \sqrt{K_s^2 + K_l^2}, \quad \phi = \text{arctg}\left(\frac{K_l}{K_s}\right),$$
$$D = \frac{K_d \sin\phi}{\omega} \tag{2}$$

The definitions of the various types of stiffness identified respectively in the phasor diagram are shown in Figure 1 and are explained below:

Complex stiffness (K^*): It is the measured peak force divided by the measured peak displacement. The complex stiffness is the vector sum of the stiffness component in phase with the displacement and the stiffness component in phase with the velocity.

Storage stiffness (K_s): It is the proportionality factor between the displacement and the component of the force phasor that is in phase with the displacement.

Loss stiffness (K_l): It is the proportionality factor between the displacement and the component of the force phasor that is in phase with the velocity.

Loss angle (ϕ): It is the phase angle between the force and the displacement signals.

3 RUBBER TECHNOLOGY

Most vibration isolators in automotive industry are made of elastomeric compounds. Rubber is the general name for the existing variety of elastomeric materials, and the term *rubber* can refer to both natural and synthetic compounds.

Elastomers have the following three distinguishing characteristics, see Lewitzke and Lee (2001):

1. Resilience and energy storage—elastomers exhibit a high degree of recovery from large or small deformations through repeated cycling, returning approximately to the original dimension without suffering permanent damage, that is, resilience. Remarkable energy storage capacity and the ability to withstand repeated flexing attribute to rubber's utility as a spring material for mountings or suspensions for vehicles, machines, engines, and instruments.
2. Large deformability—elastomers exhibit the capability to withstand relatively high amounts of extension within the working range of the material, which, in extreme cases, can reach 300%, and the ultimate elongation may reach 1000% of the original length. Comparatively, steel may not be extended more than 0.5% of the original length without exceeding the elastic limit, and the ultimate elongation seldom exceeds 25%.
3. Low modulus—when exposed to large deformation, elastomers exhibit low stress levels. Rubber is seldom subjected to stresses >7 Mpa.

Natural rubber is produced by coagulating the latex, or sap, of the *Hevea brasiliensis* tree. Additional ingredients are also used in the formulations of both natural and synthetic rubber elastomers to provide specific performance characteristics, and the function of these ingredients is outlined in Table 1, see Lewitzke and Lee (2001).

Table 2 defines the major properties of the elastomers that are most commonly used in automotive vibration isolators.

Table 1. Additional ingredients used in the formulations of natural and synthetic rubber elastomers.

Ingredient	Comment
Base polymer	Natural rubber, poisoprene, butyl, and so on.
Carbon black	Reinforcement, hardness, dynamics, processability, and tensile strength
Sulfur	Cross-linking
Oils	Processability, dynamics, and hardness
Antioxidants and antiozonants	Prevent deterioration because of ozone and oxygen
Zinc oxide and stearic acid	Activate and stabilize the heat aging of the final mix
Accelerators	Speed up the curing process

Table 2. Properties of the elastomers used in automotive vibration isolators.

Elastomer	Properties	Applications
Natural rubber or polyisoprene (NR)	Available properties satisfy a broader range of engineering application than any other elastomer family. Excellent tensile strength and tear resistance	Powertrain mounts, suspension bushings, exhaust hangers, shock, strut mounts, front axle bushings, and rear differential mounts
Styrene-butadiene (SBR)	Reinforced or stiffer compounds offer properties only slightly lower than those of NR and IR, but more economical	Powertrain mounts and jounce bumpers
Synthetic isoprene (IR)	Similar to natural rubber. Slightly lower tensile strength and tear resistance	Powertrain mounts and suspension bushings
Poly-butadiene (BR)	Properties range a little below NR and IR. Resilience and low temperature flexibility better than NR and IR	Same as natural rubber
Polyurethane	Outstanding oil and solvent resistance; good impermeability; excellent aging; resistance to oils and gasolines; and ozone resistant	Body mounts, jounce bumpers, and suspension bushings
Polychloroprene	Moderate solvent resistance; excellent aging characteristics; and flame resistant. Approaches the broad engineering properties of NR and IR	Powertrain mounts and strut mounts
Butyl or polyisobutylene (IIR, CIIR)	Outstanding impermeability, chemically inert, excellent weathering resistance, high gum strength, high damping at moderate temperatures	Cradle and body mounts, jounce bumpers, and vibration dampers
Silicon (VMQ)	The highest and the lowest useful temperature ranges of all elastomeric compounds; superlative aging properties; radiation resistant; and reasonable oil resistance	Powertrain isolators and exhaust hangers

3.1 Processing and preparation of rubber components

A machine is used to mix the ingredients used in the formulation of elastomeric compounds. The ingredients are measured to a given weight and tolerance and then transferred to the Banbury mixer for mixing. After mixing, the rubber is dropped onto a twin-roll mill, where it is "kneaded" to induce a cross blending of the various elements that produces a homogeneous mixture. The rubber is then stripped off the mill and placed in a batch to cool. After cooling, the rubber can be sent either to an injection press or to an extruder for preparing slugs to a given weight for compression or transfer molding.

Gum rubber is a very viscous, partly elastic liquid, which has no practical engineering applications because the material has extremely poor tensile strength, elongation, and dynamic modulus and fatigue life. A vulcanization process is required to transform the rubber into a useful material.

The molecules of gum rubber are long and flexible. Vulcanization is a molecular cross-linking process that produces a molecular network by chemically linking together the independent chains of long molecules. The vulcanization process begins as soon as sulfur is added to the formulation, but time, temperature, and pressure are required to complete the process. The final formation of the cross-links occurs during molding, which is not only rapid but also controllable. Vulcanizates of natural rubber can be formulated to give good tensile strength and elongation over the complete range of hardness.

3.2 Measurement of the cure cycle

To verify that the desired performance attributes will be achieved during vulcanization, parameters that characterize the cure cycle during the molding process must be measured. The rheometer test instrument is used to measure those parameters.

The rheometer test instrument consists of a rotating grooved disk inside a closed cylindrical cavity. A test sample of uncured rubber is placed in the cavity to cure, while a disk embedded in the sample rotates in an oscillatory manner through a small arc. Torque is measured and recorded as a function of time on a rheometer chart. This chart will show initial viscosity, minimum viscosity, cure rate, and the final torque.

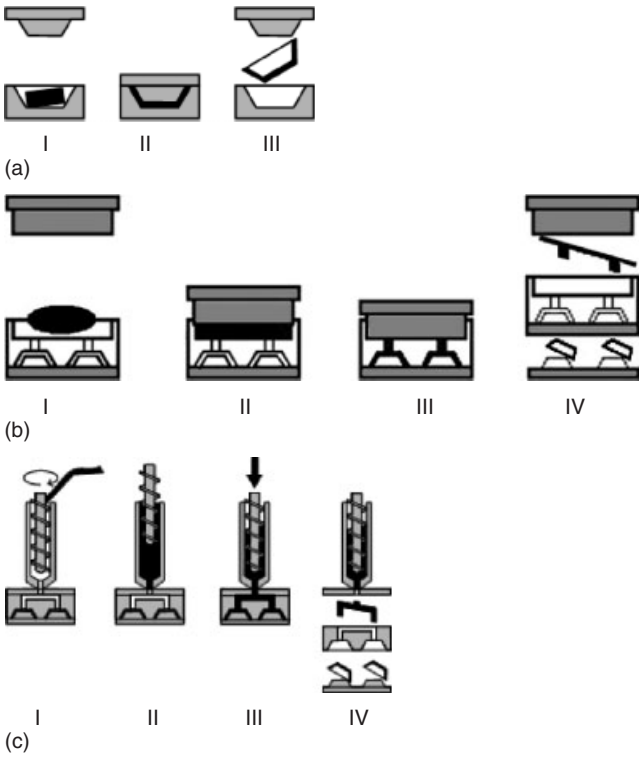

Figure 2. (a) Compression mold (semi-positive type), (b) transfer mold, and (c) injection molding.

3.3 Molding

There are three types of molding process used to manufacture rubber parts, which are described below, and the molding processes are shown in Figure 2.

1. Compression molding—a rubber slug is placed in the mold cavity. Pressure is applied as the lid is closed, which is maintained at a given temperature for a precise period of time.
2. Transfer molding—a rubber slug is placed in a pot located in the top part of the mold. As the press is closed, a ram forces the rubber through a sprue located in the bottom of the pot, and into the mold cavity.
3. Injection molding—a strip of rubber is fed into a holding pot. The holding pot contains a set of baffle gears that push a metered amount of rubber through a nozzle into the mold cavity.

Injection molding requires the shortest cure time and produces least amount of waste of the three molding processes. Table 3 provides comparative values for the time required for molding to full cure for a given part size and shape.

Table 3. Values for the time required for molding to full cure.

Modeling Type	Time
Compression molding	About 40 min
Transfer molding	20–30 min
Injection molding	4–8 min

Before molding, the metal inserts need to go through cleaning and adhesive coating operations to achieve good bonding of the rubber to metal. Cleaning operations consist of degreasing and wheel abrading. Primer and adhesive are applied to the metal parts in a two-coat operation, and then oven dried to prevent wipe-off of the primer/adhesive during molding.

After molding, pull tests are conducted, which measure the quality of the rubber-to-metal bond. Two criteria are typically used to qualify pull test results:

1. Ultimate pull force achieved before break, measured in newtons.
2. Visual Inspection—pull test results are qualified as a rubber failure, rubber/adhesive separation, and adhesive/metal separation. The acceptable pass condition is rubber failure only.

4 ENGINE MOUNTS

The functions of mounts are (i) to support the weight of the powertrain (weight support)—the powertrain weight should be well distributed among two to three load-carrying mounts; (ii) to control displacement of the powertrain center of gravity (CG) (motion control) under different quasi-static loads, such as maximum forward/reverse engine torque and shipping loads when the vehicle curies at different accelerations; (iii) to control powertrain vibration (vibration control) under tip in/back out (large torque change) and road impacts; (iv) to isolate chassis vibrations (vibration isolation) owing to the engine excitations at different operation conditions, such as idle, acceleration/deceleration, cruise, and switch on/off, see Yu, Naganathan, and Dukkipati (2001).

To satisfy with the design requirements of a powertrain mounting system (PMS, powertrain plus mounts), the mounts in a PMS are required to be soft (lower dynamic stiffness and lower damping) in order to isolate the engine excitation, and required to be hard (high stiffness and damping) in order to control the powertrain motion and vibration (see NVH Considerations in Engine Development). Therefore, the static force versus displacement (F–D) relation and DSLA of the mounts in a PMS should be designed carefully to meet the conflicting

(a) (b)

Figure 3. (a, b) Contours of complex mounts (wedge mount).

requirements for the mounts. Different kinds of mounts, from elastomeric mount (rubber mount) to hydraulic mount, and from passive mounts, semi-active mounts to active mounts, have been developed to improve the noise, vibration, and harshness (NVH) performance of a PMS, see Shangguan (2009).

4.1 Elastomeric mounts

Elastomeric mounts (rubber mounts) have been successfully used for powertrain mounts for many years. The contours of the rubber mounts are changed from standard parts (such as block or circular shapes) to complex mounts shown in Figure 3. The stiffness of the wedge mount in three axes can be adjusted by changing dimension and angle orientation of the rubber elements.

Bush-type rubber mounts used in a PMS are mainly used for controlling motion and vibration of a powertrain in the direction of crankshaft axis. Figure 4 shows a typical structure of a bush-type mounts.

The DSLA of a rubber mount under different excitation frequencies and excitation amplitudes can be found, see Shangguan and Lu (2004a, b). It is shown that the dynamic stiffness of a rubber mount under high frequency and small-amplitude excitations is larger than that under lower frequency and large-amplitude excitations. The damping of a rubber mount is relatively low, which could not meet the vibration control requirements for a powertrain under the ground excitations or output torque changes. The static F–D relation of a mount in one direction is usually nonlinear, and can be seen in Shangguan and Hou (2006).

Figure 4. Bush-type rubber mounts.

4.2 Hydraulic engine mounts

In 1962, Rasmassen patented a hydraulic engine mount (HEM) for increasing damping of a rubber mount, see Richard (1984). In 1985, all cars manufactured in GM are equipped with HEM, see Givers (1985). Today, HEMs are installed in almost all passenger cars. Moreover, it is validated that an HEM can improve the comfort and sound quality of a car, see Muller *et al*. (1994, 1996).

Different types of HEMs have been reported as shown in Table 4. The basic idea of an HEM is to use highly elastic rubber for vibration isolation and to use a hydraulic device

Third generation			

(inertia track and decoupler) to generate the large damping at a prescribed frequency for vibration control. All types of hydraulic mounts reported in the literature are conceptually similar but different in detailed structure design. Table 4 gives the developments of hydraulic mounts.

4.2.1 *First-generation mounts: viscous-, orifice-, or inertia track-damped HEM*

A viscous-damped mount consists of a rubber spring and one chamber filled with a mixture of air and highly viscous fluids (e.g., silicone) or paste. The damping is created by forcing the silicon into the air gap, which makes the air is compressed and leads to bulge the rubber spring. This type of mount provides damping at broadband frequencies with a simple and cost-effective design. However, it is poor for isolating the engine small-amplitude excitations.

Orifice- and/or inertia track-damped HEMs: these two types of HEMs consist of two chambers, a rubber spring and a plate consisting of a fluid channels that forms an orifice or/and an inertia track. The chambers are completely filled with fluid. The upper chamber is a working chamber, and the pressure in this chamber changes greatly. The thickness of the rubber bellow in the bottom of an HEM is very thin that usually <3 mm. Therefore, the pressure change in the lower chamber approaches zero. The lower chamber is usually designed to absorb the transferred fluid. The large damping of an HEM is created by the fluid flowing from one chamber to another. The inertia effects of the fluid within the orifice or inertia track have great influences on the DSLA of an HEM at high frequency excitations; see Ushijima, Takano, and Kojima (1988).

4.2.2 *Second-generation mounts: hydraulic damped mounts with a decoupler and an inertia track*

The fluid in the inertia track cannot follow the excitation under the high frequency and small-amplitude excitations for the first-generation mounts, so the orifice or inertia track may be closed and the rising pressure in the upper chamber causes the increase in the DSLA of an HEM. To meet the conflicting requirements for vibration control and isolation of a powertrain, a decoupler is integrated with the inertia track to provide low stiffness for small-amplitude

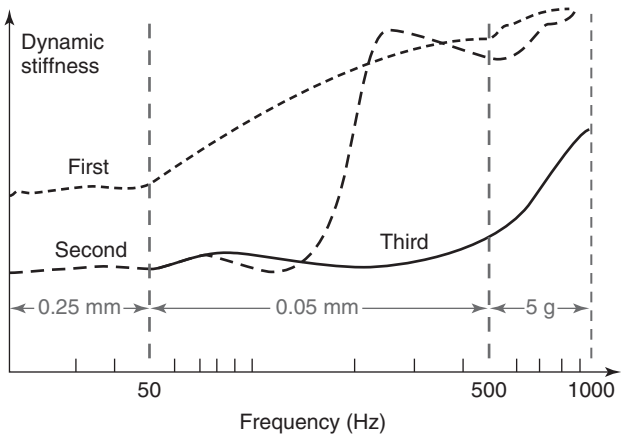

Figure 5. Dynamic stiffness of the three-generation HEMs under small-amplitude and high frequency excitations.

excitations, and to be blocked mechanically to generate large damping at large-amplitude excitations. The dynamic stiffness of an HEM without or with decoupler (the first- and second-generation HEMs) under high frequency and small-amplitude excitations can be found in Figure 5, see Tokushige, Funahashi, and Katayama (1999). It is seen that for the first generation of the HEMs, the dynamic stiffness increases if the excitation frequency is above 50 Hz, and the dynamic stiffness below 50 Hz is larger than that of the second-generation HEMs.

4.2.3 Third-generation mounts: inertia track-damped mounts with a decoupler and a plunger

If a component named "plunger" is incorporated in a second-generation mounts, a third-generation HEM is founded. The plunger subdivides the upper chamber and forms a ring-shaped channel against the chamber wall. The channel creates a high frequency inertia effect, which causes a decrease in dynamic stiffness. The frequency of the dynamic stiffness harden is determined by the radial clearance and the distance between the plunger and the rubber spring. In addition, the plunger is used as a restrictor. The dynamic stiffness of a third HEM under small-amplitude excitations can be found in Figure 5. It is shown that the frequency of dynamic stiffness harden is above 500 Hz, which is well above the frequency of dynamic stiffness harden for a second-generation HEM.

4.3 Torque struts

Torque struts are typically used in front-wheel-driven and transverse mounted powertrains (see Engine Configurations). A torque strut consists of a pair of elastomeric bushings or one elastomeric bush and one hydraulic bushing separated by a rod. A typical torque strut with one rubber bushing and one hydraulic bushing is shown in Figure 6. The function of a torque strut is to provide a torque against the powertrain pitch movement (a rotation around the engine crankshaft). In the design of a torque strut, the following factors need to be considered:

1. The resonance frequency of the mass-spring system consisting of the torque strut and bushing should be well above the fundamental orders of the engine firing frequency. This is accomplished using lightweight materials for torque strut rod and bushing housing, and by combining a soft bushing on one end of the torque strut and a stiff bushing on another end.
2. The torque strut applies a counteracting force to the load-carrying mounts in the longitudinal direction (front/after). Usually, the vertical stiffness of a mount increases rapidly with the increased longitudinal force, see Hofmann (2002). Accordingly, the stiffness and the positions of a torque strut should be designed with no consequential increase in the vertical stiffness of load-carrying mounts. An idea solution is to implement a longitudinal link with the load-carrying mounts. The link can support the longitudinal forces acting as torque strut but without increase the vertical stiffness of the mount. Such construction can be found in Figure 7.
3. In the assembly of a torque strut to a powertrain, care must be taken with the orientation of the torque strut. It will become unstable when it reacts a compression load that is along the torque strut rod direction. Even though the torque strut may be located such that it reacts forward drive loads in tension; under reverse torque conditions, torque strut will be loaded in compression, which may cause the torque to toggle over center.

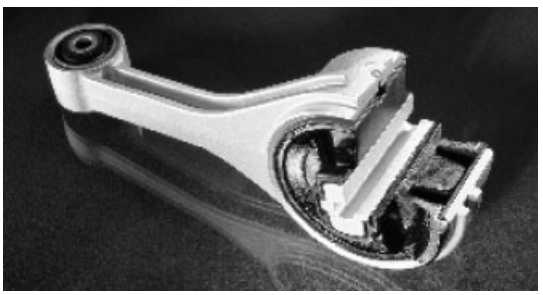

Figure 6. Torque strut.

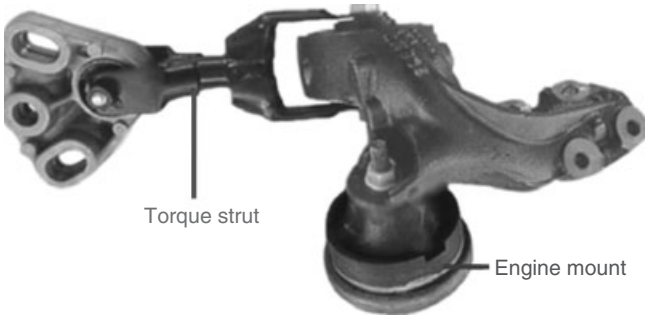

Figure 7. Integration of a torque strut and engine mount.

4.4 Semi-active mounts

A semi-active mount is an HEM with a mechanism to change the DSLA of the mount, and it is also called *switchable (on/off) mount*. A semi-active mount is used mainly for improving the car idle speed behavior. There are several types of semi-active mounts that are described below.

4.4.1 Vacuum-switchable type semi-active mount

The configuration of a vacuum-switchable type semi-active mount is shown in Figure 8. When a low stiffness is required in idling, the engine control module commands a signal to open a control valve, and a vacuum chamber is formed between the membrane and the rubber spring. The vacuum chamber decouples the fluid flow between the upper and the lower chambers through the inertia track. In driving conditions, the air in the vacuum chamber is sucked out, so the membrane is directly linked to the rubber spring and the mount behaves like a passive HEM with inertia track.

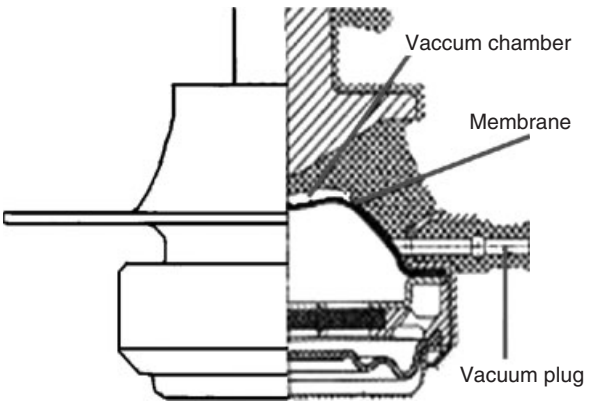

Figure 8. Vacuum-switchable type semi-active mount.

4.4.2 Orifice-controllable type semi-active mount

This type of semi-active mount consists of two chambers, a plate that forms an inertia track, and an orifice with a large diameter. The orifice can be opened or closed by a control valve. When a low stiffness is required, the orifice is opened, which allows the fluid to flow unrestricted between the two fluid chambers, resulting in a mount with low stiffness. When a high damping is required, the engine control module closes the orifice, causing fluid through the inertia track between two chambers, which produces high damping and stiffness in the mount.

4.4.3 Inertia track-controllable type semi-active mount

In some cases, especially with diesel engine, the idle vibration of a car is so significantly affected by high vibration levels transferred from the engine to the chassis through the engine mount, which means that a further reduction of the dynamic stiffness of a mount in the vertical direction is required.

The dynamic stiffness versus frequency cure of an HEM shows a notch before the stiffness increases because of resonance as Figure 9 indicates. This effect can be used to improve isolation of an engine in certain frequency ranges. The dynamic stiffness of an HEM near the notch frequency is far lower than the static stiffness of an HEM that is determined by its rubber spring. Experiments and simulations indicate that if the numbers of inertia tracks in an HEM increase, the notch frequency increases, see Zhang and Shangguan (2006). This concept is implemented in the design of a semi-active mount with controllable inertia track.

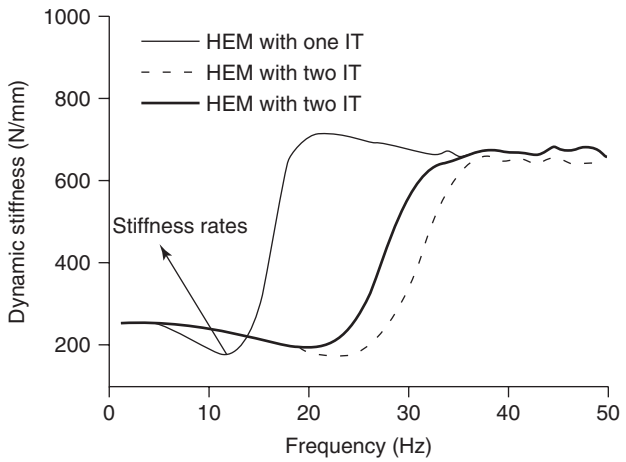

Figure 9. Dynamic stiffness of HEMs with different number of inertia tracks (IT: inertia track).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto160
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In this kind of semi-active mount, the HEM has two inertia tracks, one of which can be closed by an actuator. In idle, the control valve is open and makes the two inertia tracks work in parallel. Under this operation condition, the notch frequency of the mount is at a relatively high frequency, which results in minimum stiffness in the frequency at engine idle excitation (usually about 25 Hz), see Figure 9. By changing the inertia track sizes, the notch frequency can be adjusted. Under on-road condition, the control valve is closed and only one inertia track works. These result in large damping and stiffness at shake frequency as a conventional HEM.

4.5 Active mounts

An active mount consists of a passive mount (elastomeric or hydraulic mount), a vibration sensor, an electronic controller, and a force generating actuator. Active means that an active mount can suppress the structure vibration in actual driving conditions in very short time. Therefore, the controller for an active mount is typically implemented with the close-loop controller utilizing a linear sensor measurement. A sensor is mounted on the chassis side of the mount to measure the undesired vibration. A closed-loop control system is used to generate a secondary excitation force that is out of phase and equal in amplitude to the measured unwanted vibration, which is then applied by the linear actuator. Ideally, the secondary force cancels out the unwanted primary vibration, resulting in a zero level of transmissibility. An active mount requires significant external power and increases considerable cost and weight.

A simply type of active mount is to use electrorheological fluid (ERF) to replace ethylene glycol in a conventional HEM. The wall of the inertia track for a standard HEM is designed as electrode as shown in Figure 10. By applying high voltages, the viscosity of the ERF within the inertia track can be increased, which makes the same effect as reducing the size of the inertia track. If the voltages are high, the inertia track can be blocked. The dynamic performance of this mount can change from highly elastic nondamping mounts to highly damped mounts within one milli-second.

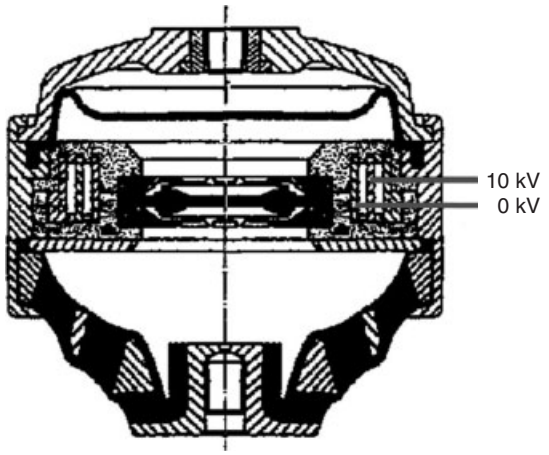

Figure 10. One type of active mount.

5 SUSPENSION BUSHINGS

Elastomeric bushings are used extensively in automobile suspension systems to withstand static, dynamic, and fatigue loads that occur under different road and driving conditions and to fulfill NVH and ride and handling targets of a vehicle. The bushings are functional parts of the control arms and are designed to attach the control arm to the front cradle as shown in Figure 11. The advantages of using elastomeric isolators in the suspension system are to eliminate the need to lubricate pivot joints. Table 5 shows suspension bushing usage.

Cylindrical bushing designs, as shown in Figure 12, are widely used in suspension systems to provide flexibility in torsion and tilt, as well as control for axial and radial displacements. The soft axial spring rate produces excellent isolation, and the high radial stiffness assures high stability. Figure 13 shows a cylindrical bushing in a trailing arm application.

A hydraulic bush in the rear control arm position shall be considered depending on vehicle requirement. It can provide large damping in axial or radial direction as shown in Figure 14. Figure 15 shows a suspension bushing with radial damping direction and vertical installation.

The dynamic characteristics of hydro bushing depend on its applications; the following gives some examples for application of hydraulic bush.

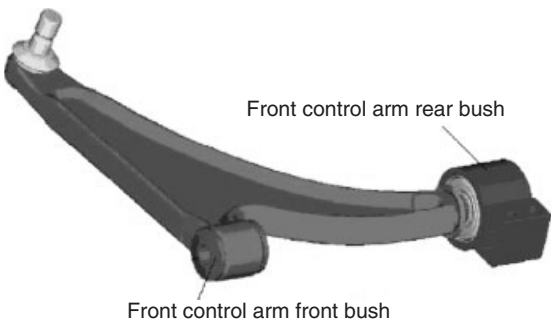

Figure 11. Bushings in a control arm.

Table 5. Bushing usage.

Type of Suspension	Bushing Locations
Solid axle, leaf—spring	Leaf-spring shackle
Twin I-beam—independent front suspension	Inner end of the axle; radius arm; and jounce bumper
Double wishbone—independent front suspension	Strut/shock mount; upper and lower; control arm; stabilizer bar; and strut bar
MacPherson strut—independent front suspension	Strut mount; jounce bumper; and anti-roll bar
Type 1 coil spring—independent front suspension	Lower control arm and upper control arm
Type 2 coil spring—independent front suspension	Lower control arm and upper control arm
Torsion bar—independent front suspension	Lower control arm; upper control arm; and eyehole pivot

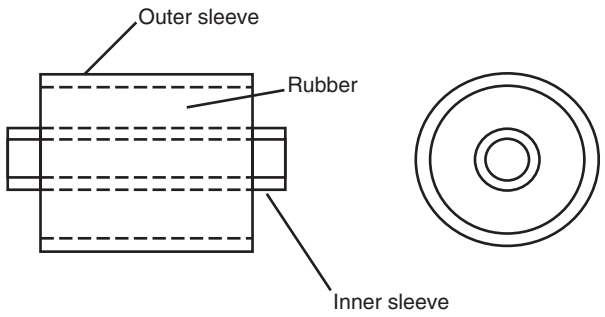

Figure 12. Cylindrical bushing design.

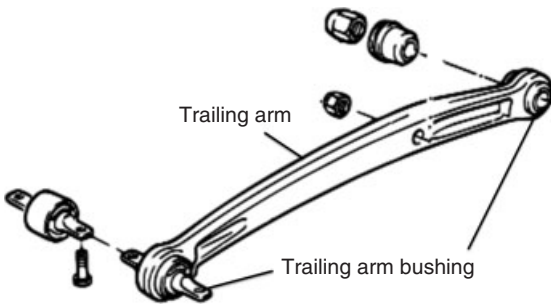

Figure 13. Trailing arm bushing.

One of the examples of the applications of hydro bushing is front lower control arm hydro bushings, which should suppress vibrations of the wheel suspension (wheel hop). Such disturbing vibrations lead to brake judder or steering wheel shimmy. Another application is twist beam hydro bushing at rear axle, which should reduce vibrations in fore/aft direction after driving over obstacles on the road. A third application of hydro damping is found at subframe bushings at front and rear suspensions. These hydro bushings reduce pitching vibrations of the subframes. All hydro bushings improve steering precision of the front and rear suspensions as well.

If a hydro bushing is replaced by a conventional bushing, one can gather the deterioration from the spider web diagram shown in Figure 16.

6 SHOCK & STRUT MOUNTS

The shock & strut mount is a component intended to provide isolation between the wheel suspension and shock absorber and the vehicle body structure, and provides position, motion control, damping, and load support of the shock absorber for the life of the vehicle. A typical

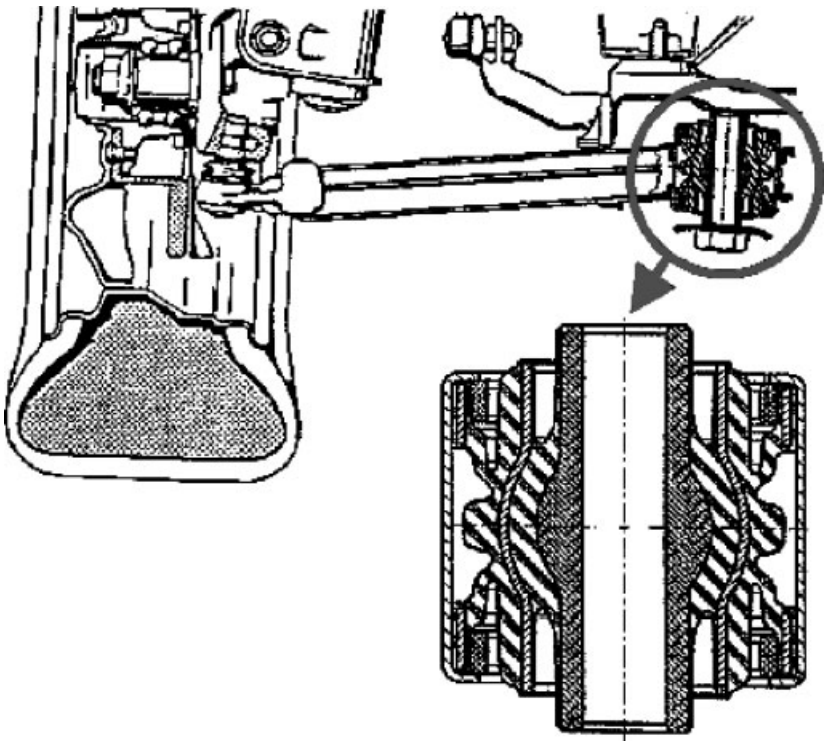

Figure 15. Suspension bushing with radial damping direction and vertical installation.

construction of a shock & strut mount is shown in Figure 17. The characteristics of the shock & strut mount is specified to obtain the correct behavior of the shock absorber under different load and driving conditions and to reduce the transmission of vibration forces from the shock absorber to the body/passenger compartment.

The flexibility of the shock & strut mount allows the strut angle to change to follow the travel of the lower ball joint, and the rubber reduces vibration and transmitted road noise. A bearing unit built into some mounts functions as the upper pivot point and forms the steering axis. When the front wheels are turned, the entire strut will pivot from the lower ball joint to the upper strut mount.

There are four types of strut & shock mount designs:

1. Single path shock & strut mount, which is shown in Figure 18: both the rod and the spring loads are isolated by the same rubber section. The rubber anchorage improves noise insulation. Initially, the deflection curve remains linear and then becomes highly progressive in the main work area, which is between 3 and 4 kN.
2. Dual path shock & strut mount, which is shown in Figure 19: the rod and the spring loads are isolated by different rubber sections. It provides good isolation, but is more expensive than the single path mount.

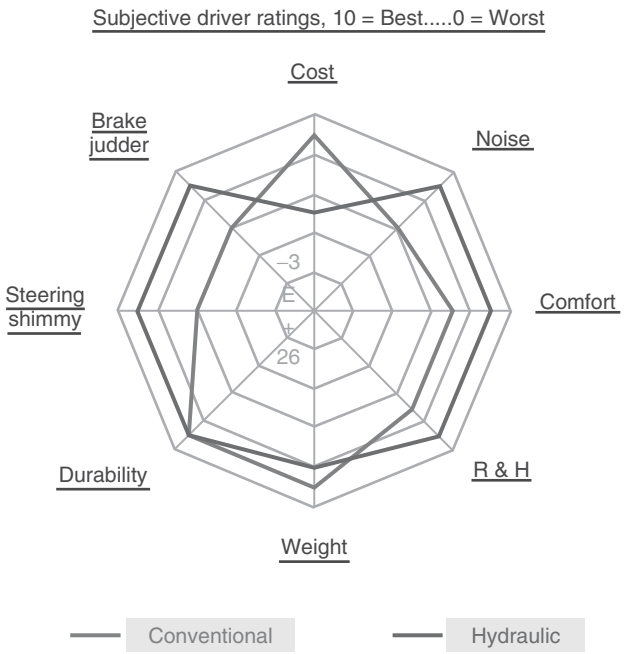

Figure 16. Comparison of conventional bushing and hydraulic bushing.

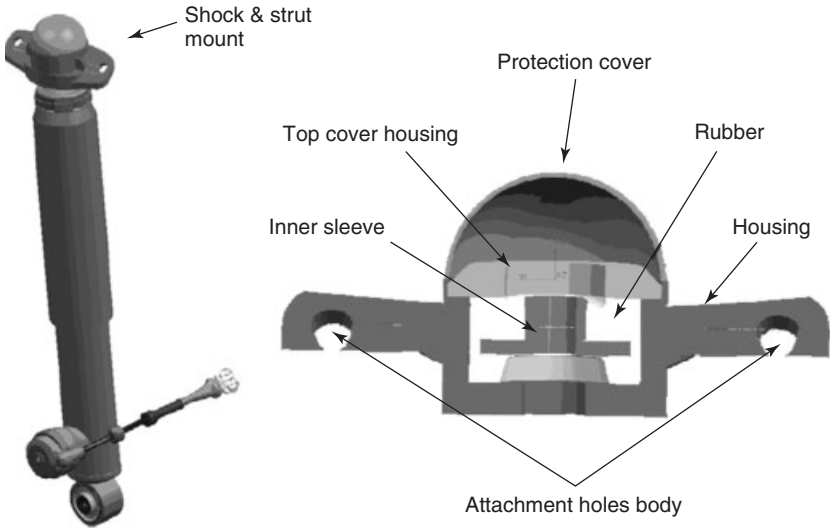

Figure 17. Construction of shock & strut mount.

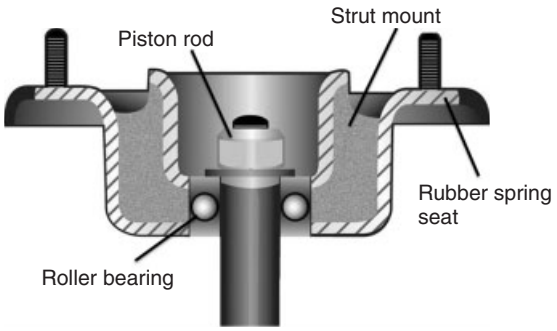

Figure 18. Single path shock & strut mount.

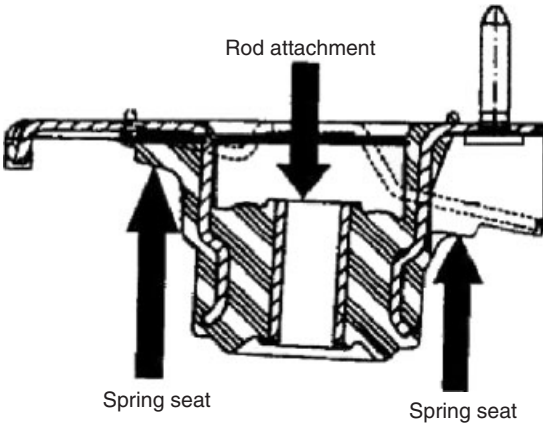

Figure 19. Dual path hock & strut mount.

1. Dual path with double isolation shock & strut mount, which is shown in Figure 20: the rod and the spring loads are isolated by different rubber sections as shown in Figure 20. The body spring and shock absorber forces are introduced into the body along two paths with variable rigidity.
   Inner path (1): The parts in inner path achieve good insulation from vibration and noise and improve the roll behavior of the body. High level of rigidity in a transverse direction is required for motion control.
   Outer path (6): The forces of the body springs are directed along the outer path, which has a considerably higher level of rigidity.

The force versus displacement for inner and outer paths is shown in Figure 21. It is seen that the stiffness in the inner path is much lower than that of the outer path.

Hydraulic top strut mounts shown in Figure 22 are also available on the market, not for damping but for isolation purposes. The fluid inertia effects within the mount are used to isolate tire-induced roll noise. By means of a dynamic decrease of stiffness, it is possible to reduce structure-borne noise through the strut mount.

7 JOUNCE BUMPERS

Jounce bumpers are typically installed on the chassis, strut assembly, control arm, or trailing arm assembly to increase the stiffness of the suspension system under high load conditions. They reduce spring stresses by transferring loads directly to the body or chassis under impact conditions. The material and shape of the jounce bumper establish the energy absorption capability of the design. These parameters also affect the maximum load transmitted

to the body or frame during road impact events and the control of these loads will enable higher axle loading or conversely a bigger safety factor against overload.

The height of a given jounce bumper design is established by the difference between the maximum metal-to-metal clearance and the desired free travel. The amount of free travel is an important parameter that affects the ride characteristics of the vehicle. The maximum deflection of the bumper is the difference between the minimum clearance and the desired free travel. Figure 23 shows the jounce bumper design height and travel limitations.

Jounce bumper performance is evaluated by the following desired objectives:

1. High amount of energy absorption; magnitude of the peak force achieved during impact is minimized.
2. Gradual rate increase at initiation of contact (soft entry).
3. Low impact deflection; low rebound characteristics.

Butyl rubber and polyurethane are common jounce bumper materials, as these materials provide a high amount of energy absorption and the lowest rebound height. The bumper height, variations in taper, base area, bumper shape, and compound hardness are the other major parameters that affect the performance of a jounce bumper. The basic bumper shapes are shown in Figure 24.

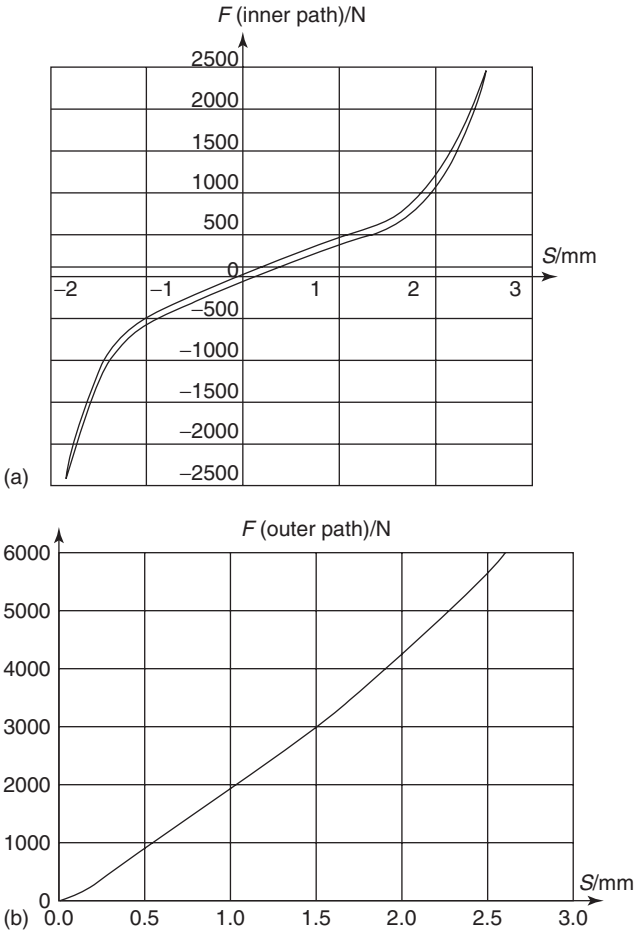

Figure 21. (a, b) Force versus displacement for inner and outer paths.

8 BODY AND SUBFRAME MOUNTS

8.1 Body mounts

Figure 25 shows the construction of a typical body/cab mount installation that consists of the load cushion, rebound cushion, the rebound cushion washer, and spacer sleeve. Body/cradle mounts are installed between the frame and the body/cab to isolate the passenger compartment from road noise, harshness, shake, and other vibrations in the chassis. The center bolt is tightened until the rebound cushion washer contacts the spacer sleeve, thus applying a compression force across both rubber parts. The load cushion supports the weight of the body. The external compression load increases the force on the load cushion and partially unloads the rebound cushion. The system behaves like two springs in parallel.

Body mounts must have the proper static rate to support the body at the proper height above the frame. Isolator dynamic rate must separate the natural frequencies of the body and frame from principal exciting frequencies, and the dynamic rate should be sufficiently low to isolate the vibrations. Isolator damping should be sufficiently high to control road-induced vibration. The polymer of the mount should have temperature stability and age resistance. Butyl rubber is used for most body/cradle mount applications, because butyl can provide more damping

compared to natural rubber. Under body weight, the body/cab mount should not deflect more than 25% for durability considerations and set resistance. Under maximum operating conditions, the preload on the isolators should not allow either the load cushion or the rebound cushion to fully unload in order to maximize isolator durability of the mount and to maintain vehicle ride quality and stability.

8.2 Subframe mounts

The application of subframe designs enables the double isolation of structure-borne noise transmitted from engine to body, and thus absorption of noise emissions and provision of vibration comfort. The layout has to consider that the additional six degrees of freedom do not create any vibration problems.

The subframe normally contains four elastic components. In most cases, the mounts are pressed into the subframe and afterward assembled to the body. The elastic elements should provide a good isolation in vertical direction, but not decrease the handling performance. The corresponding designs are normally bush-type components that are soft in axial direction and that should be designed stiffer in longitudinal and lateral directions. Figure 26 shows a conventional design of a subframe mount.

Figure 26. Conventional subframe mount.

To avoid disturbing resonances of the elastically supported subframe, radial damper components are sometimes used to prevent lateral vibration amplification. Such a design is shown in Figure 27.

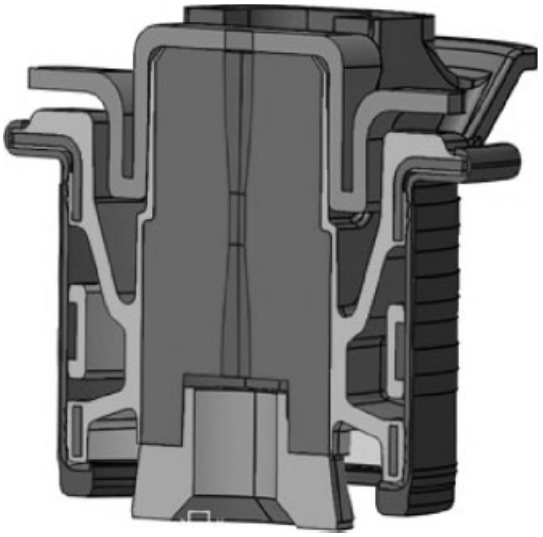

Figure 27. Hydraulic subframe mount.

9 INTERMEDIATE DRIVESHAFT MOUNTS

Rear-wheel-drive (RWD) driveshafts (propshafts) are frequently split into multiple components in order to keep the critical speed of the driveshaft below a desired limit. Two- and three-piece driveshafts require an intermediate driveshaft bearing-and-mount assembly to provide support. The flexible mounted bearing supports are shown in Figure 28. The rubber mounting provides the following two functions:

1. To accommodate a slight tilt of the shaft.
2. To act as a vibration damper and isolate any propshaft vibrations from the body.

The rubber-block bearing mount incorporates a rubber element that is mold-bonded to an external metal mounting flange and to the casing for the outer bearing race. The flexible bearing mount has a slot on each side of the rubber molding to improve flexibility. The V-section mount can fold and move about its mean position more readily as conditions demand. This also improves the vibration-damping properties of the rubber assembly. The double-fold rubber bearing mount also provides excellent damping properties, and provides greater rigidity for the bearing with increased articulation.

10 FLEXIBLE COUPLINGS

Flexible couplings are used to accommodate large angular and axial displacements with minimum resistance, reduce

torsional vibration and noise, and absorb torque fluctuations. They can replace mechanical joints, eliminating the need for lubrication and averting metal-to-metal wear conditions. Often flexible couplings are used in driveshaft systems to provide torsional and axial flexibilities. When installed in an RWD driveshaft, a centering support device is also necessary. The rubber mounting in the coupling provides a flexible support for the bearing so that a slight tilt of the shaft can be accommodated. In addition, the flexible rubber element provides isolation for the body structure from propshaft vibrations.

Flexible coupling are used widely in the rear driveshaft for an all-wheel-drive (AWD) driveline, and in a front-wheel-drive (FWD) drive axle that accommodates axial and universal movements. It reduces loads on the gearbox casing and bearings and eliminates the need for sliding splines. The flexibility provided by the elastomeric coupling reduces driveline-induced noise and vibration (roughness) in the vehicle. Flexible couplings are also used on steering columns.

11 MASS DAMPERS

Often, in the situation of a noise or vibration problem that is caused by a resonant condition, it is not practical to reduce noise or vibration levels through isolation techniques alone. A concept that is frequently applied is the use of a mass damper, which utilizes the characteristics of a second-order system to obtain a noise or vibration reduction.

The model of a dynamic absorber is shown in Figure 29.

Commonly used vibration dampers include the control of bending modes in the transmission shaft by attaching the damper to the transmission shaft and the control of flexural bending modes of the axis by locating the damper in the axis as shown in Figure 30.

Another typical application of mass damper is the chassis absorber as shown in Figure 31. As attachment points for absorbers, areas are suitable where the strongest vibrations occur. Installed components such as batteries or pumps can also be used as absorber masses wherever possible.

Absorbers for rotational excitations are used in the drive line and on the end of the crankshaft and are known as torsional vibration dampers as shown in Figure 32. They considerably reduce the torsional resonance of the crankshaft, thus ensuring a long life.

Figure 33 shows variants of crankshaft torsional vibration dampers for passenger vehicle engines. Applications cover bonded and nonbonded solutions. In nonbonded versions, a pre-vulcanized rubber ring is inserted with a lubricant into

Gas Exchange—Breathing and Air Management

Francisco Payri, José M. Desantes, José M. Luján, José Galindo, and José R. Serrano

Universitat Politècnica de València, Valencia, Spain

1 INTRODUCTION

1.1 Objectives of the process

The objective of the gas exchange process is to expel the burnt gases from the engine cylinders and to replace them with fresh charge from the intake, thus permitting the subsequent cycle. These processes are called *exhaust* and *intake processes*.

From a wider point of view, the air management or handling includes not only the exhaust and intake processes but also all the processes taking place in the exhaust and intake lines. This involves the supercharging or turbocharging systems (see Turbocharging, Supercharging and Intake Boosting); the exhaust gas recirculation (EGR) and the exhaust gas energy management systems (see Exhaust Gas Energy Recovery). Moreover, the effects of aftertreatment (see Gas Aftertreatment Systems) and silencing systems (see NVH Considerations in Engine Development) in the exhaust, as well as those of charge air cooler and filter in the intake, have to be considered.

The gas exchange process is one of the key processes in the engine cycle for several reasons. First, the amount of fresh charge introduced into the cylinders limits the maximum amount of fuel that can be burnt and thus the mechanical power (see Operating Principles). Second, this process has an energy cost, the so-called pumping work (see Operating Principles), mainly because of pressure losses in the intake and exhaust paths. Third, the quality of the combustion chamber scavenging will influence the residual gas content and, in turn, the combustion process and emissions of the subsequent cycle. Finally, because of the sequential nature of intake and exhaust processes, pressure pulsations are generated at engine valves and travel through the intake and exhaust lines to the atmosphere, resulting in noise emissions (see NVH Considerations in Engine Development).

1.2 Four- and two-stroke engines

The main difference in the gas exchange process between four-stroke (4S) and two-stroke (2S) engines is that in the former the exhaust and intake processes are carried out in one complete engine revolution, whereas in the latter, they take only a fraction of an engine revolution. This makes the gas exchange process more complicated in 2S engines

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

than in 4S engines. First, the process has to be carried out over a smaller cycle period. Second, the exhaust and intake processes are simultaneous and it is difficult to control the charge composition.

1.3 Spark- and compression-ignited engines

The main difference between spark- and compression-ignited engines, as far as gas exchange is concerned, is the load control. In spark-ignited engines, as they may operate in a narrow range of equivalence ratio, the load is controlled by the amount of fresh charge (see Petrol Engines). Compression-ignited engines, however, may run within a wide range of equivalence ratios; therefore, the engine load is controlled by the amount of fuel regardless of the air quantity (see Automotive Diesel Engine Development Trends).

2 QUANTITATIVE PARAMETERS

Figure 1 shows the fresh charge balance during an engine cycle. The intake flow is split into two parts, the one that will be trapped in the cylinders and the other that will flow directly to the exhaust system (short-circuit). In addition, a fraction of the burnt gases from the previous cycle will remain within the cylinders as residuals for the subsequent cycle. Some parameters are commonly used to quantify the different effects.

Volumetric efficiency is calculated as the ratio of the intake mass flow to a reference flow needed to fill the swept volume at a given reference condition density, as Equation 1 shows.

$$\eta_v = \frac{m_{\text{delivered}}}{m_{\text{reference}}} = \frac{\dot{m}_a}{n i V_D \rho_a} \tag{1}$$

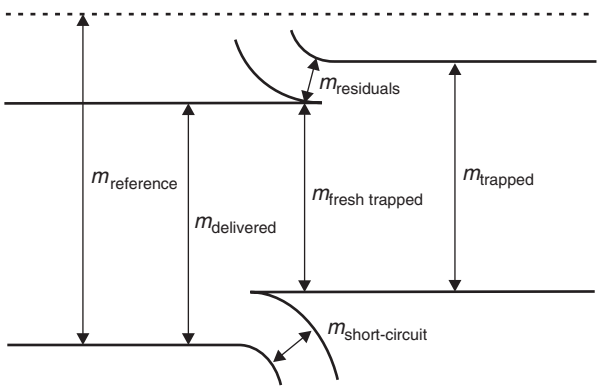

Figure 1. Charge balance during an engine cycle.

where $\dot{m}_a$ is the air mass flow, n is the engine speed, i is the number of cycles per revolution and takes the value of 1 in 2S engines and 0.5 in 4S engines, V_D is the total displaced volume, and ρ_a is the air density at a given reference conditions. This reference is the ambient in naturally aspirated engines and the boosting outlet conditions in supercharged engines (see Intake Boosting). The volumetric efficiency is commonly used in 4S engines to quantify the filling of the cylinders, because the amount of short-circuited mass is small in these engines. In 2S engines, the volumetric efficiency is usually called *delivery ratio*. Scavenging efficiency is the ratio between the fresh mass trapped in the cylinders and the total mass trapped, including residuals. Scavenging efficiency quantifies the proportion of residuals in the trapped mass.

$$\eta_s = \frac{m_{\text{fresh trapped}}}{m_{\text{trapped}}} = \frac{m_{\text{trapped}} - m_{\text{residuals}}}{m_{\text{trapped}}} = 1 - \frac{m_{\text{residuals}}}{m_{\text{trapped}}} \tag{2}$$

Trapping efficiency is the ratio between the fresh trapped mass and the delivered mass. Trapping efficiency quantifies the proportion of short-circuited mass in the delivered mass.

$$\eta_T = \frac{m_{\text{fresh trapped}}}{m_{\text{delivered}}} = \frac{m_{\text{delivered}} - m_{\text{short-circuit}}}{m_{\text{delivered}}} = 1 - \frac{m_{\text{short-circuit}}}{m_{\text{delivered}}} \tag{3}$$

3 FLOW THROUGH ORIFICES, PORTS, OR POPPET VALVES

The gas flow through singularities such as orifices, ports, or poppet valves, and the discharge to a cylinder or duct is a complex three-dimensional problem. Characterization of the permeability of these elements can be done using computational fluid dynamics tools described in Multidimensional Simulation or experimentally using a steady flow test rig schematically shown in Figure 2. A discharge coefficient is defined as the ratio between the actual (measured) mass flow rate ($\dot{m}$) and a reference mass flow rate ($\dot{m}_s$), as Equation 4 shows. Obviously, the choice of the reference mass flow rate will have a strong link to the value of C_D.

$$C_D = \frac{\dot{m}}{\dot{m}_s} \tag{4}$$

The reference mass flow rate, calculated for an isentropic compressible flow, will be obtained from Equation 5, using

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

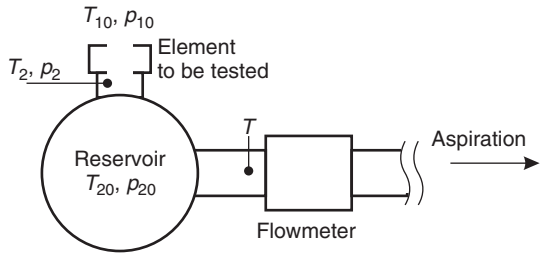

Figure 2. Schematic drawing of a steady flow test rig.

the nomenclature of Figure 2 where h is specific enthalpy; γ is the adiabatic index; R is the perfect gas constant; p is the pressure; T is the temperature; A_r is a reference or geometric flow area; and A_r is a reference flow area.

$$\begin{aligned}\dot{m}_s &= \rho A_r \sqrt{2(h_{10} - h_2)} \\ &= A_r \frac{\gamma p_{10}}{\sqrt{\gamma R T_{10}}} \left[\frac{p_2}{p_{10}}\right]^{1/\gamma} \\ &\times \sqrt{\frac{2}{\gamma - 1}\left[1 - \left(\frac{p_2}{p_{10}}\right)^{(\gamma-1)/\gamma}\right]}\end{aligned} \tag{5}$$

The flow through the singularity for real engine conditions is adiabatic and unsteady, but steady flow test rigs under cold flow operation are considered, in spite of their simplicity, quite representative of the actual discharge coefficient at a given valve lift (Desantes, Benajes, and Urchueguía, 1995). Two reasons could be argued for this: the heat exchanged between the gas and the boundaries during the flow through the singularity is small compared with the total available energy of the flow (Ward-Smith, 1980); and flow velocity is usually much larger than valve (or piston) velocity so that quasi-steady conditions can be assumed (Benson, 1982).

When the flow is choked, that is, Equation 6, the flow velocity equals the local speed of sound and the mass flow rate becomes dependent only on upstream conditions, as shown in Equation 7. Under these conditions, Mach number equals one close to the narrowest cross section of the element under study.

$$\frac{p_2}{p_{10}} \leq \left[\frac{2}{\gamma + 1}\right]^{\frac{\gamma}{\gamma-1}} \tag{6}$$

$$\dot{m}_s = A_r \frac{\gamma p_{10}}{\sqrt{\gamma R T_{10}}} \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma+1}{2(\gamma-1)}} \tag{7}$$

The reference area, A_r, is easy to identify as the open area when considering a port, where it is also usually easy to calculate. However, when referring to the open area of a poppet valve, the choice is not as straightforward and, in fact, depending on the valve lift L_v (Figure 3), the minimum area exposed to the flow will change from the valve–seat interface to the port section.

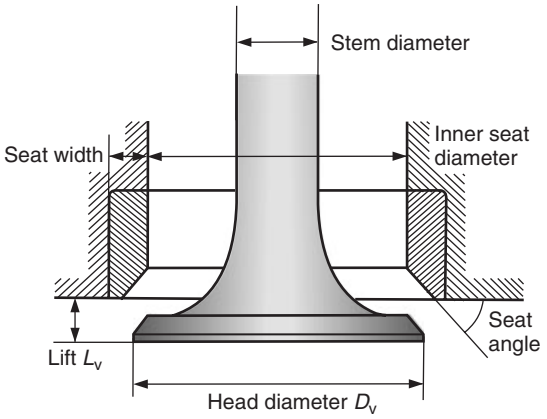

Figure 3. Parameters defining poppet valve geometry.

Two simple reference areas commonly used are the so-called *curtain area* = $\pi L_v D_v$ and *seat area* = $\pi D_v^2/4$. Figure 4 shows the experimental discharge coefficient versus the ratio L_v/D_v when using the two reference areas defined earlier. The discharge coefficient referred to the curtain area increases initially at low valve lifts and decreases for values of normalized valve lifts greater than 0.1. This nonlinear trend is due to the definition of the reference area, which increases linearly with L_v, and to the flow patterns through the valve–seat passage (Annand and Roe, 1974). For low valve lifts, the flow is attached to the walls, whereas beyond normalized valve lifts of 0.1, the flow pattern changes to a free discharge with detached flow. The discharge coefficient referred to the port area explains why actual engines are designed with maximum L_v/D_v

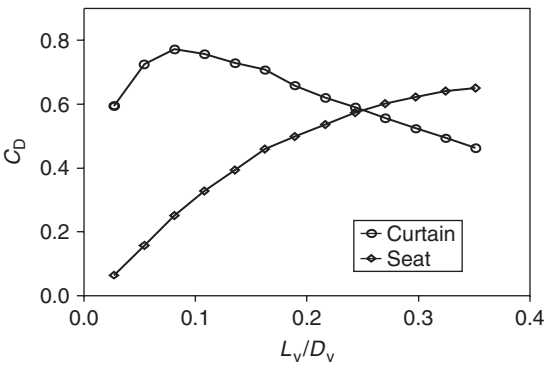

Figure 4. Discharge coefficient versus normalized valve lift.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ratios in the range 0.25–0.3. Increasing valve lift beyond this value has little influence on the discharge capacity of the valve, whereas mechanical loads on the valve train system do increase.

Inlet and exhaust valves and ports are usually the smallest cross sections in the intake/exhaust system, especially when they are not completely open. Consequently, highest flow velocities and flow compressibility effects are most noticeable at these elements, increasingly so as engine rotational speed increases.

The nondimensional parameter used to quantify the importance of the compressibility effects is the Mach number, that is, the ratio between flow velocity and the local speed of sound. During the intake (or exhaust) stroke, flow velocity in the port or valve is continuously changing because of variable thermodynamic conditions up- and downstream and a variable opening section, as Equation 5 reflects. Wave action models (Benson, Horlock, and Winterbone, 1986) are able to link the thermodynamic port conditions to the in-cylinder conditions with crank-angle resolution during the entire engine cycle making use of the discharge coefficient defined in Equation 4.

Intake flow, neglecting dynamic effects in the manifold, is controlled by the pressure difference across the intake valve generated by the piston velocity during its descending stroke (Benson, 1982). To simplify the problem and to have an overall estimator, different cycle-averaged Mach numbers have been defined. Taylor (1985) proposed the following index for the intake process

$$M_T = \frac{A_p \cdot S}{\overline{C}_D \cdot A_r \cdot a} \tag{8}$$

where A_p being the piston area, S the averaged piston speed, a the local speed of sound, and $\overline{C}_D \cdot A_r$ the average effective flow area of the intake valve during the intake stroke.

Figure 5a shows the volumetric efficiency of different engines versus the Taylor's Mach index. All the curves collapse on a single curve, which means that M_T is a good universal estimator. Figure 5 shows that for $0.3 < M_T < 0.6$ the volumetric efficiency is kept almost constant, suggesting a small effect of compressibility, whereas for values higher than 0.6, a clear deterioration of the volumetric efficiency is observed.

Fukutani and Watanabe (1982) proposed an alternative inlet Mach index, given by Equation 9, corrected with the volumetric efficiency (η_v) and the intake opening duration in crank angle degrees (IVC–IVO), where IVC and IVO are the inlet valve closing and inlet valve-opening crank angles, respectively

$$M_{FW} = M_T \frac{180}{IVC - IVO} \eta_v \tag{9}$$

The plot of the volumetric efficiency versus this corrected index appears in Figure 5b. A sudden reduction of volumetric efficiency is observed for values of $M_{FW} > 0.4$. The reduction of volumetric efficiency with increasing intake Mach index is due to the appearance of choked conditions in the valve seat passage during the intake stroke. Both indexes defined earlier are sensitive to this effect but probably the second index is able to establish a more precise limit for design purposes.

The three ways to keep a high volumetric efficiency at high engine speed are refining the design of the intake pipe-valve-seat arrangement, which in turns means a higher discharge coefficient; properly selecting the IVC and IVO; and, of course, increasing the reference area, usually by increasing the number of intake valves.

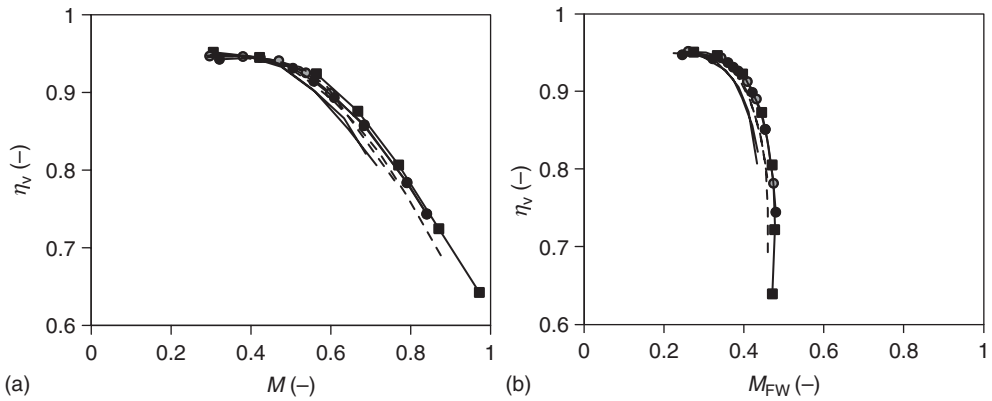

Figure 5. Volumetric efficiency versus intake Mach number for several engines: (a) Taylor definition and (b) Fukutani–Watanabe definition.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162

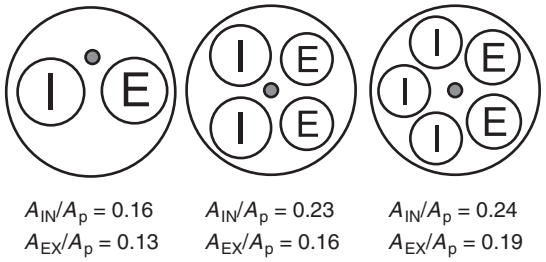

Figure 6. Schematic drawing of different cylinder head arrangements.

Exhaust flow, neglecting dynamic effects in the exhaust manifold, usually has two different periods (Figure 15). During the blowdown period, extending from exhaust valve opening (EVO) to bottom dead center (BDC) approximately, the flow is choked and controlled by the thermodynamic conditions in the cylinder. Around BDC, in-cylinder pressure has dropped to values similar to the exhaust back pressure, and from BDC to exhaust valve closing (EVC) near top dead center (TDC), exhaust flow through the valve is controlled by the piston movement during its ascending stroke, usually with Mach numbers lower than one (subsonic flow) during all this period.

Figure 6 shows schematic drawings of two-, four-, and five-valve cylinder head arrangements with values for the available reference intake (A_{IN}) and exhaust (A_{EX}) areas normalized to the piston area. Four-valve cylinder heads allow an increase of more than 40% in the available intake area and more than 20% in the exhaust area, whereas five-valve arrangements have little influence on the intake area but allow almost 20% more exhaust area.

Figure 7 shows the influence of the available intake and exhaust areas on volumetric efficiency and pumping losses versus engine speed. Figure 7 shows three curves in each chart, the first curve is for a reference effective flow area of an engine with one intake valve and one exhaust valve; the second curve corresponds also to an engine with two valves in the cylinder head but with an effective flow area 20% higher in each valve; and the third curve is for an engine with four valves in the cylinder head that corresponds to an effective flow area about 40% higher than the first configuration. From Figure 7, it is apparent that the intake flow area, and accordingly the intake system arrangement, has a large influence on the volumetric efficiency but less influence on the pumping losses of the engine. The exhaust process and the flow area through the exhaust valve on the other hand are quite irrelevant from the point of view of the volumetric efficiency of the engine, with only minor influence at very high engine speed due to the increase in residual gases. However, exhaust flow area is key in evaluating the pumping losses as explained in Section 8.

4 VALVE TIMING

The cam profile design directly affects the air management process and therefore the volumetric efficiency of the engine. The ideal valve operation would be the one

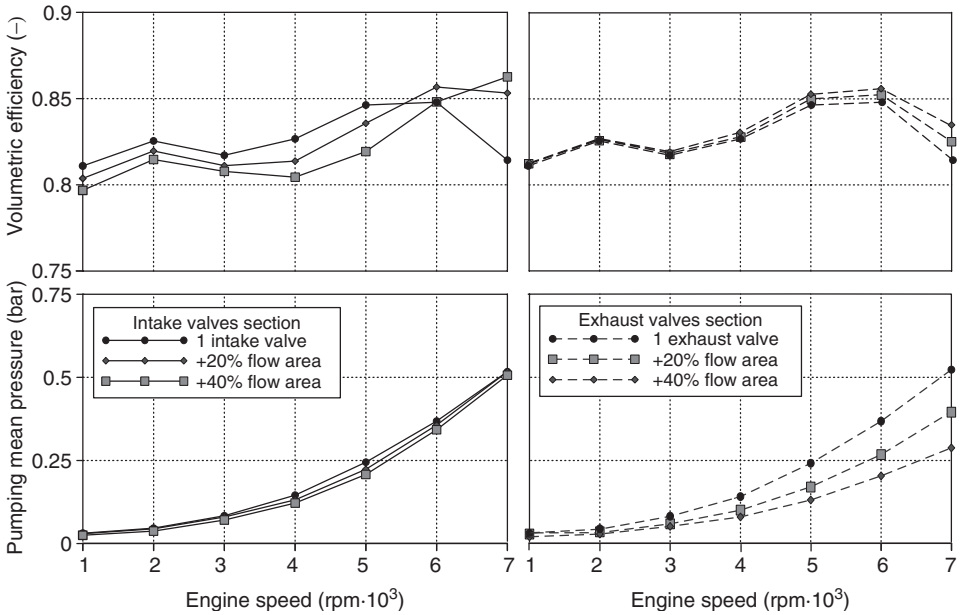

Figure 7. Influence of the intake and exhaust valve effective flow area on volumetric efficiency and pumping losses.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162

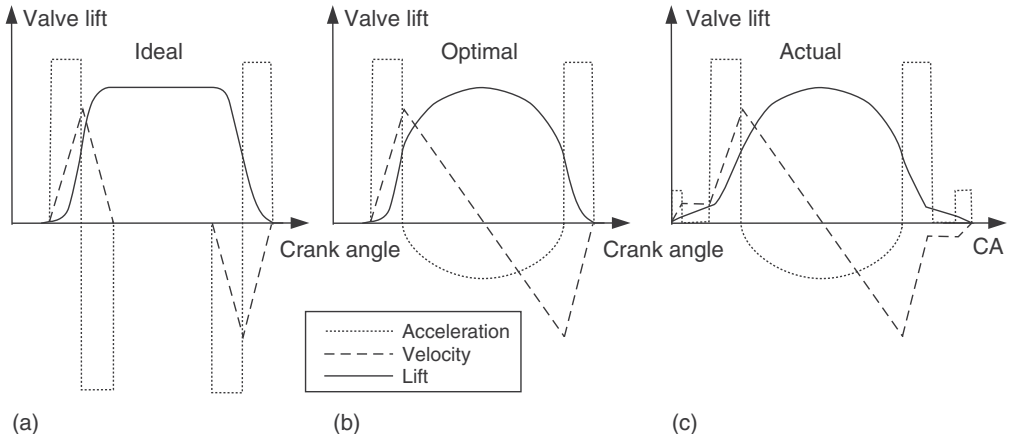

Figure 8. (a–c) Lift, velocity and acceleration of various cam profiles.

that allows maximum area for the gas flow and achieves instantaneous opening and closing with the desired timing. However, owing to stress limitations and dynamics, actual valves driven by a camshaft cannot open or close instantly but must follow a certain law. Figure 8a shows the ideal cam profile along with the optimal one (Figure 8b) that considers only valve or tappet clearance effects and the actual one (Figure 8c), which considers limitations because of both valve clearance and cam take off from the tappet.

In addition to the design of the cam profiles, it is necessary to determine the timing that achieves the optimal valve-lift law. Figure 9 represents a conventional valve-lift law.

The main objective of the valve-opening and valve-closing laws is to achieve optimal gas exchange with the minimum work (pumping losses). The selection of the values for the opening and closing angles must meet the following criteria:

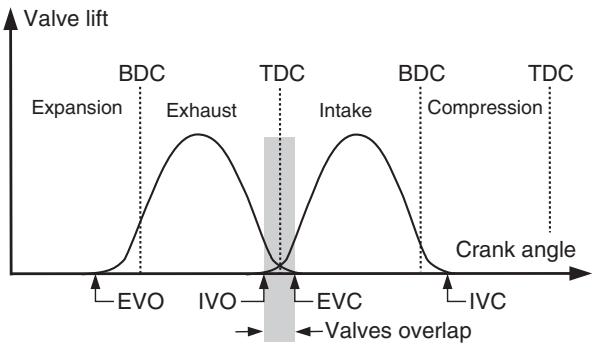

Figure 9. Exhaust and intake valve lift during a four-stroke engine cycle.

EVO: Allows the combustion gases to come out of the cylinder. A trade-off between reduction of pumping losses and reduction of piston work must be achieved as will be further discussed in Section 8. In turbocharged engines, the work produced by the turbine must also be taken into account. Typical values are between 30° and 70° before BDC.

EVC: Allows the completion of the combustion gas scavenging around TDC taking advantage of exhaust gas flow momentum. Typical values are around 2° and 15° after TDC.

IVO: Allows the entrance of fresh charge, driven by exhaust gas ejection during valve overlap period, which helps to sweep the remaining combustion gases out of the chamber around TDC. Typical values are between 2° and 15° before TDC.

IVC: Gives an extra time to fully fill the cylinder, taking advantage of the intake flow momentum achieved during the intake stroke. The optimum closing angle is when inlet flow velocity reaches zero and begins to invert its flow direction; typically between 20° and 40° after BDC.

4.1 Variable valve timing (VVT) systems

In order to determine the different parameters related to the valve motion laws, various specific aspects of reciprocating engines must be considered. Such aspects will not only be related to performance but also to other aspects such as reliability and durability of the different engine parts, as well as noise.

However, selecting the optimum parameters for valve motion laws in certain operating points does not ensure that those parameters will also be optimum for other operating

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

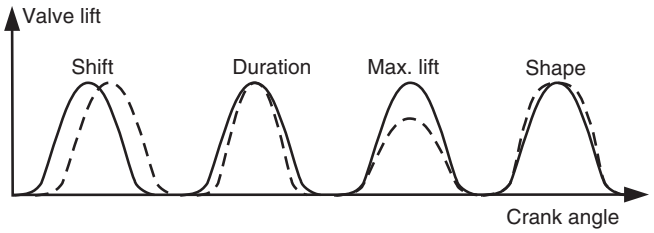

Figure 10. Valve-lift law, possible variations in a VVT system.

points. That is why VVT systems have been developed, which allow finding the optimum solution for different operating points, therefore providing a wider range of optimum engine operation.

Different configurations of VVT can be found. The valve-lift law parameters that can be adjusted with these VVT systems are valve-lift phasing at constant profile; valve-lift duration at constant maximum lift; valve-lift maximum lift at constant duration and phasing and valve-lift profile at constant duration, phasing, and maximum lift. Figure 10 shows the scheme of the described possibilities. There are also some VVT systems that may combine some of these parameters.

The valve-opening laws may be modified in a continuous way (infinite possible configurations of valve-lift laws ranging between two extreme values) or in a discrete way (allowing for two or three possible configurations) for further information, see Valvetrain development and Engine Management Systems. Figure 11 shows a comparison between a conventional camshaft and a real valve-lift law configuration for several operating conditions of an SI engine with 3.6 L of displacement volume equipped with a VVT system.

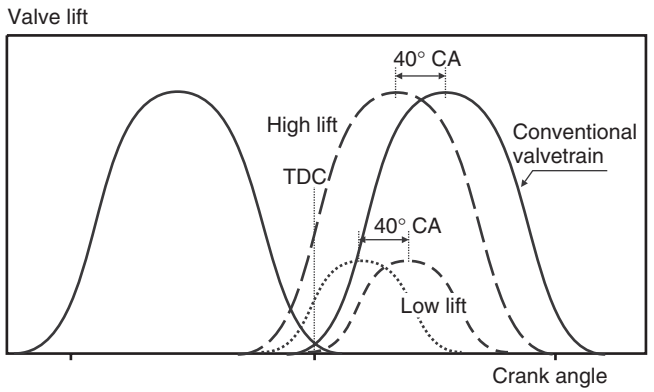

Figure 11. Valve-lift laws in a 3 l. SI engine for a sport car.

5 FLOW IN MANIFOLDS

Intake and exhaust processes are essentially unsteady because of their sequential nature. This produces unsteady pressure conditions at the valves that are transmitted throughout the entire intake and exhaust lines. Flow in manifolds can be usually considered as one dimensional (Winterbone and Pearson, 2000), and if heat transfer and friction are negligible, the flow equations become hyperbolic (Benson, 1982). The solution for these kinds of equations can be depicted as pressure and velocity perturbations that travel forward (p^+, u^+) and backward (p^-, u^-) interacting with discontinuities. Pressure p and velocity u perturbations can be related by means of Equation 10 introduced by Earnshaw (1860)

$$u = \frac{2a_0}{\gamma - 1}\left[\left(\frac{p}{p_0}\right)^{\frac{\gamma-1}{2\gamma}} - 1\right] \tag{10}$$

where a_0 and p_0 stand for the speed of sound and pressure at unperturbed flow conditions, respectively. As it can be extracted from the equation, overpressure waves can be associated to gas movement in the same direction of the wave, whereas rarefaction waves move in the opposite direction. In the first case, there is a "blowing" effect and in the second a "suction" effect in the direction of the wave.

Forward and backward waves travel within the ducts at $a+u$ and $a-u$ velocities, respectively. In a nonhomentropic flow, the shape of the waves is modified because of nonlinear effects, heat transfer, friction, or area changes (Benson, 1982). Pressure and associated velocity waves are also modified when they go through a discontinuity, such as open or closed ends, sudden area changes, branches, and temperature or composition discontinuities.

In closed ends, the zero flow velocity condition leads to a reflected component with the same amplitude as the incident wave. In open ends, pressure remains constant implying that pressure waves are reflected with the same amplitude; but overpressure waves are reflected as rarefaction waves and vice versa. The behavior at a sudden area change is shown in Figure 12. In a sudden expansion, an overpressure wave is reflected as a rarefaction wave with smaller amplitude and transmitted as a smaller amplitude overpressure wave. The sudden contraction behaves as a partially closed end. In both cases, the reflected and transmitted amplitudes depend on the area change ratio.

A pipe junction also behaves as a sudden expansion. When a pressure wave arrives from one of the pipes, it is reflected as a function of the ratio between the pipe area and the addition of the areas of the rest of the pipes (Winterbone and Pearson, 2000).

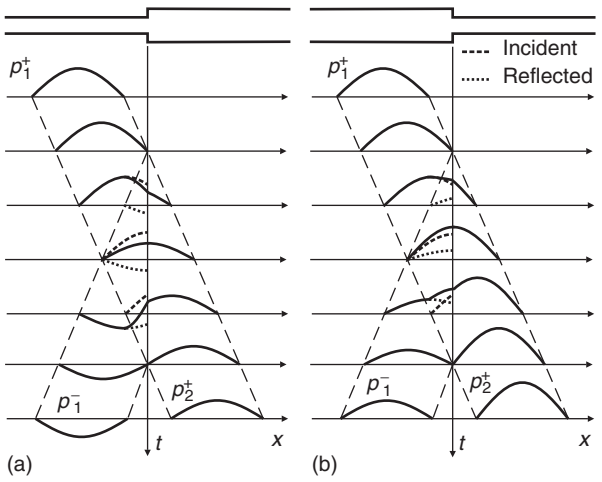

Figure 12. (a,b) Reflection and transmission of pressure waves through sudden area changes.

Flow in manifolds has been modeled by solving the flow equations for one-dimensional nonviscous flow. The first solution technique was based on the Method of Characteristics (MoC) in which the partial derivative equations are converted into total derivative equations over the so-called characteristic lines (Benson, 1982). This method has a graphical solution used before the arrival of digital computers. Later on, the MoC was adapted to numerical solution techniques that can be used in concurrence with the volume or the finite difference techniques (Blair, 1996). Solution schemes are classified according to the solution accuracy as first-order (MoC, Lax-Friedrich, one-step Lax-Wendroff), second-order (two-step Lax-Wendroff, McCormack), and higher order schemes (total variation diminishing, TVD; flux-corrected transport, FCT; and conservation element and solution element, CESE) (Payri *et al*., 2004).

Pressure waves produced during the intake and exhaust processes are a source of noise at the intake and exhaust mouths (see NVH Considerations in Engine Development). However, some advantages can be obtained using them to improve the engine filling or reduce the pumping work, both in the intake side and in the exhaust side (Winterbone and Pearson, 2000).

5.1 Dynamic effects at the intake

The aspiration of the cylinders during the intake process generates a pressure decrease at the proximity of the intake valves that travels as a rarefaction wave through the intake runners. The shape of the rarefaction wave is nearly sinusoidal. The rarefaction wave can be reflected at different discontinuities through the intake line. When the wave encounters a sudden expansion, a pipe junction, or a plenum, it is partially reflected as an overpressure wave coming back to the cylinders. This usually happens at the manifold, heat exchangers, air filters, compressors, and open ends. The reflected overpressure wave increases the pressure at the intake valve leading to an increase of the intake flow. This phenomenon is represented in Figure 13.

It is clear that the reflected wave must arrive before the intake valve closes. It has been proved that the maximum benefit is obtained if the wave arrives at the middle of the intake process. The time delay is a function of the length from the valve to the discontinuity and the speed of sound. The crank angle delay (θ) depends also on the engine speed. Therefore, for a given length and temperature, the best tuning is only achieved at a certain engine speed. This effect can be accounted for with the Strouhal number (Str), defined in Equation 11, as the ratio of the natural frequency of the system to the frequency of the pressure pulsations produced by the cylinder. For a closed/open end, the natural frequency is the speed of sound a divided by four times the system length L, and for a 4S engine, the frequency of the pulses is half of the engine speed n. Attending to Equation 11, this can be rearranged as a ratio between 360 crank angle degrees and the shift between generated and reflected pulse (θ), defined as shown in Figures 13 and 14 (Benajes *et al*., 1997)

$$\mathrm{Str} = \frac{f_{\mathrm{intake}}}{f_{\mathrm{engine}}} = \frac{\frac{a}{4L}}{\frac{n}{2}} = \frac{a}{2nL} = \frac{360}{\theta} \qquad (11)$$

Finally, the amplitude of the rarefaction wave is related to the ratio between the displacement volume and the volume available in the intake system.

The improvement of volumetric efficiency by means of the use of dynamic effects in the intake side can be considerable (Benajes *et al*., 1997). For this reason,

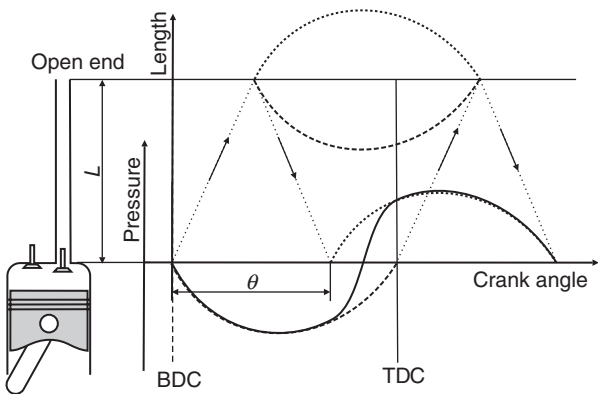

Figure 13. Scheme of pulse reflection at the intake valve.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

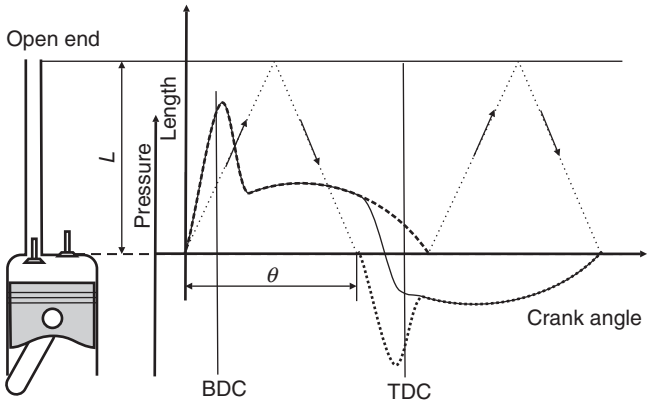

Figure 14. Scheme of pulse reflection at the exhaust valve.

this technique has been frequently used, especially in naturally aspirated engines. An issue to be considered for multicylinder engines is that the pressure waves produced at a cylinder can disturb the intake process of other cylinders. In order to reduce this negative effect, beyond a given number of cylinders (five in the case of 4S engines), the intake runners are separated into different manifolds (Winterbone and Pearson, 2000).

5.2 Dynamic effects at the exhaust

Dynamic effects at the exhaust side are similar to those explained earlier. However, some differences can be pointed out. First, the exhaust pulsations are overpressure waves generated because of the discharge of the cylinders and their shape has two separate peaks. In addition, the amplitude of the exhaust pulsation is larger than the amplitude of the intake one. This is depicted in Figure 14.

The overpressure wave travels through the exhaust ducts and can be reflected at discontinuities. When the wave encounters an increase of the duct cross section, it is partially reflected as a rarefaction wave that travels back to the cylinders and reduces the pressure at the exhaust valve. This reduces the pumping work and can also improve cylinder filling and scavenging if the reflected wave arrives during the valve overlap in a 4S engine or during the scavenging phase in a 2S engine (Blair, 1996). The reflection of the exhaust pulse can be produced at the exhaust manifold junctions, tapered pipes, catalysts, mufflers, or open ends.

Other elements such as convergent tapered pipes or turbines can reflect the exhaust wave as an overpressure wave. This can be used to reintroduce fresh charge that would be otherwise short circuited to the exhaust system. This technique is often used in naturally aspirated 2S engines as a way to improve scavenging and trapping efficiencies (Blair, 1996).

The use of tuning effects for 4S engines in exhaust systems is not as common as in intake systems for one main reason: because of the higher temperature at the exhaust side, the speed of sound is also higher; this leads to the tuned exhaust having greater length for a similar engine speed. In addition, the benefits in terms of volumetric efficiency are reduced compared to those obtained by intake tuning. Finally, turbocharged engines are not usually tuned as it is preferred to place the turbine as close as possible to the cylinders in order to reduce thermal losses.

The interferences between the different exhaust processes of a multicylinder engine are an issue as well. Furthermore, as the exhaust effective duration is longer than the intake duration, the problem is even larger. A way to reduce interference between cylinder exhausts in four-cylinder 4S engines is by means of separated manifolds (Galindo *et al*., 2004). Another way is the use of a proper design of the pipe junctions at the exhaust manifolds. The so-called pulse converters are designed to produce an ejector effect that reduces this negative effect. Two-scroll turbocharger turbines have a similar effect on reducing interferences (Watson and Janota, 1982).

5.3 Variable geometry manifolds

Dynamic effects can be exploited only at given engine speeds in which the reflected waves arrive at the cylinder valve at the appropriate moment. In some cases, two reflections at different discontinuities can be utilized at two engine speeds. A solution to overcome this limitation is to change the length that the pressure waves have to travel between the valve and the discontinuity. In these variable geometry manifolds, the length of the runners is modified to tune the reflected wave to the engine speed (Winterbone and Pearson, 2000).

6 RESIDUAL GASES AND EXHAUST GAS RECIRCULATION

6.1 Definition of residual gas and its effects on engine operation

Usually, the gas exchange process in reciprocating engines does not achieve complete removal of combustion gases in every cycle. It is therefore usual that at IVC a fraction of the total charge is still present in the cylinder coming from earlier combustion processes. This is known as *residual gas fraction*.

The residual gases will have a number of effects on engine operation. On the one hand, regarding engine performance, residual gases will reduce the work output per cycle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

This is the result of the residual gases taking up a certain volume in the cylinder, which is no longer available to the fresh charge, and thus reducing the oxygen available for combustion. This effect is worsened by the high specific volume of the hot residual gases. In homogeneous-charge, spark ignition (SI) engines, the residual charge directly limits the amount of fuel available for each cycle, because it limits the maximum amount of air–fuel mixture that can be drawn into the combustion chamber. In compression ignition engines, residual gases take up volume that will not be available to the fresh charge (which, in this case, is composed solely of air) and thus reduce the amount of oxygen available for achieving a convenient fuel oxidation. Moreover, the residual gases slow down combustion in a twofold way:

1. By reducing the probability of oxygen reacting with fuel due to the presence of an inert gas in the combustion chamber.
2. By reducing local combustion temperatures due to the higher specific heat of the residual charge with respect to that of the fresh charge.

On the other hand, residual gases will have an impact on pollutant emissions as residual gases modify combustion parameters. The most obvious effect (mainly on diesel engines) is the reduction of nitrogen oxides (NO*x*) generation because of the already discussed reduction of local combustion temperatures (see NO_x Formation and Models). This will limit the chemical reactions that result in NO*x* formation. This aspect became paramount in the last decade of twentieth century (Uchida, Daisho, and Saito, 1993) because of the focus of the different pollution regulations on reducing NO*x* emissions (e.g., Euro III and following regulations).

6.2 Residual gas and EGR: characterization and control

Inert gases can appear in the combustion chamber by two different ways.

6.2.1 Internal generation of residual gases (internal EGR)

Gases in the chamber are the sum of those introduced by the backflow that appears in the intake and exhaust valves, and the gases that are not expelled after combustion (remaining gases in the combustion chamber). The mentioned backflow originates because of the pressure difference between the cylinder and the valves, generally during the valve overlap period. Figure 15 shows the instantaneous mass flow rate through the valves. Negative values represent backflows.

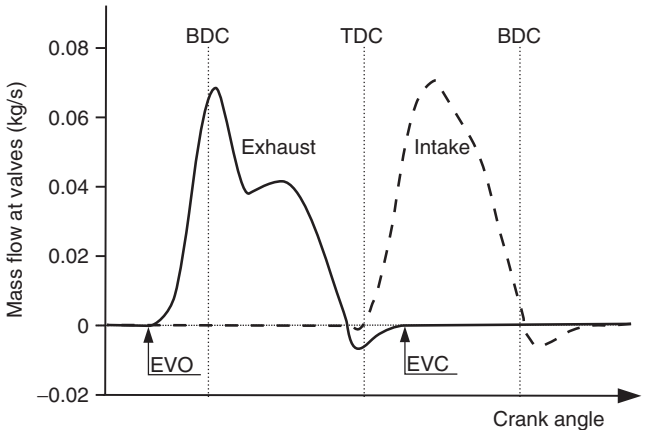

Figure 15. Instantaneous mass flow rate through intake and exhaust valves.

For each engine operating condition, valve-lift laws and geometry of the combustion chamber will determine the amount of residual gases that can be produced. Engines with conventional distribution systems generate a small amount of internal EGR (around 5% of the admitted gases). However, a number of strategies have achieved high EGR rates (higher than 40%) by modifying the values of the IVC and EVO crank angles. These strategies are the so-called intake valve prelift, exhaust valve postlift, and negative valve overlap (Benajes, Reyes, and Luján, 1996).

The internal EGR technique faces two fundamental problems that have hindered widespread application. On the one hand, it is not possible to control the amount of EGR produced, and, on the other hand, it is not possible to cool down the EGR gases, which would be very convenient for improving engine volumetric efficiency and reducing NO*x* emissions.

6.2.2 Recirculation of exhaust gases (external EGR)

This technique is aimed largely at reducing emissions of NO*x* in compression ignition engines (see Automotive Diesel Engine Development Trends). For this purpose, engines must be equipped with piping connecting the exhaust and intake systems. In SI engines, this technique finds little application, because NO*x* can be effectively removed by exhaust gas aftertreatment systems (see Gas Aftertreatment Systems and Stoichiometric Exhaust Emission Control).

Figure 16 shows a scheme for a turbocharged diesel engine with the typical external high pressure exhaust gas recirculation (HP EGR) and low pressure exhaust

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

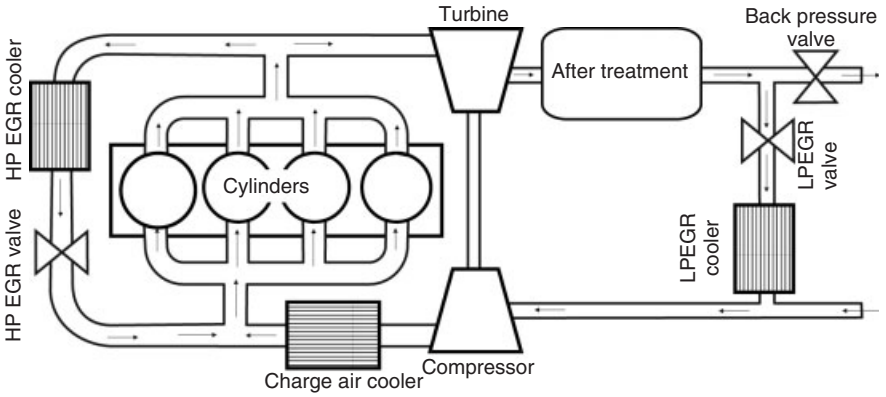

Figure 16. High pressure and low pressure EGR configurations.

gas recirculation (LP EGR) configurations, allowing for external recirculation of combustion gases.

High temperature (300–600°C) recirculated exhaust gases are usually cooled down by means of gas/liquid heat exchangers (HP EGR and LP EGR coolers). The gas temperature reduction has obvious impacts

1. It reduces the temperature of the mixture at the intake, which, in turn, reduces NO*x* generation.
2. It increases the density of the intake gas, thus increasing the amount of admitted gases (air + EGR).

EGR flow can be indirectly calculated by measuring CO_2 concentration at the intake (mixture of air and EGR) and exhaust ducts. EGR rate can be defined as the ratio of EGR mass flow rate to the total mass flow rate. This ratio is defined by Equation 12, where $[CO_2]$ refers to volumetric concentration

$$\mathrm{EGR} = 100\frac{m_{\mathrm{EGR}}}{m_{\mathrm{EGR}} + m_{\mathrm{FRESH\_AIR}}} \approx \frac{[\mathrm{CO_2}]_{\mathrm{INTAKE}} - [\mathrm{CO_2}]_{\mathrm{AMBIENT}}}{[\mathrm{CO_2}]_{\mathrm{EXHAUST}} - [\mathrm{CO_2}]_{\mathrm{AMBIENT}}} \quad (12)$$

Owing to the high cost of CO_2 analyzers, this calculation is still not implemented on mass-produced engines, even though it is commonly used in research facilities, where pollutant analyzers are essential.

The amount of inert gas introduced into the chamber (mainly CO_2 and H_2O) depends on the amount of recirculated gas and its composition. To this regard, the burned gas ratio (BGR) is defined as follows:

$$\mathrm{BGR} = \mathrm{EGR} \cdot \phi \quad (13)$$

where ϕ is the equivalence ratio.

Oxygen concentration in the combustion chamber can be calculated as follows:

$$[\mathrm{O_2}]_{\mathrm{COMBUSTION}} = [\mathrm{O_2}]_{\mathrm{AMBIENT}}[1 - \mathrm{BGR}] \quad (14)$$

The amount of recirculated gas is controlled by means of a valve placed in the EGR duct. The electronic control unit (ECU) regulates this valve based on the operating conditions of the engine (see Engine Management Systems).

Without using CO_2 analyzers (which are cost prohibitive), it is difficult to measure the amount of recirculated gas because of its high temperature and the high amount of particulates in the gas. Control of the EGR mass flow rate is achieved using an estimation of the EGR mass flow rate based on measurement of the mass flow rate of the fresh charge that enters the engine (which is easy to measure with hot wire devices and similar equipment), along with intake gas pressure and temperature measurements. Using Equation 1 and assuming constant volumetric efficiency, fresh charge displacement caused by the EGR can then be used as a means to calculate indirectly the produced EGR. Thus, the EGR amount is controlled in closed loop for each condition by setting the amount of fresh air, determined during engine calibration, and regulating this amount by controlling the EGR valve (see Engine Management Systems).

7 VOLUMETRIC EFFICIENCY CURVES

As a synthesis of the previous sections, it is worth considering the evolution of volumetric efficiency versus the two main engine operating parameters, engine speed and engine load. Figure 17 sketches the evolution of volumetric efficiency versus engine speed for different load levels for both SI and CI engine concepts.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

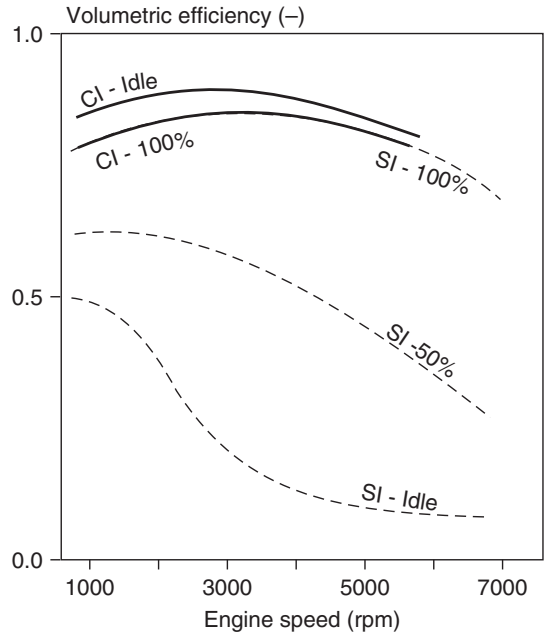

Figure 17. Volumetric efficiency versus engine speed (rpm) and load level (%) for SI and CI engines.

Focusing first on the evolution of volumetric efficiency versus engine speed at full load conditions, Figure 17 shows, with respect to the maximum, a decreasing volumetric efficiency trend when engine speed is reduced. This is true for either engine type, CI or SI. One main reason for the trend is an increase in air charge heating with the reduction of engine speed due to the lower speed and the resulting higher residence time of the air charge in the cylinders, and therefore, the higher the heat transfer from the hot cylinder walls to the intake air charge. Such heat transfer will reduce the average inlet charge density during the intake process and, consequently, the volumetric efficiency. Another equally important reason for this reduction is the increase of backflow from the cylinder to the intake ducts as the engine speed is reduced. The main reason for the backflow is that the engine valve timing is optimized for high engine speeds, that is, in order to use flow inertia and induction ram effects to improve cylinders filling and scavenging processes at rated power. Consequently, the high valve overlap periods and the late IVC, which are optimum for higher engine speeds, generate backflow that is detrimental to volumetric efficiency at reduced engine speeds.

Regarding the evolution of volumetric efficiency at full load conditions, starting from the maximum value and proceeding in the direction of increasing engine speed, Figure 17 shows an even steeper decreasing trend. The causes are twofold. The first is due to the increase of volumetric flow that increases flow friction and pressure losses in every element of the intake line, reducing the intake pressure and density. The second and main cause is due to the compressible fluid effects associated with the high Mach numbers at the intake valves, which choke flow and prevent significant mass flow increases when further increasing engine speed (Taylor, 1985). The previously commented induction ram effects can compensate, at higher engine speeds, the reduction of volumetric efficiency caused by compressible flow effects, in spite of the already mentioned backflows at lower engine speeds.

The balance between the described effects at low engine speed and high engine speed places the optimum volumetric efficiency in the medium engine speed range. Finally, tuning of cylinders, inlet and outlet ducts can generate a peak of volumetric efficiency taking advantage of the pulsating flow effects (Benajes *et al.*, 1997). Geometry of ducts may be designed for a specific range of engine speeds at which the tuning effects are maximized, considering engine service requirements and/or desired operating characteristics.

The described effects on volumetric efficiency affect in a similar way CI and SI engines at full load conditions. However, SI engines with port injection usually show lower peak values of volumetric efficiency because of flow losses from throttling (see Petrol Engines), higher residual gas fraction, intake manifold heating, and the presence of fuel vapor. This SI trend is changing although with the introduction of direct injection (DI) SI engines as full load injection is performed during the intake stroke. Introducing fuel directly inside the cylinders reduces charge temperature because of fuel vaporization and allows more trapped mass and greater volumetric efficiency.

The evolution of volumetric efficiency with engine load shows an opposite trend when comparing CI with SI engines. In the case of CI engines, and owing to the reduction of equivalence ratio with engine load, the temperatures of cylinder head walls are lower at partial loads than at full load. Therefore, the density reduction of air charge during the intake stroke due to heat transfer from the walls is less important at partial loads. Consequently, the volumetric efficiency at partial loads in CI engines is somewhat higher than at full load conditions, as it is indicated in Figure 17. This trend is exactly opposite the trend for SI engines. As SI load regulation is performed by throttling the intake line (see Petrol Engines) as already mentioned, the reduction of mass flow to maintain a constant equivalence ratio is detrimental to the SI engine volumetric efficiency. Figure 17 shows the progressive and important decrease of volumetric efficiency at any engine speed as a function of SI engine load.

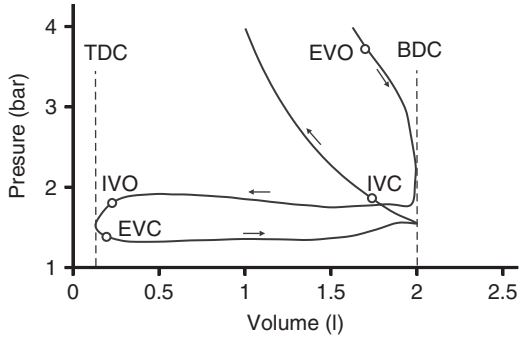

Figure 18. Counterclockwise low pressure loop corresponding to a four-stroke HD diesel engine at 1800 rpm and 25% load conditions.

8 PUMPING FRICTION LOSSES

Conceptually, pumping losses represent the necessary work to pump the combustion gases out of the cylinders during the exhaust stroke and to pull in the fresh charge for the next combustion process during the intake stroke. The pumping work per cycle can be calculated by integrating the low pressure evolution of the indicated $P-V$ diagram between the exhaust BDC and the intake BDC, as shown in Equation 15. A new effective pressure type variable (see Operating Principles) can be defined, the pumping mean effective pressure (pmep).

$$W_{\text{pumping}} = \int_{\text{BDC}_{\text{exhaust}}}^{\text{BDC}_{\text{intake}}} p(a)\mathrm{d}V(a) = \text{pmep} \cdot V_{\text{Displaced}} \tag{15}$$

Figure 18 depicts that the integral of Equation 15 includes an extra area outside of the low pressure counterclockwise loop. As this area is also considered when computing the indicated work, both magnitudes cancel when the difference between indicated and pumping work is considered. This difference is known as *net work* (W_{net}) and it can be calculated as shown in Equation 16, which defines the net mean effective pressure (nmep).

$$W_{\text{net}} = W_{\text{indicated}} - W_{\text{pumping}} = \text{nmep} \cdot V_{\text{Displaced}} \tag{16}$$

Figure 18 shows that any engine component contributing to increase in-cylinder pressure during the exhaust stroke or to decreased pressure during the intake stroke will increase pumping friction losses. Regarding pumping losses, these engine components can be separated into two groups: elements that are inside the cylinder head and those that are outside of it. The most important elements inside the cylinder head are the inlet and exhaust valves and, to a lesser extent, the inlet and exhaust ports. The pressure losses in these elements are called *valve flow work* by Heywood (1998), and they are responsible for the most important contribution to pumping work in diesel engines. The most significant pressure losses take place in the exhaust valve. The reason is that in order to prioritize the cylinder filling process with fresh air charge versus the cylinder exhaust process, the cross section of the exhaust valve is smaller than the corresponding cross section of the intake valve (Figure 6), even though similar volumetric flow rate has to flow through both of them.

Valve timing is the next parameter in importance that affects valve flow work. More specifically, advancing EVO (Figure 9) will help to maximize the balance between pmep and imep, that is, to maximize nmep. Figure 19a shows the effect of advancing EVO with respect to BDC (dashed line). In the case of the advanced EVO, the area reduction in the clockwise high pressure loop (vertical hatchings) is compensated by the spontaneous blowdown of the exhaust gases from the cylinder, thus achieving a reduction in pumping loop area (horizontal hatchings) because of a reduced in-cylinder pressure during the exhaust stroke.

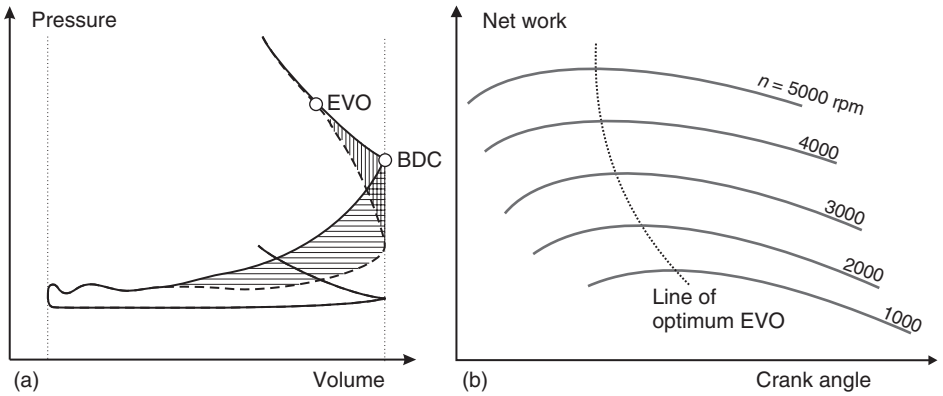

Figure 19. (a) Influence of EVO on network and (b) variation of optimum EVO as a function of engine speed.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The optimum value for EVO advance varies with engine speed, because the optimum advance should increase as the duration of the exhaust process is reduced, or, what is equivalent, as the engine speed increases. Figure 19b shows this advancement with respect to BDC in order to optimize nmep at different engine speeds. The dotted line that fits the maximum of every curve is the EVO that should be provided by a VVT system (see Engine Management Systems). In classical systems with fixed geometry camshafts, the optimum EVO is chosen at an intermediate engine speed.

In SI engines and at partial loads, the pressure losses due to throttling the intake charge overcome the importance of the exhaust valves with regard to their relative contribution to pumping friction losses; this is the case also in DI–SI engines, because the engine load remains controlled by the intake throttle.

Other elements outside the cylinder head whose design influences pumping work, but less than *throttling work* (Heywood, 1998), are the air filter, carburetor, intake manifold (on the inlet side) and the exhaust manifold, exhaust gas aftertreatment (catalytic converter, SCR, see Gas Aftertreatment Systems, and DPF, see Solid/Condensed Phase Aftertreatment Systems), muffler, and tail pipe (on the exhaust side, see NVH Considerations in Engine Development). The influence of exhaust line elements on pumping losses is threefold: the most obvious are pressure losses; following by ram effects that would help scavenging, especially during valve overlap period; and, last but not least, unsteady flow effects, already discussed in Section 5.2. Figure 20 shows an unsteady effect in the low pressure loop for two different θ values (Figure 14). If the rarefaction wave arrives around the middle of the exhaust stroke ($\theta = 90^{\circ}$), it can help to expel exhaust gases from the cylinders and to reduce pmep. However, if the rarefaction wave arrives around the valve overlap ($\theta = 180^{\circ}$), the unsteady effect does not help to reduce pumping losses,

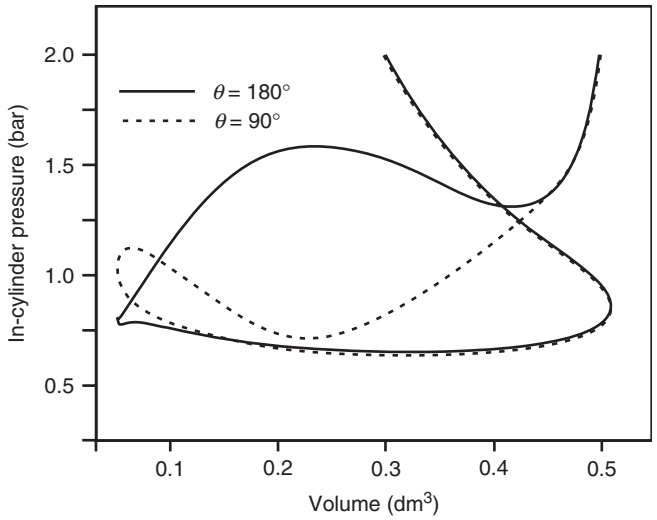

Figure 20. Influence of exhaust ducts tuning on counterclockwise low pressure loop. Results are from a naturally aspirated 2.0 L petrol engine.

although there is an aspiration effect that could increase volumetric efficiency and improve chamber scavenging.

It is also worth discussing separately, due to its relevance, the contribution to pumping losses of another element outside of the cylinder head: the turbocharger (see Intake Boosting and Turbocharging). For certain engine operating conditions, an efficient design (of both the turbocharger and its coupling with the ICE engine) can generate a clockwise low pressure loop that increases nmep over imep; despite the higher exhaust back pressure generated by the turbine (Watson and Janota, 1982). Figure 21a shows this effect in the low pressure loop of a heavy-duty (HD) diesel engine at medium speed (1200 rpm) and full load. It can be compared with typical counterclockwise low pressure loop at 1500 rpm and 50% load shown in Figure 21b for the same engine.

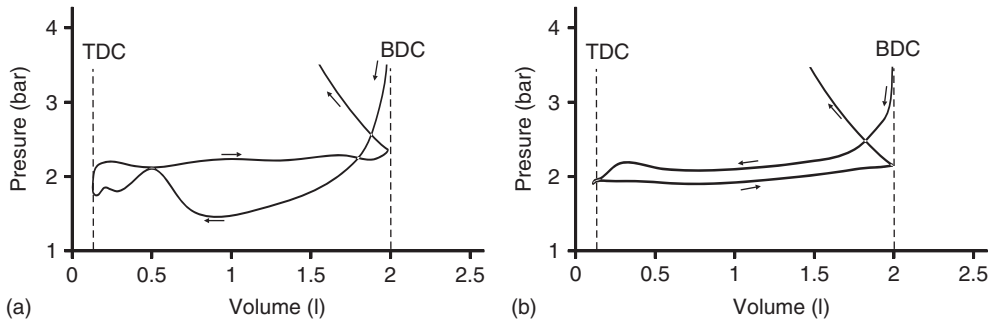

Figure 21. Low pressure loop in the $P-V$ diagrams of a turbocharged HD diesel engine. (a) 1200 rpm, full load and (b) 1500 rpm, 50% load.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto162
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In summary, with respect to how engine speed influences pumping losses, a twofold analysis has been made that covered the influence of engine speed on the optimum values of EVO and its influence on the design of the exhaust line, in order to take advantage of ram and unsteady flow effects. It can be added that generally the higher the engine speed, the higher the volumetric flow, and therefore the flow friction losses. With respect to the influence of engine load, it will be very significant in SI engines and pmep will increase as engine load is reduced because of throttling work. The influence of engine load on pmep for naturally aspirated CI engines is less important and it mainly depends on how the density of exhaust gases change and whether the volumetric flow is increased or not. In supercharged CI engines (see Turbocharging and Supercharging), the variation of mass flow with load will be much more significant than in naturally aspirated CI engines, and so will be the variation of pumping losses (Watson and Janota, 1982).

1 INTRODUCTION

The strong demand for novel materials with new functions generates considerable interest in the automotive community. Metals, ceramics, or polymers as mono materials cannot fulfill all technological needs for a variety of original applications. Researchers in chemistry and physics as well as engineers understand that to obtain materials with superior properties, they have to combine mono materials to hybrids. The definition of "*hybrid material*" given by Kickelbick is "*hybrid material* is used for many different systems across a wide area of different materials such as crystalline highly ordered coordination polymers and amorphous sol–gel compound materials with and without interactions between the inorganic and organic unit." A complete review of *hybrid materials* is given in the book by Kickelbick (2007).

For industrial applications, the development of a special *hybrid material*, the *matrix type*, is one of the most successful examples for a group of composites. A matrix is a system, in which a second type of material—in the form of fibers, particles, whiskers, lamellae, or a mesh—is integrated into a basic material. A typical example is a polymer reinforced by inorganic fibers, which possess improved mechanical properties. At present, these new systems are regularly used as lightweight materials with advanced mechanical properties for automotive or aviation applications.

In this chapter, *hybrid materials* are defined as three-layered metal–polymer–metal sheets, called *sandwich material*. They are laminates with two or more layers of minimum two different materials—called *laminae* (lamina: single ply or layer)—bonded together. With these combinations in a sandwich material, it is possible to "design" the properties of particular components with the right choice of mono materials, thus providing the functionality to fulfill the high demands on modern materials and structures (Harris, 1991). They can combine the advantages of various single materials together (e.g., low density, high bending resistance, energy absorption, and high load capacity with low weight) (Librescu and Hause, 2000; van Tooren, 2004). It should be pointed out that for sandwich materials, there are multiple possibilities of combining materials for core and skin layers.

To determine the mechanical properties of *sandwich materials*, common static, dynamic, and cyclic testing must

be performed as well as to define the conditions of failure, for example, by delamination of the layers.

According to the industrial requirements, various models and simulations of sandwich plates for deep-drawing, bending processes, or the crash behavior of sandwich material components in a vehicle body form the focal point of international research of steel–polymer sandwiches. Oh, Cho, and Kim (2005) numerically computed the delamination process of sandwich plates. Moreover, the spring-back effect was investigated using a numerical model (e.g., Liu and Wang, 2004). The study of damping, vibration, and acoustic properties of sandwich materials, which are fabricated using different polymer cores and steel or aluminum skins, is based on the theory of sandwich plates and a finite element (FEM) analysis (Chen, Hsu, and Chen, 1991; Engel and Buhl, 2011).

Using different modeling types (Roque and Thomson, 2005; Chen, Hsu, and Chen, 1991), the characterization of stress–strain conditions, structural changes, or other important effects can be determined and analyzed for both simple sandwich plates and the behavior of sandwich parts in a whole construction.

Special interest in the research of sandwich materials is given in the characterization of formability. The forming behavior of sandwiches under different loading conditions, especially bending and deep drawing has been studied intensively (Palkowski and Lange, 2007; Carradò *et al.*, 2010; Palkowski and Lange, 2008; Sokolova, Carradò, and Palkowski, 2011a; Carradò *et al.*, 2011a).

To industrially apply polymer-based sandwich materials, for example, as automotive parts, their behavior under thermal and mechanical joining (Section 3) has to be investigated, as these hybrids show both some weakness due to the core's thermal instability during the thermal joining and their elastic and/or plastic deformation by mechanical joining, thereby probably losing their prestressing force under dynamic load. In the case of thermal load, the polymer can be vaporized and cause metal corrosion (Palkowski *et al.*, 2006). A solution for this case can be provided by the use of local plate metal reinforcements (RE—reinforcing element), replacing the sandwich core at the place of future thermal or mechanical joining. Owing to the use of different materials for the REs (solid or mesh steel, see Section 3), their geometry, size, and the position of the inlays relative to the forming, these sandwiches can exhibit significantly different formability and the flow behavior of both the sandwich layers and the internal local inlays varies too (Sokolova, Carradò, and Palkowski, 2010, 2011a).

This chapter gives a short theoretical background to the use of composites in the automotive industry, followed by a study of sandwich materials that are often manufactured using a roll bonding process with a preliminary surface treatment. They consist of a polypropylene copolymer (PP–PE) (PP, polypropylene; PE, polyethylene) core and the covering AISI (American Iron and Steel Institute) SS316L austenitic stainless steel (316L) sheets. The mechanical behavior of 316L/PP–PE/316L sandwich sheets is presented together with their formability with and without metal reinforcements. This chapter concludes with a study of these systems' adhesion using a T-peel and shear test.

2 THEORETICAL BACKGROUND: CLASSIFICATIONS OF COMPOSITE STRUCTURES

Owing to the orientation, shape, and form of the components, composites can be applied in various fields of industry (Campbell, 2010; Jones, 1999; Lange, 1993). Some representatives of industrially applied sandwich materials can be classified as:

- reinforced composites with a thermoset or thermoplastic polymer matrix;
- particulate-filled composites;
- diffusion-bonded composites;
- sandwich composites.

The reinforced composites can have a polymer matrix as thermoset, thermoplastic, or elastomer. The reinforcements are used to modify specific properties, such as mechanical or electromagnetic ones, or to decrease the thermal expansion coefficient of the polymers, for example, embedding of electrical components in epoxy resins using the molding process (Rajput, 2007; Wijskamp, 2005).

Fiber-reinforced composites are lightweight composites consisting of a polymeric matrix (thermosetting resins) augmented with reinforcing fibers, some fillers, and pigments. They are classically applied for consumer products such as chairs, trays, helmets, water cooler bodies, tanks, and paneling (Vermeren *et al.*, 2003).

Some common matrix materials include epoxy or phenolic resins, polyester, polyurethane, and vinyl ester. Among these materials, resin and polyester are the most widely used ones. Epoxy, which has higher adhesion and less shrinkage than polyesters, is ranked second because of its high costs. Glass fibers are generally used as a reinforcing material in the resins and produce a combination of high strength and stiffness in the matrix. The direction of the fibers can be specially oriented or random (Kawai and Hachinohe, 2002). Fillers are commonly added to smooth

the manufacturing process and to yield special properties. The most commonly used ones are carbon/graphite fibers, beryllium carbide, beryllium oxide, aluminum oxide, glass fibers, polyamide, and natural fibers.

Owing to many attractive advantages in comparison to the more widely used thermoset composites, *ultra-lightweight carbon fiber/thermoplastic composites* are of growing interest. As reported by El-Dessouky and Lawrence (2013), their advantages are principally based on the intrinsic properties of thermoplastic polymers (e.g., polyphenylene sulfide) used and the ability to be reshaped and reused or recycled.

A new and major application in their use is presented in the low carbon vehicle technology project (LCVTP) aiming at reducing the in-use CO_2 emissions for future vehicles (LCVTP, 2010). In particular, the LCVTP is a collaboration between leading automotive companies and research partners with the goal to revolutionize the way to design and produce vehicles, including full battery vehicles and hybrid vehicles, in order to significantly reduce carbon emissions, so, in the first step, reduce weight. Actually, in the LCVTP, an innovative seat back structure using rapid-stamp formed thermoplastic composites has been developed.

Reinforced composites with a thermoset or thermoplastic polymer matrix can be manufactured using different process routes such as liquid composite molding (Rudd *et al*., 1998), injection molding (Rosato, Rosato, and Rosato, 2000), or hot and cold press forming (Rajput, 2007).

These technologies can be used for metals and polymers as well as combinations of them. *In the liquid composite molding* process, the reinforcement fibers are already impregnated with a resin (called *prepreg*). *Injection molding* is a widespread process for the processing of thermoplastic materials. The addition of reinforcement materials to the injection molding compound allows increasing the mechanical strength of the final part. *Back injection molding* is used for high strength bond of metal sheets in combination with thermoplastics in series production for many applications. This technology allows to join a metal sheet with high quality surface with the back-side injected polymer, with or without fibers and bonding agents. Moreover, this process opens the way to reproduce symbols and structures to the metal sheet in one shot.

Press forming in this context refers to sheet molding compound and bulk molding compound, respectively; compounds consisting of a thermosetting matrix and long reinforcement fibers delivered as flat or volumetric batches. The compound is placed into a heated mold and then formed to the shape of the final part by closing the mold with sufficient pressure.

Particulate-filled composites are commonly used as high strength, lightweight plates with simple geometries because of the low formability of the polymer or the ceramic matrix (Rothon, 2003). The particles used for reinforcement include ceramics and glasses, small mineral particles or metal particles, such as aluminum, and amorphous materials, including polymers and carbon black. An example of the application of particulate-reinforced composites is the car tire, which has carbon black particles in an elastomeric polymer matrix. These particles are used to enhance the strength and to decrease the ductility of the matrix. Some of the useful properties of ceramics and glasses include high melting temperature, low high strength density, high stiffness, wear resistance, and corrosion resistance. Many ceramics are used because of their proper electrical and thermal insulations or their magnetic and piezoelectric properties. Some can even be used as superconductors. One major drawback of ceramics and glasses is their brittleness.

Diffusion-bonded composites are composites with a strong molecular bonding. They can be manufactured using different interfacial bonding mechanisms: modifying the wetting and adsorption of surface elements, generating diffusion on the surface of internal phases, creating chemical and mechanical adhesions of materials or magnetic diffusive joining of metallic compounds (Shirzadi and Wallach, 1997; Guo and Derby, 1993). These composites show a good combination of the properties required, but the reproducibility and precision of the manufacturing of such systems are not currently assured. Nevertheless, these kinds of composites show great potential for future applications.

Sandwich materials—understood to be *composites*—consist of at least two or more mono-material layers with different physical and mechanical properties. They can be produced with numerous core and skin materials (e.g., steel, aluminum alloy sheets, polymer foils, or fiber-reinforced plastics, with a polymer layer being homogenous or structured). They exhibit a great potential because they are simple to manufacture using lamination, press joining, or roll-bonding processes (Jones, 1999). Such a production process is described by Palkowski and Lange (2007) and Carradò *et al*. (2011a).

These materials can be highly deformed if the laminate combines highly deformable metallic materials or when the combination of materials demonstrates high plasticity. Compared to other types of composites, sandwich materials are often used as lightweight parts in the automotive and marine industries because of their easy production and the homogeneity of the layers. In the examples given, the objects will be thin metal–polymer–metal sandwich sheets.

3 JOINING HYBRID MATERIALS

Spot welding is a commonly used, wide spread process in the automotive industry. Nevertheless, the localized heating of the material may change the mechanical properties of the materials. For hybrid joints, a combination of joining techniques is often advised (Timings, 2008).

Adhesive bonding is mostly used in combination with spot welding. High quality glues offer the possibility to join dissimilar materials at low cost. Furthermore, using adhesive bonding allows avoiding the deformation of the components and the damping of noise and vibrations. At the same time, the adhesive joint can enhance the fatigue resistance because of the reduction of stress concentrations (Barnes and Pashby, 2000; Huck and Bosshard, 2007).

Hybrid joints consisting of spot-joints (welding) with adhesive bonding, which can generally be presented in three different methods: *fixing, injection, and sequential methods*. Using the *fixing method*, the adhesive is applied to the parts being joined; then, a spot-joint is made to complete the process, followed by the hardening of the adhesive layer. In the *injection method*, the parts are joined with a spot-joint before injecting an adhesive into the gap between the components. Capillary action causes the adhesive to spread through the joint. The adhesive layer then hardens. In the *sequential method*, the parts are joined after the adhesive has been applied. Subsequently, when the adhesive has hardened, the parts are spot-joined.

Laser welding (e.g., CO_2, excimer, and Nd : YAG lasers) presents some advantages compared with conventional welding techniques (Mackwood and Crafer, 2005). They can be summarized as a modest distortion of the components, a deep penetration welding, broader spectrum of "weldable materials," and an aptitude to process different kind of materials (Mackwood and Crafer, 2005). Most plastic products still need to be joined up. Formerly, these parts were often glued or screwed together with the drawback to be time consuming. Recently, as presented by Sieben and Brunnecker (2009), laser welding of plastics is used for joining automotive parts and medical equipment as well as consumer products.

Remote laser welding is a suitable process for applications where a good positioning and high track speeds are required. Owing to the high power density at the focal point, the material to be treated heats up until reaching its melting point, thus fusing and welding (Tsoukantas *et al*., 2005; Tsoukantas and Chryssolouris, 2006).

The riveting joint is one of the important joint methods to permanently fasten two thin-walled sheet-metal parts. The riveting technology is also enhanced by the introduction of *self-piercing rivets* (Hill, 1994; Barnes and Pashby, 2000). Self-pierce riveting is a high speed mechanical fastening technique for point joining of sheet materials. It is used strongly in the automotive sector. Even investigations on combining sandwich sheets to metallic mono materials are well known (Pickin, Young, and Tuersley, 2007). The advantages of this process are their ability to join dissimilar materials without thermal damage (Grote and Antonsson, 2009). Owing to the fact that in combination with adhesives, the self-piercing technology can provide leak proof joints of high fatigue strength and a high degree of reliability (Mortimer, 2005); it offers a viable alternative to spot welding in automotive assembly.

Joining by clinching is strongly used in the automotive industry for assembling sheet plate elements (Varis, 2003). The clinching joint is produced by local stamping of joined sheets without piercing and any heat effect on the material structure. For *hybrid systems*, an adhesive often is applied additionally to one of the components being joined. Once linked, the components are immediately clinched causing a releasing of the adhesive out of the joint. Finally, the joint is left to harden.

The *roll-bonding process* is a possibility for the continuous production of sandwich metal–polymer sheet material under defined temperature–pressure–time conditions (Palkowski and Lange, 2007; Sokolova, Carradò, and Palkowski, 2011a; Carradò *et al*., 2011a). More details are given in Section 6. Table 1 provides a brief comparison of the aforesaid joining processes. The imperfection of the sandwich construction cannot grant such joining properties because of the elastic polymer core at the place of joints and probably the earlier failure of sandwich constructions by long-time or dynamic loading. In all cases, a simple method of properly joining sandwich parts can be the use of local plate inserts (RE, reinforcement) in the core (Bozhevolnaya and Lyckegaard, 2005). The method of using such reinforcements is based on placing the inlay instead of the core material before joining the layers to a sandwich sheet. Applying the local RE in a sandwich core also reduces the use of complex adaptors, which can lead to an earlier failure of sandwich constructions. Moreover, adapting the REs to the specific needs (e.g., load) allows to create a graded property change. Figure 1 shows two examples for placing REs in a sandwich sheet.

4 INDUSTRIAL APPLICATION OF LAYERED COMPOSITES

Owing to the large differences in the properties of the partners, the manufacturing process for three-dimensional components by joining and/or forming differs from the shaping of mono materials. A sandwich (Zenkert, 1997) is normally a combination of a lightweight and a material of

higher strength. In general, the lighter material is used as the core layer, covered by stronger, stiffer skins to sustain the properties of the core. The soft core supports the metal sandwich skins under various loading, defines the distance between the cover layers, dissipates the shearing forces, and serves as a high damping material. Lightweight core materials can include polymer foils, balsa wood, polymer foams, and metallic, paper, or polymer honeycombs (Hull and Clyne, 1996). These materials have been used in various combinations with skins of carbon, glass, and/or aramid fiber-reinforced polymers, as well as aluminum, titanium, or steel. Single layers are usually connected by bonding (glue bonding, metal coating, extrusion, or molding), which guarantees high tensile and shear strengths. As a result, it was decided to employ sandwich materials in lightweight application (e.g., a sandwich having a honeycomb core was used for a car body (ultra light steel auto body for chassis components) (Milton and Grove, 1997). In Table 2, a classification for sandwich composites are listed, which are already employed in different fields of industry and are currently globally available.

Used as core materials, the aluminum-skinned honeycombs or PP foils between steel sheets demonstrate a weight reduction of approximately 50% with the same stiffness of a comparable steel sheet. In addition to this, using austenitic high grade steel (Euroinox, 2012) or special deep-drawing

steel (ThyssenKrupp, 2008), an improved corrosion resistance and improved fatigue behavior can be achieved. Compared to other metals, such as aluminum or magnesium alloys, mild up to even high and ultra high grade steels exhibit a high elongation to fracture—and thereby, a high capacity for complex forming—and, at the same time, a high tensile strength (TS). One example for an automotive application of such a sandwich used for high damping and lightweight is the aluminum/PP/aluminum sandwich Kim, Kim, and Choi (2008). Hylite (Corus Group) actually followed by an improved sandwich sheet in the three-layered version steel/polyamide/steel by ThyssenKrupp Steel. The former was designed as a lightweight element and has already been employed as a roof, vehicle floor, and hood (Burchitz *et al*., 2005).

Bondal (ThyssenKrupp AG) sandwiches, composed of steel cover sheets and a polyolefin core in the range of some 10 microns, are used for sound damping of oil pans, valve, and transmission covers as well as garage doors or glass containers.

To improve their stiffness and strength, the use of glass fibers is foreseen because of their large availability and low price. The main handicap is their brittleness; indeed, subsequent to cooling down, the material cannot be deformed. Moreover, delamination or early failure under cyclic loading could be observed (Botelho *et al*., 2006). The capacity for high deformation is exhibited by the sandwich materials possessing a thermoplastic core.

5 METAL–POLYMER ADHESION

Adhesion is the physical condition of an interface layer, formed between two contacting phases by mechanical, physical, or chemical bonding (Ruokolainen and Sigler, 2008). The bondability of materials is the ability of various materials to interact between each other (Bischof *et al*., 1989).

Current research in adhesion is well presented by Possart (2005). The bonding agent or adhesive (e.g., epoxy) can permit the bonding between metal and polymer, when self-adhesion is not possible. The adhesive is commonly a viscous or temperature hardening agent. Figure 2 presents various types of contributions to adhesion in a sandwich plate consisting of "component 1" (e.g., metal skin), "component 2" (e.g., polymer core), and the "adhesive agent." The adhesion can be classified by the bonding mechanisms. Concerning metal/polymer/metal structures, the following types can be distinguished:

- *mechanical adhesion* strongly depends on the surface roughness and surface morphology of the partners;
- *chemical adhesion* is based on chemical reactions between the adhesive agent and adherends (bonded layers);
- *physical adhesion* depends on the physical processes, namely physical interpolar bonds based on the interaction forces (attraction and repulsive forces) going on

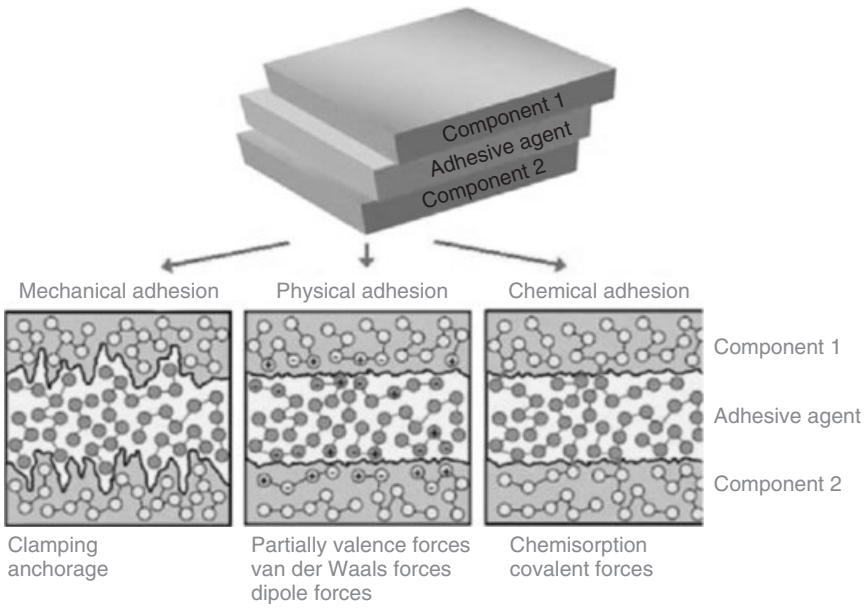

Figure 2. Introduction to bonding of different materials with an adhesive. (Reproduced from Schindel-Bidinelli and Gutherz, 1998 . © Wiley-VCH.)

by the bonding of components (Schindel-Bidinelli and Gutherz, 1998).

Adhesion can influence the processing and forming properties and, of course, significantly affect the properties of the sandwich components. The effect of the adhesion on the mechanical and formability properties of steel/polymer/steel sheets was investigated (Ruokolainen and Sigler, 2008; Carradò *et al*., 2011b).

Different theories were presented in an attempt to understand the adhesive bonding of the metal–polymer. The mechanical adhesion between the two materials (by micro-mechanical anchorage) and the auto-adhesion (inter diffusion of motile macromolecules) are based on simple mechanisms, whereas the specific adhesion is linked to physical–chemical and thermodynamic phenomena.

In "*theory of polarization*," de Bruyne describes—based on the electrical polarity of the atoms or the molecular groups—the interactions between functional groups of adherents and adhesives (de Bruyne, 1939). Experiments have shown that the adhesive forces increase with an increase in the dipole moment of the atoms or molecules. To improve the adhesion of both the adherents and the adhesives, the polymer must contain some polar groups and provide the dipoles. Some examples of such polar functional groups include oxygen- or nitrogen-containing groups such as hydroxyl, carbonyl, carboxyl, ester, amino groups, epoxy, isocyanate, or nitrile.

In comparison to other theories based only on physical bonds between adherend and components, the "*chemical adhesion model*" assumes that not only intermolecular forces but also chemical reaction can occur (Reinhart, 1954). These strong chemical bonds can be formed, such as the covalent bonds in the case of polymers. Both an incomplete absorbability and high bonding energies of the molecules have been experimentally observed during the bonding. It was found that only valence bonds can lead to this irreversible process.

A surface treatment is necessary to change and/or to improve some of the polymeric and metallic surface properties without modifying the bulk properties (Chan, 1994). The low surface energy of the polymeric surface (de Bruyne, 1939) can be raised using surface treatments such as corona ozone activation or atmospheric plasma methods. Therewith, the bonding of the metal–polymer interface can be improved, too.

Corona (Baldan, 2004; Lahti and Savolainen, 2004; Sun, Zhang, and Wadsworth, 1999) and plasma treatments (Strobel, Lyons, and Mittal, 1994; Liston, 1991; Wertheimer *et al*., 2002; Minzari *et al*., 2008) are commonly used to introduce reactive groups onto a nonpolar polymer surface such as those present in a polyolefin film (polypropylene copolymer based on a mixture of PP and PE) and to improve the wettability of the surfaces. Wettability is a measure for the hydrophobicity of surfaces using the surface tension defined by the contact angle between, for example, a liquid on a solid. Sellin *et al*. (2003) have studied the effect of corona treatment on the polymer surface using this water drop contact angle measurement. They have shown that the presence of created polar groups by corona activation depends on the aging of the polyolefin surface after the treatment. In the review of Baldan (2004), the effect of surface preparation and influence of bonding method (adhesive agent) on the adhesion between the metal and polymer surfaces were analyzed. It was observed that surface treatments, for example, corona and plasma as well as cleaning of surfaces using chemical agents before the treatment can clearly improve the polarity of polymer surfaces.

The scanning electron microscopy (SEM) images of the PP–PE films show significant changes in the surface morphology induced by the corona treatment (Figure 3a, b). Holes (pores) and an irregular porosity distribution can be detected, which are important for the adhesion properties.

Following the corona treatment, it has been verified (Carradò *et al*., 2011b) that the adhesion—studied by T-peel test—between the metal and the polymers is improved as can be seen in Figure 4. In this test, the peel resistance—or initial crack strength (P_A)—is defined as $P_A = F_A/b$ (N/mm), where F_A is the peeling load (or crack force) and b is the width of the test piece (30 mm). The mean peel resistance is $P_S = \overline{F}/b$ (N/mm), where $\overline{F}$ is the adhesion strength and b the width of the sample (30 mm). The bar chart in Figure 3 depicts a strong increase in crack-peel resistance (28%) and a mean peel resistance (43%) with increasing corona exposure time from 20 to 120 s.

A linear tendency of improvement is observed. These results can be explained by the creation of polar chemical functional groups because of the corona surface treatment.

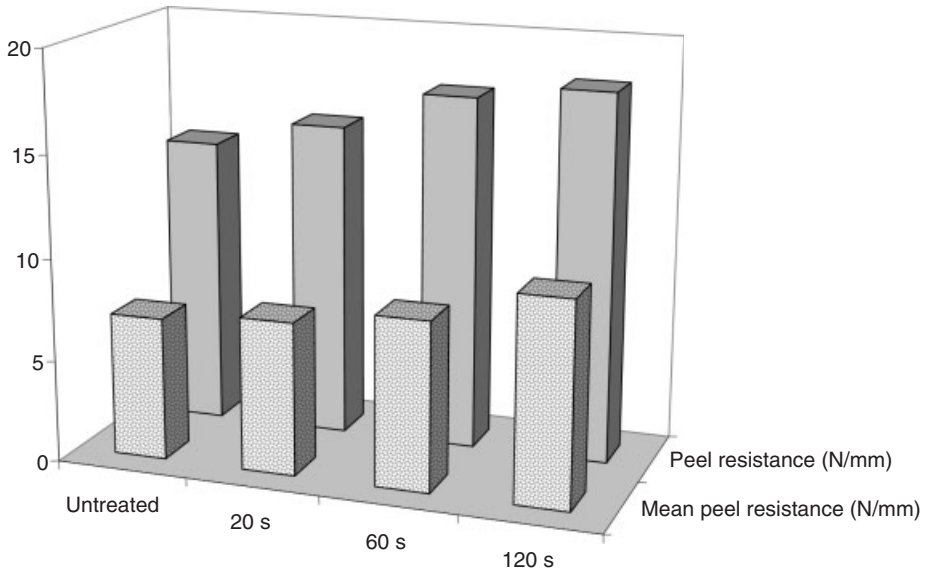

Figure 4. T-peel indexes (peel resistance and mean peel resistance) of polypropylene copolymer foil without and after corona treatment for different treatment periods (20, 60, and 120 s). (Mean ± SD, SD: standard deviation for $n = 6$). (Reproduced from Carradò *et al*. 2011b. © John Wiley & Sons, Inc.)

These groups also enhance the surface adhesion and wettability as stated by Zhang, Sun, and Wadsworth (1998).

The effect of corona treatment on the polymer under standard discharge in air is explained as an anchoring of atoms or molecules deposited onto the polymer surface (Bishopp, 2005). Moreover, the influence of the corona aging effect on the polymer surface's wettability was investigated by Pascual *et al*. (2008). The stable and high wetting capacity following a corona treatment permits corona-activated polymer sheets to be processed under standard discharge in air one day before bonding latest.

Finally, many parameters can improve the adhesion between polymers and metals to overcome the poor polarity of the polymers. In the hybrid steel/polymer/steel structure presented here, the surface is prepared by corona and/or plasma treatments before bonding. In order to chemically improve the adhesion, adhesive agents such as epoxy resin were used.

6 MANUFACTURING OF METAL/POLYMER/METAL SANDWICH SHEETS

To obtain and guarantee the desired properties of the sandwich composites, the production processes have to be adapted. The bonding of metal and polymer sheets can be performed in vacuum or standard atmospheres at room or elevated temperatures using a roll-bonding process. The advantage of the roll-bonding process is the ability to produce and to fabricate endless sheets under constant and reproducible conditions. The production process of metal–polymer sandwiches is modified in order to be carried out without adhesive agents using liquid or semi-liquid polymer cores in a press-rolling process (Kurt *et al*., 2004). A good overview of their applications and manufacturing techniques—with and without using adhesives—is given by Vinson (2005).

The AISI SS316L/polypropylene copolymer/AISI SS316L sandwich materials (SMS), manufactured in our laboratory, are produced using a roll-bonding process by means of a 2-high 10" rolling mill (Palkowski and Lange, 2008; Lange, Carradò, and Palkowski, 2009; Palkowski and Lange, 2007; Carradò, and Palkowski, 2009; Carradò *et al*., 2011a). Stainless steel AISI SS316L is a common alloy possessing excellent corrosion resistance and thermal stability, which facilitate its use in a wide range of metal–polymer–metal sandwich structures. Such steel sheets with a thickness of 0.5 mm are used for the skin material and a 0.6 mm thick polyolefin foil for the polymer core. The polyolefin, PP–PE, including PE, PP, poly(4-methyl-1-pentene), ethylene–propylene elastomer, and ethylene–propylene–diene rubber, is a widely used commercial polymer family (Chung, 2002). The PP–PE used was mixed with talc [$Mg_3Si_4O_{10}(OH)_2$], rutile (TiO_2), and barite ($BaSO_4$).

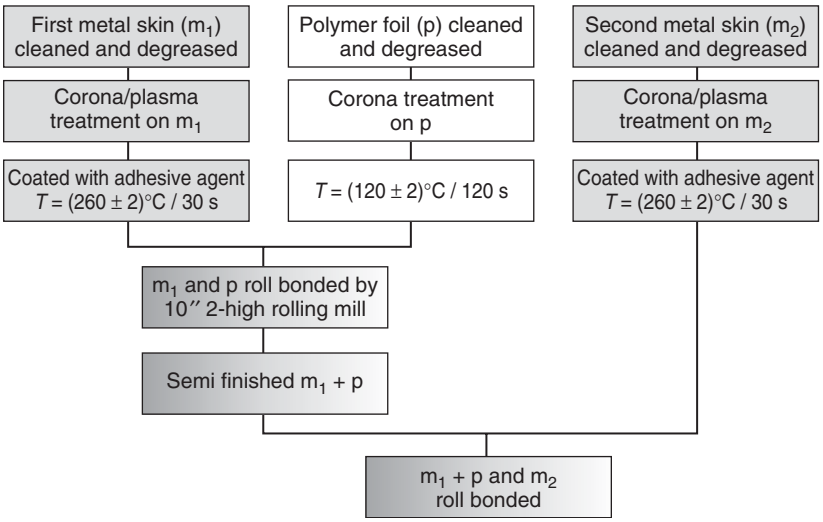

Figure 5. Laboratory roll-bonding process for the production of 316L/PP–PE/316L sandwich materials.

The roll-bonding manufacturing can be carried out as a continuous process. Under laboratory conditions, it was divided into two steps as sketched in Figure 5.

In the first step, the metal sheets (m_1) were cleaned and degreased with acetone and then coated with epoxy resin before being placed in a stationary convection furnace at (254 ± 2)°C for 30 s. Simultaneously, the PP–PE foil (p) was placed in a conventional furnace at a temperature of (120 ± 2)°C for 30 s to fit the bonding conditions with the epoxy resin. After activation of the adhesive, the upper sheet metal (m_2) was joined to the polyolefin foil using a 12" rolling mill. Before the roll bonding, a preliminary corona surface treatment was performed on the polymer core and the steel sheet was plasma treated. As discussed earlier, the corona and plasma treatments increase the surface energy and thereby improve the adhesion by means of activating the polymer (creating polar groups) and cleaning the metal before joining. The experimental conditions are given in Table 3.

As described in Section 3, a local strengthening of the hybrid structure can be achieved by a partial substitution of the core layer with a reinforcement (RE). A circular geometry was selected. Mesh (Figure 1a) and solid (Figure 1b) steel sheets were used for these REs. The diameters of the inlays were varied, the position of the local inlays was central to the deep-drawing shape or at a definite position offset from the center. The mesh inlays possessing a mesh size of $3 \times 3\,mm^2$ and a thickness of 0.5 mm were chosen to investigate the possibility and effect of additional weight saving for these sandwich structures.

Table 3. Parameters of the corona and plasma surface treatments.

Treatment	Parameters
Plasma on AISI SS316L sheets	8 kV, 500 W, time: min 20 s–max 600 s
Corona on PP–PE polypropylene copolymer foil	13 kV, 180 W, time: min 20 s–max 600 s

7 MECHANICS AND FORMABILITY OF THE HYBRID SYSTEMS

7.1 Fundamental laws of behavior

To describe how a sandwich material behaves is subjected to mechanical loading; some relations have been investigated to explain their performances.

The *rule of mixtures* refers to the expression (Equation 1) for the mechanical properties of a phase mixture in terms of the bulk or mechanical properties and the relative amounts of its constituent phases (Fan, Tsakiropoulos, and Miodownik, 1994).

$$\sigma_{US} = \sigma_{UA} V_A + \sigma_{UB} V_B \quad (1)$$

where σ_U and V indicate the uniaxial flow stress and volume fraction, and subscripts S, A, and B stand for the sandwich sheet and its A and B layers of components, respectively.

This law was tested and stated for describing the properties of fiber-reinforced composites with an acceptable degree of accuracy. However, the mixture rule for the sandwich materials has referred to the presence of negligibly small transverse stresses compared to axial or longitudinal stresses. The same law of mixtures can be modified

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto163
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to describe the Young's modulus for the composite by assuming a uniform axial strain for the whole sandwich composite.

$$\sigma_{US} = \sigma_{UA} V_A + \sigma_{UB} V_B$$
$$\varepsilon E_{US} = \varepsilon E_{UA} V_A + \varepsilon E_{UB} V_B$$
$$E_{US} = E_{UA} V_A + E_{UB} V_B \quad (2)$$

With the same indications as before and E_U: Young's modulus in the longitudinal direction.

Qualitative properties of some composite materials can be described using the *complementation theory*, which states that each constituent complements the other by separately contributing distinct properties; for example, an aluminum–steel composite, where aluminum provides the corrosion resistance and steel provides the strength (Milton, 2002).

The resulting properties of a composite material can also be described by the *concept of interaction*. It states that the property of one constituent is dependent on the property or the action of the others. The resulting composite's properties are usually intermediate to those of the constituents or can even exceed those of both; for example, ceramic matrix composites. The SiC/Si_3N_4, ceramic matrix composite, exhibits higher fracture toughness than that of its brittle constituents (Milton, 2002).

As an example for the mixture rule, the tensile test was used according to the standards (DIN 50114, 1981) to compare the SMS with the monolithic materials 316L and PP–PE (Figure 6). Yield strength (YS), TS, and elongation to rupture (ER) were measured using a universal testing machine. Because of anisotropy effects, specimens were taken at $\alpha = 0^\circ$, 45°, and 90° to the rolling direction of the sheets. Under uniaxial tensile load, the steel material

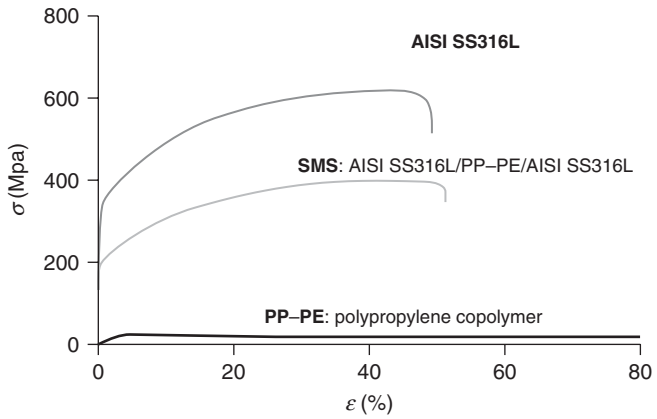

Figure 6. Stress–strain for 316L, SMS, and PP–PE at room temperature. Samples taken in rolling direction.

and SMS show macroscopically elastic deformation until the YS is reached at about 620 and 400 MPa, respectively. Rupture occurs at a strain of approximately 53% and 50%, respectively. Additionally, the tensile test summarizes the mechanical properties of the 316L skin, the PP–PE core, and the SMS and shows the reduction in yield stress following the rule of mixture for the flow stresses of the sandwich sheets, given by Equation 3:

$$\sigma_{SMS} = \frac{\sigma_{316L} \cdot V_{316L} + \sigma_{PP-PE} \cdot V_{PP-PE}}{V_{316L} + V_{PP-PE}} \quad (3)$$

where σ and V indicate the uniaxial flow stress and volume fraction. The subscripts represent "SMS" the sandwich sheet, "316L" the metal, and "PP–PE" the polymer.

7.2 Formability, stretching, and deep drawing

Formability is the capacity of the sheet metal to be formed without failure (Narasimhan, Miles, and Wagoner, 1995). Thus, formability is not easily quantified, as it depends on numerous interacting factors such as material flow properties, ductility, tool geometry, tool material, lubrication, and deformation speed. Note that no single test can quantify the formability for all types of stamping applications (Bayraktar, Isac, and Arnold, 2005).

Numerical simulations using FEM (Ayari, Lazghab, and Bayraktar, 2009; Xiao *et al*., 2011) and the deep-drawing processes of the square cup test on metal or sandwich structures under load have been reported by a number of authors (Boesemann, Godding, and Huette, 2000; Weiss *et al*., 2007).

The size of the finished sample and the distribution of the deformations depend on the geometrical conditions and the degree of forming. Figure 7 shows characteristic areas of interest for a deep-drawn square cup as well as the typical stress states in a cup during deep drawing.

To investigate the formability of the SMS for deep drawing and stretching, tests according to Erichsen and Olsen (Olsen, 1920; Kaftanoglu and Alexander, 1961) as well as deep-drawing tests were performed. The stretch-forming behavior was characterized by the Erichsen test according to DIN 50101 (1979). Figure 8a illustrates a typical experimental setup. A cone-shaped spherical plunger deforms the sample, which is restrained around its periphery, until fracture occurs (Figure 8b). The height of the cup at fracture (called the *Erichsen index*) is a measure for the stretchability and a reference value for the material.

The deep-drawing tests were carried out using a deep-drawing benchmark test. The limits of deep drawing are affected by the geometry of the tools, the material properties of the blank and the process parameters (Tschaetsch, 2006).

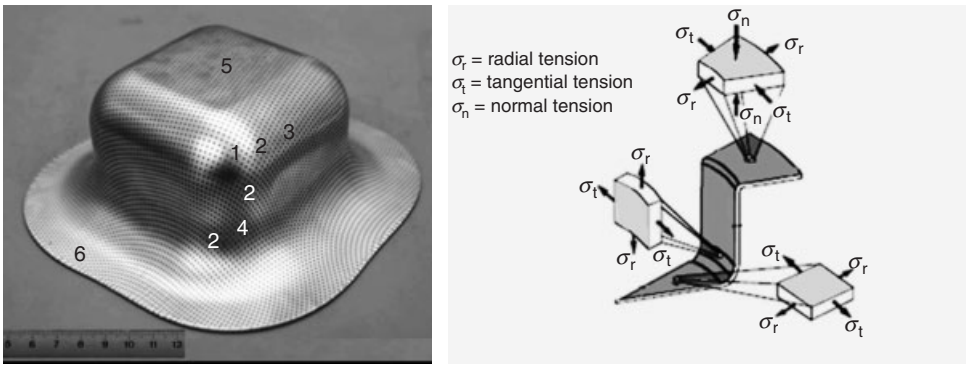

Figure 7. Forming zones of a square/rectangular cup (a) and typical stress states during deep drawing (b); 1, "corners"—punch or die rounding; 2, transition region "corner/edge"; 3, straightness of edges; 4, "edge" region (depends on forming degree); 5, "cup head" region; and 6, "flange" region.

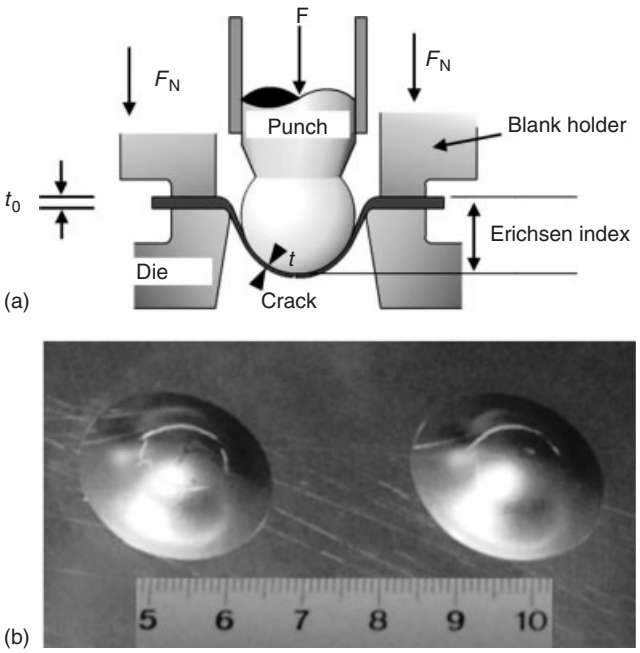

Figure 8. (a) Experimental setup for Erichsen test and (b) SMS failure (crack) in Erichsen test.

Owing to the tangential tension (σ_t), wrinkling in the flange and fracture of the cup wall can occur (Doege and Behrens, 2007). Investigations were carried out on SMS as well as on industrially manufactured materials (H400/PP/H400) (ThyssenKrupp Stahl, 2003) and pure metal sheets using the testing parameters: 225 mm^{ø} circular blank, 83 kN blank clamping force, 25 mm punch corner radius, 25 mm punch border radius, and a 25 mm drawing ring radius. The side length was 100 mm.

The results of the Erichsen tests performed show a slightly improved behavior of the laboratory-produced SMS (1.6 mm) compared to the industrially produced ones of the same layer thicknesses (H400, 1.6 mm), and come close to the value of the monolithic material (316 L, 1 mm thickness), see Figure 9. Investigations using optical light microscopy confirm that no delamination occurred.

The results of the deep-drawing tests show the same tendencies as those previously discussed for the stretching behavior. The approximately 74 mm deep-drawing depth for the SMS is comparable with that for the mono material and is slightly higher compared to the industrial material (Figure 9).

As mentioned earlier, the weakness of hybrid materials combining metals with polymers is thermal and mechanical joining. A possible solution for overcoming this weakness is to embed inlays (Figure 5) into the sandwiches. Therefore, the effect of different solid and mesh steel inlays on the formability and the flow of the material were investigated (Sokolova, Carradò, and Palkowski, 2011a). Some results are depicted in Figure 10, showing that using inlays in central position, failure by cracking occurs earlier compared to nonreinforced SMS, and that meshed inlays show an improved behavior compared to the solid REs. The SMS with 60 mm^{ø} solid REs failed by delamination caused by the small ratio of the supporting area (bonding between the single layers) to the inlay area, approaching is almost close to zero.

It can be concluded that the size as well as the geometry and the position of the inlays within the sample influence both variables (Sokolova, Carradò, and Palkowski, 2011b).

To investigate the local load conditions due to the change in thickness of the SMS, a photogrammetry method was used. This method is also known as *digital image*

correlation (*DIC*) method. As an example, Figure 11 shows the thinning of the metal on the outer surface of a circular cup for SMS with and without reinforcing inlays. The effect of the reinforcement is clearly to be seen. Maximum thinning occurs in the nonreinforced cup in the area of the punch radius and the lowest reduction is given for the solid inlay that best strengthens the sample in the critical area.

7.3 Determination of forming limit curves

Following Keeler and Backofen (1963), the forming limit diagram (FLD) presents the ultimate ductility a sheet material may demonstrate under various strain conditions and a given boundary criterion, such as failure or the onset of necking. The FLD is determined to predict the extent to which sheet materials can be formed by deep drawing, stretch forming, or other load paths. In literature, several measures are described to determine FLDs. One of these is the Nakajima test (DIN 12004-2, 2008), based on the principle of deforming metal sheets with different waist geometries using a hemispherical stamp until fracture. By varying the sample section's width, different load paths can be adjusted and plotted on a true strain diagram; from deep-drawing conditions to uniaxial tension and plane-strain up to pure biaxial strain.

To determine the principle deformations and their directions, DIC was applied to measure the displacements of selected points on the sample following stamping. The principle strain values provide one point within the FLD. The combination of the points defines the FLD. Figure 12a shows the principle load paths in a major–minor strain diagram and the different geometries used for determining the forming limit curve (FLC) (Figure 12b).

The failure of a 1.6 mm thick SMS is subjected to different load conditions and was studied using the Nakajima test as well as 1 mm thick 316L sheets for comparison. Figure 13 shows the curves for both materials. It can be concluded that the mono material possesses slightly improved properties in the region of plane strain, but shows the same level for deep-drawing and biaxial loading conditions.

8 OUTLOOK

As could be shown, the development of hybrid materials is one of the most successful examples within the group of composites. Hybrid systems demonstrate considerable potential for designed properties following the specific demands of multifunctional parts and offer properties not achievable with mono materials. The combination of metals with fibers, particles, polymers, ceramics, and other materials, materials that are normally "incompatible," permit "designed" materials to be produced possessing the combined properties of the mono materials such as

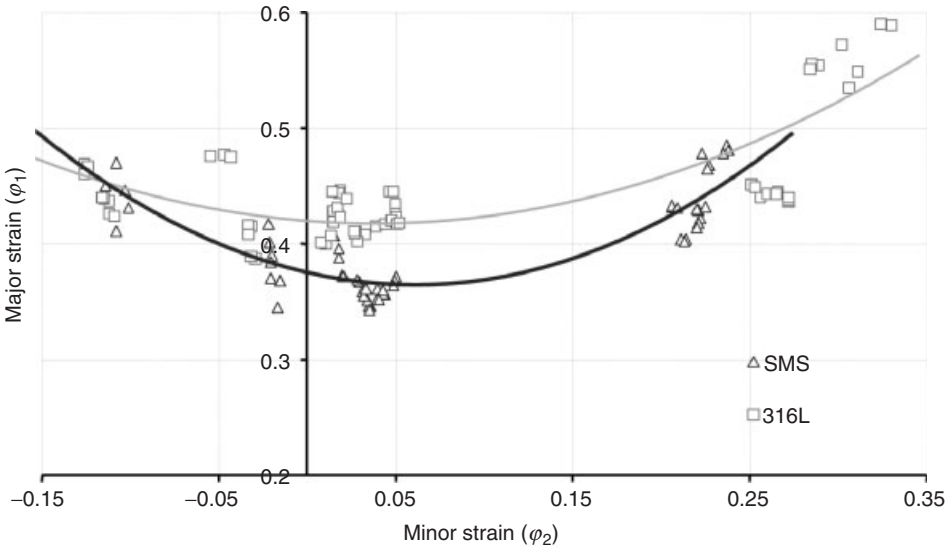

Figure 13. FLC of 316L sheet (1.0 mm) and SMS (0.5/0.6/0.5 mm).

high strength and deformability and are at the same time lightweight or have high damping, insulating, and corrosion-resistant properties.

Many of the composites currently on the market are nondeformable and are, therefore, only usable for batch production to produce final parts. For sheet parts in the automotive industry, continuous production is essential for significantly reducing the production costs. Deformable metal–polymer combinations can be a solution here.

Focusing on these types of sandwich materials, it can be concluded that compared to the mono metal, they have comparable deformation properties and show improved performances concerning lightweight and damping properties. Their weakness regarding thermal or mechanical joining can be eliminated by introducing reinforcing inlays, placed at those areas where vaporization could occur or where preloads are to be maintained under dynamic loading. Knowledge in this field is currently quite small but offers an enormous potential.

ACKNOWLEDGMENT

The authors are grateful for the support of the German Research Foundation DFG, the DAAD (D/0707603), EGIDE (PHC PROCOPE No. 17895XK), and APIC-DEU-PICS (No. 5245) for funding these investigations. Moreover, we thank ThyssenKruppNirosta for supplying us with the steel.

Recycling of Polymers and Composites

Bassam J. Jody, Edward J. Daniels, and Jeffrey S. Spangenberger

Argonne National Laboratory, Argonne, IL, USA

1 INTRODUCTION AND BACKGROUND

The worldwide automobile industry is a growing material- and energy-intensive industry (Figure 1). The growth is most rapid in developing countries, such as China and India (Figure 2). In 2001, the vehicles on the road in the United States contained 5.3% of all steel and 13.8% of all aluminum in use in the United States (USGS, 2006a, 2006b).

Figure 3 shows the changes in the composition of a typical car in the United States during 1995–2009. The newer cars contain a higher percentage of polymers and composites. This use of materials is likely to continue as the automotive industry strives to reduce the weight of vehicles and as more efficient and economical composites are developed (Bain, 2012). Despite the use of lighter materials, the average weight of a vehicle has increased from about 1675 kg in 1995 to 1775 kg in 2009 (Davis, Diegel, and Boundy, 2011). This increase is due to the increase in the number of larger sport utility vehicles (SUVs). As the new CAFE (Corporate Average Fuel Economy) regulations take effect, automobile manufacturers will be using more of the lighter materials, including high strength steels, aluminum (Al), and polymers and composites.

At present, end-of-life vehicles (ELVs) are profitably processed for materials and parts recycling by an existing market-driven infrastructure that includes dismantlers, remanufacturers, and shredders. Dismantlers process the ELVs and recover usable parts. The shredders recover ferrous and nonferrous metals from the remaining auto "hulk." Recycling the polymers and composites is limited by the lack of (i) commercially proved technologies to economically recover them as marketable products and (ii) stable post-use markets. Therefore, most of the nonmetals are landfilled as part of the shredder residue generated by the shredders that wastes the value of these materials in addition to increasing the waste volume in the landfills.

Future vehicles will also contain different power trains (electric and hybrid vehicles). All of these factors will impact the recyclability of the ELVs, including their polymers. Replacing iron and steel, which are recyclable, with lightweighting materials will reduce the recycling rate even if the lightweighting metals are recycled at the same rate

as steel and iron because the relative weight of the metals in the vehicle will decrease. Therefore, to maintain high vehicle-recycling rates, it is important that the polymers be recycled. Recycling the polymers and composites is also necessary in order to comply with emerging regulations. For example, in 2000, the European Union (EU) legislators issued a (draft) directive [Directive 2000/53/EC (September 18, 2000); Sander *et al*., 2002; Konz, 2009; Decicions, 2010; Parliament, 2010] that called for reuse and recovery rates of materials from the ELVs to be at least 85% by January 1, 2006, and 95% by January 1, 2015.

2 IMPACT OF RECYCLING AUTOMOTIVE POLYMERS ON SUSTAINABILITY OF THE INDUSTRY

Polymers and composites are energy-intensive materials that are made primarily from petroleum and can last hundreds of years in landfills. Technology is needed to recycle them economically and in an environmentally responsible manner. The focus is on recycling the thermoplastics, which constitute about 80% of the automotive polymers, and they could be remolded into new products [polypropylene (PP), polyethylene (PE), polystyrene (PS), acrylonitrile–butadiene–styrene (ABS), nylons, polycarbonate (PC), PC-ABS, and polyvinyl chloride (PVC)].

Composites consist of a polymer matrix reinforced with fibers. Teijin Ltd. (in Tokyo, Japan) announced on November 30, 2011, that it will *establish the world's first pilot plant for fully integrated production of carbon fiber-reinforced thermoplastic (CFRTP) automotive components* (Teijin, 2012). Composites have many attractive features in automotive applications, including high strength-to-weight ratio and corrosion resistance, and can be molded into complex parts, which reduce manufacturing costs (Table 1).

Optimizing the recycling of automotive materials requires an integrated approach (Reuter *et al*., 2004) by the auto companies and their suppliers, dismantlers, and shredders. ELVs start their final journey at a dismantling site where usable parts are recovered for resale. Direct reuse of a part conserves the materials and energy that would otherwise be required to produce the part from raw materials, as well as the manufacturing energy required to stamp the part and assemble the component. Some parts,

Table 1. Estimated mass and tooling investment reductions when composites are used to replace conventional automobile components.

Part	Mass Reduction (%)	Reduction in Tooling Investment (%)
Composite hoods	30–40	60–70
Fenders	25–35	55–65
Deck lids	25–35	50–60
Floor pans	30–40	Up to 60
Trunk compartments	50	70
Bumper beams	30–40	Not applicable

Data taken from Plastemart, 2011.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto164
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

such as starters, alternators, engines, and transmissions, may require rebuilding. Others, such as thermoplastic olefin (TPO) bumpers, require only cosmetic repairs. The plastics in these parts are sometimes overlooked when estimating the recycling rates, even though they represent "primary" recycling of the polymers (Duranceau, 2009).

Most automotive polymers end up in the shredder residue after the "hulks" are shredded and their metals are recovered. More than 10 million vehicles annually are scrapped in the United States (Daniels *et al*., 2004). A recent European report reported the number for the 25 EU countries to be over 14 million in 2010 compared to 12.7 million in 2005 (Parliament, 2010).

2.1 Economic viability of recycling polymers and composites from ELVs

The economics of the recycling process is governed by a number of factors, including

- Value of the recovered materials. This depends on the type and quantity of material recovered, its purity, and the consistency of its properties and composition.
- Cost of separating, purifying, and removing contaminants from the recovered materials.
- The value of recycled plastics is generally between 50% and 75% of the value of their virgin counterpart. For example, for PP, which is the most used automotive plastic, during the fourth quarter of the year 2011, the price of clean regrind or flakes was about \$1.48–1.74 per kg, and the price of virgin injection grade PP was between \$2.18 and \$2.67/kg (Plastics News Magazine, 2011).
- A big portion of the cost of recovering the automotive polymers can be the cost of purification or upgrading of the material after it is separated from the source stream. For example, polyolefins can be easily separated by sink/float techniques. However, the separated polyolefins may contain wood, rubber, foam, and other residual materials. Removal of these residual materials from the target material may cost more than the cost of separating the olefins from the source stream.

2.2 Energy value of recycled automotive polymers

Over 6 million metric tons of thermoplastics worth about \$12 billion can be recovered from obsolete vehicles annually worldwide. These numbers are determined using the following assumptions: (i) 5% of the 950 million vehicles on the road reach the end of their useful life annually, (ii) the average weight of a vehicle is 1770 kg, (iii) 10% of the weight of an ELV is polymers and composites, (iv) 80% of the polymers are thermoplastics, (v) 90% of the polymers end up in landfills (which is the case at present), and (vi) recycled polymers and composites are assumed to be worth \$1/kg.

Figure 4 summarizes the embodied energy data (energy required to produce the material or the product starting from its raw materials) for some automotive plastics. Except for some disagreements with the older Oak Ridge National Laboratory (ORNL) (ORNL, 1994) data for the olefins, the data are in good agreement. Figure 4 shows that the embodied energy for most of these plastics is between 70,000 and 100,000 kJ/kg with an average of about 85,000

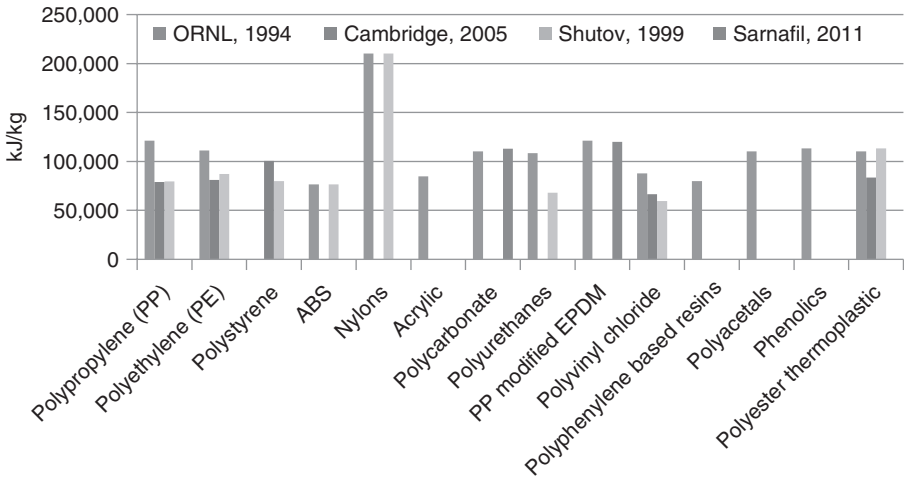

Figure 4. Embodied energy of plastics from different data sources. (Data taken from ORNL 1994, Cambridge 2005, Shutov 1999, and Sarnafil 2011.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

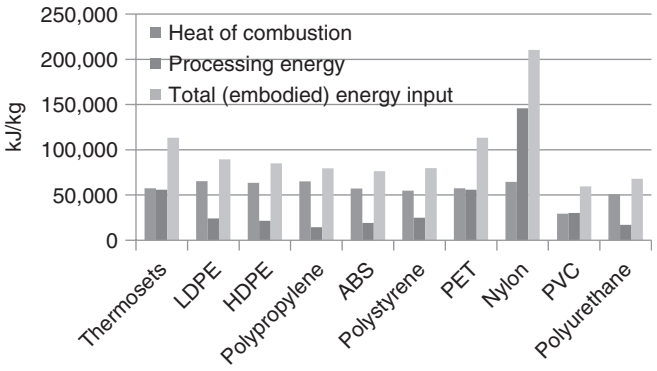

Figure 5. Breakdown of the embodied energy of polymers. (Data taken from Shutov, 1999.)

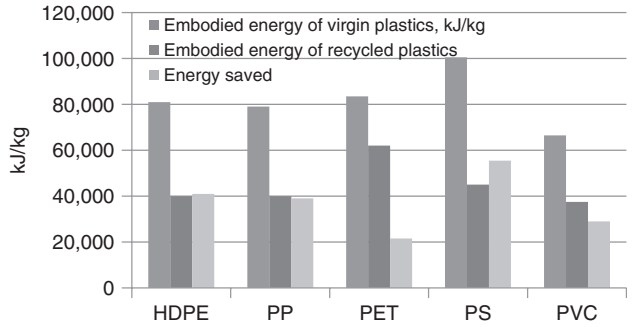

Figure 6. Embodied energies of virgin and recycled plastics. (Data taken from Cambridge, 2005.)

kJ/kg. At present, the olefins constitute about two-thirds of the plastics in vehicles. The data suggest that the average embodied energy for the automotive plastics is about 75,000 kJ/kg. Figure 5 shows the breakdown of the embodied energy of some polymers.

Figure 6 shows the approximate energy savings that can be realized by recycling some automotive plastics. Overall, the savings are about 37,500 kJ/kg of plastics recycled. As stated earlier, there are about 950 million registered vehicles in the world, and each contains about 227 kg of plastics. Recycling these plastics can result in energy savings exceeding 7.5×10^{15} kJ. The total world energy consumption in 2008 was about 475×10^{15} kJ.

2.3 Environmental impact of recycling

Recycling has many positive environmental impacts, including (i) reduction in demand for and depletion of natural resources; (ii) protection of the ecosystem by reducing the amount of waste and pollution; and (iii) energy savings, which will result in less pollution, including a reduction in the emission of greenhouse gases (GHGs).

Most plastics are derived from oil or natural gas, and processing the oil or gas to produce the monomers and polymerization of the monomers are energy-intensive processes. Assuming that 0.07 kg of CO_2 equivalent is emitted per million kilojoule of energy used, about 2.8 kg of CO_2 equivalent emissions will be avoided for every metric ton of plastics recycled. A life-cycle analyses study (Gallon and Binder, 2006) was conducted on automotive polymer recycling processes, including mechanical and chemical separation of the plastics for reuse as plastics and conversion to "fuel" or incineration to recover their heat value. The analyses concluded that both types of recycling resulted in environmental benefits. However, the environmental benefits are higher when the plastics are recovered for reuse as plastics. The maximum benefits can be obtained by combining both processes where materials that are recyclable as materials are first separated for reuse and the residual is then used to produce fuels.

3 TECHNOLOGIES FOR RECYCLING AUTOMOTIVE POLYMERS

Because most polymers and polymer composites end up in shredder residue, emphasis will be on separating and recovering them from shredder residue.

3.1 Shredder residue

Shredder residue contains polymers, composites, moisture, wood, metals, glass, sand, dirt, automotive fluids, fabrics, and fibers. Researchers van Schaik and Reuter (2004) have suggested that shredder residue data should be reported within statistical limits when used to calculate the recycling rate. Pineau, Kanari, and Menad (2005) have also estimated that a minimum sample size of 140 kg is required for the sample to be 90% representative. Table 2 shows the differences in the composition of two shredder residues processed by Argonne's process for recycling polymers from shredder residue. Table 3 compares the composition of the polymer concentrates separated from the two residues. Tables 2 and 3 represent the averages from processing over 11,000 kg of shredder residue 1 and 15,000 kg of residue 2 over a period of 6 months. Over 90% of the polymers were recovered as a "polymer concentrate."

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 2. Gross composition of two shredder residue samples.

Material	Weight % in Shredder Residue 1	Weight % in Shredder Residue 2
Fines (<6 mm)	24	60
Polymer concentrate	36	14
Oversized heavies (metals and rocks)	08	02
Lights rejects and oversized foam	11	03
Metals-rich fraction	05	06
Loss (moisture, dust, and sweeps)	16	15

Table 3. Composition of the polymer concentrates described in Table 2.

Material	Weight % in Shredder Residue 1	Weight % in Shredder Residue 2
Mixed rubber	50	30
Polyolefins	17	30
Polystyrene	2	3
ABS	5	8
Polycarbonate	3	3
Nylon	2	1
Polyvinylchloride	2	3
Unknown polymers (rich in thermosets)	13	7
Other (including metals and wood)	6	15

3.2 Separation of polymers from shredder residue as a concentrate

Many of the polymers in shredder residue have overlapping properties. Rasshofer and Schomer (2003) have stated that except for ferrous metals, it is unlikely that a material can be recovered at sufficient purity from shredder residue in a single step or by mechanical means only. Several steps are normally required: (i) separation of the polymers from shredder residue, as a polymer concentrate, (ii) separation of the plastics from the polymer concentrate, (iii) separation of wood, rubber, and inert materials from the plastics, (iv) purification of the separated plastics, and (v) cleaning of the recovered materials. Processes for the recycling of materials from shredder residue are discussed in a number of review articles (Jody *et al*., 2010, Lundqvist *et al*., 2004; Zevenhoven and Saeed, 2003).

4 TECHNOLOGIES FOR THE SEPARATION OF POLYMERS FROM SHREDDER RESIDUE AS A CONCENTRATE

The Argonne Process. Argonne National Laboratory developed and tested a process for isolating the polymers as a concentrate (Jody, *et al*., 2010). The plant recovers >90% of the polymers in the shredder residue and >90% of the metals.

The Nimco Process. This process has four subsystems: (i) sizing and separation of shredder residue, (ii) grit processing, (iii) polymer recovery, and (iv) polyurethane foam separation and cleaning (Baker, Woodruff, and Naporano, 1994).

The Witten Process. This process was developed for producing an organic-rich fraction to be used as a fuel in cement kilns (Competitive Analysis Centre, Inc. and Economic Associates Inc., 1998). The process separates the ferrous metals, size reduces the remaining material, and removes fines. Air classifiers are used to separate fibrous from nonfibrous material, which contains the polymers.

The Sortec Process. This process produces an organic fraction from shredder residue (Competitive Analysis Centre, Inc. and Economic Associates Inc., 1998). The process consists of (i) separation of fines and recovery of large metal pieces; (ii) size reduction of the remainder to <2 cm; (iii) separation of ferrous metals; and (iv) drying, screening, and air classification. The light fraction is the organic fraction, which contains the polymers.

The Wesa-SLF Process. This process (Sattler and Laage, 2000; Zevenhoven and Saeed, 2003) separates the residue by size into three fractions and then size reduces the oversized material and recovers the ferrous metals. The material is then reduced to <7 mm and combined with the middling fraction, dried, air classified, screened, and then separated from the organic fraction, which contains the polymers.

In addition, many in the shredder industry have also experimented with such similar technologies mostly for increasing their metals recovery from shredder residue.

5 TECHNOLOGIES FOR THE RECOVERY OF POLYMERS FROM THE POLYMER CONCENTRATE

Over the past decade, major advances have been made in process development for separating and recovering polymers from shredder residue. Some of these advances are discussed in the following.

The Argonne Process for the Separation and Recovery of the Plastics. Argonne developed a froth flotation process (Jody *et al*., 2011; Jody, Pomykala, and Daniels, 2003b). The process consists of the following steps: (i) separate the granulated polymer concentrate using conventional sink/float techniques into more manageable polymer groups, (ii) recover targeted plastics from the concentrated groups, and (iii) purify the targeted species to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto164
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

increase purity. Argonne built a pilot plant and a 3 tons/h module and processed about 10,000 kg of polymer concentrate. In addition, a 20 tons of shredder residue per hour plant was built at a shredder site based on this process.

The MBA Polymers Process. MBA polymers built plastics recycling plants in China and Austria and a plant in England to recover automotive plastics from shredder residue. The plant has a design capacity of 60,000 tons/year (MBA, 2012).

The Recovery Plastics International (RPI) Process. This process uses a plasticizer to modify the surface of plastics. The process was applied for the recovery of plastics from shredder residue (Wielgat, 2002).

The Salyp Process. This process used infrared (IR) heating to soften and separate the plastics. However, when this process was applied to mixtures of plastics, the purity was low because the softening temperatures of the species overlapped.

The Volkswagen-SiCon Process. Construction of the first large-scale Volkswagen-SiCon plant was in 2005, and it had an annual design capacity of 100,000 tons of shredder residue. The first stage of a smaller plant based on Volkswagen-SiCon technology was commissioned in Belgium in 2005(Guschall *et al*., 2005). SiCon launched its first own industrial plant for the treatment of shredder residue in Antwerp, Belgium. The plant has a design capacity of up to 20,000 tons/year in a three-shift operation (Recycling International, 2008).

The Galloo Process. This process is for recycling thermoplastics from end-of-life products including ELVs and produces about 25,000 ton of recycled materials per year (Recycling International, 2012). The process produces several fractions, including a plastics fraction that is processed in a wet separation system. The remaining fraction is processed in a heavy-media separation plant to recover the metals (Galloo, 2012a). It is reported that the Galloo sink/float process is able to "make density separations accurate to within two points to the third decimal place" and is continually expanding its operation (Galloo, 2012b).

Rapid Identification and Separation Processes. These include IR and near-infrared (NIR), X-ray, UV fluorescence, Raman spectroscopy, and color sorting separation equipment. Some can produce >90% pure products from some mixtures. They can be combined with color sorters to achieve greater separation. Technologies for detecting dark plastics that have high content of carbon black by IR separators are still under development. Rapid identification of polymers can be achieved using NIR spectroscopy because many polymers have unique spectra in the 1350–1800 nm region (McDermott, Jenner, and Crocombe, 2007). X-ray separation is applied mostly to PVC because the chlorine atoms in PVC generate an easy-to-detect peak in the X-ray spectrum. The UV fluorescence method has been applied mostly to the separation of mixtures containing nylons/PC and PC/polymethyl methacrylate (PMMA), because PC fluoresces and the others do not. Some color sorters can distinguish between very close colors, such as light blue and clear, and can detect more than one color simultaneously. However, many plastics exist in more than one color. Raman spectroscopy uses characteristic peaks of specific chemical groups to identify the polymers.

Many types of such equipment are commercially used to sort plastics. A few of the many organizations that developed such equipment are TITECH (Titech, 2012a, 2012b), MSS, Inc. (MSS, 2012), and NRT (NRT, 2012).

6 CHEMICAL PROCESSES FOR RECYCLING PLASTICS

6.1 Methods using organic solvents

Selective dissolution of plastics from a mixed stream can recover highly pure plastics (PIA, 1980; Tesoro, 1987; Nauman and Lynch, 1993, 1994; Jody *et al*., 1990; Jody, Daniels, and Bonsignore, 2001, Daniels, Jody, and Bonsignore, 1990). Solvent-based processes are in practice in Europe—for example, the Solvay Chemicals Company's "Vinyloop" batch process and the Delphi process.

The Solvay Process. The Solvay "Vinyloop" process recovers PVC from PVC-containing scrap. The PVC is dissolved in methyl ethyl ketone, and the solution is pumped into a recovery tank, where steam is injected into the solution to precipitate the PVC.

The Delphi Process. This process removes PVC from automotive wire harnesses using solvents to swell and soften the PVC, but not dissolve it, so that it can be separated from the copper wires by centrifugation.

The Rensselaer Polytechnic Institute Process. In this process (Nauman and Lynch, 1993, 1994), a solvent (or solvents) is used to dissolve plastics from a mixture and then flash devolatilization is used to precipitate the dissolved plastics.

The Argonne Process. Argonne's process (Jody, Daniels, and Bonsignore, 2001; Jody, Daniels, and Pomykala, 1996; Daniels, 1994; Jody *et al*., 1994) uses multiple solvents to extract plastics. The process produces ABS, PVC, and PP/PE at high purity (>98%).

6.2 Polymer depolymerization to produce monomers

Several depolymerization processes to produce monomers have been developed (American Plastics Council, 1999). Polymers such as polyethylene terephthalate (PET) and polyurethanes can be depolymerized by glycolysis, methanolysis, and hydrolysis. Nylon 6 can be reacted with high temperature steam to produce caprolactam, which is used for making nylon 6. Mixtures of nylon 6 and nylon 66 can be reacted with ammonia at elevated temperatures to produce the monomers of both nylons (American Plastics Council, 1999). InfiChem Polymers (InfiChem, 2012) commercialized a process for converting polyurethane foam to polyols, which could be used for making new foam.

7 UTILIZATION OF AUTOMOTIVE POLYMERS AS ENERGY SOURCES

The energy value of polymers can be recovered by (i) burning the polymers and recovering their heat of combustion and (ii) converting the polymers to liquid and/or gaseous fuels.

7.1 Burning with heat recovery

The heating value of shredder reside is about half that of coal, and the heating value of the polymer concentrate is more than one and a half times that of coal. Shredder residue is also low in sulfur but high in ash and moisture. Burning shredder residue can reduce its mass and volume by more than 50% and 75%, respectively. However, it is not widely accepted because landfills are less expensive in many places and because shredder residue contains substances of concern (SOCs).

The US Department of Energy (DOE) conducted a study where shredder residue was burned in a rotary kiln (Hubble, Most, and Wolman, 1987). Incineration tests were also conducted where small percentages of shredder residue were co-fired with municipal solid waste (MSW) (Keller, 2003; Mark and Fisher, 1998, 1999). No major operational problems were reported. However, dioxins/furans and Cd, As, Pb, and Zn increased, but the gas cleanup system was able to handle it. The ash showed increased levels of Zn, Cu, Sb, Ni, Pb, and Sn (Mark and Fisher, 1998, 1999).

The Competitive Analysis Centre, Inc. and Economic Associates, Inc. (1997) conducted a study to evaluate the potential use of the organic fraction of shredder residue as an energy source and as a source of reducing agents in blast furnaces. The polymers were used to replace the coke or coal supplied to the blast furnace.

7.2 Pyrolysis

Pyrolysis of polymers has been demonstrated (Banks, Lusk, and Ottinger, 1971). Problems encountered (Leidner, 1981) include (i) longer residence times because plastics have poor heat transfer properties, (ii) carbon residue sticks to the reactor walls, and (iii) plastics produce viscous material that is difficult to pump.

Keller (1999a) reported the following observations concerning pyrolysis of shredder residue: (i) iron makes up to 25% of the solid product and copper up to 5%, (ii) the concentration of polycyclic aromatic hydrocarbons (PAHs) was reduced by more than 90% and polychlorobiphenyls (PCBs) were reduced by more than 99%, and (iii) the solids could not be landfilled because of the heavy metals. Day, Cooney, and Shen (1996) described a process for pyrolyzing shredder residue at about 500°C. The combined nitrogen- and sulfur-containing compounds constituted >10% of the weight of the oil. The oil also contained a very small amount of chlorinated compounds. Pyrolysis tests were also conducted at subatmospheric pressures (Roy and Chaala, 2001; Chaala, Ciochina, and Roy, 1999). The products were 52% solids, 28% oil, 13% water, and 7% gas.

Several large-scale processes pyrolized shredder residue. Siemens-KWU developed a process followed by combustion of the products for steam production. The plant conducted one trial using 30 tons of shredder residue. The Batrec process involves pyrolysis of the shredder residue followed by mechanical separation of the metals (iron and copper) from the solids. Keller (1999a, 1999b) conducted in the plant pyrolysis tests in a 400-kg/h reactor at 600°C using shredder residue. The Takuma process was tested in a 90-ton/day plant in Japan. The shredder residue is first pyrolized and then the residual solids are sorted to recover metals. The char is combusted along with the gases produced by the pyrolysis process, and the heat is recovered in a steam boiler. The citron oxyreducer process (Brüggler, 2002) is in operation; the product gases, which are rich in CO and H_2, are used to reduce the metal oxides and hydroxides.

7.3 Gasification

Gasification is a high temperature process in which organic materials react with steam and limited amounts of oxygen to produce H_2, CO, and CO_2. Kondoh *et al*. (2001) compared gasification with other thermal methods for processing shredder residue. Some of processes that were tested for shredder residue are described in the following.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto164
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

VOEST-ALPINE Process. Tests were conducted in which the shredder residue was blended with mixed plastics, waste oils, and fuel oil (Schmitt, 1990). The product gas is considered a low-energy industrial fuel gas, which would have to be used on-site.

TwinRec Process. This process uses fluidized-bed gasification with ash melting (Selinger, Steiner, and Shin, 2003; Kummer, 2003; Ando *et al*., 2002). The process produces steam for power generation. It also produces ferrous and nonferrous metals. The fine inert residue is vitrified in the process. Zinc and fly ash from the process are sent to the zinc industry.

SVC Process. This process has recycled shredder residue for many years (Obermeier and Markowski, 2002). Tests were conducted using a ratio of 30% shredder residue/70% other solid and liquid wastes. Buttker *et al*. (2005) reported that a test was conducted using over 900 tons of shredder residue and at gasification/partial oxidation temperatures of 1300–1600°C and a pressure of 25 bars.

Plasma Processes. Plasma gasification (~5000–10,000°C) has been tested for shredder residue (Circeo, 2008; Leal-Quiros, 2004; Sawyer, 2009; Tellini *et al*., 2007; Westinghouse, 2002). The organic material is converted to a gas rich in CO and H_2. The inorganic residue is melted into a slag. Many companies have built and tested plasma systems for waste treatment.

PyroArc Technology. This technology incorporates a gasifier followed by plasma combustion of the gasifier off-gases. The temperature in the first stage is about 1000°C, and in the plasma reactor, the temperature is can be up to 5000°C (Gustavsson *et al*., 2005).

RESHMENT® Process. The material is size reduced to <5 mm and fed to the furnace, which is at ~2000°C. Oxygen is provided to assist in oxidizing the decomposition products of the organics. In the process, the metal oxides are reduced and the energy is used to produce electricity (Sauert *et al*., 2001, 2005).

Thermoselect Process. This process employs a fixed-bed oxygen-blown gasifier. It is used mostly for processing MSW (Stahlberg *et al*., 2002; also see Drost *et al*., 2004). A trial, using over 900 tons of shredder residue mixed with MSW, was conducted.

A plant for gasifying 350,000 tons of shredder residue to produce 40 MW of electricity is being developed by innovative environmental solutions (IESs)-a joint venture between European metal recycling (EMR) and Cranford, New Jersey (Waste Management World, 2012). The plant uses the "RODECS" recycling and gasification technology. The gasification process operates in the temperature range of 450–600°C. The generated gas is then heated and conditioned at temperature between 1200 and 1400°C to produce an "ultra-clean synthetic gas" (Waste Management World, 2012).

8 RECYCLING OF POLYMER COMPOSITES

8.1 Overview

Polymer composites can be made with a thermoset or thermoplastic polymer. The two major fiber composites used in the automotive industry are glass-fiber- and carbon-fiber-reinforced polymer composites. Carbon-fiber-reinforced polymer-matrix composite (PMC) has high strength-to-weight ratios. Therefore, they are ideally suited for use in the automotive applications. Because these composites are made to meet very strict properties, recycling of these materials and particularly their valuable carbon fibers should avoid significant degradation of their properties. Aggressive thermal or chemical treatment can degrade the properties of the fibers and destroy the polymer (Sunderland, 2001; Teodorescu, *et al*., 2008). Generally, the value of the polymer is small compared to the value of the carbon fibers. The recycling processes that can be used are:

- direct recycling methods,
- thermal pyrolysis to liberate the carbon fibers, and
- chemical or solvent methods to dissolve the thermoplastic resin and recover both the fibers and the resin.

One type for direct recycling involves shredding the carbon-fiber-reinforced PMC scrap to a fine powder and using the fine powder in the making of polymeric compounds such as sheet molding compounds.

Pyrolysis methods were developed by several organizations. ELG Carbon Fiber Limited acquired Recycled Carbon Fibre Ltd. (RCF) is claimed to be the first company worldwide to build and operate a commercial plant for recycling carbon-fiber-reinforced plastics (ELG, 2013). The value of the polymer in carbon-fiber composites is insignificant compared to the value of the fibers. Processes for recycling carbon fibers from composites have been developed. Some are discussed later.

Argonne National Laboratory developed a process that involves heating scrap under different environments to degrade the polymer. The process was tested in a batch oven and in a continuous thermal reactor (Jody, Pomykala, and Daniels, 2003a; Jody *et al*., 2004). Over 90% of the polymer can be removed in a few minutes. However, removing the remaining 1% or 2% requires additional treatment at different temperatures and oxygen environments. Samples of carbon fibers recovered from known "control" panels

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto164
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

were evaluated. The results showed that the carbon concentration on the surface of the recovered fibers is essentially the same as that for the treated virgin surface. The mechanical properties of the recovered fibers were also comparable to the mechanical properties of virgin fibers from the same lot. No significant change in the relative concentration of functional groups on the surface was observed.

Adherent Technologies Incorporated developed wet chemical processes that degrades the polymer and produces a "99+% clean fiber without degrading the fiber strength." Adherent Technologies has a pilot plant that can process about 45 kg of composite scrap per batch (Adherent, 2012, 2013). In this process, the PMC is broken down in a liquid under milder conditions than those used in pyrolysis to free the fibers. The process uses off-the-shelf chemical equipment (Adherent, 2013). It is also reported that the process is suitable for all fiber-reinforced composite materials. However, its economic competitiveness is established only when processing carbon-fiber-reinforced polymer composites.

Boeing and BMW reported that they have agreed to jointly work on developing process for recycling carbon fibers and to share information about carbon fiber materials and manufacturing (Boeing, 2012). It was also reported that the University of Leeds, United Kingdom, and their industrial partners have developed a combined pyrolysis/physical separation process for recycling PMC waste materials. In this process, the fibers are recovered and the polymers are converted to oil (m.com, 2013).

9 LANDFILLING OF THE NONRECYCLABLE MATERIALS

One hundred percent recycling of ELV polymer and composite materials is not technically or economically attainable. Some left over material will have to be landfilled. Worldwide regulations are calling for more recycling and less landfilling. In addition to the environmental issues associated with landfills, cost of landfilling is rising and will reduce the profitability of some metal recycling operations that result in large amounts of residue that has to be landfilled.

On the positive side, landfills contain huge amounts of polymers, metals, and other materials that could be recovered once cost-effective and environmentally friendly technology is available (American Recycler, 2008).

10 CONCLUSIONS

Shredder residue is a complex mixture of materials, and the cost-effective separation and recovery of materials and polymers from it has been a challenge. Nonetheless, through continued research, several technologies have reached advanced stages of development. The two areas that received the most attention are (i) recovery of the polymers for reuse as polymers and (ii) conversion to fuels and energy. Most of the technologies start by separating the polymers from shredder residue as a concentrate before technologies to separate individual polymers can be recovered. Processes to recycle polymer composites have been developed. These focus primarily on recovering the fibers, which are more valuable.

Many of the processes for recovering the polymers also recover the residual metals in shredder residue. The value of the residual metals improves the economics of the recycling process. Researchers have tested several separation technologies at a relatively large scale. Polymer separation technologies have successfully separated and recovered the polyolefins and engineered plastics (such as ABS) from the polymer concentrate. Dry and wet processes have also succeeded in separating and recovering a mixed-rubber fraction. Gasification and pyrolysis processes have proved that "fuels" can be produced from the automotive polymers.

Despite recent technical advancements, most of shredder residues are still disposed of in landfills or by incineration. Developing economic technology to remove the SOCs is another milestone that must be accomplished before technologies can be commercialized. An efficient and economical solution to recycling shredder residue is likely to be an integrated system of many technologies to produce quality products at the lowest cost.

Please note that the abstract and keywords will not be included in the printed book, but are required for the online presentation of this book which will be published on Wiley Online Library (http://onlinelibrary.wiley.com/). If the abstract and keywords are not present below, please take this opportunity to add them now.

The abstract should be a short paragraph of between 150–200 words in length and there should be 5 to 10 keywords

Abstract: Each year, more than 25 million vehicles reach the end of their service life throughout the world, and this number is rising as the number of vehicles on the road is increasing. In the United States, over 95% of the more than 10 million vehicles scrapped annually enter a comprehensive recycling infrastructure that includes auto parts recyclers (dismantlers), remanufacturers, and material recyclers (shredders). Over 75% of the automotive materials, primarily metals, are profitably recycled. Automobiles are the largest source of recycled ferrous scrap for the iron and steel industry. The scrap processors recover metal scrap from automobiles by shredding the obsolete automobile hulks, along with other obsolete metal-containing products and recovering the metals from the shredded material. The nonmetallic fraction that remains—commonly called *shredder residue*—constitutes about 25% of the weight of the vehicle, and most of it is landfilled.

In the past two decades, research and development has been undertaken to enhance the recycle rate of end-of-life vehicles (ELVs), including improving dismantling techniques and remanufacturing operations. However, most of the effort has been focused on developing technology to separate and recover the polymers from shredder residue. To make future vehicles more energy efficient and to meet the new Corporate Average Fuel Economy (CAFE) regulations, more lightweighting materials—primarily polymers and polymer composites, high strength steels, and aluminum—are being used by the automobile industry. The nonmetallic materials increase the percentage of shredder residue that must be disposed of, compared with the percentage of metals that are recovered. Therefore, recycling of automotive polymers will be more important in the future. In addition, recycling the polymers and the composites has the following additional benefits: (i) conserves valuable resources of materials and energy, including the energy consumed in manufacturing automotive materials; (ii) provides lower cost materials to industry; (iii) reduces the amount of waste going to the landfill; and (iv) reduces greenhouse gas (GHG) emissions.

The future will also bring an increase in hybrid and electric vehicles. This will introduce new materials for disposal, including batteries. Recycling the new materials presents technical and economic challenges to the existing automotive recycling infrastructure. New technologies will be required to sustain and maximize the ultimate recycling of the vehicles.

Automotive Environmental Life Cycle Assessment

Lynette W. Cheah

Singapore University of Technology and Design, Singapore

1 INTRODUCTION

The automotive industry is one of the world's largest manufacturing sectors, whose products are widely pervasive in our daily lives. The world vehicle population topped one billion in 2010 (Sousanis, 2011), and is expected to continue growing. Cars and trucks enable personal mobility and provide economic opportunity for billions of people. However, they also contribute to complex urban planning, environmental, and health challenges. The production of motor vehicles requires significant amounts of energy and material resources. Their popular use leads to traffic congestion, urban air and noise pollution, global warming, and increases the demand for oil. Worldwide, automobiles are estimated to be responsible for around 20% of carbon dioxide releases, a greenhouse gas that contributes to global warming, and 60% of the world's oil consumption (Figure 1) (IEA, 2010).

The notion of sustainability is undoubtedly an important consideration for the automotive industry. Automakers are facing pressures in the form of rising material and oil prices, more stringent air emissions regulation, and a push for greater fuel efficiency in vehicles. Addressing these challenges will require new vehicle designs and technologies. One useful tool or approach to evaluate the environmental impacts of these new innovations is life cycle assessment (LCA).

LCA is a systematic environmental accounting methodology, which helps quantify and evaluate the environmental impacts associated with a specific service, manufacturing process, or product over its entire life cycle. For a product such as an automobile, the assessment considers its complete life cycle, from the extraction of raw materials needed until the point at which all residuals are returned to the environment. The environmental impacts are considered over each of the product's life cycle phases, or from "cradle to grave".

An assessment of an automobile's environmental performance should consider the impact over its entire life cycle. This accounts for not only the effects of operating an automobile but also other upstream and downstream effects in its life cycle. Adopting such a life cycle perspective is more holistic and can assist in optimizing the environmental performance of an automobile. It can also be used to compare different vehicle technologies and determine the more environmentally favorable alternatives.

In this chapter, we will first review the key life cycle phases of an automobile as shown in Figure 2. We will then elaborate on the steps needed to carry out a full automotive LCA. The next section will report the results of the LCA, before we arrive at the key conclusions on the life cycle impact of automobiles.

2 AN AUTOMOBILE'S LIFE CYCLE STAGES

2.1 Raw material acquisition and processing

Let us begin by exploring each of an automobile's life cycle stages in further detail. To begin to build an automobile, mineral resources are first mined from the earth and processed into usable materials that are needed. Current automobiles are made of a mix of materials, mostly metal (around 75% by mass).

Table 1 shows the material breakdown of a typical compact gasoline car, which weighs around 1230 kg (scaled down from data reported in (Ward's Communications, 2010)). Dominant metals used are steel, iron, and aluminum. Other key automotive materials include plastics and polymer composites, rubber, and glass.

2.2 Component manufacturing

In the next stage of an automobile's life cycle, automotive parts are fabricated using semifinished materials and energy resources. For metallic components, forming operations such as stamping, extruding, casting, or machining are applied to derive the final shape and properties. For example, the engine block in an automobile is usually sand-casted out of iron or aluminum alloys. Plastic components, such as the automobile's instrument panel and interior trim panels, are molded (Figure 3).

2.3 Vehicle assembly

Next, automotive components are put together within an assembly plant to make a finished car. This stage also

Zinc	3	0.2
Powder metal parts	14	1.1
Other metals	2	0.1
Plastics and composites	128	10.4
Rubber	71	5.7
Coatings	11	0.9
Textiles	18	1.4
Glass	31	2.5
Other materials	30	2.4
Total	1235	100.0

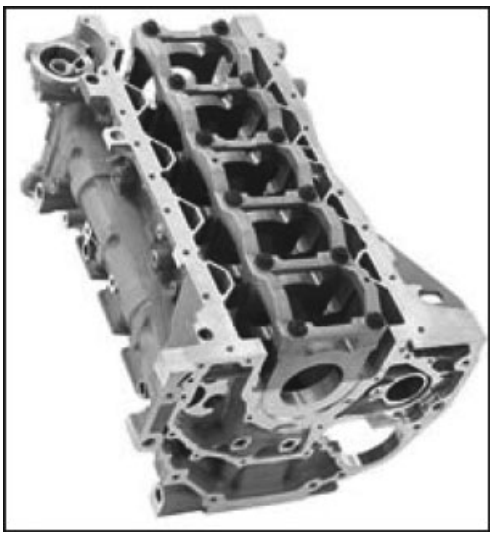

Figure 3. An aluminum engine block.

includes the processes of body welding and painting. Figure 4 portrays the set of activities that are covered during this assembly stage as well as the manufacturing stage of the automobile's life cycle.

2.4 Transportation/distribution

Transportation involves the movement of parts, components, subassemblies, or complete automobiles in between each of the automobile's life cycle stages. There are transport needs to supply the thousands of automotive parts and

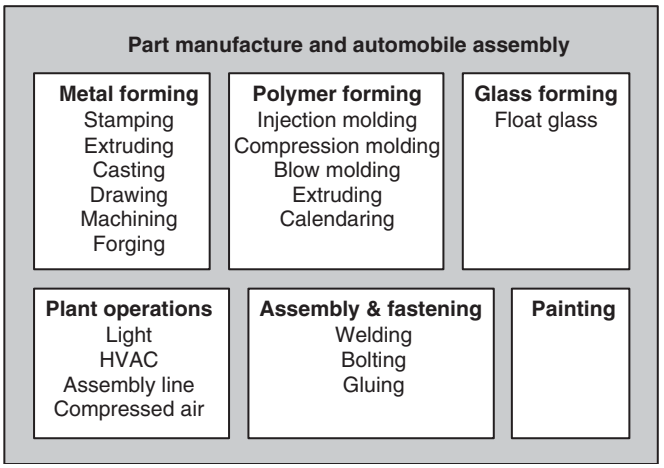

Figure 4. Activities in automobile's manufacture and assembly stages. (Reproduced from Sullivan, Burnham and Wang, 2010).

components to automotive manufacturers. Newly built automobiles are transported by rail, freight truck, or shipped to distributors, and are then forwarded to auto dealerships in order to reach end consumers. After the automobile's use phase, retired automobiles are eventually hauled to the scrappage and recycling facility (junkyard).

2.5 Use or operation

During its operation, an automobile is driven and refueled by the user to provide mobility. The total distance driven over its operation stage varies depending on the user. In the United States, this lifetime distance is estimated to be around 245,000 km (NHTSA, 2006) and has increased over the years. A typical automobile has a long service lifespan of around 10–15 years.

2.6 Fuel production and distribution

This stage of the life cycle relates to the production and supply of fuel needed over the automobile's use phase. It includes feedstock recovery, processing, storage, and transportation, followed by fuel production, transportation, storage, and distribution. The most common feedstock is crude oil (petroleum) and it is used to produce gasoline (petrol) and diesel fuels, among others. Alternative transportation fuels include compressed natural gas (CNG) and biofuels. Electricity is also an option for electric vehicles (EVs). For EVs, this stage will include the upstream activities of generating, transmitting, and distributing electricity used to charge them. Figure 5 shows various feedstock and fuel pathways that may be used to derive transportation fuels.

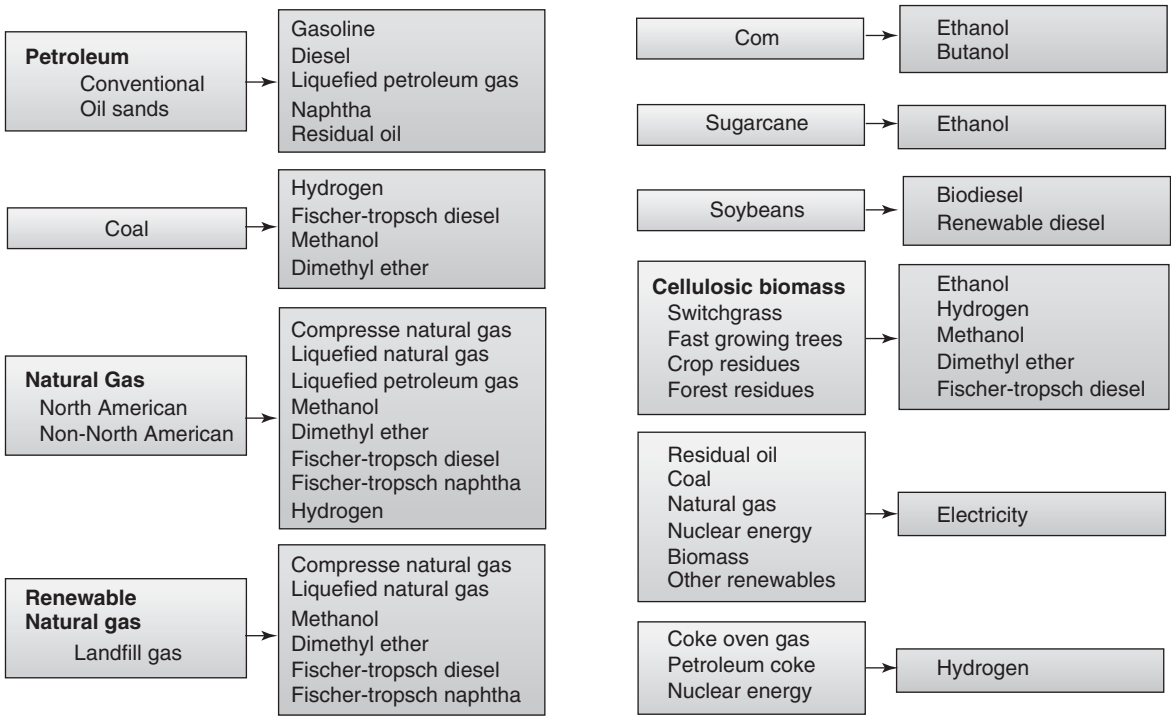

Figure 5. Possible fuel pathways, indicating fuels and electricity produced from various energy feedstock sources. (Reproduced from UChicago Argonne LLC, 2011.)

2.7 Vehicle maintenance

While the automobile is in use, maintenance processes and replacement parts are required to keep the automobile in safe, running condition and to maintain operability. These include replacing spark plugs, windshield wipers, tires, engine oil, and brake fluids, among others.

2.8 Disposal (end-of-life)

When the automobile arrives at the end of its service life, it is sent to a dismantler to remove parts that may be reused. Operating fluids and the battery are removed for recycling or proper disposal. The remaining automobile hulk, which refers to the remains of the end-of-life vehicle that is inoperable, is shredded, and metals are separated out and recycled. The remaining mix of materials is called *automotive shredder residue* (*ASR*), which is disposed of by way of landfill or incineration. Most of the automobile, being metallic, ends up being recycled. In Europe, there is an end-of-life vehicles (ELV) directive that targets 85% of an automobile's mass to be reused or recycled by year 2015.

3 LIFE CYCLE ASSESSMENT (LCA) STEPS

With an understanding of the automobile's life cycle stages, one can now begin to analyze its overall environmental impact. The International Organization for Standardization (ISO), a worldwide federation of national standards bodies, has standardized the evaluation framework for carrying out a LCA study under the series ISO 14040. According to this standard, an LCA involves four general interlinked steps:

1. Goal and scope definition;
2. Life cycle inventory (LCI) analysis;
3. Life cycle impact assessment; and
4. Interpreting the results.

Let us look into each of these steps for an automotive LCA (Figure 6).

3.1 Goal and scope definition

To begin, the LCA's purpose or study objectives should first be articulated. The project scope and system boundary are to be defined. This involves specifying the geographical and temporal scope of the project—the location and timeframe

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto165
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

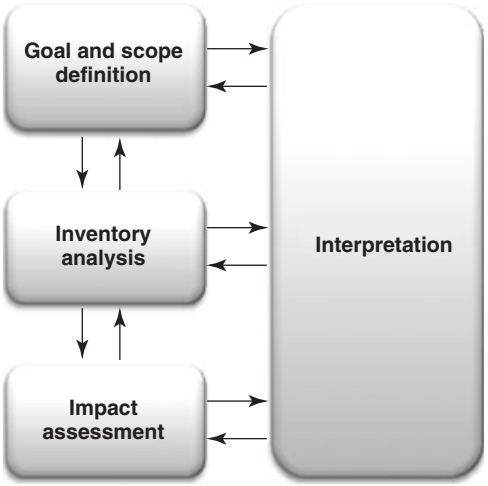

Figure 6. General life cycle assessment steps. (Reproduced from ISO, 2006. Permission to reproduce extracts from British Standards is granted by the British Standards Institution (BSI). No other use of this material is permitted.)

Table 2. Various boundaries for automotive LCA studies.

LCA Scope	Boundary Definition
Cradle to grave	Full life cycle assessment, includes all phases of the automobile's life cycle (#1–10 in Figure 2)
Cradle to gate	Partial life cycle assessment from resource extraction until the car factory gate, before it is transported to customers (#1–3 only)
Well to tank	Upstream impacts of fuel production and distribution (#6 only)
Tank to wheel	Impacts associated with driving the automobile only (#5 only)
Well to wheel	Also called the *fuel cycle*. Includes "well-to-tank" as well as "tank-to-wheel" impacts (#5 and #6)

of the analysis—as well as the system boundary, or consideration of what is or is not included in the study. Some common boundaries for assessing automobiles are shown in Table 2.

The functional unit for the LCA study should also be specified. The functional unit is the quantified performance of the automobile which is used as a reference unit in the study. One typical functional unit in an automotive LCA study would be distance traveled, say, in kilometers. So, the environmental impacts of the automobile are expressed per kilometer of travel. Other possible functional units could be simply impact per single automobile, or impact for an entire automobile fleet.

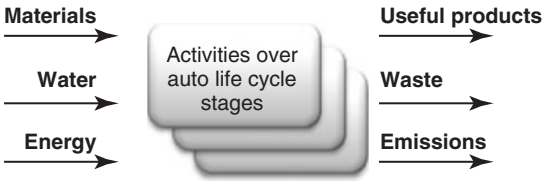

Figure 7. Life cycle inventory (inputs and outputs).

3.2 Automotive life cycle inventory (LCI)

The next step of an LCA is to compile a comprehensive inventory of the energy and raw materials inputs, as well as environmental releases (outputs or burdens) to the air, land, and water throughout the vehicle's life cycle phases of interest. All energy and material input and output flows of interest, based on the predefined study scope, are to be identified and quantified. The LCI is akin to an environmental balance sheet (Figure 7).

To illustrate the compilation of LCI, Table 3 shows the energy and emissions inventory for making stamped steel sheets that are used in automobiles (Burnham, Wang, and Wu, 2006). This inventory arises from steelmaking, as well as component fabrication. The LCI data are usually expressed per unit mass of material, in this case, per kilogram of steel product. Similar information is to be collected and organized for all other components within the automobile.

During the automobile's use phase, one aspect of the LCI is associated with the production of fuel. This "well-to-tank" (WTT) LCI depends on the fuel type and pathway

Table 3. Energy and emissions related to stamped steel production.

Life Cycle Inventory of Steelmaking	
Energy use: MJ per kg of steel product	
Total energy	37.41
Fossil fuels	35.65
Coal	15.20
Natural gas	19.51
Petroleum	0.94
Total emissions: grams per kg of steel product	
VOC	0.33
CO	39.92
NO*x*	2.85
PM10	6.10
PM2.5	2.47
SO*x*	2.73
CH_4	5.15
N_2O	0.03
CO_2	3005
CO_2-eq (VOC, CO, CO_2)	3050
Greenhouse gases	3188

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto165

taken to get from raw source (e.g., crude oil for fossil fuels) to the refueling station. Figure 8 shows the WTT greenhouse gas (GHG) intensity for different types of fuels that may be used in California (California Air Resource Board, 2009). This is expressed in grams of carbon-dioxide-equivalent GHG released during the production of fuel needed to deliver one megajoule of energy (gCO_2-eq/MJ). In the instance of gasoline, this includes the GHG emissions that occur over the processes of recovering and transporting crude oil to a typical refinery in California, gasoline storage, and transportation.

Over the automobile's long service life, the use of fuel forms a significant part of the automobile's LCI. One simple way of estimating the amount of fuel used is by taking the product of the automobile's average fuel consumption, usually expressed in liters per 100 kilometers (L/100 km), and the distance traveled over its service life. Another common reciprocal metric used to rate the fuel efficiency of the automobile is its fuel economy, expressed in mileage achieved per gallon of fuel (miles per gallon, or MPG). Depending on the type of automobile—size, segment, powertrain—and how it is driven, its fuel consumption would vary. Figure 9 shows the ranges of rated fuel consumption (in gasoline-equivalent liters) for various types of automobiles available in the US market, based on a representative drive cycle that includes a combination of urban and highway driving. In general, larger and heavier automobiles consume more fuel. Automobiles that run on

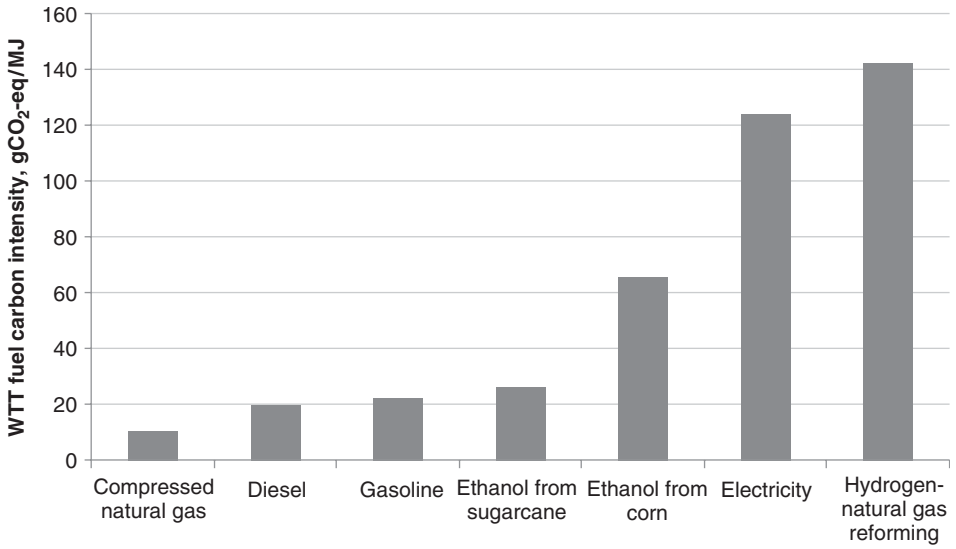

Figure 8. Well-to-tank greenhouse gas intensity of transportation fuels used in California. (Data source: CARB, 2009.)

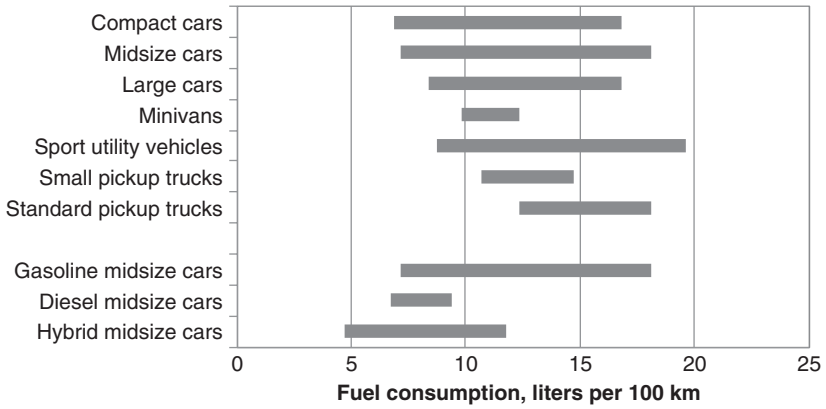

Figure 9. Ranges of the rated fuel consumption for model year 2012 vehicles sold in the United States. (Based on data from EPA, 2013.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto165
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

diesel would consume 20–25% less fuel than comparable gasoline models. Hybrid electric vehicles, which employ a battery in addition to an internal combustion engine to provide motive force, also consume less fuel. Assumptions made on the automobile's fuel consumption and the total distance traveled over the automobile's lifetime should be explicitly stated in the LCA study.

During the automobile's use phase, other items that contribute to the LCI are fuel and air-conditioning refrigerant losses due to evaporative leakage, as well as replacement parts and fluids that are needed to keep the automobile in running condition. The intensity of resource or material use for automobile maintenance depends very much on the individual customer, and data logging must be carried out, or assumptions made to determine the resulting inventory.

Table 4 below shows an estimated inventory of consumables needed to maintain an automobile over its useful life.

As one may perceive from the above illustrations, the collection of accurate and precise LCI data can be quite onerous. In lieu of collecting data at the source for each automobile, which can be resource- and time-intensive, one can turn to LCI databases. There are several LCI databases available that contain information on a large set of materials and processes. These databases provide proxy data that can help streamline the LCA effort.

For example, the Swiss Centre for Life Cycle Inventories has developed a comprehensive LCI dataset called *ecoinvent* for use in any LCA study. In the United States, the National Renewable Energy Laboratory (NREL) leads an effort to maintain a US LCI database for producing materials, components, or assemblies in the United States. The US Argonne National Laboratory has also made available another Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation (GREET) model, which was specifically developed to assess automobiles. The GREET model includes the energy and emissions inventory for producing various components used in automobiles, which was derived from the literature. It also includes the effects of automobile assembly and eventual disposal or recycling.

There are, however, inherent challenges with using LCI databases. The geographical and temporal context or scope of the study might differ from that compiled in the database. Uncertainties in LCI data also exist: precise information on material use in automobiles is lacking, given the large number (thousands) of automotive components and suppliers. The use of materials in automobiles also differs across models and is constantly evolving. An acknowledgment of LCI data uncertainties in any automotive LCA study is therefore important. Part of this LCA step includes referencing the use of databases, if any, and clearly stating all assumptions made in estimating the inventory.

Table 4. Automobile maintenance inventory—estimated replacement parts.

Replacement Part or Fluid	Quantity	Unit
Brake fluid	3	Liters
Engine coolant fluid	22.2	Liters
Engine oil	78.1	Liters
Transaxle fluid	28	Liters
Windshield cleaner fluid	44	Liters
Air filter	4.3	Pieces
Battery	1.7	Pieces
Brake pads	1	Sets
Drive belt	2	Pieces
Lamp bulbs	3.5	Pieces
Exhaust system	1	Sets
Oil filter	15.7	Pieces
PCV valve	2	Pieces
Shock absorbers	1	Sets
Spark plugs	16	Pieces
Tires	2	Sets
Transaxle fluid filter	1	Pieces
Windshield	1	Pieces
Windshield wiper blades	18.7	Pieces

3.3 Life cycle impact assessment (LCIA)

After the automobile's life cycle inventory is compiled and documented, the environmental burdens and/or human health impacts associated with the resource inputs and environmental releases are assessed. On the basis of the study scope, the impact categories should have already been defined. These could be single metrics such as the automobile's net life cycle energy use, or emission amounts. Alternatively, quantitative results of the auto LCA may be presented as aggregated values within environmental themes, also known as *categories*. Examples of these categories are the automobile's impact on human toxicity, terrestrial toxicity, ozone depletion, aquatic eutrophication, aquatic acidification, or global warming. There are also various impact indicators that attempt to represent the automobile's impacts in composite scores, such as Eco-indicator 99, or Impact 2002+.

Impact 2002+, for instance, is a LCIA methodology that interprets life cycle inventory results to four "damage" categories—human health, ecosystem quality, climate change, and resources (Jolliet *et al.* 2003). The overall framework for Impact 2002+ is shown in Figure 10, which links LCI results via "midpoint" categories to "damage" categories. The damage units are also indicated in this figure.

4 AUTOMOTIVE LCA RESULTS

In an LCA study, the final step of interpretation accompanies the results of the inventory and impact assessment, in relation to the objectives of the study. This involves reviewing, analyzing, and reporting the results. Explaining assumptions and limitations of the study, as well as generating recommendations are also part of this step.

Let us now consider two simple case studies to illustrate the application of LCA to automobiles and interpretation of the results. The cases are: (i) assessing the life cycle GHG emissions of a conventional gasoline car, followed by (ii) a comparative assessment of electric cars in the United States.

Various LCA modeling software titles are available to help practitioners carry out LCA studies. These include SimaPro, GaBi, Quantis Suite, Umberto, and openLCA, among others. These software packages usually integrate the use of LCI databases and impact assessment methods to help users derive results and generate reports more readily. In the following two case studies, none of the mentioned LCA software packages were used, however. The datasets are instead compiled and results prepared using spreadsheets.

4.1 Life cycle greenhouse gas emissions of a gasoline car

Let us first examine an average compact gasoline car that is driven in the United States. Being specific about the location where the automobile is used would provide indication of its use characteristics, such as lifetime distance driven and average fuel consumption. All of the previously discussed automobile's life cycle stages (shown in Figure 2) will be included within the "cradle-to-grave" scope of this case study. In addition, the following key assumptions will be made:

- The car's curb weight, or weight without passengers or cargo, is 1235 kg;
- The material breakdown of the car is as shown in Table 1;
- Life cycle GHG emissions inventory data are obtained primarily from the GREET database;
- The car has an average fuel consumption of 7.8 L/100 km, or 30 miles per gallon (MPG); and
- Distance traveled over its service life is 245,000 km (152,000 miles).

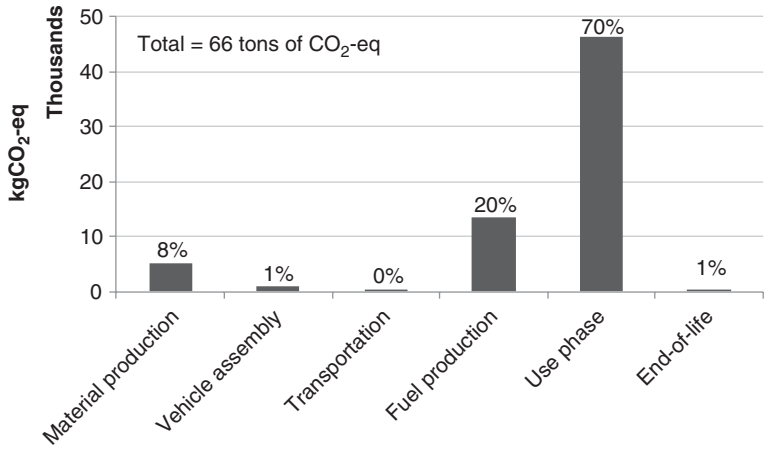

Figure 11. Life cycle greenhouse gas emissions of an average automobile, by life cycle stage.

Other assumptions relating to this LCA case study are detailed in the Appendix A.

The resulting GHG emissions by life cycle stage from an average US compact gasoline car are shown in Figure 11. The emissions are reported in the form of kilograms of carbon-dioxide-equivalent (kg CO_2-eq). Over its life span, an automobile is estimated to emit 66 metric tons of CO_2-eq. While GHG emissions arise at every stage of an automobile's life, combustion of fuel (gasoline) during automobile use accounts for the greatest share of emissions. The automobile's long use phase thus dominates (70%) its life cycle impact. The next most dominant stage is fuel production and distribution (known as *fuel cycle* or "*WTT*" *stage*, 20%), followed by material production (8%). The GHG emissions arising from the other life cycle stages—component manufacturing and vehicle assembly, transportation, maintenance, and end-of-life disposal stages, are modest (2%).

4.2 Life cycle greenhouse gas emissions of electric cars

Unlike a conventional gasoline car that relies on an internal combustion engine in its powertrain, a fully electric vehicle (EV) uses an electric motor as well as an onboard energy storage device, such as a battery, to provide motive force. Without a need to combust fuel within the vehicle, EVs have zero "tailpipe" emissions during their use phase and are generally more energy efficient.

Assessing the environmental impact of EVs is more complex and underscores the importance of a life cycle perspective. Several more inputs are required to understand the electric car's impact, in particular, the user's charging pattern and the emissions associated with generating, transmitting, and distributing electricity used to charge the automobile.

Let us now compare the life cycle impact of two similar electric cars, again in the United States. One will be charged and driven primarily within the State of California, and the other in the US Midwest. The scope will be as before—all of the previously discussed automobile's life cycle stages will be included, and the following assumptions will be made:

- The electric car is a compact car with a 100-mile range;
- Its curb weight is 1535 kg, which includes a 300-kg lithium ion battery;
- The material breakdown of the electric car is as shown in Table A.1;
- When driven, it consumes energy at an average rate of 760 kJ/km;
- Distance traveled over its service life is 245,000 km (152,000 miles);
- The GHG emissions intensity of the California electricity grid is 124 gCO_2-eq/MJ. In the Midwest, this is 2.5 times higher at 314 gCO_2-eq/MJ, due to greater reliance on coal-fired power generation; and
- The electric car's battery will be replaced once over its lifetime.

On the basis of these inputs, the total life cycle GHG emissions from the two electric cars are shown in Figure 12, and benchmarked against that previously estimated for the gasoline car. It is found that electric cars emit more GHG during their material processing and manufacturing phases compared to a conventional gasoline car, due to the additional resources and materials required in the battery and

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

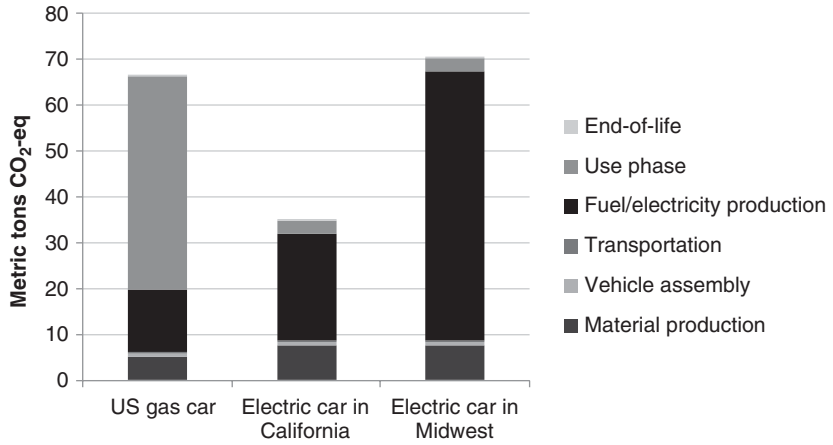

Figure 12. Life cycle greenhouse gas emissions of gasoline versus electric cars in the United States.

electric motor components. As before, emissions associated with vehicle assembly, transportation, maintenance, and end-of-life disposal are trivial.

The upstream or "WTT" phase of producing electricity used to charge these vehicles is observed to dominate their life cycle emissions. This can be significant, depending on the fuel mix used to generate electricity. In the Midwestern states in the United States, the grid relies predominantly on coal to generate electricity, which is carbon-intensive. As a result, an electric car in the Midwest would tend to emit more GHG over its life span compared to a comparable conventional gasoline car of similar size. In contrast, California's electricity generation mix features natural gas, nuclear, hydroelectric power, and renewable sources of energy, which do not emit as much GHG. In this case, driving an electric car does offer GHG savings over the benchmark gasoline automobile.

Using LCA, this case study illustrates how the net GHG emissions associated with electric vehicles depend very much on the nature of the regional electricity grid where they are located and can vary significantly.

5 SUMMARY AND DISCUSSION

LCA is a data-intensive, systematic evaluation of the environmental consequences of manufacturing, driving, and disposal of an automobile. It quantifies the environmental impact in each life cycle stage, from the extraction of raw materials, until the automobile's disposal and waste treatment. This method involves defining the scope of the study, compiling the inventory of energy and material inputs and environmental releases, assessing the environmental impact associated with the inventory, and interpreting the results.

Applications of Automotive LCAs

- Vehicle design for environment
- Material selection
- Environmental performance tracking
- Comparing new vehicle technologies

LCA can be used to assess the environmental performance of new vehicle design concepts, or the impact of new automotive material choices. This methodology can also be used to establish a baseline and track the environmental performance of vehicle models over time. One other application of automotive LCAs is to assess the net impact that result from alternative vehicle technologies and compare them with existing solutions. For example, we compared gasoline versus electric cars in one of the two case studies examined earlier in this chapter.

Using LCA, it has been found that for conventional fossil-fuel-driven automobiles, their life cycle impact is dominated by the impacts arising over their long use phase. Around 70% of total life cycle greenhouse gas emissions are estimated to result from combusting fuel needed to drive the automobile. Improving fuel efficiency is therefore an important focus area, in order to reduce the automobile's energy and environmental footprint. For electric cars, their life cycle impact is dominated by the impacts arising from electricity generation. Depending on the source of energy used to generate the electricity, their environmental performance would vary.

As we consider the automobile's lifespan and the entire set of activities, it is clear that its environmental impact is not controlled by a single company or consumer. The environmental profile of the automobile depends on the

DOI: 10.1002/9781118354179.auto165
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

environmental performance and decisions made by companies involved across its supply chain, from component manufacturers to oil companies, original equipment manufacturers (OEMs), and even highway administration, which affect the way an automobile is driven. Not only is LCA a tool to identify vehicle design aspects to focus on, it also helps identify relevant stakeholders that can influence the environmental performance of automobiles on our roads. Using findings from LCA studies to generate recommendations and engage stakeholders is thus a valuable follow-on activity.

APPENDIX A

Case study assumptions

Additional assumptions to assess the life cycle GHG emissions from an average gasoline car:

- For the raw materials processing stage,
  - The GREET database is used to derive the life cycle inventory data (Table A.2).
- For the automobile assembly stage,
  - 889 $kgCO_2$-eq is emitted (Sullivan, Burnham, and Wang, 2010).
- For the transportation stage,
  - Details on the distances, modes of transportation, and GHG intensity are shown in Table A.3. Only the following links are accounted for:
    - Transportation of iron and steel from domestic suppliers to a domestic auto manufacturer;
    - Transportation of automotive components from global suppliers to a domestic auto manufacturer;
    - Transportation of finished car from assembly plant to dealership;
    - Transportation of retired car from consumer to junk yard.
- For fuel processing,
  - The WTT impact is 22 gCO_2-eq/MJ of gasoline delivered;
  - The heating value of gasoline is 32 MJ/L.
- For the use stage,
  - The tank-to-wheel impact is 73 gCO_2-eq/MJ of gasoline used.
- For automobile maintenance (included in use stage), only the following processes are accounted for:
  - Replacement of fluids and lubricants;
  - Two battery replacements;
  - Two sets of tire replacements;
  - This additional inventory leads to 1755 $kgCO_2$-eq of emissions.
- For eventual automobile disposal,
  - 314 $kgCO_2$-eq is emitted (Burnham, Wang, and Wu, 2006).

Table A.1. Material breakdown and GHG intensity of a pure electric car.

Material	kg	$kgCO_2$-eq/kg Material
Iron	66	0.54
Regular steel	423.39	3.19
	156.95	3.19
High strength steel	179	5.35
Aluminum	91.86	6.89
	76.30	6.89
Copper and brass	123	8.48
Nickel	8	7.91
Cobalt	8	7.91
Lithium oxide (LiO_2)	16	7.91
Manganese	8	8.83
Graphite/carbon	32	14.87
Plastics	149	4.75
Rubber	23	3.19
Glass	35	1.56
Fluids and lubricants	84	7.60
Electrolyte	26	1.75
Other materials	31	7.60
Total mass, kg	1535	—
Total GHG, $kgCO_2$-eq	—	7589

Table A.2. GHG intensity of automotive material processing.

Material	$kgCO_2$-eq/kg Material
Regular steel	3.19
High strength steel	5.35
Other steels	3.19
Iron	0.54
Aluminum	6.89
Magnesium	28.59
Copper and brass	8.48
Lead	0.63
Zinc	8.83
Powder metal parts	6.17
Other metals	6.17
Plastics and composites	4.75
Rubber	3.19
Coatings	7.60
Textiles	4.75
Glass	1.56
Other materials	7.60

For the case study involving electric cars, similar assumptions have been made. In addition:

- For the raw materials processing stage, the material breakdown of the electric car is shown in Table A.1;
- For automobile maintenance (included in use stage), only the following processes are accounted for:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto165
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table A.3. Case study: details of automobile's transportation stage.

Item	Origin–Destination	Distance (km)	Mode	GHG Intensity ($kgCO_2$-eq/ton-km)
Iron and steel	Pennsylvania–Michigan	1020	Rail	0.05
All other	China–Michigan	11,810	Ocean freight	0.01
materials/parts		3670	Rail	0.05
Finished car	Michigan–California	3670	Truck	0.21
Retired car	Household–junkyard	100	Truck	0.21

- One Li-ion battery replacement;
- Two sets of tire replacements;
- This additional inventory leads to 3049 $kgCO_2$-eq of emissions.

Intelligent Transport Systems: Overview and Structure (History, Applications, and Architectures)

John C. Miles
Ankerbold Consulting, Nailsworth, Gloucestershire, UK

1 INTRODUCTION

Intelligent Transport Systems (ITS) is a generic term for the integrated application of communications, control, and information processing technologies to the transportation system. Computers, electronics, satellites, and sensors are applied to the performance of transport operations and for traffic management, journey planning, and vehicle control. The benefits are various, the most important being greater safety, efficiency, and convenience. Successfully applied, ITS can bring time, cost, and energy-efficiency gains. ITS can also help to inform travelers about their journeys, improve interconnections between different transport modes, and contribute directly and indirectly to environmental sustainability.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto166
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

> ITS covers all modes of transport and consider all elements of the transportation system – the vehicle, the infrastructure and the driver or user, interacting together dynamically. . . . The definition encompasses a broad array of techniques and approaches that may be achieved through stand-alone technological applications or as enhancements to other transportation strategies. (Chen and Miles, 2004)

The applications of ITS are often grouped into bundles, based largely on the acronyms used in the early days of ITS:

- Advanced Traffic Management Systems (ATMS)
- Advanced Traveler Information Systems (ATIS)
- Advanced Vehicle Control Systems (AVCS)
- Commercial Vehicle Operations (CVO)
- Advanced Public Transport Systems (APTS)
- Electronic Payment Systems (EP)
- Security and Safety Systems (SSS)

ITS in all these forms have become central to efficient transport operations and the relief of road traffic congestion. Computer systems for traffic management are widely used to ensure maximum efficiency of the road network: for example, the coordination of traffic signals to minimize delays or by detecting and managing incidents on the highway network. Electronic payment, access control, and enforcement systems also rely on ITS technologies and are applied to automatic tolling, road pricing, and congestion charging. People experience the benefits of ITS through satellite navigation and a variety of travel and traffic information services. In-vehicle and portable navigation devices (*SatNavs*) give door-to-door route guidance with remarkably detailed turn-by-turn instructions to the driver. Web sites are available for door-to-door

journey planning with advice on travel mode and route choices. There are roadside electronic dynamic message signs to provide important safety and traffic information to drivers; automated traffic alerts are sent by text message or digital coding to smartphone handsets and car radios.

The information on traffic and transport is becoming ever more immediate and ubiquitous. Real-time travel information will include coverage of current point-to-point journey times, current and forecast traffic and weather conditions, and information on service disruptions. Traffic camera images at congestion hot spots can be viewed remotely on smartphones and mobile handsets over the Internet. All these are examples of ITS-based information services that bring benefits though better journey planning, improved navigation, or more efficient fleet management and logistics.

Other applications of ITS include:

- traffic signal and speed enforcement using camera-based systems for vehicle license plate/number plate recognition;
- vehicle safety systems, including adaptive speed control, collision detection, automatic collision notification, and cooperative vehicle-highway systems (CVHS);
- systems that make public transport travel more attractive by providing real-time information at bus and tram stops;
- electronic ticketing systems that are more convenient for passengers and allow the operators to offer flexible, integrated ticketing;
- systems that give priority to public transport vehicles at traffic signals to reduce journey times, improve reliability and punctuality;
- automatic vehicle location systems for fleet managers to monitor service reliability and just-in-time deliveries, with vehicle tracking for stolen vehicle recovery;
- car and truck parking information systems that show availability in real time; and
- air-quality monitoring and management, such as pollution detection and prediction and implementation of strategies to ease air-quality problems.

This chapter traces the development of ITS from its early beginnings through to the present day. It looks at the structure of ITS applications that has evolved and the important role that system architecture has played in providing a framework for these developments.

2 ORIGINS OF ITS

Much of modern ITS technology was originally developed for use on road networks, with computerized urban traffic signal control systems such as SCOOT (Split Cycle Offset Optimization Technique) and SCATS (Sydney Coordinated Adaptive Traffic System). The history of developments that took place in Japan, Europe, and North America will show the origins of ITS and introduce some of the principal components.

2.1 Japan

In Japan, research and development in urban traffic control can be traced back to the initial work on the Tokyo traffic control system, begun in 1967. There followed a steady program to provide signal control across all of urban Japan through a series of 5 year plans, starting in 1971. By 1985, the number of urban traffic control centers operated by the police had reached 74. Separately the Japan Ministry of Construction, with responsibility for road construction and maintenance, had invested extensively heavily in traffic detection and surveillance equipment on the motorways. By 1990, each of the heavily congested metropolitan expressways in Tokyo and Osaka had its own control center. These urban and expressway control centers and the associated investment in traffic monitoring provided an important foundation for the development of ITS in Japan.

Japan also invested heavily in traveler information services. On the urban expressways in Tokyo automated dynamic message signs to warn of congestion first appeared in 1973. Roadside radio began in 1983, broadcasting traffic information with automatically generated voice messages using low power transmitters. Highway advisory radio was widely adopted for traffic information services on the urban expressways and busy downtown areas, even for news about parking space availability.

Along with early investment in traffic control and information systems, Japan was researching navigation systems using ground to vehicle data communications. Development of a Comprehensive Automobile Control System (CACS) began in 1973 and featured an interactive route guidance system using inductive loop antennae and an in-vehicle display unit. This was followed by the Automobile Traffic Information and Control System (ATICS), starting in 1978. ATICS culminated in a demonstration of route guidance systems known as the *Tsukuba experiment* to coincide with the Tsukuba Science Exposition in 1985 (Davis *et al*., 1991).

The next round of development involved the Japanese automotive and electronics industry in two projects to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto166
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

develop car navigation systems: RACS (Road/Automobile Communication System) and AMTICS (Advanced Mobile Traffic Information and Communication System). RACS, begun in 1984 and sponsored by the Ministry of Construction, used a dedicated beacon-based communications system on the expressways. The two AMTICS demonstrations in metropolitan Tokyo and Osaka and initiated by the National Police Agency used commercially available mobile data communications systems. In parallel, the Ministry of Construction was working on development and exploitation of the Japan Digital Roadmap (Kawashima, 1994).

Following the success of RACS and AMTICS, an important initiative emerged to promote in-vehicle navigation as a consumer product, combining route guidance with traffic information. A consortium of Japanese automotive and electronics companies, known as the *VICS Promotion Council* (*Vehicle Information and Communication System*), was formed in October 1991 with the intention of developing a national system to collect and distribute traffic information in real time (Harvey, 1999).

2.2 Europe

Developments in Europe follow similar lines to that in Japan. For example, work on vehicle navigation and route guidance started in the late 1970s in Germany with the ALI system (Autofahrer Leit- und Informationssystem) from Bosch/Blaupunkt, which like CACS in Japan used inductive loops in the roadway to communicate with the vehicles. In addition, in Germany, Siemens developed the AUTO-SCOUT system using infrared communications. The two companies collaborated on ALI-SCOUT, later called *EUROSCOUT* (Sodeikat, 1994), which used infrared beacons for a two-way roadside-vehicle data link. An important feature of ALI-SCOUT was the way equipped vehicles could be used as traffic probes to report their journey times between intersections to a central database, which could be used in real time for route planning to avoid congestion. A large-scale demonstration of ALI-SCOUT was installed in Berlin in 1988 to test these concepts. An operating company COPILOT was formed with the main shareholders Siemens and Bosch to commercially market and roll out the system. Trials began in Stuttgart but the main barrier for success was the necessity to negotiate details of infrastructure and system operation with each city's authority independently. Another barrier was the emerging mobile communication, which allowed for a more flexible communication architecture and (theoretically) faster roll out.

SCOOT, the computerized urban traffic control system that monitors and responds to traffic conditions in real time, was developed at the Transport Research Laboratory in England during the 1980s. Other game-changing research and development (R&D) programs in Europe were PROMETHEUS (1985–1993), which engaged the European automotive industry in a collaborative program of research and DRIVE (1989–1991). Results from both programs were presented at the DRIVE conference held in Brussels in February 1991 with the title *Advanced Telematics in Road Transport* (European Commission, 1991). The significance of DRIVE and PROMETHEUS is considered elsewhere in this encyclopedia (see Evolution and Future Trends).

The ALI-SCOUT technology from Germany formed the basis of the London Autoguide project, first mooted in 1986 and the subject of UK legislation to provide the necessary licensing framework. Legislation was sought because of concerns about the system sending volumes of traffic on inappropriate routes such as residential streets (so-called rat-running) this being a hot political issue in London especially for heavy good vehicles at night. The legislation permitted the Autoguide license to provide "positive-and-dynamic" route guidance to their customers, subject to terms and conditions to be specified in the operating license (Catling, Miles and Harris, 1999).

In the event, the Autoguide project was abandoned in the early 1990s because of a combination of factors, among them a failure to agree satisfactory commercial terms for the selected license. Nevertheless, there was one successful taker for a UK license to provide real-time traffic information on a commercial basis, namely TrafficMaster. An initial pilot scheme was set up in 1990 on the London orbital motorway (M25) using traffic speed sensors mounted on over-bridges at strategic intervals along the motorway, each with a telephone landline to transmit data back to the center. Data for sites with slow-moving traffic (below 50 km/h) were automatically transmitted to subscribers by telephone paging. The TrafficMaster terminal (Figure 1) presented this data to the driver in the form of a monochrome schematic map display, allowing the driver to assess the traffic conditions ahead. Over the next 10 years, some 6000 sensors were installed by this private company across the UK motorway and trunk road network to provide a national coverage. Although modest in its use of technology, TrafficMaster is significant because it was the first example of a fully commercial ITS-based real-time traffic information service.

2.3 North America

Compared with Japan and Europe, North America was fairly late in exploiting the potential of computers to assist

traffic management on city streets. Computerized urban traffic signal control was not introduced to Los Angeles until 1984, just before the Olympic Games. It was not until the 1990s that computer control of urban traffic signals began to take hold, with New York modernizing its traffic control system and an ambitious program in Los Angeles to cover all 4000 signalized intersections. A demonstration in 1993 of the SCOOT adaptive traffic control system in Toronto, Canada, showed an average reduction in vehicle delays of 14% over the existing fixed-time plans (Greenough and Kelman, 1994).

By comparison, traffic management on urban freeways in North America had a much higher profile. Electronic ramp metering was first tried in Chicago in 1963, with Los Angeles following in 1968. By 1995, ramp meters were in operation in 23 metropolitan areas of North America. Improvements in mainline speeds of 16–62% and accident reductions of 24–50% were reported. The downside in peak periods was that traffic might be held on the access ramp for a considerable time, up to 20 min, before gaining access to main line. Priority lanes for high occupancy vehicles (HOV lanes) were another way to improve the use of road space and give them priority.

The main metropolitan areas of the United States frequently experience serious freeway congestion with accidents causing long delays. Through the 1980s and 1990s, downtown freeways in cities such as Chicago, Detroit, Houston, Los Angeles, San Francisco, and Toronto were equipped with loop detectors, closed-circuit TV cameras (CCTV), and text-based electronic dynamic message signs at the roadside to alert drivers to lane closures and traffic accidents. Traffic control centers were built for staff to monitor the cameras, handle emergency calls, and operate incident management procedures in liaison with the police, breakdown trucks, and emergency services. In the Chicago area, special emergency traffic patrols with heavy-duty breakdown equipment were deployed for rapid response, known appropriately as the *Illinois Minutemen*. Automatic incident detection based on loop detection and artificial vision was another development.

The year 1992 was a turning point in North America, with three significant events. One of the first field tests of ITS technologies in the United States was launched in Oakland County on the outskirts of Detroit. Called FAST–TRAC (an acronym for *Faster and Safer Travel through Traffic Routing and Advanced Control*) it brought together the Australian system of adaptive signal control responding to real-time traffic conditions (SCATS) with the German Ali-Scout system of dynamic route guidance. Twenty-eight intersections were brought under SCATS control and a dedicated network of infrared beacons installed to transmit optimal route directions to drivers based on the current traffic situation. Vehicles were equipped with an infrared transponder and a dashboard unit that displayed turn-by-turn guidance for the driver.

In the same year, 1992, the US Department of Transportation (USDOT) and General Motors launched another landmark project in Orlando, Florida, known as *TravTek*, to demonstrate navigation and route guidance. A precursor to the ubiquitous satellite navigation consumer products of today, TravTek coverage was 10,000 miles of road with 75,000 intersections over an area of 1200 square miles. A database of yellow pages and tourist information was included in the package (USDOT, 1996).

The third significant event of 1992 was the publication by the Intelligent Vehicle-Highway Society of America, (now *ITS America*) of a strategic plan for Intelligent Vehicle-Highway Systems in the United States (Deen *et al*., 1992). This 295-page report discussed organizational roles and responsibilities and legal and institutional matters in addition to detailing the main technical opportunities. In response, the USDOT funded a 3- year study to examine the requirements for implementing ITS across America. This major piece of work embraced 29 ITS-based user services nominated by USDOT (some already in place) and was carried out by defense industry contractors with experience of planning and designing large and complex systems. It took a top-down approach to look at the potential co-dependencies, data sharing, and communications requirements that could make these services happen and matched this with an evaluation of costs and benefits. The project included extensive outreach to major stakeholders

through a series of regional and national consultation meetings. The outcome was a proposed architecture for ITS with 19 major subsystems gathered into four groups as shown in Figure 2 (Chen and Costantino, 1999).

Measured by its breadth and comprehensiveness, the US National ITS Architecture study was breaking new ground. It did a great deal to put ITS on the map in North America by creating awareness among transportation professionals of the potential benefits of ITS and the value of taking a systems approach. It spawned an intensive program of work to develop national and international standards and protocols that would promote the widespread use of ITS technology with the aim of ensuring interoperability to the maximum extent practicable. Since 2001, it has been a matter of policy in the United States that ITS projects that benefit for Federal funds shall demonstrate compliance with the national or regionally adapted ITS Architecture requirements. Canada has followed with its own variant of ITS Architecture that recognizes the need for cross-border interoperability.

3 DEVELOPMENT OF ITS PRACTICE

3.1 Emergence of ITS

With a US strategic plan for ITS in the making and commercial applications coming onstream in Europe and Japan, a world congress on *Applications of Transport Telematics and Intelligent Vehicle-Highway Systems* took place in Paris in 1994. This landmark event was organized by ERTICO, the European Road Transport Telematics Implementation Organization, now also known as *ITS Europe*. The event brought together researchers and practitioners from Europe, Japan, and the United States and laid the foundations for a series of congresses that continues today. The ITS World Congress is held every year, successively in Europe, Asia-Pacific, and North America. It provides an important platform for debating deployment issues and establishing ITS practice.

Hard on the heels of the Paris congress there were developments at a political level. In February 1995, a conference on *The Information Society* took place in Brussels for the leaders of the Group of Seven leading industrial nations. The objective was to raise awareness of the revolution in digital technologies that was occurring. Hosted by the European Commission, it included a showcase of demonstrations on how information and communications technologies were being applied to automobile engineering and transport. (Figure 1.)

That same year a second congress took place in Yokohama, organized by VERTIS (*ITS Japan*) under the banner *World Congress on Intelligent Transportation Systems*. This title has remained and with it the widely used acronym ITS. Japan paraded state-of-the-art traffic control centers in Yokohama and Tokyo with video walls that greatly

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

impressed visitors from around the world. The VICS system, mentioned earlier, was also demonstrated at the congress.

The following year in April 1996 the VICS center real-time traffic information service commenced, connecting with transmitters along major highways between Tokyo, Nagoya, and Osaka. VICS continues today as a thriving public–private partnership with a nationwide data transmission network. VICS transmits real-time traffic data that is decoded by the in-car VICS unit for display on digital maps.

The true utility and benefit of VICS is hard to quantify directly. However, simulations using models suggested that if 20% of the drivers on the metropolitan highway use VICS the congestion will be reduced by 10% (Chen and Miles, 2004). It has a reputation as one of the world's leading dynamic traffic information provision systems. Cars with receivers can get up-to-the minute information on traffic, weather, and parking. The huge sales of the VICS units in Japan attest to its popularity and the success of the VICS strategy as a model for ITS deployment. As of March 2011, there were over 30 million VICS units installed in car navigation systems (see Applications—Intelligent Vehicles: Driver Information).

South Korea and Singapore were two countries quick to follow Japan's lead. Singapore conducted trials with nonstop electronic tolling as early as 1994 and Korea hosted the fifth World Congress in Seoul in 1998. By then, Korea was advancing with operational tests of ITS and had started work on a national ITS architecture study.

One of the first examples of nonstop electronic payment was the Trondheim toll ring in 1991, set up to improve traffic conditions in the city center and to fund a package of major transport infrastructure improvements. The system was one of the first in Europe to use short-range communications between the vehicle and roadside equipment as a method of charging. In 2001, it was upgraded to as part of a national strategy to create an interoperable system for all tolls in Norway known as *AUTOPASS*. Canada followed Norway's lead in 1997 when Highway 407, one of the world's first all-electronic nonstop toll roads, opened in Toronto.

3.2 Characteristics of ITS

The movement of people, vehicles, and goods brings with it a need to determine geographical position with a known level of accuracy and with a location reference that has meaning for the user—the answer to the question: "Where am I?" President Regan's decision in 1983 to open up Global Positioning Satellites (GPS) for civilian use opened up the possibilities. A further step was taken in 2000 when selective availability of the GPS signals was turned off. This meant that positioning could be done with a level of accuracy previously only available to the military, improved from 100 m (330 ft) down to 15–20 m (66 ft). The use of differential GPS allows for further refinement, in some cases down to 10 cm (see Technologies—Positioning: GNSS). However, accurate coordinates are only part of the ITS story. Also needed is a representation of the transport network with a level of detail and accuracy to match.

Navigation databases have their origin in the mid-1980s. The Dutch provider of digital maps, *TeleAtlas*, was founded in 1984. Japan established the world's first National Digital Road Map database standards in 1988. About the same time, the Navigation Technologies Corporation (Nav-Tech, now known as *NavTeq*) began mapping the San Francisco Bay Area. High resolution digital maps drawn from transport network models and navigation databases have a very fundamental part to play in ITS. With differential GPS matched with "always on" communications and very detailed digital mapping, it becomes possible to keep track of a vehicle's position on the road in real time with a high degree of confidence (see Tracking and Navigation for Goods and People). The combination of detailed digital maps and accurate positioning systems, linked with data from in-vehicle sensors and control systems, provides a powerful platform for computing direction indications, warnings, and, if required, an automated driving response (see Applications—Intelligent Vehicles: Autonomous Vehicles).

Although these technological capabilities are impressive, our understanding of intelligence in ITS is not so well advanced. The adjectives *smart* and *intelligent* are very over-worked. Data and information are gathered, stored, and processed but does this amount to intelligence? Information is not the same as intelligence, which requires an understanding of purpose, context, and previous knowledge. Writing in 2004, Joseph Sussman, one of the authors of the seminal 1992 Strategic Plan of ITS America, observed that creating the kind of automated network management that was originally envisaged is elusive. He judged that many of the ITS-based systems developed are more correctly described as decision support systems (Sussman, 2004). It is fair to say that the whole subject of Artificial Intelligence in transport is still very much in its infancy (Miles and Walker, 2006).

By the mid-1990s, the basic set of automated vehicle controls, such as adaptive cruise control, collision warning, and automated lane keeping were sufficiently well developed to mount a demonstration of automated driving. The US National Automated Highway System Consortium (NAHSC) was formed in response to legislation passed by

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the US Congress in 1991. In August 1997, using dedicated car-pool lanes on Freeway I-15 in San Diego California, the consortium presented a convincing demonstration of seven different automated driving scenarios using some 20 fully automated vehicles. Automated highways were seen as the next evolutionary step in highway transportation systems bringing benefits to all classes of traffic (NAHS Review Committee, 1998). Similar development work was taking place in Europe with electronic coupling of trucks through the CHAUFFEUR project (Schulze *et al*., 1998) and in Japan the Advanced Cruise-Assist Highway Systems concept (MLIT, 2002) (Bishop, 2001).

Greater automation brings with it a second important question: what happens if the "intelligent" system fails though mishap or misadventure? A system failure, however caused, demands the notion of *graceful degradation* as a basic principal of traffic system design. It means that if an important component of the system drops out the failure should not be catastrophic. The system should be resilient and have the capability to adapt. In the 1980s, graceful degradation was built-in as a design feature of SCOOT and the Dutch motorway control system and has continued to inform the deployment of dynamic traffic systems ever since. System design issues such as these become critical where public safety is an issue, not least because of worries about manufacturer's liability, which is a prominent factor in the case of advanced vehicle control systems. Therefore, although vehicles began to incorporate an increasing amount of sensor technology, such as front anti-collision radar, focus area side radar, video-based road recognition sensors, GPS positioning, and navigational maps, this was usually in the form of driver support, not to take over vehicle control functions (see Driver Assistance).

3.3 Growth and consolidation

The first meeting of the PIARC (*World Road Association*) Technical Committee on Intelligent Transport took place in 1996. This PIARC committee was responsible for publishing the *ITS Handbook 2000* (PIARC, 1999) and in doing so the committee did much to spread knowledge about ITS deployments and make ITS accessible to the mainstream of highway and transportation planning practitioners, including those from countries with emerging economies. A revised edition of the handbook published in 2004 has been translated from English into French, Spanish, and Chinese (Chen and Miles, 2004).

In the United States, work continued to establish and refine the costs and benefits of public-sector ITS deployments following on from the program of field operational tests and the National ITS Architecture project. The USDOT established a database on costs and benefits, which it still maintains today (USDOT, 2013). The subject of ITS benefits and costs was the theme of a one-day workshop organized by ITS America at the seventh World Congress held in Turin, Italy, in November 2000. Out of this initiative grew IBEC, the influential International Benefits, Evaluation, and Costs group which was formally established at the 2002 ITS World Congress in Chicago (IBEC, 2013).

Meanwhile, steps were being taken in Europe to foster the deployment of cross-border ITS and services. This was in addition to the established Framework Program for Research and Technical Development, which is described by Vits (see Evolution and Future Trends). A set of proposals was published in 1997 identifying five priority areas (European Commission, 1997):

- development of Europe-wide traffic information services using RDS-TMC (the Radio Data System-Traffic Message Channel);
- traffic data exchange and information management, to progress technical standards and operating protocols;
- electronic fee collection, working toward European interoperability of systems;
- safety of onboard devices, through a code of practice for the design of the human–machine interface (HMI); and
- system architecture, with the aim of defining an open system architecture for Europe.

Similar efforts at harmonization of ITS Technologies were taking place on other continents. Among the countries that have followed the US lead and sought to adopt a reference architecture for planning and designing their ITS are Australia, Austria, Canada, Czech Republic, France, Finland, Hungary, Italy, Japan, the Netherlands, Norway, Romania, Taiwan, Slovenia, South Korea, Spain, and Switzerland.

Urban traffic management continued to develop in most European countries. The United Kingdom in 1997 began work on open systems for Urban Traffic Management and Control (UTMC). In the same year, the Swedish Parliament advanced a long-term goal known as *Vision Zero* with the intention that no one should be killed or seriously injured within the Swedish road transport system. In Japan, the National Police Agency sponsored work on driving safety support systems (DSSS) as part of their Universal Traffic Management System (UTMS).

The beginning of the twenty-first Century saw the consolidation of ITS and services regionally, which had until then existed in isolated examples, trials and demonstrations. A group of experts from Canada, the European Union, and

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the United States was formed to review experiences of successful deployment of ITS on both sides of the Atlantic (Miles *et al*., 2002). There followed a period of rapid expansion. Numerous case studies of successful ITS projects were compiled by PIARC (Chen and Miles, 2004; PIARC, 2007 and 2011).

Systems for "Active Traffic Management" of heavily trafficked and congested sections of European motorways were developed involving a combination of ITS applications. The United States put in place arrangements for a national travel information system using the 511 code. In the United Kingdom, the government sponsored the development of *Transport Direct*, a national multimodal journey planning portal. The rollout of third-generation mobile phone networks with broadband data capabilities made possible the mobile Internet. Traveler information systems took advantage of this broadband capability and the rapid take-up of "Smart" telephone handsets.

In Europe, the use of ITS-based payment and enforcement systems gathered momentum. London introduced its congestion charge in 2003 with the object of reducing congestion in the central area. It uses video enforcement based on vehicle license plate number recognition and compares the result against a database of permitted vehicles. Prepayment of the congestion charge puts the vehicle onto the permitted list for that day. Postpayment is possible up to midnight on the day. A different approach using GPS technology was adopted in Germany on the autobahns for heavy goods vehicles starting in 2005. An onboard unit tracks the vehicle's movement. Charges are calculated based on the distance driven, the number of axles, and the emission category of the vehicle. Austria also introduced a scheme for charging heavy goods vehicles but with different technology, having installed a multilane, free flow open toll system across the entire Austrian motorway network.

France illustrates the safety potential of ITS. Starting in 2003, the country invested heavily in a national automatic enforcement and penalty system for speed violations. The French system uses digital technology with over 3000 devices in operation throughout the road and highway network. The system was developed with reference to the French national ITS architecture ACTIF and allows for near-complete automation of the detection and penalty procedure covering the entire enforcement chain, from detecting offences to paying fines including the legal processes. The effect has been positive with reductions in average speed of 7.5% since 2004 and a very marked reduction in accident fatalities.

4 THE STRUCTURE OF ITS

4.1 Technologies and user services

Communications are at the heart of ITS. The emergence of the Internet in the latter part of the 1990s along with the roll out of digital cell phone networks with capabilities for data transmission proved to be highly significant. The prospect of a mobile information society came into focus that would encompass an "intelligent" transport infrastructure, intelligent strategies for operating that infrastructure, advanced vehicle technologies and widespread dynamic traffic and travel information services operating in real time. However, to achieve this vision required the development of a wealth of common systems embracing among other things: mobile communications, data models, data dictionaries, data exchange, multi-service smartcards, digital mapping, navigation databases, and location referencing standards.

Table 1 illustrates the range of technologies that are involved. They work together in various combinations but some technologies are absolutely fundamental. For example, digital communications in various forms provide the backbone of ITS (see Technologies—Communication: Mobile and Technologies—Communication: Wireless LAN-based Vehicular Communication). Data is another key element (Table 2) in ITS (see Technologies—Data Acquisition: Data fusion) and is the subject of an encyclopedia article in its own right. Data generated by ITS may provide real-time information about current conditions on a network, or on-line information for journey planning, enabling highway authorities and agencies, road operators, passenger transport, and commercial transport providers and individual travelers to make better informed, safer, more coordinated, and "smarter" use of transport networks (see Applications—Intelligent Vehicles: Driver Information).

The specific applications of ITS are usually identified by the service on offer more than by the technologies that are utilized. The colloquial *SatNav* is an exception that combines a reference to the technology along with the function. A service-based view of ITS represents what ITS applications can deliver that will benefit the user. The concept of user services allows a system or project to be developed that will address identified transport problems and user needs. The International Standards Organization (ISO) has reached broad agreement on a classification of ITS services drawing on experience from the European Union, Japan, the United States and elsewhere (ISO Technical Committee 204, 2007). ISO categorizes ITS services in 11 different service domains. For each service domain the ISO standard provides a listing of ITS

Table 1. Some of the principal enabling technologies for Intelligent Transport Systems.

Network data	*Roadway sensor technologies*
Network modeling	Traffic detectors (various types)
Tree-building algorithms	Weigh in motion
Geographical Information Systems	Weather monitoring
Network condition databases	Vehicle sensors/ traffic probes
• Real time	Spot speed detection (Radar)
• Historic	Average speed detection/Journey time monitoring (tag based and ANPR)
Location referencing systems	*Vehicle sensor technologies*
• Global positioning (Lat/Long)	Position sensors
• Mobile phone triangulation	Speed and braking sensors
• Link and node systems (Alert C, etc.)	Vehicle proximity sensors
Digital communications	Occupant comfort (sleepy driver) sensors
Fixed link (fiber, cable, and microwave)	Near-distance obstacle detection
Dedicated Short-Range Communications	Far-distance obstacle detection
• Passive microwave (tag and beacon)	*Signs, in-vehicle units, and handsets*
• Active microwave (IEEE 802.11/WAVE)	Public information points and kiosks
• Infrared	Roadside electronic variable message signs
• Wi-Fi	• Text based
• Bluetooth	• Graphics boards
3G and 4G cell phone networks	In-vehicle units:
Digital radio (DAB; FM digital side band)	• dashboard displays and audio
The Internet	• head-up displays
Navigation	• voice recognition
Global Navigation Satellite Systems	Nomadic devices:
Navigation databases	• Smartphones
Location-based services databases	• Tablet computers
Dynamic maps (local, regional, and national)	• Personal navigation devices
Digital image processing	*Electronic payment*
Automatic vehicle identification	DSRC-based systems
Artificial vision (image recognition)	GNSS-based systems
Automatic incident detection	Permitted list using ANPR (pre- and postpayments)
Vision-based sensors	Electronic ticketing
White line detection	Smartcard ticketing
	Mobile phone payment
	Contactless smartcards

services and service groups that fall into that category (Table 3). Although the services and service domains are made distinct, there are significant interdependencies and co-dependencies to be considered, sometimes across different service domains.

4.2 ITS Architecture

4.2.1 What is ITS architecture?

The amalgamation of technologies to perform advanced ITS functions is based on the principles of systems engineering. Control systems for road traffic were installed initially to provide just one or two services that worked independently as separate autonomous systems. In contrast, the application of information and control technologies to transport systems today requires complex data gathering, information management, and control systems that need careful design. As the use of ITS grows so do the possibilities for synergy between different systems, often involving data sharing beyond established organizational boundaries. System architecture provides a planning and design framework that will make the most of the available synergies.

The US National ITS Architecture was the first comprehensive vision of a future integrated ITS. From 1996 onward, the US National Architecture has been maintained

Table 2. Features of the ITS information supply chain (see Technologies—Data Acquisition: Data fusion and Applications—Intelligent Vehicles: Driver Information).

1. Data Acquisition	*4. Transmission and distribution*
Vehicle and roadway sensor data	Multiple communication channels
CCTV and webcams	Timeliness and latency of transmission
Image processing	Security and integrity of transmission
Tag readers	Geographical coverage
Event and incident data	*5. End-user interfaces*
• Automatic detection	Travel news broadcasts
• Journalistic sources	Highway advisory radio
• Crowd sourcing	Roadside VMS
Transaction processing	Internet and mobile internet
Data mining	Social media
2. Data Processing	In-vehicle unit audio and displays
Data formatting	Nomadic devices
Location referencing	Public information points and kiosks
Data dictionaries	*6. Supply & ownership issues*
Data registries	Public-sector data
Data exchange	Commercial and proprietary data
Data fusion	Information service providers
Quality controls	Information branding
3. Information management	Value-capture, revenue, and payment
Data analysis	
Contextual relevance	
Content detection	
Content processing	
Formatting for service	
User needs/preferences	

and developed and is now in its seventh version (USDOT, 2012a). It includes a number of user services that were not even thought of when the original version was published.

A national, regional, or city-wide ITS architecture is a formal statement of the preferred approach to ITS and is the first step on the way to creating detailed system designs. The term *architecture* is used here to describe a reference model to guide the implementation of ITS by different parties so that the whole can function efficiently. It is the conceptual design that defines the structure and/or behavior of an integrated ITS. The architecture will describe the following:

- the specific activities and functions that are required to deliver the ITS service (e.g., "gather traffic information" or "request a route");
- the physical entities or subsystems where these functions reside (e.g., at the roadside or with the vehicle); and
- the information flows and data flows that connect together these functions and physical subsystems to create an integrated system.

In essence, the ITS architecture is an analytical framework that shows conceptually and in some detail how different component systems and technologies should fit together.

A national, regional, or city-wide ITS architecture is by definition strategic: it provides a framework for implementation rather than a definitive system design. The key to establishing a reference architecture at this level is the selection and prioritization of user services. All the main stakeholders and actors should be involved in this process, making architecture development an opportunity for consensus building. Failure to achieve an adequate level of stakeholder involvement and buy-in has sometimes been a barrier to progress.

When developing their own ITS architecture, organizations have to make decisions about the form of architecture that they create, which may be one of three types:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Table 3. Classification of ITS services by the International Standards Organization (ISO Technical Committee 204, 2007).

Service Domain	Service Groups
Traveler information	Pre-trip information
	On-trip information
	Route guidance and navigation pre-trip
	Route guidance and navigation on-trip
	Trip planning support
	Travel services information
Traffic management and operations	Traffic management and control
	Transport-related incident management
	Demand management
	Transport infrastructure maintenance management
	Policing/enforcing traffic regulations
Vehicle services	Transport-related vision enhancement
	Automated vehicle operation
	Collision avoidance
	Safety readiness
	Precrash restraint deployment
Freight transport	*Administrative functions*:
	Commercial vehicle preclearance
	Commercial vehicle administrative processes
	Automated roadside safety inspection
	Commercial vehicle onboard safety monitoring
	Commercial functions
	Freight transport fleet management
	Intermodal information management
	Management and control of intermodal centers
	Management of dangerous freight
Public transport	Public transport management
	Demand responsive and shared transport
Emergency	Transport-related emergency notification and personal security
	After theft vehicle recovery
	Emergency vehicle management
	Emergency vehicle pre-emption
	Emergency vehicle data
	Hazardous materials and incident notification
Transport-related electronic payment	Transport-related electronic financial transactions
	Integration of transport-related electronic payment services
Road-transport-related personal safety	Public travel security
	Safety enhancements for vulnerable road users
	Safety enhancements for disabled road users
	Safety provisions for pedestrian using intelligent junctions and links
Weather and environmental conditions monitoring	Environmental conditions monitoring
Disaster response management and coordination	Disaster data management
	Disaster-response management
	Coordination with emergency agencies
National security	Monitoring and control of suspicious vehicles
	Utility or pipeline monitoring

- framework architecture, that is, an architecture consisting of user needs and a functional viewpoint but omitting the physical viewpoint. The FRAME architecture for Europe is an example of this type (FRAME Architecture Consortium, 2011). It is only really suitable for architectures at the national or regional level but it can be used to create architectures of the following two types.
- mandated architecture, which has a physical, communications, and other viewpoints, plus the other required outputs. It can be used at the national, regional, and local levels to provide close specification of what is required for ITS deployments. The contents of the physical viewpoint may be fixed, or there may be a limited range of options.
- service architecture, which is like the mandated architecture, but only supports a particular service, for example, Traveler Information and Public Transport Management.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto166
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The operating assumptions that lay at the foundation of ITS architecture need to be expressed in laymen's terms and will explain, for the benefit of the agencies directly involved, what is required. Central are the data-gathering and data-processing activities that will be involved in creating each ITS-based service and the interactions that are needed between the different agencies. Currently, in the light of emerging cooperative vehicle-highway systems (sometimes called *C-ITS*) even the traveler, himself or herself, can be regarded as an element of the ITS architecture.

Achieving a consensus view of what is required is important to inform the determination of functional requirements for the system. Sometimes this is done in a planning document called the *concept of operations* that describes the activities that are components of the total system so that everyone involved have a clear understanding of what is being planned and the interdependencies, whether overt or implicit. The concept of operations will explain the functional requirements for each service component, the character of any data or information to be exchanged, expectations of accuracy and timeliness, and any other dependencies.

4.2.2 ITS architecture viewpoints

ITS architecture is concerned with information exchange and the allocation of control functions between systems at various levels of abstraction. Even if the operational concepts are clear and well documented, there is no single view of a complex system that can convey all aspects of the system in an understandable manner (Belinova, Bures and Jesty, 2010). Instead, multiple viewpoints, depicting different aspects of the system and different types of information are needed. These viewpoints might include: a functional or logical architecture describing how various data should flow and be processed; a physical architecture allocating the functions to physical subsystems; an organizational architecture to assign functions and responsibilities to providers and recipients of selected ITS services; and a communications architecture that specifies what forms of communication are required.

Functional (logical) architecture depicts the processes and data flows that are needed to meet the functional requirements described in the concept of operations. The common ground between the various user requirements and ITS services is examined so that shared functions and common requirements can be grouped within the same set of processes. An important part of the logical architecture is to describe how the system would deal with abnormal circumstances. All failure modes need to be considered for possible safety hazards, and logical steps need to be described to achieve graceful degradation under abnormal conditions, consistent with the higher level concepts described in the concept of operations.

Physical architecture: In the context of systems engineering, the physical architecture allocates the processes defined by the logical architecture into physical subsystems, which the hardware and software will deliver. The top-level diagram of the US national physical architecture in Figure 2 (earlier in this chapter) shows a highly simplified, strategic example. The design of the physical subsystems will be based on the functional requirements, the process specifications, and the interdependencies and will be affected by whether the functions are to be performed in one or more locations. Thus, the physical architecture allocates specific processes to physical subsystems, considering the institutional responsibilities.

Organizational architecture considers ownership and business issues: who owns what, who manages what and the business/contractual relationships between the various parties involved.

> The Organization Viewpoint is usually a derivative of the Physical Viewpoint. It is used to show the organizations that will own, and/or operate, and/or maintain the Sub-Systems and Modules in the Physical Viewpoint. (FRAME Architecture Consortium, 2011)

Communications architecture determines the way in which information is exchanged and describes the kinds of communications that will be required. An example is the European cooperative ITS architecture (ETSI, 2010). The architecture is organized into four principal domains as shown in Figure 3 (COMeSafety Consortium, 2008). It covers all types of communications to and from moving vehicles: vehicle-to-vehicle (V2V), vehicle-to-roadside (V2R and R2V), and vehicle-to-infrastructure (V2I and I2V). The intention is to take advantage of multiple communications media to achieve seamless communication as the vehicle changes location. The hope is that the architecture will give sufficient flexibility for applications to be independent of communications with a degree of future proofing.

4.3 ITS standards

Technology standards have particular significance in the ITS world, firstly because of the global market for automotive products and secondly to promote interoperability of systems across national jurisdictional boundaries, especially important in Europe. Standards provide a specification for the important communications, hardware and software components, to assure that they are compatible one with

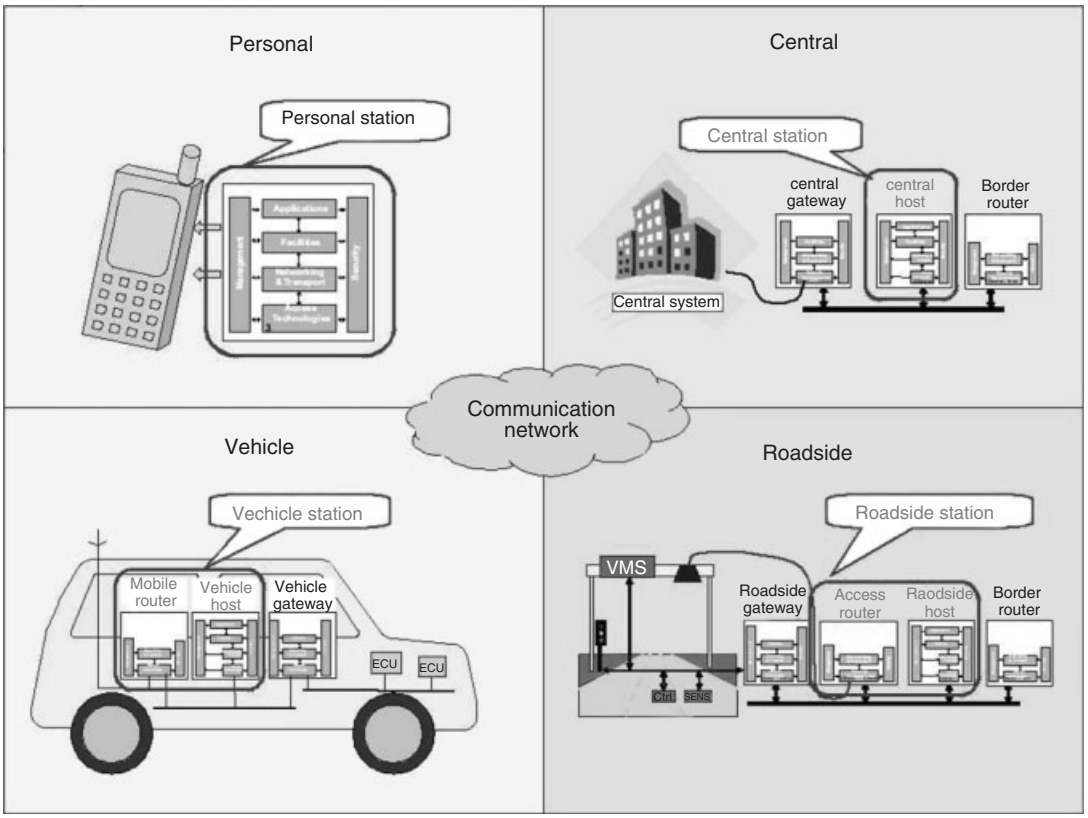

Figure 3. European ITS communication architecture subsystems. (Reproduced by permission of BMW Forschung und Technik GmbH on behalf of the COMeSafety Consortium.)

another, even when they are from competing vendors. They play an important role in bringing ITS products and services to market, lower prices for the users, and an integrated transportation system that appears seamless to the traveler.

International efforts to establish a standardized framework for ITS can be traced back to 1992 when the ISO convened Technical Committee 204 (ISO TC 204). In the same year, the Comité Européen de Normalization (CEN) established its technical committee on road transport and traffic telematics (CEN TC 278). The two committees are entirely devoted to ITS standards and work in a complementary way where possible. Japan and the United States each have their own national ITS standards programs that feed into the ISO standards consensus-building process.

There are different taxonomies of ITS standards. First and foremost, standards are needed in protocols and message sets to allow smooth data flow and information exchange among the subsystems. Protocols, such as TCP/IP for the Internet, give the formulae for passing messages, specify the details of message formats, and describe how to handle error conditions. Standard message sets, usually defined in data dictionaries, are also needed to allow accurate exchange of information between subsystems. For example, information exchange related to traffic incidents will need a coding standard for unambiguous description of the incident location (e.g., a road segment number) and the type of incident (e.g., fire and body injury). If wireless communication is needed, standardization of the frequency and modulation technique is also implied.

ITS standards may be established at the local, regional, national, international, and global levels. Some standards may be needed only up to a certain level. For example, for most commercial vehicle operations, international standards may be needed for a given continent (e.g. Europe or North America) but global standards are not required as trucks generally do not travel across continents. In contrast, standards for cargo identification should be global in order to facilitate freight identification, security checks, and movement between continents.

Like any other type of standards, ITS standards may be *de facto* standards, when everyone follows the standards set by the dominant supplier, or *consensus* standards, which are arrived through procedures established by standard setting organizations such as the ISO. Standards may also be set by government in the form of a regulation, usually as a last resort.

For the rapidly developing field of ITS, the timing of standard setting is important. Premature standards may stifle innovation. Standard setting often runs into difficulties with equipment and software suppliers who see a commercial advantage in promoting their own proprietary standards or who have an established market position and do not wish to change their products. Even when standards are agreed, practical considerations require an acceptable migration path for existing systems to move toward the new standards over a reasonable period of time. Users who have already invested in specific systems may be reluctant to switch to new standards before they have realized a reasonable return on their investment.

Those needing further information on ITS standards are referred to the *comprehensive reference book* on this subject based on the work of the ISO technical committee on ITS, TC 204 (Williams, 2008). The Japan Society of Automotive Engineers produces a very helpful introduction to the work of the committee in English (Japan SAE, 2011).

5 CONCLUSIONS

A great deal has been achieved in the two decades since ITS first emerged out of the laboratory, off the test track, and on to the open road, but much remains to be done. The intelligent algorithms and automated systems that were slow to develop in the early days of ITS are more of a reality today but the institutional challenges of ITS loom just as large as they ever did. Technology itself is not a barrier. Progress depends on the business case for ITS services and establishing operations with sufficient flexibility to cope with rising user expectations as well as technological change.

In 2005, returning to the theme of advanced highway systems, the United States launched the Vehicle Infrastructure Integration (VII) initiative bringing together a coalition of Federal and State departments of transportation and automobile manufacturers. The objective was to evaluate the technical, economic, and social/political feasibility of deploying vehicle-to-vehicle and vehicle-to-roadside communications dedicated to ITS services. This is work still in progress. What is proposed is a "connected transportation environment" through vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications and applications. The technological, institutional, and policy challenges associated with moving from research prototypes to full-scale deployment are now being considered (USDOT, 2012b). The intention is to finalizing by late 2013 the initial set of V2V technologies and safety applications.

The European Union has acted to put in place a legal framework of cooperation between the 27 EU countries to support the coordinated deployment and use of ITS. In future, a limited group of ITS applications will have to comply with European specifications made under the

so-called *ITS Directive* (European Parliament and Council, 2010). The European Standards Organizations, CEN and ETSI, will develop the necessary standards to support this legal framework, in particular to enable interoperability of cooperative ITS (European Commission, 2011).

Japan has developed its own comprehensive package for ITS deployment branded as *Smartway* based on a communications architecture that *inter alia* uses the infrastructure installed for electronic toll collection (ETC) on the expressways. In addition to ETC, there is multiple functionality through Smartway communications with the vehicle: multipurpose payment for parking and other fees; probe data collection from cars; systems for road management and operation; systems providing drivers with information and an internet connection; bus location systems, etc. (MLIT, 2007). By way of example, Figure 4 shows a blind curve warning device that has been installed on the Tokyo metropolitan expressway to provide voice warning of queue ahead to the driver. The Smartway system also has potential for other applications such as communications for vehicle diagnostic applications, drive-through establishments, entry/exit control, and payment on ferries.

Future vehicle control systems will give increased driver support and greater automatic control but will that create a dependency that would be crippling in the event of failure? Will constant monitoring of vehicle component condition, driver condition and driver performance affect a step change in road safety toward the ultimate goal of Vision Zero? The fourth-generation mobile phone networks have ultrafast broadband capability and Internet Protocol (IP)-based communications. How will this affect the data and information we send and receive? What businesses and business models will be able to feed off the mobile internet and exploit the potential of connected vehicles? The answers to these and many other questions will keep ITS developers on their toes for many years to come.

Intelligent Transport Systems: Markets and Policies

Steven E. Shladover
University of California, Berkeley, Richmond, CA, USA

1 INTRODUCTION

Since their introduction more than a century ago, road vehicles have had minimal direct interactions with each other or with the roadway infrastructure on which they operate. Indeed, virtually the only interaction between the vehicles and the infrastructure was the physical connection at the tire contact patch, and the only direct vehicle–vehicle interaction was unintentional, when they crashed into each other.

With the advent of intelligent transport systems (ITS), active exchange of data among vehicles and between the vehicles and the infrastructure assumes central importance. Indeed, not only the vehicles and the infrastructure but also the people and goods being transported in the vehicles become elements of an integrated road transport system, connected by the exchange of information, as shown in Figure 1. It is well known in systems science that it is possible to achieve much higher performance when all the relevant subsystems of a complex system of systems are explicitly treated in analysis and optimization. ITS therefore offers great opportunities to improve all the major measures of effectiveness of road transport systems: mobility, efficiency, safety, and costs (capital and operating, for both the vehicles and the infrastructure).

The concept of integrating vehicles and the infrastructure is straightforward on its face, but the implementation is challenging for a variety of reasons that will be explained in this chapter. These ITS have developed in different directions and at different rates in Europe, the Americas, and the Asia/Pacific region, based on regional differences in land development, transportation system characteristics, government structures, and the market for private vehicles.

In the remaining sections of this chapter, the opportunities and challenges associated with ITS deployment are explained. The opportunities are represented by the benefits that ITS can provide to the transportation system, the motivation for vehicle and infrastructure owners and operators to invest in the ITS market. The challenges represent a combination of institutional, technical, and economic constraints on the ability of these actors to act in favor of ITS solutions. The contrasts among the major economic regions of the world with regard to ITS deployment are then explained.

2 BENEFITS OF ITS DEPLOYMENT

ITS is a broad collection of information technology applications that can confer a wide range of benefits to the transport system and its users. Different ITS applications provide benefits in different categories, so no single ITS application or product provides the full suite of benefits.

2.1 Mobility enhancements

The original motivations for ITS were primarily associated with mobility improvements. The heavily industrialized

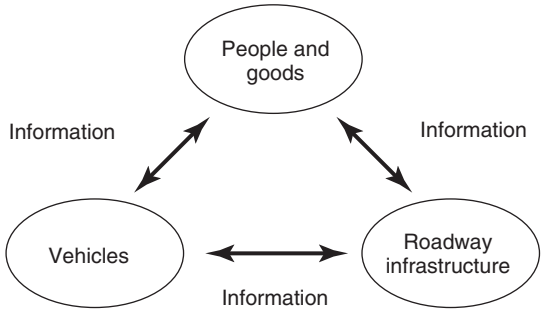

Figure 1. ITS enabling road transport to function as an integrated system.

and urbanized countries recognized in the 1980s that they could not afford to continue to expand the civil infrastructure of their roadway networks at a fast enough rate to stay ahead of the growing demand for road transport services, so they would need to use that infrastructure more efficiently. The information technology of ITS makes this possible in several ways.

2.1.1 Relieving traffic congestion

Traffic management systems on freeways can help the traffic flow more smoothly and at a higher capacity by metering the entry of vehicles at the on-ramps to avert traffic flow breakdowns or advising drivers to reduce speeds upstream of bottlenecks. Real-time traveler information systems can help travelers adjust their travel times and routes away from the worst congestion. Intelligent traffic signal control systems can help urban traffic flow more smoothly, minimizing wasted green signal time and spillback of queues to upstream intersections. Enhanced detection of incidents can enable emergency responders to reach the sites of crashes more quickly, so that the impediments to traffic can be removed and full capacity restored sooner. Integrated freeway/arterial corridor management systems can promote the most efficient use of the available roadway capacity in a corridor, especially when an incident temporarily reduces the capacity of the freeway or the arterial, promoting the shifting of traffic to the parallel facility. In the longer term, automated driving of vehicles in close-formation platoons will make it possible for each lane of a limited-access highway to carry two to three times the traffic volume (Michael *et al.*, 1998) of today's conventional highway lanes.

2.1.2 Improving public transport service quality

Public transport systems have had competitive disadvantages relative to private automobiles in all but the highest density urban locations, limiting their opportunities to attract drivers out of their cars. These can be mitigated using ITS. Transit signal priority systems enable buses to gain priority for green signal time over other classes of vehicles, providing some travel time savings (Smith, Hemily, and Ivanovic, 2005). Multimodal traveler information systems can provide potential transit riders with comprehensive information to relieve anxiety about bus arrival times and connections, so that they will be more comfortable depending on a public transport system. Fleet management systems enable bus fleet operators to make more efficient use of their assets, so that they can be more economically viable. Automatic guidance and precision docking systems enable buses to provide a quality of service to their passengers that would otherwise only be achievable on much more costly rail transit systems and to operate on busways that occupy narrower rights of way than conventional highway lanes, so that they can be implemented more easily in crowded urban environments (Shladover, 2000). In the longer term, automated buses or automated guideway transit systems can save driver labor costs, improving the economic viability of transit services.

2.1.3 Facilitating goods movement

ITS can provide specialized support to address the particular needs of truck operators, so that they can make their operations more efficient. Real-time routing advice can incorporate restrictions specific to trucks, such as limited overhead clearances and limited weight-bearing capacity of bridges. Trucks can be given priority at traffic signals, so that they are less likely to have to stop and restart than light-duty vehicles, saving time, energy, and emissions. By means of data communications with the roadside, the regulatory processes specific to truck operations can be executed without requiring the trucks to stop at every weigh station or border crossing, saving even more time, energy, and emissions. With accurate information about road grades and curves, truck operators can be given advice about the best speed profiles to follow to minimize energy consumption on each trip and to explicitly optimize the trade-offs among energy use, emissions, and travel time.

2.2 Efficiency improvements

Efficiency and mobility improvements are closely related to each other, such that improvements in one are likely to have similar benefits for the other. However, some additional efficiency improvements do not necessarily

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto167
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

affect mobility directly. For example, ITS can smooth out the transient disturbances in traffic, reducing acceleration and deceleration maneuvers, thereby saving energy and emissions (Shladover, 2011). Using ITS technologies to enable vehicles to automatically drive safely at shorter than normal gaps, aerodynamic drag can be reduced, saving significant energy in higher speed driving.

2.3 Safety improvements

Many ITS applications can improve traffic safety by warning drivers about unsafe conditions, by assisting drivers to control their vehicles more accurately and reliably, or by taking over the driving responsibilities. Although most of these applications are vehicle centered, some are based on the roadway infrastructure or involve cooperation between the vehicles and the roadway.

2.3.1 Infrastructure-based safety systems

Detection systems installed in or near the roadway can detect the presence and movements of vehicles and vulnerable road users such as bicyclists or pedestrians. On the basis of the detection information, traffic signal changes can be adjusted to minimize potential conflicts, for example, when a vehicle is predicted to run through a red signal (Zhang *et al.*, 2012). Detected hazards can be brought to drivers' attention by variable message signs, displaying information such as variable speed limits to slow traffic approaching the upstream end of a congestion queue.

2.3.2 Vehicle-based safety systems

Sensors on vehicles can detect many driving safety hazards, such as imminent lane departures, or vehicles or other obstacles in the lane ahead; vehicles in the blind spot; the proximity of obstacles at parking spaces; or driving speeds that exceed the local speed limits or the ability of the vehicle to maintain safety. Audible, visual, or haptic displays can convey this hazard information to the driver, so that he or she can take appropriate corrective action.

2.3.3 Cooperative safety systems

The latest generation of safety systems is cooperative, using wireless communications with the vehicle to take advantage of data sources in any other vehicle- or roadway-based sensor to warn the driver about an imminent unsafe condition. A wireless local area network can provide the drivers of all vehicles with the same information about all detected hazards (Sengupta *et al.*, 2007).

2.4 Cost reductions

Although ITS technologies are not free, in some cases investments in ITS can produce savings in infrastructure construction costs or vehicle operating costs. Most dramatically, when ITS operational improvements increase the effective capacity of a transport facility, they help avoid the costs of physical expansions to the facility, which would be substantially more expensive.

3 CONSTRAINTS TO ITS DEPLOYMENT

Although a few of the ITS technologies fit the typical automotive industry model of entirely in-vehicle systems, most of them involve significant interactions with the roadway infrastructure and/or other vehicles, which need to be equipped with compatible technology. This makes implementation of ITS technologies generally more complicated from an institutional and policy perspective than implementation of other automotive technologies, which can typically be done as market-based decisions between vehicle developers and their private market customers.

3.1 Challenges of public–private collaboration

As the roadway infrastructure is generally the responsibility of public agencies while vehicles are bought and sold in the private market and operated by private individuals, systems that integrate the vehicles with the infrastructure require collaboration between the public and private sector domains. Neither sector can make its decisions in isolation from the other, because the viability of the system as a whole depends on ensuring technical compatibility between the vehicle and roadway elements and their simultaneous availability in the same locations.

The public and private sectors need to work together from the start on developing the ITS operational concepts and designs, to ensure that the needs and constraints of both sectors are satisfied. This should extend to the development of technical standards for compatibility and interoperability of the vehicle and infrastructure elements. They also need to cooperate on implementation plans, so that the rollouts of the vehicle and infrastructure systems are coordinated.

These types of collaboration are challenging because of the cultural differences between public and private sector organizations in most countries. They tend to have different priorities, different economic interests, different decision-making processes and timescales, and different incentive structures. If they do not have some significant history of collaboration in other endeavors, they may not even know

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto167
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

how to work together and may lack the mutual understanding and trust needed to form effective partnerships.

3.2 Chicken-and-egg dilemma of vehicle–infrastructure cooperation

The need for close public–private cooperation is most acute for cooperative systems that require vehicle and infrastructure elements to work together. These systems, despite their great potential benefits, are hampered by a classic "chicken-and-egg" dilemma of which element goes first. Can the public sector justify deploying its cooperative infrastructure elements before there are any vehicles on the market that can interact with them? Can a private vehicle manufacturer or purchaser justify investments in new vehicle-based devices before the public sector has deployed the needed cooperative infrastructure? The answers are generally *no* in both cases, which means that they need to work together on a coordinated deployment strategy. This strategy, despite the best of intentions, can still be undermined by surprises that prevent either sector from following through on its commitment to the other.

3.3 Incompatible decision horizons of infrastructure, vehicle, and information technology industries

Public infrastructure agencies are accustomed to designing and building systems such as bridges and road networks that are expected to have usable lifetimes of multiple decades. Vehicle manufacturers design and build their vehicles to last for multiple years, but information technology companies expect their devices to become obsolete in months. Each of these organizations has decision processes and business models suitable for its respective product's functional lifetime, but with ITS, they are required to work together on a system that combines all three types of element. The ITS, as a composite of elements with lifetimes of months, years, and decades, can become an awkward hybrid that is difficult for all three industries to grasp and manage.

3.4 Introduction of information technology into more traditional capital-intensive industries

There are few industries more capital intensive or more focused on development of capital facilities than the roadway infrastructure industry. The automotive industry is also very capital intensive because of the size and complexity of the facilities needed to build motor vehicles. By contrast, the information technology industry, with its emphasis on software and small devices, is much less capital intensive and therefore more agile in adapting to change. This contrast affects organizational culture and economic models, making it more difficult for these industries to work together effectively.

3.4.1 Ratio of capital to operating and maintenance costs

When transport agencies develop new facilities, their dominant focus is on the capital costs and how to minimize them, because the annual operating costs are only a tiny fraction of the capital costs. With motor vehicles, the capital and operating costs are more evenly balanced, but with information technology, the operating and maintenance (including periodic update) costs are more likely to be dominant. This introduces tension into the design of an ITS that must be shared among the three industrial sectors, each with different economic models.

3.4.2 Development of understanding and comfort with new technologies

Public transport agencies have historically been dominated by civil engineers, whereas the automotive industry is dominated by mechanical engineers. ITS requires the integration of these technologies with electrical engineering and computer science, fields that are generally foreign to the leaders of the transport system's industries. They need to gain enough understanding of these newer technologies and develop sufficient staff expertise in these fields within their organizations to be able to manage and operate systems based on ITS technology.

3.5 Politicians' needs for fast implementation and ribbon-cutting ceremonies

The roadway infrastructure operates in the public political arena, where funds for construction, operation, and maintenance must be allocated by elected officials. These officials are always thinking about what will help them get re-elected at the next election, when they need to show the general public that they have accomplished something tangible by their investments of tax revenues. This leads them to favor construction projects, where the tangible results can be shown very publicly in ribbon-cutting ceremonies and structures can be named in their honor. It is more difficult to gain the support of politicians and the general public for ITS operational improvements, which are not nearly as visible. Improved operations of traffic signal systems or freeway ramp metering to reduce travel delays are much harder to explain and demonstrate to the general public,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto167
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

even though they are likely to produce significantly higher ratios of benefits to costs.

3.6 Limited capital and staff resources to invest in new initiatives

Public investment decisions are based not only on economic valuation criteria such as the ratio of benefits to costs (or net present value) but in many cases they are severely constrained by resource limitations. Even though a new ITS project may be expected to be highly beneficial and cost effective, it cannot necessarily be funded because there may be no funding available for new initiatives. If the existing transport infrastructure is deteriorating and needs extensive maintenance to prevent further deterioration and to keep it in operational condition, that is likely to take priority over any new initiative.

4 REGIONAL CONTRASTS IN ITS DEPLOYMENT

The degree of ITS deployment varies widely from country to country, even within the advanced industrialized countries. Many factors influence this propensity to deploy ITS, beyond national wealth and general technological sophistication.

4.1 Ease of public–private cooperation and attitudes toward industrial policy

Because of the need for public–private cooperation to implement vehicle-infrastructure cooperative ITS, as explained in Section 3.1, the ease of achieving that cooperation is a dominant factor in determining how widely ITS is deployed. The industrialized countries of east Asia (Japan, South Korea, Singapore, and now China) have particularly well-established cooperative relationships between their public sector agencies and large private companies. This makes it possible for them to agree on technical standards and coordinated investments to deploy both vehicle and infrastructure elements of ITS (Ezell, 2010). It is no coincidence that these are also the countries that are most intent on using public–private cooperation to enhance the international competitiveness of their industries, so that they can increase national wealth by exporting their products to other countries.

The European countries have lagged somewhat behind their Asian counterparts in the extent of their public–private cooperation on transport and economic development policies, but they remain far ahead of their North American counterparts. The American example is near the opposite extreme from the Asian example, because there is substantial mistrust between the public and private sectors, especially in the United States. They do not have a significant history of cooperation, and indeed, there is strong ideological opposition among a large part of the political establishment to industrial policy, by which the government would favor specific industries.

4.2 Centralization of public agency transport decision-making

Public agency decisions about transport investments and operations are handled in diverse ways in different countries. This has a major influence on the decisions about deployment of ITS. When the decisions are centralized in a national authority, it becomes possible for that authority to make a uniform decision for the entire country, so that both the technical characteristics and the scheduling of the deployment can be made consistent and predictable for the private industry partners. As the decisions become more distributed, there is a heightened risk of incompatible technical implementations and spotty scheduling, so that the availability of the ITS services may not be consistent for travelers and fleets who need to drive through multiple jurisdictions.

The east Asian countries have the most centralized transport investment decision-making processes. One national ministry can decide to deploy a specific technology or product throughout the country and can allocate the funding to ensure that it happens according to a well-specified schedule (by region or in a logical sequence from urban to rural or rural to urban). This provides the most predictable interface for private industry partners, who can plan for the introduction of the in-vehicle systems based on a known plan for the infrastructure systems.

The European countries have diverse approaches to transport investment decision-making, with some being more centralized (France) whereas others are more decentralized (Germany). Some countries have privately operated motorway networks, which add another dimension to the infrastructure decision-making.

The North Americans have the most decentralized transport decision-making processes, with the national governments having no direct responsibility for designing, building, owning, operating, or maintaining any of their roadway networks. The primary highway network is the responsibility of the states or provinces, whereas the secondary networks are under county and city governments. Within the United States alone, there are 50 states, 3000 counties, and more than 30,000 municipalities, which

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto167
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

mean that border crossings are frequent and unavoidable. Adjacent cities and counties may have very different priorities, resources, and capabilities, so the ITS deployments could vary greatly when crossing the invisible borders between these jurisdictions.

4.3 Private vehicle market willingness to pay

Automobile purchasers in different countries have different priorities with regard to the features that they are interested in having and how much they are willing to pay for them, so the vehicle manufacturers adapt their offerings to the local market interests. This applies as much to the in-vehicle ITS functions as it does to other features such as vehicle and engine sizes, transmission types, and navigation systems.

The Japanese and Korean markets tend to be the most inclined to favor new electronic gadgetry, even before the technology is mature and robust, so these markets have tended to be the earliest adopters of new ITS features. For example, the limited-edition Mitsubishi Diamante of 1995 was the first production vehicle to offer adaptive cruise control (but only in Japan). The European luxury car market, as well as the Japanese and Korean markets, has a substantial number of buyers who buy ITS features by choosing to purchase their vehicles "fully loaded" (with all options selected). Some of these buyers do not actually learn how to use all the features on their vehicles and may never use some of them. In each of these cases, the selection of a premium vehicle with premium options is more of a statement of personal pride and prestige than an explicit desire to use all the features. Other car buyers study the choice of options carefully and decide exactly which features they want to have.

The North American vehicle market tends to be more skeptical of new technology and extra-cost options. Car buyers are less inclined than their Asian or European counterparts to choose all the options, and they tend to be careful about how much they are adding to the cost of their vehicle. Furthermore, most new cars are purchased off the dealer's lot, where they have been ordered with prepackaged combinations of options. The ITS features, especially the collision warning and avoidance options, are generally only included in the "fully loaded" vehicles, so it can be hard to find them in moderately priced vehicles.

4.4 Public agency financial and technical resources

The attitudes toward public investments in transport infrastructure vary widely from country to country, which means that the resources available to the responsible public agencies vary similarly. In countries where improvements to transport infrastructure are regarded as important investments in future economic productivity, the resource allocations tend to be generous. Similarly, where transport infrastructure development and enhancement are seen as economic stimulus opportunities when economic activity is sluggish, governments are likely to maintain their transport infrastructure investments at a sustained level regardless of economic cycles.

Within the industrialized world, Japan and the United States represent the opposite ends of the spectrum. Japan assigns high priority to transport infrastructure for both long-term economic strength and near-term stimulus, whereas the United States is more likely to view this as an avoidable expense rather than an investment. Consequently, the average annual investment per kilometer of roadway infrastructure (from design to construction, operations and maintenance) at all levels of government is approximately four times as large in Japan as it is in the United States, even though the roads are more heavily utilized on average in the United States. The other Asian countries and Europe are between these two extremes, and China, with its rapid expansions to its roadway infrastructure, may well be exceeding Japan in its investments per kilometer of existing roadways.

The technical expertise available within the public agencies follows the same general trend as the financial investment. Where resources are ample, it is easier to hire people with a higher level of expertise and there is more of an incentive for highly capable and expert people to work in transport where they will have sufficient resources to do new and exciting things.

4.5 Traffic and roadway network conditions

ITS is not an end in itself but is a collection of technological tools that can be used to help solve transport problems. It is needed most urgently in the locations that have the worst transport efficiency, congestion, and safety problems but is not nearly as important in locations where traffic flows freely. Consequently, the levels of ITS deployment tend to be higher in the most congested urban areas and the locations with the highest density of heavy truck activity. The exception is the megacities of the developing world, which tend to have the worst transport problems of all but lack the financial and technological resources to implement ITS solutions. These are also the locations where the technical challenges are the greatest for ITS safety systems because of the chaotic traffic conditions and great diversity of road users.

4.6 Motivations to save energy and CO_2 emissions

As discussed in Section 2.2, ITS can improve the operating efficiency of road vehicle operations, enabling savings of energy and CO_2 emissions (Shladover, 1993). This can be a strong motivation for deployment of ITS in countries that are seriously concerned about reducing energy use and CO_2 emissions, because of either high energy costs or strong commitments to the Kyoto Protocol on CO_2. ITS is a particularly attractive set of strategies for saving energy and CO_2 because it can provide these benefits without necessarily adding inconvenience or diminishing the quality of life.

Japan has created the Energy ITS research program to study these opportunities for CO_2 reductions (Horiguchi *et al.*, 2010), the European Commission has initiated several analogous programs under more than one of its Directorates General, and the United States has the Applications for the Environment: Real-Time Information Synthesis (AERIS) program to explore how ITS can save energy, CO_2, and criteria pollutants. The Japanese and European programs started earlier and have had larger funding, reflecting the stronger commitments that their governments have made to implement the Kyoto Protocol.

5 FUTURE DIRECTIONS IN ITS

ITS changes rapidly, based on the rate of change in the information technologies on which it is based. Within the first decade of the twenty-first century, the dramatic changes in wireless technologies, smart phones, and the Internet have already had significant impacts on ITS and its use in automotive vehicles. Most of the major international automotive companies have established technical offices in California's Silicon Valley in order to get closer to the source of the newest innovations and to understand the next generations of technology as they are developed. In some quarters, the vehicle is already being seen as little more than a package for delivery of future information technologies. The younger generation is less interested in driving than in social networking and Internet use, to the extent that they would rather be a connected passenger than an unconnected driver. These trends have profound implications for the future of the automobile.

Two of the major technological trends in ITS that will affect the automotive future are the growth in connected vehicle technologies and applications and in-vehicle automation.

5.1 Connected vehicles

Although drivers now take it for granted that they can have a voice connection with people outside their vehicle at any time using mobile phones, the more significant growth will be in wireless data connections to and from vehicles. These may or may not involve the driver directly and may connect with other vehicles or with roadside or centralized infrastructure. Many of the ITS services depend on effective wireless communications with vehicles, but the technology of mobile wireless communications, combined with accurate positioning, is not yet fully mature.

Cooperative collision warning systems (Sengupta *et al.*, 2007) are based on the notion that each vehicle can identify its own position, heading angle, and speed very accurately and broadcast that information to all other vehicles in its immediate vicinity (a few hundred meters). On the basis of these broadcasts, each vehicle can know the state of all of its neighbors and can use that knowledge to predict potential collisions or other hazards and then warn its driver. This concept depends on highly reliable and low latency local communications (using an ad hoc wireless local area network formed using a technology known as *dedicated short-range communication*, DSRC), combined with very accurate positioning. The positioning needs to be within a meter accuracy in order to correctly associate vehicles with the correct lanes, but this accuracy stretches the capabilities of current Global Navigation Satellite Systems (GNSSs) in all but their most costly incarnations.

DSRC can also be used to support vehicle-infrastructure cooperative safety systems for intersection collision warnings and can enable each vehicle to serve as a traffic data probe (Shladover and Kuhn, 2008). The traffic data probe functions and other non-time-critical services such as medium-range safety warnings, traveler information, and traffic management can be implemented using the fourth-generation (4G) cellular data technologies that are already on the market and growing rapidly. As these wireless technologies become more pervasive and affordable, newer connected vehicle applications will be conceived and developed to provide mobile services that have not even been imagined yet.

5.2 Vehicle automation

Until now, road vehicles have always been operated under the direct control of a human driver. As long ago as the 1930s, futurists were already conceiving the notion of an automated vehicle that could be driven without human intervention. Research on this topic has been conducted

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto167
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

intermittently since the late 1940s (using vacuum tube analog electronics at that time), motivated by the opportunity to overcome some of the limitations of human drivers (Shladover, 1995). Under automatic control, vehicles could be driven more accurately and closer together to increase highway capacity and their speed profiles could be smoothed out to reduce energy use and pollutant emissions. As the automated control systems do not get fatigued or inattentive, there is also a potential to reduce crashes, although there are still significant challenges in software safety and fault tolerant control in order to ensure that automation failures do not create new categories of crashes (Shladover, 1999).

The enabling technologies for vehicle automation have been advancing and becoming more affordable based on the market introduction of other vehicle capabilities (ranging sensors for collision warning and adaptive cruise control systems, electromechanical steering and brake actuators for electric and hybrid vehicles). The interest of the public and the industry has been piqued by the autonomous automated vehicle demonstrations sponsored by the Defense Advanced Research Projects Agency (DARPA) and the entry of Google into this field. Ultimately, safe and high performance automated vehicles are likely to require combining the sophisticated sensing and software technologies of the autonomous automated vehicles with the connected vehicle wireless technologies, to produce cooperative automated vehicles that are capable not only of perceiving their surroundings but also of communicating actively with their peers and with their host infrastructure (Shladover, 2009).

Evolution and Future Trends

André J. Vits
Directorate-General Information Society and Media, European Commission, Brussels, Belgium

1 INTRODUCTION

The development over recent few decades of information and telecommunication technologies (ICT) has changed dramatically the transportation sector and how it operates.

The step from mainframe computers to microprocessor technology, personal computer, and handheld devices has provided the transportation and traffic engineering community with an almost unlimited toolset for on-site real-time processing of traffic data, complex modeling, and visualization of results in a highly interactive way, image processing, on-board processing units and network architectures, visualization devices, and so on.

Communication technology development became the second pillar on which basic services could be build. Mobile handsets (GSM, Global System for Mobile Communications) became not only the main voice communication channel but is today the main carrier for data communication (3G and 4G GSM generations). The necessary infrastructure for new "telematic" services became available to a wide range of potential service providers.

The demand for mobile internet has been the driver for the development of new communication protocols, such as WiFi and WiMax.

But also in other frequency bands, new opportunities became available: 5.8-GHz band became the carrier for automatic debiting, 24-GHz band for short-range radar applications (automatic cruise control), and is moving to the use of the 79-GHz band. In line with the developments worldwide, the 5.9-GHz band has been made available in Europe for (safety-related) vehicle-to-vehicle (V2V) and more general V2X communication.

While development during recent decades has been mainly driven by safety and system performance on the one side and market competition on the other side, energy efficiency and climate change have brought new challenges to be addressed. However, in all cases, it has become obvious that information technology and telecommunication services will remain the key drivers in vehicle design and the management of the transportation systems.

In the following discussions, a few aspects are elaborated that demonstrate the impact that these developments had and how this will determine our future transportation systems.

1.1 Safety and energy efficiency

Looking at the impact that ICT had, and still has, on innovations in the automotive sector, one has to recognize the importance of national and international research programs in this domain. In Europe, the (institutionalized) cooperation between original equipment manufacturers (OEM),

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

suppliers, and research institutes has boosted the development of new and performing equipment and has helped to keep the European automotive industry competitive on the global markets.

1.1.1 Setting the scene

Perhaps the first comprehensive European initiatives of the kind have been the PROMETHEUS project (Program for European traffic with highest efficiency and unprecedented safety) under the EUREKA (http://www.eurekanetwork.org/) framework.

EUREKA was created in 1985 under a multilateral agreement between European countries, with the objective to stimulate research initiatives from industry and research institutes in the participating countries. The countries committed themselves, based on a cost-shared model, to finance the efforts of their own organization(s) according to the research priorities agreed between the State Heads.

PROMETHEUS (Glathe, 1993) has probably been the most prominent from the early transport projects. The project led by the European automotive industry [BMW, Daimler, Porsche, Volkswagen, and MAN (Germany), Fiat and Matra (Italy), PSA and Renault (France), Saab and Volvo (Sweden), and Jaguar and Rolls-Royce (the United Kingdom)] involved many suppliers and research institutes.

PROMETHEUS can be considered to be the project that has set the vision for the next decades. Many of the applications elaborated in the project are on their way for broad implementation nowadays. The main objective of the project was the development of a "co-pilot," nowadays called *ADAS* (advanced driver assistance systems) that would provide the driver with a set of integrated systems to enhance his or her safety performance. The work was structured around three vertical lines of activities: PRO-CAR, PRO-NET, and PRO-ROAD and four horizontal activities: PRO-ART, PRO-CHIP, PRO-COM, and PRO-GEN (Figure 1). The project ran till 1993 with the production of a large set of test vehicles, aiming at demonstrating the feasibility of advanced in-car safety systems and smart traffic management systems.

Although the pilots were able to do so, the technology was not yet sufficient advanced to provide the necessary processing power and allow adequate integration. Much more work was needed for the development and design of industrial applications requiring more computing power, major reduction is size of equipment, fail-proved operation, and, last but not least, low production costs.

1.1.2 Major milestones

Almost simultaneously with the establishment of EUREKA, the European Union initiated his or her research policy instrument with the adoption of the EU framework program (FP) for research and technological development. In 1988, an application program was launched (DRIVE[1]) dedicated to the use of ICT in the transport sector, thus providing additional funds in the elaboration on the ideas originated not only from the research community but also from the PROMETHEUS project. The program covered not only

DOI: 10.1002/9781118354179.auto168
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

automotive applications but also telematic services and traffic management (see further).

In 2004, another milestone was taken by the project PREVENT (Schulze *et al*., 2008), focusing on preventive safety systems (Figure 1). By the end of the project, an impressive set of automotive safety systems had been integrated in the vehicles at a development stage meeting the level of precompetitive development. An international event took place in Versailles in 2007. Several of the applications demonstrated have in the mean time found themselves into commercial products, for example, intelligent cruise control, brake assist and emergency braking, pedestrian collision avoidance, and driver drowsiness control.

Considering that a modern car has more than 100 processing units on board, it is obvious that the on-board electronic architecture is of major concern to the OEM. But also the integration of several functions, for example, sensors and processing units, into one single unit is a key priority in design, both from a safety and cost perspective. A major project on this issue, InterActive (Etemad, 2010), is on-going and will present quite soon its results.

The demand for increased performance and cost reduction has made that many of the mechanical and/or hydraulic systems are replaced by electrical/electronic devices. This has paved the way for further automation of functions and potentially will some of the early ideas on "automated driving" be available for mass production quite soon. The project HAVE-IT (Hoeger *et al*., 2011) has brought this vision to reality with its concept of highly automated vehicles for intelligent transport. Main outputs of the project have been demonstrated the late 2011 and include the design of the task repartition between the driver and the codriving system (ADAS) in the joint system. A failure tolerant safe vehicle architecture including advanced redundancy management has been developed paving the way for the next generation of ADAS directed toward higher level of automation as compared to the current state of the art (see Driver Assistance).

An overview of the progress in the different regions is best illustrated by listing the major demonstration events over recent 25 years, showing evidence that the focus has moved from technical validation tests, to precommercial prototype testing, and to large-scale user acceptance testing and social cost/benefit assessment programs (Table 1).

In parallel with the development of in-car safety systems, car industry has a major interest in responding to consumers demand for comfort systems. Broadband connection is nowadays considered as a must and access to a wide range of services is part of the attractiveness of the brand. Most OEM have therefore launched this connectivity as part of their company policy, the so-called connected car. However, this is not only about comfort but also about safety. Research programs around the world have boosted the development of "cooperative systems" (the European Union), IVI—intelligent vehicle initiative (the United States), and advanced cruise-assist highway system (AHS) (Japan). Main objective is to enable the exchange of safety relevant information between vehicles and between infrastructure and vehicle using standardized messages over the most appropriate communication channel, RDS-TMC (radio data systems-traffic message channel), GPRS (general packet radio service), and short-range communication (IEEE 802.11p standard). The SIM-TD (Safe and Intelligent Mobility—Test Field Germany)project (DE) (Weiss, 2008) is using 150 probe vehicles for testing the performance of the system. Several other test sites will provide more insight on user acceptance and business potential models, for example, at the ITS (Intelligent Transport Systems) America annual Meeting 2012.

The energy crisis and in particular the need to reduce substantially green gas emissions (EU objective: −50% by 2050) has boosted the demand for electrical cars. Major research is ongoing worldwide, in particular with regard battery lifecycle and production costs (see Advanced batteries for vehicle applications). The consequences of the increase of electricity consumption by cars will have major impact on the management of the power grid. As electricity production from natural sources is increasing, vehicle batteries are considered as a potential temporary storage facility for surplus production (see Communication of Electric Vehicles). This scenario will require extensive data communication between the vehicle and the energy provider, thus giving another argument to speed up the development of a generic telematic platform in all cars.

As conclusion, one can state that the automotive industry has been able to progress along a relative clear roadmap. The large number of partners involved in the process makes progress complex and lengthy. Systems and services resulting from cooperative research is finding its way into product development and markets. Although benefits to the driver and society are obvious, the wide-scale introduction remains strongly dependent on the economical environment, further technical progress and user acceptance.

2 NAVIGATION/TELEMATIC SERVICES

2.1 Navigation systems—comfort and safety benefits

Perhaps one of the most early "telematics" systems has been the navigation devices, as paper maps are replaced by digital maps and the driver is assisted in his driving task through route guidance and turn-by-turn information.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 1. Major demonstration events worldwide.

Year	Europe	The United States	Asia
1986–1989	LISB (Leit und Informations system Berlin—DE)—Autoguide (London—UK) (information and navigation system)—V2I		RACS–AMTICS (JA) (traffic information services—V2I)
1994	**Prometheus demo** (collision avoidance, cooperative driving, and autonomous vehicles)		AHS–ASHRA (JA) (automated vehicle platooning)
1995–1996	STORM (Stuttgard—DE) Integrated traffic management system (several services)		AHS Demo, Komoro (JA) (advanced cruise assist)
1997		AHS, San Diego (automated cars, trucks, and bus on a segregated lane)	
1998	Automated vehicle guidance demo, Leiden (NL) (FP4 project results)		South Korea demo (KR) (platooning by four passenger vehicles)
1999	CHAUFFEUR I demo (FP4—truck platooning)	Demo '99 Launch of the IVI program	
2000	Torino ITS world conference (IT) (advance driver assistance, etc.)		Demo 2000 Ministry of Land, Infrastructure, and Transport (JA) (automated vehicles, crash avoidance at traffic lights, and curbs) Japan, Ministry of Economics, Trade and Industry (JA) (platooning)
2002	Demo 2002, Versailles (FR) (a wide range of applications)		
2003	CHAUFFEUR II (automatic platooning)	National IVI demo, FHWA (forward collision warning, intersection-collision warning, etc.)	
2004	Intelligent vehicles conference, Parma (IT)-IEEE (EU research projects) Cybercars Demo, Antibes (full automated public transport)		
2005	Road of the future (NL) (showcase of ADAS systems)	Innovative mobility showcase, ITS world conference, San Francisco (cooperative driving, 5.9 GHz DSRC, ADAS, etc.)	Smart demo, ITS Australia (active safety, crash notification, driver-assistance systems, etc.), AVS-3 demo, Hokkaido (JA)
2006			Demo 2006 (JA) (near-term deployment of 5.8 GHZ DSRC—several functions)
2007	PREVENT, Versailles (FR) (safe speed and safe following, lateral support, intersection safety, vulnerable road users, and collision mitigation—25 cars)		
2010	Cooperative mobility showcase 2010 (NL) (ITS App Store)		
2011	HAVE-IT, final conference (SE) (driver assistance systems—highly automated driving)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

From the early development stage, two different approaches have been pursued: the first infrastructure based and the second using autonomous system approach.

Under the leadership of Siemens (von Tomkewitsch, 1986), an innovative system for route guidance was developed, known as *ALISCOUT* (1986) or *EUROSCOUT* (1989). After entering his destination, the driver receives from the Traffic Operation Center routing information when passing beacons installed at strategic intersections. The system used infrared communication technology and gave turn-by-turn guidance. Major field trials took place in West-Berlin (LISB) 1989–1990 and also in London (Autoguide). As new technologies emerged (i.e., satellite positioning—microwave communication), the technology was abandoned.

As positioning though satellite systems was not yet available for public use, early autonomous navigation systems used odometer and gyroscope data to calculate the trajectory of the vehicle and map matching algorithms to position the vehicle on the map. Early 1990, Japan had already a sizable market for navigation systems. The development of the US GPS (global positioning system) (1978–1995) and its availability for public use (May 2000) has resulted in an explosive growth of the sector.

In Europe, major development was made through EUREKA research projects: DEMETER (Digital Electronic Mapping of European Territory) and CARMINAT, involving several OEM and equipment suppliers. The high cost of in-vehicle integrated navigation systems and the poor quality of the available maps made market deployment very low for a long time.

The mass production of personal digital assistant (PDA), integrating general-purpose processing unit and a GPS receiver, provided the platform for the implementation of navigation systems. As of May 2000, GPS signals available for public use could profit from a high accuracy and navigation equipment gave substantial improvement in user acceptance. Prices have since fallen to consumer levels and navigation systems have become a mass market item.

Worldwide the number of turn-by-turn navigation systems is estimated at 200 million devices, of which some 120 million are personal navigation devices (PNDs) and 40 million in-car integrated systems. The prospects for navigation-enabled mobile phones, estimated at 40 million in 2011, are expected to rise up to 200 million by 2015 (Berg Insight, 2011) (Figure 2).

As the GPS constellation came to completion, the deployment of the GALILEO system will allow to increase the position accuracy to a few centimeters (see Technologies—Positioning: GNSS). This will allow an additional number of potential functionalities, for example, lane departure warning and additional support in maneuvering will be provided on navigation systems. In addition, the inclusion of safety-related features in the map data base gives a number of interesting and potentially important functionalities. As part of the PREVENT (MAPS & ADAS) project, the potentials have been investigated for several applications, for example, for advanced cruise

control (ACC) and stop-and-go, where the digital map acts as a predictive sensor.

2.2 Traffic information services

Already in the early 1970s, the ARI (Autofahrer Rundfunk Information) broadcasting system was developed using the FM band. This system was the basis for the radio data system (RDS), which specifications were completed in 1984 by the EBU (European Broadcasting Union). Experiments took place in Germany and in several European countries. A further important building block for the development of telematic services has been the adoption at an early stage of the ALERT protocol (Davies, 1991), defining coding rules for a large set of messages.

Given the limited possibilities for location coding in the ALERT protocol, a new set of specifications was defined, called *TPEG* (transport protocol experts group) (Kopitz and Marks, 2003), and is on its way for deployment. These new coding specifications will enable a wider range of services to a vast range of users and devices. It allows a wider range of applications not only for road traffic information services but also for public transport information, parking information, and so on.

Each TPEG message comprises three key parts: message management, the application event, and the location referencing. The location referencing itself is partitioned into many components allowing all types of client devices to localize an event and display the localization as appropriate to the client.

Traditionally, road operators have been the main sources of traffic information as part of their responsibilities for safe operation of the network and efficient management of the service. Owing to public demand, public transport operators have become more active in this area, in particular when dealing with traffic disturbances and emergency situations. Nowadays, most operators offer direct access to timetable information and ticketing over smart phones. Bilateral agreements between operators allow access to multimodal trip information and will allow the creation of pan-European traveler information systems. Issues remain the access to real-time data and updating of traffic information, as to provide optimal support to travelers during their trip (see Applications—Intelligent Vehicles: Driver Information).

More and more service providers appear on the market collecting and broadcasting travel and traffic information. These private service providers can build their services on the data collected and made available by the operators and also from own data. The very wide deployment of mobile telephony (GSM) has allowed telecommunication operators and service providers to monitor traffic flows using the handover messages from mobiles as they travel from one cell to another. This allows the calculation of average speed and by extrapolation length of queues. A similar technique is expanding using WiFi connected devices. Although the range is much smaller, it has potential for the monitoring of traffic in urban areas.

As the number of mobile devices with GPS receiver is growing very fast, uploading location data is becoming a very attractive method to collect (real-time) traffic data.

2.3 Client feedback

Quite early, navigation system providers have integrated RDS-TMC messages into the map attributes, thus providing almost real-time traffic information (when and where available).

As map data, and in particular white page information, is very sensitive to changes, regular updates of the map database is a requirement for optimal performance, but it is also very sensitive in customer appraisal.

Triggered by the success of the social network models, customer feedback has become part of the business model, for example, TOMTOM (http://www.tomtom.com/?Lid=1) and Coyote (http://shop.coyotesystems.com/). The customer becomes part of the production and updating process. The registered user benefits from his or her participation through higher data quality. This trend will further expand and act as a model for other telematic services as data transmission costs will further decrease.

2.4 Open platforms

Smart phones have become an important alternative for OEM integrated telematic platforms, due to the price and their flexibility. A highly integrated board, including GSM, GPS modules, accelerometer, and more to come, provides a platform for an almost unlimited number of applications. Major issue remains the fact that road accidents are in the majority of cases attributed to driver distraction and mobile devices are of the kind to take driver attention for periods longer than is considered safe.

The flexibility of smart phones is challenging for the OEM as technology cycles are extremely quick and product lifetimes are very short compared with the average lifetime of a car. To provide a comparable level of applications, two different development scenarios are on the drawing table.

1. The on-board system interfaces with the portable device and limits functionalities to those considered safe while driving. This is based on the consideration

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto168
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

that most drivers own a smart phone and want to use its functionalities and stored personal data.

2. The other builds on the belief that the future generation of vehicles will have an integrated platform as a basic feature that provides connectivity to its environment. This is not only for comfort and entertainment purposes but mainly for safety purposes [C2C (car-to-car)–C2I (car-to-infrastructure)—cooperative driving] and vehicle monitoring (proactive maintenance, power train, and battery control). A further area for potential integration is related to payment systems, for example, tolling.

In both scenarios, the human machine interface (HMI) becomes an extremely important part of the overall design of the car. The challenge is to provide customer demand while ensuring that safety and security requirements are met. This need has been recognized by a large number of stakeholders and led to the creation of the HUMANIST VCE (Virtual Center of Excellence) (Médevielle, 2010). HUMANIST acts as a network of research centers, universities, and industry with the common objective to get a better understanding of human behavior and optimal design of the man–machine interface (see Driver Distraction).

3 TRAFFIC MANAGEMENT

A third area of great importance for the development and the future deployment of telematics is related to the operation and management of the road network.

The explosive growth of road traffic has put public authorities over recent decennia for the challenge to maintain reasonable traffic flow conditions. While in the past, growth could be compensated by new infrastructures, this becomes more and more difficult because of urbanization and environmental constraints.

Similar to other domains, the large-scale availability of high performing processing devices has changed the environment of the road manager. From mainly construction and maintenance technologies, ICT has taken today an important part of the investments and operation and will continue to do so. Although the advantages of wide-scale deployment of telematics/ITS are obvious, road operators are concerned about the high rate of technology changes and continuity of service. Progress in standardization and drafting of technical specifications is too slow to cope with technological developments (see Applications—Intelligent Roads and Cooperative Systems: Urban Traffic Management and Advanced Highway Management Systems).

3.1 Data acquisition and variable message signs

Perhaps the first priority of road operators is to have access to real-time data from its network. Detectors and image processing have therefore been the forerunners. Speed, volume, and vehicles classes are in real-time available and are feeding automatic incident detection (AID) algorithms. They provide the necessary statistical data for tactical decisions and calibration of simulation models.

Considering the deployment of embedded telematics in cars, many development scenarios look at the potential for the vehicle to act as sensor in the network, sending its (vehicle) data to the operators network, thus potentially reducing the cost of road infrastructure and expanding the traffic monitoring capacities to the whole network.

Most traffic control operators require a visual confirmation of the correctness of the data or the emergency call. Cameras (in the past closed-circuit TV) have become an important instrument in the traffic control centers to reduce the need to send police to the site before taking remedial action. Digital technology has made the cost of equipment and transmission (in most cases over dedicated communication network) to decrease sharply. Nowadays, on-site equipment, including cameras, can be connected to the control center through wireless links, thus making cabling requirements less stringent.

The same applies for variable message signs (VMS), where major progress has been achieved with the availability of high performance LED technology. Although low power consumption and IP-based communication are cost-efficient, the physical infrastructure on which the panels are mounted remain expensive and form a potential obstacle in case of an incident. As the "connected car" finds its way into the market, local traffic signs (messages) can be displayed on the vehicle display using he or she same communication channel as the one used for V2V communication. As shown from experiments, driver attention is increased and a safer driving behavior achieved.

3.2 Electronic toll collection

Tolling exists since the ancient times and has been a tool to finance large infrastructures, as construction and operation has been outsourced to public–private initiatives. In most cases, charging was introduced as the infrastructure became available (bridge, tunnel, and motorway). For many years, toll was collected at large toll plazas at toll booths manually and by credit cards.

From the early beginning of the European research programs, short-range communication has been a topic of research, looking at the most appropriate frequency range

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto168
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and communication protocols. After long and difficult negotiations, a standard was adopted by CEN (EN 12253:2004, etc.) using microwave transmission at 5.8 GHz. This technology has been deployed on all major toll motorways in Europe, allowing free-flow tolling, and thus reducing the land use needed for toll plazas. The European Union Directive 2004/52 EC on the interoperability of electronic road toll systems in the community (EFC, electronic fee collection) requires the operators to arrive to an interoperable system and single charging agent (one invoice) (European Commission, 2004).

The interoperability of toll services in Europe is considered as a prerequisite for the further implementation of road charging for trucks (>3.5 Ton).

Several other technologies have been used for tolling, or congestion charging (see below), but mainly license plate recognition (e.g., London and Stockholm). Charging is based on access time and duration. These schemes have been evaluated in depth and from the results it is clear that user acceptance is good if the charging fees are adapted to the specific size of the city, the alternative transport facilities, and the modal interfaces.

The progress achieved, both in navigation technology and mobile communications (GSM), led to the development of the toll collect (http://www.toll-collect.de/en/home.html) system. Toll collect has been developed in Germany for truck tolling on motorways and became fully operational as from 1 January 2005. The total network covered by toll collect is 12,600 km of motorways and trunk roads.

3.3 Mobility pricing

From an economical view, the (road) operator provides a service and it is logical that the customer (the road user) pays for this service. The price of this service should basically be depending on demand and supply. This basic principle in transport economics has been difficult to implement, due to already existing taxes and levies imposed on the road user. Many cities have implemented schemes in which price is dependent on time of day, type of vehicle (environmental zones), and so on. Poor traffic conditions and unpredictability of journey times (both private and professional) lead to the fact that more and more (road) users are inclined to accept the need to have a more flexible pricing system.

In principle are the different technologies, that is, image processing, transponders, and so on, suited for the implementation of (local) pricing schemes. If a scheme is implemented that covering a wide(r) network and compatible over different cities and countries, the GSM/GPS-based tolling system seems to be the most appropriate way forward. This requires standardized on-board-equipment and a competitive market across the European Union for service providers (see Tolling, Mobility Pricing).

3.4 Junction control

Traffic light controllers are perhaps the most sophisticated on-site equipment nowadays. Over the years, these controllers have evolved from electromechanical switching equipment to fully electronic devices, running complex control algorithms. Most cities have installed over the years a central coordination of the traffic lights, triggering the local controllers according to optimal offsets between junctions, aiming at optimizing flow on main corridors (green waves) or minimizing total delays in the network (e.g., using simulation models such as TRANSYT7).

Nowadays, distributed architectures are put in place, using mesh technology for communication between traffic controllers.

Junction control could well become one of the early applications of vehicle-to-infrastructure (V2I) communication, warning the driver on the remaining time to end-of-green, recommended speed, and so on. The high accident rate at signalized junctions could be the main rational to add this functionality into the traffic controller. RITA, the Research and Innovative Technology Administration of the United States, has made intersection control one of its priorities within the VII, also called *Connected Car*, research program.[2] Several traffic controller manufacturers are testing the application of V2I technology in close cooperation with the European efforts on "cooperative driving" through the EU research program.

Together with pricing is full network management definitely the next step to achieve acceptable levels of service, for example, not only on the highway network but also on the feeding network. As demand for mobility will further increase and environmental requirements will become more stringent, optimization across transport modes is nonavoidable. In this process, due account must be taken of the complex nature of behavior and choice of transport mode (car–train/metro–bus/tram walking). As urban centers will further grow and transport intensity increasing, it is essential that modal transfers are optimally managed. The multitude of operators, complexity in layout, and modal characteristics make this a major challenge for the future operation of our transport systems. This requires at urban and local level strong teams with specialized skills in transport management, willing to work together with a common objective.

4 FUTURE TRENDS

Looking at the technological progress made over recent 20 years, technology has fundamentally changed our view on mobility and our choices of travel modes. This choice is not any more exclusively the private car, but depending on the motive of the travel, the most appropriate mode or combination of modes to perform the trip in the most convenient way (walking, bike, tram–bus, and metro/train/airplane).

On the vehicle side, both energy supply and environmental issues will dominate the design of the next generation vehicle fleets. The electrification of the car is clearly on its way and a sizable market penetration of hybrid and full electric vehicles in the near future is realistic, in particular in the market segment of household second car and shared-car schemes. These segments are well suited as usage is characterized by short distance travel. Further deployment will depend on progress in battery technology, the use of low weight materials and size reduction.

Traffic safety needs to remain a major priority. As new designs will emerge on the market, in particular small and light vehicles, the composition of traffic flow fundamentally changes. Interaction between vehicles with significantly different dynamic characteristics could have a negative impact on road accidents. In such a case, appropriate measures of segregation of vehicles become necessary with important impact on network design and operation.

However, many issues remain which are not necessarily technological but much more relate on how society will look like in a number of years and how it will impact on the mobility of people and goods.

In this perspective, the further urbanization of society is a major driver on the evolution of our transportation systems. Owing to the concentration of activities in city centers, further restriction of individual transport will be needed to achieve environmental acceptable conditions. Even under the hypothesis of large-scale deployment of electric cars, congestion will be a sufficient reason the restrict access. This is only possible if highly performing public (collective) transport systems are available and transfer between modes is optimally organized.

The further integration of the European Union and its economy depends on an efficient and highly efficient transportation system. As these networks are used by both local and long distance traffic, traffic conditions are highly dynamical and unpredictable.

In both cases, telematic services are extremely important and will be able to show their full benefits. Although each operator runs today its own portal with traffic information (mainly roads), timetables, and booking facilities, they tend to be reliable only under normal traffic situation and perceived by the user as static data. The real challenge is to provide real-time data and, perhaps most important, information on the disruption of service and possible alternatives across modes. Within the eSafety Initiative (http://ec.europa.eu/information_society/activities/esafety/index_en.htm, 2003), traveler information has been one of the key issues addressed by stakeholders and has been taken up as one of the actions under the EC ITS Action Plan (http://ec.europa.eu/transport/themes/its/road/action-plan/, 2008).

As technology changes and our mobility needs is evolving, the role of governments and public authorities becomes critical in creating the conditions necessary to be met, both in terms of regulations and of new infrastructures. Many platforms exist addressing the transportation issues from a strategy level, for example, the United Nations and the International Transport Forum. In parallel with the ITS Action Plan, the European Union adopted a Directive on the deployment of ITS (2010/40/EU) (European Union Directive, 2010), putting in place a framework in support of the coordinated and coherent deployment and use of (ITS) within the Union, in particular across the borders between the Member States, and sets out the general conditions necessary for that purpose. The Directive also provides for the development of specifications for actions within the priority areas referred to in Article 2, as well as for the development, where appropriate, of necessary standards. One can argue if this is the appropriate instrument to address these issues. It has the benefit however that the need for common specifications and standards is brought at the attention of Member States and a platform for discussion and consensus is established.

To help the decision process, both an EU, national and regional levels, the need exists to create, or improve existing simulation and support tools able to provide a clear and objective view on the impact of policies.

5 CONCLUSIONS

Although the technology has made huge progress, large-scale deployment depends on a number of external factors such as economic growth, stakeholders' cooperation, and user acceptance. Typical for transport telematic services is their complex nature and a value chain that involves many organizations. As internet has provided the user an almost unlimited access to data and information free of charge, identifying the correct business case for new telematic services is difficult and not always successful. All innovations however demonstrate that data V2X communication has huge potentials in supporting major societal needs.

Technological breakthrough in ICT has been the main drivers for the development of transport telematics; GSM, GPS, smart phones, and social network software are the building blocks for telematic services. It is therefore extremely important that transport experts keep an open mind for developments in other sectors and take advantage of emerging technologies to provide high quality telematic services.

1 INTRODUCTION

Being connected while on the move has become a common customer expectation. This expectation goes hand in hand with a change in the observed user behavior. Nowadays, apps and connected devices have become part of people's everyday life. Cellular networks are expected to provide the required connectivity whenever and wherever needed, which is a big change compared to the situation just two decades ago. A further trend with impact on society and major economic and environmental implications is the ever-growing demand for personal and goods mobilities. A steady increase in road traffic, particularly in developed or rapidly developing counties, is spurring the demand for real-time traffic information, safety applications, and a broad set of connected car services. Hence, the underlying expectation on ubiquitous cellular connectivity is becoming increasingly important for the mobile society and the just-in-time economy. A changing perception of the usefulness of the deployed cellular networks and recent technology advancements have led to a more balanced thinking when arguing for additional large-scale investments in dedicated vehicle communication infrastructure for certain driver or passenger services. In any case, we do not discuss anymore whether cars will become connected in the future—they will! The question is rather: what is the best option to realize tailored connectivity for automotive applications from a technology perspective, considering operational, economic, and timing conditions?

This chapter provides some basic information about cellular communication systems, required to properly address those questions. Major trends in cellular communications and resulting impacts to business and society are discussed in Section 2. The various generations of cellular wireless communication systems, their key characteristics, and prime network elements are introduced in Section 3. Section 4 illustrates selected use case procedures and how core network (CN) components interact with each other in an integrated system design. Special attention is put on advanced scenarios with particular relevance for automotive communication. Finally, Section 5 provides a short introduction on the standards and regulatory frameworks related to cellular communication. An outlook on latest developments and implications concludes this chapter.

2 CELLULAR MOBILE NETWORKS

Cellular mobile digital networks are one of the fastest growing and most rapidly developing technology segments of the past few decades. Starting with the establishment

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

of the global systems for mobile communication (GSM) standardization group in 1982, with the ambition to specify a pan-European mobile cellular radio system for primarily voice communication at 900 MHz, it has laid the foundation for connecting more than 5 billion users worldwide in 2010 (More than 50 billion connected devices, 2011; City life, 2012).

The pace of development is remarkable, constantly gaining speed and spread. The decision to specify a digital system (rather than a new analog one) in 1985 was followed by the selection of the time division multiple access (TDMA) method in 1987 and the promise of all early European mobile network operators (MNOs) to have the first interoperable GSM systems running by 1 July 1991.

Over the following two decades, GSM has evolved to a digital mobile communication system that connects the world, impacting society and businesses worldwide. Recently, another major transition is materializing, comparable to the step from analog to digital telephony. Originally developed for point-to-point (PTP) voice communication, circuit-switched (CS) communication networks are gradually being replaced by the so-called all-IP (all Internet protocol) data communication networks. This new breed of networks transports IP packets rather than switching voice circuits. In Q4 2009, the data traffic volume of these so-called packet-switched (PS) networks has already overtaken the aggregated traffic in CS networks. It doubled its volume by Q1 2011. Between Q3 2011 and Q3 2012, the mobile data traffic volume doubled again (Ericsson mobility report—on the pulse of the networked society, 2012). A major driver and accelerator for this trend was the introduction of Apple's iPhone in 2007. The subsequent rapid spread of powerful smartphones has in turn led to an explosion in data traffic volume in mobile networks worldwide. According to studies done by Ericsson (Ericsson mobility report—on the pulse of the networked society, 2012), mobile data traffic is expected to grow with a compounded annual growth rate of around 50% (2012–2018), driven mainly by video. This entails growth of around 12 times by the end of 2018. In that period, data traffic will be split fairly equally between devices such as smartphones on the one hand, and PCs and tablets on the other (Figure 1).

To accommodate such tremendous communication network demands, entirely new radio technologies and new communication system designs had to be developed and deployed within just a few years, responding to capacity and bandwidth challenges. The additional demands, added by the transition of CS voice communication to voice-over Internet protocol (VoIP), are small compared to the always-on desire of the twenty-first century society, expecting Internet access and interconnected

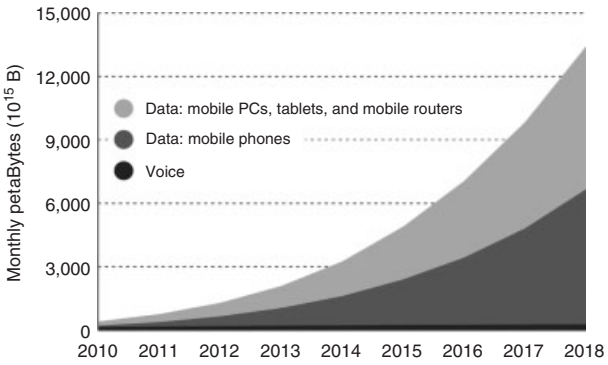

Figure 1. Mobile traffic—voice and data, 2010–2017. (Reproduced by permission of Ericsson.)

media applications to work seamlessly from all kinds of connected devices at any time.

The rapidly changing habit in human communication has deeply impacted business and business processes. With modern cellular network technologies, many types of digital devices can be connected to automate business processes and implement novel system functions in a virtually connected way. Experts predict that by 2020, there will be more than 50 billion connected devices (More than 50 billion connected devices, 2011; City life 2012). This enormous growth and requirements from entirely new application segments have put demanding new challenges to network suppliers and operators. Beside a substantial increase in network capacity and cellular communication bandwidth, also demand for a much simplified network operations and business systems management has been expressed, together with the need for communication latency reductions and a reduction in the connection establishment time in cellular networks.

Since its early GSM days, data communication speeds have been boosted from 9.6 kbps to more than 100 Mbps with long-term evolution (LTE) technology today—an increase by a factor of 10,000 in just 15 years. Latency time for data transmission has reduced from many seconds with GSM to <50 ms with LTE Release 10 in 2012 (Next generation LTE, LTE-Advanced, 2010). This breakthrough in the capabilities of cellular mobile communication technology has in turn led to a new evaluation of latest developments in connected vehicle designs, real-time telematics services, and just-in-time logistics.

The following sections will, therefore, provide a brief summary of the cellular mobile digital communication systems evolution, to the extent relevant for automotive engineering. System functions specific to CS voice communication or those being of little relevance in the automotive engineering context (such as wireline communication) will be only described on a very basic structure level.

3 SYSTEM ARCHITECTURE

3.1 System families and their evolutions

The appearance of digital radio networks, with its various technology choices, has led to a number of different network families. For simplicity reasons, their evolution steps have been mapped to a commonly used "generation numbering scheme." Analog communication is referred to as *first generation*, the first digital systems are called *second generation* (*2G*). Systems, fulfilling the requirements of the International Telecommunication Union's (ITU), the so-called IMT-2000 (International Mobile Telecommunications 2000) system (Rappaport, 2001), are counted as third generation (3G). Systems fulfilling the newer IMT-Advanced requirements are called *4G (fourth generation) systems*. Most of these system families have evolved in various steps and phases since its beginning at the mid-1990s. Figure 2 illustrates how the various cellular network families and their various versions relate to each other.

Some of the first 2G systems were only developed for just one or a few countries, such as personal digital cellular (PDC), which is used exclusively in Japan. Others gained wider acceptance, such as the IS-136 and IS-95 systems, both standardized within the Telecommunications Industry Association (TIA). IS-136 is a 2G system from the early 1990s, also called the *North American Time Division Multiple Access (TDMA)*, which has been widely used in North America, Canada, and South America. IS-95, commonly called *cdmaOne*, is already using a modern code division multiple access (CDMA) wireless access, a precursor to the radio access used in many state-of-the-art systems. cdmaOne emerged in the mid-1990s and is a popular 2G technology in the Americas, Asia, and Eastern Europe.

Originating from Europe, the 2G GSM uses TDMA, comparable to IS-136, but with a higher system capacity. GSM has first been standardized in 1990 by the European Telecommunications Standards Institute (ETSI) and is the most widely used 2G system. With the establishment of the third-generation partnership project (3GPP), the GSM standardization has been transferred from ETSI to 3GPP.

All these systems were, however, primarily designed for voice communication. The first system primarily designed for data communication, also referred to as *packet-switched communication*, was the general packet radio services (GPRSs), which is also known as *2.5G*. GPRS was later enhanced by the enhanced data-rates for global systems for mobile communication evolution (EDGE) upgrade. Although it was never considered a 3G system, it is interesting to note that EDGE even fulfills the basic requirements for IMT-2000 systems, such as peak data rates of at least 200 kbps (Rappaport, 2001).

The first true 3G system was the universal mobile telecommunications system (UMTS), standardized in 3GPP and first offered in 2001. It was primarily used in Europe, Japan, China (however, with a different radio interface), and other regions predominated by existing GSM 2G system infrastructure. Broadcast and multicast capabilities have been added through the multimedia broadcast

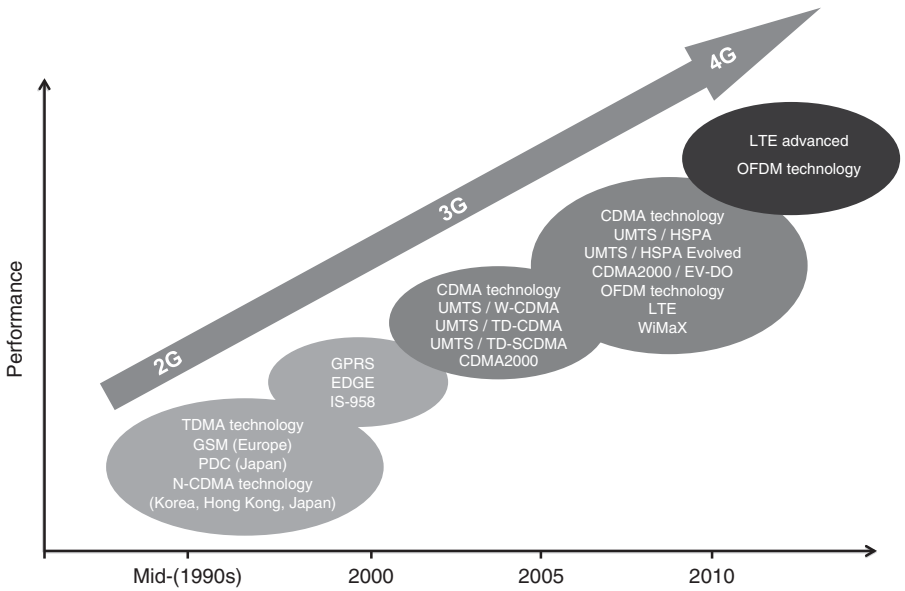

Figure 2. Evolution of cellular networks.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

multicast service (MBMS). Seamless interworking between GSM and UMTS was already part of the initial standards, so that 3G phones are typically UMTS and GSM hybrids. UMTS was further improved with the high speed downlink packet access (HSDPA) and high speed uplink packet access (HSUPA), often jointly referred to *HSPA* (*high speed packet access*). These evolution steps primarily added higher transmission speeds, but also other improvements such as faster round-trip times required for interactive applications.

UMTS is, however, not the only system fulfilling the IMT-2000 requirements, one other popular example being the CDMA2000 standard, which is the next generation of the IS-95-based cdmaOne systems. CDMA2000, first offered in 2002, is standardized by the "third-generation partnership project 2" (3GPP2) and has been used especially in the Americas, Asia, and Eastern Europe, mostly because of the installed base of 2G cdmaOne systems. The base system called *CDMA2000-1x* has symmetric bandwidth for up- and downlinks, the later CDMA2000-1x EV-DO (where DO is for data only) has introduced an asymmetric channel model optimized for data transmission. The later CDMA2000-3x systems support larger frequency bands, allowing for higher throughput. Similar to the GSM/UMTS systems, mobile phones are typically CDMA2000 and IS-95 hybrids.

The 4G standard follows the ITU's IMT-Advanced requirements. The most prominent example of a 4G system is LTE. LTE is the 4G wireless data communications technology of the 3GPP family that already standardized GSM and UMTS. The world's first publicly available LTE service was launched by TeliaSonera in the Scandinavian capitals Oslo and Stockholm in 2009. The LTE specification provides downlink peak rates of 300 Mbps, uplink peak rates of 75 Mbps, and a novel scheduling mechanism enabling round-trip times of <50 ms (Astély *et al*., 2009; Larmo *et al*., 2009). LTE has the ability to manage fast-moving mobiles and supports multicast and broadcast streams using "evolved multimedia broadcast multicast service" (eMBMS, Section 4.2.1). LTE supports scalable carrier bandwidths, from 1.4 to 20 MHz and supports both frequency division duplexing (FDD) and time division duplexing (TDD). Later releases of LTE have the name LTE-Advanced.

According to current trends, LTE is leading the convergence of various cellular network standards. For networks with an installed 3GPP base, LTE is set as default evolution path. But also network operators with existing CDMA2000 networks have a migration path toward LTE, including a solution for seamless handovers between CDMA2000 systems and LTE. Operators in North America and Asia, with a deployed CDMA system base, have already taken steps to migrate to LTE. Correspondingly, LTE is anticipated to become the first truly global communication standard for cellular mobile networks.

Mobile WiMAX (worldwide interoperability for microwave access), based on the IEEE 802.16 family, that fulfills the ITU's IMT-Advanced requirements is, therefore, formally also a 4G communication system. It can provide bit rates of up to 50 Mbps with its 2005 version. Despite the addition of mobility features, with the IEEE 802.16e enhancements, WiMAX has, however, not gained ground as a true mobile network. Its usage is seen primarily in fixed and nomadic data network installations. Figure 3 illustrates these technology convergence market trends, together with the corresponding technology standardization bodies.

An overview of most prominent cellular mobile data communication technologies is provided in Figure 4. Peak data rates have drastically improved with each generation's technology advancements. For instance, LTE Release 10 (which includes first LTE-Advanced enhancements) can support up to 1.2 Gbps peak rates under ideal channel

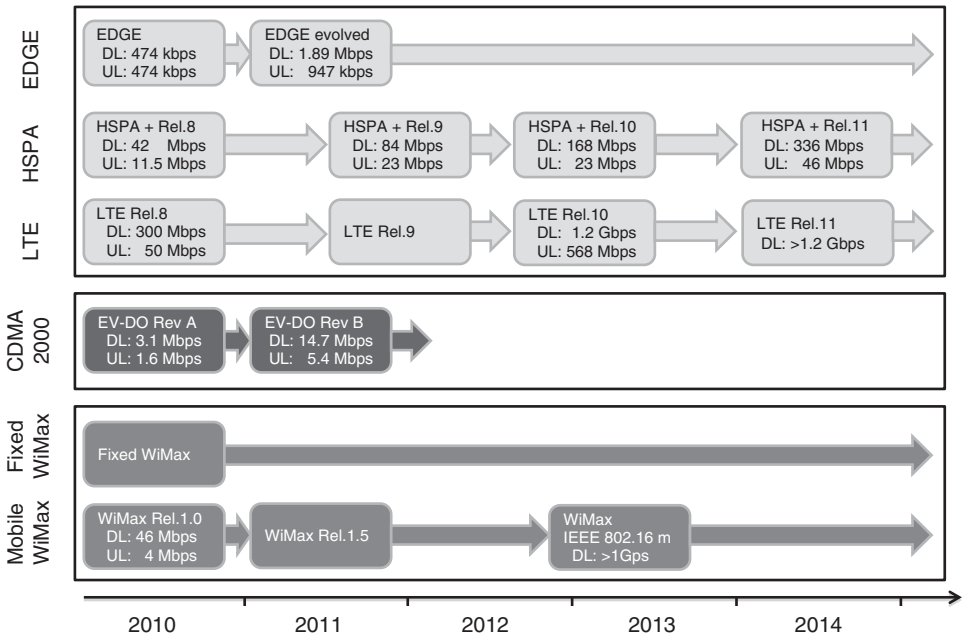

Figure 4. Yearly peak rate evolution for various wireless technologies.

conditions, nearly 2500 times higher than what EDGE technology offers. Under such conditions, LTE-Advanced provides more than three orders of magnitude higher data rates than EDGE provided only a decade ago.

We believe that with the rapid global roll out of LTE and the already confirmed technology improvements coming with the introduction of LTE-Advanced, LTE will be the main technology track for coming 4G systems. Consequently, we will focus on LTE as 4G technology base in the following sections. To stay focused, we limit the following discussion on engineering aspects and only briefly touch upon legal and regulatory aspects. The following sections provide a systematic overview of the core elements of a 3GPP cellular mobile system, its essential interfaces, and the corresponding business support functions.

3.2 Architecture overview

Core elements of an overall system blueprint are indicated in Figure 5. To help the reader with a basic understanding of a fairly complex system landscape, we provide a walk-through of these core elements in the following paragraphs. Some basic end-to-end procedures, involving several of the elements, are explained in Section 4.1. Section 4.2 details selected scenarios with particular relevance to automotive engineering. Regulatory and standardization aspects are outlined in Section 5. Section 6 concludes with an outlook on trends and developments.

Given the several cellular mobile network families, their various evolutionary stages and generations, and the enormous changes in system and service requirements, it is very challenging to provide a concise, yet comprehensive, view on corresponding architectural principles. Nevertheless, an effort is being made as follows, with a few disclaimers to be considered:

- Within each cellular communication system family, a number of gateway functions have been introduced to provide backward compatibility, interworking, or fall-back capabilities. For simplicity reasons, these gateway functions and protocol converters are largely omitted. Some operators of cellular and wireline communication networks had different technology families in operation at the same time. Corresponding interworking functions and aspects related to specific adaptations of network operation components or business support functions are omitted.
- Functionalities dealing with country-specific legal or regulatory concerns, or the so-called market adaptations, are not presented or discussed. The same holds for circuited switched voice specifics going beyond typical needs in automotive engineering. Intelligent network (IN) features, integrated services digital network (ISDN) characteristics, and multimedia messaging service (MMS) messaging capabilities are being of less relevance in the automotive engineering context and hence omitted.

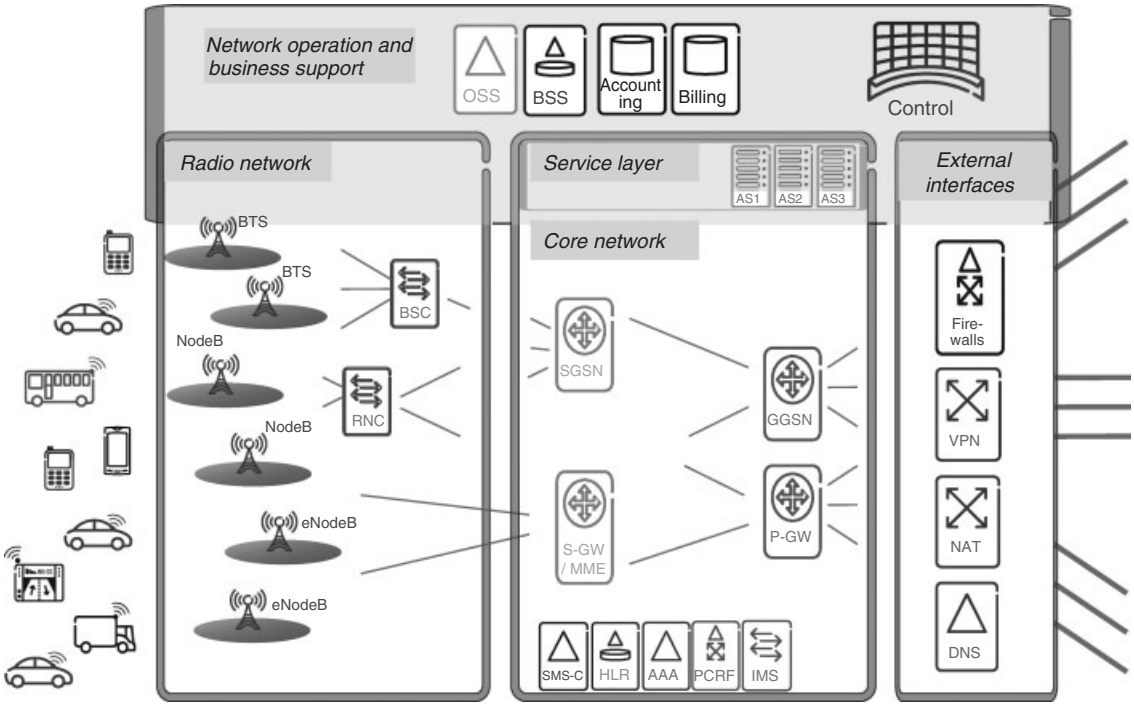

Figure 5. Basic domains of a reference cellular network.

- On the basis of the technology trends discussion in Section 3.1, we will use the 3GPP system family as architecture reference. System functions and terminology have changed many times when moving from 2G to 4G designs. For the sake of simplicity and without any claim of consistency, we will use common system component terminology for explaining the principal interactions and just refer to related names at other technology generations.

From a high level logical abstraction point of view, a cellular network architecture can be considered as a tree-like consolidation and control structure, with the geographically spread out mobile cellular terminals (Section 3.2.1) on the one end and a virtually central access node, for all incoming and outgoing data and voice communication to or from a particular mobile network, on the other end (Section 3.2.3).

The basic domains of a cellular mobile network, in a single operator instantiation, are illustrated in Figure 5. The radio sites, with its base stations (BSs), antenna systems, BS control notes, and the corresponding transmission networks, constitute the radio access network (RAN). The remaining domains are forming the core of the operational network, with its service layer extensions, interfaces to national and international connect, and operational support systems (Section 3.2.5). The latter is a cross-section function, spanning from the RAN nodes to the external interfaces (Section 3.2.4). These domains will be described in turn.

3.2.1 *Mobile terminal*

From an end user perspective, the most tangible part of a cellular communication system is the device that terminates the connection on his or her end. These devices come as a smartphone, a USB (universal serial bus) stick, connected navigation device, embedded vehicle module, or in many other forms. Their common denominator is the capability to interact with the mobile network according to the agreed standards. We will focus on this common aspect, and will, therefore, also consistently use the term *user equipment* (*UE*) throughout the following sections, which is common in 3GPP standardization.

The UE is identified through two main identifiers: The international mobile equipment identity (IMEI) and the international mobile subscriber identity (IMSI). While former identifies the physical device, the latter identifies its current user, also referred to as *subscriber*. The format of the IMSI is internationally harmonized (International Telecommunication Union Recommendation E.212, 2011) and is used in the same way in all interoperable mobile networks around the world. It consists of a three-digit mobile country code (MCC), followed by a two-digit or

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

three-digit mobile network code (MNC) and an identification number of the subscriber within the network. MCC and MNC together uniquely identify a mobile network and, therefore, also enable connecting to a user's home network when abroad (Section 4.1.4). Note, however, that the home network does not necessarily need to be physically located in the country indicated by the MCC, which is, for example, useful for complex multicountry operators. There is also a dedicated "world-wide" MCC (901) for global systems, which is, however, mainly used for satellite communication networks.

In 3GPP networks, the IMEI is hardcoded in the UE, whereas the IMSI is stored in a small chip card, commonly called *subscriber identity module* (*SIM*). Technically, this chip card is called *universal integrated circuit card* (*UICC*), which can hold different so-called applications. One of them is the SIM for 2G GSM; others are the USIM for 3G UMTS networks or the ISIM for the Internet protocol multimedia subsystems (IMSs). UICCs also come in various form factors, including surface-mounted versions that can directly be soldered onto a printed circuit board (PCB). Along with the IMSI, the SIM stores various other information such as the credentials that are used in conjunction with a personal identification number (PIN) to authenticate the UE to the network. A major advantage of the SIM is that, unless a soldered version is used, the IMSI can easily be transferred from one device to another, for example, when buying a new phone. In CDMA2000 networks, the IMSI is traditionally hardcoded on the UE, which makes hardware changes more cumbersome. Lacking a SIM and hence the ability to securely store credentials, CDMA2000 is using a username/password authentication schema to authorize the network access. CDMA2000 devices, however, increasingly use the UICC that contain a special code division multiple access-SIM (CSIM) application, so that also here the IMSI is no longer tied to the device.

In addition to the SIM, various other software components may be needed to complement the UE. Examples are a client for the IMS or common enablers such as the GeoMessaging client proxy (Jodlauk, Rembarz, and Xu, 2011) used for geographically targeted distribution of unicast messages. In CDMA networks, additional software may also be required to terminate certain communication protocols such as the point-to-point protocol (PPP) or mobile IP.

To manage radio resources, all relevant mobile networks implement different communication states for the UEs. The two most important ones are the idle state, that is, when the UE does not have an active data transmission and the active state that is used when actively transmitting data. All 3GPP systems have the notion of states. In addition, CDMA2000 networks implement such concepts,

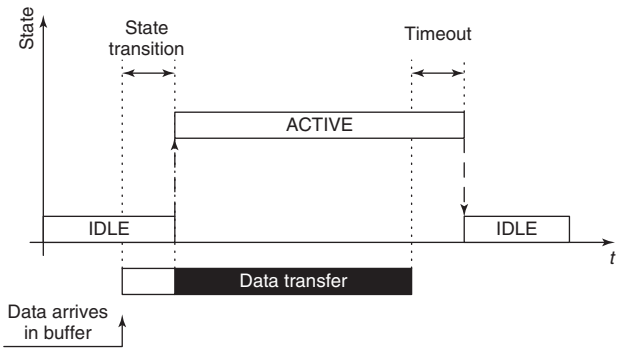

Figure 6. Transmission states.

for example, the dormant state. Most modern systems use a state model with more than two states, for example, the discontinuous reception (DRX) mode.

Although very different in terminology and implementation, all systems share a basic operating principle that is illustrated in Figure 6. When a UE first wants to transmit data, it needs to go through a certain procedure to become active, for example, to synchronize its timing with the network or to allocate network resources. After this state transition, the data transfer can commence. Following a certain inactivity timeout, the UE falls back into an idle mode that releases network resources and saves battery. A practical implication of the state model is that a certain time has to elapse before a first data transmission can start. Transitioning from idle to active mode required several seconds in UMTS and HSPA systems, with LTE this time has been reduced to <100 ms.

The UE is integrated into automotive communication in different manners:

- Fully embedded systems have an on-board unit (OBU) with integrated UE. These devices do not rely on any other device to establish a network connection. A prime advantage of this approach is its optimal connection to the on-board vehicle infrastructure, such as roof-mounted antennas or in-car communication buses.
- Carry-in communication concepts allow a user to provide the connectivity using a user-owned mobile phone. A cell phone, for example, can be tethered to the car-integrated communication network, for example, using a cable, Bluetooth, or Wi-Fi connection. One option is to have the application logic reside in the car, so that the mobile phone only operates a modem. Another option is to execute the applications on the phone and transfer the content to the in-vehicle systems using well-defined interfaces (Car Connectivity Consortium homepage). One major advantage of a carry-in concept is that no UE needs to be integrated into the car,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

which saves cost and makes upgrades to new network features easier. In addition, the connection costs are paid by the owner of the phone.

- Hybrid systems combine both approaches and split the communication between an on-board UE and a carry-in device. The on-board connectivity is typically used for car-centric services, such as remote door unlock, whereas the carry-in connectivity is used for driver-centric services, such as infotainment. As a variation of a hybrid system, a car may also offer a dedicated slot to insert a user-owned SIM only to be used for driver-centric services.

It is common that the communication modules that are finally built into vehicles support multiple of the network technologies from the various network generations (Figure 2), explained in the following sections. It should, however, be noted that not in all cases all possible frequency bands for a certain technology may be available in a given module. Especially, when a large number of frequencies are standardized for a certain technology, it is a common practice to introduce localized versions of the modules that support a subset of frequencies commonly used in the given region.

3.2.2 Radio access network

From an end-user perspective, the RAN is the most visible element of a cellular wireless communication network. UE, that is, cell phones, wireless modems or modules (Section 3.2.1), or the corresponding parts of a vehicle communication platform, constitute the mobile leaves of a large logical tree structure, as indicated in the introduction.

Once activated, the UE attaches to the so-called radio base station (BS). In 3GPP, the BSs (Figure 5) have different names, depending on the system generation: in a 2G GSM system architecture, they are called *BTS* (*base transceiver station*); in a 3G UMTS system, the BS is called *NodeB*; in 4G LTE, it is called *evolved NodeB* or *eNodeB*. The main task of the BS is to terminate the wireless radio link to the UEs, manage the radio resources in its coverage area, and facilitate UE mobility, for example, handling the communication hand-over procedures when a UE is moving from one serving BS to another. The preconditions and the more detailed procedures for a successful attach of a UE to a certain BS are detailed in Section 4.1.1.

Further on, a BS is the most remote part of a cellular communication network, that is, it represents the connectivity end point to the CN (Section 3.2.3) as illustrated in Figure 5. In 2G and 3G networks, additional active network nodes were introduced between the BS and the CN. In 2G systems, these nodes are called *base station controllers* (*BSCs*). In 3G systems, these nodes are named *radio network controllers* (*RNCs*). They serve as an additional control level for mobility management and radio resource management. Owing to the tree topology of the transmission network, voice and data traffic within a geographic area is aggregated at the sites where these elements are placed. With the 4G LTE network architecture simplifications, those nodes disappeared. Corresponding system functions were moved into the eNodeBs or were taken over by 4G CN nodes.

The connectivity between the elements of the radio network and the CN has been implemented through various transmission network components. These so-called backhaul networks were traditionally based on copper cables. Nowadays, these connections have largely been replaced by fiber-optic cables. In case of very remote BS sites, directional microwave transmission networks are used. With the enormous technology development in recent years, it is anticipated that future 4G and 5G radio networks will even be able to use their own primary radio interface for connecting itself to the CN infrastructure (self-backhauling).

3.2.3 Core network

The CN is the central data handling and control domain of a cellular mobile network. It is surrounded by a number of CN support functions, shown as network support systems in Figure 5, and a service layer, with its various application servers (ASs). The CN is complemented by an overarching networks and business operation support domain (Section 3.2.5) and the external interfaces (Section 3.2.4).

While the CN support functions constitute typical elements for network control, naming, and addressing schemas, the complementing service elements provide functionality for subscriber and UE management as well as service layer extensions, such as databases, look-up services, authentication and authorization controls, or messaging functions. Some of them are briefly described in Sections 3.3 and 4.

The strictly hierarchical structure, indicated at the introduction to Section 3.2, continues toward the CN. Incoming data traffic (seen from a BTS or RNC perspective) is handled by SGSNs (serving general packet radio service support nodes). Consolidated outgoing data traffic is handled by the GGSN (gateway general packet radio service support node).

In 2.5G (GPRS) or 3G (UMTS) systems, the GGSN (Figure 5) represents the termination point for all external IP data traffic to the CN and for IP traffic initiated at UEs and tunneled through the interim nodes and links between a UE and the GGSN. In terms if IP routing, it is the last

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

IP hop before the UE. Consequently, the (virtually single) GGSN node of a cellular mobile network provides a port for injecting IP data traffic that potentially can reach any mobile terminal within the entire cellular network of a particular operator. On the other way round, all IP data traffic originated from a UE attached to the cellular network must pass through the GGSN node before leaving the mobile network. In other words, the GGSN represents a distinguished connection port for data consolidation, traffic inspection, access control, and charging purposes.

With the introduction of 4G LTE systems, a number of more drastic changes have been introduced to the CN design and its RAN counterparts. The innovations have started on the radio side. LTE provides more efficient use of the spectrum with wider spectral bands reserved than its predecessors. This results in greater system capacity and performance. At the same time, the CN needed to change to provide a more efficient structure capable of handling high data throughput. This goal has been reached with the so-called *EPC* (*evolved packet core*), first specified in the 3GPP Release 8 standards that were finalized in 2009. It features a very much simplified and improved flat all-IP network architecture, spanning from mobile handsets and other terminal devices with embedded IP capabilities, over IP-capable eNodeBs (LTE BSs), a renewed and capacity-enhanced backhaul connectivity network (Section 3.2.2), across an EPC network, throughout the application domain—with and without IMS extension (Poikselka *et al*. 2006; Camarillo *et al*. 2011)—to the external interfaces, illustrated in Figure 5.

Four key elements of the EPC are the Serving Gateway (S-GW), the Mobility Management Entity (MME), the Packet Data Network Gateway (PDN-GW, or P-GW), and the Policy and Charging Rules Function (PCRF). The S-GW and the MME are typically co-deployed and thus illustrated as "S-GW/MME node" in Figure 5. The S-GW is a data plane element whose primary function is to manage user-plane mobility and acts as termination point of the packet data CN interface to the 4G RAN. The MME performs the signaling and control functions to manage the network access of a UE, the assignment of network resources, and the management of UE mobility states to support tracking, paging, roaming, and handovers.

Analog to the S-GW, the PDN-GW, or P-GW, in Figure 5, is the termination point of the external interfaces toward the packet data CN. Being a further anchoring point for external data network sessions (Section 3.2.4), the PDN-GW supports policy enforcement features (applies operator-defined rules for resource allocation and usage), packet filtering (e.g., deep packet inspection for application type detection), and charging support [e.g., per URL (uniform resource locator) charging]. Thus, the PDN-GW is comparable to the GGSN in a GPRS/UMTS CN. It should be noted that even though the transport network has become fully IP-capable, the IP traffic to the UE is still encapsulated in tunneling protocols in order to support mobility. From an external interface perspective, both nodes, therefore, appear as high capacity IP routers that constitute the last IP hop before the UE.

The fourth node introduced with the EPC is called *policy and charging rules function* (PCRF). The generic 3GPP policy and charging control model supports service data flow detection, policy enforcement, and flow-based charging. It provides means required for dynamic policy and/or charging control. 3GPP Release 8 enhanced the scope of the initial PCRF functionality to facilitate also policy and charging control functions for non-3GPP access to the network (i.e., Wi-Fi) or for fixed IP broadband access.

The network elements described so far are assisted by a number of network support functions. These functions ensure end-to-end quality of service (QoS) communication characteristics, implement policy control features, provide network security means, handle address name resolutions with domain name services (DNS), perform network address translation (NAT), and support IPv4 and IPv6 address allocations. The PCRF is considered part of these network support functions.

With UMTS Release 5 and with the accelerating development toward an all-IP CN design (Olsson *et al*. 2009), a call and session control system called the *IP multimedia subsystem* (IMS) (Section 3.3.2) was introduced. IMS supports IP-based multimedia and voice applications and is designed for both wireless and wireline networks. It is based on IETF[1] protocols such as the Session Initiation Protocol (SIP) or Diameter, which have been extended for the use in 3GPP networks. IMS simplifies the establishment and handling of end-to-end IP sessions, across multiuser shared radio and wireline links. As a side effect, and with particular relevance for automotive engineering, it supports service-oriented billing and QoS assignments by relating different service groups (such as telematics safety services and infotainment services) to different IMS sessions.

IMS-initiated QoS requests are further processed and implemented by PCRF node, described earlier. Depending on current system load, established QoS requests, QoS classes, and priority schemas, the PCRF responds to the requesting system node. Most modern PCRFs are multitenancy capable so that it can support 3GPP cellular networks with and without IMS extensions at the same time.

The IMS system itself consists of a number of functions, linked by standardized interfaces, and grouped to form one IMS administrative network. The call session control function (CSCF) is used to process SIP signaling packets in the IMS subsystem. There are three types of CSCF:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

proxy call session control function (P-CSCF), serving call session control function (S-CSCF), and interrogating call session control function (I-CSCF). Each CSCF node is an SIP proxy with routing capabilities, linked to control and charging functions of its underlying cellular network. The P-CSCF is the initial SIP signaling contact point for an IMS-capable UE. It is responsible for forwarding SIP registration messages from the UE to the I-CSCF and subsequent call setup requests and responses to the S-CSCF. The P-CSCF maintains the mapping between logical subscriber SIP URI address and the physical UE IP address and its security association, for both authentication and confidentiality.

As the CSCFs are pure control functions, they rely on network elements such as media gateways or media resource functions (MRFs) to handle the actual data traffic, for example, for on-the-fly media processing or further service enrichments such as multiparty calls.

Application servers (ASs) host and execute system or external services, and interface with the S-CSCF using SIP. The MRF provides media-related functionality such as media manipulation (e.g., voice stream mixing) and playing of tones and announcements. A breakout gateway control function (BGCF) is a SIP server that includes routing functionality based on telephone numbers. See (Poikselka *et al*., 2006; Camarillo *et al*., 2011) for a deeper description of the IMS system, additional functions and architecture variants.

For the network access, the UE can connect to an IMS network in various ways using IP. An IMS-capable UE can register directly on an IMS network, even when they are roaming in another network or country (the visited network). The only requirement is that the UE can use IP (typically IPv6, but also IPv4 in early IMS deployments), can run IMS-compatible SIP user agents, and has the corresponding IMS identities provisioned. All modern IP-capable access networks are supported. Older systems, such as "plain old telephone service" (POTS—the old analog telephones), H.323, and non-IMS-compatible VoIP systems, are supported through gateways.

The service layer, indicated in Figure 5, with a multitude of ASs, is complementing the CN with subscription management, access right validation, UE location functionality, and much more. Note that some nodes described here as part of the service layer can also regarded as being CN components, depending on the context. In this context, we focus on selected nodes with central coordination roles.

The home location register (HLR) acts as centralized database node, providing most static information about all subscribers and subscriptions, within the whole cellular network. Thus, it constitutes the central database of a 2G cellular network for subscription-related information. The HLR is typically colocated with the authentication centre (AuC). The AuC is a function to authenticate each SIM card that attempts to connect to the GSM CN (e.g., when the UE gets powered on and initiates an access request to a cellular network). Once the authentication is successful, the HLR is allowed to manage the SIM and the services registered with the corresponding subscription. An encryption key is generated that is subsequently used to encrypt all wireless communications [voice, SMS (short messaging services), etc.] between the mobile phone and the 2G GSM CN. For more information about the attach/detach procedures, see Section 4.1.1.

Similarly to the hierarchical transport connectivity structure, indicated in Figure 5, the HLR is assisted by a set of connected databases for temporary subscriber data, such as the currently attached BTS and corresponding serving CN nodes. These associated databases are called *VLRs* (*visitor location registers*). With the introduction of 3G UMTS, the HLR, AuC, and some further functions got consolidated into the home subscriber server (HSS).

Together with additional service-layer security means, the authentication, authorization, and accounting (AAA) functions provide one of the most value-adding features in the 3GPP network architecture. This set of functions, complemented with a dedicated legislative framework and country-specific regulatory requirements, provide the foundation for cellular MNOs becoming a kind of trusted service providers (SPs). Some operators have leveraged that position and even applied for a banking license to provide even mobile payment solutions.

In the context of cellular networks, one can distinguish two groups of services: first of all, there is a wide array of services that are either placed on the Internet or only available within the system domain of a certain network operator. A second group, however, is the so-called standardized telecommunication services. The latter are available in almost all cellular networks, work with any suitable device, and are interoperable between different cellular mobile networks.

Examples of standardized telecommunication services are: to put a voice call on hold, to have the ability of forwarding a voice call, or to get a call-waiting indication. However, also modern IP-based services for presence, chat, and video conversations fall into the category of standardized services that are interoperable and supported across network operator boundaries. Furthermore, messaging services such as the MMS, rich communications services (RCS), and SMS are standardized services. Only the latter is of bigger relevance to the implementation of telematics services and thus is described in more details in Section 4.2.1.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.2.4 External interfaces

The prime integration layer for external data communication services in Figure 5 is indicated by the external interfaces domain. Despite some shared functionalities, such as DNS, NAT, network access control, logging or monitoring functions, and dedicated firewalls, one can distinguish three types of interfaces to external SPs or communities:

1. Type 1: Connections to network elements of other cellular or fixed-line operator networks.
2. Type 2: Connections to specific enterprise networks.
3. Type 3: Connection to the public Internet.

Connections of type 1 are typically linked via special very high speed international network connections (GSMA IR.67, 2012). There are dedicated operators providing these high speed long distance and inter-Atlantic connectivity capabilities, an important precondition to provided roaming capabilities (Section 4.1.4) between different operator networks. Two groups of data protocols are used with type 1, namely IP and non-IP protocols. The latter are standardized lower-layer protocols to interconnect primarily 2G cellular systems and wireline telephony systems of various kinds. The IP links within type 1 are tailored to support end-to-end QoS across network operator domains, enable network congestion control on global levels, and link the various accounting and control functions, being engaged in multioperator data and service scenarios.

The external interfaces in types 2 and 3 are predominantly IP based. Type 2 is a value-added service that cellular MNOs provide primarily to enterprise customers (GSMA IR.67, 2012). APN configurations are provided to these enterprises that make it possible to connect to a virtual connection point at a specific GGSN or P-GW (Figure 5).

The concept of virtual private networks (VPN) can be used to provide end-to-end secured network connections from, for example, an enterprise network to a UE or vice versa. A VPN user typically experiences a VPN-connected UE as if being directly connected to a specific enterprise network.

From an external network's point of view, the GGSN and the P-GW are high capacity routers to a subnetwork, because they "hide" the further CN infrastructure from the external network. When the GGSN (or P-GW) receives data addressed to a UE (respectively to a specific user), it checks if the UE is active. In that case, the GGSN (or P-GW) forwards the data to the SGSN (or S-GW), which is serving the UE. UE-originated packets are routed to the target destination network by the GGSN (P-GW) routing function.

Access to the public Internet in type 3 is rather similar to type 2, considering the public Internet as a kind of specific enterprise network. VPN technology can be used to establish secured connections through the public Internet. This advancement has mostly replaced the need to provision and maintain expensive dedicated leased-line telecommunication circuits that used to be a common practice in wide-area network installations just a few years back.

3.2.5 OSS and BSS support systems

This topmost domain in Figure 5 is a cross-sector function with two complementing duties. The operations support system (OSS) most frequently describes "network systems" that cellular operators use for supporting processes such as maintaining network inventory, provisioning of services, configuring network components, and managing faults. The complementary term *business support systems* (*BSS*) typically refers to "business systems" dealing with customers, supporting processes such as taking orders, processing bills, and collecting payments. The two systems together are often abbreviated OSS/BSS.

Naturally, only a few elements of the OSS/BSS domain are described in this context. Elements mostly relating to the OSS subarea are control and monitoring functions for network elements and system nodes. Communication network related data traffic inspection, data volume monitoring and accounting components, QoS supervisions, network policy controls, and network security monitoring elements may add to the OSS.

The BSS system is encompassing all functionalities related to service accounting and billing, the processing of charging data records (CDRs), such as CDR mediation functions and real-time rating functions for prepaid subscribers. It also contains self-provisioning portals for enterprise customers and all functions dealing with inter-operator key performance indicator (KPI) supervision, roaming-cost related data capturing and processing, as well as data back-up handling, or country-specific business and operation adaptations.

3.3 Network security

The basic security principals of today's mobile networks have been included in the 2G GSM network already, using authentication mechanisms and encryption based on the SIM (Section 3.2.1). In 3G systems, UMTS, and later in LTE, these basic principles remain and have been further developed. Especially, in LTE and IMS on service layer, Internet and Web security mechanisms [HTTP (hypertext transfer protocol), AKA (authentication and key agreement), and internet protocol security (IPSec)] are included as well.

3.3.1 Basic telecommunication security principles

Providing data security and tapping protection is a key requirement for communication networks. As it is practically impossible to protect all network nodes and links between these nodes against unauthorized physical or logical access, it must be ensured that the information itself is protected. The requirement to be no more vulnerable to eavesdropping than fixed phones was considered in the design of GSM. It addresses these goals by providing user-related security features for authentication, confidentiality, and anonymity.

The authentication feature is intended to allow a network operator to verify the identity of a user such that it is practically impossible for someone to make fraudulent calls by masquerading as a genuine user. Confidentiality protects the user's traffic, both voice and data, and sensitive signaling data, such as dialed telephone numbers, against eavesdropping on the radio path. An anonymity feature was designed to protect the user against someone who knows the user's IMSI from using this information to track the location of the user or to identify calls made to or from the user by eavesdropping on the radio interface.

A well-known security feature, introduced with GSM, is the use of a chip card, the SIM (Section 3.2.1). The SIM contains all the identification and security-related data that the subscriber needs to make or receive a call. It is, in effect, a portable security module, personalized for the subscriber. The SIM can be used to access services in any network with which the subscriber's home network has a roaming agreement (Section 4.1.4).

During roaming, the subscriber's home network provides all the data needed by the serving network to operate the security features without revealing any of the sensitive security data stored in the subscriber's SIM.

UMTS and LTE security builds on the success of GSM by retaining the security features that have proved to be needed and that are robust. As in GSM, a smart card is used in UMTS and LTE to store all the identification- and security-related data that the subscriber needs in order to make or receive a call. In UMTS and LTE, the GSM security features have been improved, for example, extending the key length from 64 to 128 bit. This key is used for the generation of a ciphering key that is needed for the symmetric encryption of the user data.

3.3.2 IMS security

On top of the network-level security mechanisms described in Section 3.3.1, IMS (Sories, Huschke, and Phan, 2008) as service layer management system with an underlying more general security architecture (as specified in 3GPP TS 33.20331) can be used.

An IMS subscriber will have a IP multimedia private identity (IMPI), which is authenticated and stored beside all other relevant subscriber data in the central repository of the IMS system, the HSS (Section 3.2.3). During user registration, the subscriber data is transferred from the HSS to the S-CSCF. Hence, upon request by a user, the S-CSCF can match this request with the subscriber profile before access is granted, such that the home network can control access.

Overall, IMS provides five security associations in order to secure the communication between all relevant nodes of the home or a visited cellular network. The authentication and key agreement for IMS is based on the same mechanism as in UMTS.

An additional feature relevant in this context is the generic bootstrapping architecture (GBA) (3GPP TS 33.220, 2012) that makes it possible for services to reuse the existing security association between terminal and network. GBA can create special session keys during the standard authentication procedure that can later on be used to authenticate the user to a service.

As a conclusion, it can be noted that mobile networks feature extensive security mechanism that are already part of the standardized and commercial available networks. Mechanisms such as the GBA even facilitate the reuse of these proven security associations for automotive services and for corresponding end-to-end solutions.

4 END-TO-END PROCEDURES

This section provides some sample end-to-end procedures, illustrating the interworking of the various cellular network elements introduced in Section 3.2.

4.1 Basic procedures

This section delivers an overview of the most important procedures in a 3GPP cellular network. We focus on the general operating principle that is common to most systems. Detailed descriptions are available in (Dahlman, Parkvall, and Sköld, 2011; Camarillo *et al*., 2011; Olsson *et al*., 2009).

4.1.1 Registering to a network

When a UE (Section 3.2.1) is first switched on, it has to attach to the network in order to be able to establish and receive calls and connections. The procedures slightly differ depending on the exact network used, but the principles are very similar. As a very first step, the UE detects available

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

radio networks. For this purpose, all radio BSs constantly broadcast a defined set of system information, among them the identification of the mobile network and the current cell and area identifier. Different area identifiers exist, which are, however, conceptually very similar. Here, the example of the tracking area (TA) or location area (LA) code is used, which will become important later on. Using this broadcast information, the UE can determine which mobile networks are available. It will likely see more than one radio BS per network. In the simplest case, the UE will receive a signal from its home operator and will subsequently contact the BS with the strongest signal to initiate the attachment and registration procedures.

After some initial steps to synchronize the radio communication, an authentication phase follows (Section 3.3.1). The UE uses the credentials stored on the SIM card to authenticate against a corresponding set of credentials stored in HLR or HSS. The user identifies to the network using the subscriber identity (IMSI). Upon successful completion of the authentication, the user is marked as reachable in the network databases (Section 3.2.3), along with the TA and LA it is currently in.

The connection setup in 3G and 4G networks typically also involves establishing the so-called default bearer and obtaining an IP address. This bearer can then be used for basic IP communication. When the UE is IMS-capable (Poikselka *et al*., 2006; Camarillo *et al*., 2011), the IP connectivity is also used to register the user to the IMS. In addition to the default bearer, dedicated bearers with specific characteristics can be established at a later stage (Section 4.2.2).

When no data or voice transmission is required after this phase has been successfully completed, the UE turns into a power-saving idle mode (Section 3.2.1) in which it only monitors a special set of broadcast channels.

4.1.2 Call and session handling

For any kind of connection establishment, two basic cases have to be distinguished: connections initiated by the UE (mobile originated) and connections initiated by another party (mobile terminated).

For mobile-originated connections, the UE contacts the mobile network using a signaling channel. For 2G and 3G systems, dedicated signaling channels and protocols are available. For all-IP networks, for example, based on 3G or 4G, typically, the IP-based IMS (Poikselka *et al*., 2006; Camarillo *et al*., 2011) is used. The mechanisms in the mobile network locate the other party or parties, and assign the network resources to transport the actual data. In 2G GSM systems, this includes assigning the TDMA timeslot to be used. For IMS systems, this involves setting up a dedicated bearer for the IP communication related to the connection. Such a bearer is mapped to an appropriate QoS class (Section 4.2.2), which, for example, ensures that interactive voice or video conversations get priority handling in the network. The signaling mechanisms in IMS are flexible enough to set up various data sessions for virtually any application; they are not limited to setting up voice, video, or similar. A possible automotive use case would be to set up a generic data connection with special requirements, for example, with prioritized delivery for time-sensitive messages of a cooperative ITS system. This integrated process that includes resource reservations in the network is one of the major differentiators to purely Internet-based voice or video services.

Mobile-terminated calls generally follow a similar pattern. Before the procedure described earlier can, however, start, the network may need to locate the UE. When the UE has an ongoing, active connection, the network knows exactly where and how the UE can be contacted. If it is in an idle state (Section 3.2.1), the TA or LA stored in network databases (Section 3.2.3) are used to determine the approximate area in which the UE has last reported its position. As this area typically involves a larger number of radio networks cells (Section 3.2.2), a paging message is sent over the broadcast channels of all cells belonging to the area. The UE monitors these channels, receives the paging message, and establishes a connection to the radio network. The remaining procedures are carried out similarly to the mobile-originated cases. Note that also advanced features such as special sessions involving dedicated bearers can be initiated by the calling party, so that, for example, an AS in the network (Section 3.2.4) can proactively set up connections without waiting for the UE to initiate them.

4.1.3 Mobility management

Being able to maintain a connection while moving between cells (Section 3.2.2), or staying reachable despite constantly changing the locations, is a crucial functional aspect of cellular networks. The process of dealing with changing UE (Section 3.2.1) locations is referred to as *mobility management*; the actual procedure to update the location is commonly called *handover*. Two main cases have to be distinguished: handovers while the mobile is actively transmitting data and handovers while the mobile is in a power-saving idle mode (Figure 6).

The latter is by far the easier variant. In this state, the network does need to know the exact position of the UE, so that signaling every cell change is not required. Rather, the UE listens to the broadcast channels of the cells it passes, and only contacts the network when it notices that

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the TA or LA code has changed. This procedure, which can sometimes be heard when the transmissions from the UE cause interference, for example, in a car radio, ensures that the network can track the location of the UE on a sufficiently high accuracy while minimizing the signaling load and the UE's battery consumption.

When the UE is active, the network uses a sophisticated set of procedures to keep the location changes transparent to the user. The central paradigm is "make before break," that is, the handover is prepared well in advance so that no data is lost in the process. Tunneling protocols encapsulate the data stream between UE and network, so that the actual data transmission is not impacted by the handover. This is also the reason why all user data flows through the GGSN or PDN Gateway (Section 3.2.3). These nodes constitute anchor points that remain stable despite any kind of location changes. Without such an approach, handovers may impact the end-to-end data flows, as IP addresses change or the data stream suddenly needs to be routed to another access point. Such behavior would almost always lead to an at least temporary disruption in the communication, and would likely not be accepted by users. Thus, when arguing for making the IP communication accessible closer to the radio BSs, there is always a trade-off with the ability to perform transparent handovers.

Anonymized location data can also be used to observe and predict the movement patterns of the UEs. Solutions exist that correlate UE cell movement characteristics to derive road traffic pattern, so that the mobility signaling data can be used to detect road traffic congestion.

4.1.4 Roaming

Besides the ability to perform transparent handovers, another success factor of modern cellular networks is that through standardized technology, it is possible to stay connected and reachable even outside the coverage area of the home network operator. This process is commonly known as *roaming*.

From a functional perspective, the network elements used in a roaming case are jointly provided by the home network operator and the so-called visited network operator. The radio network (Section 3.2.2) and some other network elements (Sections 3.2.3 and 3.2.4) are used in the visited network, whereas central functions such as the subscriber database are still located in the home network. Thus, when registering to a visited network, the UE (Section 3.2.1) will connect to the local RAN of the visited network operator. The visited network detects that the registering UE is connecting from a foreign network and hence directs the authentication to the user database of the home network (Sections 3.3.1 and 4.1.1). Upon successful registration, the user can use the visited network. There are different options on which network elements are used in the visited networks, a particularly important choice being whether the GGSN or PDN Gateway (Section 3.2.3) in the visited network is used. Nowadays, it is still a common practice in many networks to tunnel all user traffic back to the home network, as illustrated in the simplified example in Figure 7.

In such a setup, the PDN Gateway in the home network is still the termination point for all IP traffic. This ensures that all possible services and features work just as if being connected directly to the home network operator. With the increasing usage of data connections, this, however, becomes more and more of a burden, so that using a local breakout point in the visited network will probably increasingly become the standard system setup in the future, at least for normal Internet data traffic.

Physically, the data exchanged between the home and the visited networks is transferred through interconnect networks dedicated to MNOs (Section 3.2.4). To avoid PTP connections between each and every operator, major network SPs such as Deutsche Telekom or Telia Sonera (Ala-Luuko, 2006) operate the so-called IP Packet eXchange (IPX) networks (GSMA IR.67, 2010; GSMA

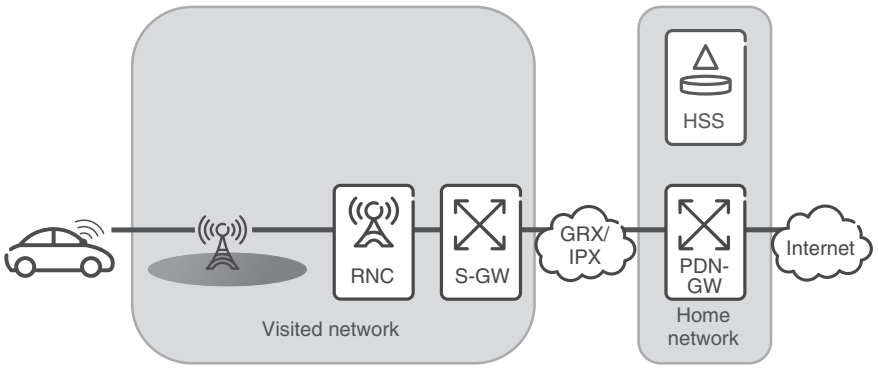

Figure 7. Simplified roaming network architecture.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

IR.34, 2012), an evolution of the earlier general packet radio service roaming exchange (GRX). These networks ensure interconnection under secure conditions and with telecommunication-grade quality. Network operators connect to one or more of these SPs, which again interconnect their IPX networks. Using IPX interconnections guarantees the high network connectivity quality enterprise customers are used from telecommunication networks, but of course also constitute a cost factor.

When roaming, a user is allowed to use the network even though the user does not have a direct contractual relation with the currently visited network operator. The standardized charging and billing mechanisms ensure that the network usage-monitoring is compatible to the system of the home network operator who will finally invoice the usage fees. There are additional fees in roaming cases, which are relevant especially for data connections. In addition, in many automotive use cases, roaming cost is a substantial cost factor in the cost calculation for telematics and infotainment services.

A prerequisite for roaming is that a user's home network operator has a roaming agreement with the network operator of the visited network. Nowadays, there is no practical limitation anymore, as almost all major network operators have agreements with at least one operator in all relevant countries around the globe. Besides these international roaming cases, it is also possible from a technical perspective to roam into another mobile network in the home country, for example, in case of poor coverage by the current cellular home network operator. While the benefit to the user would be obvious, this so-called national roaming is, due to regulatory restrictions, nowadays only allowed in exceptional cases. Typically, the regulators want to avoid the case that operators concentrate their network build-out on few lucrative areas and leave the coverage of the less business-attractive areas to other operators. In such an environment, there would be little incentive for anyone to build out good network coverage also in areas with little data or voice traffic density, such as rural areas. National roaming has, however, been permitted in cases where network sharing has helped providing better coverage in the network build-up phases.[2] Another constellation, where national roaming is usually not controversial, is in very large countries such as Russia or certain parts of Asia, where licenses are granted for subregions and where it is assumed that network operators will not be present in all those regions.

4.2 Advanced scenarios for vehicle communication

In the following section, a set of advanced capabilities, mechanisms, and functionalities of modern cellular networks are described. The scenarios detailed in Sections 4.1.1–4.2.4 are of specific relevance to automotive applications. It should be noted that the generalized capabilities are representing just a subset of a much wider portfolio, supporting a broad set of use cases and applications.

4.2.1 Cellular messaging capabilities

4.2.1.1 SMS and instant messaging services. In terms of messaging, SMS is one of the most prominent cellular services with over 8 trillion messages sent in 2011. The corresponding system control node is the short messaging services service center (SMS-C) in the service layer (Figure 5) of the CN (Section 3.2.3). The SMS-C implements a store-and-forward for SMS' to be sent. Under certain operation conditions or at certain popular events (such as New Year or a popular TV show voting), an enormous SMS messaging traffic occurs. As SMS is generally not designed to be a fully reliable service, such situation may lead to SMS-C overload situation with some messaging being dropped or becoming heavily delayed before delivering. A single SMS message size is restricted to 140 bytes or 160 text characters; however, concatenating messages is possible. Special SMS message tags can be used to make the SME appear directly on the main screen of the receiving UE (flash SMS) or to trigger auto-configuration actions. SMS can also be associated with premium services and special payment actions. With minor adaptations, the SMS service can also be made fully reliable, so that it can be used for delivering emergency notifications (emergency SMS), for example, directly to a public safety answering point (PSAP) in an emergency call scenario.

Owing to its relatively low cost and its built-in flexibility, SMS messaging capabilities were frequently used in early telematics and particularly in logistics solutions. With the global deployment of 2.5G GPRS technology (Section 2) and cross-border IP communication capabilities (Sections 3.2.4 and 4.1.4), many of these early telematics solutions were migrated to run over GPRS. With 4G LTE being an all-IP technology that does not natively support SMS, a migration wave is expected toward native IP-based messaging technology. An example for user-centric messaging is the enhanced rich communication suite standard (RCS-e), also known as *Joyn*, which shall be as interoperable as the SMS service, but add many features, such as video or group chat. As a backwards compatibility solution, the global systems for mobile communication association (GSMA) has lately released a SIP-encapsulation for SMS as part of the voice-over LTE standard (GSMA IR.92, 2013).

4.2.1.2 Broadcast and multicast services. The messaging service described in Section 4.2.1.1 is based on a PTP communication. The end points are either two telephones or, in the case of machine-to-machine (M2M) applications such as telematics services, a client–server connection.

Broadcast and multicast, on the other hand, are synonyms for point-to-multipoint (PTM) communication, where data packets are simultaneously transmitted from a single source to multiple destinations. The term *broadcast* refers to the ability to deliver content to all users. Known examples are radio and TV services, which are broadcasted over the air (OTA) (either terrestrial or via satellite) and cable networks. *Multicast*, on the other hand, refers to services that are solely delivered to users who have joined a particular multicast group. Ordinarily, a multicast group is a group of users interested in a certain kind of content, for example, traffic information. A multicast-enabled network ensures that the content is solely distributed over those links that are serving receivers that belong to the corresponding multicast group. This is thus a very resource-efficient way of delivering services to larger user groups. Multicasting was first introduced as Internet communication service.

Broadcast and multicast service capabilities for cellular networks were defined in 3GPP as the so-called multimedia broadcast and multicast service (MBMS) and in 3GPP2 as broadcast and multicast service (BCMCS). (Bakhuizen and Horn, 2005), for example, provide a comprehensive MBMS overview.

With MBMS, a new network element, the broadcast/multicast service center (BM-SC), has been introduced, providing a set of functions for controlling the broadcast/multicast delivery service.

The BM-SC serves as an entry point for content-delivery services that want to use MBMS. It sets up and controls broadcast or multicast data flows in the mobile CN (Section 3.2.3) via MBMS transport bearers and schedule and deliver efficient radio bearers (Section 4.2.2) for PTM radio transmission within a cell. The BM-SC also provides service announcements to end-devices (Section 3.2.1). These announcements contain all necessary information (such as multicast service identifier, IP multicast addresses, time of transmission, and media descriptions) that a UE demands in order to join an MBMS service. The BM-SC can be used to generate charging records for data transmitted from the content provider. It also manages the security functions specified by 3GPP for multicast mode.

In MBMS, different transmission scenarios are defined:

Broadcast mode: A pure broadcast mode provides a unidirectional PTM transmission. The broadcast mode cannot guarantee error-free reception and does not provide billing functionality. When a MBMS broadcast service starts, MBMS data is sent to all nodes of the UMTS network, from the SP down to all RNC nodes (Section 3.2.2) and to cells in the broadcast service area.

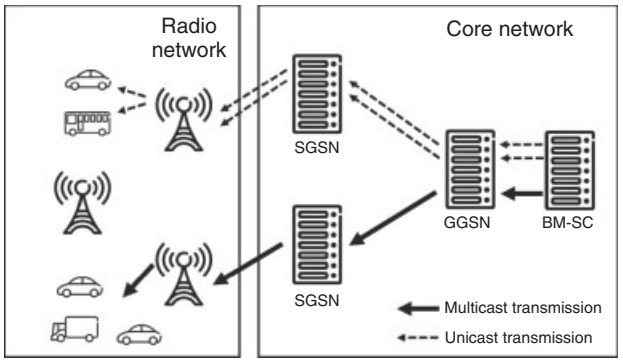

Figure 8. Unicast and multicast transmission principles.

Multicast mode: The multicast mode provides service only to groups of subscribed users. The serving RNC gets the data only once from the BM-SC by the SGSN/GGSN (Section 3.2.3). Billing functionality is included. When the MBMS multicast service starts, MBMS data is sent only to those network nodes and cells with subscribed users and its UE.

Figure 8 illustrates the differences between unicast and multicast. In unicast operation mode, each UE requests content for the same service from the BM-SC. The unicast transmission is visualized in Figure 8 as dashed arrows. From the UE toward the BM-SC (in uplink direction), the number of bearers to be handled by higher network entities increases. This is a consequence of the network's architecture hierarchy (Section 3.2) and the definition of unicast. The multicast transmission mode tries to serve the other way around: a single MBMS bearer is created at the BM-SC and is transmitted to each lower network entity requesting the associated MBMS service.

MBMS capabilities have been enhanced for LTE networks to meet additional requirements for the IP-based evolution of the cellular network architecture. Those enhancements are summarized with the term *eMBMS* (Dahlman, Parkvall, and Sköld, 2011). Correspondingly, MBMS data in LTE networks are sent from the BM-SC to the eNodeBs (Section 3.2.2) via IP multicast, a method of forwarding IP packets to multiple receiving network nodes in a single transmission. Therefore, MBMS is a resources-saving technology for the radio and the transmission network.

4.2.1.3 Location management and GeoMessaging. The cellular messaging mechanism described in Sections 4.2.1.1 and 4.2.1.2 enables the implementation of a wide variety of services, from PTP text, video, or

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

data transmission, to PTM transmission to all or a group of subscribed users, in a certain region. As MBMS was developed for the distribution of mass media services such as mobile TV, the intended distribution areas, the so-called MBMS service areas, are relatively large and static, for example, as the today's distribution areas of local radio and TV networks.

The GeoMessaging functionality (Jodlauk, Rembarz, and Xu, 2011; ETSI ITS TR 102 962, 2012; ETSI ITS TS 103 084, 2012) complements these messaging mechanism by making it possible to address recipients in a specific geographic area, which can be defined in a fast and flexible way with very fine granularity down to the size of a fraction of a single radio cell. A possible use case could be the need to inform all subscribers of a traffic information service about the traffic situation of a certain highway segment within a very short time. The basic aim of the GeoMessaging service (ETSI ITS TR 102 962, 2012) is, therefore, to deliver data from a source to all UEs within a specific geographic region. A basic prerequisite to this is that all UEs' locations are known, for example, UEs being equipped with a positioning system [such as GPS (global positioning system)], in order to determine if these nodes are located in the target geographical zone.

Owing to the hierarchical concept of cellular systems, the communication path from an AS toward a cellular-equipped car, as mobile node, is always passing several nodes of the cellular communication system (Figure 5). In order to realize GeoMessaging functionalities in cellular networks, a second basic requirement is to establish a centralized network node as dedicated GeoMessaging AS. This node receives and handles all locations and location updates from the clients (vehicles) and steers in a smart way the frequency of the location updates, such that the cellular network's signaling load, generated by localization updates, is minimized and the required precision of targeted distribution area is still maintained. Furthermore, this node distributes messages to the involved BSs (Section 3.2.2) in the concerned geographical area.

In order to realize vehicle-to-vehicle communication in cellular networks (Dietz, 2009; Gehlen *et al*. 2007; Sories, Huschke, and Phan, 2008; Phan, Rembarz, and Sories, 2011), the GeoMessaging AS may consolidate incoming messages to redistribute replication-free content back to the other vehicles in the proximity. Depending on the number of recipients in the cell, unicast or multicast transmission can be used as actual message delivery mechanism.

4.2.2 Quality of service mechanisms

Both the IP-based Internet and the PS domain work on the principle of "best effort," which means all services and applications have equal access to bandwidth, regardless of their actual needs. For example, downloading an updated navigation map is given the same priority as an Internet radio stream. The problem is that when downloading a file, the user will not experience any instant quality issues if the available bandwidth varies during the download, but when listening to Internet radio, having sufficient, constant bandwidth is crucial to the audio quality.

In the transition of telecommunications networks design from CS speech networks to all IP-based networks (PS domain), it is important that speech calls continue to be available at the same or a higher quality level than the so-called best effort services. More importantly, it must be possible to prioritize emergency calls and traffic hazard warning services to ensure that even if the networks are heavily loaded, for example, at New Year's Eve, these calls execute with a sufficient quality. This is not possible with a best-effort-only network. Therefore, the telecommunications industry defines mechanisms to ensure a specific QoS according to the individual service requirements. The QoS mechanisms defined for 3G networks were advanced and further improved in the specifications of LTE (Ekström, 2009).

Network resources can be adapted dynamically. For example, it is possible to reduce the allocated bandwidth of the wireless connection for a service if system capabilities of a vehicular user are temporary not able to cover the premium level of service. On the other hand, the provided QoS level of the network can also be reduced for nonessential services if bandwidth needs to be freed up for an emergency situation, for example, an accident involving multiple cars on a small stretch of a highway.

QoS handling in LTE networks is network controlled. Requests for altering the QoS levels can, however, be made by both the network servers and the UE. Network-initiated QoS is considered superior to UE-requested QoS. UEs can request a bearer with a specific QoS from the network; however, this requires a vendor-specific QoS API (application programming interface). By having to specify the QoS information for the bearer, it is required that the client application is "access QoS aware," that is, access-specific information is required in the signaling. UE-initiated QoS also prevents the network from modifying the existing bearer QoS settings if required.

Network-initiated QoS allows the client application to be "access QoS agnostic"; no special QoS API is required at the UE and the network can establish and modify the bearer when necessary. For example, a deep-packet inspection (DPI) function can be used to identify specific services. The required QoS parameters can be assigned and then carried over a standardized interface (Rx and/or Gx) (3GPP TS 23.203, 2012) to the network. However, in most cases,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

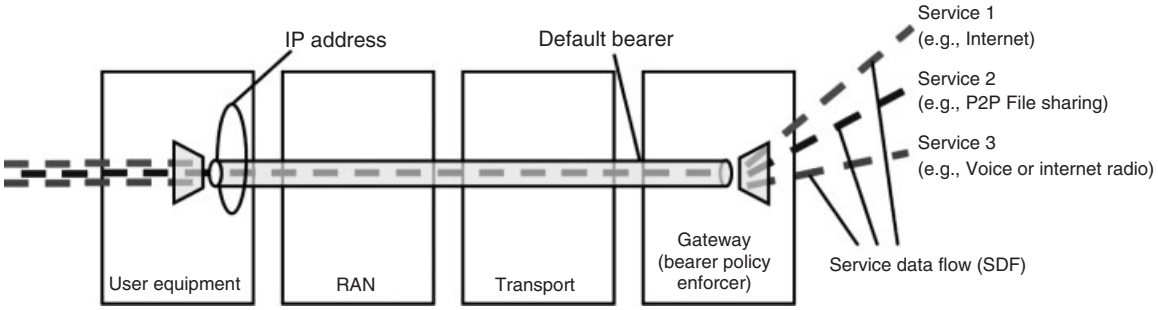

Figure 9. 3G and LTE quality of service support by dedicated bearers.

the client application is aware of the QoS that is needed in order to negotiate with the network the appropriate QoS class via application-layer signaling such as SIP (Rosenberg *et al*., 2002) and real-time streaming protocol (RTSP) (Schulzrinne *et al*., 1998). However, it should be noted that there is no access technology specific information in the signaling.

The implementation of the QoS mechanisms in the network depends on the specific cellular network technology. The QoS concept standardized in 3GPP Release 8 (Ekström, 2009) is leveraging the so-called "bearer" mechanism (Figure 9), which uniquely identifies the packet flows having the same QoS parameters.

The initial, basic connectivity is always established using a default bearer, which has no guaranteed bit rate (non-GBR). This bearer can experience issues such as packet loss because of congestion. Additionally, the UE can have one or more dedicated bearers. These can be non-GBR or GBR. A dedicated bearer with a GBR does not experience congestion-related packet loss. It is usually established "on demand," as it needs to reserve transmission resources to ensure the specific bit rate.

Each bearer, whether default or dedicated, GBR or non-GBR, is assigned a quality of service class identifier (QCI). This parameter references node-specific parameters (preconfigured by the network operator) regarding the user plane treatment (packet forwarding), for example, priority, or packet-error-loss rate. Additionally, an allocation and retention priority (ARP) parameter specifies how the setting up and retaining of bearers on the control plane is handled.

For dedicated GBR bearers, parameters such as GBR and MBR (maximum bit rate) are important for defining their priority within the network.

4.2.3 *Flexible charging and billing*

On the basis of the concept of IMS sessions (Poikselka *et al*., 2006; Camarillo *et al*., 2011) and dedicated bearers

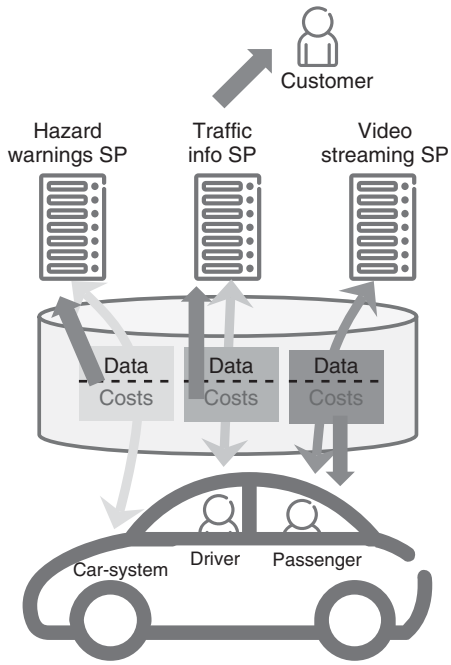

Figure 10. Flexible charging concept.

(Section 4.2.2) for each service, it is also possible to flexibly charge customers (consumers or enterprises) for the service use. The basic principle is explained in Figure 10.

Data streams, which are called *bearers* in the IMS context, are being separated within the cellular communication network (Figures 9 and 10). Thus, the charging-related parameters can vary across these data streams. In the example of having a "hazard warning" data stream, a "traffic info" data stream and a "video" data stream directed to different SPs; it is possible to charge the costs related to the data communication to different parties: the consumer (driver or passenger), an enterprise, or an SP. The enterprise entity, for example, will then be responsible for clearing the charges to their end-customers.

The outlined technical solution gives the flexibility to support a wide range of business models and differentiate

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

between regional markets and customer segments in order to address the ongoing discussion on suitable business models for cooperative vehicle services.

4.2.4 *Lifecycle management*

The provisioning process of mobile communication subscriptions is directly connected to the lifecycle of cellular-connected vehicles (Figure 11). Hence, it will be different to the provisioning of subscriptions to cell phones. Cell phones are typically produced and delivered to dealer shops without any subscription. At the time the phone gets sold to the consumer, or some time later on, the customer inserts a SIM (Section 3.2.1) and the technical relation between the phone and the cellular network, corresponding to the business relation between the SIM holder and the network operator, gets established (Section 4.1.1). In this context, it is important to mention that the SIM is part of the network architecture. It is typically owned by the cellular network operator. The SIM is the key element in the provisioning process and in terms of security (Section 3.3.1). It is used to authenticate the phone subscription to the network and to encrypt the communication link. In case a corresponding connected device becomes tightly integrated with the vehicle electronics (e.g., soldered to a PCB of a car communication unit), the traditional provisioning process may no longer be feasible.

Figure 11 illustrates a sample lifecycle of vehicle and related online services. After production, test, transport, and sale of the car, car-centric services such as eCall, remote diagnostics, software- or map updates may be activated. At the same time, first customer centric services, such as Internet access, could be subscribed to by the first owner of the car. Additional online services (such as the Web radio in Figure 11) may be used by the first owner during a shorter period of time. All of these customer-centric service subscriptions shall end after first resale of the car. Following the suspension phase, the second owner of the car should be able to subscribe to other set of services. All of these services shall be terminated when the end of life of the vehicle has been reached and the car gets scrapped.

From a technical point of view, a wide variety of provisioning mechanisms and methods are feasible to accommodate such a procedure. Several of them are implemented nowadays. The following description exemplifies two such advanced provisioning schemas.

One approach is to use the advanced provisioning process based on IMS capabilities (Poikselka *et al*., 2006; Camarillo *et al*., 2011) of modern mobile communication networks (Sections 3.2.3 and 4.1.2). The key capability is the ability to extend and alter subscription and session identity data at the SIM card, installed within the vehicle, without physically replacing a SIM card or module. It is even possible to mount SIMs on a sustained basis during the car production process and keep that SIM throughout the entire lifecycle of the car.

During the initial phase of the vehicle production, test, transport, and sales (Figure 11), default subscription identities relating to the vehicle manufacturer (OEM IDs, original equipment manufacturer) are used. Hence, at that moment, the OEM itself appears as owner and subscriber of all its newly produced cellular-connected cars to the network operator, to which the OEM has engaged in a contractual relation. No end-customer relation is in place at this phase of the production lifecycle. The OEM can now access the car systems remotely using cellular networks, for example, to check where and when a car has been shipped. After the car has reached the dealer and is being sold to a customer, a relation among the new car owner, its service packages, and the car itself gets established in the cellular network. Therewith, the car is represented by its vehicle OEM ID and the IMEI (Section 3.2.1) of the communication module of the car. The user data is known at the dealer shop. Car services or services packages, being sold to the user with the new car, get specific service package IDs (i.e., IMS IDs, Section 4.1.2). The first time the new car owner is starting his or her preconfigured car, a connection to the cellular network is established. The car owner's identity and service package IDs are provisioned to the vehicle OTA. From

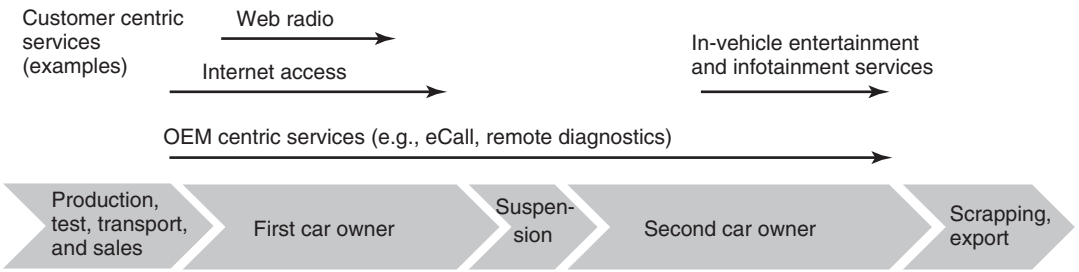

Figure 11. Sample lifecycle of a vehicle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

now onwards, service invocations and service-related data traffic get tagged with its corresponding service package IDs. Hence, cost can be clearly assigned, for example, to the car OEM for its "OEM-centric services" (Figure 11), or to the car owner for driver-centric services such as "Internet access," as shown in Figure 11. This flexible provisioning also allows reprovisioning of service IDs or cost items, without exchanging any hardware, when the car is sold to another owner.

Another approach is, utilizing the so-called "embedded SIM" concept that defines new methods for the remote (OTA) provisioning of access credentials of embedded SIMs and for managing the change of subscription credentials (Sections 3.2.1 and 3.3.1) from one cellular network operator to another. The GSMA, the association of 800 MNOs and 200 companies in the broader mobile ecosystem, defined in February 2011 requirements and use cases for the embedded SIM. New work items were established in several standards-developing organizations, such as ETSI and 3GPP (Section 5.1). The goal is to better support life-cycle management needs in long-lasting M2M businesses, likewise cellular-connected vehicles.

5 STANDARDS AND REGULATORY FRAMEWORKS

Much has been said on the previous sections on how the technical systems operate that constitutes a modern, cellular network. Mobile communication, however, has also an organizational and a regulatory dimension, which has a strong influence on technical solutions and its further development. In this section, we briefly outline three key areas, serving as examples for the complex environment that is influencing cellular network operation and its system evolution.

5.1 Standardization approach

Communication in cellular networks, as we know it today, would not be possible without standards. Nowadays, it is taken for granted that every UE (Section 3.2.1), purchased from any device vendor, can connect without problems to the cellular network of every operator, whereas the network itself is being delivered and installed by any network vendor. Harmonized numbering plans make it possible to have a truly global communication. Network operators rely on standardized interfaces, so that components purchased from different network equipment manufacturers can interact seamlessly. Finally, a major contributor to the decreasing price levels for mobile cellular communication is that research and development is more efficient if it can focus on widely accepted standards that enable reusing a product in many markets.

On the highest level, the standards enabling global communication are made by the ITU. Examples of ITU standards are global schemes for telephone numbers (International Telecommunication Union Recommendation E.164, 2010) and subscriber identities (IMSI), as well as the regulation of spectrum usage (Section 5.2). In addition, the requirement framework for the IMT-2000 that UMTS belongs to and the IMT-Advanced framework, which LTE falls into, has been set by the ITU. Only technology that fulfills these high-level requirements, defined by the ITU, can use the radio spectrum globally allocated for such technology.

ITU standards are, however, typically only the smallest common denominator among many basic principles. The detailed specifications are agreed by national and regional bodies. Over time, this work has become more and more global. The GSM standards initially developed in ETSI were the first cross-country standards that have also been adopted in many countries outside Europe. With the standardization for UMTS, the standards were already made on a global basis, but still split between the 3GPP and its counterpart 3GPP2. The next generation of systems has solely been developed in 3GPP, leading to the LTE standard, which can be seen as the first truly global cellular communication standard. A body such as 3GPP has participants from all relevant parts of the industry, most notably the cellular network operators and the equipment manufacturers. The decision process is typically consensus based, and decisions are documented in the so-called technical standard (TS) in the 3GPP case. A detailed description of the standards process is provided in Sesia *et al*. (2011).

5.2 Spectrum allocation

There is one critical natural resource that is required to operate a cellular network: the frequencies that the system uses to wirelessly transmit data. The license to use a certain frequency band in a certain country or region is one of the central assets of an MNO. Given the exponential growth in mobile data transmission, it can be expected that despite efforts to use spectrum more efficiently, additional frequency bands will be required in the foreseeable future to keep up with user demands (Ericsson mobility report—on the pulse of the networked society, 2012; More than 50 billion connected devices, 2011; City life, 2012). This section briefly describes the regulatory mechanisms that eventually lead to the allocation of frequency ranges, also referred to as *frequency spectrum* or just *spectrum*, to a mobile cellular network operator.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Cellular networks try to use low frequencies as much as possible, as radio waves travel longer distances at low frequencies and penetrate buildings more easily. Spectrum at these desirable low frequency ranges is, however, already fully allocated, so that only two alternatives remain: sharing a frequency band is a common practice, a popular example being the 802.11b/g/n Wireless LAN system operating at 2.4 GHz. For a commercial service such as a cellular network, it is, however, common to rely on spectrum with primary usage rights. This makes refarming, that is, the re-allocation of existing usage rights, the only viable option to obtain additional radio spectrum for future mobile networks. Spectrum comes in two variants: FDD systems use separate frequency bands for up- and downlinks; TDD systems share one frequency band by splitting it into time slots. Both options are actively used, depending on the region. In Europe, predominantly FDD systems are used.

On the highest level, the ITU is responsible for the allocation of spectrum. The ITU Radio Regulations govern the use of spectrum worldwide, separately for three major geographic regions (Europe, Middle-East, and Africa—America—Asia-Pacific). These regulations are revised by the World Radio Conference (WRC) that takes place approximately in 3-year intervals. Their agenda is agreed by the ITU Council 2 years ahead of the conference. The basic scope of an agenda is, however, often established even 4–6 years in advance. On the conference itself, proposals from countries (or groups of countries) are discussed and negotiated. The goal is a consensus between all participating parties. If the consensus cannot be reached, voting is possible, although in practice it is more likely that a decision is postponed to the next conference. The WRC held in February 2012 gathered participants from 153 countries.

Once a decision is taken at the WRC, it has to be translated to local regulation in the respective countries, for example, by the Bundesnetzagentur in Germany, OFCOM in the United Kingdom, or the Federal Communications Commission (FCC) in the USA. In countries such as the USA, the local regulator can directly adopt the decision and translate it into a local regulation. In other regions, such as the densely populated Europe, additional coordination is required. In the example of Europe, the European Conference of Postal and Telecommunications Administration (CEPT) coordinates the local policy-making across the members states and tries to harmonize the spectrum allocation policy among the members states. Once an agreement has been reached and national regulation is in place, a typical mode of distributing licenses for spectrum usage is an auctioning process, as recently practiced in many countries for the 3G and 4G spectra.

This short overview makes it apparent that spectrum allocation is a long-term process that is subject to discussions and consensus building on many levels. New frequency bands will not become available shortly. Corresponding processes have to be started well in advance. A recent example of successful spectrum refarming is the reallocation of digital dividend frequencies, that is, TV frequencies for analog TV broadcasting that were not needed anymore because of the higher spectral efficiency of digital transmission technology. These frequencies below 1 GHz have been allocated to cellular communication in many countries, and are, for example, used to provide broadband coverage in rural regions. In some regions of the world, mainly Asia, there are also cases where older cellular networks are switched off to use the frequencies for newer generations of cellular networks.

A second observation is that the situation around the world is becoming more and more fragmented. The usage of frequencies is different from country to country, and harmonization is not always possible. The 2G system was standardized for three main frequencies that are in use worldwide. For LTE, 25 FDD bands and 11 TDD bands had to be standardized in order to safeguard coverage for the most relevant regions around the world. In addition, the fragmented spectrum landscape makes it increasingly difficult to obtain larger contiguous blocks of radio spectrum. This has been considered for the development LTE-Advanced, which can support noncontiguous spectrum allocations.

5.3 Privacy aspects

Privacy means different things to different people, one definition can be found in Article 8 of the European Convention on Human Rights, namely the right to respect for private and family life: "*everyone has the right to respect for his private and family life, his home and his correspondence*." The issue of privacy is a good example of local regulation that also has to be fulfilled by every communication network. Privacy regulation is generally defined by the national legislation of each country. In Europe, it has been harmonized to some extent on EU level by European Directives. In this context, data security or information security plays an important rule. It is possible to provide security without privacy, but not to provide privacy without security. Therefore, protecting and controlling personal information is what the European legal concept of "data protection" is concerned with. The European Directives have in common that they represent only the minimum standard of data protection in the respective field that shall be transposed into national law. The fundamental basis is defined in the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

European Data Protection Directive. This Directive regulates the processing of personal data within the European Union and is an important provision in terms of privacy and human rights law. All members states have enacted their own data protection legislation. In the field of telecommunications, the European Data Protection Directive is accompanied by the more specific directive on privacy and electronic communications.

For determining legal effects of the processing of personal data, it is important to also consider the combined benefits of data processing for the end-user and for the bigger society. It is, for example, possible to process location data of vehicles in order to provide drivers with local relevant near real-time traffic information (including information to enhance safety) that can have effect for navigation and vehicle guidance. This purpose of data processing can be seen as a "value-added service" for the end-user. For such value-added services, the processing of location data is admitted but regulated: "*. . . such data may only be processed when they are made anonymous, or with the consent of the users or subscribers to the extent and for the duration necessary for the provision of a value added service. The service provider must inform the users or subscribers, prior to obtaining their consent*, . . . " (Article 9 of Directive on Privacy and Electronic Communications); see also (European Commission).

6 OUTLOOK

The worldwide geographical availability of cellular mobile networks as well as their technical performance has increased continuously over the last few decades. Bandwidth and latency improvements have jumped orders of magnitude in just a few years. Especially, a growing amount of spectrum below 1 GHz allocated for IMT technologies will lead to further geographic coverage and capacity improvements of high speed cellular networks. The ongoing market trend toward technology convergence, combined with the spectral efficiency gains of LTE and LTE-Advanced, is paving the way toward the first truly global communication standard for cellular mobile networks.

The global uptake is also clearly visible in numbers: as of September 2013, more than 213 cellular network operators have launched commercial LTE services in 81 countries, providing high speed mobile broadband access to 10% of the world's population by the end of 2012. More than 440 operators have publicly committed to LTE technology across 130 different countries with a large number of LTE trials currently in operation.[3] GSA confirmed September 2013 that 1064 LTE user devices have been announced by 111 manufacturers, representing around 150% annual growth.

This rapid worldwide deployment, the technological advances, and the tight integration with business processes (as briefly described in this chapter) will pave the way toward a networked society (City life, 2012) with an anticipated 50 billion connected devices by 2020 (More than 50 billion connected devices, 2011). How many of those will be cellular connected vehicles? And how many cooperative vehicle services will benefit for cellular network capabilities?

Like in the decades before, technological enhancements and innovations in key areas such as energy efficiency and processing power of the UEs will keep up the pace of development also in the future. For example, maximum data rates enhanced from 384 kbps of first UMTS networks, introduced in the 1990s, to 42 Mbps of HSPA networks, deployed just one decade later.

First LTE networks based on Release 8 of the 3GPP standard were commercially launched in 2011. While the availability of LTE-capable UEs and networks have steadily increased, the standard for the next evolutionary step, LTE-Advanced, was already finalized (Third Generation Partnership Project (3GPP)). With the defined technology improvements, LTE-Advanced targets maximum data rates of 1 Gbps and improved network performance at the cell edges.

On the other hand, enhanced connected car services such as cooperative traffic management, driver information and assistance applications, or infotainment services are gaining importance (see GSMA mAutomotive, 2012, 2025: every car connected: forecasting the growth and opportunity; GSMA mAutomotive, 2013). The authors are convinced that future car drivers and passengers expect connected car services, resulting in an increasing market demand. New trends and innovations such as in the area of electric vehicles will lead to an even faster growing need for connectivity in the car. Efficient energy management, vehicle monitoring, and services such as automatic billing at local charging stations will require communication among driver, charging stations, and utility companies.

With the geographical coverage and performance of cellular networks constantly increasing, more and more advanced connected car services will become available. A fruitful interaction between the telecommunication and the automotive industry will be key for turning the connected vehicle vision into reality; fast and in an economically viable manner. Relying on widely accepted, deployed, and open standards has been a cornerstone of the success of the global telecommunication industry. A similar approach may lead the way forward for the connected vehicle vision, with all its definite advantages to the broader society.

GLOSSARY

Term	Name	Description
2G	Second generation	Synonym for the second-generation cellular telecommunications systems.
3G	Third generation	Synonym for the third-generation cellular telecommunications systems.
3GPP	Third-generation partnership project	Standards body developing responsible for standardization of GSM, UMTS, LTE, IMS, and other systems.
3GPP2	Third-generation partnership project 2	3GPP2 is the standardization group for CDMA2000, the set of 3G standards based on earlier 2G CDMA technology. 3GPP2 is not a part of 3GPP, but rather a separate organization.
4G	Fourth generation	Synonym for the fourth-generation cellular telecommunications systems.
AAA	Authentication, authorization and accounting	A set of core network functions and system nodes dealing with subscriber authentication, service and access permissions, and charging data processing.
APN	Access point name	A configurable identifier used by a mobile device when connecting to a cellular network to indicate which external network or service the user wishes to connect to via the GGSN/PDN Gateway.
AuC	Authentication center	Used in GSM networks to authenticate SIMs that attempt to connect to the network.
BM-SC	Broadcast/multicast service center	A system control node, serving as entry point for content delivery services utilizing MBMS capabilities.
BSC	Base station controller	A 2G system node, responsible for controlling the base transceiver stations (or base stations for short) that are connected to it.
BSS	Business support systems	Supports the business operation of network operators toward the customer with functions such as billing and customer and ordering management.
BTS	Base transceiver station	The radio base station of a 2G system, responsible for termination of the wireless radio link to the UEs and manages the radio resources in its coverage area.
CDMA	Code division multiple access	A multiplexing scheme based on a coding method that assigns a specific code to each transmitter in order to allow multiple users to access the same physical channel.
CN	Core network	A set of access-technology independent nodes and functions, comprising, among others, user databases and interfaces to other networks.
CS	Circuit switched	The traditional implementation of a telecommunications network, in which two network nodes establish a dedicated end-to-end communications channel (circuit) through the network.
CSCF	Call session control function	A system node family within the IMS subsystem, used to process SIP signaling.
EDGE	Enhanced data rates for GSM evolution	Evolution of GPRS, uses advanced coding and modulation to achieve higher data rates.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

eNodeB	evolved node B	The radio base station in LTE networks, successor to the NodeB of a 3G UMTS system.
EPC	Evolved packet core	Core network architecture introduced with LTE featuring a simplified all-IP network design.
ETSI	European Telecommunications Standards Institute	Standardization organization for telecommunication technologies in Europe. ETSI is a partner of the 3GPP.
eUICC	Embedded universal integrated circuit card	Embedded version of the UICC, e.g., to be soldered on a printed circuit board.
FDD	Frequency division duplexing	Frequency division duplex systems use separate frequency bands for up- and downlinks (the so-called paired spectrum).
GGSN	Gateway GPRS support node	A core network node, responsible for the interworking between the GPRS network and external packet-switched networks such as the Internet.
GPRS	General packet radio service	A cellular communication technology that introduced IP packet transport to the 2G core network, sometimes also called *2.5G*.
GRX	GPRS roaming exchange	A dedicated type of interconnect network between mobile network operators, e.g., used for connecting home network and visited network in a roaming case.
GSA	Global supplier association	Representing the leading GSM/EDGE, WCDMA-HSPA, 4G/LTE suppliers worldwide.
GSM	Global system for mobile communications	2G cellular communication system. Primarily used for circuit-switched voice communication and SMS.
GSMA	GSM association	Official industry trade group representing GSM network operators worldwide.
HLR	Home location register	A central database that contains a record of each mobile phone subscriber that is authorized to use the GSM core network.
HSPA	High speed (downlink/uplink) packet access	Evolution of UMTS with many enhancements, among them advanced coding and modulation to achieve higher data rates in downlink (HSDPA) and uplink (HSUPA).
HSS	Home subscriber server	A core network node manages subscription-related information, includes HLR, AuC, and some further functions of the 2G system architecture.
IMEI	International mobile equipment identity	Globally unique identity of a cellular communication device. The IMEI identifies all physical devices of GSM, UMTS, and LTE networks using SIM cards.
IMS	IP multimedia subsystem	The IP multimedia subsystem is an architectural framework to deliver multimedia services such as voice-over IP services.
IMSI	International mobile subscriber identity	Globally unique user identification in mobile networks, associated with all GSM-, UMTS-, and LTE-capable mobile phones or modules. It is stored as a 64-bit field in the SIM inside the phone or module and identifies the user to the network (as opposed to the IMEI that identifies the device). The IMSI is used in internal network authentication and authorization procedures, for example, in the HLR or HSS.
IP	Internet protocol	A networking protocol that is the basis for all packet-switched communication, originally developed for Internet communication.
IPX	IP Packet Exchange	An IP-based evolution of the earlier GPRS roaming exchange (GRX) network.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ITU	International Telecommunication Union	The International Telecommunication Union is an organization of the United Nations and is responsible for basic standards, coordination, and regulation for information and communication technologies.
KPI	Key performance indicator	Typically a numeric value associated with a performance or progress related monitoring process.
Leased Line	Leased communication line	A dedicated network connectivity link, connecting two end points in a secure and QoS-ensured manner. Although in the past leased lines had been implemented as dedicated physical connections, nowadays more and more of them get implemented as QoS-managed VPN connections over high capacity telecommunication networks.
LTE	Long-term evolution	4G cellular communication system standardized by 3GPP.
M2M	Machine-to-machine	Umbrella term for communication that is not person-to-person (e.g., phone call) or person-to-machine (e.g., Web surfing), but connecting a machine of any kind to another machine.
MB	Megabyte	1024×1024 bytes (=2^20 bytes, ≈10^6 bytes). One byte consists of 8 bits, so that there is roughly a factor of 8 between Mb and MB. MB is typically used for data volumes and file sizes.
MBMS	Multimedia broadcast multicast service	MBMS systems add broadcast capabilities to mobile networks, i.e., the capability to save transmission capacity when transmitting the same data from a single source to multiple destinations.
NodeB	Node B	Radio base station in UMTS, successor to the base station of a 2G GSM system (see BTS).
OFDM	Orthogonal frequency division multiplexing	OFDM is a multiplexing scheme where a large number of closely spaced but uncorrelated (orthogonal) subcarriers are used to carry data of multiple users over the same physical channel.
OSS	Operations support system	Supports the operations of a telecommunication network, provisioning of network or telecommunication services, configuring network components, and managing faults.
OTA	Over the air	Umbrella term for end-to-end procedures carried out over a wireless connection without considering specific network segment characteristics (e.g., network load and radio resources) and not using network-assisted functionalities.
PDN-GW	PDN gateway	A system node of cellular networks, serving as entry and exit points for IP data traffic and as termination point for tunneled-IP data traffic in roaming cases. The PDN GW is the successor to the GGSN in SAE-based networks.
PS	Packet-switched	A digital networking communications paradigm that transmits any kind of data in the form of suitably sized blocks, the so-called packets.
PSTN	Public-switched telephony network	The global communication network for circuit-switched wireline communication.
QoS	Quality of service	Umbrella term for different technical measures to prioritize and differentiate traffic in a communication network in order to ensure a given network quality for a certain service.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto169
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

RAN	Radio access network	The part of a cellular communication network that implements the radio communication technology in order to connect a mobile terminal to the core network.
RNC	Radio network controller	A 3G system node, responsible for controlling the NodeBs that are connected to it.
SDP	Service delivery platform	A service enablement extension, complementing network communication and control functions.
SGSN	Serving GPRS support node	A core network node responsible for the delivery of data packets from and to the mobile stations within its geographical service area. Among other tasks, it is responsible for the mobility management (attach/detach and location management) and logical link management to a mobile station (or terminal) when moving from one serving base station to another.
SIM	Subscriber identity module	A SIM is an integrated circuit embedded into a removable SIM card that securely stores network-specific information used to authenticate and identify subscribers such as the IMSI, personal identification numbers (PIN), and authentication keys.
SLA	Service level agreement	A binding agreement between parties to safeguard the delivery of a certain service. Often expressed through a number of KPIs together with monitoring principles and information handling duties.
SMS	Short messaging service	A short text message which in size is restricted to 140 bytes or 160 characters.
TDD	Time division duplexing	Time division duplex systems share one frequency band (the so-called unpaired spectrum) by splitting it into time slots for up- and downlinks.
TDMA	Time division multiplexing access	A multiplexing scheme; a physical channel by subdividing it in the time domain.
UE	User equipment	A term originally used in 3G standardization, referring to the device that terminates the cellular connection on the user side. These devices come as smartphones, USB sticks, connected navigation devices, embedded vehicle modules, or in many other forms.
UICC	Universal integrated chip card	Multifunctional chip card for mobile devices, e.g., used as SIM card.
UMTS	Universal mobile telecommunications system	UMTS is the 3G mobile cellular system in the standards family developed and maintained by 3GPP.
VLR	Visitor location registers	A set of connected databases used for storing temporary subscriber data to support mobility management and handover procedures.
VPN	Virtual private networks	VPNs establish isolated, secure connections between individual users and a remote network or between multiple networks.
WRC	World Radiocommunication Conference	The WRC is organized by the ITU in basically 3-year intervals in order to revise the regulation for spectrum usage worldwide, separately for three major geographic regions (EMEA, Americas, and Asia-Pacific)

1 INTRODUCTION

Wireless communication to, from, and between vehicles allows vehicles to announce their current status to other traffic participants as well as to receive information that is beyond the vehicle's sensing ability and the driver's direct perception. This article discusses the use of WLAN techniques for the purpose of exchanging information among vehicles and between vehicles and the roadside infrastructure as a basis for active safety, green mobility, and traffic-efficiency applications.

Various notions have been used to address WLAN-based vehicular communication: car-to-X communication (C2X), vehicular ad hoc networks (VANET), dedicated short-range communication (DSRC), cooperative systems, intelligent transportation systems (ITS), vehicular area network, or inter-vehicular communications. While these notions themselves represent "technology-neutral" terms, their use typically refers to WLAN-based techniques, in particular to the IEEE 802.11p amendment to the IEEE 802.11 standard, in a vehicular environment. WLAN-based vehicular communication is often seen as an alternative or a complement to mobile communication based on cellular networks (see Technologies—Communication: Mobile).

Although the envisioned scenario of vehicles that exchange information using WLAN-based techniques appears intuitively convincing, the technical implementation is not straightforward. Indeed, inter-vehicle communication networks are challenged by requirements as well as by constraints and limitations that exist either because of the inherent characteristics of the considered scenario or because of the selected communication technology has not been designed for usage in such an environment in the first place.

Independent of the selected communication technology, inter-vehicle communication networks, or systems should fulfill the following key requirements.

- The communication system should allow for a transmission range of at least a few hundred meters when sending with maximum power. The received signal strength typically weakens by at least $1/d^2$ where d denotes the distance to the sender. Hence, the coverage range of a sender is limited.

- The communication system needs to be standardized to allow communication between vehicles of all makes and brands.
- The communication system needs to fulfill application requirements, for example, in the case of safety applications, it needs to guarantee low data dissemination delays and a high reliability.
- The communication system needs to be adaptive and robust in order to deal with all relevant system dynamics: the mobility of vehicles and corresponding changes in network topology, as well as the wide range of scenarios in which inter-vehicle communication networks will be deployed.
- The communication should be secure and should preserve privacy, thus, two sometimes contradictory or opposing goals need to be balanced.

Additional technology- and standardization-specific challenges are introduced with the characteristics of IEEE 802.11p standard specification and the system architecture that is built upon IEEE 802.11p:

- There exists one common control channel for safety- and signaling-related information. WLAN-based vehicular communication is intrinsically of broadcast nature, as a warning or status message sent out by a vehicle should be received by all vehicles within the transmission range.
- No central control or operator schedules and organizes the various transmissions of all vehicles. Instead, access to the wireless channel is coordinated in a distributed and cooperative fashion, that is, fundamental issues of self-organizing networks are adopted.
- The system has to support at least two types of safety messages: periodic awareness messages, which are broadcasted by any vehicle to inform neighboring vehicles about the own presence and status, as well as event-driven alert messages, which are sent out in case of an emergency situation that requires immediate attention. Periodic messages are envisioned to be only broadcasted for one hop (i.e., there is no retransmission of the identical message by another vehicle) and termed *cooperative awareness message* (CAM), *basic safety message* (BSM), or simply *beacon*. Event-driven messages (also called *decentralized environmental notification message*, DENM) may be disseminated over more than one hop. In general, the communication system should allow for prioritizing and differentiating types of communication.

General issues and limitations of wireless communications challenge WLAN-based vehicular communications in the 5.9 GHz frequency band even further (see, e.g., Molisch, 2010 for fundamentals on wireless channels and wireless local area networks):

- Owing to the 5.9 GHz carrier frequency, shadowing effects and reflections will be very prominent in inter-vehicle communication networks. As a result, severe multi-path propagation effects have to be expected, which, together with the high mobility of the vehicles, lead to a time- and frequency-selective fading of the channel impulse response. At the same time, communication "around the corner" or "through buildings" will be limited.
- As the coverage range is limited, every vehicle has a different perspective on who is currently transmitting and who is not. A distributed coordination mechanism is therefore challenged by the hidden terminal problem. As a result, simultaneous transmissions that lead to packet collisions at receiving nodes will not be an exception. Channel fading increases the severity of the hidden terminal problem.
- The capacity of the wireless channel is limited. While this is not an issue if only a few vehicles are participating in the network, it will become an issue if every vehicle is equipped. The communication system should therefore be able to support both extremes and should scale with the number of vehicles in the network, in particular with respect to resource and bandwidth allocations.

While each individual aspect alone can easily be solved separately, their combination poses a challenge for the design of an optimal or even acceptable solution. In short: the overall challenge lies in the support for applications with strong reliability requirements over a highly unreliable communication medium. For the application engineer, it is important to keep in mind that even while the field of vehicular communication advances to provide an increased level of reliability of the communication, there is always the chance that some information is not sent or received in a certain time frame.

In the following, we first present the general system architectures for WLAN-based vehicular communication systems that emerged in standardization activities in Europe and the US (Section 2). We present the basics of physical layer and medium access issues (Section 3) as well as communication protocols for WLAN-based vehicular communication, including the use of single-hop protocols and multi-hop protocols utilizing geographical positions (Section 4). Aspects of security and privacy are discussed (Section 5) and the role of radio resource management,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

particularly congestion control, as a means to deal with scalability and reliability is outlined (Section 6). We conclude this article with a view toward standardization (Section 7) and an outlook (Section 8) as well as offer references and hints for further reading.

2 SYSTEM ARCHITECTURE

The system architecture for WLAN-based vehicular communication is primarily seen as communication architecture and includes not only vehicles, but also roadside and central infrastructure that can be connected to legacy equipment, such as road sensors and traffic lights. In the context of ITS, the system can be divided into vehicle, personal (representing mobile personal devices), roadside (infrastructure), and central (back-end systems and traffic management centers) subsystems. In this architecture, WLAN-based vehicular communication is mainly in the vehicle and roadside subsystem. A central element of the system architecture is the ITS station, which is common to all subsystems. A generic protocol stack of an ITS station is shown in Figure 1 and put into relation with the ISO OSI protocol stack.

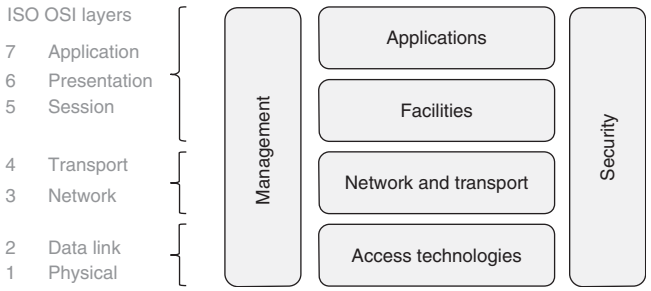

Figure 1. Generic protocol stack.

From this generic protocol stack, two stacks can be derived that are developed in the US (Figure 2) and Europe (Figure 3). The stacks are detailed in Sections 4 and 7.

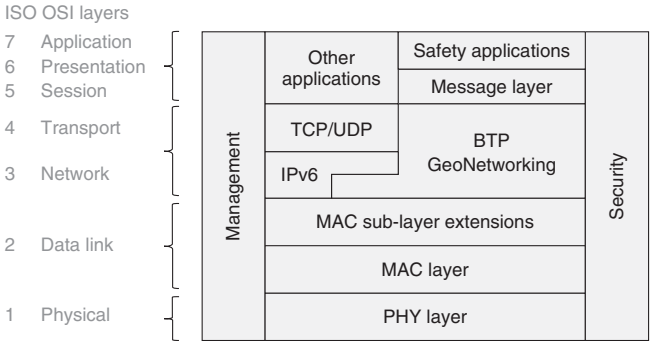

Figure 3. Protocol stack in Europe.

3 PHYSICAL LAYER AND MEDIUM ACCESS

In 1999, the Federal Communications Commission in the US assigned 75 MHz of spectrum for DSRC services (Figure 4). The frequency band ranges from 5.850 to 5.925 GHz and is commonly referred to as the *5.9-GHz band*. The 5.9-GHz band is divided into one 5-MHz guard band and seven 10-MHz channels. One of the channels (channel 178) is the control channel, to which all vehicles must listen to. To make use of the other channels, either a channel-switching scheme or a multi-channel operation based on several radios have been proposed and discussed.

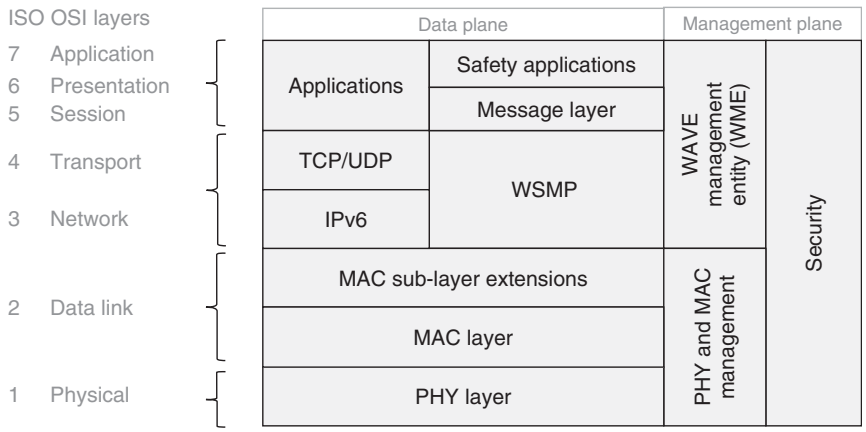

Figure 2. Protocol stack in the US.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto170
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In Europe, in August 2008 the EU allocated 30 MHz of spectrum for safety-related ITS communication. The frequency band ranges from 5.875 to 5.905 GHz and is referred to as the *ITS-G5A band*. In addition, a frequency band ranging from 5.855 to 5.875 GHz is foreseen for non-safety applications. This band is called *ITS-G5B*. ITS-G5A and ITS-G5B are divided into channels of 10 MHz. Furthermore, a frequency band called *ITS-G5C* in the range 5.470–5.725 GHz can be used for communication between fixed stations and vehicles, but not for vehicle-to-vehicle communication. Approaches for multi-channel operations, particularly dual-receiver concepts, were being discussed at the time of writing.

In Japan, a frequency band for ITS applications ranges from 5.770 to 5.850 GHz; another one, which ranges from 715 to 725 MHz, was assigned in 2007 and is dedicated to road safety applications.

Many other countries have spectrum allocated to WLAN-based vehicular communications, typically in the 5.8 and 5.9 GHz ranges. The maximum power allowed by a sender is typically restricted to 33 dBm equivalent isotropically radiated power (EIRP). To reduce inter-channel interference, regulations define transmit-spectral masks. An overview on 5.9 GHz field trials in a variety of physical environments is presented in Alexander, Haley and Grant (2011).

When modeling the corresponding radio channels, one has to consider the relatively high carrier frequency as compared to current cellular networks. The small signal wave-length of approximately 4 cm implies that any object larger than 4 cm acts as a reflector (or scatterer) and generates one (or multiple) copies of the transmitted signal that arrives at a receiver as a time-delayed echo. This phenomenon is typically called *multi-path propagation*, and, in the case of inter-vehicle communications, leads to a narrowband fading of the channel. As transmissions "through buildings" are not possible and antennas mounted only 1.5 to 2.5 m above ground, communication "around corners" (non-line-of-sight communication) will be limited. As small changes in the geometry of the vehicle also affect the radiation patterns of antennas significantly, their proper placement is a challenge as well. Likewise, signal propagation is influenced by surrounding vehicles and their mobility, as well as by the type of environment, that is, the number of buildings or trees next to the street, or the current weather conditions. Developed channel models are therefore typically classified into highway, urban, and suburban scenarios (e.g., Acosta-Marum and Ingram, 2007 and Mecklenbräuker *et al.*, 2011).

The physical layer of IEEE 802.11p and, accordingly, of the European ITS-G5 interface is based on orthogonal frequency division multiplexing (OFDM) with 52 subcarriers in order to deal with the narrowband fading characteristics of the channel. Four of these 52 subcarriers are used as pilots to track the variation of the channel over time and with respect to the frequency domain; the remaining 48 subcarriers are used for data transmission. In order to support different data rates from 3 to 27 Mbps, the data bits to be transmitted are encoded using a binary phase shift keying (BPSK), a quadrature phase shift keying (QPSK), or a quadrature amplitude modulation (QAM) with 16 or 64 constellation points. A convolutional encoder with a rate of 1/2, 2/3, or 3/4; further enables error correction capabilities at a receiver. While lower data rates are to be preferred because of their robustness against channel fading, they reduce the capacity of the network. Hence,

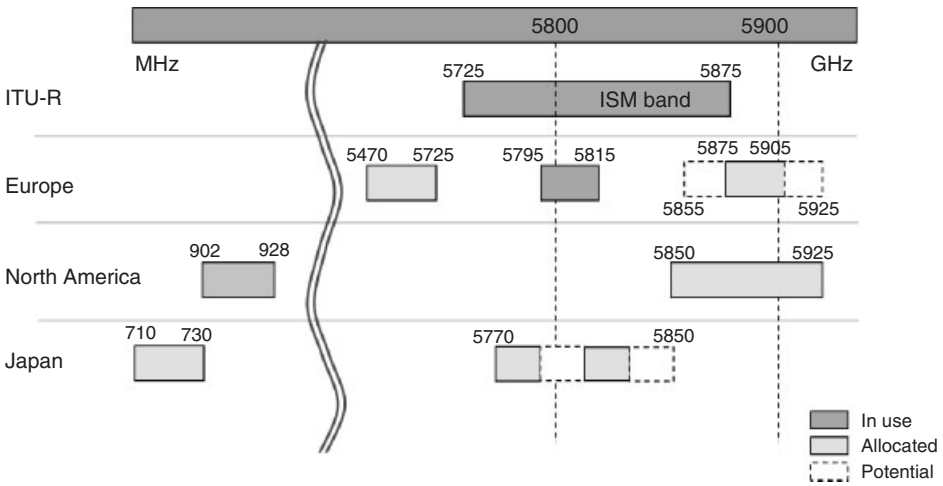

Figure 4. Frequency usage for vehicular communication worldwide.

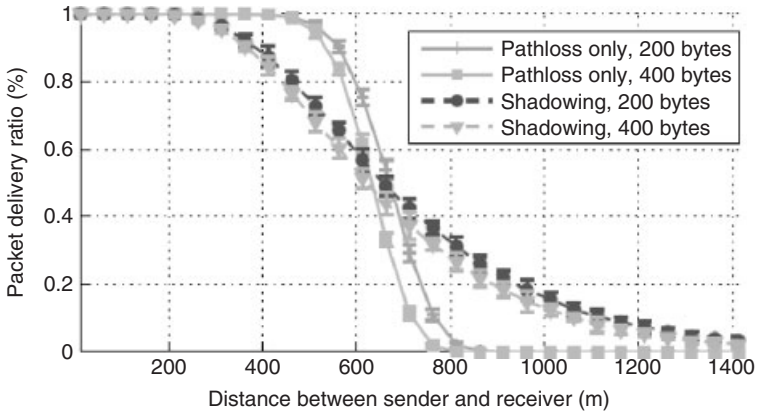

Figure 5. Packet delivery ratio (i.e., proportion of successfully received beacon messages) with respect to the distance between a single sender and a single receiver. The radio channel is assumed to follow a deterministic power-law, either including a large-scale log-normal shadowing effect or not.

a trade-off between robustness and scalability needs to be made. According to Jiang, Chen and Delgrossi (2008), a bit rate of 6 Mbps has shown to provide an optimal balance of these two aspects in typical vehicular environments. Figure 5 depicts typical packet delivery ratios with respect to the distance between a single sender and a single receiver for such a 6 Mbps configuration. The plotted ratios are based on the results of detailed physical layer simulations.

Access to the medium (medium access control, MAC) is governed by a distributed version of the carrier sense multiple access with collision avoidance (CSMA/CA) mechanism, also known as the *distributed coordination function* (DCF) in the context of IEEE 802.11 networks. With CSMA, a station listens to the medium before transmitting data. If the channel appears to be idle, the station transmits. If the channel appears to be busy, that is, someone else is currently transmitting and the corresponding signal is stronger than the clear channel assessment (CCA) threshold, the station will defer its access and waits until the channel becomes idle again. Then, the station will use a countdown-based random access to select a slot for transmission. If the channel becomes busy again before the countdown process is finished, the station interrupts its count-down for as long as the channel is busy. Packet collisions can occur on a receiving side when two stations select the same time slot accidentally or because they are not able to detect their transmitted signals (the latter case is commonly referred to as *hidden terminal problem*). While a method based on ready-to-send (RTS) and clear-to-send (CTS) signals was established for unicast communication in order to counter the hidden terminal problem, communication within vehicular networks is primarily of a broadcast nature. Hence, the benefit of the RTS/CTS approach cannot be exploited. A

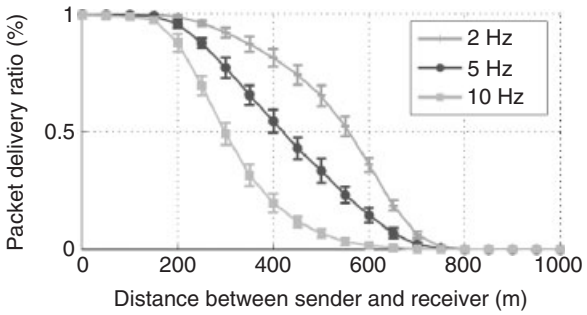

Figure 6. Expected packet delivery ratios (i.e., proportion of successfully received beacon messages) with respect to the distance between sender and receiver in a highway scenario of about 80 vehicles/km. The radio channel is assumed to follow a deterministic power-law model.

diagram showing typical packet delivery ratios with respect to the distance between sender and receiver (in this case in a highway scenario with 80 vehicles/km) is given in Figure 6. In this set-up, all vehicles transmit several beacon messages of 400 bytes/s using a 20 dBm transmission power. The radio channel is assumed to follow a deterministic power-law model. As can be seen, the packet delivery ratios decrease significantly if the beacon transmission rate increases from 2 to 10 Hz because of the increasing load on the channel. An in depth analysis on the effectiveness of CSMA in vehicular scenarios can be found in Mittag, 2012.

To allow for prioritization of certain frames over others, the enhanced distributed channel access (EDCA) can be used as part of the IEEE 802.11-2012 standard. With EDCA, the waiting times of a station between assessing whether a channel is idle or selecting a slot to start

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto170
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

transmissions vary with respect to the importance of the packet being transmitted.

While IEEE 802.11p is very close to other wireless local area networks in the IEEE 802.11 standard with respect to physical and MAC layers, it deviates quite a bit from office environments, where mobile stations and access points form so-called basic service sets (BSS) through association procedures. All these association procedures are skipped in IEEE 802.11p, and 802.11p stations are said to operate "outside the context of a basic service sets" (OCB). Therefore, other mechanisms are required for authentication and security; see Section 5.

When the number of vehicles per kilometer or square kilometer is very high, MAC based on CSMA/CA might become unstable and transmission efficiency might decrease because of packet collisions. Thus, it is important to keep the channel load below a critical value by means of congestion control approaches (Section 6). Alternatives to a CSMA-based MAC were discussed and analyzed, for example, self-organizing time division multiple access (STDMA), which is already used in the automatic identification system (AIS) for communication between ships. While reserving slots to access the channel can reduce the probability of collisions, the mobility of the vehicles and the fading characteristics challenge consistent slot reservations.

4 COMMUNICATION PROTOCOLS

The communication protocols ensure the transport of data from the source to the destinations in the VANET over the radio link. This section covers communication protocols at the network and transport layers and the application message/facilities layer.

VANET are self-organizing communication networks that operate without the need for a central control device or operator. As such, a VANET represents a special type of mobile ad hoc network with certain characteristics: (i) a potentially high number of nodes, (ii) nodes that can move at high speeds despite the constraint of road topology, (iii) frequent changes in the network topology, and (iv) the need to transmit data packets rapidly without prior signaling.

For the data in a mobile ad hoc network, two main types of communication protocols exist: single-hop protocols exchange data among nodes that are in direct communication range. With multi-hop protocols, data can be forwarded using relay nodes on the path from the source to the destination.

Routing refers to the process of finding routes and of forwarding packets at the network layer. For conventional mobile ad hoc networks, topology-based routing uses the information about the links that exist in the network in order to forward a packet. Two main classes of multi-hop, topology-based routing protocols exist: proactive routing protocols maintain routing information about the available paths even if these paths are not used. Reactive routing protocols maintain only the routes that are currently in use, typically based on a route discovery prior to packet transmission. Protocols of both classes do not cope with frequent changes in the network topology, as the route maintenance can occupy a major part of the bandwidth.

The specific characteristics of VANET have led to the development of dedicated network protocols in two main directions: (i) vehicular network protocols are optimized for single-hop communication and minimize the packet overhead, and (ii) multi-hop routing protocols for vehicular communication make use of geographical positions. The latter eliminate some of the limitations of topology-based proactive and reactive routing protocols and introduce geographical addressing for safety and traffic-efficiency applications.

On top of the network and transport protocols, additional application-related protocols, also referred to as *message protocols* or *facilities*, carry application-specific contents and provide direct support to the application processes. For safety and traffic-efficiency applications, in principle periodic and event-driven messages can be distinguished. While periodic messages convey status information, typically at a high frequency, the event-driven message is triggered upon detection of a safety-critical or safety-related situation. Periodic and event-driven messages are handled differently by the protocol stack in order to meet the application requirements on dissemination delay and reliability and the system requirements for stability and data congestion control.

Among the variety of research proposals for communication protocols, mainly two sets of communication protocols have prevailed; one in the US and standardized in IEEE and SAE, the other in Europe and standardized in ETSI and CEN. It is common to both protocol sets that they use the Internet Protocol (IP) for non-safety applications. For the safety-related column of the stack, a process to harmonize the standards is ongoing.

4.1 WSMP and BSM (US)

The US set of communication protocols include the WAVE short message protocol (WSMP) as a network protocol and the basic safety message (BSM) plus other messages as application message protocols, see Kenney (2011). They represent the left branch in the protocol stack in Figure 2.

WSMP is a network protocol that supports single-hop communication and is optimized for a minimum size of its packet header. A network packet, that is, a WAVE short

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto170
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

message (WSM), has a variable header length and variable payload length. Mandatory header fields (minimum of 5 bytes) include protocol version, provider service identifier (PSID), WAVE element identifier (WEI), and a field describing the length of the packet payload. The PSID identifies the service with which the payload is associated. The WEI indicates the format of the packet payload. Optional extension fields of variable length carry information about the channel number, data rate, and transmission power level. For operation in a multi-channel environment, the wireless access in vehicular environments service advertisement (WSA) is defined. This is a management message that informs about services offered in the vicinity of the sender. Upon reception of a WSA message, a receiver may decide to tune its transceiver to another channel.

BSM is a periodic message that is carried in the payload of the WSM. It transmits core status information of a sending vehicle, for example, position, dynamics, and size. The information carried in the BSM is shared by different safety applications, which makes the definition of application protocols unnecessary. The BSM has two parts. Part I is mandatory and must be sent by every vehicle. Part II is optional and includes fields that are required only for some safety applications, such as event flags (e.g., hard break), path history for lane-level information, path prediction for the intended driving direction, and GPS correction data. Part II allows for flexibility: data fields can be included with a lower frequency than the overall BSM rate and company-specific data fields can be used.

BSM is the most important message of the communication protocols, but a variety of other messages have been defined in SAE 2735, such as emergency vehicle alert message, signal phase and timing (SPAT) message for intersections and probe vehicle data.

4.2 GeoNetworking, BTP, CAM, and DENM (Europe)

In Europe, GeoNetworking and basic transport protocol (BTP) are the network and transport protocols standardized in ETSI. Application message protocols are the CAM and the DENM. The set of communication protocols comprise the left column of the protocol stack in Figure 3 in Section 2.

GeoNetworking is an ad hoc network layer protocol for single-hop and multi-hop communication that supports geographical positions for two main reasons: (i) it allows for addressing geographical areas in which a packet should be distributed, more precisely to address nodes in an area without using their node identifier, (ii) geographical positions are utilized in the forwarding process in order to make the packet routing efficient and scalable. GeoNetworking supports multiple transport modes: GeoUnicast for the communication between two network nodes, GeoBroadcast for the packet distribution to all nodes in a geographical area, as well as GeoAnycast to reach any (one) node in the area, see Festag, Papadimitratos, and Tielert (2010).

CAM is a periodic message with the same purpose as the BSM, that is, to transmit status information, and has a format similar to the BSM. A CAM can be sent by different types of vehicles—distinguished by profile—for which the CAM format has common data and profile-specific data. The message is structured in a header and several containers (Figure 7). Common data present in every CAM include the common header (fields for protocol version, message ID) and the basic container (time, type, etc.). In general, a CAM from a vehicle has a basic container for dynamic data (position, vehicle, and path) and for static data (vehicle size). Other containers can be added for special vehicles,

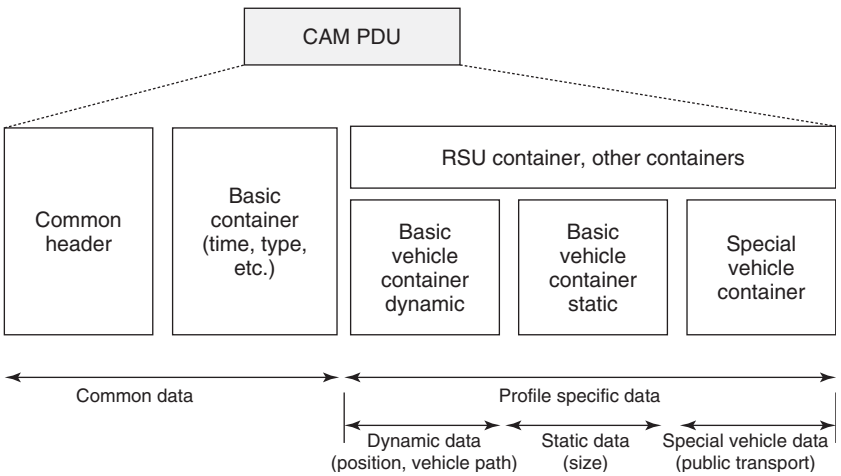

Figure 7. CAM structure.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

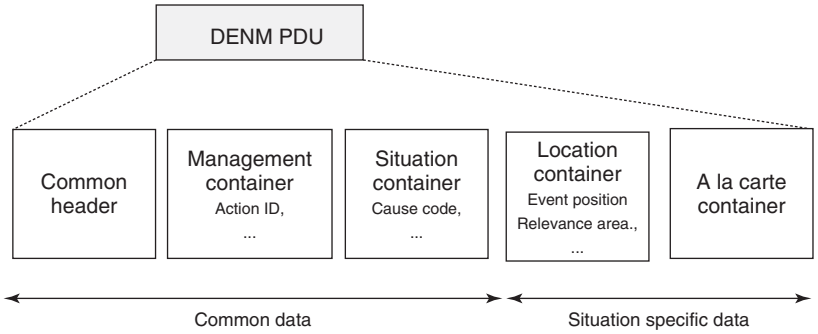

Figure 8. DENM structure.

such as for public transport or emergency vehicles). The concept of profiles ensures a flexible message format that can be adapted to the needs of the sending vehicle.

DENM is an event-triggered message, where an event gets assigned a unique action ID. As opposed to the single-hop CAM, a DENM targets a defined relevance area and can be transported using multi-hop, typically through GeoBroadcast at the network layer. Its message format has common data and situation-specific data. It is organized in a DENM header with protocol information and several containers (Figure 8). Containers for common data are the management container (e.g., fields for action identifier and data version) and the situation container (e.g., field for cause code). In the situation-specific data, the location container carries fields for the event position, the relevance area, and others. An a la carte container can be used to transmit application-specific contents. The DENM protocol handles the event lifecycle: an event with a specific action ID can be triggered and updated by the originator of the DENM, where event updates are distinguished by increasing data versions. An event can also be canceled by the originator or negated by a third station. A DENM can also be repeated by the originator, typically at a lower frequency than a CAM, to ensure that a message is received by vehicles that enter the relevance area.

Further application messages are also being standardized, such as for intersection topology (TOPO) and signal phase and timing (SPAT), which transmit static and dynamic information (e.g., traffic light phases) of intersections.

5 SECURITY AND PRIVACY

Security is a fundamental requirement for vehicular communication (Raya and Hubaux, 2007). In an example attack scenario, an adversary may publish fake traffic jams or repudiate existing ones, resulting in a chaotic road traffic situation. In a worse scenario, an adversary may fake an emergency brake message, which causes other drivers to brake hard, resulting in rear-end collisions. More systematically, the vulnerabilities of the system can be classified in: (i) jamming, (ii) forgery, (iii) in-transit traffic tampering, (iv) impersonation, (v) privacy violation, and (vi) on-board tampering. In order to cope with the vulnerabilities, five main security objectives can be identified (see ETSI TR 102 893, 2010 for more details):

- Confidentiality: messages should not be revealed to unauthorized parties. Also, unauthorized parties should not be able to deduce past or future locations, routes, and identities from communication means.
- Integrity: messages should be protected against unauthorized or malicious modifications or manipulations during transmission.
- Availability: communication should not be prevented by malicious activity.
- Accountability: audit all changes to security parameters and applications (updates, additions, and deletions).
- Authenticity: unauthorized stations should not be able to pose as authorized ones.

The security objectives can be achieved using different cryptographic means, that is, asymmetric, symmetric, and hybrid (asymmetric and symmetric) schemes. Among these, the asymmetric scheme based on digital signatures is favored (Papadimitratos *et al.*, 2008). Here, all stations obtain digital certificates and sign all their messages with their private key. The recipient verifies the integrity of the sender and data using signature verification. Optionally, depending on the case, the message payload can be encrypted to ensure confidentiality. The asymmetric scheme that is going to be used is elliptic curve cryptography (ECC). Compared to more common RSA-based methods, ECC offers moderate key and signature lengths for a reasonable duration of time for signature generation and verification.

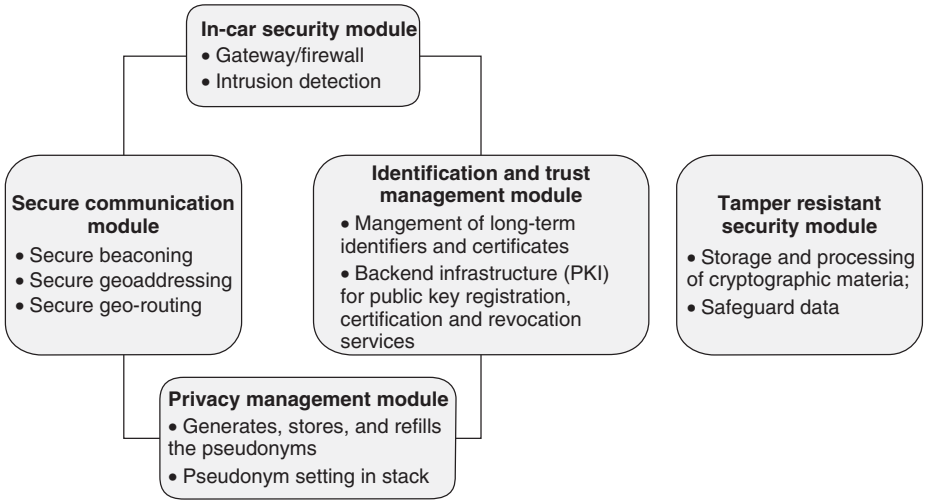

Figure 9. Security core elements. (Reproduced by permission of Kung *et al*., 2008. © Antonio Kung.)

In order to ensure confidentiality, messages can be encrypted. As encryption does not allow for location privacy, pseudonymity is applied: every station obtains a set of short-lived certificates with pseudonyms that belong to the same station and changes them frequently. If the changes occur often enough, the tracked data cannot be assigned to a single station. In order to prevent linking of new and old pseudonyms, addresses at all communication layers, including MAC addresses, must be changed simultaneously.

The cryptographic protection and privacy support using pseudonyms is complemented by plausibility checks. Such tests ensure that received data, such as position and speed values, are plausible according to system assumptions and physical rules, for example, the maximum communication range and timestamps.

An overall security architecture comprises five main components (see Kung *et al.*, 2008, baseline architecture for secure communication developed by the SeVeCom project) for secure communication, identification and trust management, in-car security, privacy management, and a tamper-resistant box to safeguard credentials (Figure 9).

6 RADIO RESOURCE MANAGEMENT AND DECENTRALIZED CONGESTION CONTROL

While it will be challenging to achieve a sufficient penetration rate in the beginning of the deployment stage, it will be even more challenging to deal with the large number of participants once every vehicle is finally equipped. As the capacity of the wireless channel is limited, congested channel situations, and therefore reduced channel access opportunities as well as increased packet collision probabilities, have to be expected. Consequently, the reliability and performance of inter-vehicle communication networks will drop significantly if no counter measures are implemented.

In order to deal with congested channel conditions, several mechanisms can be implemented: first, stations can knowingly "ignore" packet transmissions that arrive with very low signal strength and block a sender from sending. This strategy is typically referred to as an *adaptation of the CCA* threshold of the CSMA-based MAC layer, and increases the spatial reuse of the channel. Second, stations can reduce the time required to transmit a packet, for example, by adapting the modulation scheme and the coding rate used at the physical layer. While the usage of a higher order modulation scheme and coding rate will reduce the period of time that the channel is considered busy, the robustness against fading signal strengths is reduced as well. Hence, such an adaptation is not necessarily the best choice. As a third option, stations can reduce the amount of data traffic that is generated and transmitted to neighboring stations, for example, by an adjustment of the transmission power and/or the packet generation rate at the application layer (e.g., Huang *et al.*, 2010 and Tielert *et al.*, 2011). While a reduced transmit power increases the spatial reuse of the channel and limits the range within which a transmission can be detected and successfully decoded, an adaptation of the packet generation rate reduces the amount of data that may be transmitted, similar to how the transmission control protocol (TCP) of the internet protocol stack reacts to congested network conditions.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto170

Mechanisms that aim to reduce or limit the congestion on the wireless vehicular channel are usually called *congestion control protocols*. In relationship to the principles of distributed control theory, such protocols implement two core tasks: congestion detection and congestion control. As the impact of a station's transmission behavior (e.g., the used transmission power, modulation scheme, coding rate, and the average packet generation rate) cannot be determined by the station itself, but only by its neighbors, congestion detection requires the provisioning of feedback among neighboring stations, for example, through the exchange of locally measured channel congestion levels. On the basis of the collected feedback from all neighbors, the controller can then derive an appropriate reaction, for example, determine whether it should react at all, and if yes, how significantly. Similar to other control algorithms, oscillation and fairness issues have to be considered.

When considering congestion control, that is, the restriction of the load in the network, a uniform assignment of transmit power, packet generation rate, data rate, and CCA threshold values among neighboring stations can be considered as a fair solution to the scalability problem. Indeed, such an assignment would ensure that every station gets the same share of the channel. However, when considering a safety application implemented on top of the communication system, this might not be fair. A uniform allocation of channel resources might lead to different levels of safety in certain scenarios, for instance in an intersection scenario in which the awareness requirements of a vehicle that is approaching the intersection are probably higher than the awareness requirements of a vehicle that has already passed through the intersection. In order to ensure that minimum awareness (or performance) requirements are met, awareness control protocols are used in vehicular networks (Sepulcre *et al.*, 2011). Such awareness control protocols adjust the transmission parameters with respect to the current traffic situation and the corresponding safety application requirements. As those protocols each have a different objective target, their control decisions can conflict with the actions proposed by congestion control approaches.

As there are multiple ways to deal with congested channel conditions, radio resource management is clearly a cross-layer issue and cannot be solved on one layer alone. Further, the control algorithms applied to the individual layers need to consider the configuration parameters used by all other layers in order to be able to derive proper actions. It is therefore necessary to include a cross-layer configuration management in the protocol stack.

An information-theoretic formulation of the capacity of WLAN-based vehicular communication systems, considering the specific features of the system, was not available at the time of writing, as the optimal control of coding and modulation schemes, CCA, transmit power, and packet rates is further complicated by multiple and parallel application requirements, detection of radio environment, and game-theoretic considerations. Simulation results estimating the capacity for highway scenarios with two lanes in each direction are presented in Schmidt-Eisenlohr and Hartenstein (2010).

7 STANDARDIZATION

Standards enable the interoperability of devices for WLAN-based vehicular communication implemented by different manufacturers. Many standards have already been published or are still in the drafting stage. Involved standards development organizations (SDO) include global and regional/sector-based SDOs as well as industry consortia (Figure 10).

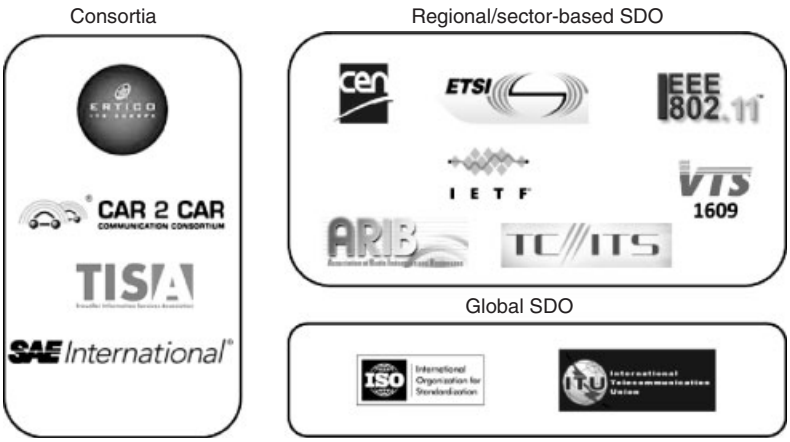

Figure 10. Standardization landscape for vehicular communication.

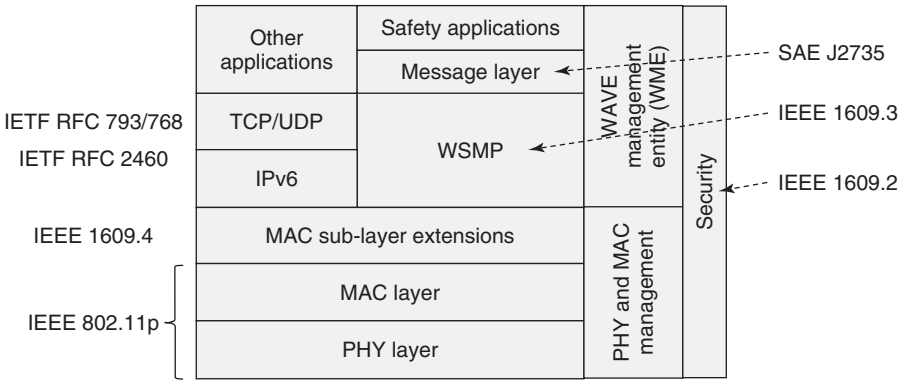

Figure 11. Standards related to the US protocol stack.

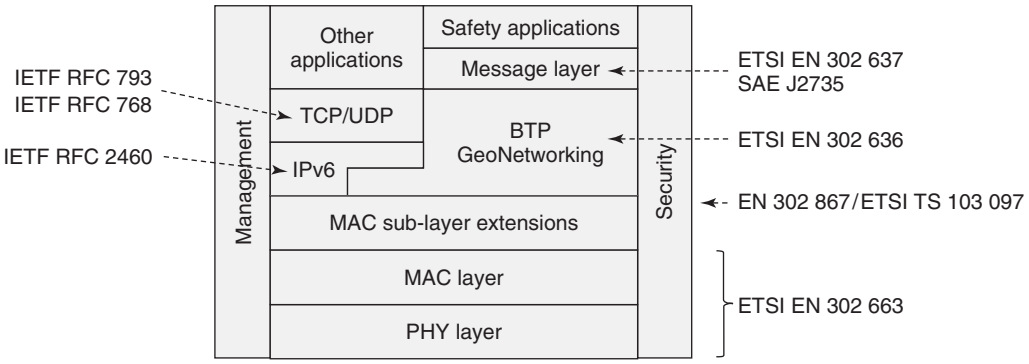

Figure 12. Standards related to the European protocol stack.

Following the main protocol stacks described in Section 4, two sets of standards are specified in the US (Figure 2) and Europe (Figure 3), respectively. At the physical and MAC layers, both stacks rely on IEEE 802.11p, referred to as *wireless access in vehicular environments* (WAVE). It is noted that IEEE 802.11p was merged into IEEE 802.11-2012, together with other variants of the same standards family. The European norm EN 302 663 standard represents a European profile of IEEE 802.11p. Also, both stacks have two branches, one for safety applications and the other for non-safety applications. Non-safety applications make use of the well-known IP protocols, specified in RFC 768, 793, 2460, and other RFCs.

The core part of the US set of standards is the IEEE 1609 family of standards: 1609.4 for channel switching, 1609.3 for networking services, in particular the WSMP and 1609.2 for security services (Figure 11). The message layer at the top of the protocol stack beneath the safety applications is specified in SAE J2735, with the WSM being the most important message.

In the European set of standards, the middle part is made up of the BTP and GeoNetworking specified in EN 302 636 and the CAM and DENM protocols in EN 302 637 (Figure 12). Other messages, such as TOPO and SPAT, follow basically the SAE J2735 standard that is also used in the US stack. Furthermore, EN 302 867 is a European profile of IEEE 1609.2. An overview of relevant standards is given in Table 1.

Beyond the main two standard sets, other standards exist, such as the ISO CALM family of standards developed by ISO TC 204 and the DSRC standards developed by the Japanese standard development organization ARIB.

8 OUTLOOK

Research and development for WLAN-based vehicular communication over the last decade has created a solid technical basis. Standards as a prerequisite for deployment are being developed. The system and technical components are currently being tested in field trials under realistic conditions in order to assess the maturity of the system and the positive impact of the system on road safety and traffic efficiency. The automotive and road infrastructure industry,

Table 1. Core communication standards.

Number	Short title
IEEE 802.11-2012	Wireless LAN medium access control (MAC) and physical layer (PHY)
IEEE 802.11p	Wireless access in vehicular environments, amendment to IEEE 802.11
IEEE 1609.1	WAVE resource manager
IEEE 1609.2	WAVE security services for applications and management messages
IEEE 1609.3	WAVE networking services
IEEE 1609.4	WAVE multi-channel operation
SAE J2735	DSRC message set dictionary
SAE 2945	DSRC minimum performance requirements
ETSI EN 302 663	Access layer specification for ITS operating in the 5 GHz frequency band
ETSI EN 302 636	ITS GeoNetworking
ETSI EN 302 637-2	ITS cooperative awareness basic service (CAM)
ETSI EN 302 637-3	ITS decentralized environmental notification basic service (DENM)
ETSI TS 101 539-1	ITS road hazard signalling (RHS) application requirements
ETSI EN 302 867	Security, stage 3 mapping for IEEE 1609.2
ETSI TS 102 941	Security identity, trust, and privacy management
TS 103 097	Security header and certificate format

together with governments and consortia, are working on the system's introduction and sustainable deployment. For the initial deployment phase the following applications are foreseen:

- emergency vehicle warning
- emergency brake light
- stationary vehicle warning, V2X rescue signal
- traffic jam ahead warning
- in-vehicle signage (speed management)
- hazardous location warning
- contextual speed limit
- road work warning (stationary and moving)
- signal violation warning
- green light optimal speed advisory.

Additional infrastructure-related applications are considered:

- traffic info and recommended itinerary
- decentralized floating car data
- signal phase and time
- secure inter urban parking zone
- interactive bus corridor
- automatic access control—parking management.

GLOSSARY

Ad hoc communication	Communication without a coordinating infrastructure
BSM	Abbreviation of basic safety message; periodic message that is carried in the payload of a WSM
BTP	Abbreviation of basic transport protocol
CAM	Abbreviation for cooperative awareness message; periodic message that is carried in the payload of a GeoNetworking packet
Control channel	Common control channel for safety- and signaling-related information
DENM	Abbreviation for distributed environmental notification message; event-triggered message that carries event-related information
DSRC	Abbreviation for dedicated short-range communication; synonym for WLAN-based vehicular communication
EDCA	Abbreviation for enhanced distributed channel access; allows prioritization of the medium access of data frames as part of the IEEE 802.11 standard
Event-driven message	Message, typically non-periodic, triggered by the detection of an event and transmits event-related information
Facilities	Layer in the protocol stack of an ITS station that provides application-related functionality
GeoNetworking	GeoNetworking is an ad hoc network layer protocol for single-hop and multi-hop communication that utilizes geographical positions
ITS station	Core element of the ITS architecture with instantiations for vehicles, roadside, and central stations
Multi-hop protocols	Exchange of data, where the data can be forwarded using

	relay nodes on the path from the source to the destination
OCB	Abbreviation for outside the context of a BSS; simplified ad hoc communication mode in IEEE 802.11p
Periodic messages	Awareness messages that are broadcasted by any vehicle about own presence and status, such as BSM and CAM
Pseudonymity	Functionality for privacy support using short-lived pseudonym
SAE 2735	Core standard for the definition of facilities messages, such as BSM
Single-hop	Exchange of data among nodes that are in direct communication range
WAVE	Abbreviation for wireless access in vehicular environments, synonym for WLAN-based vehicular communication
WSMP	Abbreviation for WAVE short message protocol; network protocol that supports single-hop communication and is optimized for a minimum size of its packet header

Technologies—Positioning GNSS

Klaus P. Jaschke[1,2]

[1] *German Aerospace Center, Institute of Transportation Systems, Braunschweig, Germany*
[2] *Thales Transportation Systems GmbH, Berlin, Germany*

1 INTRODUCTION

Global navigation satellite systems (GNSSs) are commonly used to detect the absolute position and support the navigation of objects such as cars, trucks, buses, trains, or even pedestrians and cyclists. A GNNS receiver calculates autonomously the position, velocity, time, and acceleration of the object. The two global operational and running GNSSs are the global positioning system (GPS) set up by the US and the Russian globalnaja nawigazionnaja sputnikowaja sistema (GLONASS).

GNSS is widely used in various applications to detect the position of an object; however, there are several constraints because of the physical principle of the system. There are signal runtime errors because of the ionosphere and troposphere. Additionally, biases are caused by offsets of the satellite clocks or errors in the calculated ephemerids. Some of these errors could be mitigated by the so-called augmentation systems; others such as multipath errors can only be detected and corrected with special (high budget) receivers or special antenna designs. The problem of signal shadowing, for example, in urban canyons or tunnels cannot be solved without the use of other sensors.

2 GLOBAL NAVIGATION SATELLITE SYSTEMS

An autonomous system for the absolute detection of the position of objects is the satellite-based navigation system. The first applications using this system are navigation systems that detect the position of the vehicle and calculate the routing to a defined destination that is based on the underlying map data. Additionally, positioning information is used to fuse it with other sensor data and achieve a better availability and accuracy.

2.1 Existing systems

Currently, there are two GNSSs in use. One is the US system GPS, also known as *NAVSTAR* (*navigation system for timing and ranging*), that was fully operable in 1995; the other is the Russian system GLONASS. GLONASS was fully set up and operational 1 year later (Mansfeld, 2004). Nowadays, both systems are renewed, so the second generations will be fully operable in 2014. Additionally, China is extending their local BeiDou system to the so-called compass navigation system to become a global system as well. In Europe, the European Community is setting up the Galileo positioning system that is intended only for civil use and will be compatible with the US system. Therefore, the combination of GPS and Galileo will lead to a better coverage and availability because of more satellites in sight.

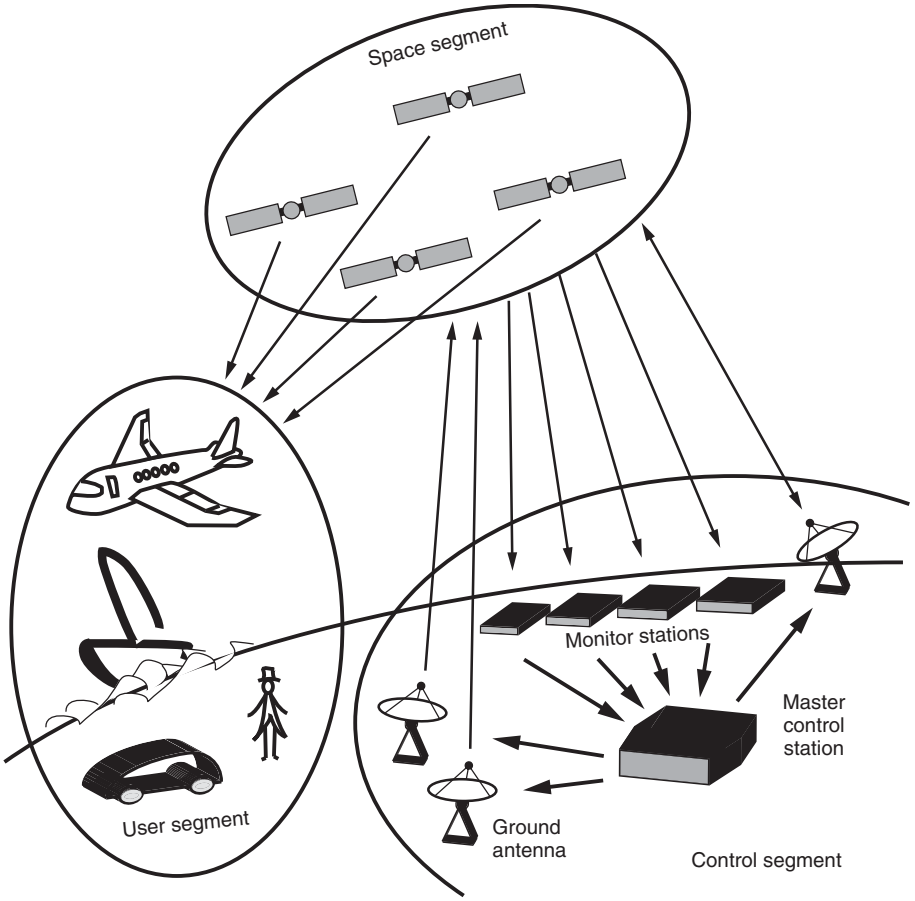

Figure 1. GPS segments.

The structure of GPS—as well as of the other systems—consists of three segments: the space, the control, and the user segment (Figure 1).

The space segment includes the constellation of the satellites and the satellites themselves. The six circular orbits are inclined at an angle of 55° relative to the equator and are separated from each other by multiples of 60° right ascension; see Figure 2 (Grewal *et al*., 2007). The orbits are arranged so that at least six satellites are always within the line of sight from almost everywhere on the Earth's surface (Kaplan and Hegarty, 2006)—while having no shadowing due to tunnels, buildings, or vegetation. The non-geostationary orbits are approximately circular, with radii of 26,560 km and orbital periods of one-half sidereal day (approximately 11.967 h).

The control segment consists of five base stations: the master control station in Colorado Springs that controls the whole operation of the system and the GPS time, and the monitoring stations and ground control station on Hawaii, Ascension Island (Atlantic Ocean), Diego Garcia (Indian Ocean), and Kwajalein (Pacific Ocean). The major tasks are the prediction of the satellite orbits, the monitoring of the satellite clocks, and the transmission of the navigation messages to the satellites (Kaplan and Hegarty, 2006). The ground control stations are the communication interface to the satellites from where the ephemerides and clock parameters are transmitted, while the monitoring stations are equipped with highly precise cesium clocks and multiple GPS receivers. These monitoring stations collect data, process these data, and correct them with ionosphere and meteorological data before transmitting them to the master control station.

The user segment consists of receivers specifically designed to receive, decode, and process the GPS satellite signal. Receivers can be stand-alone, or integrated with or embedded into other systems. GPS receivers can vary significantly in design and function depending on their application for navigation, accurate positioning, time transfer, surveying, and attitude reference (US Coast Guard, 1996).

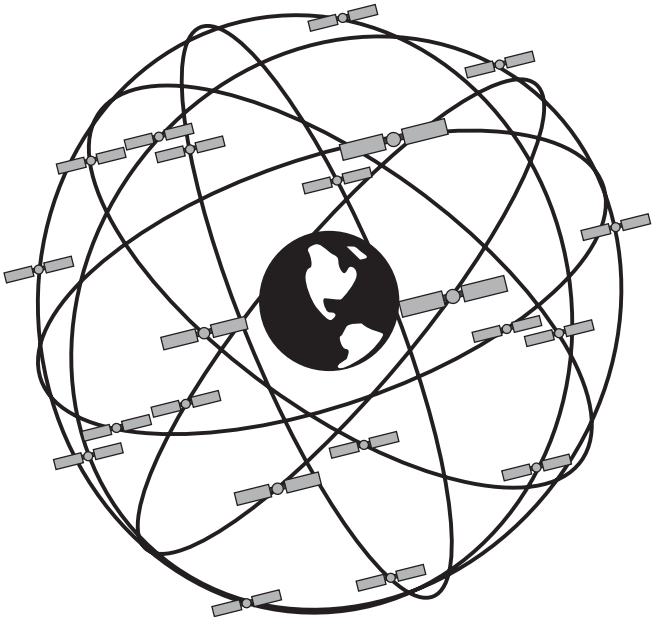

Figure 2. GPS—constellation.

2.2 General principle

For satellite-based positioning, the calculation of the position is based on a runtime measurement of the signal between the satellites and the receiver. The position of the satellites could be taken as well known, and the signal transmission speed could be approximated with the speed of light. Furthermore, the clocks of the satellites and receiver are assumed as highly precise. The principle to detect the runtime is the use of pseudo-random noise codes that are produced at the same time within the transmitter (satellite) and the receiver. Therefore, all transmitted satellite signals are stored in a reference data store. The time shift between the signals could then be derived by shifting the two signals of Δt until they match, see Figure 3 (Meyer zu Hörste and Lemmer, 2009). This can be achieved by finding the maximum cross-correlation of these two signals.

The satellites transmit the following information (Mansfeld, 1993; Grewal *et al*., 2007):

- *Satellite almanac data*: Each satellite transmits orbital data called *the almanac*, which allows the user to determine which satellites are visible. It helps the user to calculate the approximate location of every satellite in the GPS constellation at any given time at a given location.
- *Satellite ephemeris data*: Ephemeris data are only broadcast by satellites for their own position. It is a much more accurate satellite position—analogous to the almanac data—that is needed to convert signal propagation delay into an estimate of the user position. The data is valid only for several hours.
- *Signal timing data*: The 50-bps (bits per second) data stream includes time tagging. This data is needed to determine the satellite-to-user propagation delay for ranging.
- *Ionospheric delay data*: Ranging errors due to ionospheric effects can be partially canceled, while ionospheric delay correction data is broadcast in the data stream.
- *Satellite health message*: The datastream also contains information regarding the current health of the satellite, so that the receiver can ignore that satellite if it is not operating properly.

Considering two satellites, two possible intersections exist considering the signal runtime; however, only one position is real. Assuming the speed of light $c_0 \approx 2.99 \times 10^8$ m/s as the propagation speed, which is not the real propagation speed, already tiny clock errors result in big errors in the position calculation. To avoid these

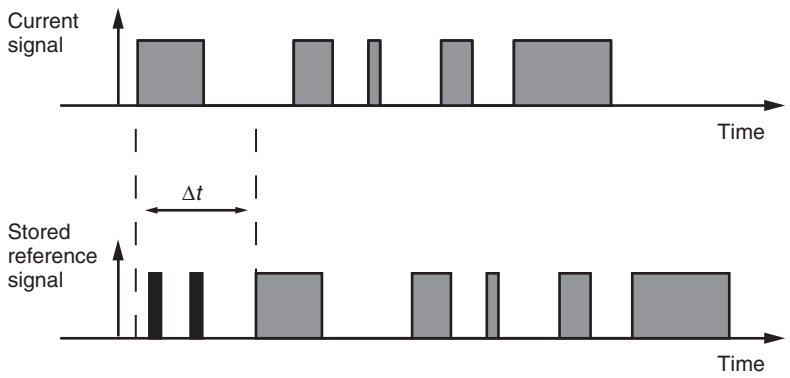

Figure 3. Time shift of transmitted and received signal.

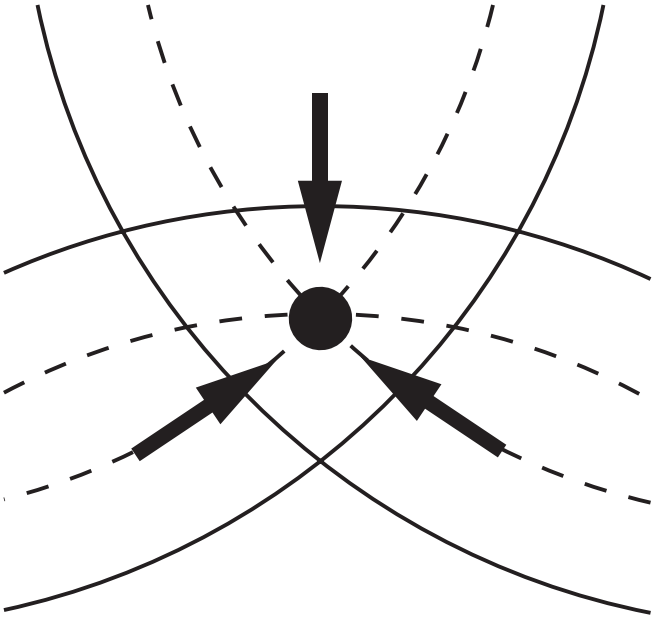

Figure 4. Triangulation—position detection in a plane using three satellites (two dimensional).

errors, compensations based on models for propagation not in vacuum and clock error compensation should be considered. The last errors could be mitigated by the use of a third satellite. On the basis of the principle of triangulation, the position can be calculated, see Figure 4.

Considering also the z-position (altitude), four satellites should be used for the calculation, see Figure 5.

Mathematically, the estimated distance between the receiver and the satellites (the so-called pseudo range ρ_r) could be expressed with the known satellite positions x_i, y_i, z_i, the radius of the earth r, the clock errors N_{rr}, and the unknown position of the receiver X, Y, Z:

$$\rho_r = \sqrt{(x-X)^2 + (y-Y)^2 + (z-Z)^2} \tag{1}$$

$$\rho_r^2 = (x^2 + y^2 + z^2) - r^2 = N_{rr} - 2Xx - 2Yy - 2Zz \tag{2}$$

$$\begin{bmatrix} \rho_{r1}^2 - x_1^2 + y_1^2 + z_1^2 - r^2 \\ \rho_{r2}^2 - x_2^2 + y_2^2 + z_2^2 - r^2 \\ \rho_{r3}^2 - x_3^2 + y_3^2 + z_3^2 - r^2 \\ \rho_{r4}^2 - x_4^2 + y_4^2 + z_4^2 - r^2 \end{bmatrix} = \begin{bmatrix} -2x_1 & -2y_1 & -2z_1 & 1 \\ -2x_2 & -2y_2 & -2z_2 & 1 \\ -2x_3 & -2y_3 & -2z_3 & 1 \\ -2x_4 & -2y_4 & -2z_4 & 1 \end{bmatrix} \times \begin{bmatrix} X \\ Y \\ Z \\ N_{rr} \end{bmatrix} \tag{3}$$

As seen from Equations 1–3, the errors derive from the inaccuracy of the position of each satellite. The satellite coordinates are available via ephemerides that are calculated on ground-based observation of the satellites (Mansfeld, 2004).

Owing to the biases with different error sources described in the next section, the position accuracy depends on the available satellites and geometrical conditions. Typically, a precision of ± 15 m could be achieved without any

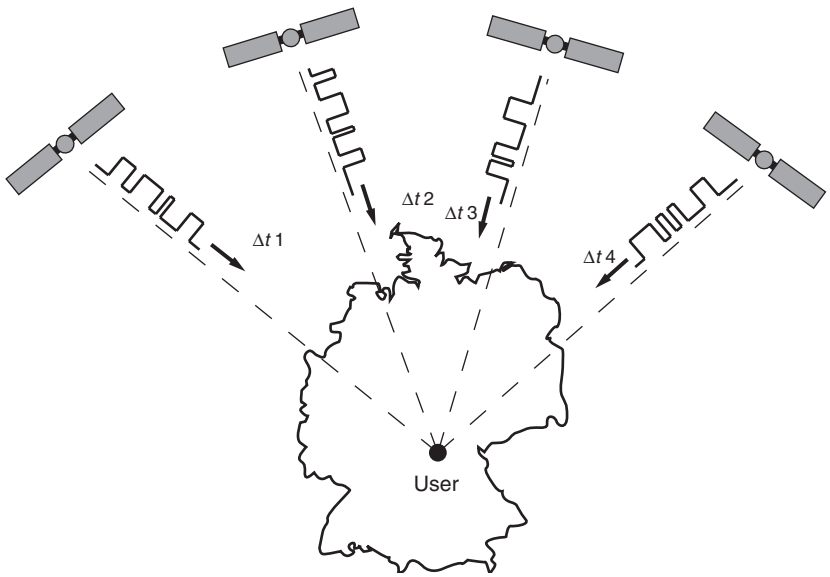

Figure 5. Detection with four satellites (three-dimensional).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

augmentation systems and ±1 to ±3 m with augmentation systems, depending on the environmental conditions, for example, open sky and urban canyons.

2.3 Error sources

As already shown in the previous section, one major bias comes for clock errors, which can be corrected by using additional satellites for the calculation of the position. Additional signal runtime delays are caused while traveling through the ionosphere. Radio signals are refracted, delayed, or scattered. Extreme travel delay may cause range errors of up to 100 m. Plasma turbulences may cause rapid fluctuations of the signal strength, well known as *ionosphere radio scintillations* (Jakowski, 2008).

Figure 6 shows the possible error sources for the positioning:

- Clocks: error between 0 and 1.5 m.
- Ephemeris error < 3 m: it becomes smaller as satellite tracking technologies improve.
- Ionosphere delay: error up to 30 m during the day and up to 6 m by night.
- Troposphere error: 0–10 m, also depends on satellite elevation angles.
- Multipath and reflection: can lead to errors up to 50 m and more, typically 0.1–3 m.

For GPS, a former problem was also the selective availability (SA), where the civilian GPS signal was disturbed to reduce the accuracy such that this signal could not be used by enemies, for example, to steer weapon systems. In 2002, President Bill Clinton ordered SA to be turned off at midnight of May 1.

Moreover, the shielding of satellite signals is a problem, which occurs in tunnels, urban canyons, or other obstacles such as trees (especially wet foliage) because of no detection at all or a reduction of visible satellites and weak detection of signals. Owing to the physical principles, this problem can be solved only by independent additional sensors, such as, for example, inertia platforms or wheel sensors and an adequate sensor data fusion.

Multipath errors such as the ones mentioned earlier could be minimized by using special antenna designs or other means. These mitigations are currently mainly used for stationary measurements and will not overcome the challenge for automotive applications (moving vehicles or vulnerable road users). Here, it has to be seen how new low cost receivers might minimize these errors by, for example, using the second frequency with the military code—which

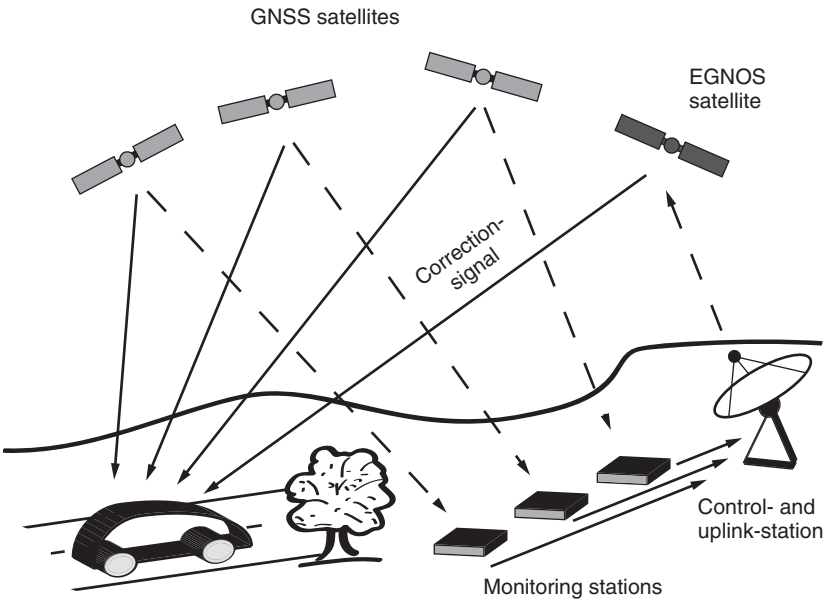

Figure 7. Satellite navigation with satellite-based augmentation, for example, EGNOS.

is not available for civilians—to estimate multipath errors or establish other algorithms for mitigation. The current way forward is still the use of other sensor data and data fusion with the GNSS position fixes.

2.4 GNSS augmentation

Some of these errors can be corrected by GNSS augmentation systems. Very well known is the local differential global positioning system (DGPS). Here, a highly precise reference position is known and is compared to a recent measurement. The difference (delta) between the reference and the measurement is used to calculate the correction data that is sent to receivers in an area very close to the reference point. Now the receivers can use this correction signal to enhance the precision of the current position calculation. DGPS belongs to the so-called ground-based augmentation system (GBAS). GBAS can be used to cover an area of approximately 20 km around the reference station.

An alternative is satellite-based augmentation systems (SBASs). Here, various ground stations exist whose positions are well known and highly precisely measured. These stations calculate with the satellites in view correction data that is then provided via satellites for the users. One of these SBASs is the European Geostationary Navigation Overlay Service (EGNOS), where correction data for the clock and orbit errors as well as corrections for the ionosphere are provided (Figure 7). For North America, the Wide-Area Augmentation System (WAAS) as air navigation aid is well known, with the goal to enhance the accuracy (lateral < 2 m, vertical < 3 m) and the availability $> 99\,\%$ of time (Grewal *et al*., 2007).

2.5 Applications

In the beginning, the use of GNSS was mainly focused on air, space, and maritime navigation and positioning systems. As the receivers (integrated or stand-alone) have become cheaper over the years and are now available as low budget off-the-shelf receivers, the market for other applications will grow tremendously.

For land applications of GNSS, it started with surveying and geodesy applications while the receivers were still of high cost. Owing to their massive cost reduction, vehicle tracking and navigation have become an emerging market, as well as hand-held receivers for hiking and for data collection of other recreational pursuits (Jacobson, 2007). While the receivers are now available as single-chip solutions, they are also integrated into smartphones and other hand-held devices to achieve precise timing and positioning at very low costs.

Looking at vehicle navigation systems, today most drivers use in-built navigation systems of the manufactures or stand-alone systems (hand-held systems or even cellular/smartphones) for navigation. In parallel with the receiver development and their cost reduction, the availability of more and more precise maps for these navigation techniques and the optimization of tracking and mapping algorithms additionally have pushed the market. With the arrival of car-2-car and car-2-infrastructure applications for

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

cooperative driver assistance, highly accurate positions of the cars are needed to calculate and predict the right interactions and also to broadcast these positions via cooperative awareness messages (CAMs) and decentralized environmental notification messages (DENM). However, there are also other applications that will use GNSS positioning, such as eCall or tolling application. Owing to the error sources mentioned earlier, most systems will not use a standard GNSS system to detect the position, but will fuse these GNSS data with other sensor data such as wheel sensors and inertia platform. Additionally, links via cellular or wireless to the Internet and other back-ends can bring further advantages and business cases in combination with GNSS.

3 OUTLOOK

Owing to the physical principles and the errors described earlier, it is still a challenge to mitigate these errors to achieve better availability and accuracy with GNSS systems only. As seen in some recent research projects, see for example, GSC (Lindholm, 2011), DemoOrt (Meyer zu Hörste and Lemmer, 2009), the low cost receivers have become more and more powerful, thereby increasing the accuracy of the position fixes. Even comparing just the latest to the last receiver generation brings added value to the accuracy and availability of the GNSS. However, the problem of no satellites being in sight due to shielding, for example, in tunnels, remain and cannot be solved by GNSS only.

Looking at the augmentation system, EGNOS and also the upcoming European Galileo system will bring advantages for accuracy in fixing the position. As EGNOS is now fully operational, at least two geostationary satellites are available to receive the correction signals. Owing to the placement of these satellites, a good coverage even in urban areas is available that could be used for the mitigation of errors. Additionally, it could be expected that new GPS receivers will be upgraded with the opportunity to use the EGNOS corrections. On the other hand, it can be foreseen that the new Galileo system will bring better coverage and availability in combination with the existing GPS. Owing to the same signal setup, receivers can use all visible GPS and Galileo satellites to calculate the position.

For cooperative drive assistance systems and other mobility-related applications, it has to be seen how the future deployment of these systems and their integration will evolve. Already, today it can be seen that a lot of indication applications are available on smartphones or other mobile devices that could be mounted on vehicles. For safety-relevant applications, especially with, for example, active interaction with the steering or breaking system of a car, GNSS alone will not be sufficient to fulfill the positioning and availability criteria. Therefore, even if augmentation systems are operational, additional sensors are needed to achieve an overall trustworthy and robust system.

ABBREVIATIONS

CAM	Cooperative awareness message
DENM	Decentralized environmental notification message
DGPS	Differential global positioning system
EGNOS	European geostationary navigation overlay service
GBAS	Ground-based augmentation systems
GLONASS	Globalnaja nawigazionnaja sputnikowaja sistema
GNSS	Global navigation satellite system
GPS	Global positioning system
SBAS	Satellite-based augmentation system
WAAS	Wide-area augmentation system

Tracking and Navigation for Goods and People

Moritz Kessel, Martin Werner, Florian Gschwandtner, and Claudia Linnhoff-Popien

Ludwig-Maximilians-University Munich, Munich, Germany

1 INTRODUCTION

Classically, the aim of positioning is mainly to give orientation and navigational aids. As the rise of the global positioning system (GPS) as an inexpensive positioning technology, many applications have been designed that make daily life easier. Nowadays, the complexity of navigating a car in foreign environments has been completely moved into the digital world. The problem is reduced to having the right map, enough electrical power, and a concrete point of interest. This is one source of interest in indoor positioning services: namely, provide a high quality orientation service inside buildings. From this perspective, it would of course be optimal to have a seamless positioning system that works inside and outside buildings equally well based on the same technology. However, such a system does not yet exist.

Sometimes, it seems that the aim for indoor navigation is a bit pointless, as often buildings are used by small, closed groups (except public buildings such as airports, shopping malls, etc.) and the problem is seldom orientation and localization. However, another reason for interest in indoor positioning comes from the areas of security management and control of production quality. High quality indoor positioning can allow activity recognition and can enable a production system to determine whether a given set of activities has been performed. As a very good example for the automotive domain, the paper by Zinnen, Wojek and Schiele (2009) explains how to use high quality ultrawideband positioning to do some type of body-model-derived primitive selection to determine, in high dependability, whether a given set of quality checks has been done to a car. The only source of information in this case comes from the 3-D localization tags mounted to the quality checkers themselves.

The main barrier to a wide adoption of such systems lies, of course, in the area of privacy: that is, does the system give enough advantage over a classical checklist, such that the worker accepts that technology keeps himself under permanent surveillance?

A third area of application is, of course, the tracking of goods and people inside buildings. For goods, it can be very important to have a clear understanding of where and when the goods have been moved inside a warehouse. The tracking of people can be important and accepted in high-risk environments, where at any point in time a rapid evacuation might become essential. A common application domain where human beings need permanent surveillance inside buildings is the domain of ambient-assisted living. The aim of ambient-assisted living is to allow elderly people to live in their own homes for a longer time using digital surveillance where nowadays living in a nursing home is

mandatory. Positioning and activity recognition are then used to detect situations where the residents need help immediately.

From this diversity of application domains and scenarios, many different positioning and navigation techniques have been developed, all of which have their strengths and weaknesses. In the following, we explain, in Section 2, the fundamentals of positioning systems and their relation to map information and different notions of position. Section 3 discusses the algorithms that can be used to infer location from observations at a high level of abstraction. In Section 4, we give a broad overview of the existing positioning systems. This section is organized along the physical sizes used for position determination and how the algorithms of Section 3 have been adopted to specific environments and systems. Section 5 concludes this article with a hint on research perspectives.

2 FUNDAMENTALS OF POSITIONING SYSTEMS

Position is possibly the most important source of context for mobile context-aware systems. However, position does not make sense without environmental information that can be used to infer some interpretation of location. This is essentially important for indoor positioning, as the determination of positions inside buildings is error-prone and hence the interpretation of positioning results becomes more complex.

2.1 Modeling of indoor locations

While for outdoor positioning, navigation, and guidance very simple maps containing a graph of roads interconnected by junctions would suffice, the problem of navigation cannot be solved by having a graph of "possible ways" inside a building. Imagine a large hallway with infinite possibilities of pedestrian movement, not only restricted to one-dimensional lines, for example, the edges of a navigation graph, but also free movement in a two-dimensional area. Providing step-by-step guidance or utilizing map matching with techniques known from outdoor car navigation is not possible. In addition, the determined positions are often not accurate enough to map the location to one single edge in a navigation graph.

As a solution to these problems, it is common practice to use more advanced environmental models than interconnected networks of points. These models are often tailored to the quality of the positioning system, the available map data, and the service demands of the intended location-based service.

Following Hightower and Boriello (2001), these models can be best understood from a classification of positioning algorithms. The authors define three types of such positioning algorithms that are described in detail in Section 3: triangulation, in which distances and angles are used to infer a position; proximity, in which the nearness to some known points is measured; and scene analysis, in which a set of observations, which vary with location, is used to infer a location of a mobile device. In the cited work, the authors limit scene analysis to a view from a particular point inside the navigation space; however, nowadays especially signal-strength patterns of existing wireless infrastructure are often used to infer positions with some method of machine intelligence that we want to include in the term "scene analysis."

On the basis of these three types of position inference, the type of position is completely different: triangulation approaches typically lead to numeric coordinates in some reference coordinate systems; proximity detection typically limits the possible set of locations to a smaller area; and scene analysis typically calculates some kind of probability distribution of location.

Hence, environmental models should be able to deal with these types of location. In consequence, environmental models inside buildings should be able to model geometric coordinates of course, but also to model symbolic coordinates such as room names. This is because, often, a scene analysis method reaches poor performance unless it is used with symbolic coordinates between which the measurements change significantly. Think for example of images taken with a camera. Two images of some object inside a room, which have been taken from different points, are still very similar, while the same movement distance between two other points might lead to fundamentally different images, because the semantic location has changed (e.g., leaving a room typically changes the complete appearance of the scene).

Consequently, indoor environmental models typically model location in a hybrid form and allow translating between symbolic and geometric coordinates. Furthermore, positioning is possibly based on symbolic coordinates, and hence on areas rather than points. To be able to calculate shortest ways, an environmental model must provide a sensible meaning of distance, spatial containment, and reachability even for symbolic places.

While the need of geometric coordinates leads to a spatial representation of the model in form of a coordinate system, where the building and relevant objects are assigned two- or three-dimensional coordinates, there are several ways to maintain symbolic coordinates. Becker and Dürr (2005) differentiate between set-based, hierarchical, and graph-based approaches. The set-based model consists of subsets of the set of all symbolic coordinates. The subsets can

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

be used to define overlapping locations, but a set-based model directly supports neither distance nor reachability queries. Hierarchical models directly model containment of symbolic locations, for example, the containment of rooms in floors, but provide no information about topological interconnections between locations. In the graph-based approach, symbolic locations are modeled as the nodes of a graph that are connected by an edge if a direct real-world connection exists. This means that two rooms (being symbolic locations) are usually connected by an edge if there is a door in between. Graph-based models explicitly describe the reachability and enable the calculation of distances, but have no means to describe spatial containment. In conclusion, an indoor environmental model should not only be hybrid in form of symbolic and geometric coordinates but also have a graph-based and a hierarchical (or set-based) representation of symbolic coordinates.

2.2 Different aspects of positioning systems

Before different methods and systems are explained in detail, we want to focus on some aspects that can be important in choosing the right systems and for which, in contrast to the situation outside buildings where most systems rely on a single source of location such as GPS, different positioning systems are favorable.

The first general consideration is about mobility: if the targets to be localized are humans, they can move freely. If the target is a machine, its movement can be limited: a car cannot move sideways. If the mobility of the target is passive, for example, given by conveyor, the possible movement is completely known. Of course, this should influence the choice of the positioning system. A simple and inexpensive radio frequency identification (RFID) detector gives a pretty exact location in time and space for a conveyor-based production system using proximity. RFID for localization of people would lead to very expensive systems, as the functionality of RFID is limited to a very small area and hence a sensor network of RFID readers would have to be deployed and maintained at high costs.

Another important general consideration is among the scaling parameter. Often, there is a correlation among cost, accuracy, and coverage. If the positioning system has to provide a highly accurate position to a single mobile entity, an expensive inertial sensor unit can be the best choice. On the other hand, systems that have to provide a coarse location to a multitude of objects will not use expensive sensors mounted on to the objects. They should rely on infrastructure-based positioning, optimally on existing infrastructure, as is the case with wireless local area network (WLAN) localization.

Cost calculations and their scaling with respect to accuracy, coverage, and the number of targets can be very important for the right choice of indoor positioning systems. From this viewpoint, one typically differentiates between terminal-based positioning, where the sensing and position calculation is carried out by the mobile entity itself, infrastructure-based positioning, where the position of a mobile item is determined by some infrastructure possibly without any communication with the mobile entity, and terminal-assisted positioning, where the position of a mobile entity is calculated by some infrastructure, but the sensing of the parameters for position estimation is done by the mobile entity.

The use of dedicated infrastructure in general leads to installation and maintenance costs that scale with the area of localization. A modern highly accurate indoor positioning system based on ultrawideband technology typically uses four or more sensors per room, all of which need dedicated power and communication cables and induce costs, of course. The use of existing infrastructure such as WLAN, however, does not incur any (additional) costs. However, indoor localization using WLAN is much less accurate than indoor localization using dedicated wideband signals.

For terminal-based positioning systems, costs basically scale with accuracy, electric power demands, and the number of items to be localized. Every mobile item has to be able to calculate its own position and basically needs a computation unit and a sensing unit. If not only the mobile entity itself is interested in the position, one additionally needs a communication unit. Nevertheless, the effort has one advantage: terminal-based positioning offers privacy, which might be a desirable goal for the sensitive location information of a human user.

For terminal-assisted positioning systems, costs basically scale with all these parameters: the area of coverage where the infrastructure has to be installed and maintained, the number of mobile objects that have to be localized, and the desired accuracy and precision of location. However, in some cases, no additional costs occur at all. Think of using existing mobile phones, which already have a WLAN interface, along with an existing WLAN infrastructure and an Internet-based localization service, which takes signal strength information and returns location. In this situation, no additional cost is generated, and truly ubiquitous and cheap indoor localization becomes possible, although limited in accuracy, as WLAN was never designed to be used for localization.

Thus, when thinking of installing an indoor positioning system, one has to carefully consider the design principles and weigh the cost against the desired accuracy and coverage. Another basis for the right choice of system is given in form of the positioning methods used, because

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

they also have an impact on the deployment, the infrastructural needs, and even the required physical properties of the site. Some systems, for example, only work in line-of-sight conditions between the positioning infrastructure and the target.

3 POSITIONING METHODS

Localization and tracking of people and goods inside buildings is much more difficult as compared to positioning outside buildings. The main reason is that radio-based methods have difficulties dealing with attenuation and multipath effects. Hence, many methods that are dedicated to deal with these circumstances and are able to even exploit these propagation complexities have been developed.

As described in the previous paragraph, a simple way to organize positioning methodology (following Hightower and Boriello (2001)) is into the three categories of triangulation, proximity detection, and scene analysis. We want to follow this organization, but add a fourth type of position determination called *dead reckoning*, in which an initial position is updated according to measurements concerning the acceleration, movement, and heading of a mobile entity.

3.1 Triangulation

The methods of triangulation are defined to be using the geometry of a plane triangle to deduce position information. One such method is lateration, in which distances between known points and a mobile entity are measured. Another such method is angulation, in which angles between different reference positions and a mobile entity are measured. Combinations are also possible: for example, the measurement of an angle and a distance from a known point resulting in a position.

3.1.1 Lateration

The most common method of triangulation is multilateration in which multiple distance measurements from multiple reference points with known locations are being used to find the position. For undisturbed measurements, a single distance estimation limits the locus of the object to be tracked to a circle centered at the given reference position with a radius given by the distance measurement. As a result, at least three reference positions (which must not be collinear) are needed to be able to uniquely identify the location of the target. In practice, such circles will not intersect in a common point because of measurement errors. It is common practice to use Gaussian least-squares regression on a linearization of the circle equation given by a Taylor series expansion. As a characteristic of such extensions, this results in a correction vector for an initial position, which could, for example, have been chosen as the middle point of all reference points. This correction vector is then used to update an initial position until this process converges to the position of minimal least-squares residuum.

A special form of lateration is given by hyperbolic lateration, where only the distance difference of a mobile entity to pairs of reference stations is known. As all points that have the same distance difference to two fixed points give the definition of a hyperbola, this is known as *hyperbolic lateration*. The method of dealing with disturbances is the same as for classical lateration; only the circle equations have to be replaced by the hyperbolic equations for the Taylor expansion.

3.1.2 Angulation

For position determination by angulation (Figure 1), the angles between given reference positions are measured, for example, by antenna arrays, and the location of the mobile entity is given by the intersection of rays starting at each reference location into the measured direction. For this intersection to take place, the orientation of the reference measurement units has to be known. Again, the method of Gaussian least-squares regression along with Taylor linearization leads to an iterative location determination algorithm. The measurement of angles at known reference locations is very dominant in practice, but it is important to mention the possibility of measuring all angles at the mobile entity. This typically leads to complexity in mobile entities, but the consistency between angles is automatic.

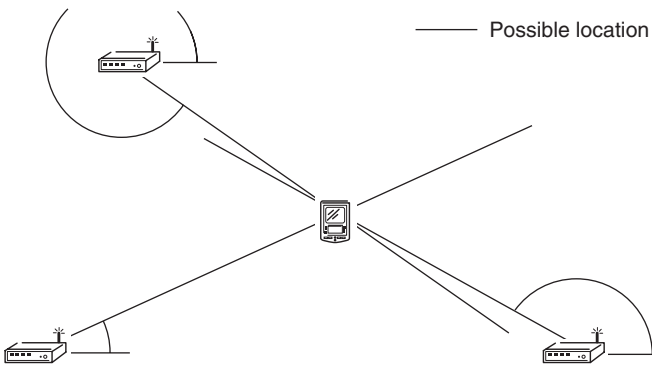

Figure 1. Location determination by angulation.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Inside buildings, it is difficult to infer a distance between two points. Consequently, lateration in general leads to erroneous results inside buildings. Nevertheless, in areas where the propagation characteristics of signals are known (typically free space for sound, light, and radio waves), lateration is used. For the determination of distances, there are two main possibilities: either a measurement of signal strength that leads to a distance estimation based on expected path loss, or a measurement of time. For time measurements, the following three main methods can be distinguished: time of arrival, time difference of arrival, and roundtrip time of flight.

3.1.3 *Time of arrival*

In the case of time of arrival, pilot signals are sent at a known time at known locations. The time difference between sending and receiving of a pilot signal can often be used to infer the distance from the propagation speed of the signal (e.g., speed of light, speed of sound). These distances are called *pseudo-ranges*, as they can be quite different from the actual distance because of time synchronization errors, reflection, scattering, shadowing, and fading. All entities have to be time-synchronized, and one pseudorange estimation leads to a circle of possible locations. The position is then given by the intersection of those circles (Figure 2). This is in effect the same method as used by GPS.

3.1.4 *Time difference of arrival*

For the case of time difference of arrival, pilot signals are emitted at the reference locations at equal times, and the mobile entity records the time difference between receiving those pilot signals. This gives a good basis for hyperbolic multilateration. The most important advantage over the classical time-of-arrival method lies in the fact that the mobile entity needs no time synchronization with the infrastructure at the reference locations. As all points that have the same distance difference to two different positions lie on a hyperbola, each distance difference estimation leads to a hyperbola and the position is given by the intersection of these hyperbolas for more pairs of reference locations.

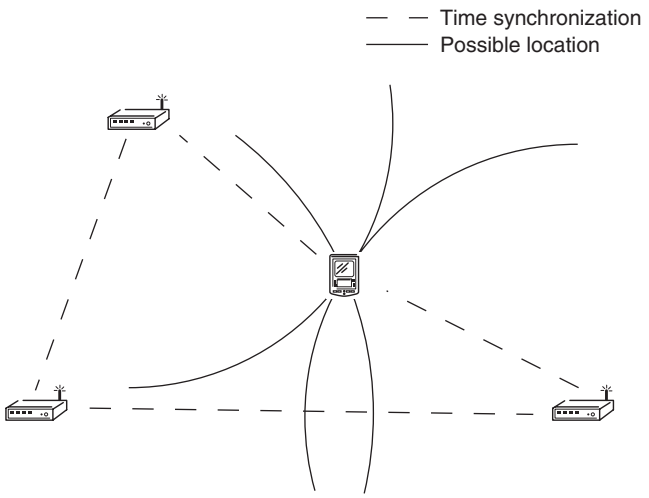

Figure 2. Time-of-arrival positioning.

3.1.5 *Roundtrip time of flight*

In scenarios of roundtrip time of flight, (typically) the mobile entity initiates a measurement by sending a signal that is mirrored back either by physical objects in space or even by active stations located at known reference locations. The mobile entity measures the time difference between sending the initial signal and receiving the reflected signal. Half of this time, possibly reduced by a processing time for active reflectors, gives the time that the signal needed to travel from the mobile entity to the reflector, which can be translated into a pseudo-range using the signal propagation speed (Figure 3).

3.1.6 *Angle of arrival/angle of emission*

For angulation, two main types of angle determination can be distinguished. The first one is associated with the term "angle of arrival," in which the angle of an incoming signal is determined, for example, by an antenna array. The second variant is called *the angle of emission* or *theta coding*, in which a signal is sent out, containing digital or analog information identifying the angle of emission. In both cases, the angle information is used along with the known reference locations to infer a position.

3.2 Dead reckoning

Dead reckoning is a method of calculating subsequent positions out of a fixed initial position. As such, dead reckoning is often based on the measurement of initial sensors giving acceleration and heading. All these sensors have in common that they measure a first or second derivative of the location (e.g., acceleration, acceleration in rotation, velocity). The location at a given time is then given as the integral of these accelerations. For discrete measurements, this integral is given by a sum. The most important problem of this type of positioning is the fact that measurement errors add up, leading to an unrealistic

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

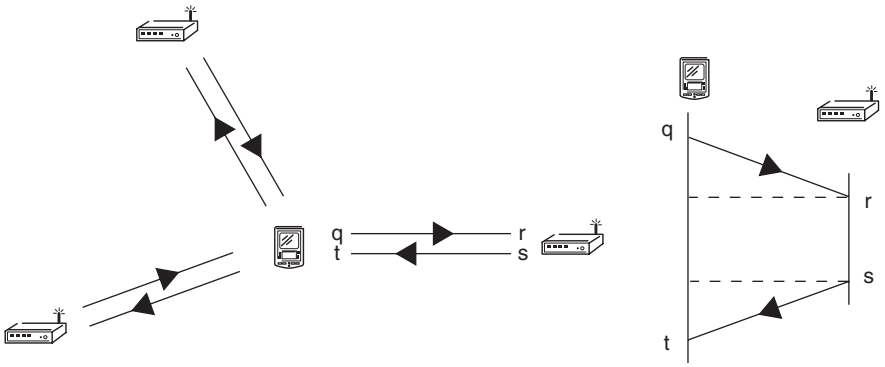

Figure 3. Roundtrip time-of-flight positioning.

movement state (e.g., nonzero speed for a stationary object) and location. Hence, dead reckoning is typically used as an intermediate method for the time between two subsequent position fixes of a slow positioning system or using high-quality, expensive sensors in a short timeframe.

3.3 Presence detection

Presence detection can be seen as a special form of lateration in which it is only known that the distance between a mobile entity and some reference point is below a fixed threshold (e.g., given by the area of coverage of a wireless network). In these cases, the position is often given as the mean of the positions of the stations that detect presence or as a symbolic coordinate.

3.4 Scene analysis

The technique of scene analysis uses methods of pattern matching and artificial intelligence to recall long-living environmental properties of given locations. A classical approach called *fingerprinting* is to divide the navigation space into cells that can be characterized by some statistics of measurable values such as the signal strength distribution of an existing wireless infrastructure. This type of positioning is often tied to a specific application and does not allow for a general description. You will find many different examples throughout the next section. In general, scene analysis is in some sense orthogonal to triangulation, as disturbances of propagation can be very characteristic for a specific place, and pattern-matching can be much more precise for highly perturbed signal propagation scenarios where the performance of geometric location determination techniques degrades. Scene analysis techniques are successfully used on almost any environmental feature that can be measured by mobile entities and varies with location (Figure 4).

4 TECHNOLOGIES FOR INDOOR POSITIONING

With the high number of positioning methods, it is no surprise that there also exist a multitude of technologies that can be used to infer the position of a target in indoor environments. Often, each technology supports multiple methods and each method can be applied with a variety of technologies. In the following, we give an overview of those technologies and the corresponding methods that are used to infer positions, accuracy levels, and application scenarios.

4.1 High sensitive GNSS, pseudolites

Signals of global navigation satellite systems (GNSSs), for example, GPS, suffer from attenuation effects and multipath mitigation in indoor areas. Therefore, those systems offer inaccurate or no position information at all, which can be compensated by senders on ground, for example, in or near the buildings, where position information is needed.

One kind of such senders, called *pseudolites*, emit GPS-like signals that can be used for lateration based on the time of arrival. Similar to satellite positioning systems, these senders need to be strongly time-synchronized and their position must be precisely known (Cobb, 1997). The signals can be used either together with existing GNSS to enhance the visibility of signals in degraded environments or to provide additional senders for more reliable and accurate positioning, or independent of any satellite system for the purpose of indoor positioning without reception of satellite signals. While pseudolites can offer very high accuracies of few centimeters or even millimeters (Cobb, 1997), they do not work well in non-line-of-sight conditions. Owing to their high accuracy, pseudolites can be used in automated industrial production.

A system similar to pseudolites is the Locata system. Locata offers a time-synchronized network of LocataLites,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

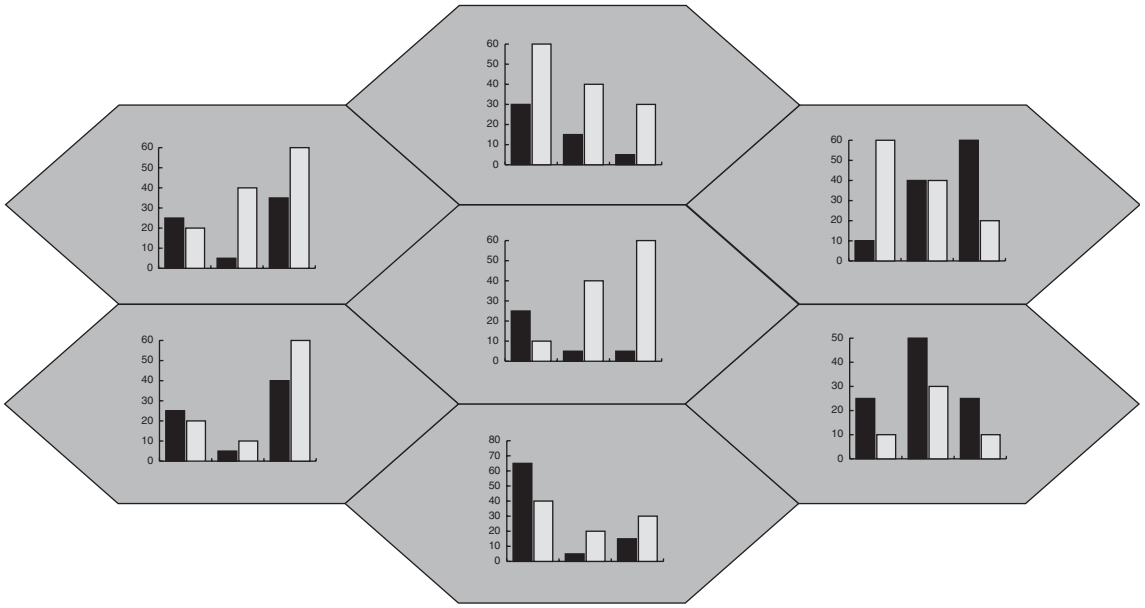

Figure 4. Scene analysis and position fingerprinting.

which transmit GPS like signals in another frequency spectrum [e.g., the license-free ISM (industrial, scientific, and medical) band at 2.4 GHz]. These signals can be used to calculate the position of a component called *Locata*. This component is able to receive standard GPS signals as well as signals from LocataLites and, therefore, is able to calculate its own position with centimeter-level accuracy even when no or too few GPS signals are available for position calculation, as long as enough LocataLites are visible (Rizos *et al*., 2010).

Despite the complex signal propagation in buildings, there are approaches to provide indoor positioning with highly sensitive GPS or GNSS receivers. Even if the signals are weak and might have been reflected, they can be detected with the help of highly sensitive receivers and utilized for position calculation. Experiments demonstrate the ability of such systems to offer positioning capabilities in indoor areas, but the accuracy is generally lower than in outdoor areas.

4.2 Light-based systems

A very promising technique for indoor localization is the use of special light. As light interacts with most indoor material in a much more deterministic way as compared to radio signals, it is possible to calculate distances to objects using the methodology of roundtrip time of flight. These systems are called *LiDAR* (light detection and ranging) systems. The term *LiDAR* reflects the fact that the basic working principle is the same as the one used by radar outside.

Travis, Simmons, and Bevly (2005) were able to detect depth information in a field of view spanning 180° with high frequency, allowing positioning and even continuous navigation using existing maps. The same system can also be used to generate three-dimensional map information using techniques of "simultaneous localization and mapping" (SLAM). Such systems can basically be enriched by the application of detectable landmarks and mirrors for the laser detection. With the use of a few such landmarks, variations in the depth image (due to existing or missing objects) do not harm the positioning process anymore. Tracking of special natural features inside buildings (such as edges, corners, and other regularities) is also possible by application of some image processing and analysis to a LiDAR-acquired depth image, possibly in combination with a camera image (Adams and Kerstens, 1998).

The same type of information can be generated by a much cheaper technology that does not rely on the measurement the roundtrip time of flight of a laser signal. By sending out a regular pattern of light, it is possible to calculate a depth image by observing the deformation of the pattern due to obstacles. The best-known example of this type of system is the Kinect, which is used by the Microsoft XBox to track movements of players. Unfortunately, the working range of such systems is bounded by the resolution of the camera used to detect the pattern.

Another class of light-based systems relies on presence detection by generating modulated light inside the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

navigation space. This modulated light can be generated by an infrastructure and detected by mobile devices allowing for self-contained positioning, or the mobile entity can send an identification code to a network of sensors (Want *et al*., 1992).

Though the use of color image information detected by a digital camera is of course a kind of light-based systems, we describe camera-based systems in a separate section because the techniques are quite different from active light-based positioning systems.

4.3 Camera-based systems

Another technology often found in indoor positioning applications is a camera. The field of camera positioning can be subdivided according to two different approaches. In the first approach, cameras are attached to a moving object with an unknown position that should be determined. This is called *camera egomotion* in the following. The other approach relies on stationary cameras with known positions, which are used to estimate the position of targets moving through the cameras' views (Mautz and Tilch, 2011).

In camera egomotion, there are again different methods for position determination. One method relies on scene analysis, where distinctive features, objects, or landmarks are extracted from the camera view. In the case of natural features, they are compared with a database of previously recorded images, where the position of recording is known. Depending on the size of the database and the resolution of the images, the matching may take some time, but offers highly reliable position information. Werner, Kessel and Marouane (2011) were able to obtain submeter-level position accuracy with natural feature matching. Problems arise from different points of view concerning the database images and the image used for positioning, which leads to scaled and rotated variations of the captured scene. Therefore, scale- and rotation-invariant descriptions of scenes, for example, generated by the well-known SIFT (scale-invariant feature transform) algorithm (Lowe, 2004), offer high reliability. Instead of natural features, artificial distinctive markers such as barcodes can be distributed in the environment. When the position of the marker is known or can be stored inside the marker itself, the problem of scene analysis can be reduced to the detection of markers in an image. This problem is much easier to solve and faster to calculate than natural features, but the markers need to be set up carefully and are prone to partial occlusion by other objects.

Another method for position estimation often encountered in camera egomotion is the use of time-domain information from consecutive images, called *optical flow*. The technologies of SLAM, for example, calculate the movement of a camera projection between adjacent frames by solving a point-set configuration problem that comes from marker or natural feature comparison between frames. This type of system suffers from accumulation of measurement errors over time, as the next position is always calculated from the previous defective position. For recalibration, SLAM often relies on a technique called *loop closure*, where the mobile entity returns to an already mapped location. By identifying the scenery, errors in the trajectory can be corrected and the map quality heavily enhanced. However, this type of algorithm soon gets very complex, as it depends on the complete history, and the point-set configuration problem in itself is very hard and often only solved using a randomized Monte Carlo method.

There are some other systems that use commercial optical mouses (or similar techniques by taking a video of the ground) for dead reckoning (similar to optical flow). These systems are, for example, found in low-cost robot localization systems, where the sensor data of the mouse is used to compensate slip effects of the robot's wheels.

Stationary cameras detect targets moving through the captured scene. As the position of the camera and the position of objects in the field of view can be calibrated, it is easy to retrieve the position of a target. However, stationary cameras are faced with the task of identifying targets in the scene to assign the calculated position to the right target. Furthermore, it can be expensive to provide full coverage for the whole area of positioning and might imply privacy problems, as photos or videos of individuals could be recorded to calculate position estimates and map them to users. In addition, image segmentation needs to be performed carefully in the case of partial occlusion when multiple users are in front of the camera. Therefore, stationary cameras are often used for high accuracy positioning of robots or construction components in automated production scenarios.

4.4 Radio-based systems

Many systems for indoor positioning are based on radio signals. However, there are many different methods and technologies, and how radio information is utilized to deduce the position of a target. There are approaches based on timing, for example, time of arrival, time difference of arrival, and roundtrip time of flight, based on signal strength, either for lateration or for scene analysis (here often called *fingerprinting*), based on angulation, or even presence detection. A similar diversity can be observed concerning the radio technologies. There exist systems based on cellular networks for mobile communication

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

such as GSM (global system for mobile communications) or CDMA (code division multiple access), personal area networks such as Bluetooth, WLAN, RFID, or ultrawideband. Even radio or television signals can be used for indoor positioning.

Utilizing radio signal for positioning is not a new idea, as in outdoor areas the common positioning technologies GPS and cellular positioning rely on radio signals. The latter also work in indoor areas, but suffer from increased inaccuracy because of the multipath propagation, fading, and attenuation. Furthermore, the physical characteristics of cellular communication enable the signals to easily penetrate walls, making it hard for fingerprinting techniques to distinguish between adjacent rooms.

Owing to the lower range (less transmit power) and the physical characteristics of the frequency band (higher frequency), WLAN-based techniques are often able to provide more accurate position estimates as compared to cellular positioning. When using fingerprinting (which is considered to be more accurate than timing approaches), the estimated position in indoor areas often lies within a few meters of the real position. Furthermore, many buildings have already an infrastructure of wireless access points installed. One of the first methods for WLAN positioning was based on fingerprinting (Bahl and Padmanabhan, 2000). However, fingerprinting requires a time-consuming calibration phase with the need for recalibration when structural changes alter the signal propagation characteristics. Much research has been done on the subject of calibration. There are approaches dealing with the simulation of propagation of WLAN signals, allowing automatic calculation of the expected signal strength [e.g., by using a building model, a propagation model, and counting walls between the known position of an access point and a certain reference position (Bahl and Padmanabhan, 2000)], automatic calibration techniques using crowd sourcing approaches, additional measurement stations, or mobile robots (Ocana *et al*., 2005). Another field of extensive research is dedicated to the algorithms for position estimation. Machine learning algorithms such as *k*-nearest neighbors, naïve Bayes or Bayesian networks, support vector machines, and neuronal networks have been proposed and extensively utilized for positioning (Liu *et al*., 2007). WLAN is often the basis of cheap pedestrian positioning systems in environments where a WLAN communication infrastructure already exists. However, a trend toward a combination of WLAN fingerprinting with additional positioning technologies such as inertial sensors exists.

While WLAN-based positioning techniques seldom acquire submeter-level accuracy, methods based on ultrawideband do. Those systems usually calculate the position based on short pulsed signal bursts from a target, which are received and evaluated in a time-synchronized infrastructure of receivers. One of the most successful commercial systems, Ubisense, combines time difference of arrival and angle of arrival for 3-D positioning with centimeter-level accuracy (Steggles and Gschwind, 2005). Owing to limitations in transmit power, most wideband-based systems typically are restricted to approximate line-of-sight conditions, that is, do not provide coverage through walls. As ultrawideband-based systems are comparatively expensive, they are often set up in industrial production scenarios in large factory halls, where the benefit compensates the expenses.

Another radio-based technology, RFID, is mainly used for presence detection in positioning scenarios. RFID readers are placed throughout the building, especially in corridors or at doors, and their position is stored according to a reference system. Whenever a target comes near such a reader, the system is able to receive a short-range signal from the target's RFID tag and can therefore deduce that it is near the position stored for that reader. While the main use of RFID is the identification, a coarse location of an identified item can also be retrieved when the location of the reader is known. This is often the case in industrial settings, for example, when RFID is used to locate and identify objects on a conveyer.

Finally, any other radio technology can be used to infer the position of a target using one of the described methods. The reason why WLAN is popular at the moment comes from the distribution of WLAN and the capability of mobile devices used for positioning. Some 20 years ago, a system would use infrared as a near-field communication and presence detection technology, while this can nowadays be achieved by near-field communication or Bluetooth. The latter could also substitute WLAN positioning, but as there often is no fixed Bluetooth infrastructure, it is seldom used for positioning.

4.5 Inertial navigation

Inertial sensors measure physical effects independent of any infrastructure. Examples are accelerometers sensing acceleration and gravity, gyroscopes measuring rotation, magnetic field sensors (i.e., compass) for orientation, barometers measuring the air pressure that can be used to deduce the altitude of the sensor, and odometers measuring wheel rotation to calculate the traveled distance. Some of these sensors provide absolute values such as the direction of a compass or the altitude of a barometer, whereas some offer relative changes such as the rotation of a gyroscope or the acceleration as a change of velocity. In general, inertial sensors do not provide a position directly, but can

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto174
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

only report changes of position. Thus, inertial measurement units (IMUs) rely on dead reckoning techniques for position estimation and generally need to be supported with an initial position. However, the drift of IMUs leads to an accumulation of the position error over time.

For indoor positioning, inertial sensors are often combined with other positioning technologies to compensate for the drift, and to offer a better accuracy, coverage, or continuity. This integration is achieved by sensor fusion mechanisms such as Kalman (Kalman, 1960) or particle filters (Arulampalam *et al*., 2002). While the Kalman filter is an approach for modeling linear dynamic systems with a Gaussian distribution, particle filters are sequential Monte Carlo methods where a continuous probability distribution is approximated by a point cloud of particles. For indoor positioning, however, both work with a state vector and two phases called *prediction* and *update*. The state vector represents all relevant information of the observed system, that is, the estimated position, speed, and orientation of the target. This vector is altered in the prediction phase according to a system model that is often based on IMU data and then corrected using a measurement model based on absolute but noisy position measurements of some other technology. From a statistical point of view, the prediction and correction can be understood as the prior and the posterior distribution in a Bayesian approach.

In the field of indoor positioning, IMUs have been investigated mainly for pedestrian positioning, utilizing accelerometers as pedometer by counting steps or to measure the speed by integrating the acceleration in combination with a compass or gyroscope for the direction of movement (Woodman and Harle, 2008). However, there is also ongoing research for robot localization and SLAM techniques.

4.6 Audio-based systems

Using audio signals for indoor positioning is one of the early approaches for indoor positioning, but has continued as an active field of research up until now. The early systems such as ActiveBat (Ward, Jones and Hopper, 1997) used ultrasonic signals emitted by a moving target, which were captured by a dense infrastructure of receivers. Those approaches offered centimeter-level accuracy at high expenses, meaning that the infrastructure was expensive and therefore was only installed in small areas such as meeting rooms. The positioning method used for these systems is often multilateration based on time of arrival or time difference of arrival.

Many other approaches, such as microphone arrays capturing the main direction of pulsed audio signals or the utilization of the acoustic background spectrum in different rooms, have also been investigated in recent years. Microphone arrays are used together with angulation techniques, where either an infrastructure of senders with known positions emit pilot signals (beacons) and the target determines its position with the help of the microphone array (by exactly measuring the time of reception or signal strength of the signal at each microphone in the array), or the target transmits audio signals and the infrastructure of microphone arrays captures the signal and calculates the position of the target.

The technique based on the acoustic background spectrum was investigated for pedestrian indoor localization with smartphones in a university building (Tarzia *et al*., 2011). The authors were able to distinguish between several rooms at different times of day, although the chatter of multiple people impeded the use of their system.

4.7 Pressure-based systems

Finally, there exist some very specialized indoor positioning systems that measure the pressure created by a target moving over the ground. One system, the Smart Floor (Orr and Abowd, 2000), is based on a network of pressure sensors in the ground to detect location and identity of pedestrians using the user's footfall signature. The system was trained with a small number of 15 persons and was able to locate and identify more than 90% of the trained persons correctly. Smart Floor has its application area in a smart home environment, where only few different users need to be tracked and identified.

5 CONCLUSION

With this article, we have given a recent overview of the topic of indoor positioning with a strong focus on the task of positioning. Positioning is very complex inside buildings and applications range from navigation over production control to activity inference and business process automation.

Obviously, a position is meaningless without a sense of position, which is typically given by an indoor map. The topics of map creation, map modeling, and navigation semantics have been described very coarsely. A good source of information is Becker and Dürr (2005), which explains very clearly why indoor maps have to be different from outdoor maps and what they have to provide. We expect that standardization will make the generation and exchange of indoor maps favorable soon. Unfortunately, at this point in time, there is neither a standard nor a

GLOSSARY

Angle of arrival	A method for determining the angle between two entities in which the angle of an incoming signal is measured, for example, by an antenna array
Angle of emission	A method for determining the angle between two entities in which the angle of an outgoing signal is coded into the signal and can be decoded by the receiver
Dead reckoning	A method for position determination based on a previously known position and measuring the change in position, for example, by measuring speed and direction of movement
Infrastructure-based positioning	Describes positioning systems that measure signals from and computes the position of a target without the need of a communication channel
Proximity detection	A method for localization based on the finite propagation distance of signals (i.e., the distance at which a signal still can be recognized), where the position can be assumed to be near the known position of the sender of the signal
Roundtrip time of flight	A method for determining the distance between an entity and a target that relies on the total traveled time of a signal whose propagation speed is known from the entity to the target and back
Scene analysis	In the context of indoor positioning, describes a method of localization by matching received signal pattern with known pattern, where the position of occurrence is known
Simultaneous localization and mapping	Stands for a technique where no initial map or reference data is available for positioning but is created on the fly and localization is performed with respect to the already generated incomplete map data
Terminal-assisted positioning	Describes positioning systems in which the mobile terminal measures signals and sends the gathered information to some fixed infrastructure, where its position is computed
Terminal-based positioning	Describes positioning systems in which a mobile terminal measures all signals and computes the position of itself without the need of a communication channel to any infrastructure
Time difference of arrival	A method of determining the distance between entities that relies on the time difference between two signals sent at the same time at different locations to identify the location of a mobile entity
Time of arrival	A method of determining the distance between entities that relies on the time of arrival of a signal to identify the time of flight of a specific signal whose propagation speed is known
Triangulation	Stands for localization techniques that make use of triangular geometry including lateration, angulation, and their combinations

In-Vehicle Sensors

Frank Niewels, Steffen Knoop, Rüdiger Jordan, and Thomas Michalke

Robert Bosch GmbH, Stuttgart, Germany

1 INTRODUCTION

In the last decades, a growing number of vehicle systems got electrified. By this, they changed from originally mechanical systems to the so-called mechatronical systems. This process still holds on. A major part in this process is played by sensors. Their task is to transform a physical or chemical quantity into an electrical quantity, a control unit can calculate with. Figure 1 gives an overview over a large variety of sensors that exist already nowadays in series vehicles (Reif, 2012).

All these sensors will surely have a relevance from the telematics point of view. This can be engine sensors for diagnosis purposes, temperature or rain sensors for weather or road condition purposes, and lots of others.

As it is not possible to mention all of them, this chapter focuses on vehicle dynamics sensors on the one hand (Section 2) and environment sensors on the other hand (Section 3).

2 VEHICLE DYNAMICS SENSORS

2.1 Introduction

Hand in hand with the introduction of different electronic vehicle dynamics control systems into series passenger vehicles such as the antilock braking system (ABS) (1978), the traction control system (TCS) (1986), and the electronic stability control (ESC) or electronic stability program (ESP) (1995), a large variety of corresponding vehicle dynamics sensors entered series vehicles (Kost *et al*., 2004). Nowadays, they are a kind of quasi-standard in series vehicles even more than any other driver assistance system (DAS) sensor.

Their main purpose is to measure and describe the vehicle motion state in three-dimensional (3D) space (e.g., velocities, accelerations, and turn rates) or adjacent variables such as wheel speeds, steering angle, and braking pressure.

There is a large variety of physical measurement principles (e.g., inductive vs Hall-wheel speed sensors) and technological building forms (e.g., surface-micromechanical vs. bulk-silicon-micromechanical acceleration sensors). The focus of this section is not to give a detailed comparison of all these technologies or latest layouts, but to give an overview of the relevant sensors and physical quantities. The corresponding main measurement principles as well as the relevance for vehicle dynamics systems and future telematics use are described.

2.2 Inertial sensors

The most important ESP sensors that are based on inertial measurement principles are acceleration and rotation-rate sensors.

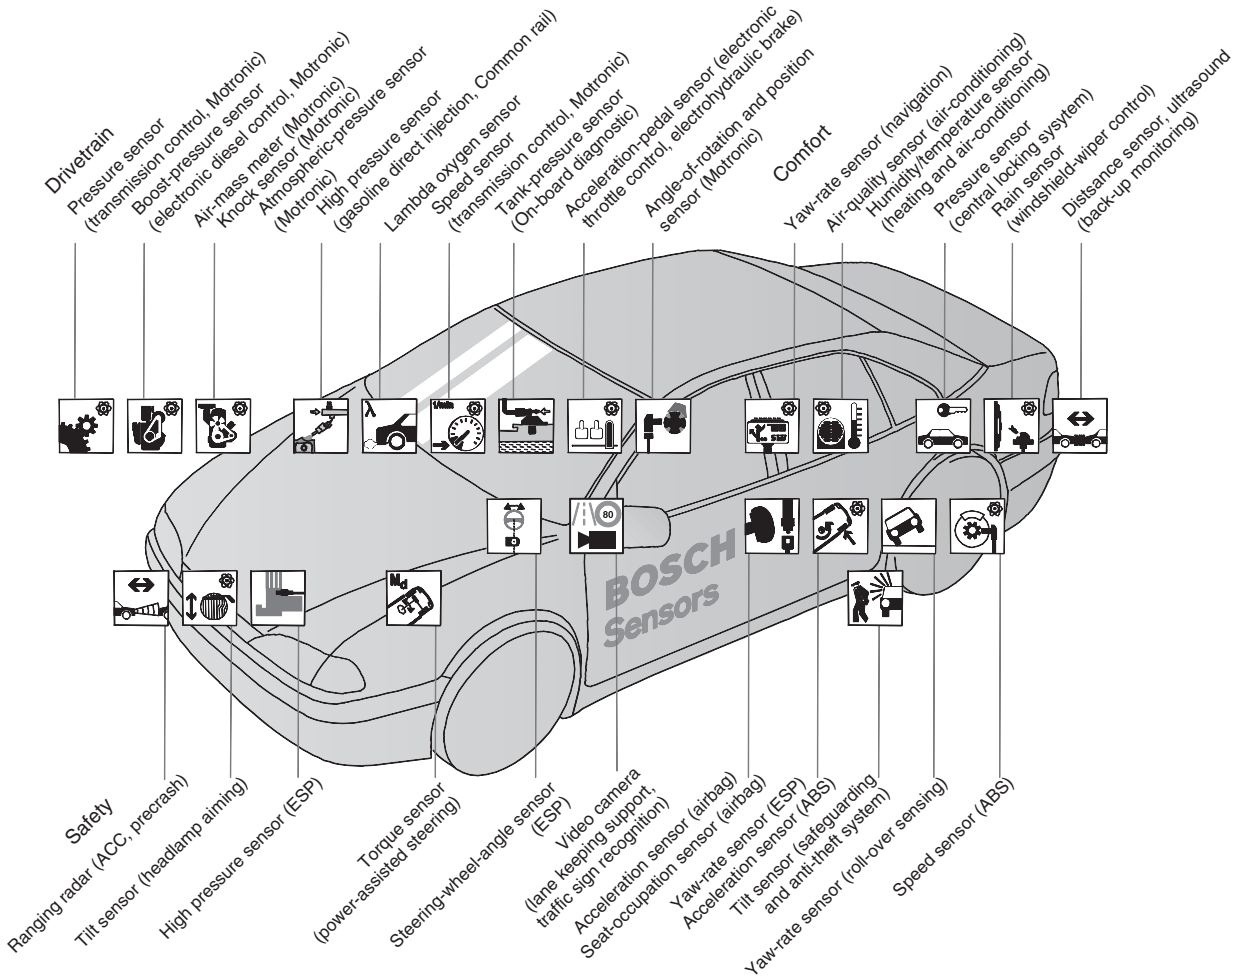

Figure 1. Data acquisition: in-vehicle sensors. (Reproduced by permission of Bosch GmbH.)

2.2.1 *Acceleration sensors*

The task of an acceleration sensor is to measure the acceleration a_B of a (vehicle-)body, it is attached to, in a predetermined measurement direction (MD). It does so, by measuring the force F on a seismic mass, which is an effect of the acceleration a_B or the acceleration a of the seismic mass, respectively. Figure 2 shows the measurement principle. Owing to the inertia of the seismic mass m, a force F results, if the (vehicle-)body is accelerated. This force is transferred to m by the two springs, which results in a corresponding elongation of the springs. Thereby, this elongation is a direct quantity for the acceleration a and with good approximation for the relevant acceleration a_B. It is measured electronically.

Figure 3 shows a surface-micromechanical realization of the principle described earlier (Kost *et al.*, 2004). The electronic measurement of the springs' elongation is

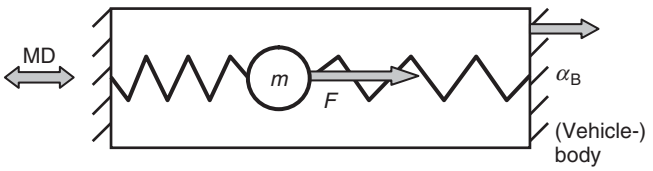

Figure 2. Measurement principle of an inertial acceleration sensor.

realized by measuring a variation of the resulting capacities C_1, C_2, and C_M.

With respect to the dimensioning of the acceleration sensor, different sensing ranges are realizable. Roughly, these ranges are separated into

- low-g, for example, ESP sensors with $a \approx 1$ g;
- high-g, for example, airbag sensors $a \approx 35 \ldots 100$ g

with $g = 9.81$ m/s^2.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

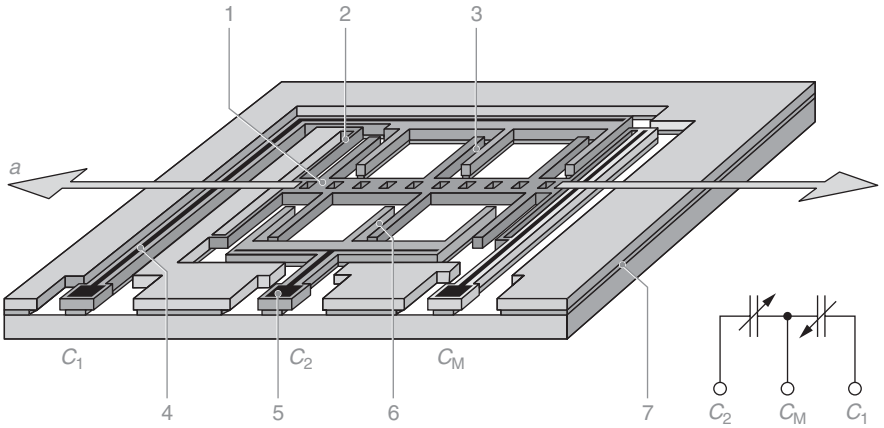

Figure 3. Surface-micromechanical realization of an acceleration sensor 1: seismic mass m; 2: spring; 3: capacity C_1; 4, 5: electric contact points; 6: capacity C_2; and 7: chassis linked to (vehicle) body. (Reproduced by permission of Bosch GmbH.)

Depending on the MD of the sensor in 3D space, an acceleration sensor measures also parts of the gravitational acceleration. For example, a sensor, mounted in z-direction (Figure 6) in a vehicle that stands still, shows $g = 9.81$ m/s^2.

2.2.2 *Rotation-rate sensors*

The task of a rotation-rate sensor is to measure the rotation rate Ω of a (vehicle-)body, it is attached to, with respect to a predetermined rotation axis (RA) of this body.

Figure 4 shows the measurement principle: an acceleration sensor element, similar to the one described earlier, is stimulated to small oscillations (OSC) relative to the (vehicle-)body, it is attached to, and vertical to its MD. If a rotation Ω around RA occurs, the seismic mass m is influenced by a Coriolis force F_C, because of the radial oscillation OSC. This force results once more in an elongation of the depicted springs, which can be measured electronically (see above). Finally, the Coriolis force—and thereby the elongation—depends only on the oscillation OSC, which is known, and the rotation rate Ω, which should be measured.

Figure 5 shows a micromechanical realization of the principle described earlier (Kost *et al.*, 2004). It contains two acceleration sensor elements, which are oscillating on

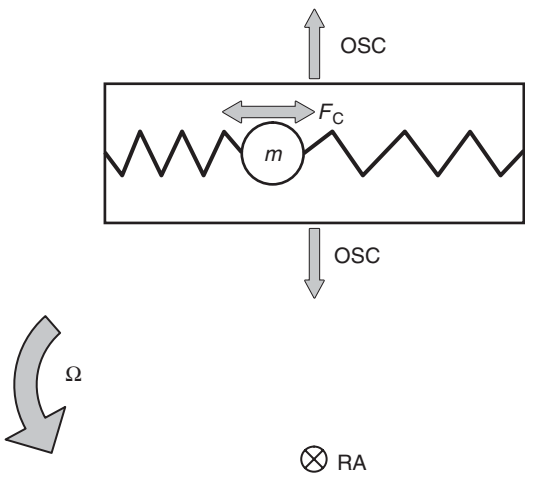

Figure 4. Measurement principle of a rotation-rate sensor.

different sides of the RA. The oscillation is stimulated by an electric current. Owing to the magnetic field B, this creates a Lorentz force and thereby makes the relevant sensor parts move, that is, oscillate. The magnetic field B is created by the poles N and S of a permanent magnet.

2.2.3 *Measurement directions and clustering of sensors*

Figure 6 depicts the six degrees of freedom (DOF) of a rigid body—representing a vehicle—in 3D space. Depending on the mounting direction of the sensors relative to the vehicle, the sensors described earlier can measure these movements: acceleration in longitudinal (x), lateral (y), and vertical (z) directions and roll-, pitch-, and yaw-rates of the vehicle around these axes.

In principle, for each of these measurements, a separate sensor element is required. Nevertheless, several of these elements can usually be combined to one sensor cluster.

Common ESP systems come along with at least a lateral acceleration sensor and a yaw-rate sensor. Suspension control systems and modern lightening systems often make use of additional vertical acceleration sensors or pitch- and roll-rate sensors. If you have even more than this, for example a 5D configuration, very precise velocity and turn-angle information plus additional quatities can be computed from this (Dissanayake *et al*., 2001). With a full 6D sensor (Figure 7), this can be done even without using any vehicle model, only using the kinematic and kinetic differential equations of a rigid body (Reim *et al*., 2008), well known, for instance, from navigation tasks in aviation.

2.3 Additional ESP sensors

Besides the inertial sensors described earlier, there are some other sensors, important for ESP systems.

2.3.1 *Wheel speed sensors*

As all forces from the road are transferred to the vehicle via the wheels. The wheel speed sensors are one the most important sensors for vehicle dynamics control systems right from the beginning with ABS. Originally, they are for measuring the rotational speed of each of the four wheels of a vehicle. From this, other important quatities can be computed, such as the wheel (rotational) acceleration, the speed of the overall vehicle, each wheel's slip, and even additional quantities such as a loss of tire pressure or—primarily in braking or accelerating cases—the friction coefficient.

In early ABS systems, wheel speed sensors were mainly inductive sensors, the so-called passive wheel speed sensors. Owing to demands concerning the accuracy and the minimum measurable wheel speed when introducing ESP, this changed to active wheel speed sensors. They use either magnetoresistance ICs (integrated circuits), that is, elements that change their electrical resistance depending on a magnetic field, or Hall ICs. A Hall element lies over an impulse wheel either permanently magnetized (Figure 8) or made of steel with an additional permanent magnet (not shown here). This impulse wheel is mounted on the vehicle's wheel, whereas the Hall IC is mounted to the vehicle's chassis. When turning the wheel—and thereby the impulse wheel—the Hall element detects the permanent variation of the magnetic field using the Hall effect and can derive the turning speed from this (Kost *et al*., 2004).

2.3.2 *Steering-angle sensors*

The purpose of a steering-angle sensor is to measure the angle of the steering wheel, usually in an interval from

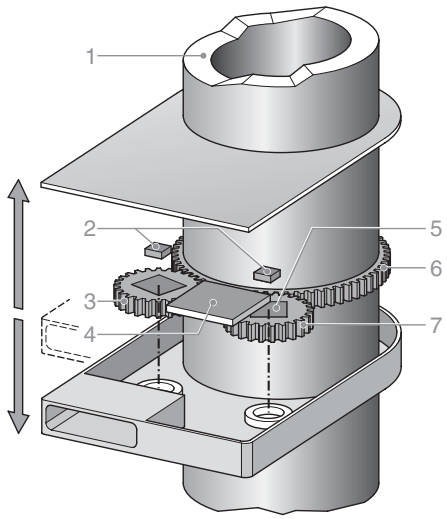

Figure 9. Steering-angle sensor. 1: steering column; 2: two magnetoresistance sensors, detecting the position of 5 and thereby of 3; 3 and 7: smaller cogwheels, with different number of cogs; 4: electronics; 5: permanent magnet; and 6: larger cogwheel. (Reproduced by permission of Bosch GmbH.)

-720° to $+720^\circ$. This indicates the intended driver's course to the system. Figure 9 shows the usual measurement principle (Kost *et al*., 2004): a cogwheel is mounted on the steering column. This larger cogwheel drives two smaller cogwheels. These smaller cogwheels have a different number of cogs. By this, it is possible to nonambiguously derive the position of the larger cogwheel (and thereby of the steering column) in an interval from -720° to $+720^\circ$ when knowing the combination of the positions of the two smaller cogwheels only in a 360° interval. These two positions are measured directly by two magnetoresistance sensors (Section 2.3.1).

2.3.3 Brake sensors

As the (wheel individual) braking system is the main actuator of an ESP system, there are different sensors measuring the state of the braking system. These are mainly sensors

- measuring instantly the actuation of the brake pedal by the driver, for example, the brake light switch;
- measuring the internal pressure state of the hydraulic system.

The latter—the use of pressure sensors—can be helpful at different positions in the hydraulic system. Basic ESP systems use a pressure sensor to measure the pressure of the brake master cylinder. To enlarge comfort or functionality, additional pressure sensors could be used, for example, to measure the pressure of each brake circuit individually.

2.4 Applications overview

Although Section 2 deals with sensors for vehicle dynamics, there are a lot of applications arising from the telematics point of view. In the following, there are given only some short hints, as there is a special chapter for this purpose in this encyclopedia.

Detection of

- friction coefficient;
- road surface conditions;
- abrupt braking maneuvers;
- accident of ego-vehicle;
- traffic jams.

Support of

- mapping;
- navigation by odometry.

3 ENVIRONMENT SENSORS

3.1 Introduction

Environment sensors are used to detect objects in the surrounding of the vehicle. The information is used by DASs to increase comfort and safety for the driver. In Figure 10, some of the most popular sensor types are displayed. Their measurement principles are described in Sections 3.2. to 3.4.

3.2 Ultrasonic sensing

3.2.1 Introduction

Ultrasonic sensing, often subsumed with the acronym SONAR (sound navigation and ranging), is a measurement technique that uses sound propagation to measure objects and distances. A widely known application field for SONAR is underwater obstacle measurement, for example, for marine navigation. Animals such as whales use related techniques for communication over large distances with water as sound propagation medium. Bats use the SONAR principle even for precise navigation and for hunting their prey.

SONAR systems can be categorized in active and passive systems. Passive systems analyze sound signals that are generated by the environment or other objects. Active systems generate a sound signal, for example, a sound pulse, measure the reflected echo(es), and thus extract information about the environment.

Automotive DASs use the active SONAR principle for measuring distances to obstacles around the host vehicle. These systems help the driver especially in low speed maneuvers, such as parking, for example, by signaling any obstacles and remaining distance in the driving direction. Typically, ultrasonic sensors are applied to detect objects in the near field of the host vehicle. Even fully automated parking maneuvers can be conducted based on state-of-the-art ultrasonic sensors, if the vehicle allows control of steering angle, throttle, and brake.

3.2.2 Fundamentals: measurement principle

Active ultrasonic sensors in the vehicle generate a sound pulse. Objects in the measurement field reflect this sound wave. The reflected wave can be measured, and the signal delay between generated and reflected pulses is used for computation of the distance between sensor and the object. Figure 11 shows a sketch of this setup.

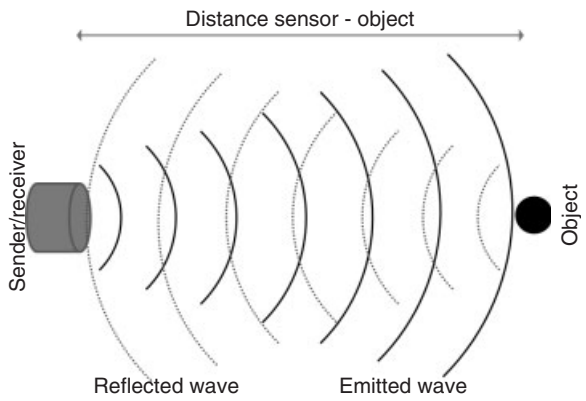

Figure 11. The generated sound pulse of the active ultrasonic sensor is marked in black. The wave is reflected by an object, and the reflected wave (light gray, dotted line) can be measured by the sensor.

Generally, the reflected sound signal contains different kinds of information about the target. This is obviously the radial distance of the object, which is coded in the signal delay. In addition, the reflected signal is affected by relative velocity between sensor and object as well as surface reflectivity of the target.

As the wavelength of the ultrasonic signal exceeds typically the roughness of objects (walls, other vehicles, etc.) in the close environment of the host vehicle, surrounding objects act as a mirror for ultrasonic signals. Thus, incident and reflection angles are equal, and only surfaces

perpendicular to an emitted pulse reflect the signal toward the sender.

3.2.2.1 Range measurement. Common ultrasonic sensors for automotive applications use only the distance information, as the signal is digitized directly in the receiver with a delay-dependent threshold.

With the information of the delay t between sending and receiving the sound pulse, the distance x between the sensor and the object is computed as follows:

$$x = \frac{c \cdot t}{2} \tag{1}$$

where c is the speed of sound. For the speed of sound, the following approximation can be used, which models the dependency from the temperature of the medium (Linder, 1999):

$$c = 331.5 + 0.6 \cdot \theta \quad (^{\circ}) \tag{2}$$

For a standard temperature of 20°C, this results in $c = 343.5$ m/s.

3.2.2.2 Trilateration. As mentioned, the delay between signal generation and receiving of the reflected response in the same sensor enables computation of the radial distance of the object. Together with the sensor opening angle, this yields a segment of a circle as possible object position. For parking assistance applications, it is necessary to achieve higher precision especially in the lateral dimension and around the vehicle corners. Measurement errors are decreased by using multiple sensors and the trilateration principle. Therefore, the detection areas of adjacent sensors overlap. An object located in the detection area of two sensors is measured by both sensors independently (direct echo). In addition, the reflected signal of one sensor sound pulse is measured in adjacent sensors (cross echo).

With at least two measurements of the same target in different sensors, the location of the target in the sensor plane can be computed geometrically. This yields, for distance a between target object and vehicle (Figure 12):

$$a = \sqrt{c^2 - \frac{(d^2 + c^2 - b^2)^2}{4d^2}} \tag{3}$$

As can be seen from Figure 12, the trilateration principle relies on the relative position of the ultrasonic sensors within the vehicle, which must be known.

An important assumption for trilateration to be valid is that both sensors measure the identical spot on the target, that is, all measured echoes originate from the same location on the target. The accuracy of the result depends on the validity of this approximation. In the example of Figure 12, the reflection centers of both sensors on the target object diverge, which results in a small error for the estimation of distance a.

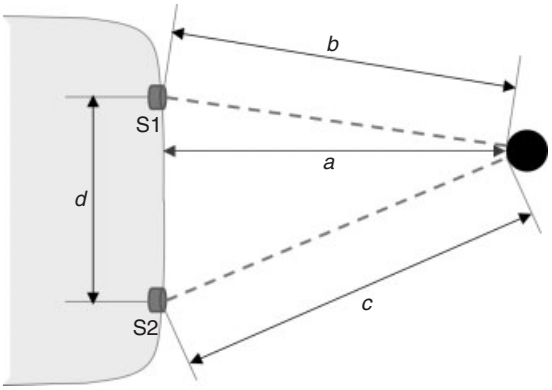

Figure 12. Trilateration: the required distance a between a vehicle and an object can be computed by combining several sensors. Measurements in different sensors.

3.2.2.3 Doppler. In addition to range measurement, the Doppler shift can be used to also measure the relative velocity between sensor and target (Raj *et al.*, 2012). In static environments, the frequency is identical between emitted and received signals. In dynamic environments, when sensor and/or target object is moving, the signal frequency is shifted by the relative velocity between sensor and target. The Doppler shift caused by the reflection is approximately

$$f_{\mathrm{d}} = \frac{2vf}{c - v} \tag{4}$$

with f_{d} as observed Doppler shift, v the radial component of the target velocity, f the emitted frequency, and c as speed of sound.

3.2.3 Sensor design and measurement

Ultrasonic sensors for automotive applications consist typically of an electroacoustic transducer, a controller, and the body, including mounting and connector (Figure 13). The acoustic part consists of a cup-shaped alloy body, with the flat floor as the active area. Inside, a piezoceramic element is used to stimulate oscillation of the alloy transducer at its resonant frequency, and to measure oscillation induced by reflected echoes. The connection to the control unit comprises power supply and one signal line that is used bidirectionally for trigger and measurement.

3.2.3.1 Transducer principle. Ultrasonic sensors typically work at frequencies of 40–50 kHz. This has proven to be a good compromise between damping of acoustic pressure, which increases with higher frequencies, and signal noise ratio (SNR), which is reduced by higher background noise at lower frequencies. With

$$c = \lambda \cdot f \tag{5}$$

this results in a wavelength of approximately 7 mm.

The transducer acts as both an emitter and a receiver of acoustic pulses. The diaphragm is, therefore, stimulated to emit an acoustic pulse, with a duration of 300–600 μs. After emitting the signal, the sensor acts as a microphone and is stimulated by the reflected ultrasonic pulse, which is again transformed into a digital signal that depicts the signal delay. After sending the pulse, it takes up to 900 μs for the mechanical oscillation to decay. During this period, it is not possible to discriminate a reflected pulse from the stimulated oscillation. This results in a minimum detection range 20–30 cm. To further reduce the decay time, it is possible to use active damping techniques. These are currently not used in automotive sensors.

Figure 14 shows signal generation and reception with two adjacent sensors. The pulse is generated in sensor 1. The reflected signal is received first in the emitting sensor, then in a second sensor, which is in listen-only mode. With both signal delays, it is possible to determine the location of the reflecting object within the sensor plane using the trilateration principle.

3.2.3.2 Detection range. The maximum detection range is limited on the one hand by damping effects and on the other hand by interference of different reflections. There

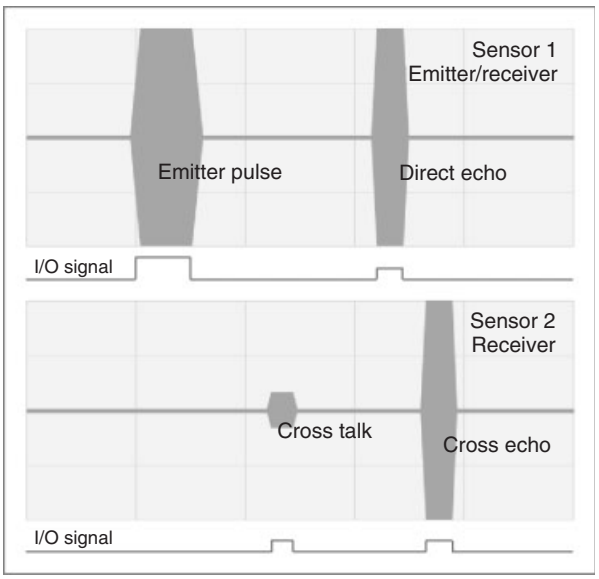

Figure 14. Pulse generation and reception of reflected signal in emitting and one adjacent sensor.

are three main damping effects: atmospheric damping, geometric damping, as given by the wave type, and, during reflection, the damping of the reflecting object. Signal reflections interfere with reflections of the ground, typically the street, which also reduces the SNR.

The detection range of ultrasonic sensors is limited to 0.25–2.5 m; new systems for extended parking assistance have a maximum range up to 5 m. To minimize ground reflections in the received echo while still detecting a maximum of obstacles, the detection characteristic is asymmetrically formed. The vertical opening angle covers ±30°, while the horizontal opening angle sums up to ±60°.

Figure 15 shows a typical antenna diagram of an ultrasonic sensor in horizontal and vertical axes.

3.2.3.3 System design. An ultrasonic assistance system consists of the sensors mounted around the vehicle in a plane parallel to ground surface and one central processing unit (CPU) that coordinates and evaluates the sensor outputs. Figure 16 shows the block diagram of the sensor and the processing unit.

The processing unit triggers pulse generation in the sensors. In listen mode, the sensors return received echo pulses to the processing unit, which then computes the distance to measured objects from all returned sensor signals. Typically, each sensor's pulse generation is triggered consecutively to avoid interference between different pulses.

3.2.4 Sensor configurations

An ultrasonic measurement system for parking assistance consists of a set of typically at least four sensors on one side of the vehicle, up to 12 sensors around the vehicle's contour. The sensors are mounted roughly in one plane, at a height of approximately 50 cm in the bumper.

The applied configuration for a certain vehicle depends on the applications implemented in the vehicle. Generally, the configurations can be categorized according to the sensor mounting position.

Most common configuration is a setup consisting of four sensors in the rear bumper, also called a *four-channel system* to detect and measure objects behind one's vehicle. Analogically, the sensors can be mounted in the front bumper to measure the distance to obstacles in front of the vehicle. Sensors on each side of the car typically serve for detecting parking spaces. Side sensors can also be used for detection of vehicles during lane changes, often referred to as *blind spot detection*. Therefore, side sensors are often configured to higher measurement distances.

3.2.5 Applications overview

The major domain of automotive applications for ultrasonic sensors is parking assistance, because of their comparatively low detection range and high field of view. The most common parking assistance system, often called *park pilot*, measures the distance to the nearest obstacle during parking maneuvers and signals the remaining distance to the driver via optical and acoustical feedbacks, often using a beeping sound with decreasing pulse repetition time while approaching the obstacle. Depending on the number and mounting position of the sensors, obstacles behind and/or in front of the vehicle are detected. These systems exist since 1991.

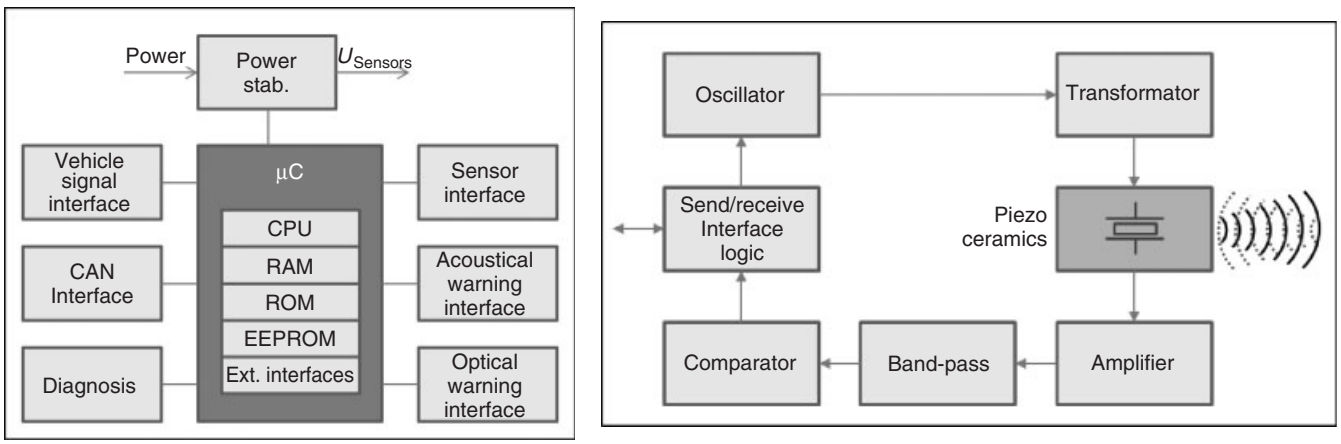

Figure 16. Block diagram of the central processing unit and of one ultrasonic sensor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In addition to the park pilot, other assistance systems exist. Sensors located at the vehicle side, often in the front fender, are used to detect and signal parking spaces. This is done by measuring the distance to side obstacles while tracking the host vehicle with respect to these objects based on its internal motion measurements. Thus, gaps between side obstacles are detected. Their length is estimated based on the host vehicle's motion and compared to the host vehicle's size. If the gap is large enough to serve as parking space, this is signaled toward the driver. This means that the driver always has to first pass a parking space at least with the sensor location (front fender, as mentioned) before the parking space can be signaled by the system. As parallel parking typically requires reversing, there is no critical system restriction.

Advanced parking assistance functions automatically compute parking trajectories from measured parking spaces. These trajectories can be applied in two different ways. "Park steer information" (PSI) systems inform the driver of the best parking trajectory, and the driver conducts parking action as advised by the system. During the maneuver, the trajectory needs to be recomputed continually to adapt to deviations. "Park steer control" (PSC) systems control the steering wheel according to the computed trajectory. Throttle and brake are typically operated by the driver, who still has full responsibility for the vehicle movements, even if the car almost automatically reaches its parking position.

3.2.6 *Summary*

Ultrasonic sensors provide a mechanism for measuring obstacles in the near field of the vehicle. This serves as a sensorial basis for DASs that support the driver in low speed maneuvers, especially parking.

An ultrasonic sound pulse is generated, and by measuring the time delay between pulse generation and its echo, the distance to reflecting objects can be computed.

By applying several sensors (e.g., four sensors in the rear bumper) and by evaluating the cross echo (Section 3.2.2), the measurement accuracy and resolution are increased. A CPU triggers and synchronizes the sensors, receives sensor measurements, and computes obstacle distances, which are then communicated to the driver.

Applications vary from simple acoustical distance indication to automatic parking. Future applications will even use ultrasonic side sensors at higher speeds for assisting the driver during lane changes, and by warning the driver of other vehicles in adjacent lanes.

3.3 Radar

3.3.1 *Introduction*

Originally developed for military use, radar (radio detection and ranging) sensors can be found in civilian vehicles since several years. The measuring principle is based on the transmission of an electromagnetic wave in the gigahertz band. The radar wave is reflected especially at metallic objects and can be detected by a radar receiver.

The distance of a target object can be determined by evaluation of the time delay between sending and receiving the radar signal. Through evaluation of the frequency shift caused by the Doppler effect, also the object's velocity can be determined. Furthermore, there exist several methods to determine the azimuth or elevation angle. By preprocessing the received radar signals with electronic circuits and a digital signal processor, the raw measurement values are generated. Typically, a radar measurement consists at least of the attributes radial distance d_r, relative speed v_r, azimuth angle α, and the received signal power P_R. The raw measurements are further processed by a tracking algorithm. This is done to reduce the measurement noise and to estimate signals that cannot be measured directly, such as the object's acceleration and signal uncertainties (e.g., signal variances).

Automotive long-range radar (LRR) sensors have a detection range of more than 200 m, which is currently not exceeded by any other type of comparable sensor. In automotive applications, radar sensors are particularly suitable for distance and speed control, as the required quantities are measured directly without any interpretation. Furthermore, collision warning or automatic emergency braking systems are often based on radar sensors (Figure 17).

3.3.2 *Fundamentals of radar technology*

3.3.2.1 Antenna gain. Usually, radar antennas are designed to send most of the radiated power toward a preferred direction. The antenna gain G describes the ratio of the maximum power density S_r of a directional antenna and the power density S_i of an (imaginary) isotropic radiator. The same principle is valid for receiving a signal. The calculation of the antenna gain is given by equation 6:

$$G = 10 \cdot \log_{10}\left(\frac{S_r}{S_i}\right) \tag{6}$$

In Figure 18, a basic antenna diagram is shown with one main and several side lobes. The half-value angle of the antenna is a measure to describe the width of the main lobe. It describes the angle area beside the direction of maximum radiation until a power drop of 3 dB.

Figure 17. Automotive LRR sensor. (Reproduced by permission of Bosch GmbH.)

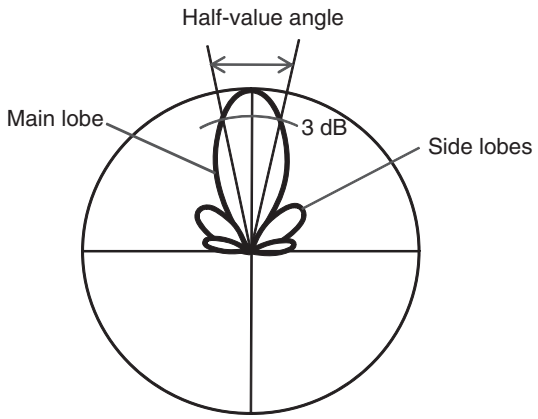

Figure 18. Basic antenna diagram.

3.3.2.2 Radar cross section. The radar cross section (RCS) describes the backscattering behavior of a single target, that is, how much of the sent-out power is reflected to the receiver. The used model is that the same signal power would be received if the specific target was replaced by a metal sphere of the given cross section. The measure is usually given in the unit square meter.

Type of reflector	Dimensions	RCS
Sphere		$\frac{\pi \cdot d^2}{4}$
Flat mirror		$4\pi \cdot \frac{(a \cdot b)^2}{\lambda^2}$
Dihedral corner reflector		$8\pi \cdot \frac{a^2 \cdot b^2}{\lambda^2}$
Triple-mirror		$\frac{4}{3}\pi \cdot \frac{a^4}{\lambda^2}$

Figure 19. RCS calculation of typical radar reflectors.

The RCS value σ is dependent on the geometry of the target object and the wavelength λ of the radar signal. In Figure 19, some examples of typical radar reflectors and their maximum RCS value are shown.

3.3.2.3 Radar equation. With the help of the radar equation, it can be calculated how much of the sent out radar power will be received after reflection. For a better understanding, the equation is derived step by step in the following. Figure 20 illustrates the mentioned variables.

If the radar transmitter has an antenna gain G and emits pulses with the power P_T, the power density at the distance r will be S_T:

$$S_T = \frac{P_T \cdot G}{4\pi \cdot r^2} \tag{7}$$

The reflected power P_B depends on the RCS σ and becomes accordingly:

$$P_B = \sigma \cdot S_T \tag{8}$$

Therefore, the power density at location of the receiving radar antenna is:

$$S_R = \frac{P_B}{4\pi \cdot r^2} \tag{9}$$

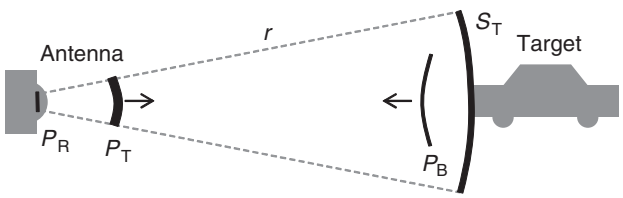

Figure 20. Derivation of the radar equation.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

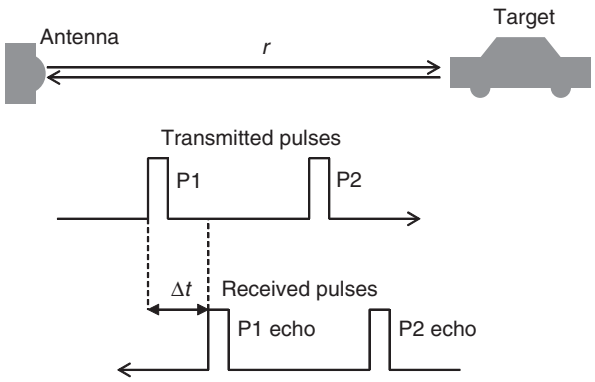

Figure 21. Distance measurement with pulse radar.

The antenna can absorb only a fraction of P_B, which is due to its limited extension. The effective antenna area A_{eff} depends on the antenna gain G and the wavelength λ:

$$A_{eff} = \frac{G \cdot \lambda^2}{4\pi} \tag{10}$$

Combining all the equations, we can derive the so-called radar equation 11 that denotes which quantities influence the received radar power:

$$P_R = S_R \cdot A_{eff} = \frac{P_T \cdot G^2 \cdot \lambda^2 \cdot \sigma}{(4\pi)^3 \cdot r^4} \tag{11}$$

3.3.3 Techniques for distance and velocity measurement

To measure the position and velocity of objects with a radar sensor, different techniques can be used, which vary in complexity, the achievable measurement accuracy, and the error rate. The following sections provide a brief overview of some well-known techniques.

3.3.3.1 Pulse-Doppler radar. The main idea of a Pulse-Doppler radar is to emit short signal pulses and to evaluate the time until the back-scattered signal is detected by the receiver (refer to Figure 21).

The time delay Δt is proportional to the distance to the reflecting object. Taking the velocity of light c, the distance r can be calculated directly:

$$r = \frac{c \cdot \Delta t}{2} \tag{12}$$

To allow the measurement of multiple objects, the received signal is sampled consecutively many times. Each sample corresponds to a particular distance, the so-called range gate.

To be able to separate objects close to each other, the duration of a pulse has to be short enough, so that two separate pulses are received (compare Figure 22). If the pulse duration would be chosen two long, the two pulses would be merged together and only one echo pulse would be received.

The distance separability Δr can be calculated as follows:

$$\Delta r = \frac{c \cdot \tau_p}{2} = \frac{c}{2 \cdot B} \tag{13}$$

where

$$\tau_p \cdot B \approx 1 \tag{14}$$

Here, c is the velocity of light, τ_p the pulse duration, and B the pulse bandwidth.

Furthermore, the time between two consecutive transmitted pulses has to be long enough that no reflections from objects positioned far away would be received in the next transmission cycle. With a given pulse repetition time T_R, the maximum distance r_a without range ambiguities is:

$$r_a = \frac{c \cdot T_R}{2} \tag{15}$$

If there is a large radar reflector at high distances, it cannot always be avoided that the reflected signal is received in the following transmission cycle. One method to exclude range ambiguities is to change the pulse repetition frequency. While true objects are measured at the same distance every time, ghost objects change the position in dependence of the pulse-repetition frequency.

The relative speed of the object is determined by evaluation of the Doppler shift. From moving objects, a slightly

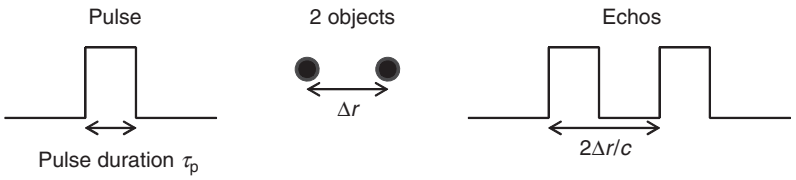

Figure 22. Distance separability.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

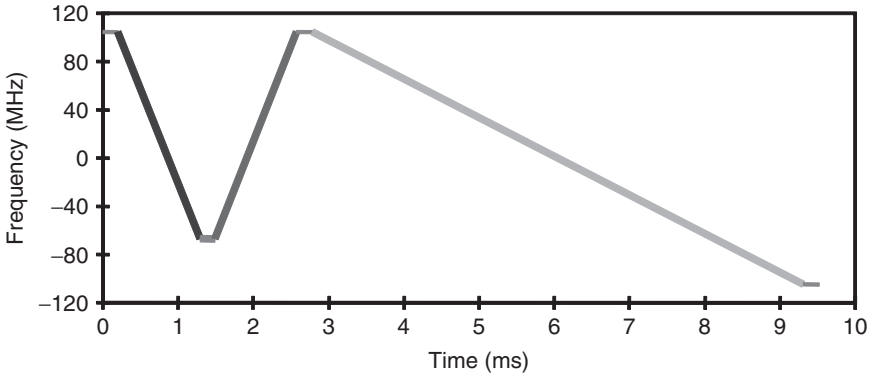

Figure 23. FMCW modulation.

changed frequency is received compared to the emitted signal. To detect this, a large number of successive samples of one range gate is collected and transformed into the frequency domain. By doing this, also the SNR is increased, as the received power of many individual pulses is integrated. The dominant frequency of the spectrum is proportional to the object's velocity.

A main advantage of the pulsed Doppler technique is that the calculation of distance and speed is made independently, which leads to a relatively low error rate. The disadvantage is, however, that sophisticated capabilities of signal processing are needed: the received signal has to be sampled at a very high frequency, and for each range gate, a frequency analysis must be performed.

3.3.3.2 Frequency-modulated continuous wave. The frequency-modulated continuous wave (FMCW) technique is characterized by a continuously transmitted radar wave, whose frequency is varied linearly over time (Figure 23). The radar wave is reflected by metallic objects and received again by the sensor. The time delay and the Doppler effect cause a frequency shift of the received signal compared to the currently emitted signal. Hence, the difference frequency is dependent on both the distance and the relative velocity of the object.

The received difference frequency f_r can be calculated from Equation 16:

$$f_r = 2\frac{s_T}{c} \cdot d_r + \frac{f_T}{c} \cdot v_r \tag{16}$$

Here, f_T is the mean transmission frequency, s_T the slope of the frequency ramp, c the speed of light, and d_r and v_r the distance and the relative velocity of the measured object, respectively. By solving Equation 16 to the relative velocity v_r and plotted over d_r, we obtain a straight line in the so-called dv-diagram (Figure 25). The slope of the emitted ramp corresponds to the slope of the line in the dv-diagram. To calculate the distance and velocity of an object, at least a second ramp with different slope has to be modulated. This way, two crossing lines are created in the dv-diagram. The intersection point describes the distance and relative velocity of the measured object. In multitarget scenarios, intersections in the dv-diagram can occur that do not represent a real target. Therefore, at least three consecutive ramps with different slopes have to be used, so that a real object is described by an intersection point of three lines in the dv-diagram.

In Figure 23, the transmitted radar signal of a 3-ramp modulation is shown. In Figure 24, the received frequency spectrum corresponding to the lines in the dv-diagram of Figure 25 can be seen. As illustrated here, two real targets (numbers 1 and 2) and one ghost target (number

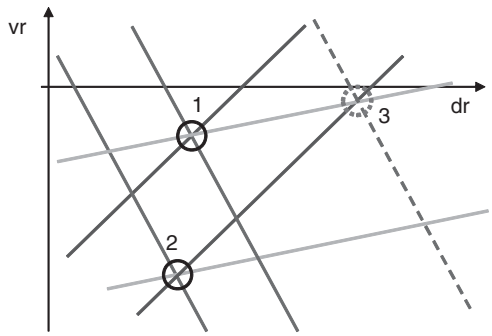

Figure 25. Frequency matching in dv-diagram.

3) can be determined. The ghost target arises from the fact that some detections incidentally generate a three-line intersection point in the dv-diagram. These wrong matches can be generated by detections of real objects or false detections because of noise or clutter (see dashed dark gray line). The probability is growing with increasing number of detection of the frequency spectrum. As the occurrence of wrong matches is almost random, ghost objects do not show a reasonable movement and thus can be refused by a tracking algorithm. Another countermeasure is the use of even more consecutive frequency ramps, which clearly lowers the probability of wrong matches.

3.3.3.3 Frequency-shift-keying. The frequency-shift keying (FSK) technique is related to the FMCW technique. Here also a continuous radar wave is transmitted and received simultaneously. In contrast to the FMCW technique, the transmission frequency remains constant for a certain time. Therefore, a frequency shift of the received signal is generated only by the Doppler effect. By performing a frequency analysis of the difference frequency between emitted and received signals, the velocities of all measured objects can be defined. To determine the corresponding distance of the objects, two blocks of slightly different frequency are emitted (Figure 26). The Doppler shift is almost the same (Figure 26) in each of the two blocks, so that a measured object is mapped to a peak at the same position in the frequency spectrum. However, the phasing of the two signals is different. From this phase shift between the two blocks, the distance of the measured object can be calculated.

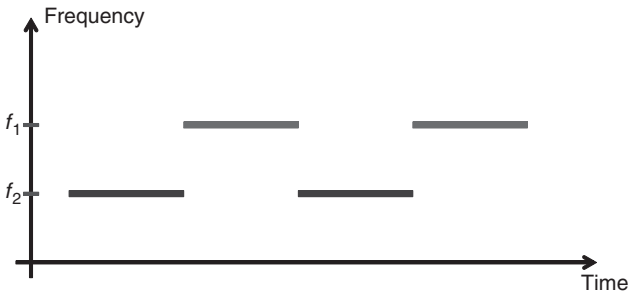

Figure 26. FSK modulation.

The hardware of an FSK radar can be realized very cost-effective, because the demands on the linearity of the transmission signal are lower compared to an FMCW radar. A disadvantage is, however, the fact that the accuracy of distance measurement is dependent on the SNR. Therefore, the distance can be determined less accurate if an object either has a low RCS or is located at a high distance. If two objects have the same relative speed, they cannot be separated by an FSK radar, because they share the same peak in the frequency spectrum. This is the case for all stationary objects. Therefore, a different radar technique (e.g., Pulse-Doppler or FMCW) should be used if the application needs to consider stationary objects.

3.3.4 Techniques for angle measurement

3.3.4.1 Monopulse. To determine the azimuth angle of an object with a single radar pulse or FMCW ramp, at least two partially overlapping radar beams are needed. In a monostatic[1] radar system, there are horizontally arranged antenna elements, which sent out, simultaneously, a coherent radar wave. Each element has its own reception channel. The angle of the measured object is calculated by comparing the received amplitude and phase information with a known antenna pattern (also called *antenna diagram*). The position in the antenna diagram, which fits best to the received signal, is most likely the azimuth angle of the measured object. In Figure 27, an example of such an antenna pattern is shown. Displayed are the amplitude values of a four-beam radar as a function of the horizontal angle.

The described beam-matching procedure is not applicable to separate two objects that are located at the same distance with same relative velocity. In this case, the determined angle would be erroneous. Nevertheless, there exist some more advanced methods to separate two objects in angle, even with a fixed-beam radar.

3.3.4.2 Mechanical scanning. The scanning principle is well known from air surveillance and sea traffic. To determine the azimuth angle of an object, a highly focused antenna is mechanically rotated or moved from side to side. Thus, the desired viewing area is scanned over time. This simple method allows a precise angle measurement in a large angular field of view.

As the angle sectors are sampled consecutively, the available measurement time for a single target object is

limited, which especially could have negative impacts on the accuracy of the velocity determination. Because the sensor installed in a vehicle is exposed to vibrations, it is challenging to guarantee the durability of the moving sensor parts.

3.3.4.3 Beam forming. An alternative to a mechanical scanning is a beam-forming method. The advantage is that no mechanical moving parts are required, although a focused radar beam can be moved over the viewing area within certain limits.

The basis of an electronic beam-forming radar is an antenna array consisting of a large number of antenna elements. If the antenna elements are supplied with signals of different amplitudes and phases in a systematic way (Figure 28), the center of the main lobe can be steered to different directions.

A disadvantage of this method is that the hardware of the sensor has to be equipped with complex and also expensive high-frequency components.

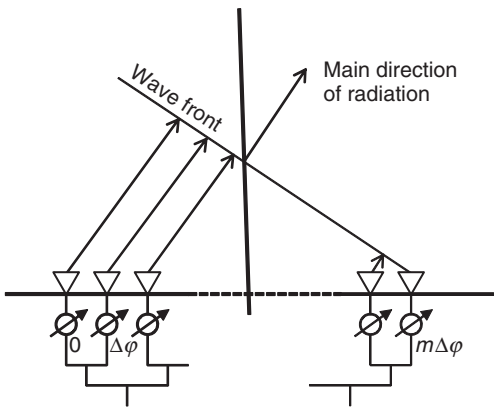

Figure 28. Electronic phase steering.

In contrast, a digital beamforming (DBF) radar supplies all antenna patches with an identical signal comparable to the monopulse method. The radar beam steering is not done physically but instead with the help of digital signal processing: after digitalization, the received signals are multiplied with complex weights. This way, a virtual radar beam can be steered to the desired direction. As the used algorithms are computationally complex, a powerful digital signal processor is needed, which increases the system costs.

3.3.5 Radar applications

Radar sensors are used for DASs since several years. One of the first applications that went into series production was the comfort system adaptive cruise control (ACC). It is an extension of the classic speed control. The vehicle automatically keeps the user-selected velocity as long as the road is clear. If a slower preceding vehicle appears, the velocity is reduced and the ego-vehicle follows in a constant distance. If the preceding vehicle disappears, for example, because of a lane change, the velocity is increased again to the initially chosen velocity. ACC takes over the task of accelerating and decelerating within comfort limits, and only the steering task remains to the driver. In situations where the area of comfortable driving has to be exeeded, for example, for a strong braking maneuver, the driver is acoustically informed by the system and he or she has to take over the longitudinal control of vehicle again. For ACC, usually a LRR sensor is used, which is capable of detecting objects at distances over 200 m.

A second class of radar applications concern safety systems that help to avoid accidents. As a first step, the driver is optically, acoustically, or haptically warned if there is a high risk of a collision with moving or stationary objects. If the driver does not react in time, a partial braking maneuver is started. As a last step, a fully automatic emergency brake is triggered in case there is no other driving maneuver left to avoid the collision. Even if the collision could not be avoided by the system, the reduction of velocity helps to mitigate the severity of the crash.

The lane change assistant (LCA) is a warning function to prevent collisions with vehicles on neighbor lanes while doing a lane change maneuver. Typically, two mid-range radar sensors observe the area behind and besides the own vehicle. The sensors are typically located behind the bumper at the left and right corners of the vehicle's rear end. The system is activated when the driver turns on the direction indicator. In case there is an approaching vehicle on the neighbor lane, a warning signal is giving to the driver, for example, a red flashing lights at the exterior mirror.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As a last example, short-range radar sensors are used for the parking assistance. The sensors are mounted behind the front and rear bumpers and inform the driver about obstacles in the near surrounding of the vehicle, when the vehicle is maneuvered at low speeds. Usually, optical and acoustic signals are used to indicate the remaining distance to other objects.

3.3.6 Summary and outlook

Radar sensors are established in automotive applications since several years. Its main advantages are the precise and reliable measurement of objects' distance, relative velocity, and azimuth angle under all weather conditions. There exist several measurement techniques, which differ in complexity and performance. Automotive radar sensors can be produced in a compact housing and can be mounted invisible, which is an important aspect for many car manufacturers.

As the sensor costs continuously decrease, radar-based DASs become attractive to the customer even in medium-class and small cars. It can be assumed that the number of radar sensors a car is equipped with will increase in the future. Radar sensors can help to improve the comfort of driving and play an important role for reducing the number of fatalities in traffic accidents.

3.4 Video

3.4.1 Introduction

A very popular and cost-efficient sensor system for capturing the features of light is the (digital) video camera—hereafter, simply called *camera*. Especially, the technological progress in the field of semiconductors has helped introducing cameras for driver assistance. The major advantage of camera-based driver assistance is its functional multipurpose character. No other automotive sensor in mass production offers the information density and hence functional potential of video signals. With stereo video, a novel sensor technology has reached the required maturity for the automotive market. Stereo video shifts known sensory constraints in terms of accuracy and availability of traffic-relevant measurands. Owing to that, customers can expect numerous novel driver assistance functions for further improving comfort and safety in driving.

The remaining section is organized as follows: in Section 3.4.2, the video measurement principle is illustrated, after which in Section 3.4.3, the focus will be on the basic design of video sensors. Section 3.4.4 elaborates on typical installation locations for cameras in vehicles. Before summarizing the chapter, in Section 3.4.5, some telematics-related automotive applications for video cameras are introduced.

3.4.2 Fundamentals: measurement principle

As for all sensor devices, a nonelectric physical quantity is transformed into an electric signal in order to allow its application in a technical system. For cameras, the driving physical principle for the required transformation is the so-called photo effect. An inner and outer photo effect can be distinguished. The latter (also called *photoelectric effect*) designates the emission of electrons from a (semi) conductor when absorbing radiation (e.g., visible light). The former (also called *photoconductive effect*) is based on a change of conductibility of a semiconductor (caused by the creation of electron–hole pairs) that is proportional to the intensity of light. The inner photo effect is exploited in (digital) cameras.

It is known that light can be interpreted as consisting of inseparable basic elements—the so-called light quantum (or photon). The notion of photons gives a very intuitive understanding for the model of a major source for noise in images. By absorbing photons, each pixel of a camera imager (a semiconductor with a photosensitive surface) gathers electrons, whose amount is proportional to the level of radiation. The current of photons (the number of gathered electrons per time interval) changes when repeatedly capturing the same scene. The number of absorbed photons is a stochastic process. When determining the relative frequency of measured pixel gray values (these are proportional to the number of gathered electrons), a specific probability density function (PDF) results. The PDF can be modeled by the Poisson distribution, which is defined as follows (with λ as the current of photons and Δt as the exposure time of a measurement cycle) (Jaehne, 2005):

$$f(\lambda \cdot \Delta t) = \frac{e^{-\lambda \cdot \Delta t}(\lambda \cdot \Delta t)^n}{n!} \text{ (with } \quad n \geq 0) \qquad (17)$$

Mean $\mu = \lambda \cdot \Delta t$ and variance $\sigma^2 = \lambda \cdot \Delta t$.

A typical imager pixel will gather more than 10,000 electrons per measuring cycle Δt, which in 68% of cases lead to a relative error σ/μ for the photon noise of $<1\%$. When analyzing σ/μ for the Poisson distribution, it can easily be derived that the relative influence of photon noise is growing with a decreasing exposure time Δt (Figure 29). Put differently and hence more intuitively, in a short exposure time Δt, a small amount of electrons is gathered. The resulting low voltage level has to be largely amplified, boosting the signal and the noise.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

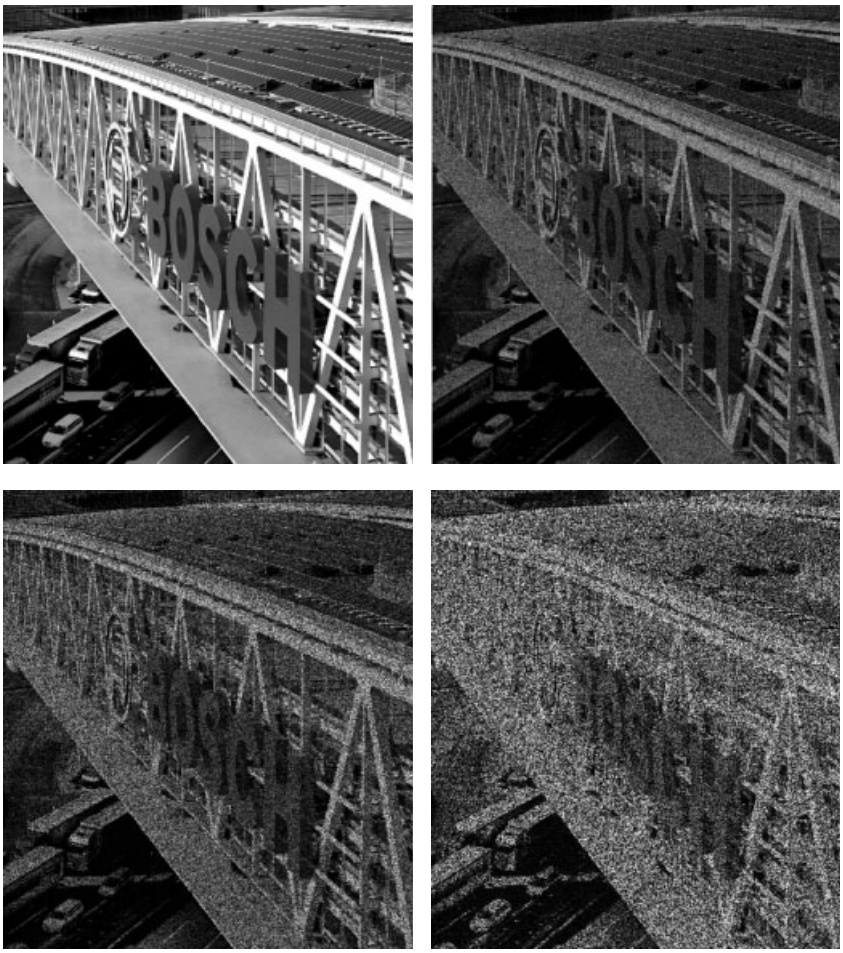

Figure 29. Increasing (synthetically generated) photon noise with decreasing exposure time $\Delta \mathbf{t}$. (Photo: Bosh. Reproduced by permission of Bosch GmbH.)

It is important to note that on moving platforms, long exposure times lead to the motion blur effect, marked by a lack of sharpness of object edges induced by fast motion. As a result, there is a trade-off between motion blur and photon noise.

As the current of photons λ reaching an image pixel linearly depends on the size of the pixel surface, it can be derived that in terms of photon noise, the effect of a growing number of image pixels can be compensated by an equally growing imager size.

3.4.3 Sensor design

In this section, after describing the general setup and specific automotive requirements to a camera, various basic design characteristics of cameras will be described. More specifically, the most common imager technologies, lens types, imager morphology, and camera types are highlighted.

3.4.3.1 Basics. A typical automotive video camera (Figure 30) consists of the following basic components:

- optics (high quality lens system);
- imager (CMOS, complementary metal oxide semiconductor);
- camera body (metal frame for dissipating heat);
- processing units (multicore CPU and/or hardware for graphic acceleration);
- communication device [CAN (controller area network), Flexray].

Different from consumer electronics, vehicle cameras require a high sensitivity to light and a higher dynamic range. These requirements lead to large imager sizes with comparatively small resolution (the number of pixels). Furthermore, vehicle cameras dispose of high quality optical lenses without an analog (hardware-based) zoom. In general, an analog zoom could be helpful in automotive

applications; however, all moving system parts are prone to defects and have to be avoided. As opposed to that, cameras in consumer electronics typically have a higher resolution (as a central measure for product marketing) with typically low quality optical systems.

3.4.3.2 Imager technology. The most prevalent video imager technologies are CCD (charge-coupled device) and CMOS sensors. Both CCD and CMOS sensors are based on the inner photo effect. The captured light-inherent energy leads to the creation of electrons and holes in the semiconductor material. An applied voltage prevents a recombination of the charge carriers. The electrons of each pixel are gathered in a potential well in order to determine the resulting charge at the end of an exposure cycle. More specifically, a charge-to-voltage conversion takes place. The resulting voltage level is digitized and stored. It is important to note that an electronic shutter is required that assures that the image pixels will stop gathering electrons at the end of the exposure time interval.

The major distinguishing characteristic of CCD is that all charges are transferred to one charge-to-voltage converter. This resembles a bucket chain for charges that are moved toward the named converter. CCD sensors tend to be susceptible to the so-called blooming effect (overflow of pixels into neighboring pixels in case of an overexposure to light). They are highly sensitive to light, which is helpful for capturing images of sufficient quality at night or in tunnels. Typical applications for the CCD technology are passive (meaning without active system interference), camera-based DASs, that display surround information (e.g., visualization of the vehicle's back region in parking maneuvers).

As opposed to that, the major distinguishing characteristic of CMOS is that each pixel disposes of its own charge-to-voltage converter. Instead of transferring charges, the voltage levels and hence signals are transferred. The initial application for CMOS sensors was in low-cost consumer products. Nowadays, various technical improvements allow their application in driver assistance. The frame rate of CMOS imagers is high (up to 30 Hz in modern CMOS sensors with rolling shutter), which allows for short exposure times, minimizing the motion blur. Motion blur results from the technical restrictions in reading the charge form all pixels at the same time (called *shutter* as a reminiscence to analog photography). Depending on the shutter technique, a specific motion blur results (e.g., the rolling shutter effect). CMOS offers a very high dynamic range up to 100 dB (as a comparison, humans dispose of 105 dB). CMOS imagers are marked by less power consumption (inherent to its functional principle) and a higher frame rate compared to CCD. The blooming effect is reduced, as the gathered charges are not transmitted (a transistor as charge-to-voltage converter is connected in parallel to each light-sensitive pixel). Current CMOS have still a comparatively low sensitivity to light, as the processing electronics is integrated on the chip, which results in a lower filling factor (share of light-sensitive surface related to the overall surface of the imager chip). On the other hand, the possibility of integrating the processing units on the same chip as the imager itself leads to lower costs and a tight packaging. Typical application for CMOS imagers is cameras for active DASs that require high frame rates together with a high dynamic range. It can be expected that the CMOS technology will outrun CCD in most automotive applications, especially when CMOS reaches a sufficient sensitivity in low-light situations.

It is important to note that CMOS imagers can be constructed which are sensitive to the wavelength of light which is below the visible light [the so-called infrared (IR)]. Although not visible, humans can sense IR radiation as heat. IR-sensitive imagers are able to deliver gray value images at night. On the basis of the requirement of illuminating devices, active and passive IR sensors can be distinguished. Short wave or near infrared (NIR) sensors require a small amount of low power LEDs (light-emitting diodes) that illuminate the scene to be captured. As opposed to that, long wave or far infrared (FIR) are passive sensors without any illuminating device. It is important to note that NIR sensors typically are superior in terms of performance and availability.

3.4.3.3 Lens types. Mainly application-driven, two major lens types are used in vehicles: (i) perspective lenses and (ii) wide-angle lenses.

Very common in driver assistance are perspective lenses (monocular cameras typically for comfort systems and stereo cameras for safety systems). Cameras with perspective lenses are typically installed behind the windshield

capturing images, for example used for intelligent headlight control or lane marking detection. A perspective projection can be expressed by the so-called pinhole camera model (refer to Figure 31a), thereby allowing a very intuitive formal description (focal length f pixel size t_u, t_v).

More specifically, a 3D world position (X, Y, Z) (refer to Figure 31b for the coordinate system) can be transformed to a 2D pixel position (u, v) using a pinhole camera model that contains all intrinsic (i.e., camera internal) and extrinsic (i.e., camera external) parameters (in detail, these are the three camera angles θ_X, θ_Y, and θ_Z, which are aggregated in the rotation matrix R, three translational camera offsets t_1, t_2, and t_3, the horizontal and vertical principal points u_0 and v_0, and the normalized horizontal and vertical focal lengths $f_u = f/t_u$ and $f_v = f/t_v$), refer to Equations 18 and 19.

$$u = -f_u \frac{r_{11}(X - t_1) + r_{12}(Y - t_2) + r_{13}(Z - t_3)}{r_{31}(X - t_1) + r_{32}(Y - t_2) + r_{33}(Z - t_3)} \tag{18}$$

$$v = -f_v \frac{r_{21}(X - t_1) + r_{22}(Y - t_2) + r_{23}(Z - t_3)}{r_{31}(X - t_1) + r_{32}(Y - t_2) + r_{33}(Z - t_3)} \tag{19}$$

$$R(\theta_X, \theta_Y, \theta_Z) = R_X R_Y R_Z = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} \tag{20}$$

with :

$$r_{11} = \cos(\theta_Z)\cos(\theta_Y)$$

$$r_{12} = -\sin(\theta_Z)\cos(\theta_X) + \cos(\theta_Z)\sin(\theta_Y)\sin(\theta_X)$$

$$r_{13} = \sin(\theta_Z)\sin(\theta_X) + \cos(\theta_Z)\sin(\theta_Y)\cos(\theta_X)$$

$$r_{21} = \sin(\theta_Z)\cos(\theta_Y)$$

$$r_{22} = \cos(\theta_Z)\cos(\theta_X) + \sin(\theta_Z)\sin(\theta_Y)\sin(\theta_X)$$

$$r_{23} = -\cos(\theta_Z)\sin(\theta_X) + \sin(\theta_Z)\sin(\theta_Y)\cos(\theta_X)$$

$$r_{31} = -\sin(\theta_Y)$$

$$r_{32} = \cos(\theta_Y)\sin(\theta_X)$$

$$r_{33} = \cos(\theta_Y)\cos(\theta_X)$$

Equations 18 and 19 can also be expressed in homogenous coordinates, which decrease the computational demands considerably. The required intrinsic and extrinsic parameters have to be determined in a calibration procedure usually applying a reference pattern (e.g., a checkerboard) that is captured from different view angles [see Heikkila and Silven (1997) for more details on the determination of camera parameters].

A second lens type of major importance is the wide-angle camera (also called *fisheye*).

Typically, for the wide-angle 3D-world-to-image projection, the so-called equidistant projection model is applied [refer to Abraham and Förster (2005) for a comparison of different projection models]. In Equations 21 and 22, the wide-angle image coordinates (u_{wide}, v_{wide}) are computed from the horizontal and vertical focal lengths given in pixels ($f_{u,\text{wide}}$, $f_{v,\text{wide}}$), the horizontal and vertical principal points ($u_{0,\text{wide}}$, $v_{0,\text{wide}}$) and the normalized wide-angle image coordinates (u^*_{wide}, v^*_{wide}).

$$u_{\text{wide}} = u^*_{\text{wide}} \cdot f_{u,\text{wide}} + u_{0,\text{wide}} \tag{21}$$

$$v_{\text{wide}} = v^*_{\text{wide}} \cdot f_{v,\text{wide}} + v_{0,\text{wide}} \tag{22}$$

The normalized wide-angle image coordinates (u^*_{wide}, v^*_{wide}) are computed from the 3D world position X_C, Y_C, Z_C (camera coordinate system) based on Equations 23 and 24

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

resembling an equidistant projection model.

$$u^*_{\text{wide}} = \frac{X_C/Z_C}{\sqrt{X_C^2 + Y_C^2}}\theta \tag{23}$$

$$v^*_{\text{wide}} = \frac{Y_C/Z_C}{\sqrt{X_C^2 + Y_C^2}}\theta \tag{24}$$

The variable θ represents the (undistorted) projection angle and is computed by Equation 25:

$$\theta = \arctan\frac{\sqrt{X_C^2 + Y_C^2}}{Z_C} \tag{25}$$

In the last step, the camera-related world coordinates $X_C = [X_C, Y_C, Z_C]$ have to be computed from the 3D world coordinates $X_W = [X, Y, Z]$ that are relative to the vehicle coordinate system (with R as the rotation matrix defined in Equation 20 and the translational world position of the camera $T = [t_1, t_2, t_3]$:

$$X_W = R \cdot X_C + T \tag{26}$$

It is important to note that (any kind of) projection model should always be applied on images that are free from lens distortions. For compensating the image distortion (also called *undistortion*), a lens distortion model is required. Such models dispose of lens-specific parameters that have to be determined offline [refer to Heikkila and Silven (1997) for details on a well-known lens distortion model for perspective lenses and Michalke, Stein, and Franke (2011) for an application using wide-angle lenses].

On the basis of the above projection equations for perspective and wide-angle lenses, image processing algorithms can be derived, for example, estimating the existence, size, and world position of traffic-relevant objects (refer to Section 3.4.5 for more details on applications for image processing).

3.4.3.4 Imager morphology. The imager pixels can have different shapes. For example, in consumer electronics, also alveolar pixel shapes exist (e.g., the super CCD sensor by Fujifilm). However, the typical pixel shape for automotive cameras is square.

Camera imagers can deliver monochrome (gray value) or RGB color images. In automotive cameras, RGB color images are realized by adding a repetitive pattern of three color filters to all pixels. Thereby, three images of reduced resolution are delivered. Pattern-specific interpolation operations (demosaicing) are used to receive a full-resolution image in three colors. The most prominent color pattern is the Bayer filter that consists of a repetitive pattern of two green, one red, and one blue pixel (Figure 32). Green was selected to fill half on the imager, in order to maximize light sensitivity. Other color pattern of inferior importance exists (e.g., RGBE for red/green/blue/emerald or CYGM for cyan/yellow/green/magenta).

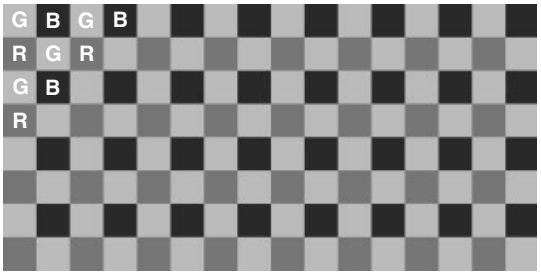

Figure 32. Bayer pattern (filter that covers the camera imager, R=red/G=green/B=blue).

For the sake of completeness, it should be mentioned that there are imagers that dispose of a pattern of one red color-filtered pixel among three unfiltered pixels. Thereby, the red-color channel can be measured together with a gray value image. In driver assistance, the color red is very important for the robust classification of traffic signs, traffic lights, and lane markings in construction sites.

3.4.3.5 Sensor system morphology and technology. Camera-based sensor systems can be distinguished into monocular (one camera) and stereo (two cameras) systems.

Until now, in automotive applications, monocular cameras are predominant. Monocular cameras are mainly used for object classification and for visualizing the close surroundings of the vehicle in parking support systems. As the driver is interested in the remaining space (e.g., in a narrow parking lot) distances and hence 3D data is required. Monocular cameras are not able to directly deliver 3D data. However, under some relaxing assumptions, it is possible to derive 3D information.

A typical relaxing assumption is the so-called flat plane assumption, that is, it is assumed that the measured world is flat. Under this assumption, the height Y can be set to 0 for all measured pixels (i.e., $Y = 0$ in Equations 18, 19, and 26, which simplifies the 3D to 2D conversion considerably). The described procedure is called *inverse perspective mapping* (refer to Broggi, 1995).

As an exemplary result, the monocular image in Figure 33a is mapped to the X–Z plane depicted in Figure 33b. It is important to note that all nonflat objects violate the initial assumption and hence are stretched to infinity, thereby leading to a mapping error.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

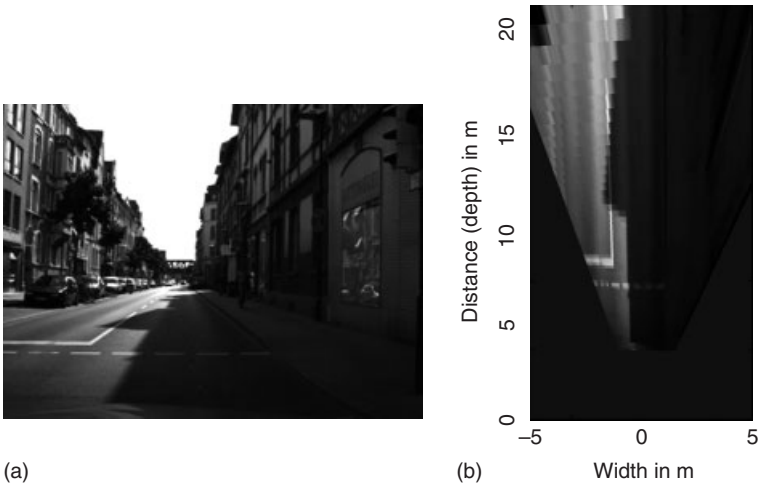

Figure 33. Inverse perspective mapping: (a) inner-city scenario (fulfilling the flat plane assumption); (b) Bird's-eye view. (Reproduced with permission from Michalke, 2010. © VDI-Verlag.)

Stereo vision is an emerging technology in cameras for consumer electronics. Also for automotive applications, stereo cameras are beginning to spread. Different from monocular cameras, using stereo cameras, it is possible to measure the 3D position of all measured image pixels without requiring any relaxation. An image pixel having a 3D position is often also called *voxel* in literature. For stereo vision, two cameras (with typically perspective lenses) are required whose relative position and orientation have to be determined based on a calibration step. More generally, when measuring data of N dimensions, a sensor system delivering $N+1$ dimensions is required.

In the following, the basic theoretical background for stereo computation is given. For computing 3D data, some mandatory preprocessing steps are required (Figure 34).

As described earlier, an undistortion step is required in order to compensate the lens distortion. After that, the images are rectified, meaning that the orientation of the optical axes of both cameras is aligned. This step is required in order to simplify the following correspondence search between the left and the right camera images. Finding correspondences is the key to computing the 3D position of pixels. In order to give some intuition to the role of correspondences in stereo processing, imagine an object being very close to two cameras that are positioned in parallel. The object will be projected on a different horizontal position at both camera imagers. As opposed to that, an object that is far away at the horizon will be positioned at virtually the same spot on both image planes. Hence, the smaller the distance of an object to the stereo camera is, the larger will be the relative horizontal shift of the object position. The horizontal shift is be called *disparity* $D(u, v)$ in the following. For computing the disparity, different approaches exist. Among the most prominent (also in the automotive domain) are correlation-based approaches (Willert *et al*., 2006), approaches relying in the so-called semi-global matching (see Hirschmüller, 2008, for some fundamental background), and approaches

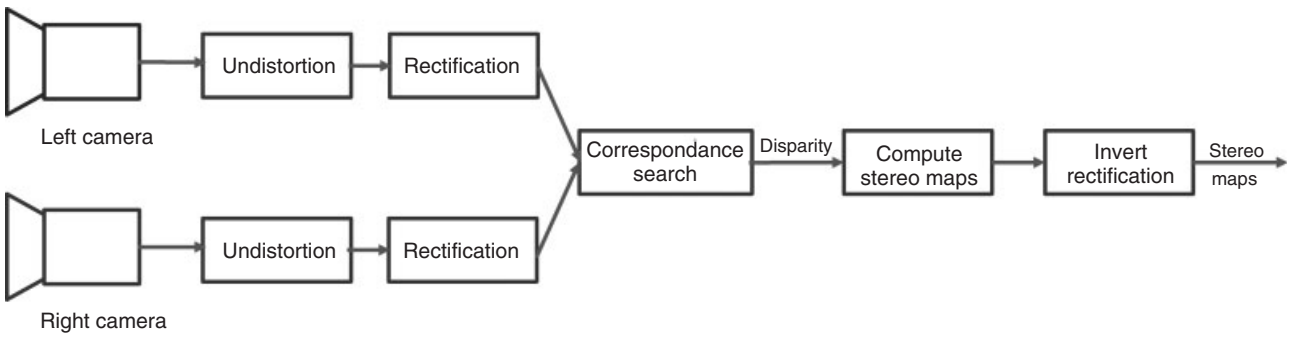

Figure 34. Stereo processing steps.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

using the census transformation (see Zabih and Woodfill (1994), for details). Following the computation of the disparity $D(u, v)$, Equations 27–29 are applied for computing the pixel 3D positions (stereo maps) relative to one of the cameras:

$$Z_{\text{stereo}} = \frac{f_u B}{D(u,v)} + t_3 \tag{27}$$

$$Y_{\text{stereo}} = \frac{Z_{\text{stereo}}(v - v_0)}{f_v} + t_2 \tag{28}$$

$$X_{\text{stereo}} = \frac{Z_{\text{stereo}}(u - u_0)}{f_u} + t_1 \tag{29}$$

In Equation 27, B is the basic distance between the left and the right camera's principal points.

Figure 35b–d visualizes the 3D positions of all image pixels for the exemplary image in Figure 35a. Please note that in the map values above the ground are negative, which is due to the chosen coordinate system (Figure 31b). Following Figure 34, as a last processing step, the stereo maps can be remapped inverting the image rectification step. Thereby, the 3D data match the undistorted input data. Thereby, for example, classification algorithms can run directly on the unrectified image raw data improving algorithmic performance (Figure 35).

3.4.4 Sensor configuration

In the automotive domain, the available installation locations are sparse. Typical locations for video sensors are as follows (Figure 36):

- Behind the windshield close to the rear mirror: NIR camera, stereo or monocular camera.
- Behind a plastic shielding at the radiator grill: FIR camera.
- Side mirrors: wide-angle camera.
- Trunk lid: wide-angle camera.

FIR sensors have to be installed at the front of the vehicle in order to avoid interference with motor heat and because the windshield would block the FIR-relevant wavelength, thereby weakening the signal. The active NIR sensors can be installed at the vehicle windshield, as the sensor can be tuned to the wavelength of the illuminating LED and because the windshield does not block the NIR-relevant wavelength.

3.4.5 Applications

DASs in general can be separated into comfort systems and safety systems. Comfort systems support drivers in standard, mainly tiresome tasks helping to center the driver attention on the remaining driving tasks. Different

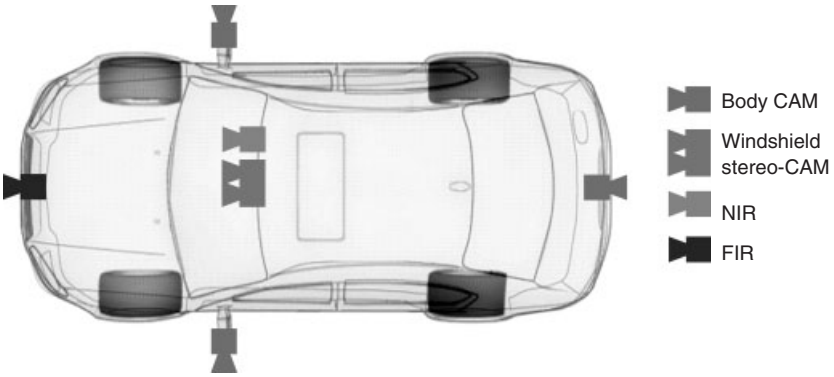

Figure 36. Typical installation locations of automotive cameras.

from safety systems, comfort systems are never activated automatically without the direct intension of the driver. Safety systems actively support the driver in dangerous driving situations and thereby help to prevent or mitigate accidents.

Camera-based comfort systems typically support the driver by offering information of the vehicle surrounding. Camera-based safety systems allow the automatic activation of safety measures such as braking and in the future also steering. In the following, different telematics-related, camera-based DASs are described.

Currently cameras are used in comfort systems for:

- detecting traffic signs. Traffic signs are projected in the head-up display or in the command unit of the vehicle. Furthermore, a warning can be triggered in case the driver surpasses a detected speed limit.
- supporting the driver in the night. More specifically, the visibility range and object resolution can be improved. Specifically, the visibility of vulnerable road users (VRU) can be improved. The gray value IR image can be used for classifying objects and displaying them to the driver.
- supporting the driver during parking maneuvers by displaying objects that are close to the vehicle rear end, or in more recent systems, the entire 360° vehicle surroundings.

Currently, cameras are used in safety systems for:

- detecting traffic participants and estimating their motion parameters in order to predict their future course. Thereby, a collision risk can be estimated. In case of an imminent collision, automatic avoidance or mitigation measures are taken (e.g., automatic emergency braking).
- achieving sensory redundancy and assuring plausibility of performance-critical sensor signals.

When gathering the individually detected signals and information in a central database, numerous innovative telematic applications could be realized, such as:

- real-time adaptation of map data;
- real-time traffic flow estimation;
- enhanced dynamic route navigation;
- support in finding parking spaces in inner city (Figure 37).

3.4.6 Summary and outlook

Section 3.4 gave insight into automotive-specific requirements of camera sensors. Different basic design characteristics of cameras were described (e.g., imager technologies, lens types, imager morphology, and camera types). Furthermore, the theoretical background required for designing camera-based driver assistance algorithms was given as well as some important references to explain specific topics. Section 3.4 specifically focused on stereo vision as an important future technology, driving the development of novel DASs.

GLOSSARY

Adaptive cruise control (ACC)	Bosch system (other trade names exist) based on a radar sensor setup that allows the system vehicle to automatically slow down when approaching another vehicle ahead and accelerate again to a preset velocity.
Antenna gain	It is a key performance figure that combines the directivity and electrical efficiency of an antenna. In case of a transmitting antenna, the gain defines the ability of the antenna to convert input power into electromagnetic waves in a specified direction. For a receiving antenna, the gain defines how well the antenna can convert the electromagnetic waves arriving from a specified direction into electrical power.
Application-specific integrated circuit (ASIC)	ASIC is an integrated circuit that is designed for a specific task or application (e.g., data compression with a specific compression algorithm). Today's ASIC can be system-on-chip architectures with complex, heterogeneous structures.
Bayer pattern	A repetitive color pattern that is set in front of a light-sensitive imager of a digital video camera. The captured single channel image can be decomposed into a multichannel color representation (e.g., RGB).
Beamforming	Approach that dynamically adapts the antenna characteristic of a radar sensor (direction and emitted power of electromagnetic waves is changed). Digital beamforming realizes the named adaptation without relying on moving parts.
Bird's-eye view	A term that is used in image processing designating an approach that transforms a perspective camera image (under some assumptions) into a view from above.
Controller area network (CAN)	An automotive microcontroller communication protocol that allows the communication between different electronic components in a vehicle.
Charge-coupled device (CCD)	A well-known technology for constructing transistors among other things on light-sensitive video imagers.
Complementary metal oxide semiconductor (CMOS)	A well-known technology for constructing transistors among other things on light-sensitive video imagers.
Correspondence search	Basic principle for computing disparity data from two or more camera images. More specifically, a pattern (representing, for example, an object) present in one image is searched in the second image.
Central processing unit (CPU)	Central computing hardware in a computer, which conducts instructions of a software program, thereby performing basic logical operations on input data and generating output data.
Disparity	Typically horizontal shift (in pixels) between one and the same objects displayed in the rectified images (with parallel optical axes) of a stereo camera setup. The bigger the disparity is, the nearer is the object to the camera.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Doppler effect	Designates a change in frequency of an (electromagnetic) wave in case the source is moving relative to an observer. Hence, from the frequency change, the object velocity can be computed.
Driver assistance system (DAS)	An electronic system installed in vehicles to assist drivers in certain driving situations. The main goals are not only the increased safety and driving comfort but also the improvement of economics.
Extrinsic camera parameters	All external parameters of a camera setup (3D position and orientation relative to the world).
Far infrared (FIR)	Related to the wavelength of electromagnetic wave, the spectral band above the visible light is called *infrared*. With a growing wavelength, the infrared spectral band can be subdivided into near-, mid-, and far-infrared.
Fisheye camera	Camera relying on a specifically formed lens that allows capturing wide-angle images (up to 180° field of view).
Flexray	An automotive microcontroller communication protocol that allows the communication between different electronic components in a vehicle.
Frequency-modulated continuous-wave technique (FMCW)	Radar technique that is characterized by a continuously transmitted radar wave, whose frequency is varied linearly over time. The time delay and the Doppler effect of the radar reflections lead to a frequency shift that can be used to derive the object's position and velocity.
Frequency-shift keying technique (FSK)	Similar to the FMCW, a continuous radar wave is transmitted. In contrast to FMCW, the transmission frequency remains constant for a certain time. Therefore, a frequency shift of the reflected signal is generated only by the Doppler effect. By emitting two different frequencies consecutively, the position and velocity of a reflecting object can be derived.
Hall effect	An electric voltage measurable at a conductor positioned in a stationary magnetic field, while being traversed by an electric current. A change in the magnetic field results in a change in voltage.
Intrinsic camera parameters	Internal sensor parameters that cannot be directly measured from outside (e.g., focal length or pixel size for video imagers).
Lane change assistant (LCA)	A driver assistance system that warns the driver if he or she intends to do a lane change maneuver, but there is a vehicle approaching on the neighbor lane.
Light-emitting diode (LED)	A light source consisting of semiconductor material.
Long-range radar (LRR) sensor	A radar sensor used to detect objects at far distances. In automotive applications, these are distances of over 200 m.
Monopulse	Radar technique that allows measuring the azimuth angle of an object with a single radar pulse or FMCW ramp.
Mechanical scanning	As opposed to digital beamforming, the antenna characteristic is changed relying on moving mechanical parts (typically, rotating cylinders) in the radar sensor.
Near infrared (NIR)	Related to the wavelength of electromagnetic wave, the spectral band above the visible light is called *infrared*. With a growing wavelength, the infrared spectral band can be subdivided into near-, mid-, and far-infrared.
Pinhole camera model	Simplified perspective camera model that allows a straightforward mapping between the 3D world and the 2D image. Its application requires undistorted images.
Piezo element	A piece of specific crystal or ceramic that reacts to mechanical pressure by accumulating a charge (or vice versa).
Poisson distribution	A well-known statistical distribution that is used to model various physical phenomena.

DOI: 10.1002/9781118354179.auto175
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Probability density function (PDF)	Mathematical model of a continuous, statistical distribution. The PDF describes the relative likelihood of a continuous random variable to take on a specific value.
Pulse-Doppler radar	Radar sensor that emits signal pulses to evaluate the time until the backscattered signal is detected by the receiver (in order to derive the object distance) as well as the Doppler frequency shift (in order to derive the object velocity).
Radio detection and ranging (RADAR)	Radar is a technique to detect objects and determine its position and relative velocity. This is achieved by sending out an electromagnetic wave and evaluating the time delay and frequency shift of the received signal that was backscattered by an object.
Radar cross section (RCS)	Radar-related measure that describes the backscattering behavior of a single target, that is, how much of the sent out power (of an electromagnetic wave) is reflected back to the receiver.
Rectification	Compensation of relative differences in the extrinsic parameters (especially orientation) of the cameras in a stereo setup. Thereby, the optical axes of the cameras are virtually aligned (made parallel), allowing a simplified correspondence search. Some authors see the undistortion step as a subpart of the rectification step. In this contribution, rectification and undistortion are handled separately.
Semi-global matching	Widely known principle for realizing correspondence search in stereo image processing.
Signal noise ratio (SNR)	A measure that compares the level of a desired signal to the level of (e.g., thermal) noise. Typically, it is defined as the ratio of signal power to the power of noise.
Sound navigation and ranging (SONAR)	A measurement technique that uses sound propagation to measure distances and velocities of objects.
Transducer	A sensor that acts as both an emitter and a receiver of an active measuring pulse.
Trilateration principle	Approach that allows calculating the 3D world position of an object measured by multiple sensors (placed at different positions) relying on triangulation.
Undistortion	Model-based compensation of image-distorting lens effects in image processing.

ENDNOTE

1. In a monostatic radar system, the same antenna is used for sending and receiving. Unlike, in a bistatic radar system, the antenna for sending is different from the antenna for receiving.

Data Acquisition by Roadside Detection

Christoph Roth
Siemens AG, Munich, Germany

1 INTRODUCTION TO DATA ACQUISITION

The management of sustainable, efficient, and competitive mobility requires innovative and reliable traffic data acquisition systems since the efficiency of many intelligent transport systems depends on the accuracy of the traffic data supplied by the roadside detection systems. High traffic flows, short travel times, and low air pollution can only be achieved with systems based on modern detection technologies. Many traffic signals, for instance, optimize the use of the road by calculating the phases for red and green based on the traffic demand. Line control systems on highways prevent congestions by reducing the speed limit in case of high traffic flow.

Many different technologies are used for the various intelligent transport systems in order to meet their specific requirements. The choice of the detection system depends on the kind of traffic data and the accuracy that best meets the demands of the overall system. For some systems, pure presence information is sufficient to achieve a high efficiency, but other systems need advanced traffic data with detailed information about the vehicle mix on the road.

This section begins with a description of the types of traffic data provided by current detection systems ranging from simple presence information to advanced traffic data, followed by an overview of use cases for traffic data acquisition systems, and the final part covers the technologies used for detection of certain traffic parameters.

2 DATA TYPES

2.1 Vehicle presence

Many detectors such as inductive loops provide information about the vehicle presence in a certain detection zone. When the vehicle enters the detection zone, the output of the detector switches on and the output is turned off once the vehicle leaves the zone. Many detectors used for intersection control such as inductive loops, video, or radar are vehicle presence detectors. Even though the information content of presence data is rather low, many systems require a very high accuracy. At intersections, small detection errors can deteriorate the quality of the signal control considerably. The detectors need to be sensitive enough to have a high detection rate even for small vehicles, motorbikes, and bicycles but they must not be disturbed by environmental conditions or vehicles on the neighboring lane. This limits the use of detectors to the ones that are specifically designed for traffic applications and that can meet these strict requirements.

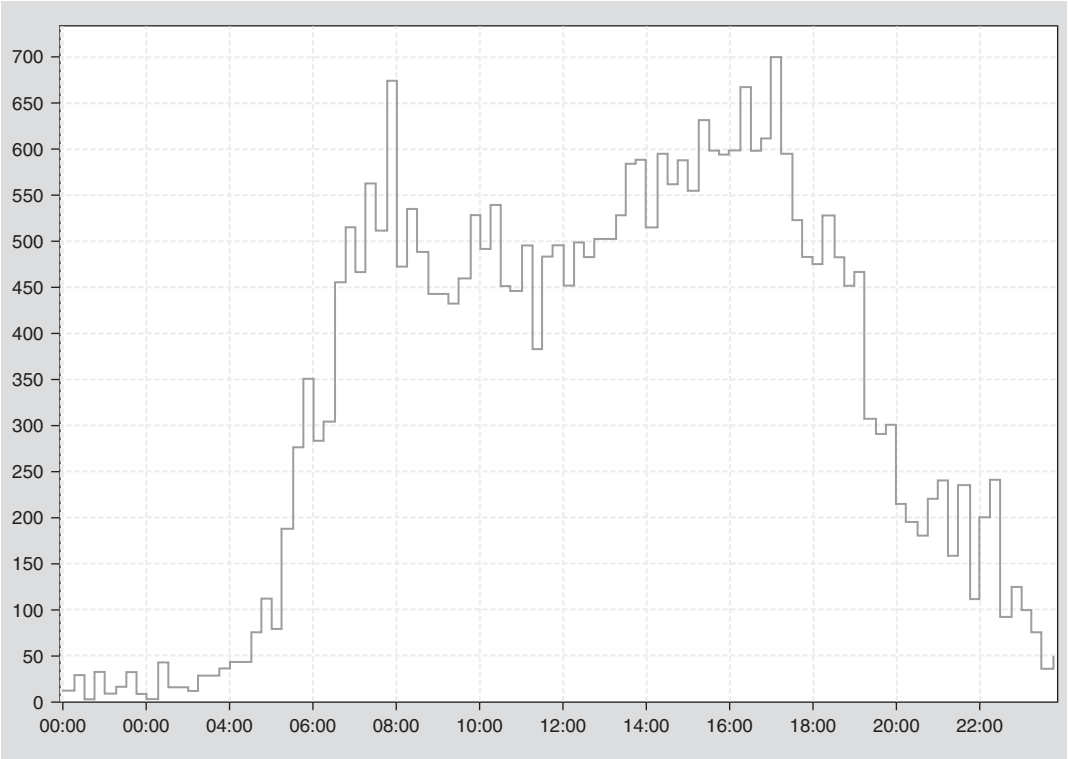

Figure 1. Typical traffic volume (vehicles per hour) with peak traffic around 8 a.m. and 5 p.m.

2.2 Traffic volume

The traffic volume is equal to the number of vehicles per time interval—usually 1 h. Nearly all traffic detectors can provide traffic volume. Even from the presence detectors described earlier, traffic volume data is derived by counting the number of output pulses in the signal controller. Figure 1 shows a typical graph of the traffic volume plotted versus the time of day in units of vehicles per hour. The distribution shows the peak traffic between 8 a.m. and 5 p.m.

Detectors for traffic volume need to be able to distinguish two consecutive vehicles from a vehicle with a trailer, as in most traffic applications a vehicle with trailer is regarded as one vehicle.

Many detectors have a detection zone that extends one or a few meters in the direction of travel. This might reduce the count accuracy in applications with frequent queues, as the spacing between successive vehicles might be smaller than the detection zone in which case the detector will not be able to separate the vehicles and count them correctly. In applications where high count accuracy is required in queued traffic detectors with small detection zones are used.

2.3 Speed

Vehicle speed is one of the main kinds of traffic data used by many intelligent transport systems. The accuracy of the speed measurement depends on the technology and often it is not the speed of individual vehicles but the average speed in a certain time interval, which is used by the overall system.

Speed can be measured either directly, for instance, with Doppler Radar technology or indirectly by two presence detectors separated by a few meters in the direction of traffic flow, for instance, double loop systems. In this case, both detectors are triggered by the vehicle and from the time difference of the trigger points the speed can be derived (Markovic *et al*., 1996).

2.4 Occupancy

The occupancy is defined as the time a certain point of the road is occupied by a vehicle divided by the length of the time interval considered. The most common unit of occupancy is percent, but sometimes it is reported in time units, provided the length of the reference interval is known.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Occupancy is often used for the assessment of the traffic condition. In free-flow traffic, the occupancy is usually in the low single digit percentage range and it increases considerably in case of congestion.

Even though the definition relates to a point detector in all practical applications, the occupancy is measured by detection zones, which have an extension of one or a few meters in the direction of traffic flow. For loop detectors, for instance, the occupancy is measured as the percentage the loop is occupied. The difference to the occupancy of a point detector is uncritical, as the absolute values of the occupancy are not important but the relative changes related to changes in the traffic condition.

2.5 Vehicle classification

Vehicle classification is used to determine the types of vehicles the traffic consists of. Worldwide, there are many different regional definitions for vehicle classes. One of the most common classification schemes is the distinction between passenger cars and trucks, where the weight or the maximum allowed weight is used for the differentiation. Examples for a more detailed classification are motorcycles, passenger cars, passenger cars with trailer, vans, trucks, trucks with trailer, semitrailer trucks, and busses.

Many detectors can classify vehicles into two classes based on the vehicle length. In case the detector can measure the length of the vehicles, the classification can easily be done by introducing a limit length below which the vehicle is classified as passenger car and above which the detector outputs a truck. In many cases, the limit length is adjustable and is set in the range between 5 and 6 m.

For more than two vehicle classes, a simple length classification is not sufficient. The detector needs to retrieve more advanced information about the vehicle for instance the height profile or the inductive signature from a loop detector. The actual classification is done by sophisticated software algorithms, which derive the information about the vehicle type from the height profile or inductive signature (Gajda *et al*., 2001).

2.6 Level of service

The level of service (LOS) describes the actual traffic situation on a certain stretch of the road network. It is a measure of the effectiveness of the road meaning the capacity to support a certain traffic flow. Many traffic management systems use three LOS levels: free flow, slow traffic, and congestion.

The LOS is derived from basic traffic data, in many cases from traffic volume and speed. At free-flow traffic, the traffic volume is low and the speed is high—usually close to the local speed limit. As traffic volume increases, the speed will not change until a critical volume is reached where the speed drops. This is the point where the traffic volume reaches the maximum capacity of the road. A further increase in traffic will result in stop and go traffic, which has even lower speed and a decreasing traffic volume. At complete congestion, the traffic volume and speed are close to zero.

The LOS levels are areas on a two-dimensional graph of traffic volume and speed (Figure 2). The location of the boundaries between the different LOS levels depends on the type of road, the maximum allowed speed limit, and the number of lanes.

2.7 Travel time measurement

While all traffic parameters mentioned earlier can be measured by local detectors, which observe a certain point in the road network, travel time measurement requires at least two detectors at different locations. The travel time is measured by reidentification of vehicles at two or more locations and comparing the time stamps of the two detection events. For reidentification, certain criteria such as the vehicle's license plate are used.

One interesting aspect of travel time measurement is the fact that a medium or low detection rate is often sufficient for a good assessment of the traffic situation. Any traffic is characterized by the fact that the speed of vehicles is highly correlated at short distance, which means that all cars have a speed that is similar to the cars in their vicinity. Therefore, it is sufficient to detect a small sample, a few percents, of the vehicles for the determination of the actual travel time. This relaxes the requirements for the detection systems, as they do not need to detect every vehicle with high accuracy.

It might be that two vehicle classes travel with different speed like on highways, where the trucks often have a different speed limit than passenger cars. But even in this case, the vehicles within one class travel with similar speed and it is sufficient to capture a sample within each vehicle class.

Several different technologies are used for travel time measurement systems ranging from cameras for automatic number plate recognition (ANPR), magnetic detectors to Bluetooth tracking. All systems are described in more detail later.

The accuracy is defined by the detection rate and the reidentification rate. The first defines the number of vehicles detected correctly by the first detection system at the beginning of the travel time section. How many of them are then reidentified correctly at the end of the section

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

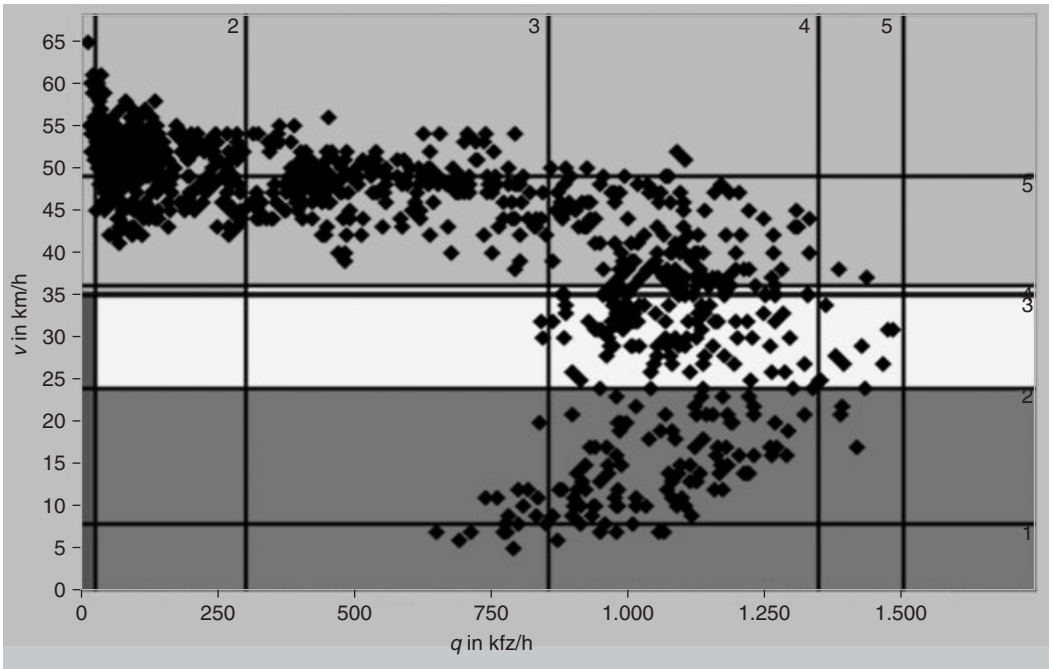

Figure 2. Example of traffic data divided into three LOS levels. Number of vehicles per hour on the *x*-axis and speed in kilometer per hour on the *y*-axis. Each data point represents a 5-min interval. (Reproduced with permission from VMZ Berlin Betreibergesellschaft mbH. Copyright VMZ Berlin Betreibergesellschaft mbH.)

is defined by the reidentification rate. Magnetic detectors, for instance, have a high detection rate; however, as the magnetic signatures are not unambiguous, the reidentification rate is usually around 50%. This means that nearly all vehicles are detected at the first location but only about every other vehicle can be correctly reidentified at the second detector location.

Bluetooth tracking systems, as another example, have a low detection rate, as only a small number of vehicles contain mobile Bluetooth devices that are switched on. Nevertheless, the reidentification rate is close to 100%, as all vehicles that are detected at the beginning of the section are with high certainty also detected at the end of the section (for more details, see Road Traffic and Travel Information (RTTI)).

2.8 Other traffic data

Many intelligent traffic systems rely on the basic traffic data such as presence information, traffic volume, speed, occupancy, and classification. Nevertheless, in some special cases, other data is used. A few examples are the headway that is defined as the temporal space between two vehicles. Specifically, the headway is the time that elapses between the front bumper of a first vehicle and the front bumper of the second vehicle. Headway is similar to the gap that relates to the time between the first vehicle's rear bumper and the front bumper of the second vehicle (University of Idaho). Average values for headway and gap can be derived from traffic volume, speed, and occupancy data.

The queue length is an interesting parameter, which is sometimes used for intersection control. It is defined as the distance between the stop line and the last vehicle that stopped at the end of the queue in meters.

3 USE CASES

Traffic data is used by many traffic systems and most of them are described in more detail, for instance, in Applications—Intelligent Roads and Cooperative Systems: Urban Traffic Management, Advanced Highway Management Systems, and Road Traffic and Travel Information (RTTI). A short summary of some of the basic use cases for roadside detectors in intelligent traffic systems are discussed in the following sections.

3.1 Vehicle detection at intersections

Detection at intersections is used to adjust the green and red phases according to the traffic demand. The traffic situation in urban environment changes often depending

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on the time of day, type of day (weekday, weekend, or holiday), and special events such as sports, games, or fairs. Furthermore, traffic always shows large fluctuations in respect to nearly all traffic parameters. In order to handle the changes especially in traffic volume, vehicle-actuated traffic signals are equipped with detectors to measure the traffic parameters and use this information to adapt the signal phases according to the actual traffic situation.

As an example, consider an intersection of a main through-road and a side road with very small traffic volume. A fixed time traffic signal would have to give green time to the side road—and at the same time, stop the traffic on the main road—in every cycle. This is likely to cause congestion on the main road during peak traffic. A vehicle-actuated traffic signal would give a green phase to the side road only when a vehicle is detected to be waiting at the stop line. This increases the green time on the main road and, therefore, increases the traffic volume this intersection can handle.

Another example is the approach detection that is often used to handle intersections of two roads with similar high traffic volume. The approach detectors are usually located 30–60 m in front of the stop line. During the red signal phase, a queue of vehicle builds up the length of which usually exceeds the distance from the stop line to the detector. When the signal switches from red to green, the queue starts to dissolve and the detector is used to find out whether the main part of the queue has already dissolved or is about to pass the intersection. If the time gap between the vehicles exceeds a certain length—usually 2–3 s—it is assumed that the queue has dissolved and a free-flow traffic situation is present at the location of the detector. This is the time when the green time for this approach will be stopped in order to give the valuable green time to the other approach where a queue has built up in the meantime. This kind of traffic control ensures that green time is used efficiently for the dissolution of queues and not wasted for free-flow traffic situations where the actual traffic volume is small.

Depending on the size and layout of the intersection, the traffic volume, and the requirements of the road operators, many different systems for the traffic actuation of the signals are used. In all cases, the detector data is used as an input for the calculation of the optimum length of the signal phases.

Nearly all intersection control systems use the detection of vehicle presence only. The detectors have one output for each detection zone, which is activated by the vehicles. The data processing such as vehicle counting or the measurement of the time gap between vehicles is done in the controller.

3.2 Adaptive traffic control system

The vehicle actuation of traffic signals increases the throughput of the intersection but it is not sufficient for urban environments with a high density of signalized intersections. For these applications, adaptive traffic control systems are required that optimize the relative timing of the phases of all traffic signals in a certain area. The simplest implementation of traffic control systems is the so-called green wave, where the timing of the green phases is adjusted such that most of the vehicles can pass all traffic lights without a stop. In many cases, more advanced systems are used, which can adapt to the actual traffic situation and optimize all traffic signals for highest traffic flow, lowest travel time, or least number of stops at the intersections.

All adaptive traffic control systems rely on accurate traffic data in order to generate efficient signal plans for all traffic lights in their area. The data of the detectors that are used for the local intersection control can sometimes be used for the adaptive control system as well. However, in many cases, additional detectors need to be installed, either because not all intersections are equipped with a sufficient number of detectors or because the adaptive control system needs additional data.

An example for adaptive traffic control systems is SCOOT (Split Cycle Offset Optimization Technique), which is used in many large cities worldwide. (Scoot)

3.3 Traffic management

While intersection control and adaptive traffic control systems are designed to optimize the traffic flow in a road network, traffic management is related to information about the actual traffic situation and the means to communicate this information to the road users. Many large cities have traffic management systems, which display the actual traffic situation in the Internet, where the city map is shown and for the main roads a color code is used to indicate LOS. In many cases, three levels are used: green for free-flow traffic, yellow for slow traffic, and red for congestion.

Most traffic management systems use detectors in the free-flow traffic, which are located at a distance of several hundred meters from an intersection. They measure traffic volume, speed, occupancy, and often a low level vehicle classification from which the LOS can be calculated in the traffic management center. The detectors at intersections can usually not be used for traffic management, as the traffic queues on every red phase. Only detectors in a large distance from the intersection can differentiate well between the different levels of service.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Recently, travel time systems have become available, which measure the traffic situation on a complete section of the road network. They are often used as additional data sources for modern traffic management systems, as they cover a much larger area than the local detectors which measure the traffic situation at one particular spot on the road.

Besides the display of the actual traffic situation in the Internet, the information is often used by other media as well; for instance, on variable message signs on the arterial roads or via traffic news in the radio. The traffic information is also used by the navigation systems to find the best route for the driver depending on the actual traffic situation.

4 DETECTOR TECHNOLOGIES

4.1 Inductive loops

Inductive loops are the most widely used technology for vehicle detection. The technology has been developed many years ago and still today it is estimated that more than 50% of all detectors are based on inductive loop technology. The main advantages are high data accuracy and reliability in all environmental conditions, which can only, in a few cases, be surpassed by other detection technologies. Inductive loops achieve high detection rates and low false detection rates in all environmental conditions.

Inductive loops are wire loops placed in the road surface. A rectangular trench is cut in the asphalt, a wire is laid in the trench with several turns—usually 3 or 4—and the trench is sealed with a sealing compound. The wires are extended to a loop detector card, which is usually located in the traffic signal controller or motorway outstation. The size of the loop depends on the application. Often, the width is slightly smaller than the traffic lane and the length—in the direction of traffic flow—extends over a few meters.

Applying a voltage to the inductive loop creates a magnetic field, which is vertical within the loop as schematically shown in Figure 3. Any metallic object close to the loop will modify the strength and direction of this magnetic field because eddy currents are induced in the object that oppose the loop field according to Lenz's law. In most cases, an AC field is induced in the loop at a frequency in the range of 30–100 kHz. An electrical resonance circuit is used to drive the loop at the respective frequency and a vehicle is detected by measuring the deviation of the loop frequency from the initial value as shown in Figure 4. The inductance of the loop changes in the presence of vehicles and causes the frequency of the system to change—usually in the order of a few percents—which can be measured by the loop detector card.

Standard in the industry are multichannel detector cards, which can drive several—often four—loops. Most often, a multiplex mode is used, which drives and measures the loops sequentially in time intervals of several milliseconds. A time resolution of about 10 ms is sufficient for most

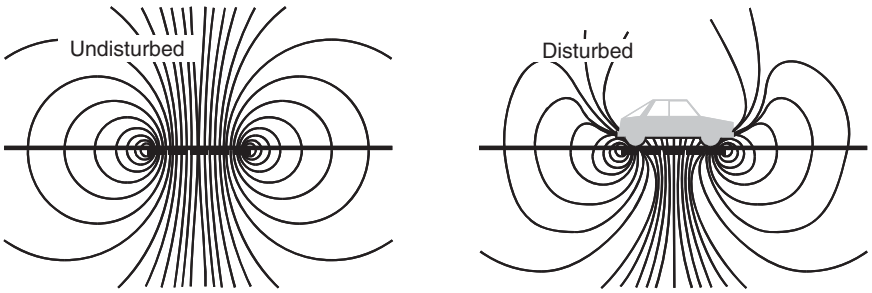

Figure 3. Magnetic field of an inductive loop detector and its change caused by vehicle presence.

applications, as even a car at 200 km/h travels only about 55 cm in this time. The frequencies of all loops connected to one detector card can be set to the same value, as they are operated in a multiplex mode, which means that only one loop is activated at any time. In case more than one detector card is used, the loop frequencies need to be set to different values in order to prevent cross talk between the loops.

The loop frequency changes with temperature, which must be compensated for by the detector card. For moving traffic, this drift compensation can be implemented easily, as the frequency changes induced by vehicles are of the order of seconds, whereas the temperature drifts have a time constant of several hours. For the detection of vehicles in parking spaces where vehicles do not move for several hours or days, an advanced signal processing is necessary, which can distinguish clearly between the signal of the vehicle and the temperature drift.

Single inductive loops are very often used for vehicle presence detection at intersections. For additional data such as speed, vehicle length, and classification, double loops are used, where two loops are installed in the road with a spacing of one or a few meters in the direction of the traffic flow. The speed is calculated from the time delay of the signals a vehicle induces in both loops, and the vehicle length can be derived from the temporal length of the loop signal. Loop detectors achieve advanced vehicle classification with high accuracy by analyzing the inductive signature, which is the complete signal a vehicle induces in the loop. From the length and the shape of this signal, advanced software algorithms can derive accurate information about the vehicle type. Compared to other detection technologies in a similar price range, loop detectors have currently the best vehicle classification accuracy.

4.2 Radar

Radar, or microwave technology as it is sometimes called, is widely used in many application areas ranging from air traffic control to antimissile systems or speed enforcement in road traffic. Radar systems detect objects by emitting microwave radiation and detecting the part that is reflected from the objects. One of the main advantages of radar systems is the fact that water in any form, such as fog, rain, snow, or sleet, is transparent for microwave radiation and the weak signals of heavy rain can be filtered out easily in the detector. This means that radar systems are well suited for outdoor applications like vehicle detection in road traffic.

Several frequency bands are allocated for the license-free use of radar systems. In road traffic, 12 and 24 GHz are most frequently used. Internationally, they are specified by the ITU; however, most countries have additional regulations, which define the available frequencies and the maximum bandwidth and radiated power in these bands. In nearly all countries, radar detectors need to be tested and certified before they are allowed to be used in outdoor systems.

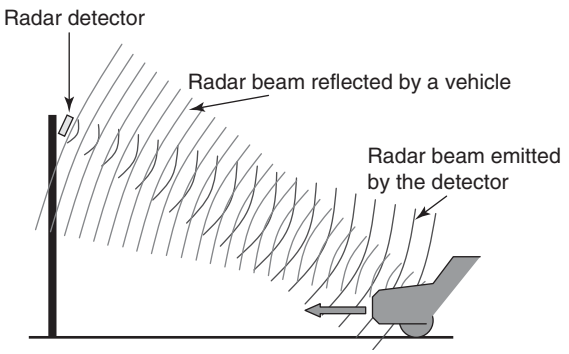

Figure 5. Principle of radar detection.

Most of the radar detectors used in road traffic use the Doppler radar technology, the principle of which is shown in Figure 5. It relies on the fact that moving objects change the frequency of microwaves, which means that the emission from the radar detector and the reflection from the vehicle have different frequencies. The effect is similar to the sound of cars, which has a higher pitch when they drive in our direction and a lower pitch when the drive away from us. Doppler radar is a quite mature technology that can be implemented on cost-effective hardware systems. The downside of Doppler radar detectors is their disability to detect stationary vehicles.

As the Doppler technology relies on the movement of the objects to be detected, stopped vehicles have a zero Doppler signal. The signal often drops below the noise level for vehicles traveling at a speed below 3–4 km/h. As many traffic signal controllers do not require the detection of stopped vehicles, but rely on the data of the moving cars, Doppler radar detectors are widely used for intersection control or traffic data acquisition.

The detection of stationary objects is possible with the FMCW (frequency-modulated continuous wave) technology. By modulating the frequency of the emitted radar beam and detecting the frequency shift of the reflected beam, the distance from the detector to the object can be determined. With FMCW radar detectors, it is, therefore, possible to detect all vehicles regardless of whether they stop in the detection zone or not, which allows a more advanced intersection control compared to the still more frequently used Doppler radar detectors.

Figure 6. Typical installation of radar detectors.

At intersections, radar detectors are one-spot detectors meaning that each detector covers one detection zone. They are installed on a pole or gantry above or on the side of the road (a typical example is shown in Figure 6) and are aligned in the direction to the location where vehicles shall be detected, usually close to the stop line or in the approach to the intersection. Depending on the detector type, they are lane selective or they cover multiple lanes. Vehicle detection at the stop line is often done lane selectively, especially when the right-turn, straight, and left-turn lanes have separate signals. For approach detection, multilane detectors can be used unless the vehicle actuation software in the controller requires a lane-selective detection.

Compared to the vehicle detection at intersections, a rather different technology is used for traffic data acquisition on interurban roads. Multilane radar detectors are mounted on the side of the road at a height of about 4 m or more and use a high functionality radar technology, which allows them to retrieve traffic data from multiple lanes (Figure 7). They are based on a two-beam technology: one radar system is used to generate two FMCW beams, such that there is a horizontal angle between them of around 10°. The detector is installed such that the two radar beams are directed almost perpendicular to the direction of traffic.

By measuring the distance of the radar reflection from the vehicles, the detector can determine on which lanes the vehicles drive. With the two radar beams, the time

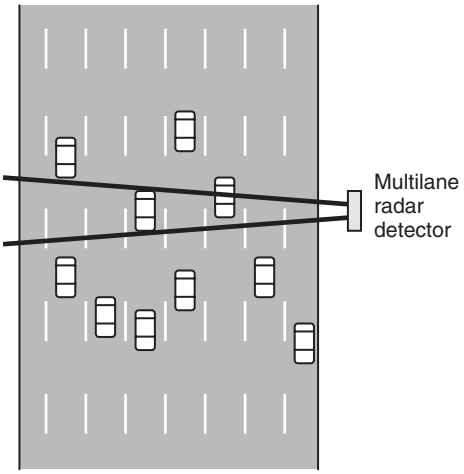

Figure 7. Example of a side-mounted multilane radar detector.

difference from the vehicle entering the first and the second beams can be measured; from this data, the speed of the vehicle can be calculated. The length of the vehicle in meters is derived from the duration of the signal in seconds and the calculated speed. Overall, the detector can measure all relevant traffic data: count, speed, vehicle length, and a classification based on the vehicle length. The accuracy might not reach the high level of inductive loop detectors but the ease and low cost of installation on a rather short pole besides the road without the need for a road closure are attractive advantages of these multilane radar detectors.

With advanced signal processing, even vehicles that are not in the direct line of sight can be detected. In case a truck on the first lane blocks a passenger car on one of the next lanes, the weak radar signal, which is redirected by the truck and which arrives at the detector, can be used for the detection of occluded vehicles.

Another application of radar detectors is based on their ability to measure the speed of objects with high accuracy and their rather low manufacturing cost. Radar detectors are often used in enforcement systems to measure vehicle speed with an accuracy which is able to stand up in court. Always when a ticket for exceeding the speed limit is generated, there is a good chance that the vehicle speed was measured by a radar detector.

4.3 Video detection

Video detectors for road traffic consist of a camera and a video image recognition system. A camera is directed to the area of the road where the vehicles shall be detected. It creates a video stream, which is fed into an automatic image recognition system where the images are analyzed

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 8. Image of a video detector with three detection zones.

in respect to the presence of vehicles. The software is designed to automatically find the vehicles in the video images and be able to detect their presence once they are in the designated zone. The locations where the vehicles shall be detected are defined during set up of the video detector by adding the detection zones as overlay on the video images. Figure 8 shows an example of a video image with three detection zones. Once a vehicle enters the detection zone, the software recognizes its presence and changes the output state for this zone to "occupied." The output returns to "not occupied" immediately after the vehicles left the zone. Depending on the type of detector, additional information such as vehicle speed, length, or classification are available.

The detectors need to work reliably at day and night, which requires the image recognition software to adjust to the outside lighting conditions. During daytime, it is mainly the contrast of the vehicle in respect to the road surface, which is used as a basis for the detection; however, at nighttimes, the detector looks for the headlights, as the body of the vehicle is dark and often difficult to recognize in the image. In most installations, the video detectors are directed opposite to the traffic flow and can, therefore, see the headlights of the vehicles. However, even in cases where the cameras look in the direction of the traffic flow, the tail lights are bright enough for the detection of the vehicles.

Even more important than the detection of a vehicle by the image recognition software is the suppression of disturbing effects. The normal lighting conditions of any outdoor scenery produce effects that are difficult to distinguish from vehicles by automatic systems. For instance, when the sun shines perpendicular to the direction of travel, each vehicle casts a shadow on the neighboring lane that has the size of a vehicle and has, under most conditions, a high contrast to the road surface in the sun light. For the image recognition software, it is quite difficult to distinguish this shadow from a real car. Other examples for disturbing effects are shadows from trees at the road side, which move in the wind, movement of the camera itself, or reflections of the headlights on the road surface at night especially when it is wet.

Many video detectors are used for presence detection at intersections, where they have a similar functionality like inductive loop detectors. However, they are also used for traffic data acquisition, where they measure speed and classification. One of the advantages of video detectors is that several detection zones can be placed in one detector. If the approach to an intersection has more than one lane, one video detector is able to detect the vehicles in all lanes separately. It often provides several outputs, one for each detection zone.

For some data types like vehicle length or speed the video detector needs to translate the coordinates in pixel space into real space coordinates. However, the length of an object in number of pixels in the image cannot directly be related to a real length in meters since they depend on the optical parameters of the camera. Most video detectors offer a semiautomatic calibration procedure during setup: a rectangle is overlaid on the video image and positioned over objects with known distance such as road markings. The size of the rectangle on the road is then input to the video detector and with additional information such as focal length of the lens and the size of the image sensor in the camera, the detector is able to translate pixel distances into real distances and measure speed and vehicle length.

Apart from vehicle presence detection and traffic data acquisition, video detectors are widely used for incident detection in tunnels and on highways. In order to increase the safety of tunnels or critical parts of highways, automatic incident detection systems based on video technology are used. Several cameras are installed at about equal distance, so that the complete stretch of the road is covered and the images of neighboring cameras overlap slightly. Like with the detectors for vehicle detection, an automatic image recognition software analyzes the video images and looks for possible incidents. The software mainly looks for stopped vehicles, as any incident or accident will result in one or more vehicles that are not able to move anymore. In free-flow traffic, it is rather easy to detect stopped vehicles; however, during congestions where all vehicles move at a low speed or stop, it is difficult to distinguish this traffic situation from an incident. Nevertheless, modern video systems have advanced algorithms, which achieve high detection rates for incidents in nearly all traffic situations.

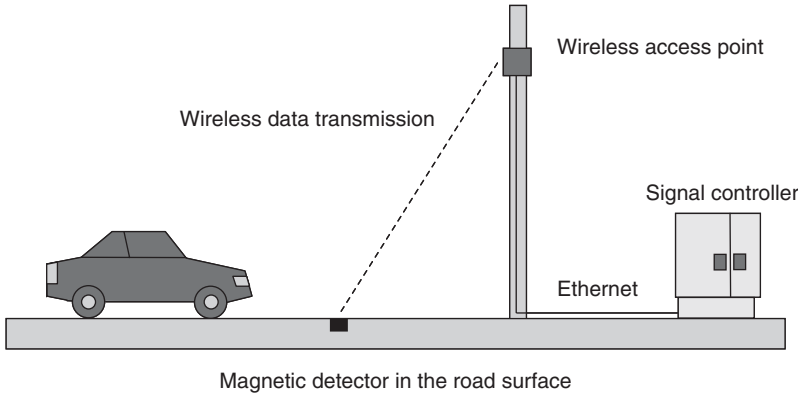

Figure 9. Schematic of a wireless magnetic detection system.

4.4 Magnetic field sensors

All vehicles or more generally all metallic or magnetic objects change the natural magnetic field of the Earth in their vicinity. Magnetic field sensors utilize this effect and measure the change of the magnetic field to detect vehicles. Most modern magnetic detectors are equipped with three magnetic sensors for the measurement of the field strength in all three spatial directions in order to detect all changes, which can possibly be caused by vehicles.

The strongest change in magnetic field can be observed close to the vehicles. With distance from the object, the signal amplitude decreases. The best results are achieved with detectors placed in the road surface, so that the vehicles drive directly above them. There are above ground detectors based on magnetic detection in the market but as the distance to the vehicles is rather large, their detection rate is limited.

Positioned in the road surface, magnetic detectors achieve high detection rates similar to inductive loop detectors. The sensitivity of the sensor is set such that the detection area has a diameter of about 2–3 m, which allows lane-selective detections and which means that only those vehicles are detected which drive on the respective lane. Vehicles on neighboring lanes are not detected.

One of the advantages of magnetic detectors is their small size and low power consumption. They can operate on battery power for 10 years or longer and combined with wireless data transmission, the detectors can be installed without any cables. This reduces the installation cost considerably and adds flexibility to the location of the detectors. A typical wireless magnetic detector system is shown in Figure 9, an example of the detector itself in Figure 10.

Similar to inductive loops, magnetic detectors detect only the vehicle presence. For additional data such as vehicle speed, length, and classification, two detectors are used, which are spaced within a distance of a few meters in the direction of traffic flow.

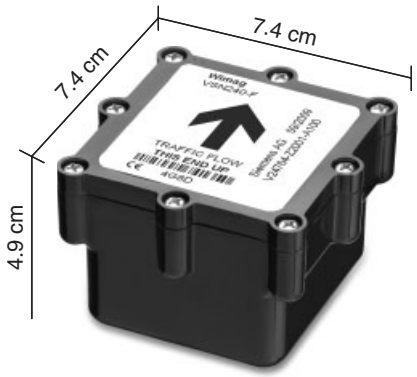

Figure 10. Example of a wireless magnetic detector.

Even though wireless magnetic detectors have not been long in the market, they are already widely used. One of the reasons is their reliability in all environmental conditions, as temperature, rain, snow, day, or night have hardly any effect on the magnetic signal.

4.5 Automatic number plate recognition

Automatic number plate reading cameras (ANPR cameras) are based on video technology, nevertheless they are described here in a separate section since they differ from the "standard" video detectors mentioned in Section 4.3. Many modern ANPR cameras are integrated devices including a video camera, illumination of the detection area (usually infrared LEDs), and a processing unit for the image analysis (Figure 11). The process of reading a license plate consists of several steps. The video camera generates

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 11. Example of an ANPR camera.

a continuous stream of images of the detection area. All images are analyzed by an image processing unit, which detects vehicles in the detection area. Once a vehicle is present in the respective location, a high resolution image is taken that is analyzed by the plate finding software, which looks for the location of the license plate in the image. This can be a difficult task when vehicles have more than one license plate, for instance, trucks, which often have private plates behind the wind screen. Once the license plate has been found in the image, the respective part of the image is transferred to the OCR (optical character recognition) module, which reads the plate. The challenge is to read the license plate under all conditions such as different angles depending on camera position, all lighting conditions, and the level of pollution on the plate. The result of the OCR is validated against the syntax of the plates meaning the position of the characters and numerals before it is released as the reading result. OCRs are usually optimized for plates of specific countries, as they are trained for the fonts used on the respective plates. The use in other countries often requires a new training of the OCR.

ANPR cameras are used in many applications ranging from tolling to travel time measurement or access control. The London congestion charge, for instance, is enforced with ANPR cameras within the congestion charge zone that read the number plates of all vehicles and check whether

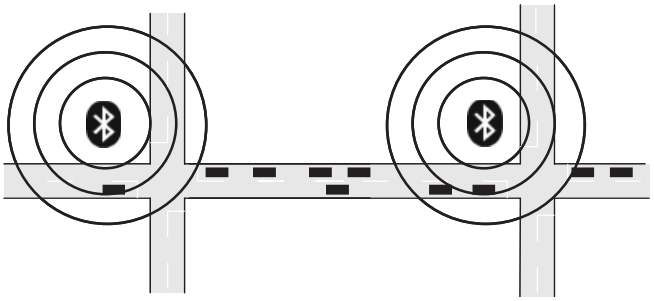

Figure 12. Bluetooth tracking system for travel time measurement.

the car owner has paid the toll. If a license plate is found that is not registered as paid, the system issues a ticket to be sent to the vehicle owner.

Another application is the access control to company parking lots. All vehicles that are permitted to use the parking lot are registered in the system and when the ANPR camera reads one of these plates, the entrance barrier is opened and access to the parking lot is granted.

A rather new use case is section speed control for the enforcement of speed limits. At two locations within the speed limit zone, which are usually spaced by one or several kilometers, the license plates of the vehicles are read and sent to a central office with the respective time stamps. By subtracting the time stamps of the same plate reading at the two locations, the average speed of the vehicle can be calculated and in case it exceeded the local speed limit, the normal enforcement process is started.

4.6 Bluetooth tracking

Bluetooth tracking systems were developed with the objective to get travel time information in road traffic and to reduce the cost of the road side equipment. Travel time systems measure the average time of the vehicles driving between two points in the road network. Similar to floating car data, the travel time information is used for traffic management to determine the LOS.

Bluetooth tracking systems rely on the fact that many vehicles are equipped with mobile devices such as mobile phones, headsets, navigation systems, and handsfree systems. Bluetooth tracking systems are installed at the road side and scan the area for visible Bluetooth devices (Figure 12). Once they receive a reply, a time stamp is added to the MAC address of the device and sent to the central office. The traffic center looks for matches of the MAC addresses from different locations and can calculate the travel time from the respective time stamps.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

One of the main advantages of the Bluetooth travel time systems is the affordability and the ease of installation of the Bluetooth scanners at the road side.

The reidentification rate of Bluetooth scanners is very high: once a Bluetooth device has been detected, it can be reidentified at a second location with high certainty. The limits of the technology are related to the penetration rate of visible Bluetooth devices in the vehicles. In urban areas, around 20% are detected; however, on highways, the rate is often above 25%. This means that Bluetooth systems are well suited for travel time measurement on highways or on arterial roads with high traffic volume.

4.7 Floating car data

Conventional systems require detectors to be mounted at the road side or above the road to measure the traffic situation at this location. This means that the acquisition of traffic data requires investment in the infrastructure, as the detectors need to be purchased, installed, and maintained. A completely different approach is to use signals from the vehicles itself without any roadside equipment, which would reduce the cost of the data acquisition system considerably.

Some vehicles are equipped with navigation systems that always measure their location via GPS. In the floating car data system, these vehicles report their position via mobile data transmission (GPRS or UMTS) at regular intervals to the traffic centers, where this information can easily be used to derive the traffic situation, LOS, and actual travel times.

Even though the technology is available since many years, only a few systems have been implemented. The major advantage that no roadside equipment is needed is offset by the fact that the communication between the vehicles and the traffic center is not free of charge, which means that the operation of an FCD system incurs running costs. As they work best when many vehicles are included and the location information is transmitted in short intervals, a reduction in communication cost—which means lower number of vehicles or less frequent transmissions to the traffic center—degrades the performance of the system.

The commercial situation is less critical for vehicles that have already a wireless communication link to a central office. Taxis, for instance, are often equipped with on-board units for the communication to the taxi-office where the position information is used for an optimization of the fleet management. In these cases where the position information of the vehicles is available without additional cost, the information can be used as floating car data for the traffic management as well. Even though the data is available at low cost, the technology is limited by the fact that taxis often have different driving patterns compared to other vehicles. Taxis often know where congestions are and avoid this route, which means that the information about these traffic jams does not reach the traffic center.

Recently, some suppliers of car navigation systems introduced floating car systems, where some of the navigation devices report their position to a data center. The cost for the communication is paid for by the user who in return receives online traffic data and advanced routing based on the actual traffic situation.

Floating car data is used in some traffic management systems as additional data source to existing detectors. The accuracy of the data is currently limited by the low penetration rate of these systems, as only a small fraction of the vehicles are equipped with these devices. More detailed information about floating car data can be found in Road Traffic and Travel Information (RTTI).

4.8 Public transport priority systems

In order to increase the attractiveness of busses and streetcars, many operators want to give priority to these transport means, so that these vehicles move faster through the city and experience shorter travel times. Many larger cities have priority systems in operation, which accelerate the public transport traffic.

The basic technology of public transport priority systems is a communication between the bus or streetcar and the traffic signal controller. When approaching the intersection, the bus transmits a call to the traffic controller that adjusts the phases so that the bus or streetcar will experience no or only a small waiting time. The green phase for this approach will start earlier or will be extended depending on the approximate arrival time of the public transport vehicle at the signal.

The bus or streetcar needs to be equipped with a positioning system such as GPS or in older systems via infrared communication to roadside equipment. Once the position system indicates the correct location in the approach to the intersection, a wireless signal is sent to the controller. The main information are the current position of the bus relative to the intersection and an information whether it will turn right or left or go straight at the intersection. In many cases, the bus transmits its line number to the controller where a list exists with all information about the different bus lines. In many cases, there are bus stops close to the intersection, which have to be considered when designing the priority system at that intersection. The bus might send additional information to the controller when arriving at the bus stop or when opening and closing the doors. Once the bus has passed the intersection, it will send this information

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto176
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to the intersection controller in order for it to switch back to normal signal control.

Experience has shown that priority systems can shorten the travel time of public transport vehicles significantly. The actual reduction in travel time depends on many factors such as the number of signalized intersections on the route, overall traffic volume, and the flexibility of the signal control (upper and lower limits for the length of the phases).

There are many different technical implementations of priority systems. Modern systems rely on GPS positioning of the transport vehicle and use wireless communication from the vehicle to the intersection.

4.9 Other detection technologies

Many different technologies are used for vehicle detection and within the scope of this chapter; only the most frequently used ones can be described. Passive infrared, active infrared (laser), ultrasound, or acoustic detection are further examples of technologies used in vehicle detectors.

The accuracy of the traffic data can be increased by the use of several different sensor technologies in one detector. Combination detectors, for instance, with infrared, ultrasound, and radar sensors are often used as above ground detectors on highways. They are mounted on gantries above the road and achieve advanced vehicle classification with high accuracy.

GLOSSARY

Occupancy	Occupancy defines the percentage of time a certain point of the road is occupied by a vehicle.
Level of service	The LOS is a measure of the current traffic situation of a certain part of the road network. In many cases, several LOS levels are defined such as free-flow traffic, slow traffic, congestion, or stationary traffic.
Inductive loop detectors	Inductive loop detector systems consist of a wire loop in the road and a electronic unit that induces an alternating electromagnetic field in the loop and measures the electromagnetic field induces by metallic objects such as vehicles in the vicinity of the loop. Inductive loop detectors are used for vehicle detection.
Vehicle actuation	Vehicle actuation describes the use of traffic data for the calculation of the signal phases at a signalized intersection.
Traffic volume	Traffic volume is defined by the number of vehicles per unit time (usually 1 h) crossing a section of road.
Traveltime	Traveltime measures the time it takes a vehicle to travel from point A to B, where A and B are two points in a road network.
Radar	Radar is an object-detection system that uses radio waves. Radar is the acronym for radio detection and ranging.
Bluetooth	Bluetooth is a wireless technology standard for data transmission over short distance in the ISM band from 2400–2480 MHz. It is defined in the IEEE 802.15.1.

Data Fusion

Axel Leonhardt[1] and Álvaro Catalá-Prat[2]

[1] *PTV AG, Karlsruhe, Germany*
[2] *DLR, Braunschweig, Germany*

1 INTRODUCTION

With the recent developments of intelligent transportation systems and intelligent vehicles, data fusion gains more and more attention as a technique to make optimal use of a wide range of in-vehicle and roadside sensors. Applications include various approaches for object and incident detection, state estimation, and state forecasting.

This chapter gives an overview of data fusion methods and applications from the vehicular as well as the roadside perspectives. It also gives an introduction of the main concepts of data fusion. Section 2 describes the commonly used methods. The main part consists of two sample applications, one detailed example from the area of vehicle automation (Section 3) and the other example from the area of traffic state estimation and prediction, which is described in Section 4. Finally, in Section 5, a summary and an outlook on sensor data fusion is given.

1.1 What is data fusion?

The term *data fusion* is widely used in the industry and there exist a wide range of definitions. In general, data fusion can be described as the intelligent processing and combination of information from many diverse sources. In particular, data fusion is applied to gather information by combining different sources that is of higher value than information from only one source. If only sensors are used as sources, often the term *sensor data fusion* is used.

There are different occurrences of data fusion.

Cooperative data fusion is applied on independent data sources to get information that would not be available from the single sensor. For example, using two 2D camera images, a stereo 3D image can be generated. Moreover, by the combination of two sensor perspectives, the whole object size can be detected. Another example is the derivation of vehicle densities on a stretch of road with upstream and downstream detectors.

Complementary data fusion means that data from different sources are combined in order to give a more complete picture of the observed phenomenon. For example, the front area and rear area sensors of a vehicle can be fused to an all-around detection system.

Competitive data fusion means that in a multisensor setting, each sensor delivers independent measurements of the same characteristic.

Data fusion is applied to reach one or several of the following advantages:

- Extension of the detection area: The detection area of two or more sensors can be fused into a common one.

- Extension of detectable features (see examples of cooperative data fusion earlier).
- Improvement of accuracy: By the fusion of two data sources with known accuracy, a better common accuracy can be reached. For example, by fusing many samples of a quantity, a better estimation of the quantity is possible.
- Increasing confidence: The combination of two detection sources can provide more confident detection rates. For example, the use of different data sources can help reduce false positive and false negative rates of an object detection system. A further example is the application of several incident detection algorithms in parallel.
- Higher availability: By means of sensor data fusion, the effects of temporary limitations of acquisition systems can be reduced. For example, a multisensor fusion system may be able to provide output even if one of the sensors is failing.
- Increased robustness: The fusion system is more able to cope with errors during execution, for example, errors due to data outliers, data noise, or sensor failure.

1.2 Sensor data fusion levels

Commonly, data fusion systems are based on one of the following abstraction levels:

Sensor level or low level fusion: The raw data of the sensors is processed closely together (usually in a cooperative way). These systems can reach very high accuracy and reliability. However, in case of failure of one of the sensors, the whole system may fail. The calculation of stereo-information and the projection of radar data on a camera image for target confirmation are examples of low level fusion.

Object level or mid-level fusion: In this case, the data of each sensor is preprocessed separately before it is fused (usually in a competitive way). The aim of the preprocessing is to reduce the amount of data to the features or objects to be fused, getting thus more abstract data. On the one hand, this means that a higher independence of the sensors used. Moreover, the system can usually reach high reliability and availability because it does not depend on all of the sensors to work. In case that one of the sensors has a short failure or malfunction (e.g., the camera is glared), the fusion system is still able to provide output based on the other one. The system offers high availability and data rate as well, which comes from the sum of both sensor rates.

Depending on the abstraction level of preprocessed data, different sublevels are defined:

1. feature level (image features, such as edges, can be fused with laser scanner features, such as reflections);
2. object level (object observations extracted from different sensors are fused to object hypotheses);
3. tracking level (each sensor carries out its own tracking and the tracks are then associated and fused).

Information level or high level fusion: This term is used to define data fusion systems in which the involved input sources already contain a complete data processing. These systems usually combine semantic information about the observed objects or scene. For example, in relation to a driving situation, information about vehicle properties, maneuvers, intentions, or dangers can be obtained.

1.3 Spatial and temporal scopes

For the system design, it is important to know the spatial and temporal scopes of the data fusion configuration. Spatial scope here means the location of the sensors. How the sensors are distributed (one detector station or several detectors along a road, sensors in one vehicle or in several vehicles) determines the requirements for communication channels. The temporal scope describes if only data from the current interval are used or also data from the past (last 15 min, past 2 years). This has an impact on the system design in terms of data storage capabilities.

2 DATA FUSION METHODS

Many data fusion methodologies have been proposed in the literature, including statistical approaches, artificial intelligence, and filter approaches. This section gives a brief overview of the commonly applied methods.

2.1 Logic-based data fusion

Logic-based methods, as described here, are rather straightforward and easy-to-implement data fusion methods. They are basically a set of IF, AND, and OR statements to compare and evaluate information from different data sources. In logic-based data fusion, there are rules and reasoning statements used to combine and utilize different information sources, for example, in the following form:

Rule: IF $X > a$ *AND* $Y < b$ *THEN* $Z > c$
Reasoning: IF $X > a$ *AND* $Y < b$ *AND* $Z < c \rightarrow Z$ *is implausible*

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where X, Y, and Z are measurements from different sensors and a, b, and c are thresholds of observables, for example, derived based on fundamental physical principles or based on a range of (plausible) observations.

In the field of traffic engineering, these rules can be applied, for example, to estimate whether detector data is plausible or not. For practical application, rule-based error checking methods for detectors have been implemented in national guidelines; for example, the German guidelines for the quality management of traffic detectors (FGSV, 2006) and the German guidelines for quality management of road weather and road surface condition sensors (FGSV, 2010).

An example for a plausibility check is shown in Figure 1, where data from a road visibility sensor and relative air humidity sensor are fused to identify implausible (or at least suspect) visibility measurements. The reasoning rule is simply *IF Visibility < Visibility_Threshold AND RelativeHumidity < RelativeHumidity_Threshold → Visibility is implausible*. The reasoning is based on two phenomena: (i) the physical or meteorological principle that a low visibility (fog) can be observed only if relative humidity is high and (ii) the experience that the relative air humidity measurement is in general much more reliable than a visibility measurement.

Fuzzy logic (or fuzzy reasoning) generalizes the traditional logic concept and allows not only binary outcomes (false/true) but also "degrees of truth." Fuzzy Logic is rather popular for data fusion, as it naturally allows to deal with incomplete information (e.g., data from one source is missing). In the data fusion context, the degrees of truth can be utilized, for example, to express the extent to which the different sources support the presence of a certain system state. The final state estimation is done based on a set of fuzzy rules (inference) and the so-called defuzzyfication process. An example is the automatic incident detection system proposed by Busch and Ghio (1994), which fuses different incident detection algorithms to get a more reliable incident detection.

2.2 Data mining methods

In the context of data fusion, data mining can be regarded as a group of methods that automatically learn input–output relationships based on training data. Hence, data mining deals with large collections of data and its main objectives are to automatically detect and process patterns. For detailed introductions, the reader is referred to the respective textbooks, such as Hastie, Tibshirani, and Friedman (2001), Sankar and Pabitra (2004), Takezawa (2005), and Berthold and Hand (1999).

Regression analysis as a subarea of pattern recognition deals with the estimation and prediction of numerical data and is widely used to facilitate sensor data fusion. Observations (training data) are used to learn functional relationships between an input pattern (independent variables) X, with $X = x_1, \ldots, x_n$, and an output (dependent variable) y. The goal of a regression model is to find a suitable function or a model that solves $y' = f(X)$, given a set

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of observations (y, X). Models frequently used for regression are parametric regression methods, artificial neural networks (ANNs), adaptive expert systems, and nonparametric regression.

2.2.1 Parametric regression models

Parametric regression models describe input–output relationships by polynomial functions, with the polynomial coefficients to be estimated based on training data. A simple example is the well-known linear regression, where two coefficients have to be estimated. Parametric regression is applied to fuse data sources in the field of traffic state estimation by Kwon and Petty (2005). They apply a varying coefficient linear regression model to predict travel times on freeways segments based on local traffic data and an estimate for the current travel time. Sun *et al*. (2003) describe a method to predict travel times on freeways using a local linear regression model using past and the current observations of the variable to be predicted (travel time). Maier (2010) applies a segmented linear regression approach to estimate travel times observed with probe vehicles and local detector data.

2.2.2 Artificial neural networks (ANNs)

ANNs are flexible function approximators that consist of simple processing units (neurons) and emulate a human brain's learning and decision-making processes. In particular, their structure allows the application of efficient learning algorithms that optimize the connections between the neurons to map an input pattern to an output.

ANN are used extensively for data fusion in traffic engineering, especially for traffic state estimation and short-term prediction, in particular, as they are well suited to approximate highly nonlinear relationships between input and output patterns. For example, Park and Rilett (1998) propose a two-step approach. In the first step, historical link travel times are segmented using unsupervised learning. In the second step, one ANN is calibrated for each class, forming a system of situation-specific ANN. Dailey, Harn, and Lin (1996) give a comprehensive overview over ANNs and their applications in the area of intelligent transportation systems.

2.2.3 Adaptive expert systems

Adaptive expert systems are hybrid methods that incorporate expert knowledge in the form of prototypical rules, examples, or decision trees. These preformulated rules are optimized based on training data. Linauer *et al*. (2006) use an ANFIS (adaptive neuro-fuzzy inference system) for the prediction of travel speeds on routes in urban networks. Speed and traffic volume of one local detector on the respective route are used to predict the travel speed; training data to optimize the fuzzy membership function are derived from taxi probe data.

2.2.4 Nonparametric regression models

Instance-based learning (or nonparametric regression/k-nearest-neighbor methods) is a data mining method to solve regression problems, where the output variable is estimated based on the most relevant observations. It basically compares a present pattern X with its counterparts in the database with respect to a defined measure of similarity (distance metric) and calculates y' online based on the observed y that correspond to the k most similar patterns in the database.

2.3 Bayesian data fusion

Bayesian data fusion is based on Bayes' theorem, which basically allows deriving the probabilities of events given some a priori knowledge. The joint probability P of two events A and B occurring is the probability of event A, given that event B already has occurred:

$$P(A,B) = P(A|B) \cdot P(B) \tag{1}$$

Bayes' rule now states that the probability of event A given that event B already occurred is:

$$P(A|B) = P(B|A) \cdot \frac{P(A)}{P(B)} \tag{2}$$

or in case there are several events A_i,

$$P(A_i|B) = P(B|A_i) \cdot \frac{P(A_i)}{\mathrm{SUM}(P(B|A_i) \cdot P(A_i))} \tag{3}$$

It becomes clear that there is some a priori knowledge needed to successfully apply Bayes' rule. It is necessary to know $P(B|A)$ or $P(B|A_i)$ and the a priori probabilities of events $P(A_i)$.

One example for the application of Bayes' fusion is the classification of vehicles. There are two sensors (e.g., a radar sensor to measure the speed and an ultrasonic sensor to sense the vehicle's signature) that deliver signals, which can be used for vehicle classification (e.g., two classes: passenger car and passenger car with trailer). Furthermore, the a priori probabilities of a vehicle being in a certain class (e.g., based on a known fleet distribution) are given, as well as the individual probabilities that a signal belongs

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to a certain class. On the basis of initial probabilities and the individual probabilities, the probability that the vehicle is, for example, a passenger car can be estimated with higher certainty than based on one of the individual probabilities.

Further examples and applications can be found in the literature, for example, in El Faouzi (2006), for travel time estimation and Koks and Challa (2005) for sensor tracking.

2.4 Dempster–Shafer theory of evidence

The Dempster–Shafer theory can be understood as a generalization of the Bayesian method, as it employs a confidence interval of certainty instead of the single-point probability of the Bayesian method. Thus, it offers a way to combine uncertain information from different data sources and each sensor can contribute at a different level of detail, as described by Sarma and Raju (1991). Especially, Dempster–Shafer theory introduces two new concepts: support and plausibility. Support can be interpreted as a lower limit of uncertainty, whereas plausibility can be regarded as the upper limit of uncertainty.

Examples and applications can be found in the literature, for example, in El Faouzi (2006) and Dailey, Harn, and Lin (1996).

2.5 Filtering methods

The ground principles of data fusion can often be found in the area of estimation and tracking. In relation to these topics, a large amount of literature can be found, such as Bar-Shalom and Li (1995), Brooks and Iyengar (1998), Brown and Hwang (1997), and Maybeck (1979). This section aims at giving a short overview of theory and methods of estimation and tracking that are frequently used in the literature for the purpose of data fusion.

In automotive area, it often comes to estimating the state of a dynamic object, such as the position of the ego-car, or the position of other vehicles or pedestrians, which is often referred to as *tracking*. The input for estimation is given in the form of observations or measurements, coming from sensors or other data sources.

Many different approaches and methods can be applied in the task of tracking. Most of them are based on the concepts of linear regression (Section 2.2) and linear Bayes' estimation (Section 2.3), which are enumerated in the following.

State vector $x(t)$—containing all relevant information to estimate and from which all future states (predictions) can be derived. The system engineer decides the dynamic model for the tracking.

Error covariance matrix $P(t)$—representing the estimation accuracy or prediction accuracy as well as the correlation between its components.

Transition matrix $F(t)$—expressing the relationship between two consecutive states in time. It is defined according to the dynamic model as well.

Control input $u(t)$ and control input matrix $B(t)$—meaning an additional known input in the tracked system.

Process noise $w(t)$ and process noise matrix $Q(t)$—representing dynamic factors nonconsidered by the dynamic model. It is assumed to be white noise, that is, a random process with expected value 0 and autocovariance matrix $Q(t)$.

The relationship between the two state vectors in different instants is given as:

$$x(t_{k+1}) = F(t_{k+1}) \cdot x(t_k) + B(t_{k+1}) \cdot u(t_{k+1}) + w(t_{k+1}) \tag{4}$$

Observation or measurement vector $z(t)$—containing the data provided by the sensor or the data source.

Observation or measurement matrix $H(t)$—representing the linear relationship between the state vector and a corresponding observation.

Measurement noise $v(t)$ and measurement noise matrix $R(t)$—representing the accuracy of the measurement vector (i.e., the current accuracy of the sensor or the extraction system). It is assumed to be white noise too, characterized by the autocovariance matrix $R(t)$.

The relationship between a state vector and the corresponding observation is given by the measurement equation:

$$x(t_k) = H(t_k) \cdot x(t_k) + v(t_k) \tag{5}$$

A recursive, optimized estimator based on these principles is the well-known Kalman filter. The Kalman filter consists of two cyclical phases. In each filter step, the state vector is predicted to the time of the new measurement t_{k+1} and then it is updated by means of this measurement. A detailed description and its mathematical functions can be found in Kalman (1960).

Other nonlinear (and nonoptimal) solutions exist, such as the extended Kalman filter or the unscented Kalman filter. Another possibility for nonlinear systems consists of the particle filter, based on a Monte Carlo sampling of the estimate.

The pure estimation is usually not enough in order to get a proper tracking. There are multiple aspects, such as special noise, maneuvering targets, or data outliers, which make it necessary to define additional mechanisms for a robust tracking. Such mechanisms may include adaptive process noise (fudge factor), input estimation, variable state dimension, multimodel filter, and interacting multimodel

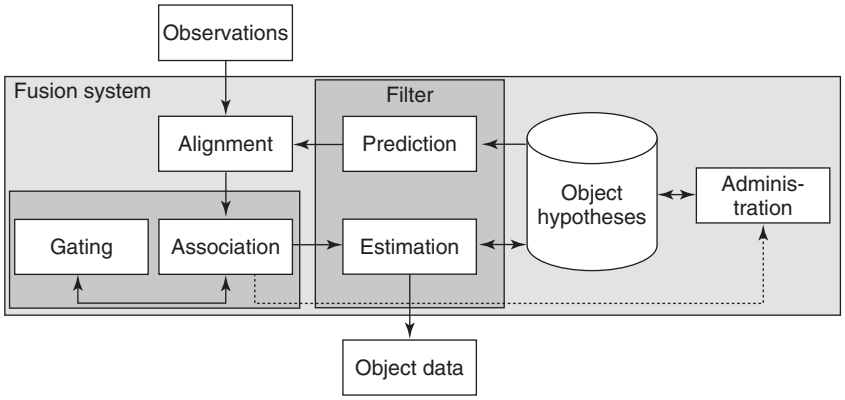

Figure 2. Multitarget tracking scheme.

(IMM). See the literature sources given at the beginning of this section for more details.

2.6 Multitarget-tracking

Object detection and tracking systems are frequently based on the well-known multitarget tracking scheme (Bar-Shalom and Li, 1995), as shown in Figure 2. This cyclical model has a list of observations as input at each cycle.

In a first step, the state of the object hypotheses already existing in the system is predicted to the current time-stamp of the observations according to the dynamic model.

Then, the incoming observations are aligned with the list of predicted objects. Alignment usually affects synchronization and coordinate transformation, in order to get the data in a common time axis and reference coordinate system.

After alignment, the association between observations and predictions takes place. For this step, a metric must be defined in order to evaluate each combination between an observation and a prediction. For example, direct distance, Mahalanobis distance, or similarity metrics are often applied. To decide the associations, different approaches can be used, such as the nearest-neighbor, the probabilistic data association filter (PDAF), or variations of them. The basics of these methods are common to the ones given in Sections 2.2, 2.3, and 2.4. In parallel to association, statistically or physically improbable combinations are excluded by a gating mechanism.

On the basis of associations set, a new estimation step takes place for each object hypothesis, for example, by means of the Kalman filter.

Additionally, some administrative tasks are carried out on the object list, such as initializing, deleting, and managing object hypotheses.

3 DATA FUSION FOR OBJECT RECOGNITION AND TRACKING WITH CAMERA AND LASER SCANNER

This section presents an application of sensor data fusion in the area of vehicular sensor data to sketch a more precise picture of sensor data fusion in practice. It consists of an object detection and tracking system based on a camera and a laser scanner.

3.1 Introduction

Object detection and tracking is a crucial component of advanced driver assistance and automation systems, such as adaptive cruise control (ACC), brake assistant, collision avoidance system, blind spot assistant, or maneuver planner. For the task of object detection, high reliability, availability, and accuracy are required. In addition, further important challenges appear, as schematically shown in Figure 3 and listed as follows:

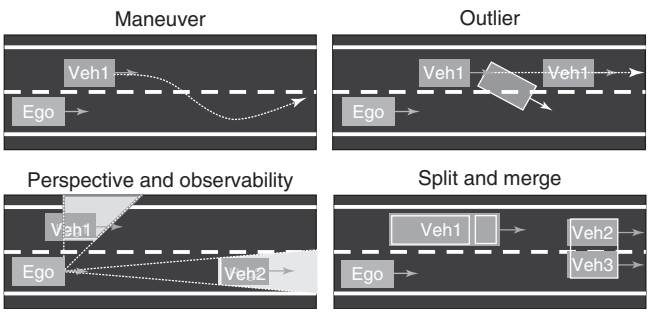

Figure 3. Selected challenges at object detection and tracking.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- uncertain sensor data and data outliers;
- maneuvering objects, whose movement differs from the expected dynamic model;
- partial observability due to sensor characteristics, perspective changes, and objects covering each other;
- splitting and merging of observations.

This example system, presented as well by Catalá-Prat and Köster (2011), provides a compact solution to address object detection and tracking, with special focus on the challenging situations mentioned earlier.

Concretely, it means that the system shall be able to detect objects near the ego vehicle. Their position shall be determined accurately and independently of the objects' constellation. In case of object occlusion, the observable parts of the object shall be modeled correctly. Moreover, objects shall be tracked in the course of time, irrespective of their movement. The tracking system must be able to follow maneuvering objects and deal with data outliers as well as split and merge effects.

All in all, high accuracy, reliability, availability, and robustness are desired. The system shall be kept modular, expandable, and sensor independent.

3.2 State of the art

Object detection and tracking systems are frequently aimed in the automotive area. These solutions can be classified according to their level of abstraction.

Aiming at a high performance, many systems are based on the sensor level fusion. An example of such systems is given by Kato, Ninomiya, Masaki (2002), who combine a radar and a camera by projecting the radar targets into the camera image. Another example is given by Vu, Aycard, and Appenrodt (2007), who apply an occupancy grid as a base for alignment and association between the different sensors.

Further solutions are based on the feature level. For example, Kaempchen *et al*. (2004) extract features from a camera and a laser scanner and use them as input to the fusion (feature level fusion). There, the alignment between observations and predictions requires a transformation corresponding to the sensor model. For tracking, they propose an IMM filter at object level.

At object level, Weiss, Stüker, and Kirchner (2003) use a model-switching mechanism instead. Stüker (2004) extracts object observations from each sensor, which are used as input for the fusion system. Moreover, he also explicitly considers the objects' partial observability and the adaptive measurement noise.

Finally, Thomaidis, Spinoulas, and Lytrivis (2010) fuse at tracking level, which means that objects are tracked for each sensor separately and are then integrated.

3.3 Approach

The modular structure of the proposed solution is shown in Figure 4. The central fusion takes place at object level and uses the scheme represented in Figure 2. The advantages of

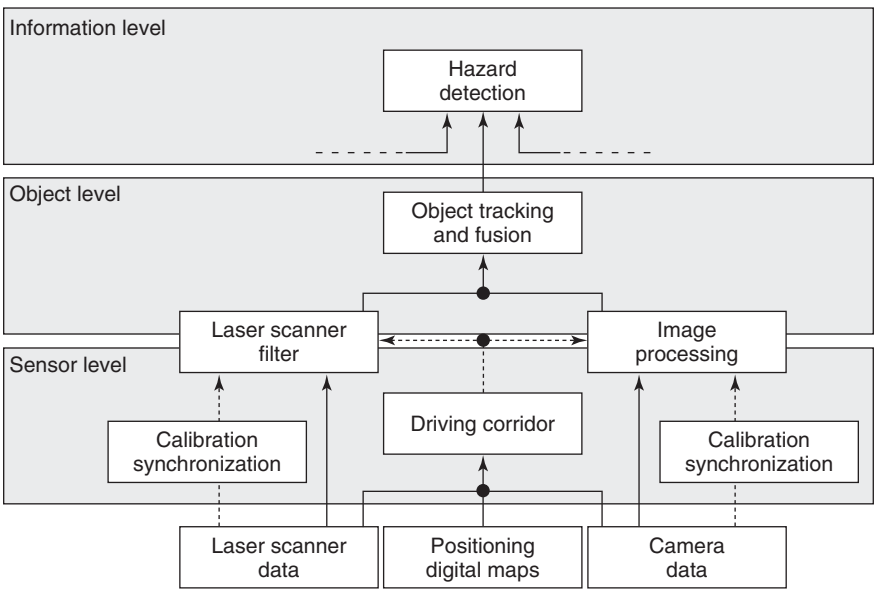

Figure 4. Proposed solution.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177

object level fusion for this application are its competitive character, the higher independence from the sensors used, and the higher reliability and availability.

In order to feed the object fusion, object observations are extracted from the data of each sensor. Preliminarily, the sensors must have been accurately calibrated, referenced, and synchronized.

Camera image and laser scanner preprocessing are not in the focus of this chapter. Some details can be found in Catalá-Prat, Köster, and Reulke (2010). The extraction of object observations out of images is done based on texture-based image segmentation. Laser scanner preprocessing for object extraction is done by a fast shape indicator based on the internal angles of the detected object contours. Figure 5 shows an example of a situation with camera and laser scanner observations.

In order to filter and reduce the amount of data to fuse, the boundaries of the current driving corridor are determined and used as area of interest in the data processing. The driving corridor is understood as the road in which the vehicle is driving and other immediate neighboring vehicles can be found (e.g., one motorway direction, a road, or even a whole intersection). Determining the driving corridor is done by means of an early sensor data fusion (based on an occupancy grid) of digital map data, lane information from the camera, and raw laser scanner data.

At object level, the observations of both sensors are fused in a multitarget tracking system. As outcome, a robust list of detected and tracked objects is provided.

A central aspect of the multitarget tracking system is the object model, on which both the object extraction modules and the object fusion itself (and its output) are based. In this example application, the object model consists of a box, represented by its size, heading angle, and a reference point. The reference point, described by position and velocity, can be changed depending on observability issues. The chosen dynamic model consists of a straight constant velocity movement, which corresponds to a simple model and allows quick initialization and convergence of tracking. As central estimation filter, the information filter is applied (Rao, Durrant-Whyte, and Sheen, 1993). This filter is equivalent to the Kalman filter (Section 2.5) and allows parallel input data from different sources at a time.

In order to allow a robust object detection and tracking, the following fusion strategies have been developed:

- adaptive measurement and process noise, to simulate nonconsidered acceleration or yaw rate;
- changing logical reference, as mentioned earlier, in order to always represent an object by the optimally observable reference point (Figure 6);
- partial observability matrix, in order to only consider observable parts in the estimation;
- multiple association, to deal with split or merged observations;
- object hypothesis duplication by unclear association;
- object hypothesis unification by high overlap.

The two latter strategies are well suited to deal with different challenges such as split or merged object hypotheses, with maneuvering objects and data outliers (Figure 7).

Finally, after object detection and tracking, further modules use this outcome at information level. In this framework, an early hazard detection approach has been developed. The approach is based on the detection of atypical events or situations, which possibly can represent hazards. However, the information level is not at the aim of this publication.

3.4 Results

The presented methods and strategies have been exhaustively tested in different manners. On the one hand, in

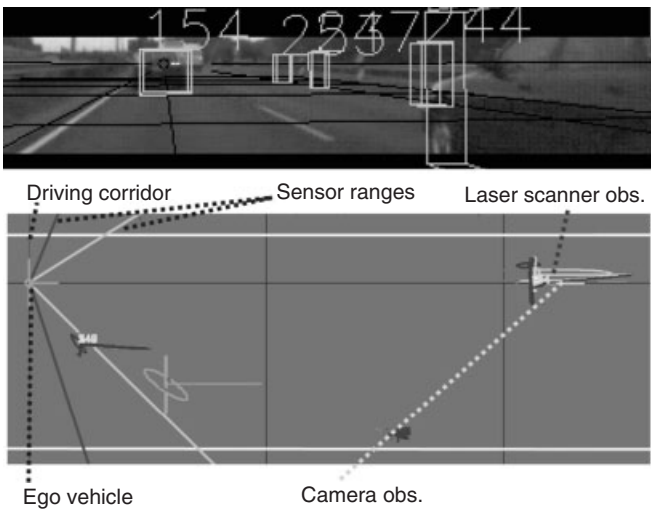

Figure 5. Examples of observations extracted from the camera and the laser scanner.

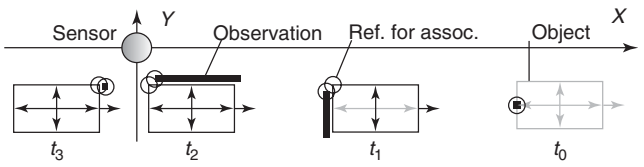

Figure 6. Example of changing object reference in the course of time.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

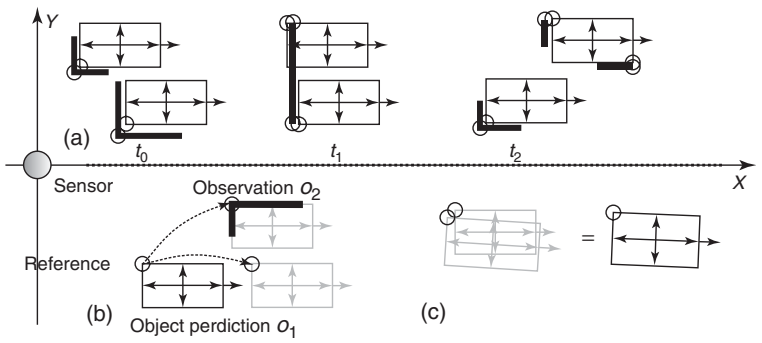

Figure 7. (a–c) Examples for avoiding split and merge of objects (see details in the text).

order to evaluate the methods, a simulation framework has been used. The advantages are the knowledge about the ground truth, the repeatability, and the testing of the system in extreme situations. The experiments consisted of motorway scenarios and contained different maneuvers, such as approaching, lane change, and overtaking. On the other hand, in order to validate the simulated results, real test drives have also been carried out in motorway scenarios with a test vehicle equipped with a camera and laser scanner sensors.

Comparing to the raw data, the object tracking has shown very promising results, such as a higher system availability, higher accuracy, lower false positive rates due to high confident tracking, and low false negative rates.

To sum up, the results show that objects were initialized very quickly, and that a smooth and uninterrupted tracking was possible because of the high availability of both sensors. Moreover, maneuvering objects, outliers, and split and merge did not have major negative effects on the object fusion and tracking. The focus of these first experiments has been set on the quality of the results. Thus, not all system components have been optimized for real-time yet. However, the structure of the strategies allows for a straightforward optimization.

4 DATA FUSION FOR TRAFFIC STATE ESTIMATION AND PREDICTION

In addition to the vehicular application presented in Section 3, this section sketches an instance-based learning method for the estimation and short-term prediction of traffic variables using spatiotemporal traffic patterns from multiple data sources. In the following, it is described how the methodology is applied for travel time estimation. Yet, the approach is generic and can be applied to other input–output data sets as well.

4.1 Introduction

Typically, in any urban network that exceeds a certain size and complexity, there are data from local traffic detectors available. The richness of the data varies, depending on the technology used, with at least traffic flow and occupancy (vehicle presence) being available.

Methods to measure travel times became more and more available in recent years. With the evolution of positioning devices and advances in wireless communication techniques, the use of vehicle positioning data has gained more and more attention. Travel time can be derived based on vehicle position and time stamp by applying some map matching and path reconstruction methods. Taxis are a particularly useful data source. They are equipped with GPS (global positioning system) devices for disposition and transmit their positioning data regularly to a central control system, where they can be accessed.

Today's IT infrastructures allow to gather and store huge amounts of data—and this holds true for traffic data as well. Given a setup with several local measurement devices and at least occasionally observed travel times, this can be used as a training data basis to derive a model that is able, based on the typically continuously available data, to estimate and predict the occasionally observable variable. Data mining methods are particularly suitable to be used for such a task (see Section 2.2 for an overview of different data mining methods).

4.2 State of the art

Friedrich, Matschke, and Heinig (2004) present a holistic approach on the integration of floating car data (FCD) in traffic state estimation (based on detector data) on different network levels (Figure 8). In particular, probe vehicle data are used to get samples for queue length at an intersection level, travel times on a link/route level, and origin–destination (OD) patterns on a network level.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

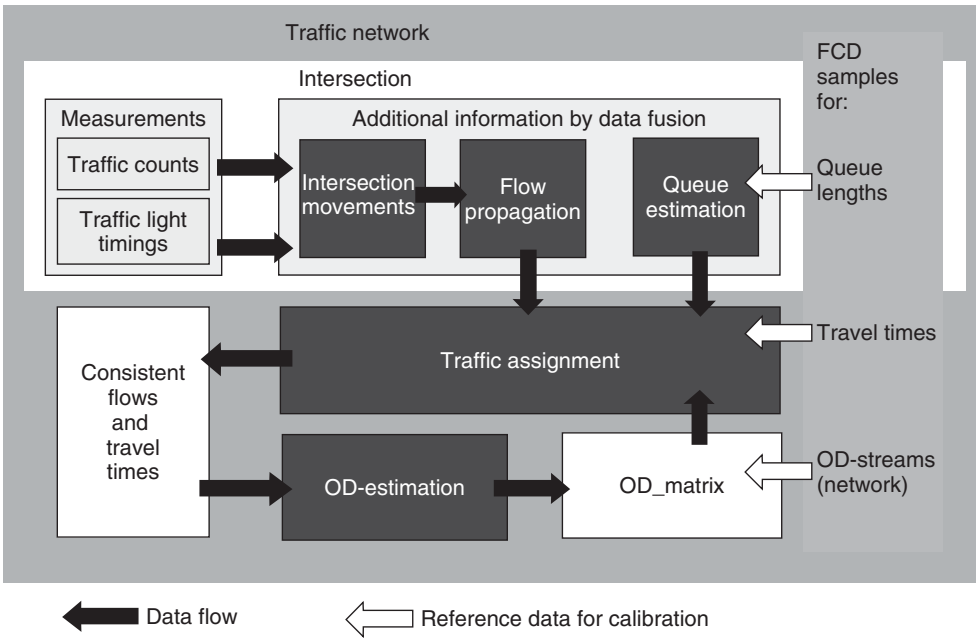

Figure 8. Data fusion in the context of traffic state estimation. (Reproduced with permission from Friedrich *et al.* 2004. © TRISTAN V).

Several approaches apply pattern recognition techniques to fuse data from different sources: Robinson and Polak (2005) propose a method to estimate travel times using *k*-nearest neighbors. Travel times are gathered from license plate readers, local occupancy and volume data from detectors on the respective routes are used as independent variables. The method has been applied to two routes and outperformed several benchmark algorithms, including simple regression models and ANN. Turochy and Pierce (2004) investigated *k*-nearest neighbors to predict local speeds on freeways for one time step. Davis and Nihan (1991) developed an algorithm to predict occupancy and volume based on occupancy and volume from several surrounding detectors from the previous interval. Smith and Demetsky (1997) found that the instance-based learning method they used outperformed an ARIMA (autoregressive integrated moving average) and an ANN for the prediction of traffic volumes. You and Kim (2000) use probe vehicle data for both, training and input variable. Data from the last hour is used; the *k*-nearest-neighbor method was applied in an urban network.

4.3 Approach

Figure 9 shows the overall framework from data collection through the processing steps down to the actual estimation or prediction corresponding to the example application described in the following.

Continuously available traffic data (here, local traffic data) is collected and used as independent variables X. The traffic data of interest needs to be observed (at least) occasionally (e.g., vehicle positions from a GPS-equipped vehicle) and processed to make up usable traffic variables y. These steps include data plausibility checking and smoothing of local traffic data time series, as well as necessary processing steps to, for example, derive travel times from vehicle position data.

The data is organized in a database with time stamp and location information, such that for each pair of data points, their spatial distance ds and their temporal distance dt can be determined.

If a prediction $y'_r(t+\Delta t)$ is queried (e.g., travel time on route r for a prediction horizon Δt), for all observations y_r in the database, the relevant features are identified to form the pattern X_r. X_r consists of traffic data (e.g., occupancy data) that are spatially and temporally close to y_r, with individual data points $x \in X$ to be weighted according to their spatial and temporal positions. In addition, the so-called calendar attributes are included into the pattern (day of week and time of day).

In the next step, the k most similar instances from the database are identified by applying a distance metric to compute the distance D. y'_r is estimated based on the observations $y_{r,k}$ that correspond to the identified instances, applying a Gaussian kernel to derive the relative weights w_k of the k-nearest neighbors.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

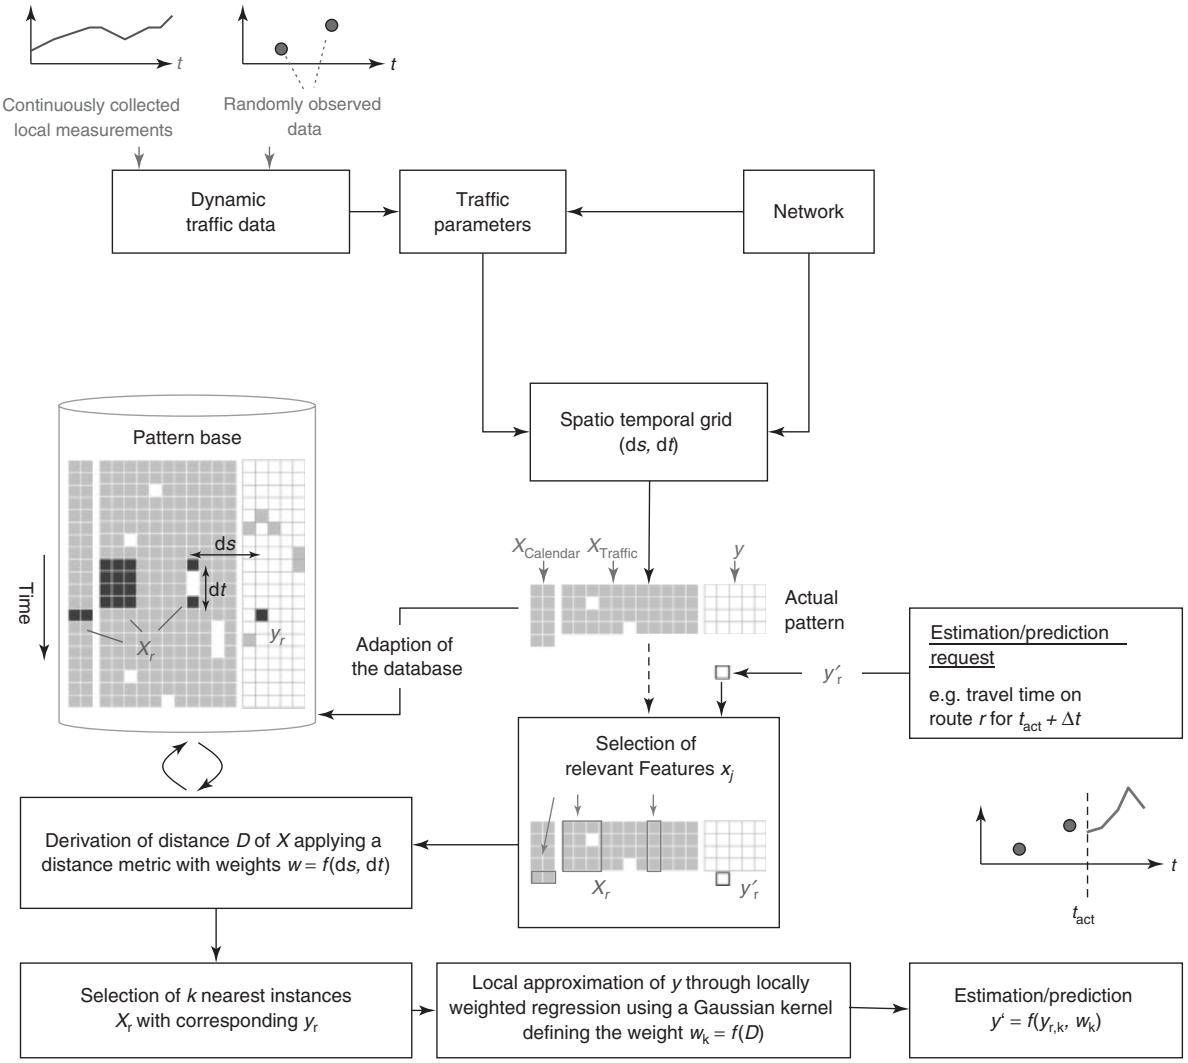

Figure 9. Overall framework of the estimation and prediction processes.

A detailed description of the method can be found in Leonhardt and Steiner (2012).

4.4 Results

Figure 10 shows some exemplary results of the method applied to estimate travel times on one route in Munich/Germany (a) and one route in Graz/Austria (b). Note that the "measured" travel times are only displayed as some sort of a reference time series and are not used to derive the estimation (light solid line). It can be seen that the method produced plausible results by exhibiting day-to-day dynamics and the extraordinary high travel times.

The instance-based learning method has been compared to three other methods. These comparisons indicate that

- the method outperforms the simple, calendar-based prediction (i.e., predicting the travel time based on day of week and time of day only without considering current measurements);
- the method performs comparable to different ANN topologies (multilayer feed architecture, trained with back propagation), yet yielding the advantage of being a rather transparent approach (not a "Black Box").

5 SUMMARY

In this chapter, an overview of sensor data fusion methods and applications has been given. Section 1 has described the most important terms related to data fusion. In Section 2, the most common data fusion methods are briefly introduced.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto177
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

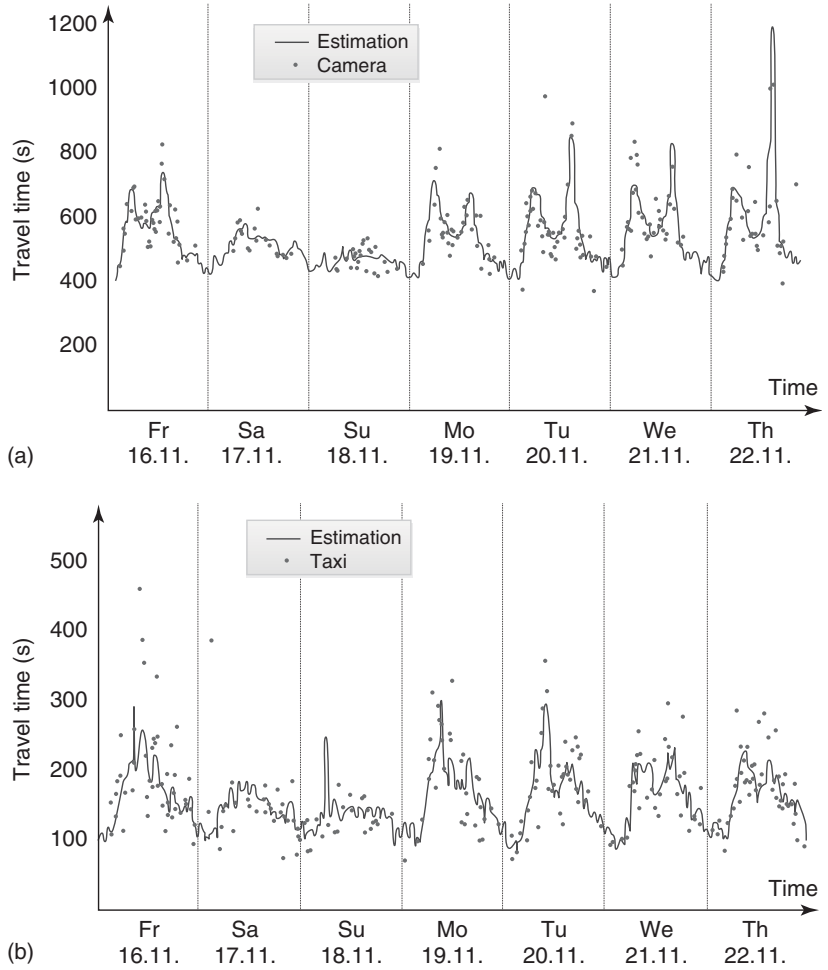

Figure 10. Estimated travel time and training data from vehicle (a) reidentification and (b) taxi probes.

In Section 3, an object tracking system based on an object level fusion and further strategies has been presented. The system has been exemplified with the extracted observations of a camera and a laser scanner. On the choice of object level, a high reliability and system flexibility can be reached. However, effects such as perspective changes, maneuvering objects, and split and merge effects must be treated apart. Thus, a variable logical reference is proposed, which might be adapted for alignment between observations and object hypotheses. Furthermore, a partial observability matrix is introduced, which allows keeping a general object model and tracking only observable model parts. Finally, strategies of hypothesis duplication and unification have been presented, which are used for both tracking maneuvering objects and dealing with sensor typical split and merge effects. These strategies have proven to bring an improvement of the quality of the test results. The methods presented have been prototypically implemented and tested. The results have shown an increase of the object data quality. Although not all components have been real-time optimized yet, a core of these strategies has already been adopted to the autonomously driving test vehicle FASCar (Löper *et al*., 2011), which has been successfully used within different demonstrations.

In Section 4, an instance-based learning method to fuse data from local detector stations and probe vehicles to estimate and predict travel times in road networks has been described. This application demonstrates the benefit of data fusion in case there is a very valuable information observed only occasionally (here, travel times) and other data (less valuable, but usable as independent variable) is available permanently. A potential application in traffic managements is the information of drivers with network-wide traffic state information, either in the form of tables, where the travel times for different routes can be displayed, or visually as "level of service maps."

GLOSSARY

Term	Definition
Sensor	Device to convert physical quantities into (analogical or digital) signals that can be further processed.
Sensor data fusion	Combining or processing information from multiple sensors with the objective of improving quality and/or quantity of information compared to only using a single sensor.
Estimation	Calculating an approximate value of a (physical) variable based on observation data (input data set), which may be incomplete or uncertain.
Prediction	Estimation of a (physical) variable as of a future time point.
Filtering	Processing a (sensor) signal with the objective of removing noise or other irrelevant parts in order to estimate the target variable.
Tracking	Estimating the state of a dynamic object in the course of time, such as the position of the ego-car or the position of other vehicles or pedestrians. Tracking contains normally a filtering effect and is thus often used as a synonym of it.
Object	Representation of a physical object (e.g., vehicle) in data processing.
Observation	Detection of objects or phenomena out of raw sensor data.
Hypothesis	Proposed or assumed explanation for a phenomenon. In relation to object detection and tracking, an object hypothesis consists of an object estimation.
Laser scanner	Sensor consisting of controlled laser beaming to measure distances, often with the objective to detect the environment, that is, objects.
Camera	Optical device for image (or image sequence) acquisition.
Artificial intelligence	Science that aims at replicating or using principles of human intelligence by means of computer programs.
Data mining	Process of discovering patterns and information in large databases using algorithms.
Training data	Set of observations used to detect relationships for estimation and prediction, for example, input data (independent variables) and output data (dependent variables).
Probe vehicle	Vehicles that are participating in the traffic flow and collect state data (e.g., position and speed). Data are stored or transmitted online for further processing.
Floating car data (FCD)	Data collected by means of probe vehicles.
Plausibility	Validity of an observation or measurement, possibly estimated using data fusion.
Smoothing	Process of finding an approximate function for a signal that reduces or eliminates noise while keeping or emphasizing the wanted signal. (Related to filtering.)
Time series	Sequence of data, in temporal order.
Cooperative data fusion	Using several independent data sources to get information that would not be available from the single sensors.
Complementary data fusion	Using several independent data sources to get a more complete picture of the observed phenomenon.
Competitive data fusion	Using several independent data sources to get independent measurements of the same characteristic.
Sensor level fusion (low level fusion)	The raw data of the sensors is processed closely together.
Object level fusion (mid-level fusion)	Data of each sensor is preprocessed separately before it is fused.
Information level fusion (high level fusion)	Data fusion systems in which the involved input sources already contain a complete data processing, in order to provide semantic information.

Applications—Intelligent Vehicles: Driver Information

Bernd Rech, Stephan Glaser, and Christian Wewetzer

Volkswagen AG, Wolfsburg, Germany

1 INTRODUCTION

This chapter gives an overview about the current state and possible future of driver information applications. In the context of telematics, a driver information application can be regarded as a software component that wirelessly receives data, processes it, and presents it to the driver and/or the passengers with the goal of supporting long-term decisions (e.g., what route should the driver select) or short-term decisions (the driver should react soon because of a certain event) in driving, or providing other information relevant to the trip (e.g., historical information on nearby landmarks) or the comfort of the driver and passengers (e.g., a personalized entertainment program). In this sense, three classes of driver information applications can be distinguished:

- strategical applications with a horizon of several kilometers (route choice, planning the trip);
- tactical applications with a horizon of a few hundred meters (notification/recommended actions regarding events right ahead);
- value-added services/entertainment (making a trip entertaining, informative, and convenient)

From a system architecture point of view, a driver information application is a part of a driver information system. This system can be split up into two domains: a vehicle domain and an infrastructure domain. Concerning the vehicle domain, a driver information system consists of a communication unit for wirelessly sending and receiving data, a processing unit for evaluating data, and a human–machine interface to interact with driver and/or passengers. The infrastructure domain can, in short, be regarded as one or more data centers where information for vehicles is hosted and preprocessed.

While this chapter does not cover issues around the human–machine interface for driver information applications in vehicles, some general guidelines hold when designing such interfaces. Driver distraction should be avoided in all cases—a holistic concept-of-use for all different interfaces in the vehicle (e.g., multifunction display, navigation screen, and speakers) should increase driver awareness and understanding of the current traffic situation. Furthermore, applications should be designed considering the driver and the vehicle need for security and protection of privacy. Finally, the already large and always increasing number of public, private, free-of-charge, and commercial sources offering information for such application creates a challenge: when two or more sources have different or even contradictory information for a road

ISBN: 978-0-470-97402-5

segment, which version is correct? This assessment should not be left to the driver, but the vehicle should have enough meta-information available to evaluate information accuracy and timeliness.

The ultimate goal of the driver information applications is to inform—not to decide. The driver should not be overstimulated. The driver should be aware of the traffic situation on his or her journey, know about possible alternatives and consequences when driving. The well-informed driver will make well-thought-out decisions.

First, in Section 2, the technologies relevant for driver information applications are identified. Second, the different types of driver information applications are outlined: value-added services (Section 3), strategical driver information applications (Section 4), and tactical driver information applications (Section 5).

2 TECHNICAL ASPECTS

Driver information applications over recent years have experienced a surge of innovation. To understand the circumstances that led to this, it is interesting to look backward on means of driver information in the past. Until the 1990s, the only means of driver information were a map, the signs along the road, and the radio. Thanks to the breakthrough of personal computers and their increasing processing power; first route planning applications for home personal computers were released based on a digital map. These applications took the task of route planning over for the driver—of course, this was static before departure. Then, in the 1990s, three additional technology breakthroughs again changed the navigation and telecommunication world:

1. With the global positioning system (GPS) becoming available for civil use, it was then possible to identify the position of a vehicle, enabling the first in-vehicle navigation systems (see Technologies—Positioning: GNSS).
2. The Internet evolved and formed the basis for the evolution of services and online communities available nowadays.
3. Mobile communication systems [GPRS (general packet radio service), EDGE (enhanced data rate for GSM evolution), UMTS (universal mobile telecommunications system), and LTE (long term evolution)] paved the way for packet-based communication to and from vehicles (see Technologies—Communication: Mobile).

Because of the longer innovation and development cycles in the automotive domain, it took until the end of the 1990s and the beginning of the twenty-first century for new technologies to be introduced in vehicles, resulting, for example, in detailed and updated digital maps and new means of dynamic trip planning.

Some applications mentioned in the following sections, such as an emergency vehicle warning, are highly localized, in the sense that this situation affects only vehicles in the immediate vicinity. From a network design perspective, with respect to scalability, ideally vehicles should communicate directly and locally instead of relying on the infrastructure of a cellular network and a data center. This physically keeps the communication network traffic in the area where the information is relevant. As a solution, the automotive industry is working on a communication technology to enable *ad hoc* direct short-range wireless communication among vehicles, as well as between vehicles and road-side units: IEEE 802.11p (adopted in Europe according to the local frequency regulation as profile standard ETSI ITS G5) (see Technologies—Communication: Wireless LAN-based Vehicular Communication), which is a variant of the IEEE 802.11 [wireless LAN (local area network)] standard (IEEE Computer Society LAN/MAN Standards Committee, 1997). This technology enables communication with a latency of less than 10 ms (Lin *et al*., 2010) in situations where the driver needs to be aware of and/or take immediate action (tactical driver information applications). To make efficient use of the wireless channel, in Europe, it is intended that applications make use of two multipurpose messages instead of each application having its own message: the cooperative awareness message (CAM) (European Telecommunication Standards Institute, 2011), which is a heartbeat message with information such as position and speed that each vehicle sends periodically, and the decentralized environmental notification (DEN) (European Telecommunication Standards Institute, 2010), which is an event-based message.

In the past, many service providers and communities around the world have regionally deployed wireless access points based on the wireless LAN standard. These networks are intended for people to connect to a local network or the Internet, or to provide local point-of-interest information. With a corresponding communication module, such access points can also be accessed from the vehicle to retrieve information from a local server or a data center in the Internet. Figure 1 depicts all the aforementioned communication technologies in a comprehensive scenario.

3 VALUE-ADDED SERVICES

With the help of telematics, a wide range of value-added services can be offered in the vehicle. These services can be classified into map-based and map-independent services (Figure 2).

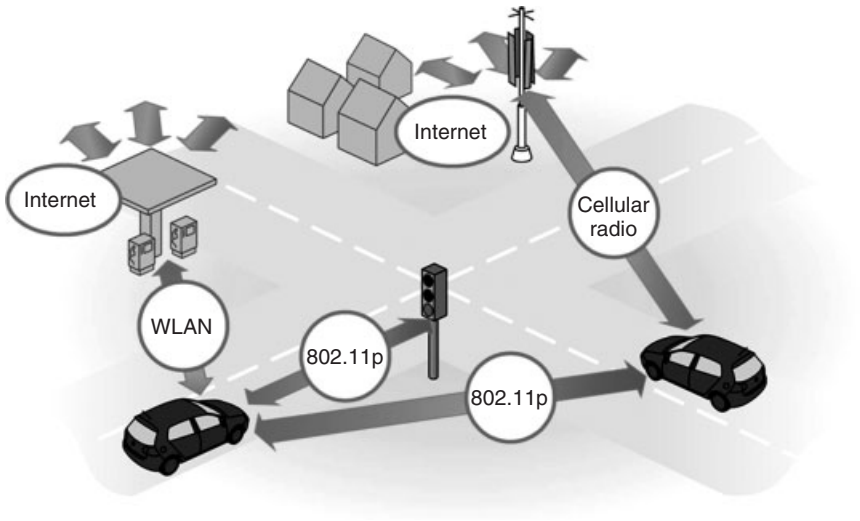

Figure 1. Illustration of communication technologies for driver information applications.

Figure 2. Community-based information in a map.

In general, all kind of information attributed with location data can provide an additional layer to a digital map (Cristani *et al*., 2008). The augmentation of a digital map with points of interest such as restaurants, landmarks, and shops is a typical example of a map-based value-added service. The map view can also be enhanced with aerial or satellite images, or with geo-tagged pictures from the area.

Another possibility is to integrate a friend-finder application (Palazzi, 2004), so that a live view of companion vehicles on the map is provided.

Many map-independent applications are available to increase the comfort of the driver and passengers. Vehicle diagnostics applications monitor the internal vehicle diagnostics status and can help in maintenance scheduling and preparation of the service at the dealership. A personal vehicle homepage on the Internet (see Figure 3 for an illustration) is a variant of a web portal (Tatnall, 2005) to display detailed vehicle status information, for example, on fuel consumption, and allow the remote upload of music as well to check and control the door lock status. Communication applications connect customers by means of voice e-mail and text messaging. An emergency crash response application transmits crash-relevant data such as location and impact speed to the service provider and/or emergency call center. Crisis assist services offer personalized assistance in providing detailed situation reports and giving directions out of dangerous situations. Stolen vehicle assistance is a security application that allows for features ranging from GPS-based tracking to possibly disable stolen vehicles.

Another value-added service is Internet radio, a very valuable addition to terrestrial audio broadcast services. It provides additional radio channels and, in particular, a multitude of special-interest programs. Further, the set of available stations does not depend on the location of the user and subscription fees do not exist. As audio entertainment is the most prominent form of in-car entertainment, it is very desirable to offer Internet radio to the driver. This holds especially true for markets where

Figure 3. Personal vehicle portal in the Internet.

special-interest stations are not available through broadcast services. Cellular data services are currently the only available technology to enable such a data service with reasonable coverage.

Challenges of in-car Internet radio are connectivity related. While data rates required to transport audio material are moderate, there exist precise constraints for data delay. If packet delays exceed a given threshold, playback gaps affect the user experience. Delays in packet transmission especially occur within cells under heavy load and when channel conditions are poor. Using a large-sized buffer at the receiver mitigates this problem but leads to long waiting times at startup and channel switching.

Remedies for these problems are server-based buffering methods or quality-of-service guarantees by the provider. The latter may become available by mobile networks of the fourth generation.

4 STRATEGICAL DRIVER INFORMATION: NAVIGATION AND EFFICIENT DRIVING

4.1 Navigation and traffic information

Navigation systems take over the task of finding a preferable route to the destination and providing the driver with directions while in traffic. Thus, the driver is able to focus more on the current traffic situation, reacting only to precise acoustic and visual driving instructions. Thereby, navigation systems certainly deliver increased comfort for drivers and passengers before and during the journey. Without navigation systems, getting directions on the journey and planning possible detours is often only possible with the help of a passenger, and are subject to errors because navigation and decision-making often happen as immediate reaction to changes in the traffic situation.

While navigation even without online connectivity is already an immense improvement over passenger-assisted navigation, the underlying map data is static. Thereby, it is already a common practice to include time-dependent travel times per segment. This way, recurring impacts such as rush-hour traffic are considered. Unforeseeable events (e.g., accidents, weather conditions, and road works) are not reflected in this map, which is why the computed travel time may become inaccurate on a journey. Ideally, the vehicle would be aware of all incidents and current travel times on the candidate routes (Figures 4 and 5). While travel time is the main decision criterion for most drivers, other factors such as fuel efficiency can be additional decision criteria. Map providers have recognized this, and nowadays, digital maps are available that include detailed information relevant for fuel consumption.

Contemporary navigation systems improve the lack of incident information in static maps by including information from the radio broadcast service traffic message channel (TMC) (Traffic Message Channel (RDS-TMC), 2003). As of 2012, TMC is available in most European countries, Russia, North America, China, and Australia, as well as in some countries in South America and Africa (TISA, 2012). This free-of-charge service is complemented by national commercial services, such as Navteq Traffic (formerly known as *TMCpro*) in Germany. Roadside sensors, inductive loops, and a number of vehicles provide their travel-time measurement as information sources of these services.

Besides receiving radio broadcasts, travel time and incident data can be acquired from service providers with the help of telematics. Thereby, a vehicle can play two roles: it can be information consumer (receive data) and information provider (send data from current/past journey). Nowadays, a large number of free and commercial fleet-based services are available. Waze is an example of an open-source community software for providing traffic information (Lequerica *et al.*, 2010; Milo, 2011). HD traffic from TomTom (Schäfer, 2009) is a commercial example, which

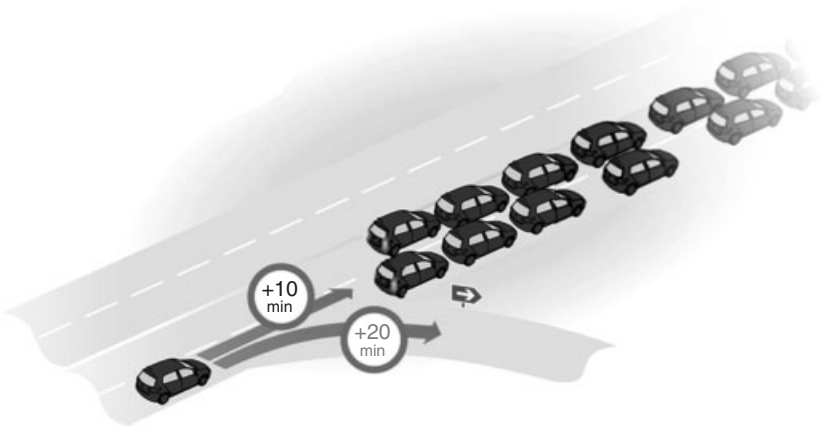

Figure 4. Travel time information.

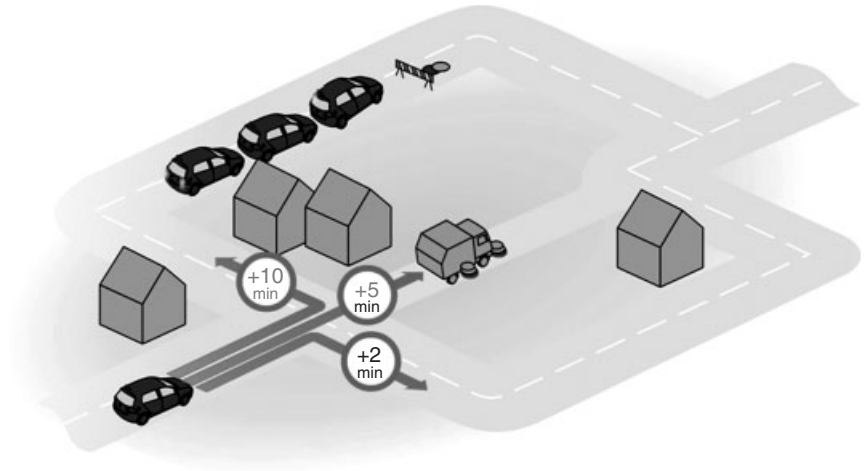

Figure 5. Incident information.

collects movements of mobile phones and GPS traces from the TomTom devices equipped with GSM modules to calculate travel times.

In research, ideas have been developed and evaluated for a wireless LAN-based self-organizing traffic information system (SOTIS) (Wischhof *et al*., 2003). Thereby, the vehicles would receive, aggregate, carry forward, and redistribute information to other nearby vehicles. Finally, telematics enable updates of all map data, for example, to include new roads or reconstructed road networks.

4.2 Parking and charging

Parking is a major issue especially when traveling into crowded regions. With the emergence of electric vehicles, it can be expected that also the availability of charging spots will play a role in destination and route choice. The associated parking search traffic is a burden for the population and other drivers. The availability of parking and charging spots affects route and destination choice in these areas; thus, the provision of accurate availability information is an important strategical driver information application. Nowadays, a number of cities already provide information on available parking spots in the Internet.

In future, it is also conceivable that vehicles distribute such information via short-range communication (Caliskan *et al*., 2006). With the vehicle sensors available nowadays, it is possible to detect free parking spots (Park *et al*., 2008). While these sensors provide information on currently available parking spots, the most convenient and reliable way of traveling would be to reserve a specific parking

spot for the time of arrival with the help of a booking system (Hilton, 1989).

4.3 Fleet management

Since the 1990s, shipping companies have deployed fleet management systems (FMSs). The first FMSs consisted of a trip optimization system, personnel and vehicle planning, customer databases, order processing, and invoice processing. In the beginning, trunked radio was used for communication with the driver.

With mobile communication and navigation systems, communication between the fleet and the control center is increasingly automated (Thong *et al*., 2007): vehicles are located and delivery status updates are provided. Delivery routes are adapted based on the traffic situation. Drivers can also ask for support in case of delivery problems, which minimizes search traffic and fleet downtime.

4.4 Multimodal trip planning

Even though many vehicles are equipped with navigation systems, journeys are still frequently planned well before the driver enters the vehicle. Applications for home personal computers or mobile devices such as smartphones can support the driver in planning his or her journey. Such planners can be multimodal, in the sense that they do not only include the vehicle but also other means of transport (Rehrl *et al*., 2005; Booth *et al*., 2009; Bustillos *et al*., 2011). In such planners, the user enters a destination and several means of transport (own vehicle, car-sharing, bus, train, aircraft, etc.) are then compared with regard to travel time, cost, and enviroment-friendliness.

5 TACTICAL DRIVER INFORMATION: WARNINGS AND RECOMMENDED ACTIONS

Tactical driver information applications improve traffic safety and efficiency. Drivers are given recommendations for accelerating, decelerating, or steering maneuvers, and/or they are warned of incidents right ahead to support anticipatory driving.

With the help of telematics, vehicles may immediately notify other vehicles (either directly via short-range communication or indirectly via mobile communication with a data center) when detecting dangerous situations. One example of a hazard warning is depicted in Figure 6, where a vehicle is notified of an approaching emergency vehicle. An emergency vehicle approaching an intersection is a dangerous situation, which requires the increased attention of all nearby vehicles. With communication among vehicles, the emergency vehicle is able to report its position, speed, and driving direction, so that other vehicles are aware of the situation and can react accordingly (Buchenscheit *et al*., 2009). In the end, this helps avoid accidents and supports the emergency vehicle to reach its intended destination as fast as possible.

When a lead vehicle is braking, for example, because of an obstacle ahead, the driver of the vehicle immediately behind is warned by the brake lights. Other vehicles behind often are unable to observe this braking maneuver (Figure 7). A warning message generated, in the case of a hard-braking maneuver, can help in anticipatory driving and avoiding rear-end collisions (Zang *et al*., 2008; Segata and Lo Cigno, 2011). This also avoids congestion of vehicles in dense traffic and thereby smoothens traffic flow.

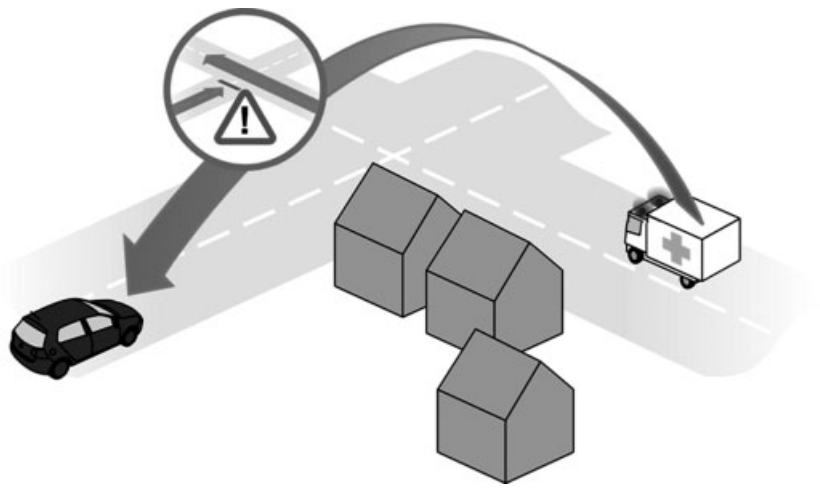

Figure 6. Emergency vehicle warning.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

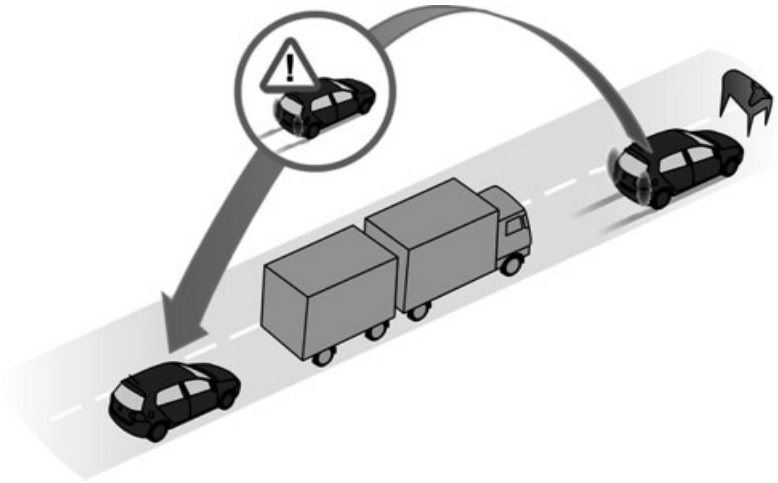

Figure 7. Electronic emergency brake lights.

Further examples of hazardous situations are slippery roads or reduced visibility because of heavy rain, snow, fog, smoke, or sand. Another kind of dangerous situation arises when a vehicle must stop. It may be easy to spot in an open-space environment, but when located behind a turn or a hill, there is always a risk that the driver of an approaching vehicle does not notice it. In this case, there is an increased accident risk. Thus, the stopped vehicle can warn approaching vehicles, for example, by sending warning messages when the vehicle warning lights are switched on or a deceleration threshold is reached. Such a warning message can also be sent by emergency vehicles securing a dangerous location. Dangerous situations may also occur at the end of a traffic jam, which are often difficult to detect by approaching vehicles, especially, when the line of sight is obstructed, for example, by a curve. However, when provided with an awareness of positions and speeds of vehicles in its vicinity via short-range communication, a vehicle can recognize it is approaching or is a part of the end of a traffic jam and report this situation to other vehicles (Kojima and Tsugawa, 2008; Padron, 2009; Bauza *et al*., 2010).

The aforementioned applications for dangerous situations in traffic are cooperative vehicle-to-vehicle applications (Caveney, 2010): they rely on vehicle-to-vehicle communication—either directly via short-range communication or indirectly via a data center. Such cooperative applications—such as telephones at the times they were introduced—suffer from network effects: the first vehicle equipped with a new communication technology will have no or only few other vehicles as communication partners. Thus, except for the feeling of being a pioneer, the use of these applications is very limited.

Therefore, the introduction of these cooperative applications should happen hand in hand with measures on the road infrastructure side; for example, the equipment of traffic lights to enable the provision of traffic light phase schedules. Figure 8 illustrates the idea of this application, which can greatly improve traffic efficiency (Wegener *et al*., 2008; Katsaros *et al*., 2011). By broadcasting its phase schedule via short-range communication, the traffic light helps vehicles waiting at the intersection to prepare for the upcoming green phase, increasing throughput at the traffic light. This can be further improved when the vehicles communicate with each other to help coordinate the driver to start and accelerate at the traffic light.

Vehicles approaching the traffic light can benefit from the phase schedule information by adapting their approaching speed accordingly. This way, vehicles can drive fuel efficiently by adapting to green waves and avoiding unnecessary braking. When traffic lights are equipped with wireless communication units, it is also conceivable that they receive information that vehicles are approaching or waiting at the traffic light. This way, wireless communication can be regarded as another sensor in addition to (or instead of) loop detectors or cameras. The traffic light can then adapt its schedule to the current traffic conditions.

Like traffic light phase schedules, information on traffic signs for the route ahead (especially, variable message signs) can be provided to vehicles. Technically, this could happen via short-range communication or via cellular networks and a data center. This way, for example, a vehicle could be able to detect when a driver is in the risk of passing a red light and issue a warning when appropriate. Vehicles may receive information about road construction, where orientation may be difficult especially when combined with

darkness or adverse weather conditions. Therein, information on lane geometry and the current traffic conditions at the construction site are important.

GLOSSARY

CAM	A cooperative awareness message (CAM) is a heartbeat message that each equipped vehicle sends out periodically delivering information such as position and speed.
DEN	A decentralized environmental notification is an event-based message delivering information about events such as obstacles on the road or the end of a traffic jam.
FMS	A fleet management system is typically used by the operators of a commercial vehicle fleet consisting of a trip optimization system, personnel and vehicle planning, customer databases, and order and invoice processing.
ITS G5	ITS G5 is a standardized protocol based on IEEE 802.11p, which defines enhancements to IEEE 802.11 necessary for vehicle-to-vehicle communication.
Multimodal	A multimodal trip includes not only the vehicle but also others means of transportation such as train or bus.
Network effect	The network effect describes the phenomenon that the first vehicle being a part of a cooperative system will have no or only few other vehicles as communication partners. Hence, the use of these applications will be limited.

Driver Assistance

Dirk Wisselmann and Werner Huber
BMW Group, Munich, Germany

1 INTRODUCTION

The term *driver assistance* describes, in a literal sense, the capability of a vehicle to support the driver in his or her driving task. In the context of *intelligent vehicles*, this term is used for vehicle functions that measure and interpret the near and far-field driving environments using appropriate sensor technology. A key characteristic for categorizing these functions is the so-called "degree of automation," ranging from

- informing (e.g., display of current speed limit);
- warning [e.g., lane departure warning (LDW)];
- actively intervening (e.g., distance and speed control) to
- autonomously acting systems.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto179
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

According to the RESPONSE definition (ACEA, 2009), the so-called advanced driver assistance systems (ADAS) monitor vehicle surroundings and can (autonomously) take over control of the lateral and/or longitudinal movement of a vehicle under defined circumstances, as long as the driver does not intervene. ADAS are generally characterized by the following features. They

- support the driver in his or her primary driving task;
- provide active support for lateral and/or longitudinal control;
- detect and evaluate the vehicle environment;
- use complex signal processing;
- enable direct interaction between the driver and the system.

ADAS aim to improve driving safety, efficiency, and comfort. The design task requires separate objective quality measures for each of these aims.

With the goal of achieving maximum *safety performance*, ADAS are designed for particular critical driving situations, such as unintentional lane departures or impending rear-end collisions. The criticality assessments of these situations are derived from detailed accident analyses and statistics, which are utilized to generate objective requirements on ADAS design. Objective criteria for *efficiency* (e.g., CO_2 emission per kilometer) can be derived in a similar manner.

Definition of objective ADAS design targets for *driving comfort* is complicated by the need to consider multiple aspects: increased driving comfort from the driver's point of view is achieved when driving burden is reduced and subjectively experienced driving enjoyment is increased. However, the relationship between burden and performance also needs to be considered, as shown in Figure 1. In the low workload regime, that is, in monotonous situations such as driving in traffic jams, automatic braking and acceleration

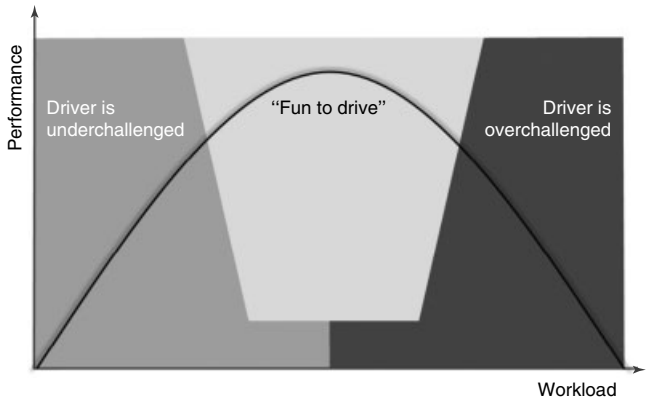

Figure 1. Driver performance versus workload (comp. Yerkes–Dodson law). (Reproduced by permission of BMW AG.)

by the vehicle reduces the driver's burden and is perceived quite positively by drivers. On a demanding, curvy stretch of road—a driving situation with typically moderate workload and requiring high performance—activation of the same function is perceived negatively by drivers, who usually enjoy driving curvy stretches of road, because system activation would actually decrease their enjoyment. In such situations, drivers are usually content with information and light/sight assistance, systems that preserve or enhance the driver's driving competence. If the driver is over-challenged, advanced driving assistance is strongly appreciated and can even play an essential role in avoiding accidents. A typical example of a conflict situation that over-challenges the driver is an impending pedestrian collision. Here, preventive safety systems can contribute strongly to accident prevention or at least mitigation of accident severity.

ADAS should be specifically designed for different driving situations, so that a "symbiotic" relationship between the driving task and the controller functionality of the ADAS is established. Consistent with this strategy, several general design principles can be formulated (Kompass and Huber, 2006) to guide development:

- ADAS operate like a virtual copilot;
- ADAS increase the competence of the driver;
- ADAS are supportive and do not dominate the driver;
- ADAS can always be overridden;
- ADAS can be operated intuitively and simply;
- ADAS can be switched on/off any time by the driver;
- ADAS exhibit transparent system behavior;
- ADAS are controllable with low effort;
- ADAS keep the driver activated;
- Individual ADAS functions interact flawlessly.

In general, driver assistance systems should always be oriented toward the driver's need for support in a particular driving and should consider the traffic situation. The degree and extent of automation appropriate for each driving task should be determined within a comprehensive, self-consistent concept including considerations such as customer acceptance and compliance, product and market philosophy, product liability, and impacts on traffic (Naab and Reichart, 1998, Bubb 2003). ADAS should support the responsible, active driver in his or her role as the controlling element in the system of driver–vehicle–environment. This requires a clear separation and recognition of the roles of the driver and the system. This recognition is particularly important at the boundaries of function activation, where controllability must be assured and over-challenging the driver is to be avoided.

2 BRIEF REVIEW OF PROMETHEUS

The essential groundwork for modern ADAS was laid in the research project "PROMETHEUS" (PROgraMme for a European Traffic of Highest Efficiency and Unprecedented Safety), which was carried out from 1987 to 1994 (Braess and Reichart, 1995). Figure 2 illustrates the project vision, which aims toward intermodal traffic with maximum safety and efficiency by means of comprehensive, mutual networking of all participants in traffic. The basic vision of the project is still valid even today. Automatic cruise control (ACC), which was the first ADAS capable of influencing vehicle dynamics that achieved production status in Europe, was mainly developed within PROMETHEUS. Key elements of image processing and night vision technologies were also advanced in this trend-setting project. Internationally, comparable projects were also carried out in Japan (ASV) and the USA (California Path), though with a smaller number of partners and a more limited scope.

3 ROLE OF ENVIRONMENT SENSING

The fundamental requirement for driver assistance systems is data acquisition to measure the vehicle environment using machine perception (Figure 3). The degree of support for tasks previously carried out by the driver is directly dependent on how comprehensively, completely, and reliably the information available to the assistance system can be supplied. Data and information can be acquired from sensors (e.g., radar, digital video processing, and lidar), telecommunication (e.g., GSM), on-board knowledge bases (e.g., navigation data), or a combination of these approaches. However, none of the currently available

sensor systems can provide a comprehensive, 100% reliable representation of the driving environment under all relevant traffic and environmental conditions. An appropriate methodology for integrating uncertain information is thus a key aspect of development and design of driver assistance systems. Approaches for dealing with uncertainty include utilization of data redundancies or model-based plausibility testing, use of *a priori* or contextual knowledge as well as sensor data fusion. Owing to this complexity, enhancement and optimization of environmental sensing and scene

interpretation continue to represent one of the main challenges in ADAS development (Maurer and Stiller, 2005).

4 ADAS STATE OF THE ART

Figure 4 shows an overview of the key ADAS introduced into the European market since 1990; the number of functions has increased dramatically since 2005. This process began in the premium and upper intermediate market segments; however, currently, "basis driver assistance systems" [ACC, LDW, lane change warning (LCW), etc.] are quite prevalent even in the lower intermediate segments and are being rolled out in the economy segments. The trend toward both a broader range of vehicles offering ADAS and an increase in the number of available functions has encouraged stronger customer awareness and thus increasing demand for ADAS in new vehicles.

In the following section, important, "representative" driver assistance systems (classified according to the vehicle functions comfort and safety) are discussed in detail (Winner, Hakuil and Wolf, 2009, Eskandarian, 2012).

5 ADAS-FUNCTIONS FOR COMFORT

5.1 Automatic cruise control (ACC)

5.1.1 Basis function

As in conventional cruise control, ACC automatically regulates the vehicle speed to a target speed set by the driver. However, if there is a slower vehicle in front, ACC extends ordinary cruise control by regulating the driver's speed to consider the leading vehicle's speed and to maintain a following distance close to a target determined by the driver. Figure 5 illustrates the functionality of an ACC system. The limits of acceleration and deceleration for ACC are determined by the ISO 15622 norm. In the interests of maintaining a safety margin, these limits are set well below the corresponding values that the vehicle is technically capable of reaching. The first ACC systems were able to be activated in the speed range from 30 to180 km/h. With the advent of the so-called Stop&Go function, the current speed range of more advanced systems has been extended to include a complete stop of the vehicle, so that advanced

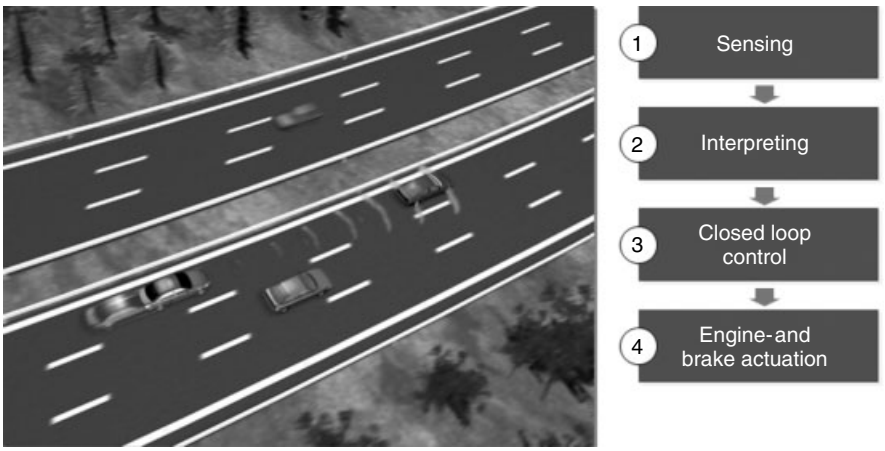

Figure 5. Principles of automatic cruise control. (Reproduced by permission of BMW AG.)

systems continue to operate even in traffic jam situations. This capability was enabled by additional sensors acting to secure the area immediately in front of the vehicle.

5.1.2 Sensors

All ACC systems currently on the market in Europe utilize radar sensors for distance and speed measurements. This choice of sensors is mainly due to the robustness of radar sensor measurements under adverse weather conditions and the ability to directly measure the leading vehicle's speed by the Doppler effect. Systems operating with lidar or stereo camera sensors are available in Japan.

5.1.3 Human–machine interface

The system is operated either by a lever located on the steering column or by buttons on the steering wheel itself. The driver can observe that a leading vehicle has been detected and that speed control is active either in the information display or in the head-up display.

5.2 Lane-keeping support (LKS)

5.2.1 Basis function and sensors

In addition to the longitudinal control (acceleration/deceleration), the driver must continually exert lateral control (steering) as a second control task: the lane-keeping support (LKS) system serves to support this driving task. Using a CMOS (complementary metal-oxide semiconductor) camera, lane separation markings of the current lane are detected, so that the lateral position of the vehicle relative to lane separation markings can be measured. Using this input signal, LKS steers the vehicle (in most cases) toward the center of the lane. The main aim of LKS is to enhance driving comfort by supporting lane keeping. LKS also leads to increased safety as a secondary benefit by preventing unintended lane departures (compare safety function *Lane departure warning*).

5.2.2 Human–machine interface

In addition to the on/off switch, the human–machine interface (HMI) of a lane-keeping system includes a readiness display indicating operating status (availability). It informs the driver whether the camera has detected lane markings and thus indicates whether the system is ready. A further key driver feedback loop utilizes a "haptic" channel, that is, by steering wheel movements informing the driver whether or not the system is properly operating. By utilizing the driver's sense of touch, the vehicle can rapidly and dependably signal the driver that he or she needs to take over lateral control if required.

5.3 Parking maneuvers

5.3.1 Basis function and sensors

Parking (particularly parallel parking) was the first task supported by driver assistance using environmental sensors. Using ultrasound sensors, parking distance control (PDC) informs the driver of obstacles within about 3 m of the vehicle to the front and sides. Since the introduction of PDC, the number of different parking functions has increased substantially. These new capabilities and completely novel functions are partly due to installation of video cameras as additional sensors (e.g., top view). In addition, the original, purely informative PDC systems have been extended to active systems. Parking maneuver

assistants automatically measure potential parking spaces and steer automatically into the space. Table 1 shows a summary of current parking functions, classified according to whether they display information or actually steer the vehicle.

6 ADAS SAFETY FUNCTIONS

6.1 Forward collision warning (FCW) and forward collision avoidance (FCA)

Forward collision warning (FCW) and forward collision avoidance (FCA) aim to avoid rear-end collisions with a leading vehicle or mitigate their severity and are offered by practically all motor vehicle manufacturers. The term *precrash* system is often used synonymously, but in fact precrash systems usually include preventive activation of passive safety devices in the vehicle as an additional feature.

Although details vary according to design, four distinct phases of a possible accident sequence (Figure 6) can generally be distinguished for system operation. These phases are triggered according to the estimated time to collision (TTC), which is computed on the basis of sensor information and kinematics as the time available until a collision. During the first phase, the brakes are prepared for rapid emergency response by lowering the brake assistance threshold and

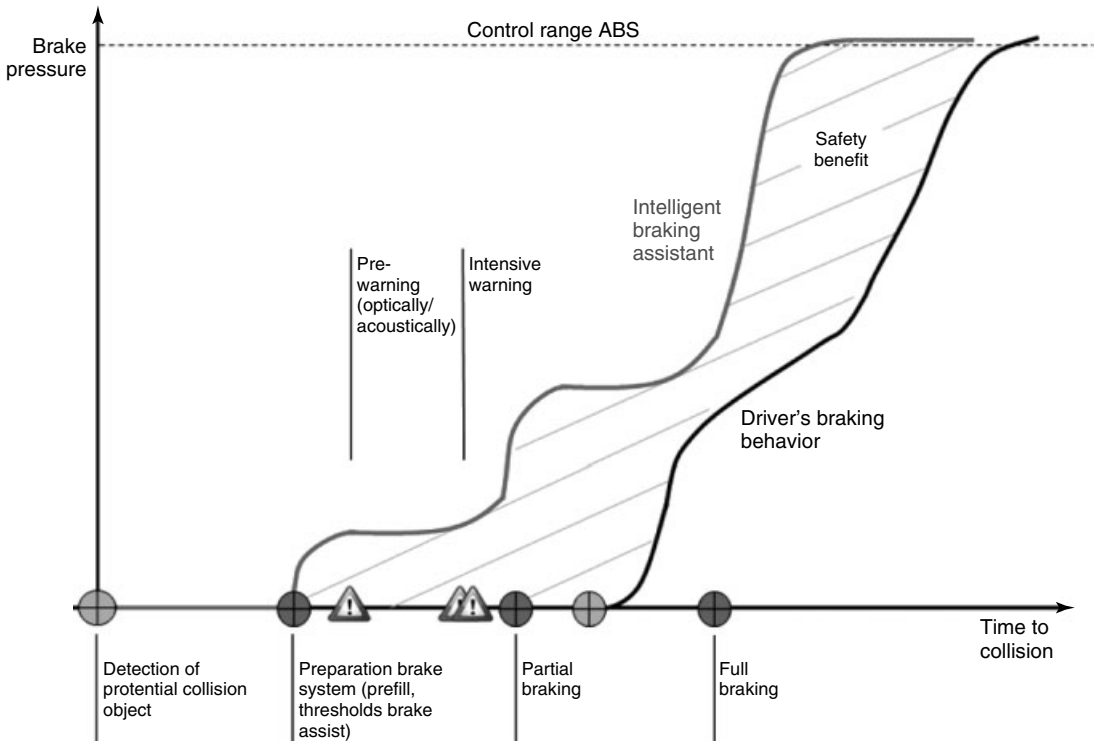

Figure 6. Phases of AEB systems. (Reproduced by permission of BMW AG.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto179
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

by prefilling (a slight increase of hydraulic pressure); these steps occur typically by a TTC of 2.5 s. During the second phase (generally between 2.5 and 1.5 s before collision), the driver receives an acoustic, haptic (touch), or kinesthetic warning. The third phase is characterized by active deceleration, that is, braking at about 4 m/s^2, with the aim of reducing the energy that needs to be absorbed at impact. Usually, this phase is supported by an intensive acoustical warning (acute warning). If a collision is unavoidable ("point of no return"), maximal braking deceleration is triggered for about 0.5 s.

As far as sensors are concerned, systems are mostly based on forward-looking ray sensors (radar and lidar) or cameras. The situations and speed regimes (e.g., urban or freeway traffic) that can be effectively addressed depend on the sensors or sensor combinations installed. Owing to the need to grab the driver's attention and focus on the task of rapid, effective accident avoidance actions, a key design element is the display concept. Depending on collision risk assessment, passive safety devices in the vehicle may be preconditioned, for example, by pretensioning seatbelts, closing windows, and placing seats in the optimal position. Owing to the relevance in accidents, forward front protection systems are on the way to become mandatory items, for example, in European Union (EU), from November 1, 2015 onwards for all new trucks.

6.2 Protection of vulnerable road users

In the past, the focus of vehicle-based preventive pedestrian systems was directed to passive safety, with the goal of mitigating the consequences of pedestrian collisions. More recently, the importance of preventive active pedestrian safety measures is increasing rapidly—owing in large part to European regulatory and consumer protection initiatives. If there is an impending collision, these active systems aim to avoid the collision entirely or at least decrease collision severity by countermeasures taken during the precrash phase. Effective operation of active pedestrian protection systems requires sensors capable of rapidly and reliably detecting pedestrians, a computational logic for estimating and updating collision probability and a decision logic for selecting and activating the appropriate warning and/or intervention sequence. Collision probability is estimated on the basis of analysis and prediction of the relative trajectories of the vehicle and the pedestrian. Analog to the aforementioned collision warning systems, a sequentially escalating warning and intervention strategy is also used for preventive pedestrian protection:

- timely warning of the driver;
- preparation of the braking system by prefilling (intelligent braking assistant), so that maximum braking pressure is immediately supplied if the driver initiates any braking response at all;
- active braking intervention up to maximum braking to reduce the collision speed, which has a direct impact on injury severity;
- in the future, active support of swerving to avoid the pedestrian.

Cameras, laser scanners, or photonic mixing devices (PMD)—possibly with radar sensors—are utilized for pedestrian detection. The sensors have the task of monitoring the region in front of the vehicle and proving timely and reliable pedestrian detection. These devices require a visual line of sight to the pedestrian; however, this requirement is unfortunately not always satisfied because of occlusion by objects in the way (e.g., delivery vans and parked cars). In order to detect occluded objects, considerable research is currently focused on cooperative measurement and tracking technologies that require radio contact between the vehicle and the pedestrian.

The driver is generally made aware of the hazard by means of an acoustic and/or optical warning or by a kinesthetic signal (e.g., a brief braking impulse).

Night vision assistance represents a special case of preventive pedestrian protection. Night vision extends the limits of human vision at night and thus enables foresighted driving even under low light or very low light conditions. Technologically, two current sensor approaches can be distinguished: far infrared and near infrared ("near" and "far" referring here to the closeness of the wavelength to that detectable by the human eye). The former technology is based on a heat-sensitive camera located at the front of the vehicle, which acts as a passive sensor and measures the "heat radiation" emitted by objects at a range of until 300 m in front of the vehicle. In the latter approach (a "near-infrared" system), the key sensor technologies consist of an active infrared light source together with a camera sensitive to near-infrared frequencies. A range of about 150 m can be achieved by this approach.

In the first-generation night vision systems, the processed infrared images were depicted in black and white on a vehicle display; warm objects such as animals or humans appear as lighter shapes on a darker background. The second-generation systems evaluate the camera image, highlight pedestrians or animals within the image, and warn in case of a collision hazard. In the third-generation devices, the driver's attention is focused directly onto the detected object by means of a targeted light beam, requiring an active light source (Figure 7).

Figure 7. Far-infrared night vision systems with active light beam. (Reproduced by permission of BMW AG.)

6.3 Lane departure warning

As the name suggests, the purpose of this function is to warn the driver against unintended lane departures. Most of current systems operate by detecting the lane boundary markings by video camera image processing. The forward-looking camera generates a warning before the vehicle actually reaches the lane boundary. There are also infrared-based sensors on the market. These sensors are located in bumper and operate by scanning the roadway to detect contrast changes. The resulting warnings typically occur significantly later than in camera-based systems. There are various modes or channels used for the feedback loop to the driver, which vary somewhat according to the HMI strategy and philosophy of individual manufacturers:

- vibration of the steering wheel before lane departure;
- compensatory torque on the steering wheel;
- generation of vehicle torque by an asymmetric braking intervention;
- side-coded acoustic warning and/or seat vibrations.

6.4 Lane changing and blind spot warning

Accident statistics show that more than 5% of all accidents take place during lane changes; a majority of these accidents occur on trunk roads or motorways (Bartels, Meinecke, and Steinmeyer, 2012). These accidents can be attributed firstly to a deficit of the driver in estimating the approach speed of vehicles seen in the rear-view mirror and secondly to the existence of a blind spot, essentially an area blocked by the vehicle itself, which is not visible in the rear view mirror. Planned (intentional) lane changing maneuvers are secured using an appropriate rear-facing sensor based on radar or video image processing that can identify vehicles approaching from the rear and the side. The driver establishes his or her intention typically by signaling the lane change. If the system identifies a lane change hazard, it warns the driver by light symbols located in the side mirrors or by vibrations in the signal lever or in an active steering wheel. The driver can respond by revising the lane-changing decision or by aborting a lane change already begun. ISO standard 17387 "lane change decision aid system" differentiates between three different types of systems. The "blind spot warning" monitors the blind spot on the left and the right adjacent to the driver's own vehicle. The "closing vehicle warning" monitors the adjacent lanes to the left and the right behind the driver's own vehicle in order to detect vehicles approaching from behind. The "LCW" combines the functions of "blind spot warning" and "closing vehicle warning" (Bartels, Meinecke, and Steinmeyer, 2012).

7 FUTURE ADAS

Aside from gradual refinements in current systems, three main trends can be identified for future ADAS:

- increased degree of automation in ADAS designed for increased comfort;
- introduction of novel ADAS for traffic safety;
- introduction of ADAS for improved efficiency.

7.1 Future ADAS for driving comfort

The next generation of ADAS designed to enhance driver comfort will exhibit an increasing degree of automation. The so-called "partially-automated" ADAS will be introduced during the next few years. An example of partial automation is the traffic jam assistant, which takes over both longitudinal control and steering of the vehicle under jam situations. However, partially automated ADAS are designed to be monitored by the driver at all times (BASt, 2012). The so-called "highly automated" ADAS are designed to go a large step further: the driver may at least temporarily delegate the driving task entirely to the vehicle (Waldmann and Niehues, 2010). According to current legal interpretations, highly automated ADAS are not approved for production in Europe. In addition, key liability questions posed by introduction of highly automated ADAS

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto179
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

remain unresolved until now. However, as, on the whole, these systems are generally thought to enhance traffic safety considerably, there is an ongoing dialog between manufacturers and public authorities with the goal of defining a process for achieving approval and for dealing with liability issues. The path toward highly automated driving is evolving gradually by continued development of current ADAS for driver comfort. Examples of this evolution are the extension of ACC and LKS to the traffic jam assistant and to the highway pilot, which are initially being introduced as partially automated functions but have the potential for further development as highly automated functions (Wisselmann *et al*., 2012).

7.1.1 Traffic jam assistant and highway pilot

In the traffic jam assistant, the vehicle performs both the longitudinal and the steering control tasks. This assistance is perceived by drivers as very pleasant in traffic jam situations, as he or she avoids the need to perform tedious, repetitive operations of steering and speed/distance control and can relax while observing the traffic situation. The traffic jam assistant utilizes sensor capabilities extended from the requirements of ACC and LKS to include measurement of the area immediately adjacent to the vehicle. Series production of the traffic jam assistant has been announced by the manufacturers BMW and Mercedes for the year 2013. Increasing the upper operating limit for vehicle speed in the traffic jam assistant results in the highway pilot, which supports comfortable freeway cruising. In this function, the transition from partial to high automation can be realized by means of sensors with an extended forward detection range. A highly automated highway pilot needs to be able to predict the traffic situation independently with a sufficient forecasting horizon to allow a driver who is completely out of the driving control loop, upon receiving a take-over request, sufficient time to react, become oriented, and resume control of the vehicle. Basic research to this end is currently being performed (Damböck *et al*., 2012).

7.2 Future ADAS for safety

Further development of ADAS for safety is dependent on expansion of the area in the vehicle environment that is monitored by measurements and on improved sensor reliability. Some novel sensor concepts will also be required, such as the Car2X technology in intersection assist. The three functions evasion assistance, intersection assistance, and emergency stopping assistance illustrate these relationships.

7.2.1 Evasion assistance

Steering and evasion assistance aim to avoid an impending collision with other traffic participants by a steering (swerving) maneuver. The function identifies the need for swerving by means of object detection in the area in front of the vehicle and assessment of the available stopping distance for a braking maneuver. If the available gap is insufficient to avoid a collision by braking, there may still be time to avoid the collision by swerving, and this may be the only feasible alternative. Three different system layouts can be distinguished: driver-initiated evasion, corrective evasion, and automatic evasion.

In driver-initiated evasion (swerving), steering activity initiated by the driver is supported, and dynamic stability and traction of the vehicle are automatically controlled. The function initially facilitates an agile initial steering impulse away from the hazard, then guides the vehicle around the obstacle along a stable trajectory, and prepares the vehicle for the reverse steering impulse. This layout prevents the vehicle from losing traction and achieves a stable trajectory around the hazardous object, but operates only if the driver initiates swerving.

Corrective evasion—which is not yet an available option—takes this function to the next level by introducing "system-initiated" evasive steering (swerving). Automatic evasion carries out the complete swerving maneuver automatically and is the subject of research activities in this area (Dang *et al*., 2012).

7.2.2 Intersection assistant

Several distinct functions are subsumed in the term *intersection assistant* (Ehmanns, Hopstock, and Spannheimer, 2005):

- turning/crossing assistance (prevention of collisions when a vehicle turns into or crosses an intersection);
- left/right-turn assistance (prevention of collisions with opposing vehicles that have the right of way);
- traffic light assistance (warning if the driver is about to run a red light);
- stop sign warning (warning if the driver is about to run a stop sign).

The full spectrum of intersection assistance functions places demands on detection of the vehicle surroundings that cannot be fulfilled by current vehicle-based sensors alone. These functions require communication-based Car2X technologies, a focus of current research, which can transmit data on obscured vehicles (SimTD, 2009).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

7.2.3 *Emergency stopping assistance*

The emergency stopping assistance function can be thought of as an intelligent vehicle service feature for health-related emergencies. The vehicle switches to high automation mode and carries out a secure emergency stopping maneuver (Kämpchen *et al.*, 2010): the vehicle activates the hazard flasher, carries out a controlled, independent maneuver to the road shoulder—while considering surrounding traffic and if necessary over multiple lanes—and stops there. The unique feature is that the vehicle goes beyond supporting the driver to take over the complete driving task, as in highly automated driving. The vehicle's maneuvering strategy is based on reliable localization of the vehicle within the current lane and in particular on detection of all other vehicles and objects in the immediate surroundings of the vehicle using a comprehensive sensor system and redundancy to provide robust detection. The emergency stopping assistant thus builds on available driver assistance systems but requires technical extensions and adaptations.

7.3 ADAS for efficiency

In the future, ADAS will also be designed for optimization of driving efficiency (Liebl, 2010). This aim can be illustrated by two functions:

7.3.1 *Signal light assistance*

A vehicle approaching a traffic signal will receive the scheduled phase change times by Car2X communication. If a stop is certain to occur, then the vehicle can carry out an optimal, energy-efficient brake sequence, for example, with recuperation and/or engine switch-off.

7.3.2 *Green ACC*

In the future, the ACC function will have the capability to optimize energy efficiency of the vehicle's longitudinal control (acceleration/braking). This function will require "data fusion," that is, processing of Car2X communication data (light phases) and integration with on-board sensor and digital map data. In this way, the vehicle will be able to anticipate its speed out to an "electronic horizon" and use this information to support optimal, far-sighted driving.

8 CONCLUSION

In the next few years, ADAS will continue to represent a key focus for innovation in vehicle development. The capabilities of the vehicle to create a comprehensive operational representation of the static and dynamic driving environment using sensors and communication are continually improving. These capabilities promise to increase the range and reliability of the vehicle's electronic horizon and generate substantial benefits for driving safety, comfort, and efficiency.

Road Traffic and Travel Information

Fritz Bolte
BASt, Federal Highway Research Institute, Bergisch Gladbach, Germany

1 DEFINITION

Real Traffic and Travel Information (RTTI) stands for all information that drivers need to plan their journeys, carry them out, and reach their destinations safely and in time. The range of information includes transport networks, usability of their parts, limitations with respect to their categories and regulations, existing and expected operational conditions, and travel times and costs. RTTI is used both pretrip with forecasts for travel disposition and on-trip real-time while driving to adapt driver behavior and route choice to prevailing conditions.

RTTI is provided through different information channels (see Technologies—Communication: Mobile, Technologies—Communication: Wireless LAN-based Vehicular Communication, Technologies—Communication: Broadcast), for example, radio broadcasts, RDS-TMC transmission, DAB services, telephone, mobile phone, and internet (Figure 1).

RTTI services are generally based on the following functions (see In-vehicle sensors, Data Acquisition by Roadside Detection, Technologies—Data Acquisition: Data fusion):

- Data collection
- Data fusion and processing
- Service provisions
- Data distribution

RTTI services usually include activities of various actors that need to cooperate on fixed rules and standards that are described below.

In this context, the focus is on road networks although extension onto other transport networks such as rail and air could be advisable. Intermodality would be a useful complement to exploit all possible transport facilities. The limitation on road transport should help to better understand existing RTTI systems, their possibilities and problems and emerging new developments.

2 OBJECTIVES OF RTTI

Safe and efficient transport systems are a precondition to modern life in a globalized world. Mobility of people and

ISBN: 978-0-470-97402-5

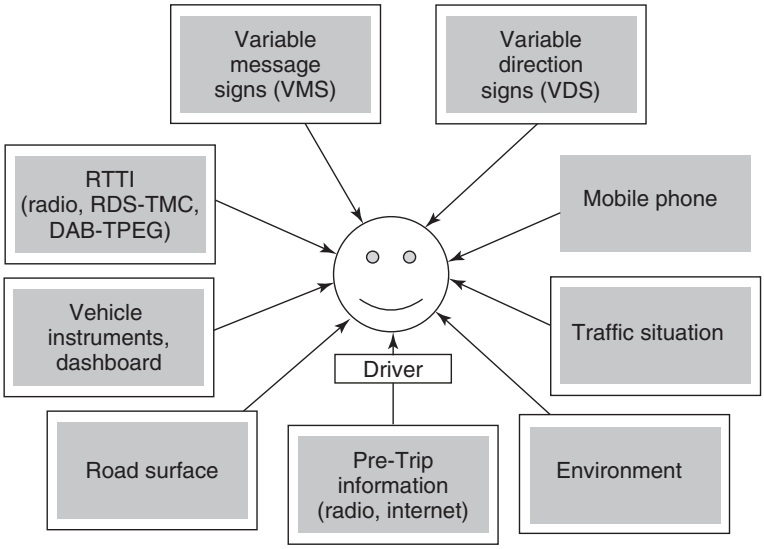

Figure 1. Driver information channels and sources. (Reproduced with permission from Bolte, 1997–2007. © Fritz Bolte.)

goods requires efficient transportation networks enabling timely accessibility of locations, production facilities, distribution and market places, recreational locations, and other places of interest. Quality of transportation is given high political priority.

In many countries, road networks carry the main load of transportation of people and goods as far as transport quantities are concerned; rail, ship, and air transport usually have different roles and importance.

2.1 Safety

Accurate, reliable, and on-time RTTI has the potential to increase the safety and efficiency of the transport system in many ways. With RTTI, road users can avoid congestion and bottlenecks, select alternative routes or transport modes, and avoid secondary accidents and incidents in urban areas and the motorway network. Informing the driver of the "operating conditions" of the traffic environment and the road conditions during her/his journey is the necessary complement to active and passive safety systems of the vehicle. Multiple services are in use in Europe, with various technologies (eSafety RTTI WG, 2007).

2.2 Exploitation of available transport capacity

The increase in the volume of road transport in the European Union associated with the growth of the European economy and mobility requirements of citizens is—together with roadworks and accidents—the main cause of increasing congestion of road infrastructure and rising energy consumption, as well as a source of environmental and social problems.

The response to those major challenges cannot be limited to traditional measures, inter alia the expansion of the existing road transport infrastructure. Innovation will have a major role to play in finding appropriate solutions for the European Union.

Intelligent Transport Systems (ITSs) are advanced applications, which, without embodying intelligence as such, aim to provide innovative services relating to different modes of transport and traffic management and enable various users to be better informed and make safer, more coordinated, and "smarter" use of transport networks (European Parliament and Council, 2010). RTTI systems are regarded as highly efficient tools to achieve these goals.

2.3 Economic aspects

Increasing congestion and accident numbers jeopardize transport economy and economic conditions generally. Transport costs are an important factor in globalized production and service provision. Vehicle and fleet operators need good and reliable transport conditions to deliver their goods and services as required and in time.

Another aspect is the negative impacts of traffic congestion on environment that require suitable and efficient measures against unfavorable traffic conditions and developments.

The creation and maintenance of favorable transport conditions is considered a political target of high priority. RTTI systems are regarded as promising tools to improve

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

traffic safety and transport efficiency and to reduce environmental impacts. Setting up and operating RTTI services is, on the one hand, challenging for engineers and organizers but, on the other hand, provides and safeguards employment.

RTTI services provide advantages for traffic flow and safety as well as for economic welfare. The introduction and operation of RTTI provides favorable potentials for high-end industrial products and various information services.

3 HISTORY OF RTTI, DEVELOPMENT, AND PROBLEMS OCCURRING

The various developments of new RTTI systems in many parts of the world reflect different geographic, economic, and technological environments and political demands in the respective countries. Design and layout of RTTI systems depend on frame conditions as set by the involved actors whose objectives may be identical, but may also be different or even conflicting. Basic information sources in this sense are drivers' experiences, their knowledge of the road network, and expected traffic and weather conditions. This store of knowledge may not be sufficient under all circumstances: additional input to the driver can be provided by RTTI systems that—due to their specific data provision—have a better overview about existing or expected road and traffic conditions.

It is difficult to identify the day traffic information services were started. In Germany, regular radio broadcasts of traffic information were set up as an answer to increasing congestion and the demand of drivers to be kept informed. Traffic broadcasting was started originally in the 1960s when increasing weekend and seasonal traffic caused heavy congestion on road networks. Drivers were warned against expected overloads of roads and especially of motorways. Information sources were experiences from the past that—in the following years—were complemented by traffic observations from police and motoring clubs with the help of patrol cars or helicopters.

With increasing motorization, more and more commuters used their cars on their way to work, and congestion became a daily phenomenon. Radio stations established daily traffic broadcastings every full hour, then every half hour, and finally by immediate program interruption for "urgent" traffic messages. Surveys revealed that traffic information was highly appreciated by most listeners and not only motorists. Consequently, all (public) broadcasters started competing against each other to provide high quality traffic information. Specific traffic information studios were set up gathering traffic information from different sources, for example, police, road maintenance units, emergency services, motoring clubs. Telephone and fax were used for communication between actors.

This caused a number of different results, positive and negative: on the one hand, more and better on-time information but, on the other, sometimes contradictory information from different sources. Another effect was an increasing number of traffic messages: drivers were "showered" with messages, most of which were irrelevant on their individual trip. Radio program directors and radio listeners were annoyed by increasing program interruptions caused by traffic messages.

In other countries, traffic information services originally were made up and operated by non-government organizations, for example, by motoring clubs or private and commercial entities, with the objective to provide good service to their members or to profit from revenues. However, despite differing developments, the problems were similar. New ways to overcome the difficulties had to be found.

The tendency to improve traffic information services through

- comprehensive information
- in-time messages
- correct messages
- understandable messages

overloaded existing radio and information technologies at the end of the 1970s. An additional challenge was the growing trans-border traffic caused by ongoing integration in Europe (European Union). International traffic means that a great number of foreign vehicle drivers are driving on European roads, who are not familiar with local road networks, traffic regulation, and signalization and do not understand local languages. They can hardly be reached by local traffic broadcast messages, although they may need them most urgently.

4 FUNCTIONS

RTTI systems include the following basic functions that had to be improved.

4.1 Data and information collection

Originally, police and road authorities had been the main providers of information from visual observations. From experience, they knew the "traffic hot spots" on the main arterials and reported incidents that occurred. With increasing traffic, the number of problem areas increased as well and it was more and more impossible to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

compile comprehensive and complete traffic reports. New information sources such as the following had to be found and exploited:

- Automatic detectors (such as inductive loops) as used for traffic management purposes to control variable message signs (VMSs) and variable direction signs (VDSs): Their data are used to automatically generate traffic messages. Usually automatic detection systems are installed in problem areas of high category roads (motorways, trunk roads). In some countries, commercial content or service providers have installed their own detection systems, especially on main roads such as motorways. As these roadside detection systems do not necessarily cover the complete network, "black spots" remain (see Applications—Intelligent Roads and Cooperative Systems: Urban Traffic Management, Advanced Highway Management Systems, Road Traffic and Travel Information (RTTI)).
- "Congestion reporters": Volunteers report, using mobile phones, their traffic observations to an information collection center operated by motoring clubs, radio stations, and the like. Reporters are registered; in order to safeguard credibility of reports, registrations are canceled if a reporter sends frequently incorrect messages. Each message must pass plausibility checks before being used for traffic information services.
- Information gained by evaluation of movements of mobile phones: Several technologies have been developed to identify the position of mobile phones and their movements (see In-vehicle sensors, Data Acquisition by Roadside Detection, Technologies—Data Acquisition: Data fusion).

4.2 Data compilation and fusion

RTTI is usually based on contents received from various sources. Automatically collected data from local detectors normally include local throughput (vehicles per time period), local speed (km/h at the measuring point), section speed (km/h on the road section), traffic density (veh/km), often per vehicle class, and statistical parameters. Reliability of these data depends on the density of measuring points and detector accuracy. Measured data can achieve a high accurateness. Incidents, for example, accidents, are usually not measured, but may be deduced from traffic model supported data interpretation or detected by visual observation (staff or video camera).

Floating car data (FCD) and floating phone data (FPD) use tracking data to determine speeds on road sections.

Information gained from human observation is less objective, but may be helpful to identify events that impact traffic flow. Video observation is increasingly used, often in connection with automatic video evaluation.

Current data from all available sources together with reported events are fused in order to get a comprehensive overview about the traffic situation and expectable trends. Interpretations are supported by historic traffic data of comparable traffic situations. Traffic models are used to get a realistic view of the current situation as well as short- and medium-term forecasts to be used for traffic management measures and for navigation devices.

4.3 Data interpretation, recommendations, and responsibilities

Road authorities, on the one hand, are mandated to manage/regulate traffic flows to reach the optimum of the whole traffic system; RTTI services, on the other, may tend to achieve the optimum for the individual driver/client. This is a critical mixture where responsibilities of road authorities and interests of RTTI service providers are concerned: Suitable agreements are needed in order to ensure that measures as indicated on VMSs do not conflict with messages of in-car navigation devices. Traffic management strategies as selected by road authorities need to be taken into account by RTTI service providers in their recommendations to their clients. This is important for route recommendations that should observe official road classifications to avoid route guidance through sensitive parts of road networks, for example, residential areas.

4.4 Distribution and presentation to end users

RTTI is processed and transmitted in coded form to be language independent, based on international standards as listed below. This includes the description of locations, events, and recommendations, which can be processed in the different stations of the message chain and finally decoded in the receiver unit to inform the end user in his desired language either in words (text-to-speech) and/or in graphic form displaying maps and symbols. Depending on the type of receiver, the encoded message can be used to update route recommendations. Message display may be according to the driving direction and area, and the road and route used. This allows for selection of relevant messages and suppression of messages that do not concern the individual trip.

A number of (independent) parties are active in the creation, processing, and transmission of RTTI and their "backstage systems." Besides the above-mentioned activities to generate content, to fuse and verify it, and finally to distribute it to the end user, the manufacturers

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of equipment—detection systems, traffic management equipment, broadcasting and telecommunication systems, and receiver units—are involved. Activities are carried out by different actors, in different ways, and with different interests that need to be elaborated on to understand the processes and possible conflicts.

5 REQUIREMENTS

The perception that former RTTI systems could not fulfill future requirements was an incentive to study the necessities of all involved actors, the potentials of new technical developments in the field of information technologies, and organizational frame conditions and barriers. Technological, operational, and organizational improvements were needed in all parts of the information chain.

5.1 Drivers as end users

It is evident that knowledge of the road network topology, as laid down on road maps on paper or electronic navigation maps, is an indispensable prerequisite for any trip. However, most driver are acquainted only with limited parts of road networks, for example, of their neighborhood or of the trunk road network. Frequent usage improves the network overview. Changes in the network—new road links or road closures—are more or less long-term events. Besides the mere network geometry, a number of specific road characteristics are important:

- Road design parameters: gradients, curvature, cross section, number of lanes, emergency lanes
- Limitations: height and width limitations, weight restrictions
- Regulations: speed limits, restrictions for specific vehicles or user groups, route guidance, environmental restrictions, etc.

Dynamic traffic management as used in heavily loaded road networks often applies dynamic regulations using VMSs and dynamic routing signs. Information such as the following is needed about permanent and temporary limitations of road usage:

- Weather dependent: road closures in winter; dangerous road surface, black-ice, prescription of snow-chains, reduced visibility, heavy rain, and snowfall
- Impairment by road maintenance operation: long-term and short-term road works, lane restrictions or blockages, and rerouting
- Expected or current traffic problems

Road users are increasingly confronted with traffic problems, when road transport demand exceeds road capacity. Road users want pre-trip and on-trip information about the following:

- Pretrip information supporting disposition of trips
- Expected traffic situations, for example, in connection with mass events such as sports events, fairs, seasonal, and weekend traffic
- Current congestion due to overload of roads, accidents, incidents, and road works
- Exceptional transports impacting road capacity and traffic flow
- Recommended alternative routes

The information demand varies among individual user groups. Commuters are usually well aware of oncoming daily road and traffic situations. Occasional road users and drivers over weekends and during seasonal traffic often lack information about the situation they have to face. Drivers of heavy goods vehicles, especially with loads to be delivered on time, urgently need information about road and traffic on their route including availability of parking lots for their prescribed pauses. The same holds for haulers and dispatchers planning and supervising transports. This enumeration is not exhaustive, but clearly indicates that specific needs of specific user groups require to "individualize," to tailor information to individual end user needs.

RTTI can reach drivers only if it is presented to them in an understandable way, that is, with symbols and graphics and/or in a language of their choice. This is an important demand to be considered in the design of RTTI systems.

5.2 Road operators and traffic managers

Motorways, or generally "A-Class roads of the trunk road network," are the most efficient category of road networks (eSafety RTTI WG, 2007). In order to improve traffic flow and to increase safety, most critical parts of the motorway network are equipped with dynamic traffic management such as stretch control (speed regulation, lane allocations, danger warnings), dynamic direction sign systems (rerouting traffic in case of incidents onto less loaded parts of the network), ramp metering systems (to avoid traffic flow breakdowns due to overload), and temporary use of hard shoulders for running traffic (especially in built-up areas).

Most of these systems are automatically controlled in closed or open loops. Comprehensive collection of traffic data and traffic-related environmental data is needed as input for possible control measures. These data are also

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

used to automatically produce traffic messages in case of incidents. These messages are often enhanced by observations from police or congestion reporters, the so-called jam busters, who are registered road users reporting their observations via the mobile phone.

Most of the above-mentioned systems use VMSs to transmit information, warnings, or regulations to users. The content of these variable message signs is limited because of the fact that drivers are only able to perceive and understand a limited amount of information when passing often at high speeds, especially when they are not capable of reading the language (e.g., if not in native language) and/or are not familiar with the geographical environment to understand exit recommendations (Figure 2).

From a traffic management point of view, it is vital to inform drivers accordingly and thus achieve the best possible rule compliance and acceptance for regulations. Therefore, in-vehicle traffic messages in national language or easily understandable icons play an important role as they complement roadside information and regulations on VMS or VDS. While VMS/VDS are only locally effective, traffic information can be transmitted to drivers anywhere on the road network, on-trip and pre-trip. RTTI is an advanced possibility to influence driver behavior, road choice, and also modal choice.

With increasing market penetration of navigation systems using digitally transmitted traffic information (RDS-TMC) to enable dynamic navigation to avoid congestion by updating route resistances according to prevailing conditions, traffic information gains even more importance in influencing road network operation. This is a fact to be considered when planning improvements and necessary enhancement of traffic information services. Navigation systems tend to reroute traffic from the motorway network to secondary roads if events or disturbances are reported on the motorway. However, traffic situations outside motorways and especially in urban areas are rarely monitored. Therefore, the situation on these secondary networks is more or less unknown to traffic managers. Available experience from the past and knowledge of normal traffic loads on these secondary networks can help overcome the situation but cannot really solve the problem. For efficient road network operation, there is an urgent need to improve traffic monitoring in all major (strategic) road networks (eSafety RTTI WG, 2007).

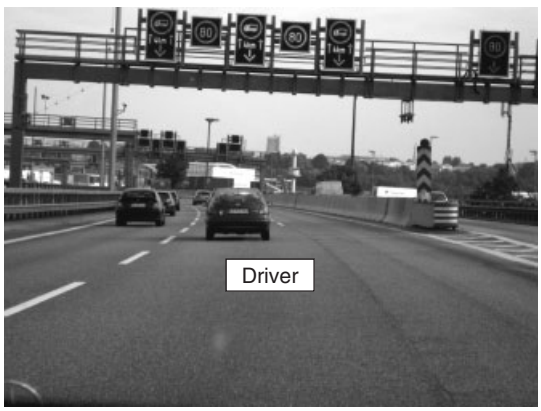

Figure 2. VMS legends with limited amount of information.

Therefore, in this context also, road operators need to be mentioned as "user group." They need information about expected and current road and traffic situation as well in order to anticipate and possibly avoid congestion by adequate traffic management measures or to react in case of incidents and accidents.

5.3 Service providers

Service providers pursue the objective of distributing/selling the best possible RTTI to their clients. Commercial companies, in competition with others, defend their market position by offering as best a service as possible. Economic results depend on acceptance by drivers and thus on the reputation of their clients and the possibility to "sell" RTTI. Establishment of own data collection is a means to improve the quality of RTTI as a commercial product.

5.4 Broadcasters and telecommunication services

Broadcasters—public as well as private companies—compete with their neighboring broadcasters covering the same transmission area. Quality of RTTI is an important factor in competition.

Public broadcasters, for example, in Germany, have been cooperating with road administrations and police since the establishment of RTTI services to distribute traffic information as a specific type of "news," which they are mandated to supply their listeners with by their concessions. Their RTTI service is given without extra pay for their listeners; it is included in the general broadcasting fee.

Private broadcasters finance themselves by broadcasting commercial advertising. There is no mandate for them to distribute RTTI free of charge. It is their own decision to deliver (free or paid) RTTI service.

Telecommunication service providers may act as content providers and RTTI distributors. Operational data of mobile phones may be used as data sources by tracking movements of their telephone clients. Mobile phones can be used to get RTTI "on demand." Economic motivations for telecommunication services are the sale of telephone airtime and the sale of content for other RTTI services, and also the provision of RTTI service for self.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 3. Early RDS-TMC receivers.

5.5 Equipment manufacturers

Equipment manufacturers need clearly defined standards for their products, enabling a variety of different products to be offered to the market to satisfy varying demands. This applies as much for encoding messages and their semantics as for transmission technologies over different channels. Global markets and trans-border traffic require language-independent RTTI messages as provided by RDS-TMC and TPEG (Transport Protocol Expert Group) standards (see appended list of CEN/ISO standards). While RDS-TMC is a transmission channel with very limited capacity, TPEG is designed for the transmission of RTTI over digital broadcasting channels with high capacity, enabling more detailed messages (CEN/TC 278/WG8 and ISO/TC 204/WG9).

On the basis of standards, manufacturers are able to design a variety of low and high end products of RTTI receivers as requested by the market (Figure 3). An increasing number of RTTI service providers operate their services, often in cooperation with other actors of the RTTI scene.

6 SYNERGIES BY COOPERATION

6.1 Actors and their interests

Based on their specific history of origin many different RTTI systems can be identified in Europe and beyond. However, similar actors are involved, although with differing degrees of involvement and commitment. Actors and their interests in participation can generally be categorized (Table 1).

6.2 Typical functions of actors

Data and information collection means the acquisition of all data describing road network topology, weather-influenced road surface conditions, current traffic situation, and events affecting traffic demand and traffic flow. It includes the collection of information on expected events and traffic situations. Table 2 lists the main actors and their main collection procedures in the case of own data sources.

Table 2 indicates that in principle all types of data/information are available, although at different levels of completeness, and in different entities. Some of them are public authorities, some are commercial companies, and others are individual drivers or motoring clubs. No entity by itself can provide a full and comprehensive overview of the current traffic situation. Cooperation and access to data pools are needed to gain a reliable basis and a full overview to provide satisfactory RTTI services. The basis for cooperation are standards, gateways to data pools, and clear and fair economic agreements between partners.

6.3 Accessibility of data sources

6.3.1 Standards

Early RTTI services were built as proprietary solutions. Their internal definitions of protocols, semantics, and data hindered exchange of information between potential partners, especially across national borders and languages. A means to overcome these obstacles is the international standardization of traffic messages and their digital coding as done in CEN/ISO 14819 Parts 1–6 of *Traffic and Travel Information (TTI)—TTI Messages via traffic message coding*. This is used as the basis for setting up the so-called Traffic Message Channel within the Radio Data System (RDS-TMC) to broadcast digitally encoded traffic messages via FM Radio.

The installation of RDS-TMC to transmit traffic messages is an important milestone for the improvement of RTTI services (see below). Meanwhile, RDS-TMC-based services are available nearly worldwide, partly as free services and partly as pay-services.

The method to code data and traffic messages (location, incident, length of queue, expected duration, recommendation, etc.) accelerates the procedure from content collection up to the distribution of the message to the end user.

Further standards enable transition to digital transmission media (DAB, GSM, DSRC, etc.) and information

Table 1. Actors and their interests.

Sector [1)]	Entity	Interests, Motivation
Public sector		
	Road authority	Political Objectives • Enabling mobility of people and goods • Safety • Exploitation of available road capacity • Transport economy • Protection of the environment (Ecology)
	Police	Political objectives • Safety • Prevention of accidents • Sanction of misbehaviour • Adequate reaction on accidents
	Emergency services	Rescue of lives
	Meteorological services	Alerts against hazardous weather conditions
	Telecom operators	Economic profit
	Map makers	Economic profit
	Broad casters	Public: public mandate to inform the public Private: economic profit
	Drivers	• Reliable trip disposition • In-time arrivals • Mobilty • Safety • Undisturbed travelling • Timely information about expectable and current obstacles and difficulties
	Motoring clubs	• Service to their members • Lead position against competitors
	RTTI Services	Economic profit
	Event managers	Easy accessibility of their events
Private (Commercial) actors		

[a] Remark: The transition between public and private sector is transient and differs from country to country.

interchange between actors in the information chain (DATEX, TPEG, etc.; see below).

6.3.2 *Data pools*

Table 2 explains that data pools needed for RTTI services exist, but are owned by different public and commercial parties.

The European Directive 2003/98/EU (Official Journal of the European Union of 31.12.2003, p. 90–96) regulates the reuse of public data, that is, the reuse of public data or public information held by public sector bodies of Member States. However, the definition of "public data or public information" and "public sector bodies" is left to the European Member States and is not done in a consistent manner. As a result, access to public road and traffic data is regulated nationally and differs across Europe (European Commission, DG TREN, 2008).

In some countries, RTTI systems originally have been established by public sector bodies (e.g., road administrations, police authorities, and public broadcasters); private services followed later with the intention to merchandise traffic information. Public basic services of satisfactory quality are available on the basis of public data pools, commercial services offer paid traffic information, and individual service, usually on the basis of public data and their own data pools.

In other countries, the private sector was to start RTTI services first on a commercial basis, establishing their data collection systems. In the latter case, public data pools are less developed. Commercial, that is, private data are protected by intellectual property rights and not accessible to other entities without specific contracts with the owner.

For the target to establish high quality RTTI services, it is recommendable to exploit all existing data pools and to avoid double investments and competing parallel and possibly contradictory information.

Cooperation between public actors and commercial companies needs to be based on clear technical, organizational, and operational regulations. European regulations, national legislation, and existing setups of RTTI services must be considered.

6.3.3 Organizational models

Access to foreign data pools was a matter of bilateral technical (proprietary data formats, coding, semantics, and exchange protocols) and commercial agreements. A variety of individual access points and gateways are needed if no coordinated access rules exist (Figure 4).

6.3.3.1 National Data Warehouse for Traffic Information. Different possibilities to organize access to separated data pools exist (Cornelissen, 2011). In the Netherlands, for instance, the so-called National Data Warehouse (NDW) for Traffic Information is operating. The reason is to improve the nationwide overview of traffic situation and the inadequate quality of data from different sources that did not allow for reliable traffic information and selection of suitable traffic management measures. This, as consequence, jeopardized optimal traffic management at the network level and resulted in more congestion than necessary.

NDW acts as a national database that pools data from all suitable sources to provide accurate and consistent traffic data and information. It acts as a single point of contact for all data suppliers on the one hand and traffic managers and service providers as users on the other.

NDW collects and distributes real-time traffic data (speed, traffic intensity, travel time, and classification), traffic situation information, and traffic management measures as well as statistics.

Data suppliers have to prove the quality of their data, which is checked regularly by NDW. Different quality levels have been defined according to road categories and importance. Loops, cameras, and floating phone data are used as data collection technologies; Bluetooth as a new technology has been tested (Cornelissen, 2011).

6.3.3.2 Mobility Data Market Place (Mobilitäts Daten Marktplatz). A different approach is the creation of a Mobility Data Market Place (Mobilitäts Daten Marktplatz, MDM) (Mobilitäts Daten Marktplatz Benutzerhandbuch, 2012). An MDM enables an internet portal, the MDM platform, to offer, search, and subscribe online traffic data or other data with relevance for traffic as well as to distribute these online data between data suppliers and data clients.

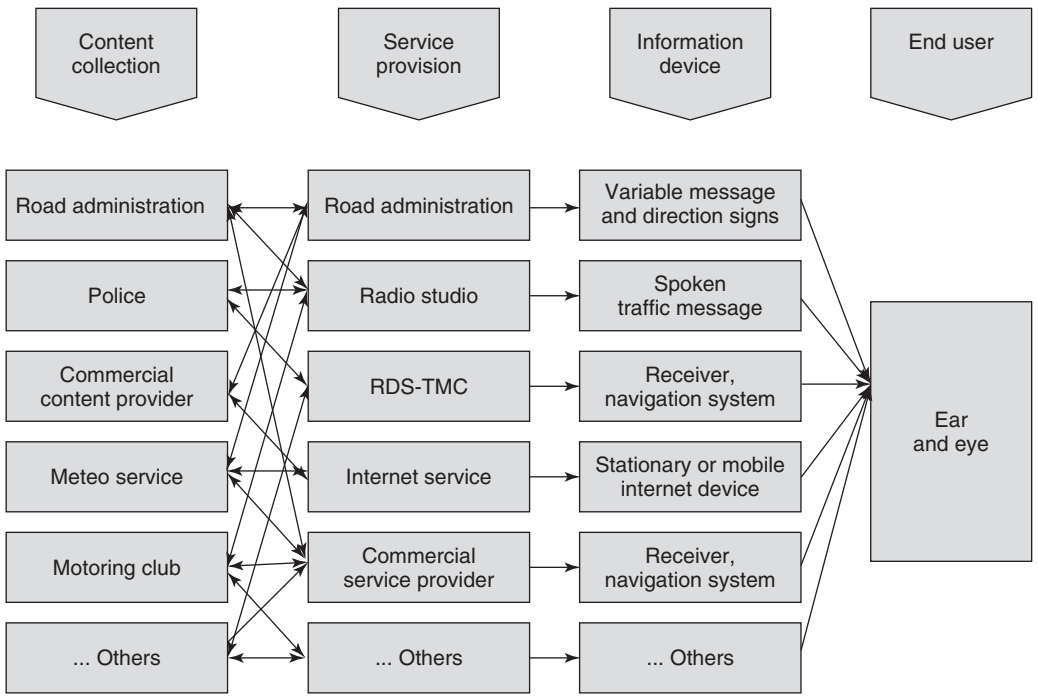

Figure 4. Multiple data sourcing and complex networking between content and service providers.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

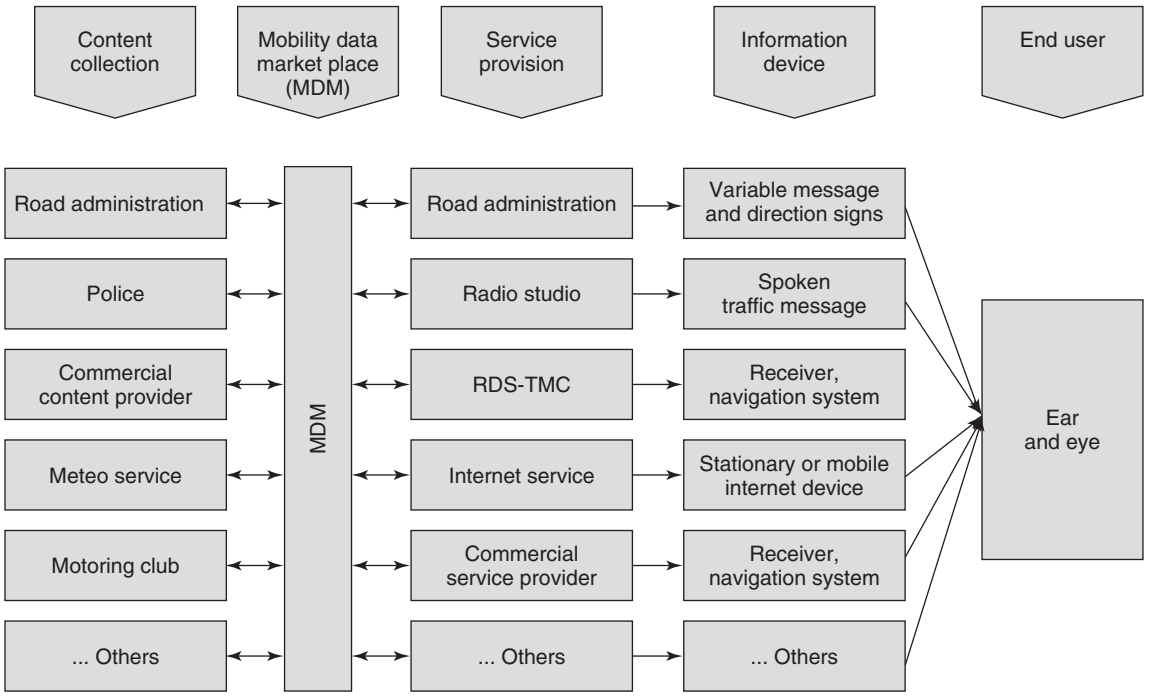

Figure 5. Multiple data sourcing and simplified networking between content providers and service providers via Mobility Data Market Place (MDM).

The function of MDM is to enable the exchange of data without checking or changing them. It is not its task to harmonize contents of data from different sources, but to enable access to different databases via one single portal (Figure 5). In contrast to the Dutch NDW, data and information are not held in a central data bank; all data handling and storage is decentralized. Users can download information about available data, their formats, interfaces, and commercial conditions to exploit data pools.

7 FRAME CONDITIONS AND REGULATIONS

The roles and task distributions between public partners and commercial actors are extremely complex questions. On the one hand, the supply of drivers with traffic information is considered as a very important contribution to traffic safety; on the other, commercial actors may consider public RTTI service as a competing service limiting their market chances.

The above-mentioned organizational schemes are technical provisions creating possibilities to collect and exchange data and information from different actors as the basis for RTTI; however, they do not touch upon the problem of which organization—public or commercial services—should deliver which type of information to drivers as end users and under what conditions: which type of information should be available free of charge and which should be paid for. Discussions differ from country to country, depending on their RTTI history.

In some countries, commercial actors that had been the first to distribute RTTI are operating pay-services exclusively for their customers. Nonsubscribers having no access to their RTTI have to restrict themselves to less developed public information sources.

Public RTTI services, for example, as operated jointly by road administrations, police, and public broadcasters in Germany, are mandated by their political assignment to take care of traffic safety, respectively, to inform their listeners as best as possible: This includes well-developed RTTI and has been done for decades. Emerging commercial RTTI services in such counties try to "limit" these public activities in order to get a broader market share.

7.1 eSafety Initiative of the European Commission

European integration with increasing cross-border traffic requires harmonized conditions for RTTI services to enable barrier-free access to traffic information. After intensive discussions, in order for "traffic information" to be

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 3. Conclusions of the Conference on the European Commission's eSafety Initiative 5/6 June 2007.

1. *The Conference agreed that traffic information is highly relevant to road safety. Both the users and the players involved in the information chain are calling for further improvements in terms of quality and coverage in order to meet the objectives of improving road safety and to assist the driver in performing his driving task. Realistic and feasible quality standards should be developed jointly, with the involvement of all stakeholders.*
2. *The Conference notes that traffic information services should cover not only the primary networks (e.g., motorways) but also sizeable sections of the secondary networks. To this end, "strategic networks" are to be defined. Here, it is quite conceivable that different quality levels could be applied to the individual network sections.*
3. *The increasing number of traffic messages makes it necessary to transmit traffic information digitally so that it can be automatically processed in an appropriate manner, both during the generation and management of the messages and by the users' receivers. For this purpose, the "Radio Data System Traffic Message Channel (RDS-TMC)" has been developed, which is already in operation in numerous European countries, albeit with varying degrees of intensity.*
   If the secondary networks are to be included, it might become necessary to change over from analog radio channels to digital broadcast channels (e.g., DAB, DRM). To ensure universal coverage in conurbations, provision will have to be made for appropriate transmission capacity. Joint implementation strategies should be developed on a Europe-wide basis to facilitate access to this information, which is not based on a specific language. The aim is to create relatively uniform information services within the European Union.
4. *In Europe, there are both freely accessible "public" traffic information services and commercial information services, which users can access by paying a fee. The Conference notes that, from a transport policy perspective, access to safety-related traffic information should be possible worldwide without users having to pay additional costs. Some countries have already categorized safety-related information by way of example. The minimum scope of safety-related traffic information should also be defined on a Europe-wide basis. This will not rule out the possibility of individual countries going beyond this scope when providing freely accessible information.*
5. *Commercial information services have their place alongside freely available traffic information services. The services they offer may go significantly beyond those offered by public information services and cater to the individual needs of customers.*
6. *The Conference believes that Member States should, in accordance with the principle of subsidiarity, also make the necessary rules and arrangements for the free provision of safety-related traffic information within the framework of public–private partnerships (PPPs).*

(Conclusions of the Conference on the European Commission's eSafety Initiative 5/6 June 2007.)

preferably considered as "indispensable contribution to transport policy objectives" or as "commercially exploitable merchandise," a balanced proposal was made by a European working group of experts (eSafety RTTI WG, 2007) in the context of the European eSafety Initiative of the European Commission and forwarded to the EU Commission and Council.

The European eSafety Initiative was set up with the objective to cut down the number of fatalities on European roads. Experts discussed all types of new technologies and their possible contribution to this objective. Besides a number of merely vehicle-bound systems, systems with vehicle-to-vehicle and vehicle-to-infrastructure communication enabling immediate interactions between vehicles and road infrastructure RTTI services are highlighted as promising means to improve safety and traffic flow. RTTI is acknowledged as a means with the possibility to achieve results very soon because of the fact that RTTI systems are already operational in many countries, although with differing quality and with high potential for improvement. International working groups elaborated quality criteria for RTTI systems and their subsystems and proposed regulations to enable coexistence of public and commercial RTTI services.

The Conference on the European Commission's eSafety initiative on 5/6 June 2007 concluded on the key issue of Real-Time Traffic Information (Table 3) (Communication from the Government of the Federal Republic of Germany, 2007).

7.2 Free access to "safety-related traffic information"

These demands were taken up by the European Commission and Parliament, for example, in Directive 2010/40/EU of the European Parliament and the Council of 7 July 2010 on the framework for the deployment of Intelligent Transport Systems in the field of road transport and for interfaces with other modes of transport (eSafety RTTI WG, 2007).

This directive states among others as priority actions

(a) the provision of EU-wide multimodal travel information services;
(b) the provision of EU-wide real-time traffic information services;
(c) data and procedures for the provision, where possible, of road-safety-related minimum universal traffic information free of charge to users, and so on.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Besides these European regulations, national rules exist, which, if necessary, have to be adapted to these frame conditions.

Further development and deployment of RTTI systems as a prioritized ITS within the European Union need to take these frame conditions into account. It is also laid down in the directive of the European Parliament and Council (2010): "To ensure a coordinated and effective deployment of ITS within the Union as a whole, specifications, including, where appropriate, standards, defining further detailed provisions and procedures should be introduced. This latter regulation aims at providing international application and usage of Intelligent Transport Systems."

7.3 Definition of "safety-related traffic information"

For the definition of safety relevance, traffic messages had to be categorized. The idea of a classification (Table 4) as unanimously agreed by the German Traffic Information Platform in March 2006 (BMVBS/BASt, 2000–2008) was generally accepted as the basis for the following discussions at the European level.

The concept of a minimum set of important safety-related messages is still being discussed. Different sectors of the service chain, public authorities, commercial service providers, etc. all have slightly different views of which traffic messages are most important. There is a basic understanding that each meaningful message may be safety related as it reduces uncertainty and thus eliminates a source of potential stress for the driver. However, for example, the same message might be "safety related" if received by drivers immediately approaching an incident or may be just "informative" for drivers still far away. Further, the ownership of gathered data and the further processing of data, eventually combined with specific, value-adding knowledge bases, may create the need for specific arrangements of business models and responsibilities. Therefore, Member States will have to establish solutions based on their given conditions. The European Commission will have to take necessary steps to coordinate the cross-border flow of information. (eSafety RTTI WG, 2007).

Table 4. Classification of traffic messages by the German Traffic Information Platform (AG TMC-VID, March 2006) (BMVBS/BASt, 2000–2008).

Level	Hazard Prevention	Event Examples
I	+++++	High-risk situations, for example, "wrong-way drivers"
II	++++	High-risk situations, for example, "people, animals, or foreign objects on the road"
III	+++	Disruptions, for example, "road closure"
IV	+++	Disruptions, for example, "standstill"
V	+++	Disruptions, for example, "slow-moving traffic"
VI	++	Restoring normal traffic flow by cutting delays
VII	+	Maintaining smooth traffic flows with a view to lessening the economic impact

(Reproduced from BMVBS/BASt, 2000–2008.)

Discussions about safety relevance are not yet finished. In Table 5 (European Commission, DG TREN, 2008), column 1 lists traffic problems and messages as defined in the TISA list of Events (Traveller Information Service Association (2), 2012). Column 2 lists the TSIS-DATEX II definitions (CEN/TC 278/WG8 and ISO/TC 204/WG9). Column 3 tries to better describe events in a more concrete form. DATEX II incident codes can be mapped to TMC event codes.

The assessment of safety relevance differs slightly from country to country, as mentioned earlier. Some road administrations consider RTTI as an integral element and tool for traffic management. RTTI helps avoid accidents and development or prolongation of congestion by early information to drivers and supporting the efficiency of roadside VMSs and dynamic route guidance. To achieve these effects, it is of high importance that RTTI can address all drivers concerned and this can be expected to be better if RTTI is available free of charge. This exceeds the minimum requirements as laid down in the directive of the European Parliament and Council (2010) and further elaborated in the final report by the European Commission, DG TREN (2008), which must be seen as a compromise.

8 ACQUISITION OF AND ACCESS TO DATA

8.1 Payment models

Public as well as commercial RTTI content and messages present a value created by one or several actors in a value chain. Each contributor creates a part of the value of the end product. RTTI as end product is paid for. Public RTTI is financed, for example, by tax and/or by radio license fees,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 5. Classification of traffic messages by TISA and DATEX.

TISA Definition	TSIS-DATEX II Definition	Description
Ghost driver	Included in the definition for category 4	Vehicle on wrong carriageway of a dual-carriageway road
Dangerous road surface	All traffic elements of class Road conditions	All specified road conditions, for example, black ice, icy patches, oil on road, poor road surface, etc.
Danger due to reduced visibility	All traffic elements of class Poor environment conditions where minimum visibility distance is specified	Any environmental condition reducing visibility. For example, hail or fog with visibility of less than 50 m
Animal/people/debris in the road way	All traffic elements of class obstructions or disturbance activity or authority operation	All obstructions on the road (e.g., fallen trees, animals, burning vehicle). All public disorder or alerts with the potential to disrupt traffic (e.g., demonstration, assault). All authority-initiated operation or activity that could disrupt traffic (e.g., police investigation, bomb squad in action)
Blockade of road, tunnels	All operator actions of class network management	All road operator activities to manage the road network, for example, rerouting, road/lane closures, warnings (e.g., reduce speed) and recommendations (e.g., snow tires)
Unprotected accident area	All traffic elements of class accidents	All accidents
Temporary roadwork	All operator actions of class Road works where urgent road works = true	All urgent repairs on the road network
End of queue	All traffic elements of class abnormal traffic where urgency =(urgent or extremely urgent)	Any congestion that is uncommon

Comments:

The definition excludes nonurgent information, that is:

- Measured data, for example, real-time and predicted travel times
- "Abnormal traffic," that is, incidents reporting on traffic flow
- Road works
- Equipment or system failures
- Weather conditions not related to the road surface
- Public events
- Non-road-related information, for example, parking information

The excluded incident reports can be defined as safety-related if labeled "urgent," for example, in case of a tailback at a dangerous location, or a blizzard warning.

Table 6. Payment models (eSafety RTTI WG, 2007).

1.	TTI "free," as public service user paid via tax (internet, radio)
2.	TTI included in broadcasting service fee (RDS/TMC via FM, DAB)
3.	TTI included in purchase of equipment (radio, navigation system)
4.	TTI included once-per-lifetime (purchase of car, radio, navigation system)
5.	TTI as subscription service (Automobile Club, service provider)
6.	TTI pay-per-use (toll number)
7.	Manufacturer pays service provider for end-user service (subscription)
8.	Service provider pays traffic information center (TIC) for TTI
9.	Traffic information center pays content provider(s) for data
10.	Public authorities co-finance broadcasting infrastructure TTI (FM, DAB)
11.	Public authorities (co-)finance private service provider(s)
12.	Public authorities (co-)finance TIC and use TTI for their own traffic management responsibilities
13.	Public authorities (co-)finance content gathering
14.	Service providers pay telco's for delivery of TTI to their customers
other	Each party has to finance their investments and operations

(Reproduced from eSafety RTTI WG, 2007. © European Commission.)

and commercial RTTI by a number of different payment methods (Table 6) (eSafety RTTI WG, 2007).

8.2 Value chain

It is reasonable that cooperation of public and commercial actors is realized in order to reach adequate quality of RTTI. Each partner can contribute his/her information or his/her content-handling procedures to increase the quality of RTTI. The value chain includes actions form different actors from content provision to message distribution. Figure 6 displays a generic model of this value chain.

The contribution of all partners has to be reimbursed according to the value added. The value of contributions is subject to economic considerations and negotiations between content providers and RTTI services. Major aspects in the commercial calculations are

- costs of content provision and handling
- (free) availability of public data
- "value" of data as seen by RTTI service provider (reliability, timeliness, etc.; see Table 7)
- willingness of end users to pay.

8.3 Quality levels of RTTI content and service

Some criteria to assess the value of data and information of RTTI are listed and defined in Table 7 (EasyWay (1), 2012).

These core criteria include factors to assess message contents as well as the service as experienced by the driver as end user.

It is economically not feasible to apply a 100% quality level of content and service to all parts of road networks. Suitable levels need to be defined according to criticality of roads, road layout and category, and traffic importance.

EasyWay (EasyWay (4), 2010) notes that the operating environments are obtained through a qualitative approach in order to make it simple and easily used in any part of the road network. The general layout starts by assigning a letter code to the different physical characteristics:

- C for critical spots (bridges, tunnels, reversible lane sections, etc.)
- T for motorways
- R for roads
- S for motorway corridors or networks
- N for road corridors or networks
- P for peri-urban road networks

With this general classification, EASYWAY proposes a more detailed schedule of roads as displayed in Table 8 (EasyWay (1), 2012).

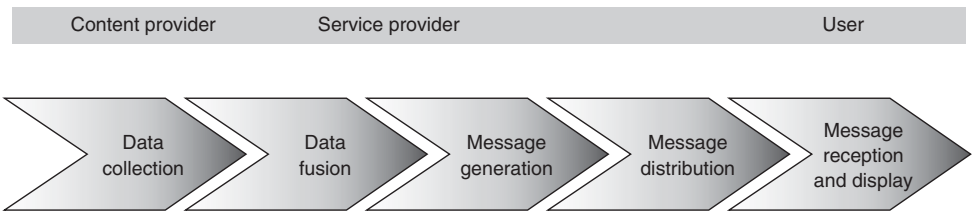

Figure 6. Generic model of RTTI value chain.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 7. Criteria to assess levels of quality (EasyWay (1), 2012).

Core Criteria	Definition
Accessibility	*Qualifies the user's exposure to the information service* For instance, the number of users reached by the information on each of the technology platforms deployed in relation to the % km of the relevant area concerned
Availability	*Qualifies the period during which the availability of the service to the specified standard is defined/guaranteed*. Degree to which (geographic) data would be available at a certain place and at a defined time. This may be by time of day/week/month or other special periods (e.g., 24/7 excluding national holiday periods)
Timeliness	*Time delay between the event detection and the provision of information to the end-user* (around 10s with new technologies)
Update frequency	*Qualifies the frequency of updating information or data update interval*. For instance, on occurrence (updates are made as and when a change occurs), periodic (regular or periodic updates) or on request update, etc
Quality assurance	*Incorporates the need to undertake partial checks* if deemed appropriate for parts of the chain (Level 1 for instance) or a full check of the service chain (Level 2) or a full check, which has the additional quality assurance through application of standards
Reliability (cross verified)	*Degree of certainty of the information*, considering whether the data value has been cross-verified from one or more additional sources, confirming the data
Accuracy	Degree of adherence of (geographic) data to the most plausible true value (can be absolute, relative, quantitative, and temporal)

(Reproduced with permission from EasyWay (1), 2012. © EasyWay ITS. EasyWay Deployment Guideline Document, Final Version December 2012 (www.easyway-its.eu).)

Table 8. EasyWay operating environments for Core European ITS Services.

C1	Critical spots, local flow-related traffic impact and/or potential safety concerns
T1	Motorway (link), no flow-related traffic impact and no major safety concerns
T2	Motorway (link), no flow-related traffic impact, potential safety concerns
T3	Motorway (link), seasonal or daily flow-related traffic impact, no major safety concerns
T4	Motorway (link), seasonal or daily flow-related traffic impact, potential safety concerns
R1	Two-lane road (link), no flow-related traffic impact, no major safety concerns
R2	Two-lane road (link), no flow-related traffic impact, potential safety concerns
R3	Two-lane road (link), seasonal or daily flow-related traffic impact, no major safety concerns
R4	Two-lane road (link), seasonal or daily flow-related traffic impact, potential safety concerns
R5	Three-/four-lane road (link), no flow related traffic impact, no major safety concerns
R6	Three-/four-lane road (link), no flow related traffic impact, potential safety concerns
R7	Three-/four-lane road (link), seasonal or daily flow related traffic impact, no major safety concerns
R8	Three-/four-lane road (link), seasonal or daily flow related traffic impact, potential safety concerns
S1	Motorway corridor or network, at most seasonal flow-related impact, possibly safety concerns
S2	Motorway corridor or network, daily flow-related traffic impact, possibly safety concerns
N1	Road corridor or network, at most seasonal flow-related traffic impact, possibly safety concerns
N2	Road corridor or network, daily flow-related traffic impact, possibly safety concerns
P1	Peri-urban motorway or road interfacing urban environment, possibly safety concerns

(Reproduced with permission from EasyWay (1), 2012. © EasyWay ITS. EasyWay Deployment Guideline Document, Final Version December 2012 (www.easyway-its.eu).)

The aim of the classification in Table 8 is to provide harmonized RTTI services allover Europe so that a road user can expect similar RTTI services in comparable road environments. EasyWay outlines a scheme of levels of quality for traffic condition and travel time information services (Table 9) (EasyWay (2), 2012).

9 END USER'S ACCESS TO RTTI

Drivers as end users can access RTTI over a number of information and communication channels, enabling them to get general as well as individually targeted information. Pre-trip information can be accessed in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 9. Levels of quality table: traffic condition and travel time information services.

Criteria	0	1	2	3
Accessibility	Only on hotspots	On main routes where problems often occur	On all routes	
Availability	Not guaranteed	Guaranteed to a minimum level	Guaranteed to a medium level	Guaranteed all the time
Timeliness	Not guaranteed 30 min	15 min	1 min around 10 s	
Update frequency	Only on an irregular basis	On a regular basis	As frequent as currently possible respectively as a significant change of traffic conditions	
Quality assurance	No regulation	Either input or output (partial check)	Service chain check (full)	Information Quality Assurance
Cross verified	Not defined	Data from one or more sources—reliability not confirmed	Data from one or more sources—reliability confirmed	Collaboration from more than one source (data fusion) reliability confirmed
Accuracy	N/A	N/A	N/A	N/A
Service grade	Not guaranteed	Guaranteed to a time interval	In real time	
Forecast horizon	Only current situation	Current situation and short time prediction	Current situation and short as well as long time prediction	

Legend:
- Accuracy: this criterion is covered by
  - LoS: level of detail and
  - LoQ: forecast horizon
- Service grade: A specific traffic condition and travel time information quality criterion, in which the service is guaranteed
- Forecast horizon: A specific traffic condition and travel time information quality criterion, which defines the prediction time for the service

Table 10. Information and communication channels for drivers as end-users.

Time	Information/ Communication Channel	Used for
Pre-trip	Print media, radio, TV, Internet portals, telephone services	Information used for trip planning, for example, work sites, expected traffic situation, expected usability of roads, bridges, tunnels, vehicle-class-specific information, etc.
On-trip	Variable message signs (VMS)	Mandatory signs (e.g., temporary speed limits), lane allocation, temporary use of emergency lanes for flowing traffic, warning signs Limited information in order to limit mental load for drivers
On-trip	Variable direction signs (VDS)	Dynamic rerouting, management of event traffic
On-trip	Spoken traffic messages	Limited amount of general traffic information
On-trip	RDS-TMC messages	Up to 300 messages with limited local resolution, used and displayed in navigation devices
On-trip	TPEG messages	High number of detailed messages with high local resolution, precise information for navigation devices, and route calculation
On-trip	Mobile phones	Information on demand, potential to integrate internet functions yielding permanent or temporary access to data/information sources

the planning phase of trips to decide about departure time, expected arrival time, route to be used, or choice of transport mode (vehicle, public transport, train, and airplane). On-trip information helps drivers to choose an adequate way of driving, creates better awareness of oncoming traffic or road problems, and enables alternative route choices. Some main possibilities are listed in Table 10.

10 COEXISTENCE AND COOPERATION OF PUBLIC AND COMMERCIAL RTTI

In some countries, public and commercial RTTI services have agreed to cooperate, each side taking advantage from joint efforts, complementing each other, and avoiding duplication of efforts and expenses. Although some overlap

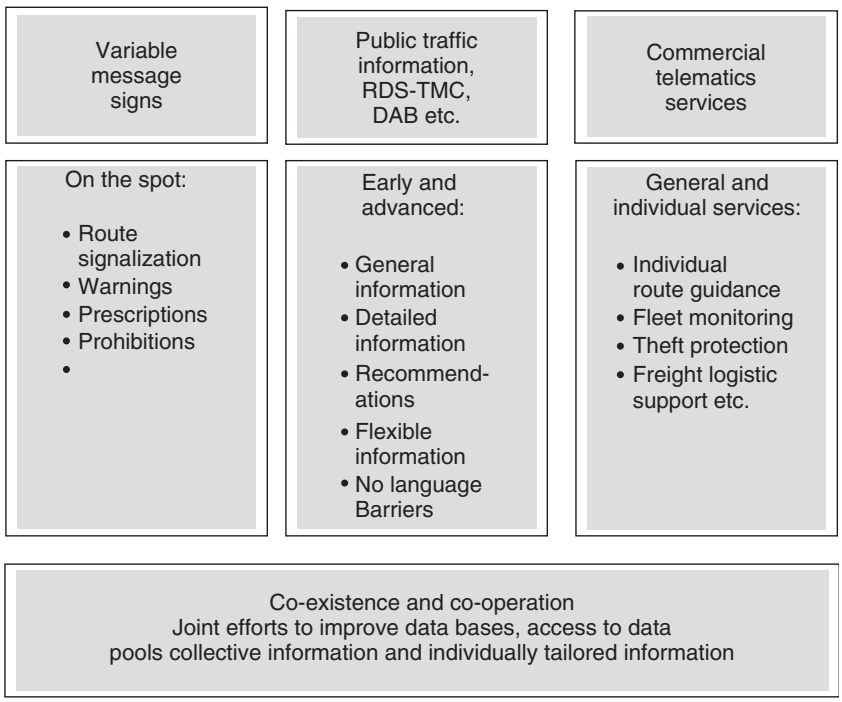

Figure 7. Synergy of public and commercial RTTI services. (Reproduced with permission from Bolte, 1997–2007. © Fritz Bolte.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

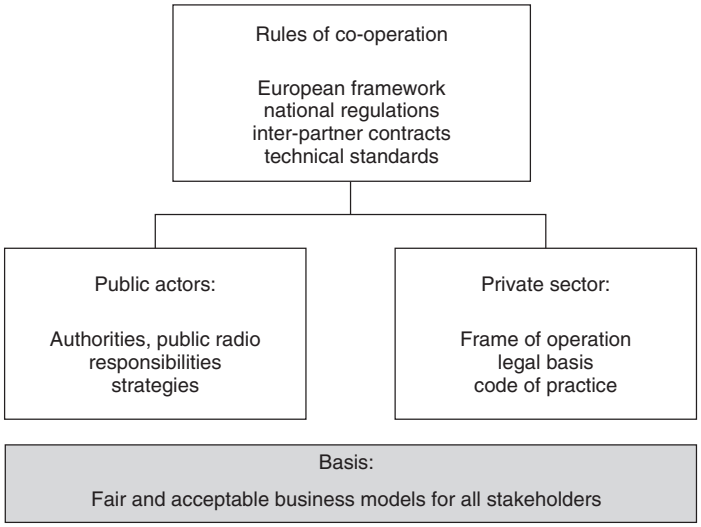

Figure 8. Hierarchy of regulations and contracts.

is possible, each side has specifically targeted services to offer. Public RTTI supplements other information media for traffic safety and management purposes, transmitting general information relevant for all drivers in the affected road or area. Commercial RTTI services can deliver more detailed and "individualized" information, tailored to the individual driver (Figure 7).

European frame conditions, completed by adequate national regulations, suitable business models, and contracts between partners, enable coexistence and fair cooperation of public and commercials RTTI services (Figure 8).

It should be noted that European regulations form the framework for RTTI services in Europe. Drivers should find consistent RTTI services in Europe. The request to deliver safety-relevant information free of charge, without extra payment, addresses the European Member States; it is their task to find suitable solutions in the context of their specific situation.

11 IMPORTANT CEN/ISO STANDARDS (EASYWAY (1), 2012)

CEN ISO/TS 14822–1:2006 Traffic and Travel Information—General specifications for medium-range preinformation via dedicated short-range communication—Part 1: Downlink (ISO/TS 14822–1:2006)-

CEN ISO/TS 14823:2008 Traffic and Travel information—Messages via media-independent stationary dissemination systems—Graphic data dictionary for pre-trip and in-trip information dissemination systems (ISO/TS 14823:2008)-

CEN ISO/TS 14907–1:2010/AC:2010Road transport and traffic telematics—Electronic fee collection—Test procedures for user and fixed equipment—Part 1: Description of test procedures (ISO/TS 14907–1:2010/Cor 1:2010)-

CEN ISO/TS 18234–1:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 1: Introduction, Numbering, and Versions (ISO/TS 18234–1:2006)-

CEN ISO/TS 18234–2:2006 Traffic and Traveler Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 2: Syntax, Semantics, and Framing Structure (SSF) (ISO/TS 18234–2:2006)-

CEN ISO/TS 18234–3:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 3: Service and Network Information (SNI) application (ISO/TS 18234–3:2006)-

CEN ISO/TS 18234–4:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 4: Road Traffic Message (RTM) application (ISO/TS 18234–4:2006)-

CEN ISO/TS 18234–5:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 5: Public Transport Information (PTI) application (ISO/TS 18234–5:2006)-

CEN ISO/TS 18234–6:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Expert Group (TPEG) data streams—Part 6: Location referencing applications (ISO/TS 18234–6:2006)-

CEN ISO/TS 24530–1:2006 Traffic and Travel Information (TTI)—TTI via Transport Protocol Experts Group (TPEG) Extensible Markup Language (XML)—Part 1:

12 GLOSSARY (ESAFETY RTTI WG, 2007)

3G	"Third Generation"/Universal Mobile Telecommunications System (UMTS) mobile telephone services, characterized by high performance and high bandwidth data services
AGORA-C	Flexible on-the-fly (does not need pre-encoded locations) location referencing method

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto183
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ALERT-C	Traffic information encoding used for TMC messages—uses pre-encoded event description and location reference, decoded in the receiver using look-up tables
DAB	Digital Audio Broadcast—digital method of broadcasting, offering higher data capacity than FM radio channels
DRM	Digital Radio Mondiale—digital audio broadcasting for AM broadcast, which can fit more channels than AM, at higher quality, into a given amount of bandwidth
DVB-T	Digital Video Broadcast—Terrestrial—method of broadcasting audio, video, and other data as already used for terrestrial digital television broadcast
FPD	Floating Phone Data—as FVD but monitoring the location of mobile telephones—can be performed at GSM network level without requiring special hardware in the telephone or vehicle
FVD, FCD	Floating Vehicle (Car) Data—monitoring the locations and movements of a set of vehicles, such as through collecting locations regularly using GPS devices mounted in a fleet of vehicles, and using the data (usually anonymized) to understand more about the overall road conditions and congestion
ITS	Intelligent transport systems
LoQ	Level of quality
LoS	Level of service
RDS-TMC, TMC	Radio Data System Traffic Message Channel—a method of sending traffic information as silent messages alongside regular radio broadcasts, optimized for FM broadcast and typically received by compatible satellite navigation systems and used for driver information and dynamic navigation (rerouting). TMC is an ODA (Open Data Application) built upon RDS
RBDS	North American standard for FM radio data. Very closely related to RDS, but with some small differences that must be taken into account when implementing TMC or other data services
RTTI	Real (Real-time) Traffic and Travel Information
TISA	Traveler Information Services Association is a market-driven membership association with worldwide scope, established as a nonprofit company focused on proactive implementation of traffic and travel information services and products based on existing standards, including primarily RDS-TMC and TPEG technologies
Telematics	Telematics is a combination of the subjects "telecommunications" and "informatics." "Transport Telematics" is the application of telematics on the whole field of transport and is the basis for "Intelligent Transport Systems (ITS)"
TM	Traffic Management
TPEG	Transport Protocol Expert Group—Method of encoding and sending traffic and travel information as silent messages alongside regular radio broadcasts, optimized for DAB broadcast but also applicable to other digital bearers; requires more bandwidth than TMC but can exploit this bandwidth with more/richer services
VDS	Variable direction sign
VMS	Variable message sign

Logistics and Fleet Management

Oliver Kunze
Hochschule Neu-Ulm, University of Applied Sciences, Neu-Ulm, Germany

1 INTRODUCTION

Telematics solutions for logistics and fleet management (LFM telematics) are becoming an integral element of transport operations worldwide.

A recent study (Dudek and Köppel, 2011) on a panel of 116 fleet operating companies (equivalent to a total amount of 10,446 vehicles, which mainly operate in Germany and Europe[1]) has shown that 48% of the companies in the panel had their fleet completely equipped with LFM telematics, 41% of the panel had a partly equipped fleet, and 11% were not equipped with LFM telematics solutions. The study also has shown that two predominant reasons for the implementation of LFM telematics solutions were "process improvement" and "documented evidence of service toward the customer."

At the same time, the National Transport Commission of Australia (NTC) states that "the road freight sector has not, however, embraced new and innovative technologies as fast or as wholly as many other industries. As a result, the full economic, social and environmental benefits to the Australian community have not been realized." (NTC, 2011, p. 1).

However, even if the implementation rate of LFM telematics may still show differences on a global scale, its benefits to transport service providers and their customers, as well as its benefits to the public (especially because of its technical means to enforce regulations on maximal driving times and thus reduce the risk of accidents because of driver's fatigue), both promote the use of LFM telematics.

1.1 Focus of chapter

This chapter focuses on *applications* of telematics in LFM. Technical details on communication (see Cellular Mobile Networks), positioning (see Technologies—Positioning: GNSS), or sensors (see In-vehicle sensors) are not discussed in this chapter.

After introducing some selected terms and definitions, this chapter explains the process context of LFM telematics, and the three user groups of LFM telematics systems. Then, the application scopes and functionalities for the different user groups are discussed. This chapter ends with a short overview on technical components needed for an LFM telematics solution and some thoughts on standardization.

ISBN: 978-0-470-97402-5

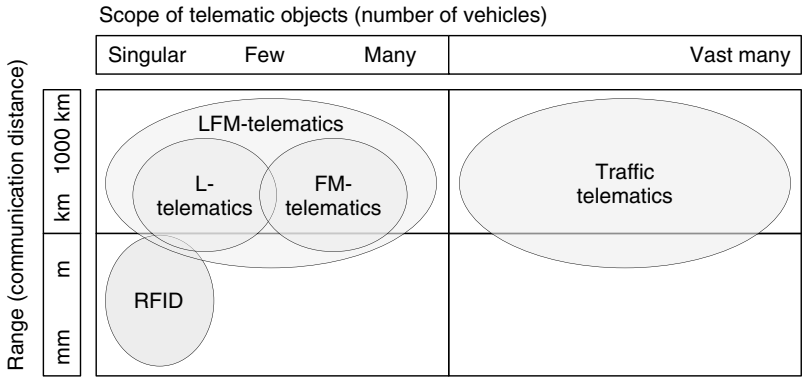

Figure 1. Delimitation of LFM telematics.

1.2 Terms and definitions

In this chapter, the term *telematics in logistics and fleet management* (*LFM telematics*) is used to describe the application of "information and telecommunication technology" (ITC) within the domain of transport logistics.

LFM telematics is different to "traffic-telematics" (see Applications—Intelligent Roads and Cooperative Systems: Urban Traffic Management, Advanced Highway Management Systems, and Road Traffic and Travel Information (RTTI)), as LFM telematics is used to support planning, execution, and monitoring of transports (L-telematics) as well as to support scheduling and monitoring of individual vehicles (FM-telematics), whereas traffic-telematics is used to monitor and control traffic flows.

Another ITC technology that is widely used in transport logistics is RFID (radio-frequency identification). It can identify objects over relatively short distances. However, even if in some cases, RFID technology may be put to use within LFM telematics applications, LFM telematics is clearly different to RFID.[2]

Using the two dimensions, "scope" (number of vehicles involved) and "range" (communication distance), the terms discussed earlier may roughly be positioned in relation to each other as shown in Figure 1. For definition of further terms, please refer to the glossary.

2 PROCESS CONTEXT OF TELEMATICS IN LOGISTICS

Key to understand the value of LFM telematics is a process-centered view of transport logistics.

2.1 Users, roles, and tasks

The transport logistics process has two main stakeholders—the customers (i.e., the shipper and the consignee of a transport) and the transport logistics operators (i.e., the service providers involved in the transport of goods—this includes forwarding agents, carriers, and in-company units, which plan and execute goods transports).

Each customer may employ several staff members who are involved in (or affected by) the execution of a transport depending on their respective roles. Allowing for some degree of simplification, these roles on the customer's side are as follows:

- the sales manager—he or she needs to know which goods are available where and when, in order to be able to make the relevant commitments toward his or her customers;
- the service manager—he or she needs to know which goods are available where and when, in order to be able to schedule service teams accordingly;
- the warehouse manager—he or she needs to provide the information on which goods are on stock and ready for shipping (outbound side) or he or she needs the information on which goods are expected when in order to control the relevant stock levels (inbound side);
- the production manager—he or she needs to provide the information on which goods are ready for shipping (outbound side—make to order goods) and he or she needs the information on which raw materials or components are expected when in order to control the relevant production processes (inbound side—especially for JIS and JIT goods).

On the transport logistics operator's side, three main roles can be defined (allowing for some simplification):

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- the driver—he or she executes the transport and, therefore, needs to know what has to be picked up/delivered where and when during his or her route;
- the dispatcher—he or she plans the transport and schedules the own vehicles and drivers or the subcontractors accordingly;
- the fleet manager—he or she is responsible for fleet maintenance, for compliance with legal regulations (especially maximum driving times and breaks of drivers) and for driver training.

The relevant tasks and obligations related to these roles are usually supported by different IT systems, which can roughly be categorized as

- "OnBoard IT" (IT installed within the vehicle either on a built-in on-board computer or on a mobile device, for example, PDA or smart phone), which is operated by the driver and often automatically fed with vehicle sensor data;
- "Fleet IT" (this includes *dispatching systems* for transport planning, *fleet monitoring systems* for monitoring of and communication with the respective vehicles and *fleet management systems* for documentation of fleet status, maintenance management, and KPI generation), which is linked to the OnBoard IT via appropriate means of data communication and operated by the staff of the transport logistics operators; and
- "Customer's IT" (especially CRM, SCM, and ERP systems), which is operated by the staff of the customers, and usually exchanges data with the Fleet IT via interfaces.

2.2 Process units

LFM telematics solutions interconnect these different IT systems by means of telecommunication in order to support the relevant processes. From a transport logistics focused point of view, these processes roughly can be categorized as *preceding processes* (any processes on customers side related to sales, service, warehousing, or production, which initiate transports), *transport planning* (route generation and vehicle and driver scheduling), *transport execution* (physical execution and monitoring of transports plus exception handling), *transport post-processing* (internal evaluation of conducted transports by means of report and KPI generation and external invoicing of transports either based on actually conducted routes or in accordance with tariffs), and *succeeding processes* (any processes on customers side related to sales, service, warehousing, production, or financial settlement, which require data about transports).

2.3 Process flow

Processes in LFM telematics are not widely standardized—they may differ significantly by vertical industry and even by company.

Still, the process flow shown in Figure 3 may be considered as an approximate general process model for telematics in logistics, which also covers the relevant aspects of fleet management telematics.

Transport planning is based on the *transport order data* and the data on available driver and vehicle resources, which stem from previously executed routes (*route execution data*). Transport planning generates the relevant *route plans*, which are needed for transport monitoring. Per route, the individual *route details* are forwarded to the relevant vehicle for *transport execution*, that is, they are transferred to the relevant OnBoard-IT system.[3] As transport execution proceeds, the relevant *status* messages (loading confirmed; route departure, break, etc.), *events* (delay, breakdown, etc.), and vehicle *positions* (GPS coordinates) are send back to *transport monitoring and exception handling*. In case of minor disturbances, the differences between plan and execution are only registered as deviations. In case of major disturbances (long delay, breakdown, etc.), the original plans need to be modified as needed (*revised route plans*).[4] In this case, the *revised route details* have to be transmitted to the effected vehicles.

While transports are executed, *transport monitoring and exception handling* needs to determine which information is relevant for the subsequent customer processes, and thus either sends *confirmations* (e.g., ETA confirmations or delivery notices) or *alerts* (e.g., excess of refrigeration temperature on a food delivery vehicle, extraordinary shock detections on a vehicle, which has loaded sensitive electronic equipment, and significant ETA delays) to the relevant customer applications as needed.

Once transport execution is completed, the *route execution data* are processed further

- by *transport KPI generation* in order to create input for controlling purposes of the transport logistics operator, for example, average waiting time at unloading location *x* or average fuel consumption of driver *y*,
- by *transport invoicing* in order to generate the data basis (e.g., mileage, loading, and unloading times) for commercial remuneration of the provided transport services with the customers,[5] and
- by *maintenance management* in order to register the vehicle usage and schedule maintenance intervals accordingly.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As possible delays may have an impact on subsequent vehicle or driver scheduling, these data also need to be send back to *transport planning* (①).

2.4 A three-tier concept of LFM telematics

In Section 2.1, three different groups of users (Figure 2) as well as three interrelated IT systems (Figure 3) for LFM telematics systems have been described. Consequently, LFM telematics applications may be grouped into three tiers, which build on each other:

- Tier 1: ITC for vehicle operations with focus on vehicle and driver (OnBoard IT),
- Tier 2: ITC for transport logistics operators (Central IT) and
- Tier 3: ITC for staff of customer's operations (customer's IT).

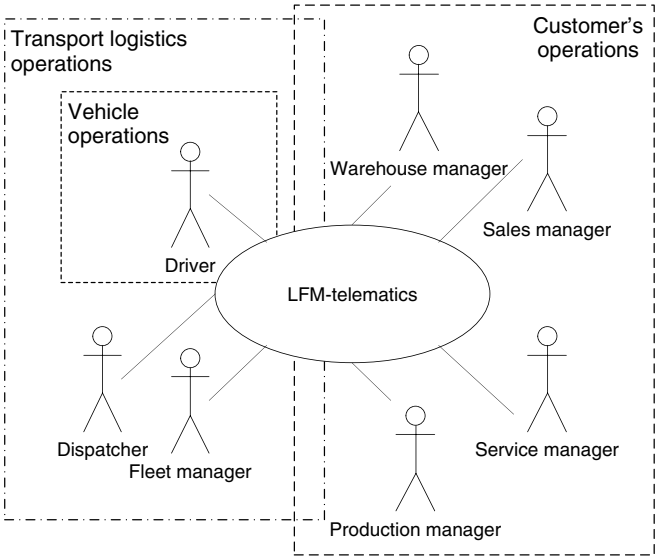

Figure 2. Users of LFM telematics.

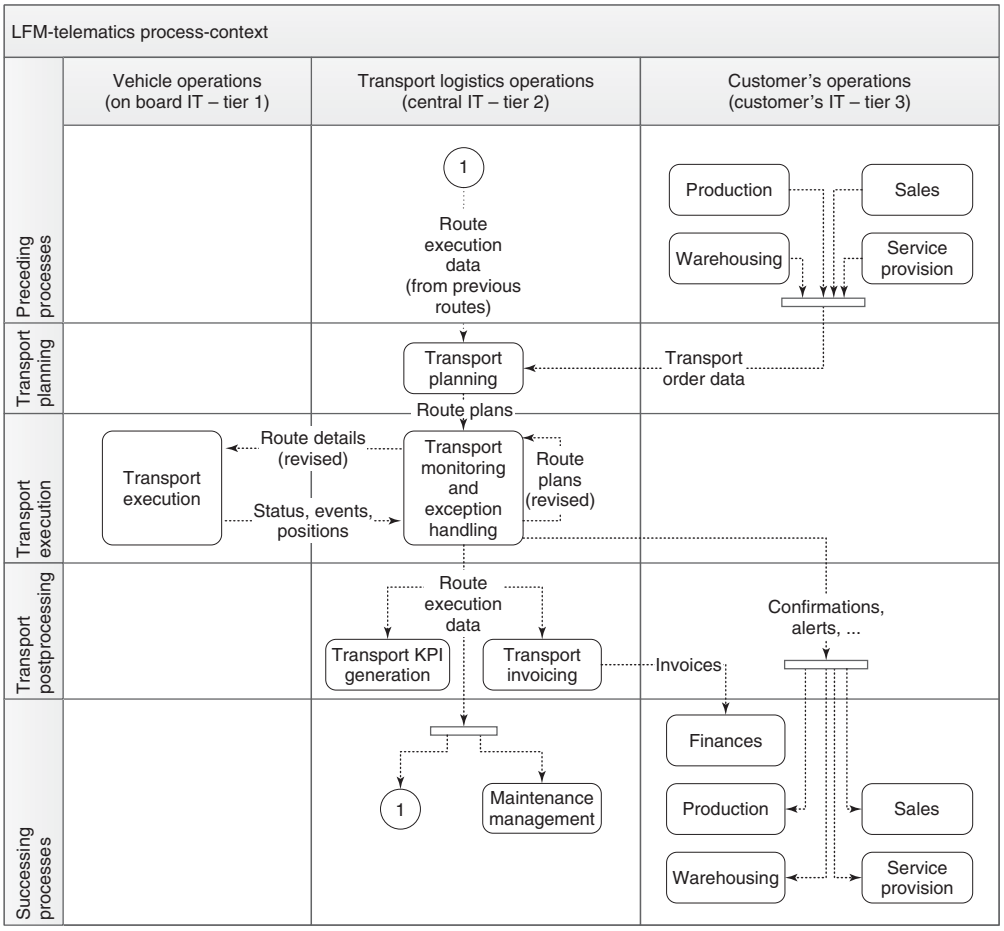

Figure 3. Process context of LFM telematics.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Tiers 1 and 2 are obvious elements of LFM telematics,[6] but tier 3 creates significant added value for customers operations, and thus requires to be considered, if one wants to assess LFM telematics solutions. Section 3 discusses the different applications by tier.

3 TIER 1—FOCUS: VEHICLE AND DRIVER

Telematics functions that support "driving as such", as for instance, "driver information systems", "driver assistance systems", or "autonomous vehicles" are discussed in the "Intelligent Vehicles" chapters of this encyclopedia (see Applications—Intelligent Vehicles: Driver Information, Driver Assistance, and Applications—Intelligent Vehicles: Autonomous Vehicles).

In addition to these intelligent vehicle functions, tier 1 of LFM telematics provides means to

- process data that stem from tiers 2 and 3 in order to support the driver (e.g., upload itineraries for navigation and receive additional pick up orders),
- capture data that are relevant for tiers 1, 2, and 3 by means of interfaces, sensors, or by means of a man-to-machine interfaces, for example, GPS positions, temperature in vehicle cargo bay, current fuel consumption rate, waiting times at customer locations or driver breaks,
- bidirectionally exchange these data with tier 2 (either online or via offline batch data exchange).

3.1 Vehicle and driver data capture

For many LFM functions, the capture of vehicle-related data is mandatory.

3.1.1 Sensor data

If no other options are available, the vehicle needs to be specially equipped with the relevant sensors (e.g., for temperature and moisture surveillance of the cargo hold, shock detection, and state of electronic seals), which require a significant amount of physical wiring and IT plugging. Therefore, one may state a *subsidiarity principle* for vehicle data capture: "if sufficient data are available via interfaces, use these instead of rigging additional sensors." Thus, standardized access to the vehicle data bus and the digital tachograph play an important role in this context.

3.1.2 Vehicle data bus

The vehicle data bus is used to exchange data between different vehicle components (a commonly used type of a vehicle data bus for trucks is the CAN-bus—for technical details, see ISO 11898, 2007; ISO 11992, 2005a). A standardized interface (see Logistics and Fleet Management, Section 7) to the vehicle data bus enables tier 1 LFM telematics applications to receive data from different vehicle components for further processing. (For further details on the vehicle bus itself, see In-Vehicle Network).

3.1.3 Digital tachograph (EU)/electronic on-board recorder (US and CAN)

The digital tachograph is a recording device for trucks, which is required by European law. Its general characteristics and functions are defined as follows.

"The purpose of the recording equipment is to record, store, display, print, and output data related to driver activities. The recording equipment includes cables, a motion sensor, and a vehicle unit. The interface between motion sensors and vehicle units shall be compliant with ISO 16844 (2005b). The vehicle unit includes a processing unit, a data memory, a real time clock, two smart card interface devices (driver and codriver), a printer, a display, a visual warning, a calibration/downloading connector, and facilities for entry of user's inputs…" (European Community, 2011, S. ANNEX I B, II. 1).

"The recording equipment shall ensure the following functions:

- speed and distance measurement, time measurement,
- monitoring driver activities, monitoring driving status,
- drivers manual entries,
- entry of places where daily work periods begin and/or end,
- manual entry of driver activities,
- entry of specific conditions,
- detection of events and/or faults,
- data downloading to external media, output data to additional external devices" (European Community, 2011, S. ANNEX I B, II. 2).

A device similar to the digital tachograph, the electronic on-board recorder for over-the-road motor carriers (EOBR), originally was introduced in the United States by legal regulations in 2010 (FMCSA, 2010). Even though this regulation was overturned by the US Court of Appeals for the 7th Circuit in August 2011 (Schulz and Berman, 2011). FMSCA indicated that they will go through a new rule-making process, and thus regulations in the United

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

States (similar to those in the European Union) are to be expected.

The Canadian Council of Motor Transport Administrators (CCMTA) indicated that they also see a "...need to consider a national EOBR standard ..." (CCMTA, 2009).

Tier 1 applications should usually have an interface to the digital tachograph (or to equivalent units) in order to avoid redundant data capture on driver activities (such as driving, work, availability, or break/rest—for details, see (European Community, 2011, S. ANNEX I B, III. 4.).

3.2 Transport and route data transfer

Transport data (transport orders) and route data (itinerary, loading list, etc.) uploaded form tier 2 to tier 1 help the driver to perform his or her tasks (e.g., checking consignments at loading, picking the right items for unloading, or navigating from stop to stop).

The download (tier 1 to tier 2) of the relevant execution status and event data per transport order (begin/end of loading, waiting times caused by customers at loading or unloading, delivery rejection by customer, etc.) or per route (traffic jam, driver break, overnight stay, etc.) is the basis for tier 2&3 applications. While some of the status and event data may be generated automatically (e.g., the arrival at a predefined GPS coordinate), usually the driver is required to key in some data manually.

3.3 Exception handling

On top of sheer transport and route data transfer, advanced LFM telematics solutions support exception handling procedures. These include timely exceptions (e.g., continuous ETA calculation and generation of proactive delay alerts), schedule exceptions (e.g., inclusion of previously unscheduled additional pickups or deliveries and additional legal driver breaks for significantly delayed routes), cargo integrity exceptions (e.g., temperature warnings for food transports; generation of additional watering stops for animal transports in case of delays), and security exceptions (e.g., automated accident alerts and panic button).

Standardizing exception handling procedures, on the one hand (tier 1), helps to reduce the communication effort for the driver (i.e., a call via mobile phone to the dispatcher in order to discuss the specific exception and the required actions). On the other hand (tiers 2 and 3), standardized exception handling rules increase the robustness and transparency within the transport process.

The relevant tier 1 in-vehicle applications, therefore, usually provide exception handling process templates by means of predefined workflows within the GUI of the application (e.g., guidance through a check-list/to-do-list).

3.4 Navigation

The list of uploaded route stop locations can be used as input for point to point navigation. This is beneficiary for the driver, as he or she can avoid searching for unknown stop locations, can circumnavigate traffic jams (increase of productivity), and, with modern navigation systems, he or she may get warnings on speed limits (reduced risk of speeding tickets).

Often specific *truck navigation* applications are required, as standard car navigation systems may not consider specifics, for example, maximum vehicle height (bridges), maximum vehicle length (hairpin bends), roads closed for dangerous goods transports (water protection areas), temporary ban of truck transports (Sunday driving bans), and others.

3.5 Geo-fencing

A virtual geo-fence is a digitally defined geographic delimiter (usually a circle or a rectangle) around the coordinates of an object of interest. The virtual geo-fence is used to detect when a monitored vehicle (e.g., by means of GPS tracking) has entered or left the vicinity of an object of interest.

Geo-fences may be used to just monitor vehicles in tier 2 applications. However, some tier 1 applications make use of this concept, too. For theft protection, for instance, the opening of a seal or valve (sensor data) outside a predefined geo-fence may either trigger an alert or be disabled altogether (Figure 4).

4 TIER 2—FOCUS: FORWARDING AGENT AND CARRIER

Tier 2 applications focus on the logistics operator as a transport service provider. Therefore, staff (excluding drivers) of external transport service providers (forwarding agents and carriers) and internal transport departments may all be seen as users of tier 2 applications. The different applications in tier 2 are described in accordance with the structure laid out in Figure 3.

4.1 Transport planning

Transport planning is one of the key elements for LFM telematics solutions, as many data needed elsewhere are a result of transport planning.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

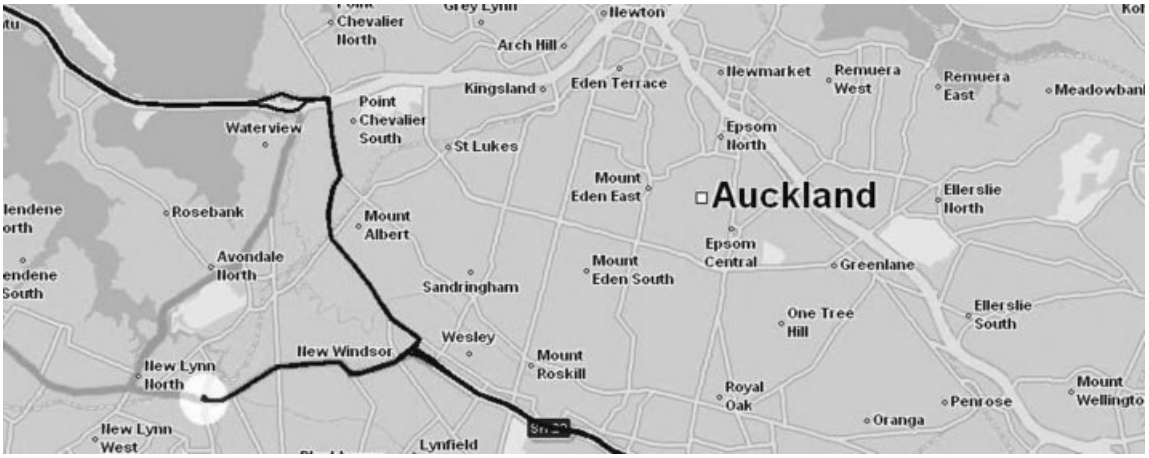

Figure 4. Vehicle track with circular geo-fence. (Reproduced with permission from Lomosoft. © Lomosoft GmbH, 2012.)

Input data for transport planning are transport order data (which stem from the customers) and the current availability of vehicles and drivers (which stem from previously generated schedules). Especially, the up-to-date information on the availability of vehicle and driver is a value adding aspect of LFM telematics, as plans based on these up-to-date availabilities can be considered more robust, and tend to require less changes than plans that have to rely on availability estimates, only.

On the basis of these input data, the dispatcher conducts the transport planning. Depending on the type of transports, different *planning algorithms* are helpful to support the dispatcher in this task. While groupage usually is planned by algorithms designed to solve vehicle routing problems (VRPs), full truck load (FTL), and less than full truck load (LTL), transports are mainly planned by algorithms designed to solve matching problems (MPs). Still, even if suitable algorithms are available for planning, some *manual dispatching*, usually, is required to compensate for gaps in data content or in data structure (i.e., data-wise nonmodeled aspects of planning).

Output data from transport planning are routes and schedules, which are then transferred to tier 1 applications (either online or offline, see Figure 7).

4.2 Transport execution

As discussed, the transport execution data are collected by tier 1 applications and sent to tier 2 applications for further processing.

Transport monitoring uses the results of transport planning to compare the current status of the transports with the plans. Most prominent data in this context are:

- Current latitude–longitude positions (unprocessed, these data usually do not have a big value, but as together with navigation systems, estimated times of arrival ETA may be computed for all subsequent stops of a route, this is a valuable input for proactive detection of delays),
- Status messages—these encompass order status (e.g., loaded, en route, delivered, and rejected), route status (e.g., loading, driving, break, waiting, and unloading), vehicle status (engine off, engine on and idle, driving), and driver status (loading, driving, unloading, waiting, and idle), and
- Event messages (e.g., break of cool chain, shock detection, crossing of virtual geo-fences, and accident).

As long as no changes to the original plans are made, one may talk about sheer transport monitoring.

As soon as significant exceptions (especially longer delays) occur, it may be necessary to revise the original plans (see "revised route plans" in Figure 3) and communicate these revised plans to the tier 1 (and tier 3) applications.

4.3 Dynamic transport planning

Dynamic planning (or continuously revised planning) could be a part of "transport monitoring and exception handling"—but dynamic planning requires all planning functionalities of "transport planning." Therefore, "transport planning" and "transport monitoring and exception handling" should be performed within one integrated system, if possible.[4]

However, dynamic planning is more than just reaction to plan deviations. Three examples illustrate this point.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Firstly, if homogeneous goods (e.g., an assortment of flowers) are transported, routes may start before precise transport orders are known. This could be the case, for instance, with flower transports, where the trucks may be heading to their destination areas without knowing how many roses and tulips to deliver where, yet. While the trucks head toward their destination areas, sales could fix the orders with the customers, and then transfer the transport order data to the tier 1 applications only after the routes have begun.

Secondly, if again homogeneous and perishable goods (e.g., a frozen food assortment) are loaded for multi-stop home delivery transports, and some regularly visited customers are not at home when the truck arrives, two things have to be cared about: (i) the customers who have not been met need to be revisited later the same day or on the following day and (ii) the subsequent customers will be visited earlier (if a previous customer is not met) or later than planned (if an additional stop to revisit a customer is inserted into the route earlier on). Here, dynamic planning is required to organize the driver's workload as well as to update ETAs [for internal tier 2 use or tier 3 use (e.g., ETA announcement via web or SMS)].

Thirdly, consider truck-meets-truck transports in FTL or LTL operations, where two trucks from different transport operators and different geographical areas need to make a delivery in the respective area. Instead of heading to their remote destinations and ending up there without a back load, they could meet half way, exchange their goods and carry out the delivery of the partner's goods in their home area. If any delays occur in such transports, this may affect the plans of two different transport operators, and thus the respective data need to be exchanged between different LFM telematics systems. In this case, process and interface standards to support this dynamic planning and execution are needed (for further details, see Kunze *et al*., 2011; Baumgärtel *et al*., 2011).

4.4 Transport postprocessing

Transport postprocessing encompasses all activities that are executed after the relevant transport has been carried out.

4.4.1 Invoicing

Invoicing usually occurs in two constellations:

- between *transport operator and shipper* (object of invoice is the performed transport service) and
- between *shipper and consignee* (object of invoice is the transported goods).

For both constellations, LFM telematics provides a significant benefit.

Invoicing of transport services is based on contractual calculation schemes. Some of these calculation schemes are based on the mileage as executed, some on the mileage as planned, and some on other schemes (e.g., zone tariffs). In case "mileage as executed" is used, the benefit of LFM telematics is obvious, as the relevant data can be extracted from data captured in tier 1.

However, also for the other calculation schemes, LFM telematics provide a twofold benefit:

- invoice initiation without delay (as soon as the transport order status "delivered" is set, the relevant invoice can be triggered) helps to improve the monetary liquidity of transport operators and
- invoice matching with transport-related costs (as transport-related calculation costs become transparent within tier-2-applications, they can be matched to the relevant invoice volumes), increases transparency on the cost-revenue-ratio for the transport operator.

The invoice initiation without delay plays a role in the *shipper–consignee relation*, too, as a "quasi-online" information to the shipper on the fact that its goods have been duly delivered is beneficiary to the invoice processes of the shipper.

4.4.2 Transport KPI generation

KPIs (key performance indicators) are needed from a transport operator's point of view as well as from a shipper's point of view.

From a transport operator's point of view, there are three main issues that require adequate KPIs on tier 2: economics, compliance with legal regulations (especially driving times), and service quality.

From a shipper's point of view, KPIs on service quality are of special interest. These KPIs can either be generated by the shipper itself based on the data provided by tier 3 applications, or those KPIs generated by the transport operator in tier 2 may be made transparent to the shipper.

4.4.2.1 Economic KPIs. As briefly discussed in Section 4.4.1, matching revenue data with related cost KPIs is important to make a profitable business. It is no trivial task to assign costs to individual transport orders (e.g., how shall the costs of a groupage route with 10 customers be distributed if each stop has a different distance to the depot, each stop receives different transport volumes, and due to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

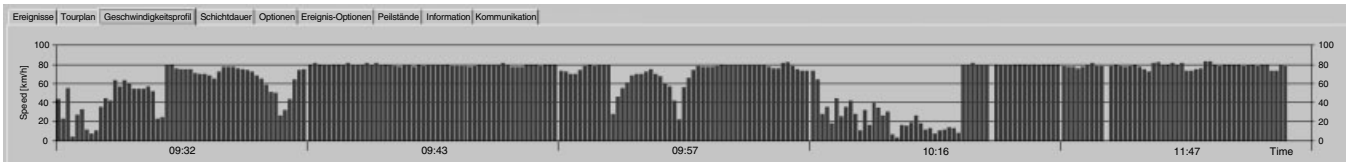

Figure 5. Speed profile. (Reproduced with permission from Lomosoft. © Lomosoft GmbH, 2012.)

different conditions at the stop premises, each stop requires a different unloading time?).

Even though these calculations tend to be difficult or imprecise, LFM telematics at least help to provide a most detailed database for the generation of these KPIs in retrospect.

However, LFM telematics also help to positively influence some of these KPIs. Two examples shall illustrate this point.

Example 1 relates to waiting times at customer locations before loading or unloading. In some vertical industries, the transport operators are kept waiting for several hours, before they can load the cargo (because of process insufficiencies of the shipper) or unload the cargo (because of process insufficiencies of the consignee). If these unproductive waiting times are monitored by loading or unloading location, they can be the basis for contractual incentive or penalty systems for shippers and/or consignees.

Example 2 relates to imprecise transport order volume data. Envision a route that is economically planned based on volume data provided by the shipper. At arrival for pickup, the real volumes differ from the ordered volumes. Then either the volumes are too small, and the route becomes noneconomic because of the unused loading space, or even worse, the volumes are too large. This may result in the need to generate additional transports on short notice, as not all originally planned transports can be handled as planned, or, if the transport operator refuses to load additional volumes, its ability to perform flexible services may be questioned. Again, transparency on this issue by means of LFM telematics combined with a contractual incentive or penalty system may help to overcome this problem.

4.4.2.2 Driver monitoring KPIs. Driver monitoring by means of LFM telematics provides a twofold benefit to the transport operator.

On the one hand, it helps (and forces) the transport operator to register the work and driving times in accordance with the legal regulations, and take adequate actions in case of violations. The relevant data are acquired by tier 1 applications (for example by the digital tachograph) and evaluated by tier 2 applications. A quasi-online connectivity is not required for this use case.

On the other hand, the driving style of a driver has an immediate impact on the fuel costs and CO_2 emissions of the transport operator. If the driver accelerates and breaks more intensely than required, the result is an unnecessary consumption of fuel. Eco[7]-drive trainings (with focus on preactive driving) in combination with tracking of individual speed profiles (Figure 5) and continuous calculation of relevant KPIs (Figure 6) may have a significant impact on the overall fleet consumption (without continuous monitoring of the drive patterns and without a related incentive or penalty system for the drivers, these positive impacts of eco-drive training tend to evaporate quickly).

In addition to these aspects, vehicle tracking and comparison of planned versus executed routes may reduce unnecessary detours. Owing to the multitude of routes, significant deviations in this respect may easily be detected by a deviation-KPI per route, which states the relevant difference. Only those routes that exceed a certain KPI limit will then need to be checked in detail.

4.4.2.3 Service quality KPIs. KPIs measuring service quality are relevant for transport operators as well as for their customers. Such KPIs are average time to delivery, average delay of delivery, average match of agreed delivery deadlines [%], and others. Basis for these KPIs are the delivery data captured by tier 1 applications. Depending on the business, these KPIs could be generated on a high level (e.g., company or region wide) or on a detail level (e.g., per consignee).

4.5 Maintenance management

Maintenance management for vehicle fleets requires scheduling maintenance works for the individual vehicles at appropriate times. This scheduling needs to consider

- the technical state of the relevant vehicle (or the state of the different vehicle components),
- the need of the vehicle as a physical resource in transport logistics operations, and

- the time slot availabilities of the different garages that are qualified to perform the required maintenance works.

Considering these three aspects, the fleet manager decides on *when which* vehicle needs to be taken *where* out of operational service, so that maintenance works can be performed as required. LFM telematics can support this task in the following way.

4.5.1 *Capture of technical state*

Capturing the technical state of the different vehicle components is key to determine when the next maintenance works are needed. Some of these data may be captured by tier 1 applications via the in-vehicle bus and then be transferred online or offline to the relevant tier 2 applications. Data on minor damages (i.e. repair can wait until the next scheduled maintenance break) can be captured by the driver in tier 1 man-to-machine dialogs. Other data (e.g., the remaining time until replacement of tires) can be estimated based on operational data stored in tier 2 applications.

Additional data (e.g., regular and usage-independent technical check intervals imposed by authorities) can be obtained without LFM telematics from vehicle master data records.

4.5.2 *Maintenance scheduling*

Scheduling maintenance breaks requires the alignment of technical maintenance needs for the different vehicle components on the one hand and schedules (vehicle schedules and garage schedules) on the other hand. Provided that all relevant data have been captured, this alignment itself might be carried out without any further use of LFM telematics. However, the results of maintenance scheduling can be transferred to the relevant drivers by means of "go to garage"-transport-orders via the "tier 2 to tier 1"-interface.

5 TIER 3—FOCUS: SHIPPER AND CONSIGNEE

One key benefit of LFM telematics is its ability to extend the reach of customer's processes (i.e., processes of the shipper or the consignee) in such a way that transports are an integral part of these processes (and are not intransparent black box activities). As soon as customer's processes are linked to LFM telematics, this establishes tier 3 applications.

As the number of potential tier 3 applications is unlimited, only a few selected examples shall be discussed in this chapter.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.1 Automotive

Transports for the automotive industry are often JIT (just in time) or even JIS (just in sequence) transports. As safety stock levels have often been reduced to a minimum or even to zero, delays in transports of automotive parts or components may have a significant negative effect on the assembly. Therefore, tier 3 LFM telematics solutions are required which can generate precise ETAs for the consignee.

In addition to that, dock management is an issue in the automotive industry. Owing to the multitude of parts and components, and the high amount of outsourced production processes, the sheer number of transports per day poses a problem for the consignees' goods reception. To avoid queues at the unloading docks, some consignees create preassigned time windows for deliveries. These need to be considered by the logistics operator during *transport planning*, and thus this issue requires tier 3 integration toward the dock-management system of the consignee.[8]

5.2 Construction

In 2006, Günthner, Kessler, and Sanladerer designed an LFM telematics system for the construction industry (Günthner, Kessler, and Sanladerer, 2006). Since then, the application of LFM telematics in the construction industry has become more and more popular, as deliveries to construction sites often show three special characteristics: (i) certain deliveries are extremely time critical (e.g., delivery of premixed liquid concrete, which solidifies after a certain time span, or delivery of heavy goods, which require a crane for unloading), (ii) owing to possible delays on site, the delivery service may require a high level of flexibility,[9] and (iii) the goods recipient does not necessarily have permanent staff on site (staff of a contractor may only be present while certain works need to be performed, and the workers may not have a permanent office on site). Therefore, in many cases,

- a highly *precise* scheduling of delivery times,
- a *flexible* readjustment of deliveries (dynamic planning), and
- details on the *exact location* of the point of delivery on site

are required.

Precision already can be achieved by a classical tier 1 and 2 LFM telematics solution, where deliveries are preplanned and executed in accordance with the preplanned schedule, and ETA times are continuously updated and transferred to the customer's staff on site. In case of delays on the transport side, new ETA times will allow for adequate adjustments on site (e.g., if a crane was originally scheduled for unloading the now-delayed truck, it may be used for other craning activities in the meantime).

As soon as *flexibility* is required, too, an LFM telematics solution is required that allows dynamic planning (tier 2) based on input from the customer (tier 3 interfacing) plus readjustment of transports in execution (tiers 1 and 2). If, for instance, several hundred cubic meters of concrete are needed, and the concrete casting process is somehow delayed, the loaded concrete trucks cannot wait without limit. Therefore, such a delay will also affect the loading at the concrete mixing plant (and even the operative production planning there). Thus a two-face tier 3 process integration is required (dynamic planning with process integration toward construction site and concrete mixing plant).

The *exact location* of the point of delivery on site may be determined by different approaches, for example, by free text messages (e.g., "gray bureau container 50 m northwest of crane"; tier 2 to 1 communication requires exchange of free text messages), by scans of construction site maps where relevant location is indicated (tier 2 to 1 communication requires exchange of data, which can graphically be displayed by the tier 1 application), or by latitude–longitude coordinates for a navigation system (the first driver who has successfully searched for the precise delivery location sends back his or her coordinates to tier 2, and subsequently arriving drivers get these coordinates sent to their tier 1 navigation system).

5.3 Courier, express, and parcel

Courier, express, and parcel logistics (CEP logistics) sometimes is perceived as sheer physical transport services. However, information on when the relevant items were shipped and when they were delivered are an integral part of the CEP services. Nowadays, customers of CEP services want to have transparency on where the goods are even while the physical transport takes place. The related service is called *track and trace* (*T&T*), and, depending on the designed T&T granularity and the related LFM telematics system design, one can achieve gateway-based T&T (i.e., identify an item when it passes a gateway which captures its ID) or continuous T&T (i.e., identify the ships, planes, trains, or trucks the items are loaded on, track these carriers by means of locating services,[10] and thus indirectly track the loaded objects).

In order to be able to identify objects for T&T, the relevant objects need an ID, and this ID needs to be related to the relevant sender and recipient data (minimal data are names and addresses). Until recently, this identification was

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

widely done by means of a barcode sticker, which carried the ID for scanning. The related sender and recipient data were somehow entered into the IT system of the transport operator (either by data import via interfaces or via internet access frontends or by manual data capture on a scanner handheld), and then linked to the relevant ID. Nowadays, RFIDs start to be used instead of/in addition to the barcodes as identifiers (further details, see DHL, 2011).

On a regional level,[11] CEP *transport execution* performs two overlaying operations: collection of (*a priori* not necessarily identified) items from customers to consolidation centers and delivery of (previously identified) items from consolidation centers to customers. Both operations are supported by LFM telematics:

5.3.1 Pickup services

In case the items have not been identified beforehand, the driver who runs the pickup routes needs to issue an ID and capture the relevant data (this is usually done by a tier 1 handheld device). Else, he or she scans the relevant IDs (reads the relevant RFIDs) while he or she collects the items.

Regular CEP customers (customers who ship parcels every day) are visited by daily master pickup routes. As irregular customers are only served if they require a pickup, a need for LFM telematics that enables *dynamic planning* arises (see Logistics and Fleet Management, Section 4.3).

5.3.2 Delivery services

For delivery services, the routes for the relevant items need to be planned (tier 2) and then the trucks need to be loaded accordingly. To avoid wrongly loaded items or missing items on a truck, the items may be scanned at loading. A tier 1 application may then generate alerts (for missing or wrongly loaded items) or confirm the completeness of all items to be delivered on the relevant route.

To achieve continuous T&T for the loaded items, the relevant handling processes (loading, delivery,[12] intermediate storage, and return to the sender) and the relevant vehicle positions have to be traced (tiers 1 and 2), and thus a high transparence on the transport process can be achieved for (i) the logistics operator (tier 2) and (ii) the relevant shippers and consignees if relevant data are provided to them via interfaces or via T&T web frontends (tier 3). In other words, if, for instance, a web shop, a furniture store, or a reseller of white goods wants to keep its customers up to date on when to expect the delivery, they require a logistics operator who is equipped with an adequate three-tier LFM telematics system.

5.4 Mineral oil

Product availability and safety are the two main objectives in transport of mineral oil. For replenishment of fuel stations, the limited tank storage space at the fuel stations combined with fluctuating demand requires an efficient replenishment process to guarantee the product availability close to 100%. Safety during loading, transport, and unloading requires technical means as well as process means. Both aspects—product availability and safety—determine the mineral oil-specific processes, which are supported by LFM telematics. These specific processes can be matched to the generic processes shown in Figure 3 as follows:

Initially, a close link to "customer's IT" is needed to generate the relevant *transport order data* (based on current local product volumes and consumption rates per fuel station).

Transport planning needs to consider different product types (regular, premium, and gasoline) and the different compartment volumes of each truck. Transport planning also requires knowledge on which product type was loaded in which compartment of the truck during the preceding delivery run in order to determine if compartment cleansing (additional preloading time needed) is required or not. Therefore, tier 1 LFM telematics applications continuously capture loaded product volumes as well as product-compartment assignments.

During *transport execution* (loading, transport, and unloading), the workflow design of the tier 1 applications helps to increase safety by means of process standardization. Before *loading*, a check of the previously loaded product can be performed, and in case of product incompatibility, a mandatory compartment cleansing can be required by the tier 1 application. During *transport*, a specific navigation for dangerous goods transports (which avoids water reserve areas) can guide the driver, and in case of temperatures close to 0°C, a glaze alert can require the driver to reduce his or her speed.[13] Before *unloading*, a check of the current vehicle position versus a predefined virtual geo-fence can be conducted, in order to grant that no product is unloaded outside this geo-fence (theft protection). For this usage, the tier 1 application may either trigger an alert to a tier 2 application or even have access to actuators in order to block any valve operations outside the geo-fences.

Transport monitoring and exception handling are specifically required if planned delivery volumes cannot be unloaded (leftover products in truck) or if vehicle loads need to be (partially) redirected because of unexpected product shortages at a third fuel station. Such deviations from planned order volumes also need to be considered for *invoicing* between shipper and consignee, and thus

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the capture of data on real delivered volumes (via tier 1 applications connected to meters or electronic dipsticks) are vital for shippers and consignees, as well as for the transport operators (especially, if such volume deviations lead to additional mileage).

5.5 Further tier 3 applications

Tier 3 LFM telematics has a wide scope of further applications. A few more of them shall be discussed in brief.

5.5.1 Food

For food transports (fresh as well as frozen foods), the uninterrupted cold chain is of importance. Therefore, sensors in the cargo bay need to track the temperature (and sometimes the moisture too), and these tracks are recorded by the tier 1 application. In case there is a threat that the cold chain becomes broken (excess of a warning temperature level), the tier 1 application can generate a warning (see "events" in Figure 3) and the dispatcher can deal with the problem. Shipper as well as consignee can then be informed on this event via tier-2-to-3-interfaces.

5.5.2 Sensitive electronics

For transport of sensitive electronic components, a shock-free transport is of importance. Especially, if such goods are damaged by a shock somewhere between shipper and consignee, it is helpful for the transport operator that he or she can prove the shock-free transport if the shock event was caused by another party.

5.5.3 Technical services

Technical service providers (e.g., elevator repair services and kitchen installation services) can only conduct the service if the relevant items are available. Therefore, the scheduling of the items and the scheduling of the technicians often requires synchronization (tier 3 integration of item transports with technicians scheduling).

Also, the time needed for such services is difficult to assess *a priori*. If several service orders are to be carried out on the same day, and an earlier service requires more (or significantly less) time than planned, the subsequent services are affected, and, therefore, ETA information update has a high benefit for the service customers.

6 TECHNOLOGY AND DATA

The functionality of an LFM telematics system is limited by its technologic design and by the data model used.

6.1 Technical components of LFM telematics

As there is no one-size-fits-all-architecture for LFM telematics, specific LFM telematics systems show a wide range

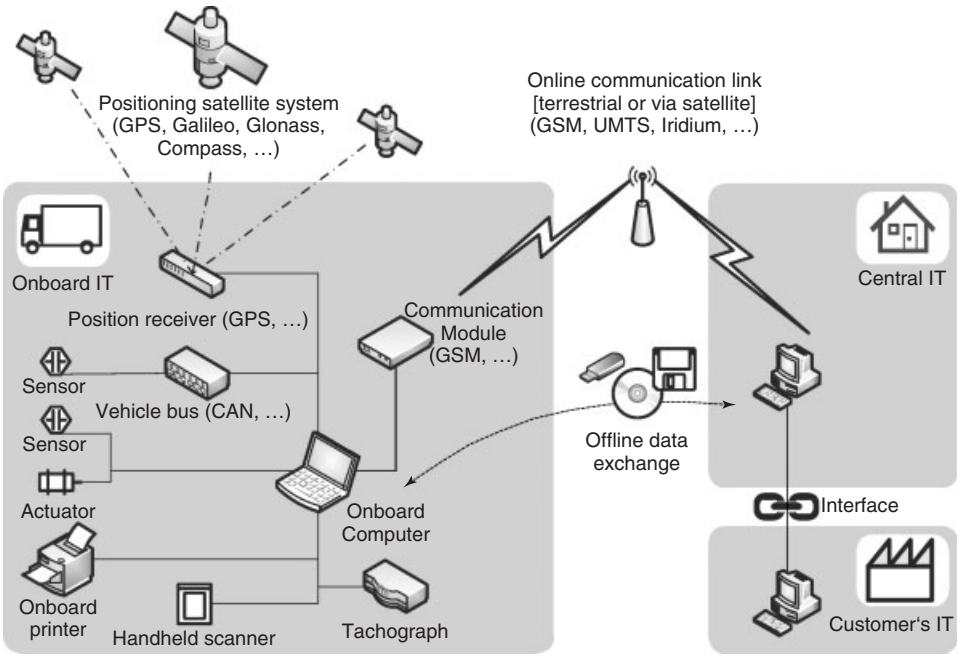

Figure 7. Generalized technical layout of an LFM-telematics system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of diversity from a physical implementation point of view. Still, Figure 7 shows a generalized layout of technical components, which establish an LFM telematics system.

The key unit of the OnBoard IT is the OnBoard Computer (OBC). It hosts the relevant LFM telematics in-vehicle tier 1 applications, provides a user interface to the driver, and ideally is linked to

- a position receiver (in order to compute the current position of the vehicle and provide navigation support to the driver)—even if today, such a receiver often is a GPS receiver, it could also be a position receiver based on Galileo (EU), Glonass (RU), or Compass (CN);
- the in-vehicle sensors directly or indirectly via the vehicle bus (e.g., to capture temperature or moisture data in the cargo hold or to log speed and fuel consumption data);
- the in-vehicle actuators (e.g., to block electronic locks of cargo bay);
- the electronic tachograph (only in case when the vehicle is equipped with an electronic tachograph in order to make use of the drive and work-time-related data, which are stored there for legal purposes anyhow);
- a handheld scanner (in order to enable the driver to scan barcode labels/read RFID tags on the cargo and manually key in data as needed outside the cab);
- an OnBoard printer (e.g., to print damage reports, proof of delivery certificates, or invoices);
- a communication module, which enables "quasi-online" data exchange with the central IT.

The term *quasi-online* is used, because a recent study (Dudek and Köppel, 2011, S. 55f) has shown that regular update cycles are as follows (Table 1).

Some mass data do not require quasi-online data transfer, and thus may be exchanged with the central IT via batch data up- and download (by means of either physical exchange of data storage media or a LAN at the fleet base).

The component layout shown in Figure 7 does not require to be implemented by means of distinct hardware units, as Figure 7 may suggest. If some features (e.g., sensor data capture, barcode scanning, or printing) are not required for a specific use case, and other features are integrated within one physical unit, the layout of technical components that establish an LFM telematics system may get as simple as shown in Figure 8.

Table 1. Update cycles.

Vehicle tracking cycle	Percentage of interviewed LFM-telematics users (%)
$\leq 1\times$/s	1
$\leq 1\times$/30 s	20
$\leq 1\times$/min	25
$>1\times$/min (ø 9 min)	54

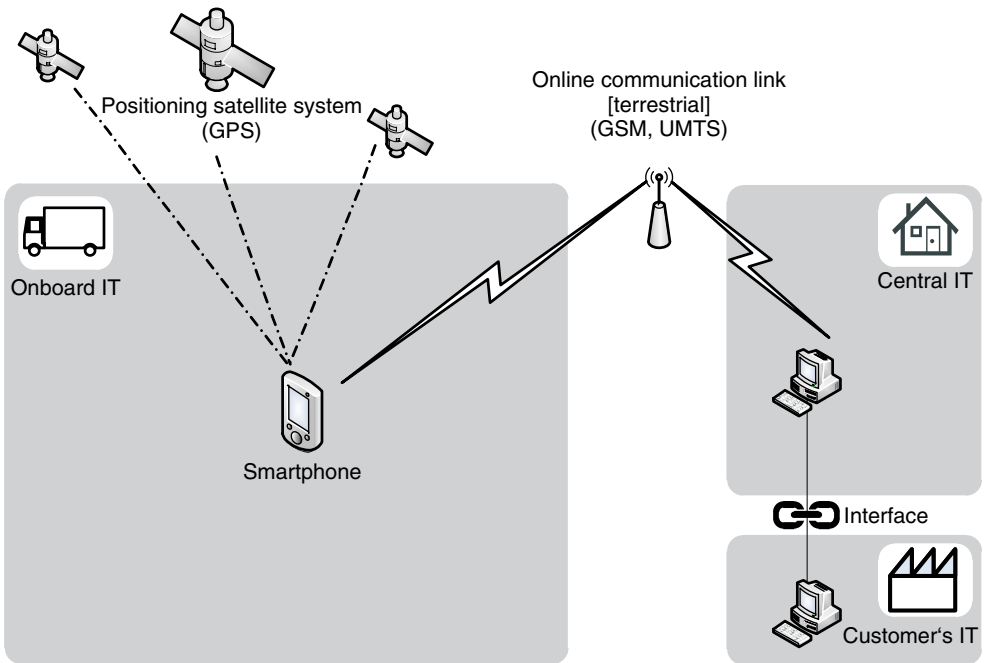

Figure 8. Simplified technical layout of an LFM-telematics system.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

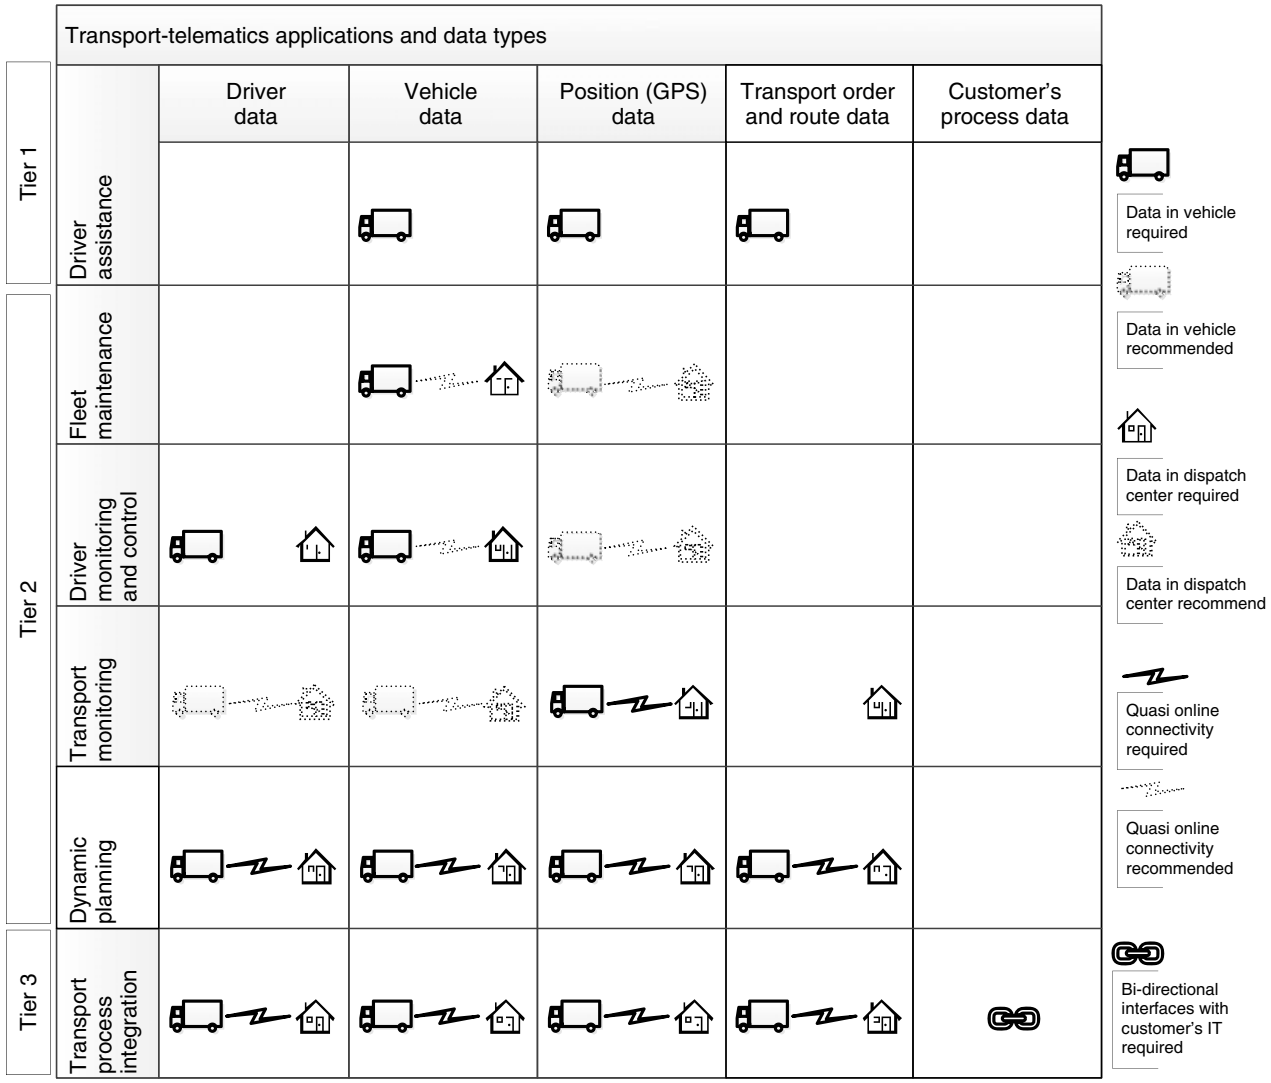

Figure 9. LFM telematics applications and data types.

6.2 Data for LFM telematics

The different applications in each tier require different data. On a high aggregation level, Figure 9 depicts which types of data are needed for which application.

Figure 9 also shows which data need to be synchronized quasi-online (i.e., in regular intervals) and which data only require offline batch data transfer (i.e., up- or download of data when the vehicle is at its home premises).

7 STANDARDIZATION

Standardization, or better the lack of sufficient standardization, today is the key hindrance factor to generate better LFM telematics systems.

If a transport operator with a heterogeneous fleet wants to implement an LFM telematics system, it is facing a number of integration challenges. These challenges concern:

- process and interface standards;
- communication standards;
- software & hardware (SW&HW) standards;
- connectivity to sensors, actuators, and/or vehicle data bus.

Again, the word "standard" is misleading, as "many standards" actually means that there is not one generally accepted standard, which is used.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto184
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

7.1 Process and interface standards

From a logistics operator's point of view, creating a three-tier LFM telematics solutions requires to integrate its own in-house processes (which are usually supported by his or her in-house software) and the processes of its customers (i.e., the shipper and/or consignee) via interfaces.

Currently, the degree of cross-company process standardization in logistics operations is not very advanced. Almost every IT system used in the industry provides own process templates, and many tailor-made adaptions of the so-called standard software can be found, as these adaptions are required to mirror specifics of the relevant transport operator. Therefore, the in-house processes of transport operators can be regarded as "individual process implementations". This issue was recently researched by Kunze and Baumgärtel, who presented a process and interface standard for cross-company dispatching of truck-meets-truck transports (Kunze *et al*., 2011).

On the customer side, the world market leading ERP systems tend to represent "quasi-industrial" process standards and interface standards.

Thus, a significant effort for process and interface integration (internal and external) is necessary to implement a three-tier LFM telematics solution.

7.2 Communication standards

The choice of communication standards (second-generation GSM, third-generation UTMS, fourth-generation LTE, satellite communication, etc.) needs to balance communication network coverage (if a vehicle is out of range of the communication net, LFM telematics is interrupted; data buffering may help to overcome small regional gaps in communication, but if coverage is too low in general, it renders LFM telematics useless), speed or data throughput (a low throughput may be compensated by applications which are designed to minimize communication data volume), and costs (flat rates have reduced the importance of this issue recently).

7.3 In-vehicle HW and SW standards

In-vehicle HW and SW for tier 1 applications are usually defined by the choice of the relevant technology provider.

7.4 Connectivity to sensors, actuators, and vehicle data bus

The issue of access to the data provided by the in-vehicle data bus has been addressed by a group of European truck manufacturers.[14] They have agreed to implement and support an open standard to give third parties access to vehicle bus data. This standard is called *FMS* (*fleet management systems interface*) and is administered by the ACEA European Automobile Manufacturers' Association (for further details, see ACEA, 2009).

In case sensors and/or actuators are needed for an LFM telematics solution, which cannot be addressed by the OBC via FMS, specific wiring and IT-integration works are required, which lead to extra costs.

8 SUMMARY AND OUTLOOK

LFM telematics solutions provide benefits not only for the drivers (driver's assistance) but also to the logistics operators (transport monitoring and dynamic planning) and to the shippers and consignees (transport process transparency). The key hindrance to generate these benefits is the low level of substantial standardization (of processes, interfaces, and technology).

Owing to outsourcing and subcontracting, today's value chains have become more and more dependent on transports. Consequently, transport logistics continues to evolve from "sheer physical box moving" to "transport, process, and information logistics". Therefore, the use of LFM telematics is likely to grow further in number of installations as well as in scope of functions.

GLOSSARY

Carrier	Company (with own vehicles) that executes transports physically.
Consignee	Recipient of goods.
Forwarding agent	Company (with or without own vehicles) that organizes transports.
Transport logistics operator	Term used to describe service providers involved in the transport of goods—this includes forwarding agents, carriers and in-company departments which plan and execute goods transports.
Shipper	Sender of goods.
Role	Term stems from process modeling, and describes a number of tasks and obligations of a person who acts within this role.

ENDNOTES

1. Only 9% of the vehicles in the panel operate outside Europe, too.
2. Note that the delimitation of these terms is not coherent throughout literature. ITS (2011) for instance has defined the term *intelligent transportation systems—commercial vehicle operations* (which is similar to our definition of "LFM telematics"), but that definition includes RFID applications for cargo management systems [see (ITSA, 2011, p. 62)].
3. Without an OnBoard-IT system, the *route details* are handed over to the driver as printouts of the route itinerary and the bill of loading.
4. Note: In case "transport monitoring and exception handling" does not provide any replanning features, the relevant order-, vehicle-, and driver data have to be rerouted to "transport planning" in order to make the needed changes in the *route plans*.
5. In an increasing number of cases, "transport invoicing" is replaced by "transport crediting." This inverts the financial subprocess, but the need to match route execution data with financial transactions remains unchanged, as in the case of "transport crediting" the transport logistics operator(s) need to double check the credit notes.
6. For example, the summary of ITS applications as shown in ITSA (2011; p. 62 f) focuses on tier 2 and 1 applications, only, with very few exceptions of tier 3 applications and significant overlap of traffic-telematics applications.
7. "Eco" stands for both economic and ecological driving in this context.
8. Sometimes, the same applies to the shipper, who also wants to impose time windows for pick up.

Tolling, Mobility Pricing

Martial Chevreuil
Egis, Guyancourt, France

1 INTRODUCTION

The term *toll* is quoted in the Greek mythology where the ferryman Charon used to charge a toll to carry the souls of the dead across the River Styx separating the world of the living from the world of the dead.

Toll roads are at least 2700 years old, as tolls had to be paid by travelers using the Susa–Babylon highway under the regime of Ashurbanipal, who reigned in the seventh century BC (Gilliet, 1990).

In the ancient times, in various parts of the world, travelers were obliged to pay a toll for passing some particular points on the road (e.g., bridges and mountain passes). However, toll is different from the "octroi," which was a tax levied on some goods entering cities, invented by Romans and still existing in some countries in the world.

Tolls were in use, during fourteenth and fifteenth centuries, in the Holy Roman Empire. In fourteenth-century England, some of the most heavily used roads were repaired with the money raised from tolls.

According to FHWA (Federal Highway Administration),[1] "tolling involves the imposition of a per-use fee on motorists for a given highway facility. Historically, these fees have generally been flat tolls that may vary by number of axles and distance driven, but not by time of day.[2]" These charges were originally used for generating revenue for financing, maintaining, and operating the road, bridge, or tunnel that are used.

However, with the time, the objective of tolls has evolved, and the name itself has changed in order to better cope with the different usages of tolls. Road pricing [or road user charging (RUC)] is the general term used nowadays that encompasses the various types of tolled road infrastructures.

In another way, we can say that road pricing defines the different policies of pricing the road usage, whereas tolling is the physical way of levying the fee directly from the user. Road pricing includes the charges levied for the use of the road infrastructure; these charges may be used for repaying the infrastructure costs or compensating the social costs of road transports, that is, paying for negative externalities [noise, pollutant and GHG (greenhouse gas) emissions, visual intrusion in the landscape, and accidents]. Making the charge varying with time of day, or week, is also a way of managing the travel demand. In that case, road pricing is used as a transport demand management tool to reduce traffic intensity during peak periods and is termed *road congestion charging*. Singapore and Hong Kong have been pioneers in implementing this concept. The charges may also vary according to the tailpipe emissions of the vehicle: such measures are implemented in some cities in the world to discourage more polluting vehicles to enter the city centers.

2 A VARIETY OF TOLLING SCHEMES

2.1 Toll for financing infrastructure

This is the historical reason for tolling roads: tolls are in that case a contribution that covers fully or partially the cost of road construction, maintenance, and operation. In case of partial coverage, the missing part is paid by government or local authorities' subsidies; the reason given being, for example, that the road infrastructure is also contributing to the local economy and to the society in general. The road can be publicly or privately built with a concession scheme: loans necessary to pay for the construction and maintenance of the roads are issued with the expectation that they will be paid back over time by tolls. When the loans are paid off, the road should usually revert to the authority that owns the land it was built on. In practice, a toll is often maintained in order to ensure proper maintenance and operations. In particular, during the estimated lifetime of the concession, it often appears necessary to upgrade the road because of the traffic growth.

Tolls usually vary by vehicle type, weight, height, or number of axles. We can distinguish two types of toll systems: open or closed. A closed toll system is a system where the user crosses a first tollgate when entering the road (access point to the network, where the user takes a ticket, real or virtual) and a second tollgate when exiting the network, where he or she pays after presentation of the ticket. In that case, the user pays according to the distance between the entry and the exit. Contrarily, on an open toll system, all users of the same category pay the same toll at a toll plaza, whatever their origin and destination are, and independently from the distance really traveled. Open toll systems are used for isolated stretches of road, such as tunnels and bridges, or on stretch of road networks where most of the users have similar origins and destinations of journeys, particularly in urban environment. By implementing several toll plazas on an intercity motorway, the toll paid for a long distance depends approximately of the distance traveled.

Both systems have advantages and drawbacks: the open toll system is simpler, as there is no need to calculate the toll according to the distance really traveled. Generally, the toll amounts are low. Therefore, the tollgate crossing delay is minimized, which is very important for high trafficked stretches of roads. The closed system is more appropriate for long distance road networks where the diversity of origins and destinations is large, and the toll fee may be high for certain journeys.

On a wide network, both systems can coexist. In any case, selecting the toll system type requires knowing quite precisely the travel patterns of the region, which is irrigated by the toll road network.

Until now, access to tolled roads is generally restricted by barrier arms, which open when the driver has paid or taken a ticket. Initially, tolls were collected by hand by employees at tollbooths. Owing to the fact that toll amount on open toll system is a lump sum by category, these systems have been the first to be automatized: the user deposits coins in a basket, which measures the amount and opens the barrier allowing passage if sufficient.

Nowadays, credit card terminals have replaced the coin-collecting baskets in many places, allowing at the same time automation of tolls for closed networks.

In the last decade, we have seen the rapid extension of electronic toll collection (ETC), which is defined by the use of electronic contactless communication from a transponder installed in the vehicle and the toll collection system. In case of preexisting tollgate, the communication that supports the transaction process is established at the tollgate: preexisting tollgates are generally kept for occasional users and also as a mean to control the access in order to avoid the installation of a specific enforcement system. We will see in the following sections that ETC can be implemented in different contexts where the tollgate is no more necessary. Some examples are presented on the photos hereafter (Figures 1, 2).

2.2 Mobility pricing

Like in many domains, pricing is a tool for management. Applied to transport policy, it leads to the concept of mobility pricing. The first idea, suggested by transport economists, is to make the user (traveler or shipper for goods transport) pays the real cost of using the transport facility. However, here, we start facing a first difficulty; in theory, this real cost should integrate all aspects: amortization of the transport facility (infrastructure, rolling stock, vehicles, equipment, etc.), operation costs, and externalities (emissions, noise, etc.), some of these costs varying with the traffic load and transport occupancy! On the one hand, as some of these costs are supported by the community (public investment and externalities), they are partly paid by taxes. On the other hand, public authorities provide subsidy for public transport as an incentive measure for sustainable development. If we add to that, the different users' categories, mobility pricing is a complex policy calling for various measures and tools. Owing to the predominance of road as transport mode in developed countries, road pricing plays a key role in mobility pricing and we will elaborate on this aspect in Section 2.3.

2.3 Road pricing

Some countries have planned to implement a national road pricing scheme in order that the users pay for the "real" cost of using the infrastructure. Studies for implementing such a scheme were conducted in the Netherlands, late 1980s (Rekeningrijden project). The idea starts from the fact that increasing gas taxes is not always feasible; especially in small countries, where users can fill in their car tank in the neighboring countries where taxes are sometimes lower. Owing to political changes, the Dutch project was abandoned; however, the idea was reintroduced several times during the last 20 years, without success.

Owing to the large impact of heavy goods vehicles (HGVs) in terms of emission, energy consumption, and damage on the pavements, the idea of charging specifically the HGVs has encountered a better success, particularly in Europe, where the first step had been to introduce the "Eurovignette."[3] Different pricing schemes are existing, based on distance traveled, weight, and, more recently, on motorization (EURO classes in Europe) (Figure 3).

HGV or lorry RUC are in operation in New Zealand (called *RUC*), Switzerland [LSVA, Leistungsabhängige Schwerverkehrsabgabe (Performance-related heavy vehicle fee)], Germany (LKW-Maut, Lastkraftwagen), Austria (Go-Maut), Czech Republic, Slovakia, Poland, and four US states: Oregon, New York, Kentucky, and New Mexico.

The enclosed map from the European Commission presents the current situation in the different European countries.

Various technologies are used for tolling. The main drivers for choosing the technology are the system implementation and operating costs, its reliability, and its ability to prevent fraud. In some cases, the costs of collecting tolls can reach 30% of the amount to be collected. Section 2.4 presents three typical examples of road pricing contexts with an introduction of the various technologies that can be used.

2.4 HGV road pricing/user charging

It is certainly New Zealand that introduced for the first time an RUC system in 1978. All the revenue from RUC goes into the National Land Transport Fund. The fund is used mainly for road construction and maintenance, along with other activities benefiting to road users. It is a distance-related charging system where rates are set according to vehicle type and weight and vary in proportion to the road usage costs. This is intended to encourage transport operators to make efficient choices when transporting freight, that is, to use vehicles that balance direct operating costs and damage to roads. The distance traveled is controlled by "hubodometers" (mechanic odometers installed on vehicles and trailers axles). In 2012,[4] some modifications have been introduced in the legislation, but the principles remain the same. The RUC scheme is applicable to vehicles over 3.5 ton manufacturer's gross laden weight and all vehicles of 3.5 ton or less, powered by a fuel not taxed at source. In New Zealand, diesel fuel is not taxed at source, as it is used for 1/3 off road. Nowadays, the mechanical distance-measuring system has been replaced by on-board units (OBUs) not only based on the odometers, now electronic, but also using satellite positioning and able to report remotely via cellular communications to their base stations the distance traveled.

Switzerland has adopted in 2000 a similar system; the toll is applicable on the whole road network. This toll scheme was adopted by a federal referendum in 1997.

Toll must be paid for all the vehicles and trailers, which

- have a total weight of more than 3.5 ton;
- are used for the carriage of goods;
- are licensed in Switzerland and abroad and drive on Switzerland's public roads network.

The rate considers

- mileage traveled within Switzerland;
- the maximum authorized weight;
- the level of pollutant emission.

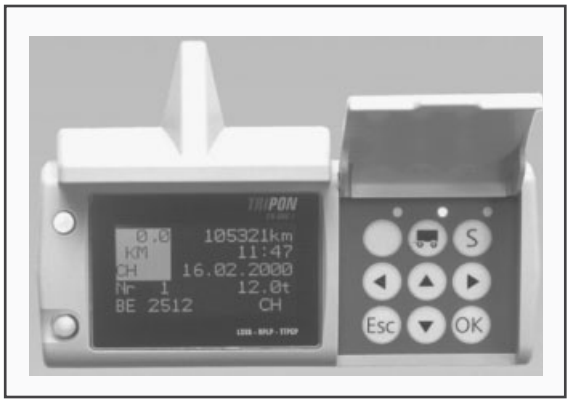

Figure 4. On-board unit for the Swiss HGV charging system.

The toll is collected on a self-declaration mode: each month, the vehicle owner must send to the customs the information registered on the OBU. Data are stored on a chip card and are transferred by internet connection, or the chip card is sent by Post (Figure 4).

The OBU is a multitechnology device that allows:

- the automatic recording of the distance traveled, thanks to a connection with the electronic tachograph;
- to start or stop this recording when crossing the border, thanks to a DSRC[5] link between the OBU and beacons;
- to interrupt the recording when abroad, thanks to GPS (global positioning system), or when the vehicle is on a train, thanks to a movement detector device;
- comparison between distances computed from the tachograph data and distances obtained by GPS tracking. This comparison may be used for odometer calibration;
- To detect if a trailer is present or not.

The OBU is mandatory for vehicles registered in Switzerland and freely available for the HGV owner. However, the owner is responsible and pays for the installation. Exempted vehicles are equipped with a DSRC tag for facilitating the control tasks.

For foreign vehicles, terminals are installed at the borders. Drivers must register the first time they enter the country and declare on the terminals the distance traveled in the country when they leave the country. For regular journeys, they can pay in advance for a defined distance.

Germany introduced a distance-based road pricing system in 2005. Only HGV with total weight over 12 ton and circulating on the federal motorway network (12 000 km) are charged. Rates vary according to the number of axles and pollutant emissions. As the toll is only applicable

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto185
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on motorways, the system must identify precisely the position of the vehicle.

The toll collection system is based on a specific OBU equipping around 500 000 vehicles. Owing to the cost of the OBU (around €500) and the installation constraints that force to immobilize the vehicle for half a day, it appeared difficult to make it mandatory. Therefore, a manual system has been implemented for the nonequipped vehicles (around one million at the early stage).

The OBU (heavy client type) includes the following features:

- A location system based on three components: satellite positioning, in-vehicle equipment (compass and odometer), and infrared communication with roadside beacons, which is used for regular recalibration of the position, especially where the GPS signal is not reliable, and for control purpose.
- A communication module based on cellular GSM/GPRS (global system for mobile communications/general packet radio service) network.
- An embedded computer that calculates in real time the toll amount due according to the vehicle characteristics and a tariff table that is downloaded from the central office.
- A 5.8 GHz DSRC interface ready for ensuring interoperability with DSRC-based toll systems in other countries.
- A digital map of the network, regularly updated through the cellular network.

The computerized toll amount that is calculated on-board is regularly sent to the toll collection center. The digital map, the on-board software releases, and tariffs are updated by the toll center and regularly sent via the cellular radio network to each registered vehicle.

Control is ensured by fixed equipment (gantries) and mobile patrols, both equipped with infrared communication devices, which can check remotely the OBU status. In case of nonconformity, the video cameras installed on the gantries take a photo of the license plate, or the patrol intercepts the vehicle.

The manual system is based on a "reservation" by the driver of the itinerary he or she intends to follow. This can be done via Internet or on the terminals installed at the borders and on service areas. According to the vehicle parameters, the length of the itinerary, and the dates of travel, an invoice is established and the user pays online. All data are transmitted to the toll center, which can track the registered vehicle on the declared itinerary and verify that the followed itinerary is in line with the reservation.

2.5 Tolling in urban areas and congestion pricing

According to the World Road Association (PIARC, Permanent International Association of Road Congresses),[6] "congestion pricing works by shifting some less critical or more discretionary rush-hour highway travel to other transportation modes or to off-peak periods, taking advantage of the fact that the majority of rush-hour drivers on a typical urban highway are not commuters. By removing a fraction (even as small as 5%) of the vehicles from a congested roadway, pricing enables the system to flow much more efficiently, allowing more cars to move through the same physical space."

Congestion pricing or congestion charges are based on market economics principles, assuming that users have to pay for the additional negative externalities they create when they drive during peak periods. The objective is also to educate the drivers on the impact their behavior has on the environment. Application is mainly in urban areas suffering from traffic congestion during the commuting peak periods.

We can distinguish three types of systems:

- a cordon area around a city center, with charges for passing the cordon line;
- area-wide congestion pricing, which charges for being inside an area;
- targeted pricing, where access to a corridor, a lane, or a part of the street network is priced.

In 1975, Singapore was the first city in the world to introduce an area-wide congestion charging scheme system. Access to the city center was only permitted to motorists having paid a license and displayed a vignette on the windscreen. Gantries were installed in order to clearly demarcate the charging zone. These gantries were monitored by police officers who carried out visual checks and recorded any violations. At that time, the toll rate was flat ($3 a day). In 1998, the system was replaced by an electronic system: the vignette has been replaced by a tag, which communicates with beacons installed on gantries, via a DSRC link. The tag bears an electronic purse (cash card) and each time the user drives through the gantry, a certain amount is deduced. This amount varies and depends on the location and time. In case of insufficient credit, or absence of tag, a photo is taken and a fine is sent to the registered vehicle owner.

London introduced its congestion charging system in 2003 covering the London CBD (central business district) (around 21 km^2). From that date, each motorist who enters the charge zone, parks, or drives inside must pay a daily

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto185
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

charge of £10 (2012 tariff) between 7:00 and 18:00 Monday to Friday, except during bank holidays.

Payment is made in advance by registering via various means. Users can subscribe to various options (for 1 week or 1 month) and obtain discounts. Residents have a 90% discount. Registration is attached to a vehicle number plate and the control is ensured by video cameras installed at the entries and inside the charging zone, which allow with an automatic number plate recognition (ANPR) facility to check if the passing vehicles have been registered in the central database.

There are as well special measures for companies' vehicle fleet and commercial vehicles.

The Stockholm congestion charge or "Stockholm congestion tax" is a congestion pricing system implemented with the purpose of reducing the central city congestion and improves the environmental situation. It was implemented on a permanent basis on August 1, 2007, after a 7-month trial period between January 3, 2006 and July 31, 2006, and a referendum held in September 2006, which resulted in a yes from the city residents. Though the neighboring municipalities voted against, the newly elected parliament decided for a permanent implementation in June 2007. The tax is levied on weekdays between 6.30 a.m. and 6.29 p.m. No tax is charged on public holidays, the day before a public holiday, or during the month of July (Figure 5).

1. The car passes a laser detector, which activates the cameras. (When the OBU was in use, this also communicated with the transceiver aerials.)
2. The front number plates are photographed.
3. The rear number plates are photographed.

During the trial phase, the technology used was DSRC with tags equipping the vehicles. Gantries have been installed at 18 entries to the city center. It is worth to mention that Stockholm is an archipelago, which makes the access control easier than in other cities of this size.

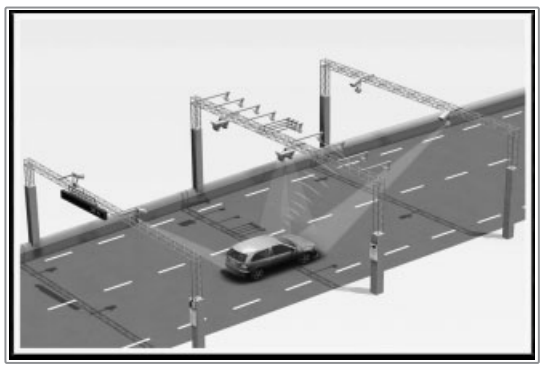

Figure 5. Stockholm toll system. (Reproduced from Swedish Transport Agency. © Swedish Transport Agency.)

When the system entered in the full operation phase, the DSRC component and the tags have been abandoned. The system relies now only on video.

Implementation of the congestion pricing has reduced car traffic in the city by 20–25% and queues by 30–50%, the impact being similar to what has been observed for London. Most of the travel demand has been transferred to public transport and a part has shift to noncharged periods of the day.

Though currently limited to a small number of cities in the world, concerns about nonrenewable energy consumption, emissions, and climate change are currently leading politicians and local authorities to think on different solutions to limit car usage in cities. Solutions can be road pricing, with charges limited to more pollutant vehicles, or even banning them from the city centers. This is the aim of the low emission zone (LEZ) policy developed by Europe.

3 ELECTRONIC TOLL COLLECTION FEATURES

ETC is a generic term that refers to all types of systems based on electronics, which allows drivers to ride on a tolled road and pay without stopping at a tollgate, the tollgate existing or not!

As introduced earlier, ETC has facilitated the development of modern infrastructures with concession to the private sector of the construction and operation, and has made possible a more equitable contribution of the transport of goods to road maintenance and operation costs. It has also made feasible the implementation of traffic demand management strategies in urban context for alleviating the congestion.

Now, a little bit of history. According to Wikipedia, in 1959, Nobel Economics Prize winner William Vickrey was the first to propose a system of electronic tolling for the Washington metropolitan area. He proposed that each car would be equipped with a transponder. "The transponder's personalized signal would be picked up when the car passed through an intersection, and then relayed to a central computer, which would calculate the charge according to the intersection and the time of day and add it to the car's bill."[7]

Several pilots were undertaken between the 1960s and the 1980s. For example, in 1986, on the eastern motorway near Paris at Coutevroult, ETC was tested for the first time with fixed transponders at the undersides of the vehicles and readers consisting of magnetic loops, which were located under the pavement.

Norway has certainly been the world's pioneer in the implementation of this technology. ETC was first introduced in Bergen, in 1986, operating together with traditional tollbooths. In the 1990s, many European countries with tolled motorways started implementing ETC systems. Boosted by industry and also by the European Commission who included in its first R&D program dedicated to transport (DRIVE I—dedicated road infrastructure for vehicle safety in Europe), various technologies were tested and implemented.

One challenge has been to introduce free-flow tolling or open road tolling (ORT) where there is no more the need for motorists to stop or slow down. The first system implemented was the E 407 near Toronto, Canada in 1997. The system is based on two technologies: motorists can choose to use a transponder (mandatory for HGV) or not. In that case, a photo of their license plate is taken and an ANPR process allows identifying them. Toll bills are sent to motorists on a monthly basis. As the operating costs of the video solution are higher than using the transponder facility, an additional fee is charged to nonregistered motorists.

Another pioneer in free-flow tolling system is that of Melbourne CityLink, opened in 2000. The innovative nature of this toll system was a deciding factor in the concession holder consortium's choice of this urban freeway. The CityLink was one of the world's largest multilane ETC systems at that time, based on DSRC technology. It is divided into eight separate toll sections. These are freeway sections where users pay a toll on entering. In order to use the CityLink, motorists must, therefore, take out a contract with the operator. Occasional users can pay the toll by phone in the days before or following their use of the toll road. The contract can be prepaid or per day. To protect against fraud, a video camera system enabling car registration numbers to be photographed and an automatic vehicle classification (AVC) system have been installed on the gantries. A major difference with E 407 is that motorists are encouraged to subscribe and get a tag. If they are not equipped with the tag and if they do not pay within the allowed period, maximum 2 days after, they are considered as defrauders and are charged with penalties.

Nowadays, in the world, a great variety of technologies for ETC are used. They are presented in Section 3.1.

3.1 Technologies

ETC scheme rely on three major components: "toll event" identification and characterization [which includes automatic vehicle identification (AVI) and classification and environment parameters], transaction (invoicing and processing), and violation enforcement, as shown in Figure 6. In addition to the pure transaction process, support functions are necessary, particularly CRM (customer relationship management) for managing the contracts with the subscribers, delivering the equipment (tags, OBU, etc.), and manage incidents, exceptions.

The three main components are somewhat independent, and can use different technologies. They can also call for different operating bodies, and this is a general trend in order to facilitate the interoperability between different operators. However, in any case, implementing an ETC scheme requires adopting a comprehensive system approach.

3.2 Toll event

The objective of this component is to collect all the information necessary to establish the toll amount due by

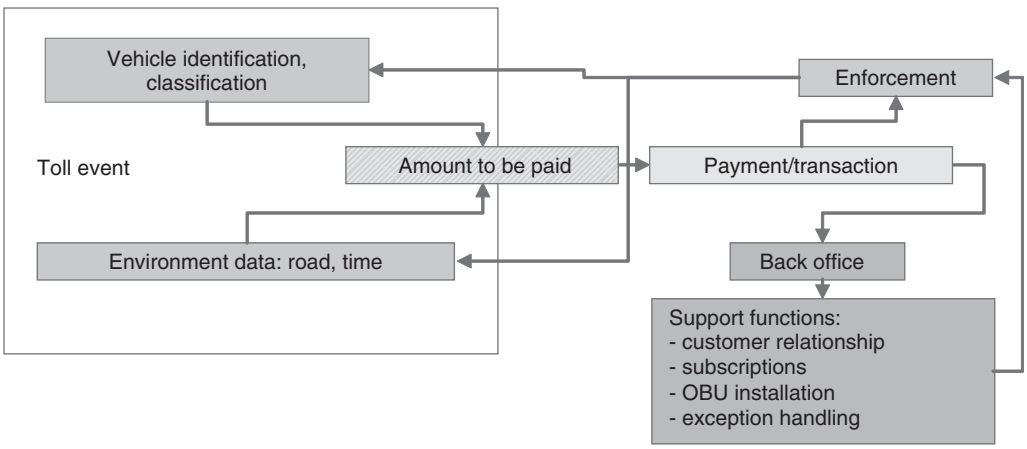

Figure 6. Tolling process. (Reproduced by permission of Egis. © Egis.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the user. It relies on different functions such as AVI and AVC.

AVI is the process of determining the identity of a vehicle subject to tolls at one point of the road network.

This point may be a point materialized on the road, for example, a classical tollgate with or without barriers, or a gantry. In that case, AVI can be performed, thanks to

- radio-frequency identification (RFID), where a beacon installed on the infrastructure communicates with a transponder on the vehicle via short-range communication. The transponder may be an RFID tag (e.g., the Salik System in Dubai) or a read/write microwave transponder (European DSRC);
- video system taking photo of the vehicle and license plates (front and/or rear plates) like in London and Stockholm.

For toll systems based on satellite positioning, the toll point is virtual, as it is not materialized on the road. The toll point is identified by the OBU within a database, or a digital map (German HGV toll system).

AVC: as most toll systems charge different rates for different types of vehicles, it is necessary to distinguish the categories of vehicle. The first and basic method is to reserve at tollgates some lanes for light vehicle equipped with a gantry at a limited height. However, this method cannot be used for meeting the current requirement of road pricing schemes that distinguish many other criteria than only the vehicle height.

The current method is to store the vehicle class in the tag or in the OBU, and use the AVI data to look up the vehicle class and parameters. However, simple tags cannot deal with vehicles that may change category, such as trucks with trailers. OBU can integrate this facility (see Switzerland).

More complex systems use a variety of sensors for counting the number of axles, as a vehicle passes over them. Light-curtain laser profilers record the shape of the vehicle, which can allow to distinguish clearly the type of vehicle but they are quite expensive.

In addition to vehicle identification and classification, establishing the toll amount requires to consider the different other charging criteria such as the time, date, and toll rate at the location. The process for calculating the toll amount is in fact between the toll event characterization and the transaction process.

3.2.1 *Transaction processing*

Different options exist depending on the systems used; in most case, the toll due is calculated at the toll center with the data collected from the toll point and/or the vehicle. However, in some case, the amount due is calculated by the OBU (German case) or on site (prepaid card coupled with DSRC tag, for example); the amount due is immediately deducted.

Transaction processing is performed through the back office. The processes are very similar to those of mobile phone companies. It consists of user accounts management, posting toll transactions and user payments to the accounts, and handling user inquiries. The user is in fact a consumer of road facilities and the transaction-processing component of some systems is referred to as a *customer service center*.

As we have seen in the different examples given, customer accounts may be postpaid (toll transactions are invoiced to the user on a periodic basis) or prepaid (the user funds a balance in the account that is then depleted as toll transactions occur).

3.2.2 *Violation enforcement*

With the development of ETC without physical barriers, the risk of fraud has increased. A violation enforcement system (VES) is necessary for limiting the number of unpaid tolls. Several methods and techniques are used to dissuade toll violation and to identify defrauders.

As ETC is based on dematerialization of processes, police visual checks are no more effective. ANPR, already used in some case as the vehicle identification method, is the basic tool in violation enforcement. Basically, the VES works in conjunction with a detection system that verifies if the vehicle is respecting the ETC rules:

- For ETC using transponders (RFID, DSRC tags, etc.), the first verification consists in detecting if the vehicle is equipped. If not, a photo of the number plate is taken and verification is made with the database of registered users: it can be occasional users who have registered for a daily pass, for example. It can be also subscribers who have obtained a tag, but have neglected to put in on the windscreen; in that case, generally, they will not be considered as violators and a simple warning will be sent to them with notification of an excess charge. If the identified vehicle does not enter in these categories, a violation notice will be issued and generally transferred to the authorities who can have access to the vehicle registration database (very few countries allow that the toll operators have access to this database).
- Concerning ETC using "smart transponders," the first verification can be more in depth: a communication is established with the roadside equipment (RSE) in order to check if the user's account is in order, if the vehicle class corresponds, and so on. The same process

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto185
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is undertaken for ETC based on satellite positioning and dedicated OBUs. It requires that the OBUs are equipped with the proper interface in order to set up this communication.

Therefore, the checking procedure necessitates that RSE are installed in various locations of the network. The equipment can be fixed, removable, or mobile. Fixed equipment is typically gantries over the road supporting the checking equipment (beacons) and the video system. Communication is ensured with a processing center via wire or wireless connection. Mobile enforcement can be also achieved with vehicle patrols equipped with similar equipment. Using patrols allows as well intercepting immediately the "suspicious vehicle."

A major issue concerning enforcement is that of the legislative context: the ANPR allows identifying the vehicle owner and not the driver, and in some countries, modification of the law has been necessary for being able to make the owner responsible of the traffic offences under some circumstances.

4 INTEROPERABILITY

With the development of toll systems, for different objectives leading to specific technical solutions within a country or a region, users and particularly professional users and commercial vehicles are facing a new difficulty, which is to be obliged to subscribe to various toll operators and be equipped with different tags or OBUs.

The problem was raised in Europe and in the United States during the early 1990s and several projects and pilot projects were undertaken to overpass the difficulty. The solution, which could have been to adopt a standardized system and choose a sole technology, was not feasible because of the investment already made and also to the different context of tolling.

In Europe, however, a first step was made by adopting a standard for DSRC-based tolling systems, with the selection of 5.8 GHz as the telecommunication bearer. This standard (CEN/ISO 14906) has been used also in different other countries such as Australia (Melbourne CityLink) and South America.

For example, in France, the seven different motorway companies that were operating in the mid-1990s, adopted for light vehicles, the first published toll standard, under the brand Liber-T and developed bilateral agreements between them. The system is still in place and the user can subscribe to any toll company provider and drive everywhere in France. All travels are recorded by each company where the user drives (toll charger). A single bill is then established by the toll service operator (the one to which the user has subscribed) after reconciliation of all travels. This system needs bilateral agreements between each of the companies, which becomes complex with the apparition of new toll operators. A further step has been to allow external service providers to offer the toll service, with specific advantages.

This evolution has led to a clear distinction of the roles between the road operator (termed *toll charger*) and the organization that provide the toll service (the toll service operator).

The toll service architecture can be represented as in Figure 7, according to the recommendations of the EU-related projects[8] and standardization bodies (CEN TC 278 and ISO TC 204).

This model has allowed to clearly identify where the standards need to be developed, that is, for ensuring proper communications at the interfaces between the four entities. A common approach has been developed between CEN and ISO in order to optimize the resources dedicated to this complex work. The WGs involved in this task are the WG1 (electronic fee collection) and the WG5 (fee and toll collection), respectively for the CEN TC 278 and the ISO TC 204.

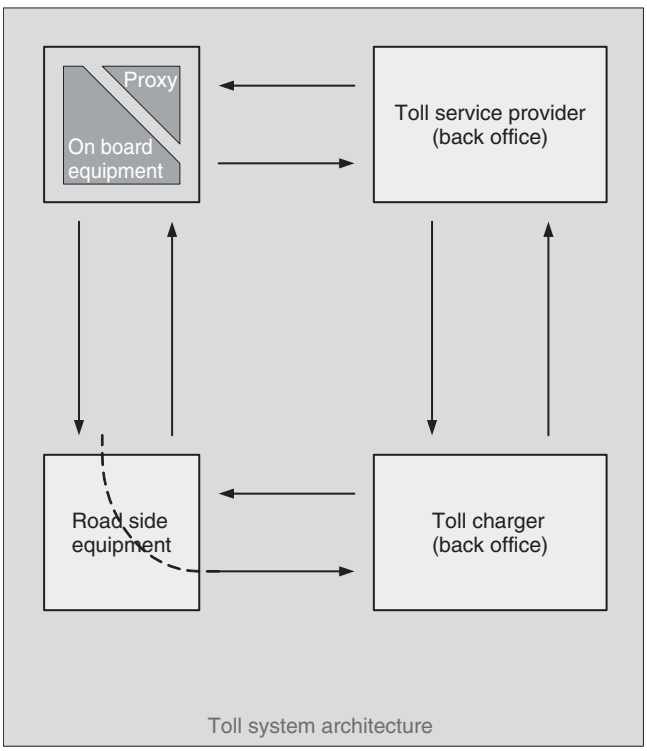

Figure 7. European EETS system architecture.

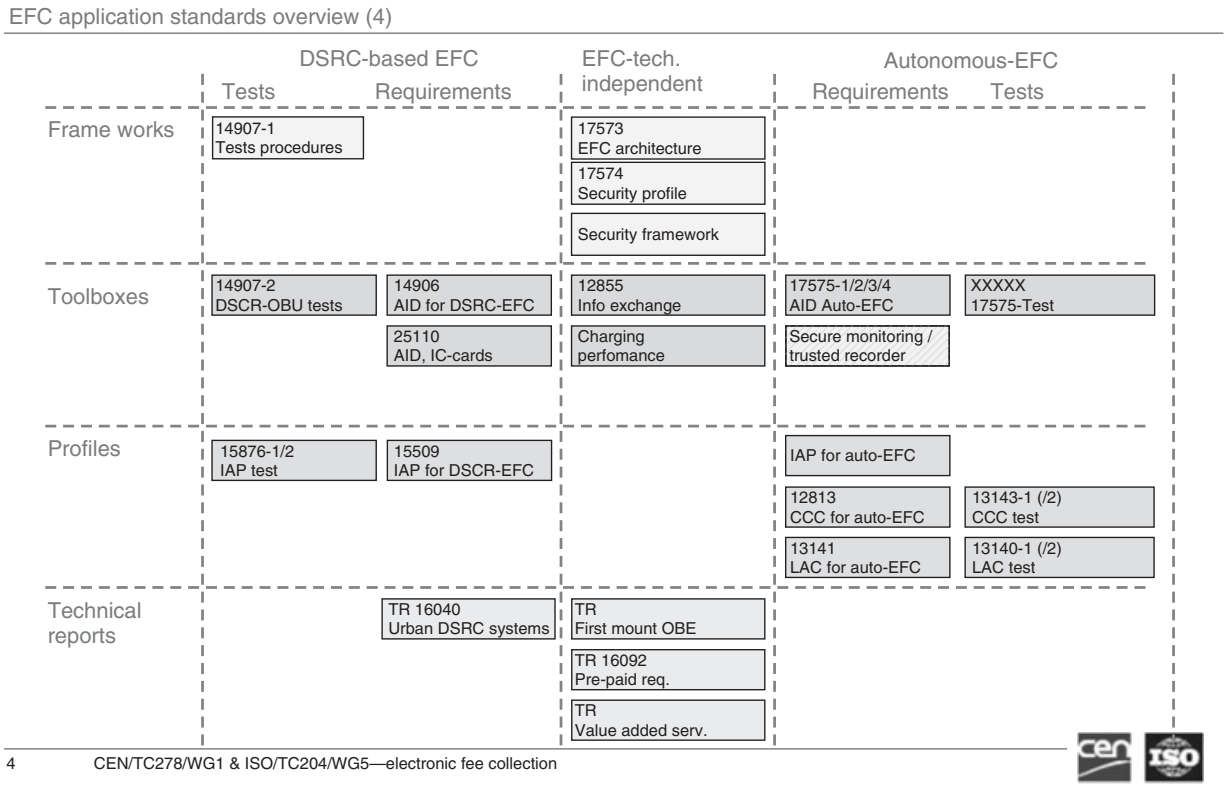

Figure 8. Overview of involved standards in ETC.

Figure 8 gives an overview of the standards that support the ETC services.

Within the RCI project,[9] 27 principal road charging stakeholders in Europe defined, implemented, demonstrated, and recommended this standard architecture for offering a European road charging service to the user based on "one box, one contract, and one invoice."

The final and ultimate task within the project was the demonstration phase in Spring 2008 when two trucks, each equipped with one interoperable OBE (on-board equipment) that seamlessly, and without user intervention, adapting functional behavior when crossing borders, drove through different countries according to the rules that apply for the different tolling schemes, that is, German (Toll Collect), Swiss (LSVA), French (TIS-PL, Télépéage Inter Sociétés pour les Poids-Lourds), Spanish (VIA-T), Italian (TELEPASS), and Austrian (ASFINAG, Autobahnen- und Schnellstraßen-Finanzierungs-Aktiengesellschaft).

Thanks to the work undertaken by the different parties and the willingness of the EU member states to go for interoperability of ETC system in Europe, which is considered as a necessity for supporting the free circulation of persons and goods; the European Union issued the Directive 2004/52/EC and the related Decision 2009/750/EC in order to set up the European Electronic Toll Service (EETS).

The directive, called *directive on interoperability*, stipulates that new toll systems using electronic solutions should use one or more of the following technologies:

1. satellite positioning;
2. mobile communications using the GSM–GPRS standards (reference GSM TS 03.60/23.060);
3. 5.8 GHz microwave technology.

The Guide for the application of Directive 2004/52/EC of the European Parliament and of the Council and of Commission Decision 2009/750/EC[10] details all aspects to be considered for setting up the EETS; the target date for starting EETS was October 2012. Some delays are expected, mainly because of contractual and commercial issues, the technical problems being theoretically solved.

In the United States, projects are also in development. The E-Zpass toll service was the first interagency service to be implemented, starting with seven toll agencies in 1991 and currently there are 25 toll agencies working with E-Zpass. Other projects are underway, with the objective of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto185
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

creating clearinghouse bodies for facilitating the interoperability of toll services.

One difference between Europe and the United States on this matter is certainly due to the difference in the road user market segments: in Europe, the first target for toll interoperability is the long distance HGV crossing several countries. Each transaction represents several tens of Euros. Toll chargers are, therefore, attached to stay in the loop and develop alliances to become EETS providers. In United States, the market is more open and the mean value of transaction is quite low. Owing to the huge amount of the total transactions, if we consider as well the parking and public transport payments, the bank sector is very much interested in being the main actor (Opiola, 2011).

5 CONCLUSION

The tolling domain is an important component of the traffic system. From the initial stage where the objective was mainly to finance new infrastructures, the toll systems have evolved in tolling services, offering new opportunities for the traffic and road network operators.

With the introduction of ICT in the transport domain and particularly in tolling, leading to the ETC concept, tolling has certainly been the pioneer of the connected car concept.

New actors have emerged for taking in charge the new opportunities of services in the domain. They will play certainly a key role in the development of the connected car services, for which the business models are still uncertain.[11]

6 GLOSSARY

ANPR	Automatic number plate recognition
AVI	Automatic vehicle identification
AVC	Automatic vehicle classification

Applications: Emergency Services and eCall

Frank Försterling

Continental Automotive GmbH, Hanover, Germany

1 INTRODUCTION

Emergency services—which are also named *emergency management services* (*EMSs*)—are considered as one of the areas of intelligent transportation system (ITS) applications (Figure 1).

EMS comprises a wide range of incident response, public safety management, and disaster management services. EMS includes the management and coordination of emergency response resources, infrastructure protection, emergency warnings, disaster response and recovery, and evacuation and reentry management. An overview of EMS categories has been proposed by the US administration RITA (Research and Innovative Technology Administration):

- Hazardous materials management
  ITS applications associated with hazardous materials shipment can accomplish several major functions intended to provide safe and secure transport of hazardous materials by road.
- Emergency medical services
  Advanced automated collision notification and telemedicine address the detection of and response to incidents, such as vehicle collisions or other incidents requiring emergency responders.
- Response and recovery
  The variety of sensors deployed on the transportation infrastructure can help provide an early warning system to detect large-scale emergencies, including natural disasters and technological and man-made disasters.

The emergency call service—commonly named eCall (service)—is one of the most important EMSs.

The use of eCall to deploy emergency assistance will save lives and reduce the social burden of road accidents by improving the notification of such accidents; speeding up the emergency service response; and lowering the subsequent effects on fatalities, severity of injuries, and traffic flows. On the basis of impact assessment provided by the European Commission (EC), the mandatory introduction of eCall in Europe will cause the following effects:

- Reduction in traffic death rates (5%) and number of severe injuries (15%) across Europe.
- Reduction of response time 40%–50% ("golden hour"): from approximately 21 min to approximately 11 min.
- Reduction of traffic congestion by 20%.

Owing to the importance of eCall for our society, this contribution will be focused on a detailed explanation of the eCall service only.

Figure 1. Emergency management services as part of ITS applications.

In the following, we first present the definition of an eCall and classify the different eCall options (Section 2). Afterwards, we describe the technical aspects of an eCall service (Section 3). Section 4 describes the aspects of a standardized pan-European eCall, which most probably will be implemented from 2015 onward. In addition to the EC member states, Russia plans to introduce a mandatory eCall as well, which is called *ERA GLONASS*. On the one hand, ERA GLONASS will enable interoperability with the pan-European eCall, while on the other hand it is characterized by several differences. Section 5 considers the ERA GLONASS approach. Section 6 gives an overview of all standardization activities with relevance to the eCall (Europe, Russia). We close this chapter with an outlook on the next steps once eCall has been deployed successfully (Section 7).

2 ECALL DEFINITION AND CLASSIFICATION

2.1 Definition of eCall

The *eCall* is an emergency call either generated manually by vehicle occupants or automatically via activation of in-vehicle sensors when an accident occurs. When activated, the in-vehicle eCall system establishes a voice connection directly with the relevant service provider (SP), which is a public authority or a private eCall center. At the same time, a set of data—including key information about the accident such as time, location, and vehicle description—is sent to the SP operator receiving the voice call. The set of data may also contain the link to a potential further SP by including its IP address and phone number.

2.2 Classification of eCall

2.2.1 Private eCall

The private eCall—also called *third-party services* (*TPSs*) eCall—follows the above-mentioned definition.

- In-vehicle detection of emergency situation (manually or automatically).
- Initiation of an emergency call (any number defined by the eCall provider).
- Provision of data defined by the eCall provider.
- SP receives eCall and initiates emergency measures.

The private eCall has already been implemented by several car manufacturers and works very well.

The drawback of the private eCall solutions are as follows:

- Closed technical solution due to missing common standards;
- Limited deployment (country specific) due to missing infrastructure.

Recognizing the drawbacks of private eCall solutions on the one hand and accepting the social-economical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

importance of the global rollout of standardized eCall solutions on the other hand, several governments decided to go for a standardized eCall solution.

2.2.2 Pan-European eCall

The pan-European eCall is based on an initiative of the EC and its member states. It is based on well-defined standards and follows the above-mentioned definition.

- In-vehicle detection of emergency situation (manually or automatically).
- Initiation of an emergency voice call (based on 112, Europe wide).
- Provision of a well-defined data set—the minimum set of data (MSD)—from the car to the SP.
- The SP is called *public safety answering point* (*PSAP*), which is a public authority or a private eCall center that operates under the regulation and/or authorization of a public body.
- The PSAP receives eCall and initiates emergency measures.
- The network operator identifies the 112 call as an eCall and marks this call via an eCall discriminator, adds location information as well as calling line identification (CLI) data.

The difference between a 112 call, an E112 call and a (pan-European) eCall is as follows:

- 112 is the single European emergency number, which was recently generalized in the entire European Union.
- E112 emergency calls support the immediate localization of the caller.
- The (pan-European) eCall is an E112 call initiated by a vehicle and which, in addition to the voice call, transfers the MSD data set.

2.2.3 ERA GLONASS eCall

The ERA GLONASS eCall is based on the decision of the Russian government to introduce a standardized eCall solution for Russia, which

- follows the definition of the pan-European eCall,
- is interoperable with the pan-European eCall,
- includes additional features for the Russian market.

The key differentiator of ERA GLONASS in comparison to the pan-European eCall is the in-vehicle identification of the position of the vehicle. The Russian government requires to apply the satellite system of Russia (which is called *GLONASS*), whereas the pan-European eCall is based on the US satellite system GPS (global positioning system).

Further differences will be explained in Section 5.

2.2.4 Personal eCall

The personal eCall utilizes for the initiation of the emergency call a Smartphone or any kind of mobile device instead of an in-vehicle system (IVS). The personal eCall is not standardized. Especially, the transfer of additional data is not part of this kind of eCall: neither the MSD nor any kind of other data.

2.2.5 eCall for PTW

The eCall for PTW (powered two-wheelers) seems to be the next important step for further improvements of road safety and life saving. Intense discussions are on at the European level for the integration of PTW eCall into the pan-European eCall standards. First PTW eCall solutions already have been implemented and are part of European interoperability tests (e.g., within the HeERO 2 project).

But the motorcycle industry faces several challenges, among them the most important once are

- insufficient crash sensors to detect an eCall situation;
- different hardware design necessary: the absence of a passenger compartment and different PTW usages require an adapted engineering of motorcycle eCalls;
- cost impact of eCall and PTW.

The amount of unresolved issues does not presently provide the necessary certainties required for making eCall available to all PTWs.

2.2.6 eCall for HGV

The rapid increase in HGVs (heavy goods vehicles) on the roads requires an extension of the pan-European eCall solution for HGV.

The key challenge for an HGV eCall is the extension of the data message as part of an eCall. A rapid assistance will benefit in early knowledge about dangerous goods involved in an accident. The current eCall MSD standard offers no designated coding scheme for information about dangerous goods.

Furthermore, owing to the time and capacity limitations of (MSD-based) in-band messaging, the provision of additional dangerous goods data might require alternative architectural approaches with implications to all parts of an eCall solution (IVS, PSAP, etc.).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Standardization activities have been started within CEN (European Committee for Standardization) in order to define solutions (Section 6).

3 eCALL TECHNICAL ASPECTS

This section describes all the technical aspects of an eCall service. The technical description is based on the pan-European eCall definition. When describing aspects of other eCall solutions, we will make an explicit note.

3.1 End-to-end consideration

For the implementation of a pan-European eCall, we have to consider three major stakeholders (Figure 2):

- The IVS, owned by the car manufacturer.
- The network infrastructure, owned by the mobile network operator (MNO).
- The PSAPs, owned by the public authorities.

Furthermore, depending on the severity of the potential vehicle crash, further stakeholders such as the road authorities, the medical emergency services, and other stakeholders might be involved in resolving the emergency situation. These further stakeholders will be informed and managed via the PSAP.

In case a serious accident occurs, in-vehicle sensors will automatically trigger an eCall. When the system is activated, the IVS establishes a 112-voice connection. As soon as the communication channel is successfully connected, an emergency data message—the MSD—is sent. The MSD includes key information about the accident, such as time, accurate location, driving direction, and vehicle description. The MSD is sent in-band via the voice channel. During the time of the MSD transfer, the voice channel is blocked (the voice part is muted) and cannot be used for direct caller–operator talks. In general, the MSD transfer takes a few seconds. Afterwards, the voice channel will be utilized for direct "PSAP operator to vehicle occupants" talks.

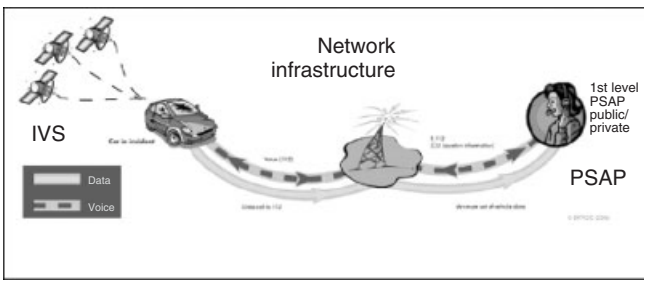

Figure 2. High level architecture of an eCall.

The eCall can also be activated manually.

The MNO identifies that the 112 call is an eCall based on the "eCall discriminator" provided by the vehicle's network access device (NAD), which is part of the IVS. The MNO handles the eCall just as any other 112 call and routes the call to the most appropriate emergency response center—the PSAP. The MNO extends the 112 call toward an E112 call by adding further information to the call such as CLI and the cell identification of the originated eCall.

The PSAP operator will receive both the MSD message and the voice call. The information provided by the MSD will be decoded and displayed on the PSAP operator screen. The location and driving direction of the vehicle can be shown using a geographic information system (GIS).

As soon as the MSD message transfer has been completed, the PSAP operator will be able to talk directly to the vehicle occupants and listen to what happened in the vehicle. This will help the operator ascertain which emergency services are needed at the accident scene (e.g., ambulance, firemen, and police) and to rapidly dispatch the alert and all relevant information to the right service organizations.

Furthermore, the PSAP operator will be able to immediately inform the road/traffic management centers about the incident. The operator provides information about, for example, the specific location and the severity of the incident. On the basis of this information, the road authorities can immediately disseminate this information to other road users and thus prevent secondary accidents. They are enabled to conduct an accelerated clearance of the carriageway, which will reduce congestion situations.

3.2 In-vehicle system (IVS)

The eCall IVS comprises different parts:

- Vehicle interface unit (VIU)
- Positioning system
- Communication system
- Human–machine interaction (HMI) unit.

3.2.1 Vehicle interface unit (VIU)

The VIU as part of the IVS provides the direct secured interface to all in-car components via the in-vehicle network (IVN). The IVN connects the necessary "crash" sensors. This includes pressure, acceleration, and roll-over sensors. In addition, seat occupancy recognition sensors indicate

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the number of potentially injured persons. The sensors measures, for example, the deceleration (loss of speed) and captures the time of air-back inflations. From these values received via the VIU, the IVS calculates the crash severity. The crash data is available after 100 ms. In the future, more sensors may be developed, in order to improve the evaluation results.

An eCall will be initiated only in case of accident recognition by at least 2 of the "crash" sensors. All necessary data will be collected and put into the MSD.

3.2.2 *Positioning system*

The positioning subsystem provides the accurate location of the vehicle as well as its direction of driving.

The pan-European eCall specifications refer to standard GPS positioning service without deeper consideration of possible vulnerabilities and limitations of the position estimation process. Later, the GNSS (global navigation satellite system) solution Galileo will be applied for the pan-European eCall. The Russian eCall is based on the GLONASS solution.

The sole utilization of a single position estimation method will leave considerable gaps in performance (e.g., in tunnels, urban areas), causing potentially dangerous effects on emergency operations and restoration of the traffic flow after the accident.

The standard GPS positioning performance can be enhanced by the utilization of, for example,

- satellite navigation augmentation systems, such as the European geostationary navigation overlay system (EGNOS) by the provision of three additional GPS-like signals;
- accelerometers: in combination with the GPS, accelerometers provide an inertial add-on solution that will continuously provide accurate position estimates with the temporal lack of GPS signals;
- map matching algorithms of modern cars (in case the vehicle is equipped with a car navigation solution);
- the network resources of the MNO, delivered by the IVS communication system.

3.2.3 *Communication system*

The communication subsystem basically comprises the NAD necessary to

- create the "eCall discriminator,"
- set up the 112 voice call,
- forward the data message (in case of the pan-European eCall the MSD)

via the public land mobile network (PLMN) through the MNOs to the most relevant PSAP.

The NAD operates in either of two modes: GSM (global system for mobile communications) or UMTS (universal mobile telecommunications system). For the pan-European eCall, the final decision of the requested network mode is still pending (status January 2013). The ERA GLONASS solution requires the support of both network types (GSM and UMTS).

The NAD has to support an embedded SIM in order to guarantee the "always available" feature. In case the communication system is configured to perform emergency calls only, the execution of mobility management procedures shall be avoided.

The eCall system uses an in-band data modem to transmit the MSD information over the voice path to the PSAP. For this purpose, the NAD (as well as the PSAP) has to be equipped additionally with a data modem. The data modem solution is based on a proposal of Qualcomm and was endorsed by the 3GPP in September 2008. This license-free approach enables the eCall solution to be quickly deployed end-to-end in-vehicle IVSs and PSAPs without modifications to the existing cellular and wireline infrastructure.

The pan-European eCall allows the transfer of data via the in-band modem solution only. Other options for the data messaging are

- SMS (short messaging service)-based data transfer (e.g., specified as a backup solution within ERA GLONASS);
- data transfer via (voice channel) out-band data channels [e.g., via USSD (unstructured supplementary service data) or GPRS (general packet radio service)].

The advantage of utilizing data messaging outside of the voice channel is the option of enlarging the amount of data to be transferred. The MSD data size is no longer a limitation for the data transfer. The disadvantage of this kind of data communication is mainly related to the potentially real-time and performance challenges. Owing to missing standardization activities, the out-band data transfer can be applied to TPS eCall solutions only.

3.2.4 *Human–machine interaction (HMI) unit*

The HMI Unit includes the necessary components to inform the vehicle occupants about the status of the eCall system, as well as the status of the eCall transaction when triggered.

Parts of the HMI unit are at least a microphone and a loudspeaker. Potentially, the vehicle's display might be used as well.

The HMI unit may be dedicated to the eCall device or part of the general vehicle HMI.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.3 Network infrastructure

MNOs have the responsibility of handling eCalls as any other 112/E112 emergency call, including the CLI and caller location information, and supporting the "eCall discriminator." The eCall has to have the same priority and reliability as any other emergency call through the MNO network.

The responsibility for processing eCalls and routing them to the correct PSAP always lies within the network serving the vehicle at the time of activation.

For the proper deployment of the pan-European eCall, the MNOs have to deploy a technical upgrade of their network infrastructure:

- MNOs need to design and implement the "eCall discriminator" (also called *eCall flag*) in their mobile switching centers (MSCs) of the MNO network infrastructure.
- 3GPP approved the "eCall discriminator" and included it in Release 8 of the technical specifications, with which the mobile telecommunications systems must comply. This discriminator will differentiate between 112 calls from mobile terminals and eCalls, and also between manual and automatically triggered eCalls.
- On the basis of this "eCall discriminator," MNOs have to identify eCalls and route the voice and the MSD to the most appropriate PSAP as defined by national authorities in accordance to the national arrangements.
- MNOs need to agree with the public authorities on the "eCall discriminator" implementation plan.
- Furthermore, the MNOs have to upgrade the dialed 112 number toward an E112 call, which includes additional location information from the network (CLI and cell originator information).

The application of TPS-based eCalls does not impact the network infrastructure. TPS eCalls are not based on the 112 numbering scheme.

Maintaining the network infrastructure, the MNOs have to ensure that the network infrastructure of the future still supports the "eCall discriminator" as well as in-band modem functionality. The MNO has to make sure that after finalizing the MSD transfer via the in-band modem, the voice channel can be reopened for voice calls.

Finally, further specification work is necessary in order to deploy the pan-European eCall in long-term evolution (LTE)-based networks as well.

3.4 Service provider

The PSAP is the public-controlled call center responsible for providing a first point of contact to a 112 call. The PSAP thus receives the emergency 112-voice call and the MSD.

On the basis of the voice connection and the MSD content, the PSAP operator decides the handover to the correct dispatcher, which will handle the remaining part of the specific emergency response. The PSAP's source of information is the voice, the MSD, and the location information provided by E112.

The PSAP's operational models vary from country to country and—in some European member states—also between the different regions. This situation caused the necessity of running several eCall implementation and interoperability trials. One of the most important interoperability trials is the HeERO project of the EC.

The transformation of a call center into a PSAP requires a few technical upgrades, as follows:

- Update the equipment of a server with in-band modem capabilities, which allow to receiving of eCalls and extracting/translating the MSD. The server should be designed according to the number of expected eCalls for this PSAP.
- Server software upgrade for the decoding of the complete MSD.
- Server software upgrade with a GIS and an incident management system in order to allow efficient handling of the emergency call.
- Ensure connectivity to all subsequent emergency organizations (ambulance, police, etc.) as well as to the appropriate road authority organizations.
- Ensure the connectivity to TPS SPs (in accordance with the standards).

The integration into the eCall chain of a third-party service provider (TPSP) and its interworking with the PSAP operator is described in the standard "EN 16102 intelligent transport systems—eSafety—TPS supported eCall—operating requirements" (Figure 3).

The TPSP involvement into an eCall identifies additional options:

- Avoidance of false calls
  Because TPS has its SP as the "bridge" to the PSAP, it can filter out "false" calls, e.g., nonemergency calls or accidental calls.
- Efficient provision of MSD
  The PSAP requires the "MSD." In case of a TPS eCall, a few of those data might be stored in the TPSP database

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

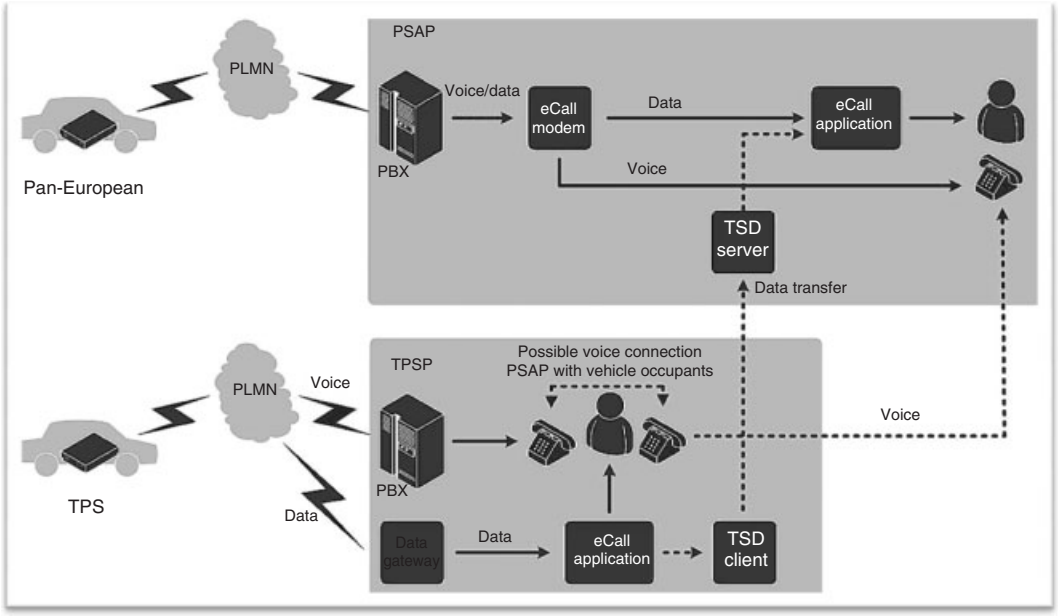

Figure 3. Integration of a third-party service provider (example).

instead of being transferred from the IVS, reducing the load on its communication with the vehicle.

- Efficient provision of additional relevant data (FSD—full set of data)
  The TPSP is also able to add additional data. For example, its customer may request that relevant medical data, or mobility information, is passed to the PSAP.
- Improved call completion rate
  In situations where the MSD transfer fails, the TPSP, although not still in contact with the vehicle, has received an alarm from the vehicle, and can forward what information it has to the PSAP.

3.5 Minimum set of data (MSD)

The MSD has been defined in the following standard: European Committee for Standardization TC 278 WG, "Road transport and traffic telematics—eSafety—eCall MSD" (Table 1).

The MSD message amounts to a maximum of 140 bytes, its main contents being:

- "When": the timestamp of the accident,
- "Where": the geographical position of the accident,
- "Who": eCall activation indicator (manual or automatic),
- "Car": vehicle type and identification number (VIN),
- number of passengers,
- optional data.

Table 1. Minimum set of data (MSD).

Name	Size (B)	Type	Description
Control	1	Integer	Bit7: Automatic activation Bit6: Manual activation Bit5: Test call Bit4: No confidence in position Bit3–Bit0: Reserved
Vehicle identification	20	String	VIN number according to ISO 3779
Time stamp	4	Integer	UTC seconds
Location	4	Integer	Latitude (WGS-84) in milliarcseconds
	4	Integer	Longitude (WGS-84) in milliarcseconds
	1	Byte	Direction in degrees. The nearest integer of 360.0 * value/255.0
Service provider	4	Byte[4]	Service provider IP address or blank field
Optional data	102	String	Further data (e.g., crash information) or blank field
Total bytes	140	—	—

The initial eCall specifications also included the attempt to define—in addition to the MSD—an FSD.

For the time being, a standardized FSD specification is not available. The provision of additional data will be

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

part of TPS eCall specifications. Technically, most of the additional data will be stored on a subscription base in an SPs database. In case of an eCall, the TPSP can retrieve the FSD locally.

Examples of an extended set of data are health data, last will data, whom to contact data, and so on. In case of the deployment of an HGV eCall, goods-related data have to be made available.

4 PAN-EUROPEAN eCALL

The use of eCall to deploy emergency assistance will save lives and reduce the social burden of road accidents by improving the notification of such accidents; speeding up the emergency service response; and lowering the subsequent effects on fatalities, severity of injuries, and traffic flows.

This led to an initiative to standardize the eCall in the European Union and to create the pan-European eCall.

The memorandum of understanding (MoU) for realization of interoperable in-vehicle eCall was submitted to the EC back in May 2004 within the context of the eSafety initiative and addressed mainly the automotive industry, MNOs, motoring associations, insurance companies, and the EU member states.

So far (as of January 2013), the MoU has been signed by

- 22 member states
- 4 further European countries
- more than 60 companies and nonprofit organizations.

The MoU lists the necessary arrangements for implementation of the eCall action plan and sets out the measures to be taken by the EC, member states, automotive industry, telecoms, and insurance industries. The MoU's key message is that eCall should work in any EU member state and that eCall should be based on the single pan-European emergency call number 112 (Figure 4).

Unfortunately, the progress of the pan-European eCall definition and deployment strategy did not show the expected results within a reasonable time frame. The EC decided to work on an eCall impact assessment.

The impact assessment on the deployment of eCall was published by the EC on 8 September 2011. The conclusion of the report, which considered a number of different options, was for the mandatory introduction of the harmonized interoperable EU-wide eCall service, based on 112 and on the pan-European standards developed by the European Standardization Organizations—in all vehicles in Europe starting by certain categories (i.e., passenger cars and light duty vehicles)—including the upgrade of MNOs and PSAPs to receive/forward and handle the eCalls. This service may coexist with the private eCall services.

The result of the impact assessment is that the EC is now actively working toward the mandated implementation of an EU-wide eCall service, with a projected introduction date of 2015 for all new type-approved vehicles.

Furthermore, the EC published an ITS action plan with 6 action areas. One of the focus areas is called *road safety and security* (area 3). This area includes as one of the important actions the "Introduction of Europe-wide eCall" (Figure 5).

The target date for the introduction of the pan-European eCall is 2015 for all new passenger and light vehicle cars.

Although the vast majority of all technical implications have been solved, a few challenges still remain open (status January 2013):

- The type approval procedure has not yet been published.
- The question of warranty is still open.
- Upgrade procedures have not yet been defined (relevant to the IVS, the communication network as well as the PSAP).
- The business model for the eCall rollout and for potential upgrade requirements is critical.

5 ERA-GLONASS-BASED eCALL

Russia has begun implementing an emergency call service, which builds upon common elements of the European eCall, extending the approach to include additional features such as GLONASS GNSS positioning and backup data transmission mechanism using SMS. The major differences between the pan-European eCall and ERA GLONASS are highlighted in Table 2.

First, ERA GLONASS deployments will be targeting dangerous cargo transportation and collective passenger transportation by October 2014. All new passenger vehicles (e.g., automobiles and light vehicles) getting new (first) type approval will be required to have the ERA GLONASS IVS installed from January 2015.

6 STANDARDIZATION

This section provides a comprehensive overview about all eCall-related standards for the purpose of introduction of the pan-European eCall as well as for the ERA GLONASS solution (Table 3).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

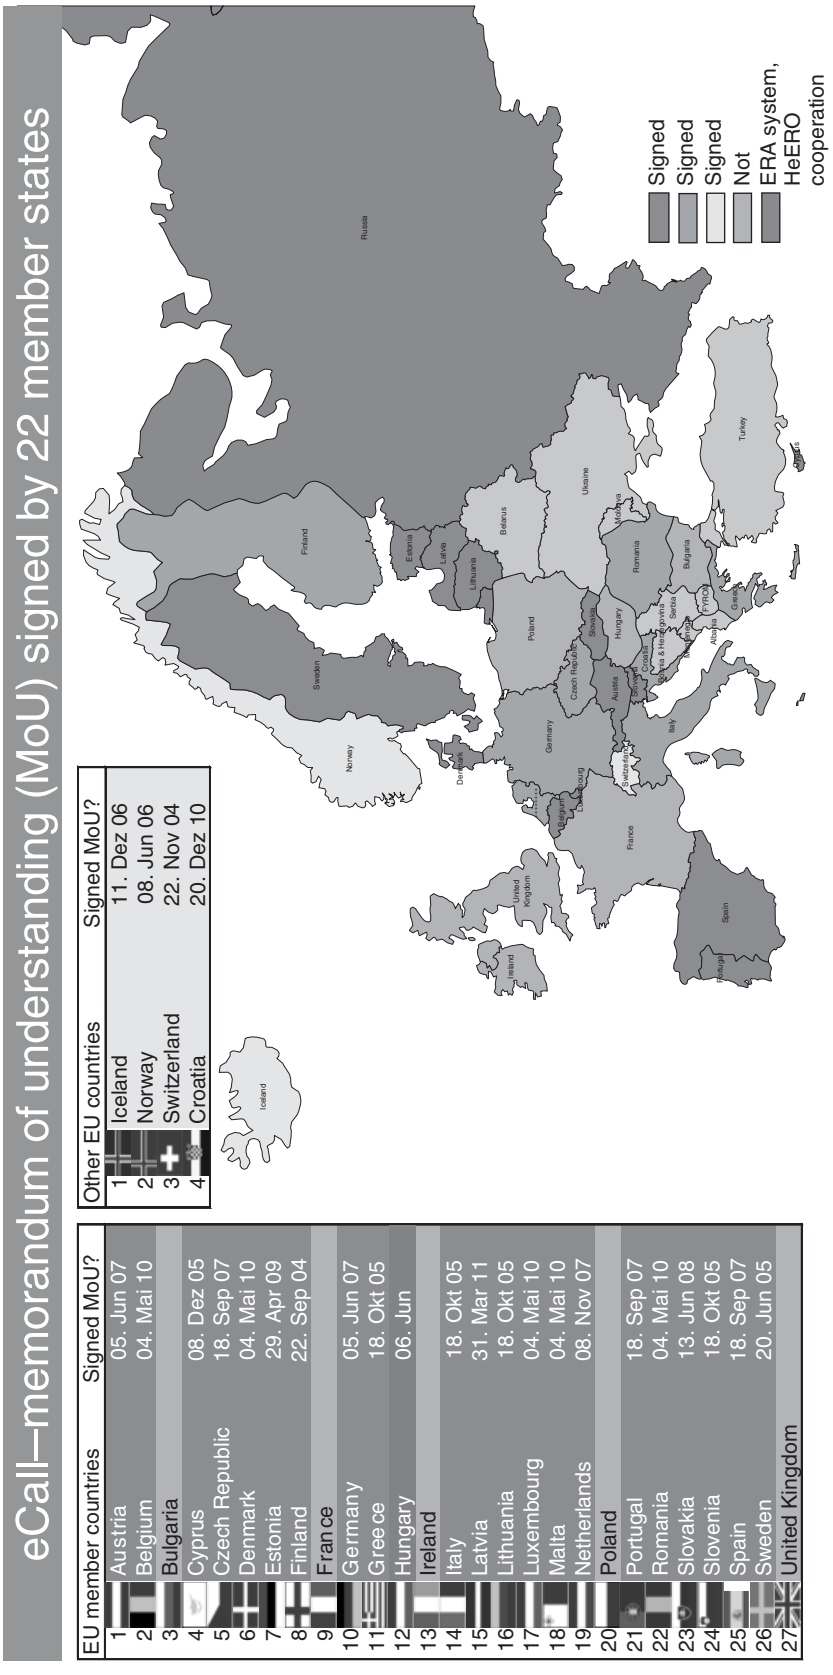

Figure 4. The eCall MoU—signature overview.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

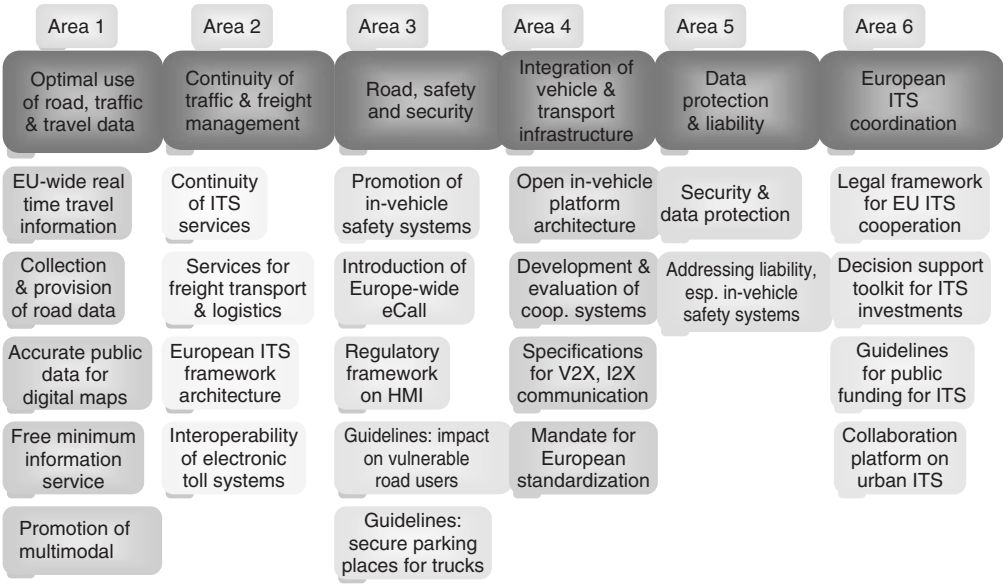

Figure 5. ITS action plan of the European Commission.

Table 2. Comparison between the ERA GLONASS and the pan-European eCalls.

Pan-European eCall	ERA GLONASS
In-vehicle unit with support of GPS (or Galileo once available)	In-vehicle unit with support of GLONASS or GLONASS/GPS
Triggered automatically by the in-vehicle device, or manually by vehicle occupants	Triggered automatically by the in-vehicle, or manually by vehicle occupants
Based on 112 emergency call (112 and E112)	Based on 112 emergency number (starting 2012)
Creates a voice link to the closest PSAP and sends a data message (minimum set of data) at the beginning of the voice call	Creates a voice link to the closest NIS Regional Center and sends a data message (minimum set of data) via voice band modem (SMS as backup)
PSAP to use local process and resources to, for example, dispatch ambulance, inform traffic centers, etc.	NIS Regional Center distributes the calls to local police PSAP, local ambulance PSAP, and local Emercom
Intention of the eCall system is to enable additional services in the vehicles and jump start telematics and ITS applications in Europe	Infrastructure of ERA GLONASS system will be served as a base for additional location-based services (e.g., fleet management, SVT)
—	Support of UMTS and GSM
—	"Blackbox" function
—	Remote IVS configuration and SW upgrade

ERA GLONASS is based on the following standards:

- GOST R 54620-2011 "GNSS. Road accident emergency response system. In-vehicle emergency call system. General technical requirements."
- GOST R 54721-2011 "GNSS. Road accident emergency response system. Base service description."

7 OUTLOOK

The pan-European eCall service utilizes technical components (such as satellite positioning, processing, and communication capabilities) that could also provide the basis for several other in-vehicle applications and services, including those required by existing or planned regulations. Such

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto186
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

services might affect commercial or private vehicles and can be summarized as

- digital tachograph services
- electronic toll collection services
- transport of dangerous goods and live-animal-oriented services
- any kind of further TPS

that utilizes the basic infrastructure, which has been introduced via the eCall solution.

Streamlining and integration of all these services within a coherent, open-system architecture could yield better efficiency and usability. This approach might reduce costs and could enable the "plug and play" integration of future new or upgraded services.

Such a modular approach could be the basis to address further services in the areas of road safety, personal mobility, logistics support, or it could provide access to multimodal information.

The definition of an "open in-vehicle platform" concept is part of the ITS action plan, and the introduction of eCall based on this concept would positively contribute to its momentum.

The automotive industry, the telecommunications industry, the SPs and all TPSPs will benefit from new services based on the introduction of the eCall telematics platform in all vehicles.

GLOSSARY

CLI	Calling line identification
EC	European Commission
EMS	Emergency management services
ERA GLONASS (Russian)	Ekstrennoje reagirovanije pri avarijakh—the eCall specified for the Russian Market (based on GLONASS)
FSD	Full set of data
GIS	Geographic information system
GLONASS (Russian)	Globalnaja Navigazionnaja Sputnikovaja Sistema—the radio-based satellite navigation system operated for the Russian government
GNSS	Global navigation satellite system
GPRS	General packet radio service
GPS	Global positioning system
GSM	Global system for mobile communications—second-generation network
HGV	Heavy goods vehicle
HMI	Human–machine interaction
IVN	In-vehicle network
IVS	In-vehicle system
LTE	Long-term evolution—fourth-generation network
MNO	Mobile network operator
MSD	Minimum set of data
MSC	Mobile switching center
NAD	Network access device—the communication part of an IVS
PLMN	Public land mobile network
PSAP	Public safety answering point
PTW	Powered two-wheelers
SMS	Short messaging service
SP	Service provider
TPS	Third-party service
TPSP	Third-party service provider
UMTS	Universal mobile telecommunications system—third-generation network
USSD	Unstructured supplementary service data
VIU	Vehicle interface unit

IT Security for Communicating Automotive Systems

Florian Friederici, Rafael Grote, and Ilja Radusch

Fraunhofer Institute for Open Communication Systems, Berlin, Germany

1 INTRODUCTION

Information technology (IT) has become an integral part of automotive systems. Therefore, these are also affected by IT security threats. Considering IT security is of vital importance in order to ensure correct system operation, to prove that the system was designed according to the state-of-the-art security, to prevent product liability trouble, and to avoid bad press from major security incidents.

Connected vehicles utilize different symmetric communications channels, such as mobile cellular-based communications and Wi-Fi networks as well as unidirectional communications such as FM broadcast. Along those, sensors allow information transmission into the vehicle as well. These include complex sensors such as positioning or even simple sensors such as temperature probes. Sensors and communications both allow transmitting information into applications, and are, therefore, subject to IT security considerations. The applications themselves may typically belong to one of the following categories: informative, assistive, autonomous, emergency, and accounting.

This chapter is using terminologies from the following references. The definition of common terms is given in ISO 7498-2 (1989) (International Organization for Standardization), clause 3. Further terms and principles are described in Saltzer and Schroeder (1975). While both references are foundational IT security, this chapter is focused on IT security in the context of automotive telematics. According to ISO/IEC 27000 (2009) (International Electrotechnical Commission), information security is defined as the "preservation of confidentiality, integrity, and availability of information."

Independent of the concrete threats and vulnerabilities a system might face, there are always three primary security objectives. Those are confidentiality, integrity, and authenticity. *Confidentiality* refers to the ability to prevent unauthorized read access to information. That may be broadened to unauthorized information gain by any means, for example, by eavesdropping communications or observe involved devices or parties. *Integrity* refers to the converse ability of unauthorized write access to information, or more general to unauthorized information manipulation by any means. As both, confidentiality and integrity, require authorization to be applied, the last primary security objective is authenticity. *Authenticity* refers to the ability to prevent false identification, which may lead to false authorization.

Those three primary security objectives can be applied to any IT system and to different scopes within the IT system. Possible scopes are communications, data processing, and storage. Abstract roles in IT security consist of *subjects* and *objects*. *Authorization* of subjects requires a proper *identification*. Access or modification of objects is then granted based on this authorization.

Along with the primary security objectives, a couple of secondary objectives may be derived. Those are mainly related to the actions undertaken. Nonrepudiation, plausible deniability, and availability are examples for those.

Nonrepudiation refers to the ability to prove any action undertaken by the subject. *Plausible deniability* is the contrary, when it is not possible to prove that a specific subject conducted the action. As both may not be achieved at the same time, it is required to select the desired behavior of the IT system based on the purpose. An accounting system that is raising bills requires nonrepudiation of the customers, for example. An anonymous advice center, on the other hand, must offer plausible deniability to its clients.

Further examples for secondary security objectives are availability, access control, and permissions. *Availability* refers to the way the subject tries to access the object. That is typically some kind of service. Making the service unavailable is a security threat, because the system operation is halted or disabled. *Access control* and *permissions* allow a fine-grained specification of the actions allowed for a certain subject or group of subjects.

A combined security architecture that offer the former objectives are the *Triple-A* systems used in telecommunications. They utilize protocols and procedures to ensure *authentication*, *authorization*, and *accounting* (*AAA*), which allow authenticating the identity of an entity, determining the authorization for actions, and tracking of the resource consumption.

1.1 Methodology

Security engineering is often seen as black art to outsiders. It is of course no magic, but a widely unknown methodology behind. While the methodology is very deterministic and formal overall, some steps require an educated guess, which makes it to appear arbitrary to some extent. The quality of such an assessment is, however, very dependent on good assumptions. It requires some experience and imaginative power to make them.

The *ETSI TVRA* (European Telecommunications Standards Institute—threat, vulnerability, and risk analysis) method, described in TS 102 165-1 (2011) (technical specification), offers a formal way of analyzing the threats, risks, and vulnerabilities of a telecommunications system. It is commonly used in the standardization at ETSI including ETSI TC ITS (European Telecommunications Standards Institute Technical Committee—intelligent transportation systems). The method guides the security engineer through the identification of the assets within the given environment, grouping the objectives into the categories such as confidentiality, integrity, and authenticity and specification of detailed security requirements. On the basis of the knowledge of the assets and their specification, weaknesses are identified and classified into vulnerabilities and threats. The ability of an attacker to mount an attack is estimated based on the time required, the expertise necessary, the opportunity and the availability, and complexity of essentials equipment. The estimation leads to a quantified likelihood and impact of the threats. Along with that, the intensity of an attack is evaluated to determine the risk. From that evaluation, the selection of countermeasures is possible to reduce the likelihood and/or the impact of an attack. Through iteration after countermeasure selection, a comparison between the unprotected functionality to the protected functionality is possible. The TVRA for ITS is available in technical report (ETSI TR 102 893 V1.1.1, 2010).

Other evaluations criteria and requirements are TCSEC (trusted computer system evaluation criteria) (DoD 5200.28-STD, 1985), ITSEC (information technology security evaluation criteria) (ITSEC, 1991), and Common Criteria for Information Security Evaluation (ISO/IEC 15408-1, 2009; ISO/IEC 15408-2, 2008; ISO/IEC 15408-3, 2008). The *Common Criteria* are general IT security criteria and supersede the older standards TCSEC from the United States and ITSEC from Europe. While the ETSI TVRA method is focused on telecommunications, Common Criteria are applicable for general IT systems. *ETSI TVRA*, however, also refers to parts of the Common Criteria.

Security requirements for cryptographic modules are specified in *FIPS 140-2* (Federal Information Processing Standards) (FIPS PUB 140-2, 2001) for the use by US federal organizations. However, private and commercial organizations are free to adopt the specification of course. Software and/or hardware offering the functionality of a cryptographic module can be certified according to this standard.

1.2 Threats and countermeasures

A large, distributed computer system introduces a huge degree of complexity. That is what IT-equipped connected vehicles are. Such a system consists of stationary and mobile nodes, connected through various types of communication links. Dependent on the viewpoint, different scopes are possible with several emphases.

The *system perspective* is a bird's eye view on the overall system behavior and functionality. While looking from far, it is easy to understand the relationship of all participants and the way they are interacting. In addition, the bigger impact of security flaws can be imagined here. Main asset on system level is a well-done architecture with proper policies.

To better analyze potential vulnerabilities, it is useful to zoom in and have a look at the *single-node perspective*. This is focused on the functionality and interfaces of a

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

single entity within the network. Besides the outside world interfaces, the secure function of the node itself is very important.

An inside look into the node allows to take the *application perspective*. Applications represent the functional logic embedded into a node, which is providing the essential use. Flaws on application level are often not by design, but by poor implementation.

Finally, the *communications perspective* highlights the information interchanges between the nodes in the network. In this perspective, nodes are considered as interconnected black boxes.

Weaknesses may be found in any of those perspectives. Separating them helps to keep the high complexity manageable. Even though, an exploited weakness in the application level may have an impact on the system level.

The single-node and application perspectives for IT-equipped vehicles are very similar to every IT system. Security here is mostly about to tamper resistant devices and to secure application design to the required extent. Nevertheless, even a single node can be consisting of several devices and sensors, which may be seen as a distributed system itself. Again, a separation of viewpoints is then possible and useful.

For this chapter, a look at the internode communications and overall system perspective is most important for two reasons. First, an attacker can easily access the air interface even over large distances, in contrast to attacking a single node, which requires physical access. Moreover, security within a single node is not specific to ITS and is widely addressed in other domains.

ITS, in general, consist of a huge number of nodes from different suppliers and applications from different vendors. The standardized secure operation of them together in the overall system of ITS is one of the biggest challenges in the telematics area.

Possible attacks on communication systems can be categorized into four groups, which are described as follows. The groups intentionally reflect the three primary security objectives that are confidentiality, integrity, and authenticity and availability from the introduction. In addition, they show prominent attacks from a communications perspective to any of them. All of the attacks mounted on communications level affect the system functionality. Pure attacks on the system perspective mainly target the policies and procedures and are not to be discussed in this chapter.

The first group is *bogus message injection and message alteration*. This refers to any attempt in manipulating information interchanged by either forging valid-looking messages with false information included or altering genuine messages in transit to convey false information. This can be done in a couple of ways, including manipulating a genuine node. This case, however, is out of scope of this chapter. In summary, the first group is all about attacking the information integrity.

The second group is *eavesdropping* the communications. This refers to unauthorized information retrieval by passively listening to the wireless communications. For example, most information exchanged in ITS communications is unencrypted by intention. The system is designed to spread information from participating nodes by broadcasting to the adjacent neighbors and by utilizing multihop communications to a certain target area. Additionally, information compilation can be done by central infrastructure elements. It is, therefore, difficult to distinguish between authorized receivers and malicious listeners. The risk at this point is that an attacker is capable of reassembling privacy infringing information from the publicly available made data and, therefore, this group is about confidentiality issues.

The third group is *identity falsification*. As explained in the introduction, it is very important to identify properly the entities in communications to assign authorization. If an attacker is able to fake his or her identity or to appear as multiple entities, he or she is able to undermine the systems policies. The impersonation of multiple entities is known as *Sybil attack*. This group is about authenticity.

The fourth and last group in this classification is *resource and network jamming*. Even though the information is neither changed nor accessed by the attacker, taking the communications out of order breaks the systems functionality. This group refers to availability.

Countermeasures in terms of security engineering are provisions taken to lower the likelihood or impact of a successful attack. In general, they can only mitigate the risks. The efforts undertaken to protect may be exceeded by the efforts undertaken to break the protection. Therefore, the selection of countermeasures is usually based not only on the technical possibility but also on a cost-benefit assessment.

Some objectives can be a priori protected, for example, the eavesdropping case. A break of integrity may only be a posteriori detected. In the latter case, a proper reaction is necessary. Such reactions range from simple "drop message" to advanced cooperative actions, involving other network participants. The exact behavior must be defined in a set of policies.

Furthermore, the system design has an impact on the vulnerabilities against certain attacks. Especially, resource and network jamming can be countered from the first by tolerant resource strategy and frequency agility.

1.3 Applied cryptography

Implementing security measures for computers in communications is not about building walls or fences, but utilizing math to grant certain behaviors. That includes, for example, one-way functions, statistics, and probability.

The probably most famous use case for math in security is *encryption*. Even nonprofessionals do usually have an understanding of the target for encryption. Generally speaking, encryption allows transforming a given plaintext into a ciphertext using a secret key. The knowledge of the secret key is required to recreate the plaintext from the ciphertext, which means that the ciphertext is not understandable without the secret key. This technique allows an a priori protection of confidentiality and there exist many variations to encrypt data.

Attaching checksums usually does integrity protection in communications. A secure variant of a checksum is a cryptographic *signature*. Signatures offer a dual functionality; they identify the signer and validate the information. The identification, however, is dependent on additional information on trust and relationships and, therefore, not the key element of the signature itself, the integrity protection is.

Creating signatures requires the ability to make a short summary of the plaintext to be signed. Using *computational secure hash functions* does this. A hash functions simply takes an input of arbitrary length and generates a digest of a fixed length out of it. The digest is basically a number of, for example, 256 bit length. Any changes in the plaintext directly lead to changes in the digest. A good (computational secure) hash function will create digests that cannot be easily predicted and change a lot, even if only a single bit in the plaintext was changed. In this way, it is very hard to create a plaintext that matches to a given digest. As the plaintext can be a lot longer than the fixed size of a digest, collisions are still possible, but very hard to exploit for meaningful purposes.

One-way functions are foundational for doing such calculations. Those are basically mathematic functions that can be calculated efficiently in one direction, but cannot be solved easily in reverse. Examples for that are discrete exponentiation and logarithm.

Using encryption and hash functions together enables the creation of a cryptographic signature. The signer first calculates the digest of the to-be-signed plaintext. Secondly, he or she is encrypting the digest. The output of this operation is the signature, typically with the same length like the digest. A receiver can validate the signature using the same hash function on the plaintext and comparing it to the encrypted digest.

To prevent everybody that knows the secret key to generate valid signatures, a split key methodology is required. The so-called *public key cryptography* enables this. In public key cryptography, there is not a single secret key, but a key pair. One part of the key pair is private and has to be kept secret, which is the private key. The second part of the key pair is public and can be safely shared. Public key cryptography can be used for the same operations described earlier. It is possible to encrypt plaintext using the public key. The resulting ciphertext, however, can only be decrypted using the private key. This way, everybody can encrypt a plaintext and only the owner of the private key is able to decrypt the ciphertext afterwards. This procedure is widely used, for example in e-mail communications.

Using public key cryptography together with computational secure hash functions enables signatures that can only be created by the owner of the private key and can be validated by everybody who knows the public key.

The first introduced principle using a single secure key is called *symmetric cryptography*. The second introduced principle using public and private key pairs is called *asymmetric cryptography*. Asymmetric cryptography cannot replace symmetric cryptography, because both principles have different strength and weaknesses. While symmetric cryptography requires shared secret keys, implementations are faster and more secure compared to asymmetric cryptography. On the other hand, asymmetric cryptography requires longer keys and more calculations to offer the same level of security. Symmetric cryptography is, therefore, best to encrypt huge amount of plaintext. Asymmetric cryptography is better suited for signing plaintext. Both can be combined to a hybrid where the asymmetric cryptography is used for symmetric key exchange. This combination offers the best of both worlds.

1.4 Security protocols and standards

Implementations of security software and hardware that require interoperability between different vendors are based on well-established protocols and standards. Because of the nature of security functionality, it is wise to follow approved concepts to avoid rookie mistakes.

Today's most used symmetric cryptography algorithm is the *advanced encryption standard* (*AES*) specified in FIPS PUB 197 (2001). The most used asymmetric cryptography algorithms are the older *RSA algorithm*, named after Ron Rivest, Adi Shamir, and Leonard Adleman, specified in PKCS#1 (public key cryptography standards) (RSA Laboratories PKCS #1 v2.1, 2002) and the newer *elliptic curve cryptography* (*ECC*).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

From a user perspective, both RSA and ECC can be used for the same purposes. They differ in the underlying math. RSA is utilizing the difficulty of factoring large integers; in contrast, ECC is based on the algebraic structure of elliptic curves over finite fields.

A suite of algorithms that can be used for digital signatures is specified in the digital signature standard (DSS) (FIPS PUB 186-3, 2009). It includes the principles on how to create digital signatures as well as procedures to create digital signatures using the RSA algorithm and ECC. The latter is commonly known as *elliptic curve digital signature algorithm* (*ECDSA*).

Besides using hybrid asymmetric and symmetric cryptography together to exchange keys, there are also dedicated key exchange protocols for symmetric cryptography. The Diffie–Hellman key exchange protocol (IETF RFC 2631, 1999) can be used to exchange keys between communication partners to negotiate symmetric keys. It is, however, prone to man-in-the-middle attacks.

A commonly used format for certificates in the Internet is specified in X.509 (IETF RFC 5280, 2008) along with the according public key infrastructure and certificate revocation list (CRL) profile.

Revocation of certificates can be done by simple CRL or according to the online certificate status protocol (OCSP) (IETF RFC 2560, 1999). Using OCSP not only gives negative statements on revoked certificates but also allows faster revocation and additionally positive statements about the validity of certificates.

Authentication over a nonsecure network can be done using the Kerberos protocol (IETF RFC 4120, 2005). It allows the authentication of a client to a service by tickets issued from an authentication server. There are protocols for combined AAA. They are the remote authentication dial-in user service (RADIUS) specified in IETF RFC 2058 (1997) and the newer alternative diameter specified in IETF RFC 3588 (2003).

Security measures in IT are founded mainly by security policies and protocols. While policies are just a matter of having a good rule set and enforcing them, protocols have to be implemented in devices, either in hardware or in software. For protocols utilizing strong cryptography and lot of connections, the use of processing accelerators can be useful.

The underlying algorithms can be usually implemented very efficient in hardware. The key material used requires to be kept secret. Dedicated hardware can be built in a tamper evident or to some extend tamper-proof way. Key material that has to be carried around to be used as authentication token can also be stored inside a physical token. This allows easy use and better protection, because it is harder to counterfeit them.

2 ITS COMMUNICATIONS SECURITY

The *ITS communications system* consists of a novel combination of technologies involved. This leads to a slightly different set of requirements on the overall system in general, as well as the security system in particular. First, the main communications link in ITS is the 5.9 GHz wireless channel. It is used in *ad hoc* mode, that is, there is no base station required for operation. The information transmission is mainly based on broadcasting messages to all audience in the vicinity. For simplification reasons, in this chapter, a separation into message types is only made into three classes. More detailed communication patterns are classified in Schoch *et al*. (2008).

Regularly sent *beacons* contain information on the condition of the sending vehicle. Beacons are unidirectional, single-hop broadcast messages. Event-triggered *notifications* contain information on the particular event. Event notifications are unidirectional, multihop broadcast messages. They are usually restricted to a geographic area. *Unicast messages* are used for communication with backend infrastructure services or in specific V2X (vehicle to anything) applications. Unicast messages may be unidirectional or bidirectional as well as single or multihopped depending on the application or backend service.

Because of the *ad hoc* nature of the main communications link, any infrastructure-based security protocols and principles are not suitable for ITS. Even though some vehicles may offer additional cellular-based communications, the basic functionality must be available offline.

The computing devices used in automotive environment have to follow special operation requirements. That concerns the operating temperature ranges, shock resistance, energy efficiency, and budget. Such requirements lead to limited processing power, compared to desktop computers or entertainment devices. Performing calculation-intensive security processing on those devices is not possible. Therefore, it is very likely to see specialized cryptographic coprocessors to offload the calculations. As a side benefit, those coprocessors may offer a secure domain for key material.

2.1 Integrity through digital signatures

As described in the introduction, bogus message injection and message manipulation are dangers to ITS communications. An attacker might try to manipulate or fake messages with the purpose of influencing the behavior of other drivers or vehicles to his or her advantage. As many ITS use cases rely on incoming beacons and notifications, this system is particularly vulnerable to bogus message attacks.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Example attack: faked hard-brake warning lead to safety reaction. Neighboring vehicles are warned about hard brakes in hazardous situations through V2X event notifications. This leads usually to a safety reaction in following vehicles, which might be a displayed warning message or sound or, in future, maybe even an autonomous driving maneuver controlled by the vehicle itself. Through injecting faked hard-brake warnings, an attacker might exploit this use case in order to influence drivers/vehicles to stop or to trigger an emergency brake. This attack might even provoke an accident.

As a countermeasure, the integrity (and authenticity, see Section 2.2) of messages must be assured. Therefore, every ITS message must be cryptographically signed by its sender. For this purpose, an ITS node needs to own a digital certificate and a private key, which is used to calculate a signature over each outgoing message. The resulting signature is attached to the message together with the node's public certificate. This enables receiving nodes to identify the sender of incoming messages and cryptographically verifying the integrity of the data.

2.2 Authenticity through trusted certificates

Signatures ensure data integrity and identify the originator of a message, but have no implication on the validity of the originator itself. In other words, nothing prevents an attacker from generating his or her own key pair and certificate for sending signed messages, which might in fact appear perfectly valid at the first glance.

Example attack: emergency vehicle spoofing. Emergency vehicles prove themselves to be prioritized by sending specific beacons. During operations—when the light bar and sirens are activated—their special rights are indicated with the beacons, so that the neighboring vehicles are warned and may possibly bear right. An attacker might exploit that fact to stop other vehicles and have a free road on his or her own. Therefore, the attacker generates his or her own certificates to sign beacons, which claim to be from a privileged emergency vehicle. Additionally, the beacons might indicate light bar or siren usage.

Distinguishing between valid and invalid originators requires a trust anchor to legitimate certificates. Thus, certificates are issued and signed by a centralized—and trusted—certificate authority (CA). Checking authenticity means verifying the signature, not only of a message itself, but also of the originator's certificate. Illegitimate senders do not own a trusted certificate. Consequently, they can neither create valid signatures nor inject any bogus message to ITS communications.

2.3 Confidentiality through data encryption

Even though most ITS communications consist of broadcast messages, there are also use cases that require unicast messaging. This comprises, for example, communication to backend systems or specific V2V (vehicle to vehicle) use cases, where two individual vehicles communicate with each other. In these cases, messages are dedicated to a specific recipient. By eavesdropping communications, an attacker might gain confidential data.

Example attack: steal confidential data from V2I (vehicle to infrastructure) communication. The attacker records the communication between a vehicle and the infrastructure service that provides security credentials. This communication conveys personal data, which the attacker could misuse, for example, for linking identities described in the later sections.

Provided the sender knows the recipient's public encryption key, confidentiality could easily be provided through *message encryption*. Fortunately, this is most certainly the case, as certificates are usually disseminated to neighboring nodes, for example, attached to beacons. This is required for message verification on receiving nodes, but the same certificate is conversely also suitable for encryption.

However, the vast majority of messages—including regularly sent beacons and event-based sent notifications—are not dedicated to a single recipient, and remain, therefore, unencrypted. Data encryption is consequently an exclusive solution for only a few use cases.

2.4 Privacy through pseudonymity

Confidentiality of broadcast communications can, in principle, not base on secrecy, as the distributed information is intended for public consumption. The ITS system design deliberately allows tracking of neighboring vehicles and collecting information on their condition. Many use cases actually require this behavior for proper operation. At the same time, it threatens gravely the privacy of drivers and passengers in ITS-enabled vehicles.

ITS messages may include addressing information, operational conditions, and positioning data. Addressing information is required to distinguish sender and addressees. The receiver information is not required in a broadcast scenario; the sender information allows identifying the sender. Together with the included positioning data, a very accurate usage profile may be recorded by only listening to the beacons sent. The information included in ITS broadcast messages might be used to derive personal behavior and should, therefore, be considered as personal data. Consequently, confidentiality in ITS systems is primarily a matter of privacy and less of secrecy.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Example attack: illegal data mining. Marketing analysts commonly tend to gather all available pieces of information about customers. A local storeowner could, for example, be interested in data of visiting as well as potential (i.e., passing) clients. Recording ITS messages of nearby vehicles would supply him or her with a plethora of facts about his or her clients, including time and duration of visit (or pass-by) as well as detailed information on the vehicle and the client's style of driving (e.g., speed, acceleration, deceleration, steering angle, emergency stops, and other hazardous situations). Allocation between vehicles and individual clients could, for example, take place at the barrier of the store's parking site.

Anonymity is generally accepted as the most effective instrument to protect privacy. As a naive approach, one might try to separate the vehicle identity completely from the driver's identity. Indeed, it would be impossible to hide the ownership of a vehicle (or in general, the allocation to a driver) as long as it is moved in the public. Hence, a more sophisticated approach obscures the identity of the vehicle itself.

To prevent attackers from gaining information through eavesdropping, a pseudonymity concept was proposed in Dötzer (2005) and Golle, Greene, and Staddon (2004). This concept allows the required short-duration tracking, but prevents long-term tracking of vehicles. Addressing information and any static identifier is replaced by exchangeable pseudonyms. After switching a pseudonym, a vehicle is not recognizable for a listening third party any longer. Summarized, pseudonymity permits to track a vehicle during a specific traffic situation (i.e., within lifetime of a pseudonym), but not when it comes across the next day (i.e., exceeding lifetime of a pseudonym). As a result, it is not possible to map data that was collected over a long period to individual vehicles or even persons.

For the idea of changing pseudonyms, it is essential to change effectively all identifiers that are exposed including each communication layer. A single static identifier, for example, a static Wi-Fi MAC (media access control) address, would reveal the vehicle's identity. This applies naturally on identifiers on the security layer, too. In particular, the digital signer certificate is explicitly related to a single vehicle and is perfectly suitable to identify it unambiguously. Consequently, also digital certificates must be replaced on each pseudonym change.

2.5 Two-stage credential system

At this point, the security targets of authenticity and privacy are conflicting to each other. On the one hand, a message receiver wants to validate the sending vehicle to be a legitimate originator; on the other hand, the same vehicle should stay anonymous or at least pseudonymous to the receiver. In order to solve this discrepancy, a two-staged credential system has been introduced in PRE-DRIVE C2X (2009). Its rationale is splitting the single vehicle certificate up into one durable long-term certificate (enrolment credentials) and multiple short-living certificates (authorization tickets).

The *enrolment credentials* are never used in V2X communications. They generally stay secret to message receivers. Hence, pseudonym changes do not comprise replacement of the long-term certificate, which gives vehicles a consistent private identity. Enrolment credentials enable vehicles to authorize against backend systems with the purpose of equipment with new authorization tickets. To protect their confidentiality, long-term certificates are exclusively used for interaction with trusted authorities over encrypted communication links.

Authorization tickets are used in regular ITS communications for generating message signatures and encryption. They may not be resolved to any enrolment credentials or to each other. Being exposed to public V2X communications, short-term certificates must be switched along with the pseudonyms. In order to enhance privacy, it is discouraged to reuse a short-term certificate. Consequently, depending on the pseudonym change interval, a huge number of authorization tickets are required during the lifetime of a vehicle. Even though, a single certificate may consume only a few bytes of storage, it is not possible to hold enough of them for years, especially if a secure storage is used. Therefore, authorization tickets are renewed frequently, which results in the requirement of a credential enrolment infrastructure.

2.6 Certificate deployment through public key infrastructures

Resulting from the two-stage credential system, a backend infrastructure for issuing, deployment, and management of certificates is required. This infrastructure consists of several independent services. In the first place, a root *CA* builds the foundation of trust. Through a chain of trust, every valid certificate of subsidiary CAs and ITS nodes is trusted directly—or indirectly—by the root CA.

Additional CAs fulfill the task of issuing and signing enrolment credentials (enrolment authority) as well as authorization tickets (authorization authority). While issuing and deployment of enrolment credentials is a one-time operation and might be part of a vehicle's manufacturing process, the *enrolment authority* is also responsible for administration of certificates and issuing CRLs regularly. Enrolment credential revocations are

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

only relevant to the authorization authority, as enrolment credentials are secret to other ITS nodes.

The *authorization authority* issues authorization tickets. As ITS nodes frequently renew these, the deployment works over an online connection, which can be established via multihop routing or by any other communications link, such as cellular or Wi-Fi. For the process of requesting a new authorization ticket, the requesting ITS node first generates a new key pair, wraps the public key into an request envelope, signs it using its enrolment credentials, and sends the request via an encrypted channel. The authorization authority checks the validity and replies with a signed certificate. Authorization tickets may be revoked implicitly through revocation of the enrolment credentials, which prevents the affected node from requesting new authorization tickets. Alternatively, explicit revocation of authorization tickets is possible through deployment of CRLs directly to the nodes.

2.7 Remaining security risks and summary

In summary, ITS communications security comprises signing and verifying messages to ensure integrity, encryption to provide confidentiality on unicast communications, usage of frequently changing pseudonyms instead of static identifiers to protect privacy in broadcast communications, resulting from that a two-stage credential system that separates long-term enrolment credentials from short-term authorization tickets, and finally a public key backend infrastructure for credential management and enrolment of authorization tickets. Nonetheless, there are remaining security risks, which are described below.

An attacker is able to link two pseudonyms to each other by analyzing beacons shortly before and after a pseudonym change. This privacy protection vulnerability results from the fact that most data in beacons of a single vehicle varies only slightly within a short time interval. Hence, it is possible to recognize a vehicle, for example, by its position, which changes only marginally between beacons. This attack depends on the vehicle density (i.e., more vehicles in area increase privacy) and the interval between two captured beacons, that is, the attacker must "see" the pseudonym change. The risk is consequently limited to attackers that follow a vehicle or observe a large area. In both cases, tracking of vehicles does not require ITS beacons; however, it could also rely on different technologies, for example, cameras with number-plate recognition or classic observation by humans.

Another remaining risk regarding privacy consists in fixed vehicle properties, for example, vehicle width and length or manufacturer (Gerlach and Guttler, 2007). A combination of a large number of fixed properties has the same impact as a static identifier. The more the fixed properties are used, the greater is the chance for the resulting identifier to become unique within a set of vehicles. For that reason, broadcasting static vehicle properties with beacons should be avoided whenever possible.

3 SECURITY-RELATED ITS STANDARDS AROUND THE GLOBE

The principles described so far are valid all around the world. Nevertheless, systems deployed in Asia, Europe, and the United States differ in requirements and functionality. Therefore, also the security systems are slightly different.

So far, the complete US ITS stack is described in the IEEE 1609 (Institute of Electrical and Electronics Engineers) set, with IEEE 1609.2 (2006) being the security part. IEEE 1609.2-2006 was the first security standard for ITS communications published and had a major impact on the development in Europe as well. It was designed around the message set and applications used in the United States, called *wireless access in vehicular environments* (*WAVE*), and introduced a very useful set of provisions for secure ITS communications.

Main features are the format description for secure messages and certificates. Secure messages offer an envelope for signed and encrypted application message content. This and the WAVE certificate format were specially designed for the requirements in ITS communications and allow a low overhead on the communications channel compared to existing certificate and message formats.

Since the first trial-use standard from 2006, a revised version is under development, which will integrate the experience made in the first place and also requirements and results from the European development.

The organizations ETSI and CEN (Comité Européen de Normalisation) provide the European standards for ITS communications. The ITS security-related standards are assigned to ETSIs TC ITS. The WG5 (working group) is dedicated to security standardization. The process of standardization is still going on; nonetheless, first results have been already published. The foundation was made in the TVRA (ETSI TR 102 893 V1.1.1, 2010); the basic security architecture is defined in ETSI TS 102 731 V1.1.1 (2010).

Generally, the European security standards are derived from the American IEEE 1609.2. It differs particularly in the following aspects. The applications and message set to be secured fit to the European specifications. The European ITS approach features a dedicated networking protocol

DOI: 10.1002/9781118354179.auto188
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

that has to be considered for security measures as well. The two-stage credential system for privacy preserving ITS communication was considered from the beginning. Contrary to the single IEEE standard for ITS security, ETSI TC ITS WG5 is developing separate documents for the single security aspects TVRA, architecture, formats, and service access points.

The situation in Japan slightly differs from the rest of the world. There are already infrastructure-based communication systems in place that can be used for similar purposes similarly to the discussed systems in Europe and the United States. ITS communications in the same way similarly to the European and the US systems, but in a different frequency band, are specified in ARIB STD-T109 (2012) by the Association of Radio Industries and Businesses (ARIB). Security methods are, however, not specified in this standard.

GLOSSARY

AAA	Authentication, authorization, and accounting (Triple A)
AES	Advanced encryption standard
ARIB	Association of Radio Industries and Businesses
CA	Certificate authority
CEN	Comité Européen de Normalisation
CRL	Certificate revocation list
DSS	Digital signature standard
ECC	Elliptic curve cryptography
ECDSA	Elliptic curve digital signature algorithm
ETSI	European Telecommunications Standards Institute
FIPS	Federal Information Processing Standards
IEEE	Institute of Electrical and Electronics Engineers
ISO	International Organization for Standardization
IT	Information technology
ITSEC	Information technology security evaluation criteria
ITS	Intelligent transportation systems
MAC	Media access control
OCSP	Online certificate status protocol
PKCS	Public key cryptography standards
RSA	Algorithm named after Ron Rivest, Adi Shamir, and Leonard Adleman
TC	Technical committee
TCSEC	Trusted computer system evaluation criteria
TR	Technical report
TS	Technical specification
TVRA	Threat, vulnerability, and risk analysis
V2I	Vehicle to infrastructure (communication)
V2V	Vehicle to vehicle (communication)
V2X	Vehicle to anything (communication)
WAVE	Wireless access in vehicular environments
WG	Working group

Driver Distraction

Klaus Bengler

Technische Universität München, Garching bei München, Germany

1 INTRODUCTION

The basic human drive to be mobile is reflected in more than 125 years of automotive history. At first glance, car driving seems to be a complex but clearly defined activity. A closer look, however, reveals that driving a car is in fact a multitask activity where additional tasks, besides driving, are negotiated by the driver. Historically, drivers had to balance the operation of a vehicle and engine management along with the primary driving tasks of speed control and lane keeping. On the basis of this, the primary driving task is divided into three subtasks: stabilization, maneuvering, and navigating.

Operating a vehicle is a highly complex psychomotor activity that is accomplished by multitasking. In addition, the driver has to react to most activities within certain time frames, otherwise the vehicle would be at risk to venture off the roadway or to collide with other vehicles. It has always been of interest to investigate the mechanisms that allow the driver to solve the complex task of driving, along with the subtasks of stabilization, maneuvering, and navigation. In driving, much information is gathered via different sensory modalities and then processed continuously while leading the car (stabilization). This necessarily means that continuous input, via steering wheel and pedals, is needed in normal, nonassisted manual driving. Current research claims that most or even all multitasking phenomena can be explained by quick and successful sequencing and task switching. This would indicate that no parallel processing occurs, but rather very efficient task switching between highly trained subtasks. Therefore, any system integrated into the vehicle must not disturb driving and lead to distraction.

Following user needs and technological advances, an increasing number of additional functions and features are integrated into modern vehicles that are not directly related to driving (Freymann, 2006). They are often considered "tertiary tasks," which explains their relation to primary driving tasks (longitudinal and lateral controls) and secondary tasks (e.g., signaling, controlling the windowshield wipers, and lighting).

The number of these tertiary tasks increases with the introduction of more in-vehicle information systems (IVIS) in cars. The question regarding their distraction potential and the evaluation of the suitability of a given human–machine interaction (HMI) concept is of increasing importance. Suitability, in this case, refers to the idea that a given interaction concept is controllable, compatible (with the driving task), and efficient, in addition to being easy to use while learning the system (ISO 17287, 2003).

A differentiation should be made between distraction and diversion; whereby, distraction means that the attention of the driver is misled and not allocated toward the driving task in an adequate way. This effect can be caused by distracters

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto189
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

inside or outside the car. Lee in Regan *et al*., 2009 gives an excellent overview of different definitions of distraction, including basic explanations thereof.

Diversion also includes a shift of the driver's attention away from the driving task, induced by the driver and introduced by preparatory activities in order to compensate for the attentional cost of the diversion in advance (i.e., intense visual scanning of the environment before reading a navigation display).

Poor information and interaction design can lead to driver diversion and, ultimately, distracted driving. This could be caused by illegible displays, feedback delays, and further faults of the human–machine interface and interaction concepts.

The term *driver distraction* is primarily identified as coming from in-vehicle devices; however, it can also arise from the environment, in-vehicle applications, or from the driver (e.g., while daydreaming). Following this rationale, distraction has to be reduced and can be moderated in different ways: by suitable traffic system layout, in-vehicle design, and, additionally, driver behavior.

Numerous studies report everyday distractive driver behavior that ranges from eating, drinking, and other "all day" activities to tasks typically associated with distracted driving, such as phoning and the operation of in-vehicle functionality (Stutts *et al*., 2005; Dingus *et al*., 2006).

In general, the terms driver distraction or distracted driving are used manifoldly and describe the situation where a driver does not allocate an adequate amount of resources to manage the driving task. A reasonable question, in this context, is whether all available attentional resources of the driver have to be allocated in order to perform the driving task or the measurable driving performance can tell us whether "enough" resources were allocated to the given driving task. Several observable behavioral metrics can be used to assess online whether a driver is distracted by a certain event or operation in a given situation. Zwahlen *et al*. (1987) and many others outlined how and how much visual resources should be minimally allocated.

Another approach to investigate driver distraction can be seen when driver distraction is used as a *post hoc* explanation of a critical incident and accident analyses; specifically helping to explain why drivers failed to turn a critical situation into normal driving. A basic question is, therefore, under which conditions is distracted driving the root cause or a related, both leading to risky behavior and, finally, an accident. Here, the publications around the 100 car study give insight that glancing away from the road scene remarkably increases the accident risk (Dingus *et al*., 2006). Unfortunately, accident data seem to identify distraction as a "standard" root cause for accidents, leading to distorted statistics about this topic.

During its development, the automobile continued to become much functional and more complex. In the first half of the twentieth century, this meant the addition of a few mechanical controls and indicators. The following 50 years have been characterized by the fact that the scope of action for the driver is constantly expanding. This allows the driver to initiate multiple functions and processes, and then to let them run in parallel. A prime example of this would be extended comfort systems and related automatic climate control systems for increasing the comfort of the interior. Modern means of communication, keeping up with mobile phones, lead to a significant increase in function. In summary, it is clear that the increase in HMI in the car is characterized by a constant process of function development; existing functions to be automated, additional functionality being integrated. Many studies focus on the increasing amount of IVIS in cars that would lead to a higher distraction potential. At first glance, the increase could lead to more driving situations that include distracted driving and, therefore, an increased risk. A more differentiated analysis shows that additional information, provided that the information presentation is well designed, helps the driver to manage the driving task and thereby reduces the accident risk, even though additional glances are necessary to gather information. A typical example is the usage of navigation information and navigation systems that help drivers, especially those in unknown environments, to focus on maneuvering and stabilization. In this sense, the ongoing integration of functionalities has to increase comfort, entertain, and inform the driver in a way that emphasizes to him the importance of reducing overall driver distraction potential.

The increase of complexity in the vehicle interior can be compensated for by suitable design measures. The design of vehicle cockpits has to be an expression of the current psychological and ergonomic knowledge, and must also avoid driver distraction effects, such that all activities can be occur in harmony with the driving task.

2 REQUIREMENTS AND SOLUTIONS

Following this rationale and focusing on tertiary tasks, the questions are

- what are the guidelines that enable the optimization of HMI for in-vehicle systems and also minimize distraction;
- what are the procedures and metrics to measure the distraction potential of a given function or information presentation while being developed to avoid the *post hoc* experience.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto189
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.1 Guidelines and standards

There are clear guidelines and recommendations, specifically, the European Statement of Principles (ESOP) (Commission of the European Communities, 2006), the AAM-Guidelines (AAM, 2002), the JAMA Guidelines (JAMA, 2004), and the NHTSA Guidelines (NHTSA, 2013), which integrate existing knowledge and focus this issue while recommending suitable means of interaction design or appropriate methodologies and metrics for evaluation.

A comparison of the aforementioned guidelines reveals a great degree of overlap in their basic messages. However, significant differences are also observed in terms of specific criteria values or explicit functionalities. This is primarily due to the fact of the date of their publication and the region and stakeholders they address. A detailed overview is given by Stevens, Burns, and Akamatsu in separate chapters in Regan *et al*. (2009).

2.2 How to minimize distraction

The ergonomic quality of complex products has grown to a remarkable differentiating success factor, also addressing the property of minimized distraction. For this reason, ergonomic knowledge is applied over the whole duration of the development process. Advances in basic ergonomic research within the past decades have been very high in number. In addition, a number of ergonomic criteria, including benchmark values and evaluation methods, have been developed, empirically validated, and even some of them have been taken as in international standards.

As a selection, the above-mentioned ESOP gives recommendations on five main sections:

- installation principles;
- information presentation principles;
- principles on interaction with displays and controls;
- system behavior principles;
- principles on information about the system.

The topic of driver distraction is explicitly handled in the introducing section on Overall design goals: "the system does not distract or visually entertain the driver."

Especially, principles on installation, information presentation, interaction, and system behavior give detailed advice on potential sources for driver distraction and how to avoid them by good design or how to test for them during development [see also Stevens (2009) for more information and the development of the document.].

A slightly different structural approach is taken by the Visual-Manual NHTSA Driver Distraction Guidelines for in-vehicle electronic devices released by the National Highway Traffic Safety Administration in 2013. This document addresses clearly the given functionalities or function groups of IVIS and focuses on existing evaluation methodologies, explicitly defining criteria values (such as the AAM Guidelines). Additionally, the document provides information on relevant studies that its messages are based on.

A similar sectional structure, such as in the ESOP, can be found reading the AAM Guidelines. Although these two documents, and the shorter JAMA Guidelines, differ in their formulation and rigidity of the criteria, they agree on statements regarding the actions that shall be taken in order to minimize distraction. The most relevant formulations could only be quoted here from several ESOP principles, leaving the examples, references, and detailed recommendations, behind. Therefore, the reader should refer to the original document for more detailed information.

As several principles reference driver distraction, it is obvious that distraction may be caused by different reasons, but can also be reduced by different actions during the development process. These principles are also related to different evaluation approaches that will be further explained in the following paragraphs.

3 MEASUREMENT AND EVALUATION METHODS

Given the fact that guidelines exist, the compliance of an IVIS can be tested during development (Burns *et al*., 2010) using different methodological approaches.

Principles and different dimensions have to be considered in order to come to an ergonomic solution. Among others, these are

- geometric layout;
- interaction design;
- cognitive aspects (Table 1).

Table 1. Selected examples of evaluation dimensions for different ergonomic requirements.

Geometric	Interaction	Cognitive
Reachability of devices	Task duration	Complexity of information
Availability of space	Consistency of interaction concept	Learnability of interaction
Visibility of displays	Visual demand of interaction	
Readability of characters	Interrutibility of interaction	
Glare of displays

3.1 Expert judgment and checklists

In many cases, human factors judgment is considered a suitable method for the qualification of a given interaction. Stevens (2009) and Green (2009) give an overview of existing checklists that are, as the TRL checklist is, highly related to the specified guideline and recommendation documents. It is important to state that especially in the early development stages, this method delivers important contributions to the reduction of distraction.

3.2 Model-based test of perceptive requirements

Meanwhile, digital human models, such as RAMSIS (Bubb *et al*., 2006), have been extended by perceptive functions that lead to a RAMSIS-kognitiv™. Considering what is known about the processing of visual information, this digital model implements features that allow the engineer to check for visual occlusions, given a specified seating position and car environment. This is possible for the analysis of interior as well as exterior visibilities. Moreover, models for age-specific acuity are integrated and allow for differentiated checks of instrumentation and infotainment display readability (Lorenz and Remlinger, 2011) (Figure 1).

Again, the engineer is able to check at an early stage of development if instruments are occluded by the steering wheel or if mobile devices fixed to the windscreen fit for different anthropometries. Additionally, the engineer can also check whether standards on the readability of letters and characters, formulated in ISO 15008, are met by the given instrumentations under specified reading distances and acuities (Figure 2).

Using RAMSIS as a model, in addition, it is possible to estimate the duration of visual diversion for a given display location. RAMSIS-kognitiv™ implements a visual behavior model that calculates the time needed for a saccade and fixation, based on the eccentricity of the display or information in relation to the driving scenery.

Figure 1. Model-based check of visibility of a secondary display using RAMSIS as a model (Lorenz and Remlinger, 2011). (Reproduced by permission of VDI Wissensforum GmbH.)

Figure 2. Model-based check of instrumentation readability (Lorenz and Remlinger, 2011). (Reproduced by permission of VDI Wissensforum GmbH.)

3.3 The occlusion test

Even if information is in the right place and readable, many distraction effects are related to the fact that the duration needed for the gathering of visual information is too long or that the driver is not able to easily interrupt the interaction (Baumann *et al*., 2004; Foley, 2010).

Poor examples include cluttered displays, too high graphical density or running texts, and banners. There are different methodologies available that assess visual demand and interruptibility, but differ in the experimental effort. It could be mentioned that the above-mentioned properties can be investigated already in early stages of development with the occlusion technique or method of interrupted vision. The principle of this method is that while the subject interacts with a given functionality, visual perception of the display is interrupted using LCD goggles. These goggles toggle between transparent intervals, where vision is permitted, and opaque intervals, where vision is not permitted, typically at a pace of 1500 ms per interval. These experiments include an occlusion session and a nonoccluded session.

The occlusion session simulates the requirement of the driving task saying that the driver should not divert from the driving scenery longer than 2000 ms (Zwahlen *et al*., 1987) and needs a given amount of time to resume the driving scenery after a diversion.

The sum of vision intervalls called *total shutter open time* (TSOT) is a very good estimate of visual demand of a

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 3. Subject in interaction wearing the goggles in an intransparent interval.

display; increasing, for example, not only with the graphical complexity of the display but also with the total task time (TTT).

The ratio between TSOT and TTT in a nonoccluded condition delivers the interruptibility ratio *R*, which is a metric for the resumability of an interaction; increasing *R* values indicate bad interruptibility and can be caused by high degrees of visuomotor coordination in a bad touch concept, moving text, or animations.

Setting, procedure, and equipment are standardized in ISO 16673 (Figure 3).

The application of an occlusion test clearly classifies concepts that need improvement in the area of information presentation and/or interaction.

3.4 Simulated lane change test

Another surrogate method is the so-called simulated lane change test (LCT). This procedure (ISO 26022) is based on a simplified driving situation (Mattes and Hallen, 2009). It can be performed in a driving simulator environment or as a simple desktop setup. Three lanes are displayed and the driver has to change lanes instantly after perceiving a sign at the roadside while operating an IVIS (Figure 4).

The lane keeping performance and lane change behavior are integrated and compared to a normative (ideal) model, which delivers a deviation area (filled area in Figure 5) as a metric for the driving quality and for the distraction caused

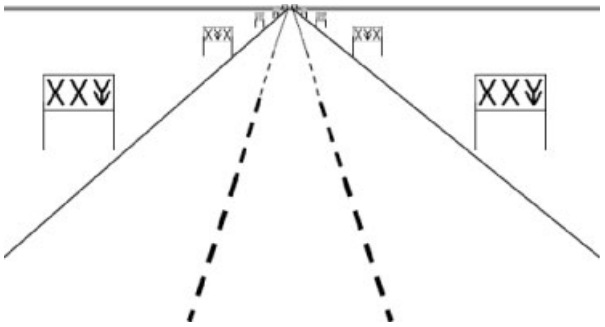

Figure 4. The driving scene. In this example, the driver should change to the right lane. (Reproduced with permission from ISO 26022, 2010. © BSI Group. Permission to reproduce extracts from ISO 26022:2010 is granted by BSI. British Standards can be obtained in PDF or hard copy formats from the BSI online shop: www.bsigroup.com/Shop or by contacting BSI Customer Services for hardcopies only: Tel: +44 (0)20 8996 9001, Email: cservices@bsigroup.com.)

by the device. The metric is called *MDEV (mean deviation)*. Bengler *et al*. (2010) show that the method—provided correctly applied—delivers highly reproducible results.

Like the occlusion test, the LCT provides information on the quality of information presentation and interaction. It is furthermore applicable to tasks that could produce distraction effects not only in the visual area but also by capturing the cognitive resources of the driver, such as the phone or listening do.

3.5 The detection response task

The increase of IVIS based less on visual–manual interaction but rather use voice input–output technologies (speech interfaces, e-books, and text to speech interfaces), question how to evaluate them considering cognitive workload and estimate their effects on driver attention. Merat and Jamson (2008) showed the potential of detection response experiments to be reliable and valid assessments.

The basic idea of this method is to present visual stimuli via LEDs in the periphery, close to the eye or tactile stimuli (i.e., vibration), while the subject operates an IVIS and measure response times and misses to assess the attentional demand of the IVIS task. The tests can be performed with or without an additional driving task. Currently, the method is under standardization to fix values for the equipment, analysis, and instructions, so that results from different assessments can be comparable (van der Horst and Martens, 2010; Engström, 2010; Bengler, Kohlmann, and Lange, 2012; Conti, Dlugosch and Bengler, 2012).

The basis for the detection respose task (DRT) stems from the multiple resource theory of attention, which states

British Standards can be obtained in PDF or hard copy formats from the BSI online shop: www.bsigroup.com/Shop or by contacting BSI Customer Services for hardcopies only: Tel: +44 (0)20 8996 9001, Email: cservices@bsigroup.com.)

that the operation of a cognitive task should have an effect on the operation of a parallel task in a dual-task setting. The LCT and DRT settings are typical examples of the multiple task situation, realistic enough to mimic the primary driving task and the potential distraction by additional in-vehicle activities. Additionally, the DRT can be used to evaluate the effects of roadside distractors, such as information clutter, by poorly arranged traffic information, or the assessment of attentional effects related to dynamic traffic situations.

3.6 Driving simulator tests and field trials

While field testing was, and is still, an established method to assess driver distraction, the power and sophistication of driving simulation is at a level that makes it a more than appropriate method of investigating attentional behavior under standardized and safe conditions (Reed and Green, 1999). The field of simulators is very heterogeneous, ranging from static one screen to moving base simulators with 360° projection systems.

The projects ADAM (Advanced Driver Attention Metrics), adaptive integrated driver–vehicle interface (AIDE), and human–machine interface and the safety of traffic in Europe (HASTE) as well as CAMP investigated the validity of different driving simulators, which is often questioned and delivered valuable information on the metrics that can be derived from driving simulator experiments to assess distraction effects with validity. Moreover, ADAM specified a standard highway scenario, which is documented in Bengler *et al*. (2003) and incorporated in AAM (2002), and showed that valid IVIS evaluations can be performed using a static, single screen system.

As most powerful metrics proved the standard deviation of lane position (SDLP), this metric is defined as the standard deviation of all recorded n deviations from given reference point (car center) and the left or right lane boundary d, root squared, with d_{avg} as the average of all recorded distances and n the number of measurements and the number of lane exceedances (Knappe *et al*., 2007). Therefore, it is necessary to understand and document the implementation of the vehicle dynamics used for a given test, as it can highly influence these metrics (Knappe *et al*., 2007; Engström *et al*., 2005).

The usage of eye tracking equipment to record the visual behavior of a driver, while driving in the simulator or field, is highly recommended in addition to being supported by powerful analysis systems. ISO 15007/1 and 15007/2 give valuable information on how to conduct visual behavioral studies and how to treat the data.

4 THE NEED FOR CALIBRATION AND THE QUESTION OF VALIDITY

After the established methods and metrics have been presented, it has to be mentioned that they rely, as models (RAMSIS) or experiments, on human behavioral data. Especially the surrogate methods (occlusion, LCT, and DRT) have to prove that they deliver valid measurements for distraction effects that could occur in real traffic.

For the methods and models described earlier, these validation studies have been conducted and showed strong correlations between relevant visual behavior measurements (eyes of road time) or driver performance metrics in simulators and surrogate metrics: resumability metric R (occlusion), MDEV (LCT), and SDLP, and object and event detection in different driving simulators. Also, there are remarkable correlations for TSOT (occlusion) and TGT (driving simulation or field).

In this context, not only is the validity of the measurements relevant but also their reliability. This means that the repetition of an assessment, for example, in another laboratory leads to comparable results (Bengler *et al*., 2010).

5 RELEVANT PROCESS STANDARDS

On the process level, ISO 17287 provides valuable input how to avoid distraction by more sophisticated specification and helps to document the data derived from experimental studies and evaluations in a structured way. This process standard describes an approach that includes the following steps:

- intended use and usage context;
- nonintended operations (while driving);
- countermeasures to prohibit these nonintended operations;
- measures to avoid foreseeable misuse;
- ways to present system failures to the driver;
- information about experimental studies including the results.

6 SUMMARY

Given that driving is a complex continuous task and that an increasing amount of information is available for the driver inside and outside the vehicle, the assessment of distraction effects is a highly relevant topic. On the other hand, there is a well-established set of evaluation methods addressing different aspects of distraction. Also, process- and interaction-related recommendations are compiled in several documents to give different stakeholders (OEM, supplier, mobile device manufacturer, and civil engineer) guidelines for the reduction of distraction.

This should be a situation that allows the use of potential future IVISs, while simultaneously maintaining traffic safety.

GLOSSARY

In-vehicle HMI	Human–machine interaction performed while driving or in standstill using displays and controls in the interior of a vehicle.
IVIS	In-vehicle information systems (e.g., navigation, audio, route guidance, and traffic information systems).
Human factors	Scientific discipline covering the aspects of human information processing and the optimization of technology to user requirements.
Human–machine interaction	Structured system of input, output, and transformations between, and by, a user and a technical system.
Lane change test	Standardized procedure to test the visual demand of in-vehicle information systems using a standardized driving-like task.
Occlusion test	Standardized procedure to test the visual demand of in-vehicle information systems using the method of interrupted vision.

Battery Charging Standards

Peter Van den Bossche
Erasmus University College Brussels, Brussels, Belgium
Vrije Universiteit Brussels, Brussels, Belgium

1 GENERALITIES

In urban traffic, owing to their beneficial effect on environment, electrically propelled vehicles are an important factor for the improvement of traffic and more particularly for a healthier living environment. One of the main benefits of the electric vehicle is its use of mains electricity as energy source, allowing, on the one hand, to displace finite fossil fuel sources with renewables and, on the other hand, a zero-emission operation at point of use, with reduced or zero indirect emissions at generation level.

On board the vehicle, the electric energy is stored in traction batteries, which are the key critical components of the vehicle. The transfer of the energy from the grid to the vehicle creates the need for charging infrastructures. The transfer can be done conductively, the most widely used system, or wirelessly by induction, eliminating the need for cables and connectors.

To allow a wide deployment of electric vehicles, they should have universal access to charging infrastructures, which highlights the need for drafting comprehensive standards on the matter. This chapter gives an overview of global developments in the field.

2 THE STANDARDIZATION LANDSCAPE

2.1 Historical background

The need for the availability of standardized charging infrastructures already arose in the first golden age of the electric vehicle in the early twentieth century. The first ever standard to be developed for electric vehicles concerned in fact the charging plug, a standard sheet for which was presented in 1913 (Van den Bossche, 2003; Electric Vehicle Association of America, 1914), which would be adopted on an international level as British Standard 74 (BS74, 1917).

2.2 Global standardization

Standardization, on a global level, is mainly dealt with by three institutions: the *International Electrotechnical Commission* (IEC), founded in 1904, dealing with all things electrical, the International Organization for Standardization (ISO), founded in 1948, dealing with all other technologies, and the *International Telecommunication Union* (ITU), founded in 1865, deals with telecommunications and related matters. IEC and ISO are nongovernmental organizations, whereas ITU is an agency of the United Nations.

With the standardization of the electric road vehicle becoming a key issue, the question arises is which standardization body would have the main responsibility for electric vehicle standards? This may seem a trivial problem; however, one has to consider that the electric vehicle is a device mixing two technologies: it is, on the one hand, a "road vehicle," but, on the other hand, when it is charging connected to the grid, it becomes an "electrical appliance."

For historical reasons, the approach taken toward standardization in both these realms is fundamentally different. One can speak of radically diverging "standardization cultures."

The electrotechnical industry has a long tradition in standardization (as stated earlier, IEC was founded much earlier than ISO). In the electrical world, many things are standardized, including subjects such as the color code of wires are standardized (e.g., green and yellow for the protective or earth conductor). This standardization is based on both the strong regulatory influence, concerning electrical safety and wiring codes on the one hand, and the role of specialist component manufacturers, acting as suppliers to equipment manufacturers on the other hand.

As for electric traction equipment, there is a culture of component standardization: electric traction motors, for example, are described in elaborate international standards detailing their performances and the way to measure them. This is also due to the fact that electric traction customers are more likely to be powerful corporations (e.g., railway companies) who tend to enforce very strict specifications on the equipment they order or purchase, hence the need for more elaborate component standards to ensure the compliance of the equipment.

In the automotive manufacturing world, things are different. The major manufacturing companies have grown into vertically integrated structures that have less need for international standardization. Although there are strong government regulations regarding vehicle safety and type approval, there is less need perceived for individual component standards. Furthermore, the automobile industry is based on mass production, and routine tests as prescribed, for example, for rail traction motors would be way too expensive to perform for road vehicle motors. The automotive customer is also more likely to be a "consumer" who is less interested in compliance to specific international standards.

Technical committees specifically dealing with electric vehicle and infrastructure standardization were established in the 1970s: IEC TC69 and ISO TC22 SC21. The committees reflected their background, IEC representing electricians and component manufacturers, and ISO mostly representing vehicle manufacturers. Collaboration has not always run smooth, however, and there have been considerable discussions between the two groups as to the division of the work, in which there were a number of overlaps and issues for discussion. By the end of the 1990s, a consensus was agreed defining the specific competences of the respective committees, as shown in Table 1.

Table 1. Basic division of work in IEC/ISO.

ISO	IEC
Work related to the electric vehicle as a whole	Work related to electric components and electric supply infrastructure

The charging interface where the vehicle connects to the grid is the main contact point between the automotive and the electrical realms.

2.3 Regional standardization

2.3.1 Europe

Within Europe, CENELEC (European Committee for Electrotechnical Standardization) and CEN (European Committee for Standardization) operate as the pendants of IEC and ISO. Both have been active in electric vehicle standardization in the 1990s, through their technical committees CENELEC TC69X and CEN TC301. However, much of this work was parallel to the global standardization work, with the European standards created superseded by international standards when these were available.

Both committees went dormant around the turn of the century. TC301 was reactivated as a general CEN technical committee dealing with road vehicles. TC69X was reactivated in 2011 following the activities of the CEN–CENELEC Focus Group on electromobility, with the aim of expediting the European adoption of IEC TC69 documents. As to avoid the duplication of work, TC69X specifically avoids to do actual standardization work and prefers to follow up the work performed globally by IEC. Specific European standards in the field will only be drafted where is a clear need, for example, facing European regulations.

The new activities of the European groups were inspired by European Union initiatives, with the DG Enterprise and Industry of the European commission issuing in June 2010 its Mandate M468 concerning the charging of electric vehicles (Commission of the European Communities, 2010).

Its scope was to develop or review existing standards in order to:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- ensure interoperability and connectivity between the electricity supply point and the charger of electric vehicles, including the charger of their removable batteries, so that this charger can be connected and be interoperable in all EU States;
- ensure interoperability and connectivity between the charger of electric vehicle–if the charger is not on board–and the electric vehicle and its removable battery, so that a charger can be connected and interoperable and recharge all types of electric vehicles and their batteries;
- appropriately consider any smart–charging issue with respect to the charging of electric vehicles;
- appropriately consider safety risks and electromagnetic compatibility (EMC) of the charger of electric vehicles in the field of LVD (low voltage directive) 2006/95/EC (Commission of the European Communities, 2006) and EMC directive 2004/108/EC (Commission of the European Communities, 2004a).

The mandate was addressed not only to CEN and CENELEC but also to the telecommunications standards body ETSI (European Telecommunications Standards Institute).

To respond to the demands of the mandate, CEN and CENELEC constituted the *Focus Group on European Electromobility—standardization for road vehicles and associated infrastructure*—as a (informal) joint working group, reporting to the CEN and CENELEC Technical Boards. The Focus Group considered, in the first instance, European requirements relating to standardization for road vehicles and associated infrastructure, and assessed ways to address them. It aimed mainly at charging infrastructure, but also covered related subject such as the standardization of batteries (in view of battery exchange systems), as well as EMC issues, where particularly the case of conducted emissions and power quality will have to be considered when introducing electric vehicle charging on a large scale.

The Focus Group is not destined to itself create standards documents nor create regulatory requirements. This remains the competence of the relevant standardization organizations and regulatory authorities.

The Focus Group had a very wide participation, including representatives of the CEN and CENELEC national members—often from local industry or Governments—and of all major European associations of stakeholders in the field. Observers fully participating have included representatives of technical standards committees in CEN, CENELEC, ISO, and IEC, from some other standards organizations, and from the European Commission services.

The final report in response to the commission mandate was presented to CEN and CENELEC technical boards in June 2011 (CEN—CENELEC, 2011), formulating a number of recommendations affecting the development of electric vehicle standardization issues in Europe. It is aimed at the relevant standards committees, also involving other committees that are relevant to the subject such as IEC TC64 (safety of electrical installations), IEC TC13 (metering), IEC SC17D (low voltage switchgear and control gear assemblies), IEC SC23H (plugs and sockets), and IEC TC57 (smart grid), as well as the corresponding European technical committees in the framework of CENELEC.

For the sake of communication, interaction will also be sought with ETSI.

The work of the Focus Group will be pursued by the CEN–CENELEC Electromobility Coordination Group, which first met in March 2011 and which has the aim to support coordination of standardization activities during the critical phase of writing new standards or updating existing standards on electromobility, and make recommendations accordingly.

2.3.2 *USA*

In the United States, although global IEC and ISO standards are followed and collaborated to, there is a strong tradition of sectoral standardization. The Society of Automotive Engineers (SAE) thus also performs in the field and publishes standards and recommended practices concerning various aspects of electric vehicle technology, including charging infrastructure.

2.3.3 *Japan*

In Japan, electric vehicle standardization is coordinated by the Japan Automobile Research Institute (JARI) that performs activities on national level as well as acting as national committee for both IEC and ISO.

2.3.4 *China*

In China, electric vehicle standardization is conducted by the Electric Vehicle Subcommittee SC27 of the Technical Committee TC114 of the Standardization Administration of the People's Republic of China (SAC).

It was established in 1988 with its secretariat located at the China Automotive Technology and Research Centre (CATARC) in Tianjin City, China. It is supervised by both the Technical Committee TC114 of the SAC and the National Technical Committee of Auto Standardization (NTCAS) under the Ministry of Industry and Information Technology (MIIT). The electric vehicle standardization in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

China has an interface with international standards ISO TC22 SC21 and IEC TC69, and the World Forum for Harmonization of Vehicle Regulations, which is a working party (WP 29) of the United Nations Economic Commission for Europe (UNECE). It is tasked with creating a uniform set of regulations for vehicle design to facilitate international trade. The forum works on regulations covering vehicle safety, environmental protection, energy efficiency, and theft resistance.

Until the writing of this chapter, there were over 50 of Chinese EV standards issued, 12 EV standards are pending for approval, 14 new EV standards are under development, and 45 EV standards are under preliminary research. The issued standards discussed earlier include electric vehicle standards, key components standards, and infrastructure standards.

In China, there are two types of standards. First is National Standard (GB, Guobiao) supervised by the SAC. Second is Industrial Standard (QC, quality control) supervised by the MIIT.

2.4 Regulatory aspects

One should always consider the fundamental difference between standards and regulations: while standards are technical documents issued by independent bodies and in principle voluntary, regulations come out of governmental sources and are mandatory. There are, however, common points as in the European "New Approach" directive where reference is made to harmonized standards, the adherence to which presumes conformity with the regulations.

For vehicle type approval reference should be made of the UNECE regulations that contain specific requirements for the electrical safety of electric vehicles (UNECE–R100, 2011). On the other hand, electrical installations have to conform to electric wiring regulations, which may differ strongly between different countries. Electrical safety is a vital requirement and protection against electric shocks remains the key driver of electric equipment standardization.

3 ENERGY NEEDS FOR CHARGING

3.1 Energy consumption

Although the actual energy consumption of electric road vehicles is strongly dependent on the vehicle's mission and usage profile such as the number of stops, a good approximation of the grid consumption of a battery-electric vehicle with current technology in mixed city traffic can be given by the empirical formula (Van den Bossche, 1992):

$$E_s = 80 + \frac{80}{m} \tag{1}$$

where

- E_s is the specific energy consumption in $\frac{\text{Wh}}{\text{T•km}}$
- m is the mass of the vehicle in tonnes.

A typical medium-sized vehicle, for example, weighing 1500 kg would thus have an energy consumption of

$$E = 1.5 \times \left(80 + \frac{80}{1.5}\right) = 200\frac{\text{Wh}}{\text{km}} \tag{2}$$

To drive this vehicle over a distance of 50 km, a typical urban range for battery-electrics or plug-in hybrids, the following amount of energy would be needed from the grid:

$$E = 50\ \text{km} \times 200\frac{\text{Wh}}{\text{km}} = 10,000\ \text{Wh} = 10\ \text{kWh} \tag{3}$$

The time needed for charging will depend on the power available and on the rating of the charger.

In this context, the notion of *charging speed* could be introduced, corresponding to the distance that can be covered by the amount of electrical energy charged during 1 h.

3.2 Charging power levels

Several power levels can be defined according to the power taken from the grid and the associated charging speed possible.

3.2.1 "Standard" charging

Standard or *Normal* charging uses a power level typical for a standard residential power outlet. This corresponds to the concept *level 1* charging as defined in the United States (Toepfer, 1994).

This level 1 charging only offers a limited performance, because of the low 120 V supply voltage in North America. A standard 15 A outlet will yield up to 1.8 kW, giving a "charge speed" of 9 km/h.

European countries use the 230 V voltage rating, with current up to 16 A (United Kingdom and Switzerland have 13 and 10 A, respectively), giving a "charge speed" of around 15 km/h. The power offered by a residential outlet is fully adequate for overnight charging (typically most of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

charging of both private and commercial electric vehicles will be done overnight); for opportunity charging, however, the power is rather limited.

3.2.2 "Semifast" charging

Semifast or *accelerated* charging uses higher current levels beyond those of a standard domestic outlet, but which are readily available in a typical residential or commercial installation. This corresponds to *level 2* charging in the United States.

In this context, one could use either a higher current single-phase connection (e.g., 32 A, which corresponds to the rating of a typical electric kitchen range) or a three-phase connection. Three-phase system, the most common system, is a four-wire distribution 3×400 V, with a phase voltage of 230 V and a line voltage of 400 V. In some countries such as Norway, Italy, and parts of Belgium, three-wire 3×230 V networks with a phase voltage of 230 V, without neutral wire, can also be found.

This three-phase connection allows considerably higher power for a modest current, with just 16 A per phase, one can get:

$$P = \sqrt{3} \times 400 \times 16 \times \cos\varphi = 11.1 \text{ kW} \quad (\cos\varphi = 1) \quad (4)$$

This allows charging, for example, the vehicle in just within 1 h for a range of 50 km, or a "charge speed" of 55 km/h.

With a current of 32 A, put to 22 kW are available. This allows considerably fast charging for most small- and medium-sized vehicles (for heavy vehicles such as buses, this power level will correspond to a "normal" charge/dots), using current levels that can be implemented more easily than the high single-phase current of nearly 100 A, which would be required to deliver this power.

The use of three-phase connection has the further advantage to be more beneficial for the load spreading of the electric network.

The on-board battery charger on the vehicle shall of course be configured to accept a three-phase connection.

An overview of the available power for normal and semifast charging is given in Table 2 (Van den Bossche, 2010a). The last two columns of this table give the section of copper needed for the cable (based on the standard ratings of 16 A for 2.5 mm^2 wire and 32 A for 6mm^2 wire, and not including neutral or earth conductors), and the relationship between power and copper section. It can clearly be seen that the use of three phases, allows a much better utilization of the conductors, and hence the use of lighter cables and accessories.

Table 2. Power levels for charging ($\cos\varphi = 1$).

	Voltage	Phases	Current	Power (kW)	Copper (mm^2)	kW/mm^2
Standard	230	1	16	3.7	5	0.74
Semifast	230	1	32	7.4	12	0.62
Semifast	230	3	16	6.4	7.5	0.85
Semifast	400	3	16	11.1	7.5	1.48
Semifast	400	3	32	22.2	18	1.23

3.3 "Fast" charging

For "fast" charging (called *level 3* charging in the United States), higher power levels are used, which create the need for specific infrastructure beyond standard domestic or industrial socket outlets. The charging can be either performed with a DC or an AC connection between the vehicle and the charging post.

In the DC case, a fixed battery charger (rectifier) is connected to the battery, and more heavy and expensive fixed infrastructure is thus needed, whereas, for AC fast charging, the rectifying is done on board the vehicle, most commonly using the traction inverter that is able to recharge the battery at a high current (for regenerative braking) and can also be fed by the grid (Figure 1).

Fast charging infrastructure is being proposed for power levels up to 250 kW (Szczepanek and Botsford, 2009), claiming to be able to charge an electric vehicle in < 10 min, comparable with the refueling time of a gasoline-powered legacy vehicle.

The high flexibility and apparent user-friendliness of fast charging comes, however, with a number of drawbacks:

- the high cost of the fixed infrastructure involved compared with semifast charging;
- the need for heavy cables, which for practical purposes are usually fixed to the charging station (case "C" in

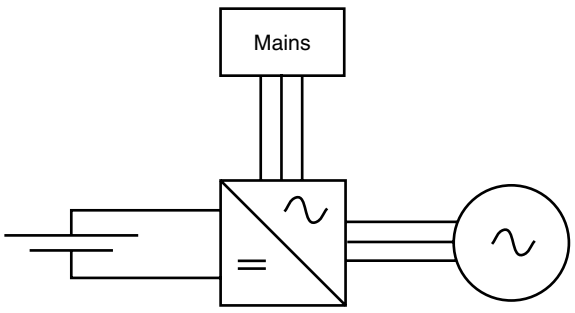

Figure 1. Charging with inverter.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

IEC61851), exposing them to copper theft, which is a growing problem in most countries;
- the high burden on the distribution network with high level point loads, and the high cost of electricity at peak times in particular. This can be alleviated by providing an energy buffer such as a stationary battery at the charging station (which would be charged overnight at low rates); however, such solution increases the investment cost even more while introducing additional losses because of battery and charger efficiencies;
- the fast charging cycle provides only opportunity charging and does not allow final charge, which takes a certain time at a low current, periodical (overnight) charging will thus remain necessary;
- the high strain on the battery through fast charging may have an influence on battery cycle life and hence cost.

Fast charging will thus be more expensive for the user and most charging will make use of normal or semifast charging points located both at private locations (residential garages or corporate parking places) and at publicly accessible charging points.

The presence and availability of fast charging stations, however, provide a psychological advantage to electric vehicle drivers, allowing them to fully exploit the range envelope of their vehicle and to overcome "range anxiety." A few well-located fast charging stations in an urban area can fulfill this need. They will be accessed mostly for "emergency" uses or in case of an unexpected change in mission, with the bulk of the electric energy delivered to the vehicles by cheap overnight charging.

The psychological advantage of the fast charging stations is comparable in fact to the plug-in hybrid vehicle, where the presence of an auxiliary power unit gives users the confidence to use the full range of their battery, overcoming the range anxiety typical for many battery-electric drivers who do not have specialist knowledge of the behavior of their battery (Botsford and Szczepanek, 2009).

The high power connection of the "fast" charging station makes it furthermore particularly interesting for "vehicle-to-grid" applications.

4 CHARGING MODES FOR CONDUCTIVE CHARGING

While Section 3 dealt with the power levels to be used, one should also consider the way the infrastructure is used for connecting the vehicle. This leads to the definition of the so-called *charging modes*, introduced in the international standard IEC61851-1 (IEC61851-1, 2010).

4.1 Mode 1 charging

Mode 1 charging refers to the connection of the EV to the AC supply network (mains) utilizing standardized socket outlets (i.e., meeting the requirements of any national or international standard), with currents up to 16 A. This corresponds to nondedicated infrastructures, such as domestic socket outlets, to which electric vehicles are connected for charging.

These socket outlets can easily and cheaply deliver the desired power, and owing to their availability, mode 1 charging is the most common option for charging electric vehicles, particularly when existing infrastructures are to be used.

There are, however, a number of safety concerns to be considered. The safe operation of a mode 1 charging point depends on the presence of suitable protections on the supply side: a fuse or circuit breaker to protect against overcurrent, a proper earthing connection, and a residual current device (RCD) switching off the supply if a leakage current greater than a certain value (typically 30 mA) is detected.

In most countries, RCDs are now prescribed for all new electric installations. There are, however, still a lot of older installations without RCD, and it is often difficult for the EV user to know, when plugging in the vehicle, whether or not an RCD is present. While some countries leave this responsibility to the user, mode 1 has, therefore, been outlawed in a number of countries such as the United States.

Some countries such as Italy do not allow mode 1 charging for charging places accessible to the public and limit its use to private premises, out of concern that live standard socket outlets in public places may be exposed to the elements, vandalism, or unauthorized access.

In countries where the use of mode 1 charging is allowed, its simplicity and low investment cost make it a preferred mode for private premises (including residential garages and corporate parking lots). Mode 1 allows charging in full safety when used in a reliable electrical installation.

However, the uncertainty faced by the user about the presence of an RCD when plugging in the electric vehicle in an arbitrary standard outlet makes that a potential hazard may be present. For this reason, vehicle manufacturers steer away from mode 1 charging, preferring mode 3, with mode 2 as a transitory solution.

Mode 1 charging will, in the future, thus mostly be relevant as the main mode for small vehicles such as scooters and quadricycles (CEN–CENELEC, 2011).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

4.2 Mode 2 charging

Mode 2 charging connection of the EV to the AC supply network (mains) also makes use of standardized socket outlets. It provides, however, additional protection by adding an *in-cable control box* (ICCB) with a control pilot (CP) function (Section 4.3.2) between the EV and the control box.

The introduction of mode 2 charging was initially mainly aimed at the United States, as a transitional solution in the first edition of the IEC61851-1 standard. It is now, however, receiving new interest to replace mode 1 for charging at nondedicated outlets and is used by most car manufacturers.

The main disadvantage of mode 2 is that the control box protects the downstream cable and the vehicle, but not the plug itself, whereas the plug is one of the components more liable to be damaged in use. Furthermore, the use of the ICCB is not elegant and not always very practical, for example, in public environments.

The CEN–CENELEC Focus Group recommended that occasional charging on private premises should preferably be done using mode 2 to ensure RCD protection (CEN–CENELEC, 2011).

4.3 Mode 3 charging

4.3.1 Definition

Mode 3 charging involves the direct connection of the EV to the AC supply network utilizing dedicated electric vehicle supply equipment (EVSE). This refers to private or public charging stations. The standard IEC61851-1 (IEC61851-1, 2010) mandates CP protection between equipment permanently connected to the AC supply network and the electric vehicle.

4.3.2 Control pilot

For mode 3 charging, the IEC61851-1 standard foresees additional protection measures to be provided by the so-called *CP*, a device that has the following functions mandated by the standard:

- verification that the vehicle is properly connected;
- continuous verification of the protective earth conductor integrity;
- energization and de-energization of the system;
- selection of the charging rate (ampacity).

This function is typically performed through an extra conductor in the charging cable assembly, in addition to the phase(s), neutral, and earth conductor. Annex A of IEC61851-1 specifies the CP circuit given in Figure 2, showing the operation of the system. A control signal (1 kHz PWM, pulse-width modulation) is sent through the CP conductor. The switch on the vehicle allows to control the charging, whereas the duty cycle of the PWM signal controls the current absorbed by the charger, thus allowing dynamic ampacity control (Section 9).

When no vehicle is connected to the socket outlet, the socket is dead. This provides a key safety advantage particularly for publicly accessible charging points. Power is delivered only when the plug is correctly inserted and the earth circuit is proved to be sound.

The new version of IEC61851-1, now under development, further refines the use of the CP for the interaction

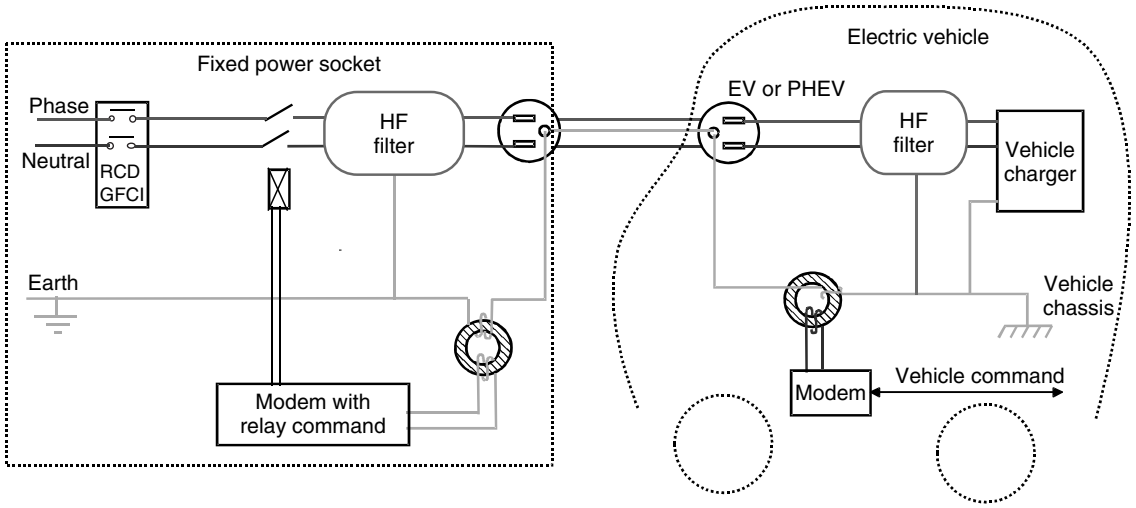

Figure 3. Control pilot function with power line communication.

between the electric vehicle and the EVSE, defining several states of operation:

Table 3. Charging states.

A	Vehicle not connected
B	Vehicle connected, not ready for charging
C	Vehicle charging, ventilation not required
D	Vehicle charging, ventilation required
E and F	Vehicle connected, EVSE not available for charging

The use of a CP conductor in charging equipment was first proposed around 1990 for charging stations for electric boats deployed in the Norfolk Broads in England (Benning Ltd., 1990).

The use of a CP function with fourth wire is also included in the SAE standard J1772 (SAE J1772, 2009).

4.3.3 Control pilot conductor alternatives

The use of a dedicated conductor for the CP necessitates an extra conductor and thus the use of special cables and accessories. The functionality of the CP can, however, also be achieved in alternative ways; the standard 61851-1 (IEC61851-1, 2010) defines the functional requirements described in Section 9 of the *CP function*, mandatory for mode 3 charging, which can be achieved by a pilot conductor or by other means. These include various wireless data transfer systems and power line communication. An interesting implementation of the latter has been developed by Electricité de France (Bleijs, 2009). The principle as described in an informative annex to 61851-1 is illustrated in Figure 3.

In this implementation, the CP signal is a common-mode signal between the phase wires and the earth conductor, using a 110 kHz carrier frequency. This signal is generated by the vehicle electronics and transmitted to the earth wire through a transformer (ferrite torus). Filter circuits are present as to avoid the unwanted transmission of data signals from the charging system to the mains, and to be compliant with the relevant standards concerning electrical equipment to be connected to the grid, which proscribe any earth-line communication upstream of the EVSE (EN50065-1, 2002).

The system is able to perform all CP functionalities over a three-wire connection. This basic protection can be implemented using a cheap and light set of electrical components and would thus also be suited for light vehicles such as electric two wheelers, where the extra cost coming with the use of special accessories should be avoided.

The proposed system presents, however, several other interesting opportunities, as it is able not only to carry the CP signal but also to perform data exchange functions to be used in smart charging and billing (Section 9).

Unfortunately, this system has not been adopted yet by vehicle manufacturers.

4.3.4 Implementation of mode 3

The inherent safety features, as well as the potential for smart grid integration, make mode 3 a preferred solution. It was thus recommended by the Focus Group for public charging stations as well as for home charging using dedicated outlet (CEN–CENELEC, 2011).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Most electric vehicles appearing on the market nowadays are mode 3-ready.

4.4 Mode 4 charging

Mode 4 charging is defined as the indirect connection of the EV to the AC supply network (mains) utilizing an off-board charger, where the CP conductor extends to equipment permanently connected to the AC supply (IEC61851-1, 2010).

This pertains to DC charging stations, which are mostly used for fast charging. As the charger is located off board, a communication link is necessary to allow the charger to be informed about the type and the state of charge of the battery to provide it with the right voltage and current.

5 WIRELESS CHARGING

5.1 Introduction

All charging systems described earlier rely on a conductive coupling and thus have the need for cables, plugs, and sockets. The use of wireless systems has been proposed to allow an improvement of electric safety on the one hand and an enhanced user friendliness on the other hand, removing the need of handling cables and all the associated hazards.

Most wireless charging systems are based on inductive power transfer, using a two-part transformer with the primary connected to the network and the secondary installed on the vehicle. Charging can be performed after juxtaposition of the two parts.

One type of inductive charging has been introduced and extensively promoted by General Motors in the 1990s, making use of a paddle-shaped primary inductor coil to be inserted in a slot on board the vehicle. This lightweight, high frequency system could be used over a wide power range, but it still necessitated the use of a cable and had a much higher cost than conductive solutions. Further development of/and interest in this system was halted by the end of the twentieth century. International standardization work had already been started, but did not proceed beyond CD (committee draft) level (IEC61980-1/CD, 2000; IEC61980-2/CD, 2000).

5.2 Automatic connection

The real advantage of wireless systems is to do away with cables. Cable-free charging can be made possible by appropriate design and location of the inductors: it is sufficient to park the vehicle adjacent to the primary inductor, which can be done in one of the following ways (Figure 4):

1. special charging post design;
2. fixed devices, flush with road surface;
3. fixed devices, not flush with road surface;
4. devices on road surface, which include moving parts;
5. special kerb designs.

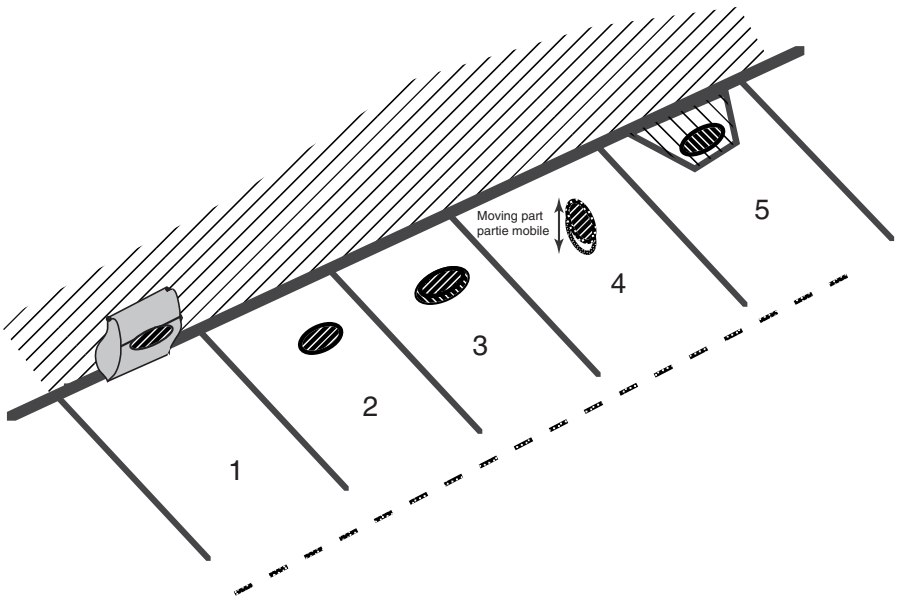

Figure 4. Automatic charger connections.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As such, systems require a specific approach to both the vehicle and the charging point architecture. Their use will be mostly limited to niche applications such as captive fleets for special use and automatic rent-a-car systems. This should also be seen in the framework of the inductive energy transfer systems now being implemented for powering trams and electric buses without overhead cables.

5.3 New developments for standardization

Wireless charging systems have recently known a renewed interest and the standardization work on the subject has been revived. The project team on 61980 started again in the spring of 2011 and will at first focus on the general requirements of the inductive charging systems, particularly highlighting the safety aspects involved with exposure to magnetic fields in the vicinity of the inductive coils. Other wireless transfer systems, for example, based on capacitive energy transfer, will also be considered.

6 BATTERY EXCHANGE

A fast replenishment of the energy on board of the vehicle can be performed by replacing the whole battery pack with a freshly charged one. This technology, which has been used in the past for niche applications such as industrial electric vehicles, has now gained new interest for general use. Its implementation, however, will entail specific standardization problems.

On the one hand, exchangeable batteries will need a standardization of pack dimensions and interfaces. Battery technology, particularly in the field of lithium batteries, is rapidly evolving, and standardization of battery module sizes can only be reasonably achieved when the technology is sufficiently mature. First steps are now, however, being taken to standardize battery cell sizes, supported by both the electrical community (through IEC TC21) and the automotive community (through ISO TC22 SC21).

On the other hand, the exchange of batteries between vehicles and the deployment of "second-life" vehicle batteries for other applications such as stationary energy storage for grid support necessitate means to accurately estimate the *state of health* of a battery. The state of health of a battery reflects the general conditions of a battery and its ability to store electric energy and deliver specified performance, compared with the rated performances of a new battery. Determination of the state of health is not straightforward, as it is highly dependent on the understanding of a battery's chemistry and environment and the evolution of aging processes. The CEN–CENELEC Focus Group recommends that parameters for state of health should be defined in standards to allow for second-life use of batteries (CEN–CENELEC, 2011).

7 EMC ISSUES FOR CHARGING

The influence of the extended use of power electronic converters as used in battery chargers will have to be closely followed up in order to avoid potential problems regarding electromagnetic interference either in the form of radiated electromagnetic waves or as conducted interference on the interconnecting cables. EMC is defined as the ability of an equipment or a system to function satisfactorily in its electromagnetic environment without introducing intolerable electromagnetic disturbances to anything in that environment.

EMC is subject to heavy regulation; in the European Union, there is, on the one hand, the EMC directive 2004/108/EC (Commission of the European Communities, 2004a) that pertains to electric and electronic equipment and, on the other hand, the vehicle EMC directive 2004/104/EC (Commission of the European Communities, 2004b) that pertains to road vehicles.

Furthermore, there are numerous international standards published by IEC, ISO, and CISPR (International Special Committee on Radio Interference) dealing with the matter.

The current set of standards covers most of the EMC needs for low frequency phenomena, except in the frequency range between 2 and 150 kHz, a frequency band that contains the typical operating frequencies of power electronic converters as used in electric vehicle traction systems and battery chargers. It will thus be necessary that this frequency range is addressed by standardization as soon as possible.

The low frequency range below 2 kHz is mostly relevant for conductive emissions (power quality and harmonics), for which limits are given by international standards such as IEC61000-3-2 (IEC61000-3-2, 2005) and 61000-3-12 (IEC61000-3-12, 2011).

The specific EMC problems related with electric vehicle charging are being treated in the new edition of the IEC61851-21 standard, work on which has started in 2011.

8 REGULATORY ISSUES OF CHARGING

The difference in national electric regulations and wiring codes constitutes a major challenge for the specification of a single-charging system usable in various countries.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Some nations, for example, require shutters on socket outlets in domestic environments, whereas others do not.

A typical discussion point is also to define the extension of the scope of the European Union LVD (Commission of the European Communities, 2006). The vehicle itself is explicitly excluded from this scope, but the charging equipment and the cable are clearly covered. The vehicle inlet (where the connector is coupled) is still a matter of discussion, however.

Standardization work is now being performed by IEC TC64 on particular requirements for low voltage installations intended to supply energy for electric vehicles (IEC60364-7-722/CD, 2012).

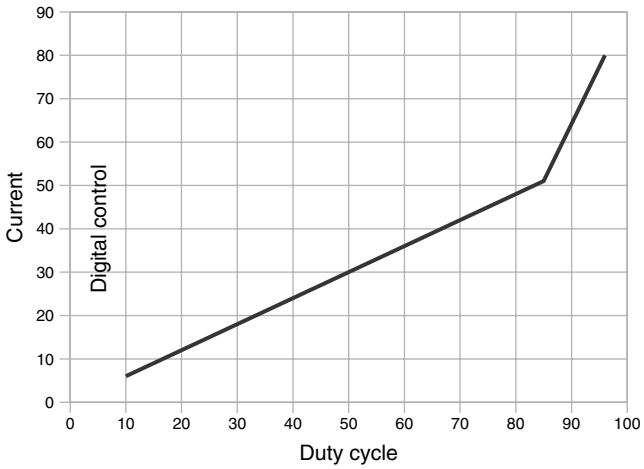

Figure 5. PWM signal. (Taken from data in IEC61851-1 (2010).)

9 COMMUNICATION ISSUES

9.1 Generalities

The vehicle needs to establish a communication with the charging post, which can be developed in several ways, with increasing sophistication.

In mode 1 or mode 2 charging, where standard nondedicated socket outlets are used, there is no communication at all.

9.2 Control pilot PWM communication

Mode 3 introduces communication through the CP function. The principle is defined in IEC61851.

In its most basic way of operation (as developed in the first edition of 61851), the CP only fulfills its essential safety function. The pilot signal is just a small current sent through the CP loop to ensure that the vehicle is properly connected and the earth connection is sound.

More functionality can be added using a PWM signal in the CP circuit. The PWM signal can convey information about the maximum ampacity of the charging point through the variation of its duty cycle.

This feature presents several operational benefits:

- The charger can adjust itself to the maximum allowable current that can be delivered by various charging points, for example, a standard value of 16 A, reduced value of 10 A, and higher value of 32 A for semifast charging points.
- The charging point can control the amount of current absorbed by the charger, in the framework of a smart grid load management or to optimize the tarification of the electric energy.

The relationship is illustrated in Figure 5. A duty cycle $< 5\%$ conveys the message that charging current is controlled through advanced serial communication; for duty cycles $> 97\%$, charging is impeded.

9.3 Control pilot baseband communication

As to allow further functionalities to be included in the CP signal, the new version of IEC61851-1 currently under development also proposes to use the CP for baseband serial communication, which is a bidirectional, half-duplex, point-to-point serial communication link on the CP. It provides an extended CP function that is backwards compatible with either vehicles of charging stations fitted with the standard PWM CP (albeit without the extra communication options of course). The actual protocol used for the communication is covered in other standards; using the CAN (controller area network) protocol (ISO11898-1, 2003) is an option.

9.4 Communication for DC charging (mode 4)

Off-board chargers, which supply a direct current to the vehicle battery, must communicate with the vehicle battery in order to supply it with the correct voltage and current. This is particularly the case with nondedicated chargers as used in public charging stations, which should be able to supply vehicles with varying battery voltages and chemistries.

Early development in this field was described in the CENELEC Technical Specification 50457-2 (CENELEC TS50457-2, 2006), with a protocol largely based on the ISO road vehicle diagnostic standards as defined in ISO14229

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and ISO14230 (ISO14230-1, 1999; ISO14230-2, 1999; ISO14230-3, 1999; ISO14229-1, 2006). These concern requirements for diagnostic systems are implemented on a serial data link layer, which allows a tester to control diagnostic functions in and on vehicle electronic control unit.

The protocols were specifically adapted for the selected application: after the initialization phase by the off-board charger, the vehicle's charge control unit controls the charging process of the off-board charger. Contrary to the standard communication according to ISO14230 where the server and the client are fixed during all the session, their roles are definitively reversed after the initialization phase.

This document is now, however, to be considered obsolete and will be superseded by the new standards now under development.

The new developments in the field of DC charging have led to the drafting of IEC61851-24 on a global level. The work has started in 2010 and is now at CD stage (IEC61851-24/CD, 2011).

This standard will define the messages of digital/data communication to be used during charging control between off-board DC charging system and electric road vehicle. It states the basic specifications of the communication circuit, which is based on "CAN" principles. The document focuses on the upper two layers (6 and 7) of the OSI (open system interconnection) concept (ISO/IEC7498-1, 1994) (Figure 6); the lower two layers being described in the CAN standard ISO11898 (ISO11898-1, 2003; ISO11898-2, 2003).

Annexes to IEC61851-24 will describe several practical protocols reflecting the solutions described in the annexes IEC61851-23 (IEC61851-23/CD, 2011), among which the "CHAdeMO" concept.

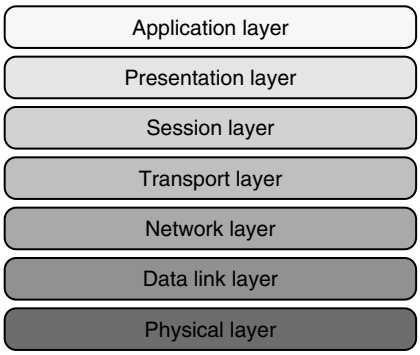

Figure 6. Open system interconnection layers.

9.5 High level communication and grid management

The development of new concepts such as "smart grid" or "vehicle to grid" has created the need for an appropriate communication protocol for electric vehicle charging, allowing functionalities such as:

- vehicle identification and billing, allowing payment for charging at public charging stations;
- individual billing of used energy to the user's account when the vehicle is charged at any outlet connected to a smart meter outside of the vehicle's common operating area (roaming);
- charge cost optimization by choosing the most appropriate time window where electricity rates are the lowest;
- grid load optimization by controlling charger ampacity in function of grid demand;
- peak-shaving functionality using electric vehicles connected to the grid as a spinning reserve (vehicle-to-grid);
- appropriate billing and user compensation functions for vehicle-to-grid operation.

Communication protocols for this issue will be typically based on the well-known 7-layer OSI reference model defined in international standards (ISO/IEC7498-1, 1994) (Figure 6).

The development of a communication protocol involves several actors, including physical devices such as the charging post or the vehicle controller, entities such as electricity suppliers or grid operators, and last but not the least the vehicle user. An overview is shown in Figure 7.

The local or remote communication system may have the function of a "clearing house" for the authentication, collection, and consolidation of grid and billing parameters from the actors as well as transmitting charging process information to the respective actors. Not all such functions are necessarily required for the basic charging functions, and some may be performed locally or remotely. The system can thus become either simple or rather complex, and several issues are still to be resolved.

Owing to the complex and multidisciplinary nature of the subject, its standardization of this issue is being addressed by a joint working group uniting ISO TC22 SC3 (electric equipment on road vehicles, including on-board communication systems) and IEC TC69 (electric road vehicles).

This joint working group is currently drafting a family of standards called *ISO/IEC15118* "road vehicles—vehicle

to grid communication interface," to describe the communication, in terms of data format and message content, between the electric vehicle (including battery-electric vehicles and plug-in hybrid electric vehicles) and the EVSE (charging post), as well as message content and data structure to enable billing communication and grid management. Provisions for additional communication aspects (such as vehicle charge status information and configuration) are being considered to allow for interoperability of all vehicles with all charging stations. As the communication parts of those generic equipments are the electric vehicle communication controller (EVCC) and the supply equipment communication controller (SECC), this standard describes the communication between these components. All connections beyond the EVCC and how the messages will be exchanged are considered to be out of the scope as specific use cases.

The basic document of the ISO/IEC15118 family cases is part 1 "General Information and Use-case Definition" (ISO/IEC15118-1/CDV, 2012), which circulated as CDV (committee draft for voting) in the Spring of 2012. ISO/IEC15118-1 provides a general overview and a common understanding of aspects influencing the charge process, payment, and load leveling. It specifies furthermore the initial startup process and security issues for charging.

Communication between vehicle and charging post is defined by two different concepts called *basic signaling* and *high level communication*.

- Basic signaling shall be used to define items such as states and duty cycle for safety and initialization of the charging (CP function, cf. Section 9.2).
- High level communication shall be used to define issues such as identification, load leveling, and value-added services. In all cases, charging itself shall be controlled by the EV and the EVSE does not need to have a charging load controller. Information exchange with high level communication only occurs if both EV and EVSE are equipped with a high level communication device.

The specific actors involved with the charging process can be divided into primary actors, which directly involved with the charging process, and secondary actors, which may be involved because of the supply of information needed for the charging process.

All envisageable charging processes have to be contextualized in the so-called "use cases" in order to define communication needs. To this effect, the charging process is separated into eight functional groups where elementary use cases can be defined:

- beginning of charging process;
- communication setup;
- identification;
- authorization;
- target setting and charge scheduling;
- charge controlling and rescheduling;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

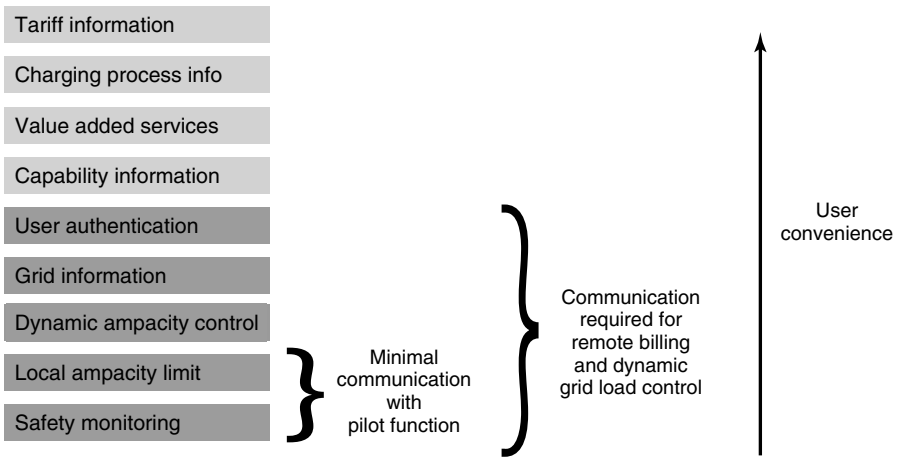

Figure 8. Communication and use cases. (Reproduced with permission from Van den Bossche, 2010b. © World Electric Vehicle Association.)

- value-added services;
- end of charging process.

Each use case will be constituted of a combination of elementary use cases, which can be used to construct specific charging scenarios.

These scenarios allow functionalities to be implemented with increased complexity, as illustrated in Figure 8; the increase of user convenience necessitates an extension of data structures to be exchanged.

Part 2 of ISO/IEC15118, which was also circulated as CD in the Spring of 2011 (ISO/IEC15118-2/CD, 2011), is called *technical protocol description and OSI layer requirements*. This document focuses on the top two layers of the OSI: the physical layer and the data link layer, for the communication between vehicle and EVSE.

Part 3 describes the physical and data link layers for a high level communication. It covers the overall information exchange between all actors involved in the electrical energy exchange. This document was circulated as CD in the Fall of 2011 (ISO/IEC15118-3/CD, 2011).

The interaction between the parts of the standard is shown in Figure 9.

For each use case, different scenarios are to be defined, relating to the desired control of charging by the grid operator, the used billing scheme, and the communication system for the user. Several systems are now under consideration and/or used in experimental fleets:

- use of an RFID (radio-frequency identification) tag;
- communication over the CP conductor;
- communication (at low or high data rate) through power line communication;
- communication with the vehicle's CAN-Bus system;
- wireless communication through Bluetooth or ZigBee devices;
- communication via mobile phone.

In order to define the communication messages, every such scenario shall be translated into a sequence diagram in unified modeling language (ISO/IEC19501, 2005).

It is clear that considerable standardization work remains to be performed in this field. The drafting of ISO/IEC15118 will form a good base for a generally applicable family of standards.

To be a true global solution, however, there should not be reliance on proprietary protocols allowing global use by all concerned parties.

9.6 Billing

The practice of charging of electric vehicles at public charging stations also raises the problem of billing the user for the energy consumed. Payment systems can make use of coins (vulnerable to vandalism), credit cards (creating the necessity of communication systems and involving transaction costs), or dedicated access devices (cards or RFID).

As the value of the electricity typically charged in one opportunity charging session is quite low compared to the parking cost in city centre environments, one can consider to charge the user according to time rather than to energy used, which dispenses the need for (more expensive) electricity counters. Some legal issues have also been considered here, as in some countries, the sale of electricity as such is heavily regulated. Furthermore, the real cost of electricity is not constant but varies with the peak load of the grid.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

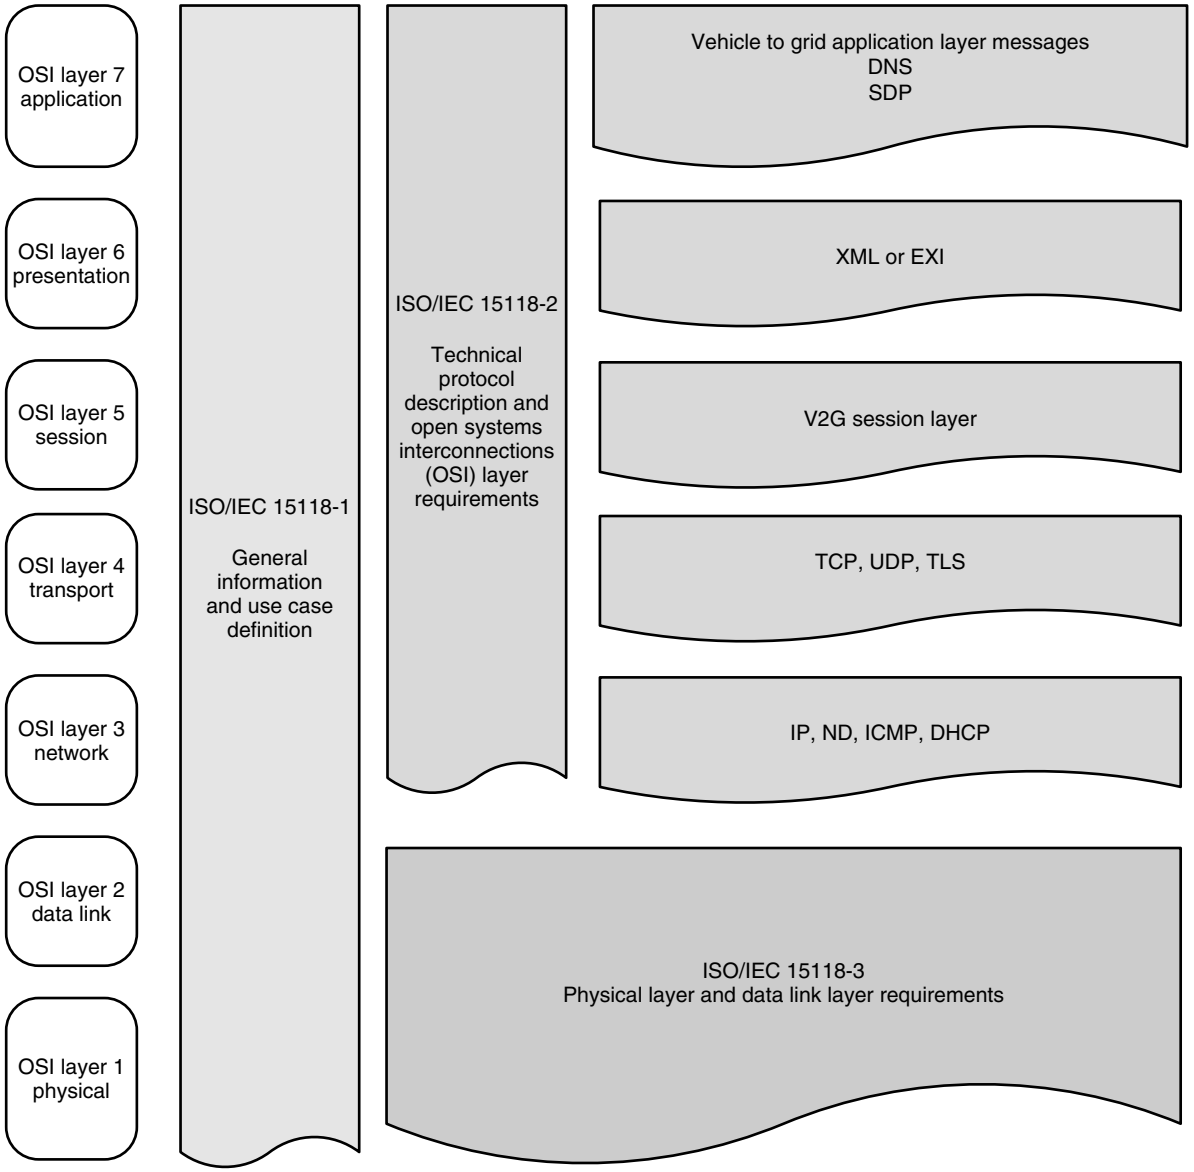

Figure 9. Parts of ISO/IEC15118.

The new developments in communication will allow a more sophisticated approach of this issue, with user identification and communication using wireless devices or mobile phones, differential tariffication according to time of the day and grid load, and compensation for energy returned to the grid under a "vehicle to grid" scheme. Furthermore, vehicles being charged at varying locations in a "smart grid" environment will charge the user in a transparent "roaming" way: wherever the user charges his or her vehicle, it will be charged on his or her own bill.

One should consider the complexity and cost of the proposed system facing the actual energy cost: most charging taking place in privately owned premises can be billed on existing meters without the need for complex business models.

10 ACCESSORIES FOR CONDUCTIVE CHARGING

10.1 Connection cases

The connection of the cable between the vehicle and the charging outlet can be carried out in three ways as defined in IEC61851-1 (IEC61851-1, 2010):

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto192
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- Case "A": where the cable and the plug are permanently attached to the vehicle. This case is generally found only in very light vehicles.
- Case "B": where the cable assembly is detachable, and connected to the vehicle with a connector. This is the most common case for normal and semifast charging.
- Case "C": where the cable and the vehicle connector are permanently attached to the supply equipment. This arrangement is typically used for fast charging (mode 4), so that drivers do not have to carry heavy cables around. Public charging stations using this case are, however, at a higher risk of copper theft.

10.2 Connection accessories

10.2.1 Standard domestic plugs

For mode 1 and mode 2 charging (also for mode 3 charging with power-line communication), standard plugs and sockets can be used encompassing only phase, neutral, and earth contacts. In most areas, this will usually be the standard domestic plugs as described in various national standards, and typically rated 10–16 A (IEC/TR60083, 2009).

One has to recognize, however, that these domestic plugs, particularly not the low cost versions mostly used on consumer grade equipment, are not really suited for the heavy-duty operation of electric vehicle charging, characterized by

- long-time operation at near rated current;
- frequent operation, including disconnection under rated load;
- exposure to outdoor conditions.

This leads to a shorter lifetime of the accessories and to contact problems, which may cause hazardous situations. It is thus recommended to limit the rating of the charging equipment using such plugs to a lower value, up to 10 A; their use being confined to small vehicles such as scooters (for which this current level is largely sufficient), as well as for occasional charging of larger vehicles (the "grandma" solution).

10.2.2 Standard industrial plugs

A better alternative is to use industrial plugs and sockets as defined by the international standard IEC60309-2 (IEC60309-2, 2005). These plugs (in standard, blue color for 230 V and red for 400 V) are widely used, particularly in Europe, for industrial equipment but also for outdoor use by the general public on venues such as camping sites and marinas, where they function in an operation mode comparable to an electric vehicle charging station. Their "industrial" nature and their relatively high insertion force, particularly for higher current versions, has been cited as an issue affecting user-friendliness for electric vehicle deployment.

These accessories are widely spread on the market and are relatively inexpensive, making them the preferable solution for mode 1 or mode 2 charging. The Focus Group (CEN–CENELEC, 2011) proposed them as interim solution pending development of dedicated accessories.

10.2.3 Dedicated electric vehicle accessories

The use of a physical CP conductor necessitates the introduction of specific accessories for electric vehicle use. Such plugs and sockets are described in the international standard IEC62196 "Plugs, Socket-Outlets, Vehicle Couplers and Vehicle Inlets–Conductive Charging of Electric Vehicles."

Part 1 of this standard (IEC62196-1, 2011) gives general functional requirements; it integrates general requirements from the industrial plug standard IEC60309-1 (IEC60309-1, 2005) with the electric vehicle requirements of IEC61851-1 (IEC61851-1, 2010).

Physical dimensions are treated in part 2. IEC62196-2 (2011), published in 2012. It does present standard sheets for several types of accessories:

- Type 1 (Figure 10)
  Type 1 is a single-phase coupler rated for 250 V and 32 A (30 A in the United States and Japan). It is fitted with two extra contacts: one for the CP and the other for an auxiliary coupler contact (CS), which can be used to indicate the presence of the connector to the vehicle and to signal the correct insertion of the vehicle connector into the vehicle inlet. With a diameter of 44

Figure 11. Type 2 plug. (Reproduced with permission from Peter Van den Bossche. © Peter Van den Bossche.)

mm, this connector is made in a compact way. Type 1, corresponding to the SAE J1172 coupler (SAE J1772, 2009), is intended as a vehicle connector only to be used in a case "C" configuration in mode 3, or with an ICCB in mode 2.

- Type 2 (Figure 11)
  European car manufacturers and utilities, however, recognizing the potential benefits of three-phase charging and the availability of three-phase supply in most European countries (cf. Section 3.2.2), expressed the desire for three-phase accessories.
  Type 2 is a three-phase coupler rated for currents up to 63 A, and has two auxiliary contacts. It is illustrated in Figure 11 based on a realization by the German company Mennekes. It comes in both a "plug–socket outlet" and a "connector–vehicle inlet" combination, which are of similar build but not intermateable. For the European market, the automobile industry is presently considering mounting both type 1 and type 2 inlets on cars and light trucks.
- Type 3 (Figure 12)
  Type 3 is also a three-phase type, based on a design by the Italian company SCAME further adopted by the "EV Plug Alliance." Its design is derived from a single-phase plug adopted as national standard in Italy (CEI-69-6, 2001) where it is in widespread use particularly for light electric vehicles such as two wheelers.
  One main difference between type 2 and type 3 accessories is the presence of "shutters" on the latter, providing IPXXD protection.

The CEN–CENELEC Focus Group recommended to define a unique footprint for the AC plug and socket outlet, encompassing five power contacts (three phases, neutral, and earth) and two auxiliary contacts to allow mode 3 charging. Both type 2 and type 3 fit this definition, the final choice between both types should be made rapidly. At this moment, type 2 plugs seem to be preferred in most European countries except where shutters are required by law such as in France and Italy.

Figure 12. CHAdeMO DC (left) and type 1 AC (right) inlets on a Nissan Leaf vehicle. (Reproduced with permission from Peter Van den Bossche. © Peter Van den Bossche.)

10.3 Connectors for DC charging

Accessories for DC charging are being treated in IEC62196-3, which is presently under development. This will only pertain to connectors and vehicle inlets, as DC charging stations will typically use a case "C" connection.

Solutions considered include the DC connector proposed by the CHAdeMO association (Figure 13).

Furthermore, solutions are proposed encompassing both AC and DC connections in one unit, the so-called "combo" connectors.

The distinct parts of IEC62196-2, which are being prepared, will likely have the character of "catalogue standards," presenting standard sheets for various solutions without, however, making a distinct choice for one particular solution.

10.4 Battery connectors

Battery connectors are widely standardized for use in industrial electric vehicles. Functional requirements are given in the European standard EN1175-1 (EN1175-1, 1998). Several families of connectors in use conform to this standard, such as the so-called Euroconnectors (FEM 4.007b, 1993; DIN43589-1, 1994) and the "Anderson" connectors. These connectors are available with or without auxiliary contacts, for DC currents up to 350 A.

Although such connectors are sometimes found in electric road vehicles for internal connections, their use for (mode 4) charging of road vehicles is not advisable, particularly by the general public, as they are not designed for the higher battery voltage levels now in use or for connecting to cable assemblies. Furthermore, they lack earth conductors and are not designed to break a load.

11 CONCLUSIONS

The charging of electrically propelled vehicles remains a key issue for future standardization work. As with all standardization matters, charging standards pertain to the three main pillars of the house of standardization: safety, compatibility, and performance.

Safety standards ensure protection against electric shock and other related hazards, as well as controlling EMC issues, allowing the charging infrastructure to be used safely in all its potential environments.

Compatibility standards obviously refer to the definition of suitable plugs and sockets for electric vehicle charging. They also cover the communication needs of charging and allow the electric vehicle to be deployed in an extended area and the infrastructure to be universally usable.

Performance measurement standards, in the framework of this study, pertain to the management of energy measurement for billing as well as battery state of charge and state of health.

Intensive work is now being performed by international standardization committees in order to realize unified solutions, which will be a key factor in allowing the deployment of electrically propelled vehicles on a global level, highlighting the technical and societal relevance of standardization.

Hardware-in-the-Loop Simulation

Susanne Köhl and Markus Plöger
dSPACE GmbH, Paderborn, Germany

1 INTRODUCTION TO AND OBJECTIVES OF HARDWARE-IN-THE-LOOP SIMULATION

Hardware-in-the-loop (HIL) simulation enables electronic control unit (ECU) functionality to be tested in real time and in a realistic test environment during ECU software development, without the real environment (vehicle, other ECUs, and connected actuators/sensors) actually being available. The static and dynamic processes in the ECU's environment are simulated in real time. The unit under test and the simulation environment form a closed loop (Figure 1).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

Tests on a HIL simulator range from early tests of single functions to release tests for the entire ECU network, and have become an integral part in the ECU development processes at original equipment manufacturers (OEMs) and suppliers. This has given the electronics development process another milestone for enhancing vehicle quality by eliminating errors. ISO 26262, the ISO (International Organization for Standardization) standard for safety-relevant in-vehicle electric/electronic systems, also acknowledges HIL to be an important element in developing and testing safety-relevant functions.

ECUs for all vehicle domains—powertrain and vehicle dynamics, chassis, comfort and safety, and so on—are tested on HIL systems. In recent years, topics such as electrification and driver assistance systems have been added to this list (Plöger and Köhl, 2006).

The ECU's output signals and bus signals are measured in real time. These signals are input values for the real-time simulation model of the controlled system. The actuators, driven by the output signals of the ECU, are either electrically simulated or included in the simulation model. The sensor signals that the ECU expects for its operations are generated by the HIL simulator according to the state of the simulated controlled system. The bus signals [CAN (controller area network), LIN (local interconnect network), FlexRay, Ethernet, MOST, proprietary serial buses, and so on], which in a real vehicle would be sent by other ECUs or other sensors, are simulated and generated in parallel to this. Simulating the communication network in this way is also called *restbus simulation*. In addition to an ECU's good behavior being simulated, its behavior in response to a fault can also be tested by means of electrical failure simulation at the input, output, or bus channels.

HIL tests differ from other functionality test methods in the following ways: ECU benches and test drives are expensive and labor-intensive, tests on these systems can be

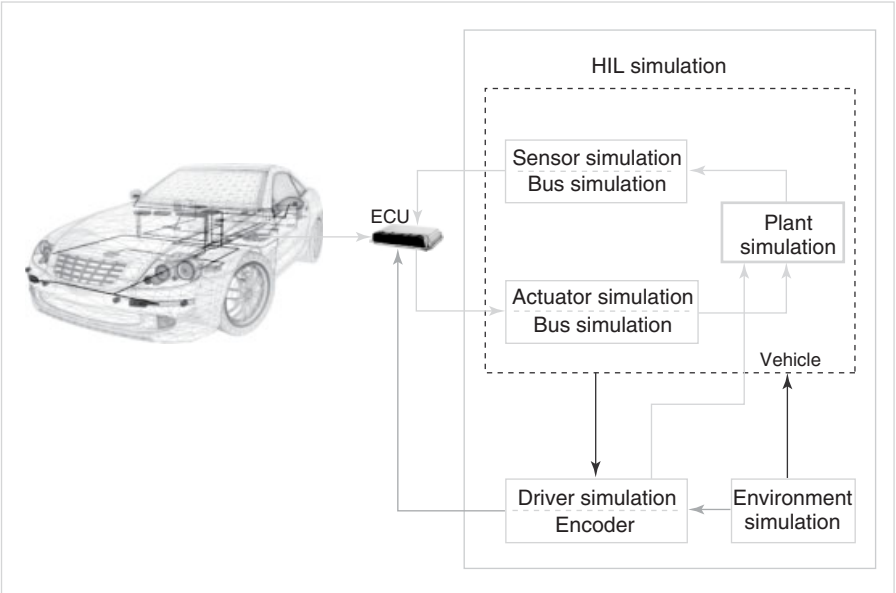

Figure 1. Signal flow in HIL simulation.

automated only partially or not at all, and can, therefore, not be reproduced. Such tests cannot be performed until the required components are actually available. With HIL, individual components can be tested before all the vehicle electronics are available. In test drives, it is dangerous to test at the extremes of ranges. Unlike tests on a test bench, HIL system testing allows operating points to be set in any way desired, for example, to cover the entire engine speed range. Automation can be used on a HIL system to make reproducibility considerably more precise. The cost of testing is reduced because fewer test vehicles are needed. Up to 90% of all faults occurring in test drives can be reproduced by means of HIL simulation (Lamberg, 2006).

It is automation that makes regression tests possible at all. Automation also means that testing can be done round the clock and on seven days a week (24/7 tests) (Plöger and Köhl, 2006).

2 ROLES IN ECU SOFTWARE TESTING

One task performed by car manufacturers is to integrate the electrics/electronics components into the overall system. They, therefore, also have the task of testing how ECUs from different suppliers interact in the overall system (ECU network testing). At this point in time, the suppliers should already have verified that the individual ECUs (or smaller networks provided by them) fulfill the specifications.

Until now, car manufacturers have also often performed functional tests on the ECUs. To save time and money, however, it must not be allowed to happen that a manufacturer discovers errors at the component level while performing network tests (Plöger and Köhl, 2006).

2.1 Task assignment between OEM and suppliers

Before delivering a new ECU version for integration into the overall vehicle, the supplier (which can also be a department within the OEM) must first run component tests to verify the version. Subsequently, integrating into a (sub)system the various components supplied by external suppliers is a critical phase in the development process. Misunderstandings and imperfect specifications can result in errors not being found until the car manufacturer performs tests on a subsystem (e.g., within one vehicle domain) or the overall system (Honisch, Hutter, and Schmid, 2004). However, the real objective of the manufacturer's system tests is to verify the interaction between the components and to verify functions that are implemented across several ECUs. These distributed functions (the central algorithm, sensors and actuators, and operating and display elements are located on different ECUs) can be verified only during interaction between all the ECUs involved.

If the suppliers and the OEM use compatible test systems, they can easily exchange and compare tests and test results. Shared concepts and clearly apportioned responsibilities avoid unnecessary redundancies and increase test case coverage.

In some circumstances, the OEM has to provide a restbus simulation of the other ECUs, so that the supplier can

run tests at component level (Figure 2). In the other direction, the supplier often provides the OEM with parameterized models representing the environment of the delivered ECU.

The roles involved in the different development phases and the resulting requirements for the HIL system are explained later (Köhl and Jegminat, 2005). Figure 3 provides an overview.

2.2 Function developer at supplier (or at OEM)

The function developer tests single functions and the control strategies. The typical objective is function approval.

The following requirements for the HIL system are typical:

- It is a common practice for suppliers to reuse a control algorithm in different ECU variants. This requires flexible simulator hardware that is easy to adapt to different ECU variants. The HIL software components (SWCs), such as submodels, parameter sets, and test scripts, have to be suitably managed.
- Simulator experiment software that can be used flexibly and interactively is also desirable.
- Usually, only a small amount of automation is necessary (test scripts are often created only in parallel to ECU/function development).

Because ECU diagnostics depend on signal values that are not (or cannot be) calibrated until later, function testing in this phase is frequently performed on an ECU with its diagnostic functionality deactivated.

To save time and effort, tests that were performed during function development should not have to be repeated in the integration phase (Plöger, 2006).

2.3 ECU team lead at OEM (or supplier)

As soon as the functions have been integrated on the target hardware together with the lower software layers (operating system and I/O drivers, e.g.), the ECU has to undergo macroscopic tests. These include tests on overlapping administration layers, for example, in the handling of diagnostic memory.

Either the manufacturer or the supplier performs the ECU release test. The objective is to release the complete ECU, including diagnostics, as error-free.

Automated tests are indispensable for ECU integration tests. Interactive testing is necessary only for test development or if the source of a detected error has to be found.

Typically, there are several integration stages with different quality gates. If new software versions are supplied, or if OEMs use ECUs from different suppliers but with identical functionalities (second source principle), regression tests are the best form of testing. In ECU (integration) tests, managing the simulator's SWCs (submodels, test scripts, and so on) is even more important than during function tests (Plöger, 2006).

2.4 System team lead at OEM

As already mentioned, for efficiency reasons, tests that were already finished at the component level should not be repeated for (sub)system testing. When system-release tests are performed on a HIL system, the focus lies explicitly on testing distributed functions and bus communication. Network management is also tested in this context. The test objective for HIL release tests is an error-free overall system, including diagnostics.

Frequently, different vehicle configurations have to be tested. Country-specific variants, different equipment variants, and special vehicle models make it necessary to handle different configurations. Combinatorial tests are, therefore, needed. The HIL system must support numerous different controlled system models, I/O channels, and bus communications.

Automated tests are again indispensable. Tests designed for the system must be easy to repeat for all ECU/vehicle variants. The higher the degree of automation, the higher the test coverage is.

Another important aspect is that tests verifying the functionality during vehicle development can also be used to examine warranty claims after vehicle production has begun (Plöger, 2006).

At this point, it should be mentioned that simulation always carries with it a residual risk because of imprecisions in the simulation models and situations that were not anticipated. With in-vehicle system tests, there is no longer any risk from any issues neglected during model creation. In addition, functionalities that require driver interaction can better be tested in a driving simulator or in a test drive. Additive test drives are indispensable for these very reasons. The final release of the entire system must, therefore, still be carried out in the vehicle (Schäuffele and Zurawka, 2003).

2.5 Roles within one company

To cope with the complexity involved in ECU development and HIL simulation, there is often a clearly defined task separation among system team leads, function team leads, test system experts, test developers, and test users.

The test system expert is often already involved in project planning for the test system and putting it into operation. He or she is frequently someone from the HIL test system supplier. Two increasingly important roles are those of test developer and test user. The test developer creates the test specification or test plan together with the system team lead or function team lead. The test developer then bases the actual test implementation on this

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and makes it available for test execution. The test user is responsible for test execution. He or she puts together the tests required for a specific test task, parameterizes them, and executes them. With major projects, an overall test manager coordinates the activities (Wallentowitz and Reif, 2006; Lamberg, 2006).

3 COMPONENTS OF A HIL SIMULATOR

Although requirement details vary in different application fields (Section 2), the essential components of the HIL simulator are always similar. The individual components of a HIL simulator and the requirements that apply to them are described in more detail later (Schütte *et al*., 2001). Figure 4 shows all the essential components for a HIL simulator for a single ECU.

3.1 Hardware

3.1.1 Real-time processors

With its increasingly complex and precise models (Section 3.2), HIL simulation makes particularly tough demands on the processing power of the real-time processors. The models are usually computed with a step size of 100 μs to 1 ms to meet the requirements of real-time behavior. Motor sports are one example of short processing times. Highly dynamic electric motors, such as those installed in modern hybrid or electrical vehicles, need to be simulated even faster than 100 μs. As a rule, the simulation models for these are simulated synchronously (pulse-center-aligned) to the frequency of the pulse width modulation (PWM) control on the real-time processor. Sample times of <100 μs are usual.

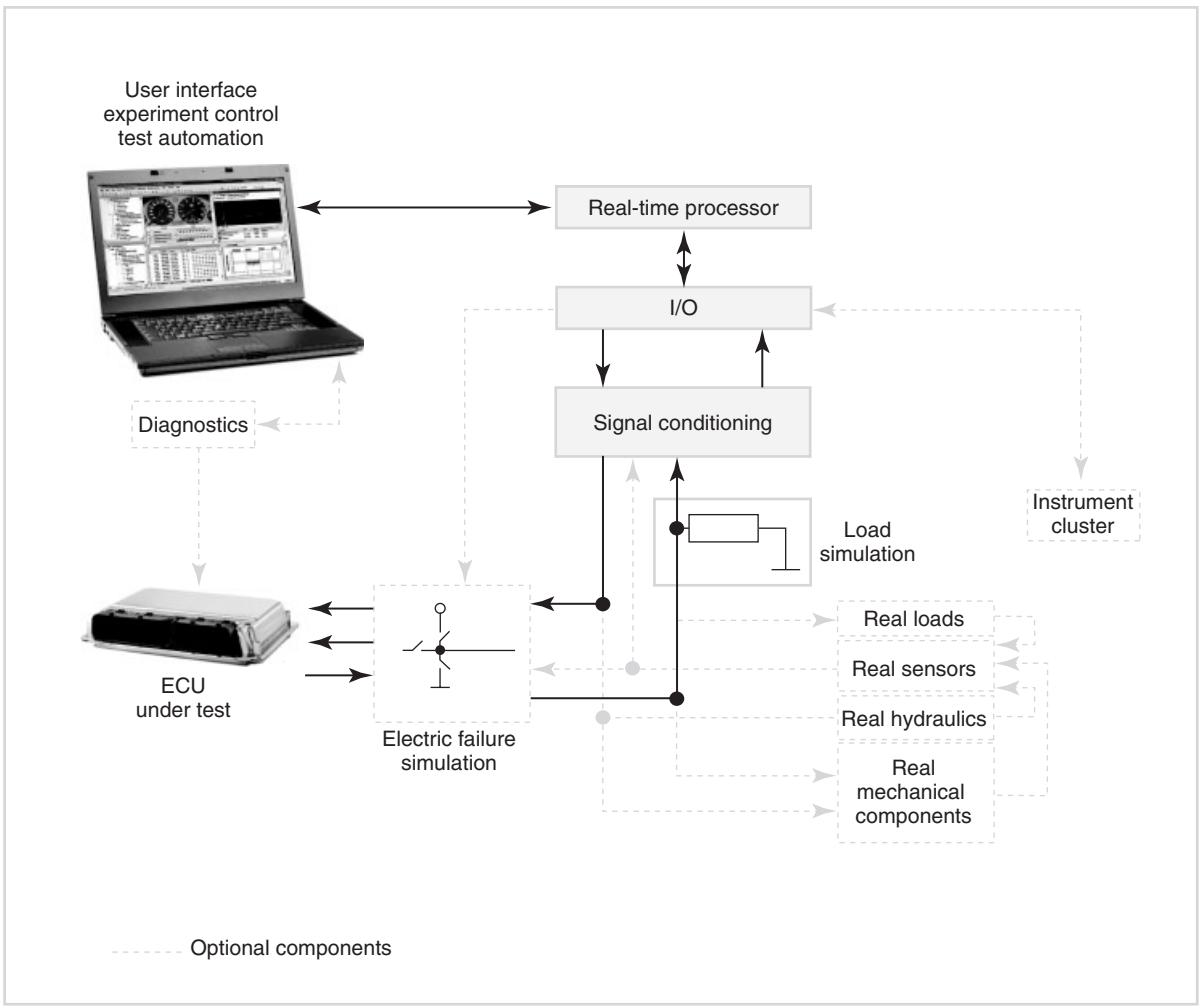

Figure 4. Components of a HIL simulator (Plöger and Köhl, 2006). (Reproduced by permission of Springer Vieweg.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For even higher requirements, parts of the model such as the electric winding model are executed on an additional FPGA (field-programmable gate array). This makes it possible to achieve sample times of 1 μs and far less. It also provides far more precise representation of currents because of motor inductivities compared with processor-based electric motor simulation. In addition, the effect of discontinuities (e.g., switching events of diodes and transistors) can be simulated more precisely and easily by means of fast-running models of the motor and the power electronics on FPGAs (Schulte, Kiffe, and Puschmann, 2011).

The complexity of the required models has grown continuously over the last few years, and the required processing power has risen with it. PC processors have become more important in HIL technology because they now outperform the PowerPC processors that were previously used. More and more multicore processors are also being used. These perform distributed and, therefore, parallel computation of complex models.

To couple several single simulators to create a networked system, processors can be connected to form a distributed multiprocessor system. Nowadays, with distributed multiprocessor systems, HIL simulators for ECU networks are implemented to test all the ECUs installed in a vehicle. Note that it is perfectly possible for a top-of-the-range vehicle to have over 60 ECUs (Gehring and Schütte, 2002; Köhl, Lemp, and Plöger, 2003).

Next to pure processing power, fast connection of I/O simulation is also extremely important. Standard PC interfaces are not usually designed for this, so high performance HIL systems use proprietary protocols to ensure real-time performance. With flexible network topologies and high bandwidths, spatially separated I/O boards can also be connected without the need for a local processor node (dSPACE GmbH, 2011; Plöger and Köhl, 2006).

3.1.2 *Generating and capturing signals*

The I/O components used in general measurement and control engineering are often unsuitable for representing sensor signals and capturing actuator control signals from an ECU. For example, special requirements apply to generating and capturing powertrain signals in real time. Here, it is the combination of angle- and time-based signals that requires special preparation:

- Ignition and injection signals must be captured precisely with regard to crankshaft position and duration.
- It must be possible to specify any arbitrary signal forms for position encoders and generate them angle-synchronously with high precision.
- Knock signals and ionization currents or cylinder in-pressure sensor signals must be triggered crank angle-synchronously, and also generated on a time basis or partly on an angle basis. Particular characteristics of the signals (damping, dependence on current engine load, and so on) need to be changed online in the simulation raster.

These requirements can be met by special hardware architectures (e.g., in FPGA technology). Resolutions of 0.01° crankshaft angle over the entire speed range 0–30,000 rpm are no longer any problem.

The HIL simulation of fast electric motor controllers also brings with it new requirements for generating and capturing I/O signals. For example, the typical six PWM signals of a synchronous motor ECU have to be measured with high precision. The duty cycle, period times, and power-up times of individual signals, as well as the dead times between neighboring signals, have to be measured synchronously to the PWM frequency at defined sample time points. Interrupts for triggering the associated simulation model also have to be issued at the same point in time (see earlier). Because the electric motor control requires the exact angle position of the rotor, this must also be computed and output with a high time resolution (25 ns is common). I/O modules with FPGA technology are also used for these tasks (Plöger and Köhl, 2006).

3.1.3 *In-vehicle communication*

Another fundamental requirement is for the real-time system to support all the automotive bus systems. The CAN bus, with all its variations such as high speed, low speed, single-wire fault tolerant, and 24-V trailer CAN, has been the most important of these for a long time. An example of CAN is, therefore, given here.

For HIL operation of one or a few ECUs, the first step is to read in the CAN messages sent by the ECU(s) in real time, typically in a 1-ms task. However, to simulate the environment of the ECUs under test, it is also important to simulate the CAN bus traffic of ECUs that are not actually present and couple it with the test object (restbus simulation). Where several, or even all, of the ECUs on a CAN bus have to be tested in the network, it may be necessary to run a series of tests where the messages exchanged between the real ECUs are manipulated. This can be done by means of a CAN error gateway.

The automotive industry is also increasingly using other bus systems apart from CAN. The HIL system must of course support these, too. They include the LIN bus (especially used in interior/comfort functions) and increasingly

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

also time-triggered buses such as FlexRay. The MOST bus, which has been used for infotainment until now, is being replaced more and more by Ethernet.

3.1.4 Signal conditioning

The main task of signal conditioning is to adjust the signal levels between the ECUs and the I/O boards. The amplitudes of incoming analog signals usually have to be reduced. Some real sensors output only very low signal voltages; therefore, for the HIL system to simulate these sensors, the output voltage of the I/O channel must be reduced without losing resolution. With analog signals especially, it is essential to ensure that the signals are passed to the ECU differentially. This avoids errors because of mass displacement. Moreover, for digital signals, signal conditioning must represent the characteristics of the real signals. For example, the digital outputs of the HIL system must be configured among open collector, pull-down, and pull-up. Signal conditioning also filters analog signals and protects I/O boards from overvoltage and overcurrent.

Systems that were specially developed for use in HIL systems already have signal conditioning integrated. It is then most important that the signal conditioning is as flexible and configurable as possible. This can be achieved by systems with software-configurable signal conditioning for typical signal levels (such as SCALEXIO from dSPACE) (Plöger and Köhl, 2006).

3.1.5 Load simulation

Each ECU monitors its own outputs for electrical failures such as short circuits or broken wires. To prevent the ECU assuming a broken wire when tested during normal operation, a real load or suitable load simulation must be connected to each ECU output. There are different approaches to load simulation, depending on how sensitive the diagnostics are.

In the simplest case, it is enough to connect a replacement load with higher impedance compared to the real load. This can often be plugged directly into the system or the cable harness to the ECU, as in normal cases, it does not require cooling.

If the ECU also monitors the current flowing at a critical output, at least an electrically equivalent load must be installed and connected in the HIL simulator. This could be a load resistance mounted on a heat sink, for example.

In particular cases, the real load needs to be integrated, for example, if it is a current-regulated hydraulic valve whose inductance is difficult to simulate.

The HIL simulator usually measures the control signals directly at the load and uses them as input values for the real-time simulation model. With current-regulated loads, the load current first has to be converted into a voltage by suitable converters (Hall sensors or shunt resistors) and filtered in the HIL simulator before it can be read in.

Sometimes, it is necessary to simulate a load with a complex I/O behavior, for example, an inductive load with high dynamics. Electronic load modules are used for these purposes. They provide current sink and source capability with high speed current regulation. Combining them with an FPGA board running a model of the load to be simulated (e.g., an E-motor) yields an emulation of the electric motor on electric power level (Plöger and Köhl, 2006).

3.1.6 Test benches

Sometimes, it is necessary to test the ECU together with real loads, which need physical stimulation. For example, the developer of an electronic power steering (EPS) system wants to test the controller, power stages, and steering motor. In these cases, a test bench is built in which a second load motor is mechanically coupled to the steering motor. The load motor continuously receives its set points for torque and speed from the real-time model. As a result, the overall steering system can be tested in a realistic HIL set up.

3.1.7 ECUs with integrated sensors

Some ECUs have integrated sensors inside their enclosures, and these sensors have to be physically stimulated in order to operate the ECU. One example is transmission ECUs that are installed directly at the transmission. They detect the input or output speed by means of integrated Hall sensors. Another example is inclination sensors that are integrated into ECUs for electric park brake functionality. The HIL system cannot stimulate the sensors electrically in these cases. The same applies to sensors that communicate with the ECU via a secret protocol. This is the case with crash sensors, the speed sensor of a tachograph, and so on. There are two ways to treat these sensors in HIL simulation.

One way is to use the real physical value to stimulate the sensor. For example, an integrated speed sensor can be stimulated by an alternating magnetic field generated by electric magnets, and the electric park brake ECU can be inclined by mounting it on a tilting platform.

An alternative way is to open ("crack") the ECU or the sensors to access the electrical interface. This is a suitable method for the acceleration sensors of an airbag ECU, for example (Plöger and Köhl, 2006).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.1.8 *Electric failure simulation*

HIL simulation is used not only to test ECU functions in normal operation; another important use case is to test diagnostic functions. This begins by testing whether a fault such as a detached sensor is detected correctly. The next tests check whether the ECU activates any associated limp home function, for example, by calculating a substitute value for a missing sensor. Powerful, automatable electric failure simulation is a necessary prerequisite for these tests and should cover at least the following fault cases: broken wire, short circuit to ground, short circuit to battery, and short circuits between ECU pins. To simulate poor contacts, it might be necessary to switch modifiable line resistances between two ECU pins, or between an ECU pin and a reference (mass or battery voltage). Loose contacts at switch inputs can be simulated by high frequency pulse patterns (Plöger and Köhl, 2006).

3.2 Software

The software for a HIL system can be separated into real-time software running on the simulator hardware on the one hand and experiment and test automation software running on the host PC on the other (Figure 5).

3.2.1 *Real-time behavior models*

To test ECUs in virtual environments, the controlled system and its environment need to be simulated. This is variously called *the simulation model*, *the plant model*, *the behavior model*, or *the real-time model* of the controlled system.

HIL testing requires the model and the simulator to perform in real time. The requirements regarding mathematical plant models vary greatly according to application area. The models should be as precise as possible to provide plausible signals to the ECU in all operating states, that is, to close all the control loops, such that the ECU's diagnostics do not detect a fault.

The modeling requirements vary according to vehicle domain.

For engine simulation including diagnostics, complex models are common. Often, these models have crankshaft-angle-synchronous tasks. In modern engines, it is also necessary to simulate the in-cylinder behavior: this again is even more complex: Pressure behaviors are no longer simulated in mean-value models. On-board diagnostic functions in modern engine ECUs require relatively precise dynamic modeling of the exhaust gas system including temperatures and pressures or more precise catalytic converter models than was necessary just a few years ago. The more sensitive the diagnostic functions, the greater the necessary model complexity.

Typically, planetary transmission models are no longer signal flow-based but acausal, which allows object-oriented, physical modeling.

When driver assistance systems have to be tested, traffic simulation is important. Besides sensors for object detection, it is also important to simulate

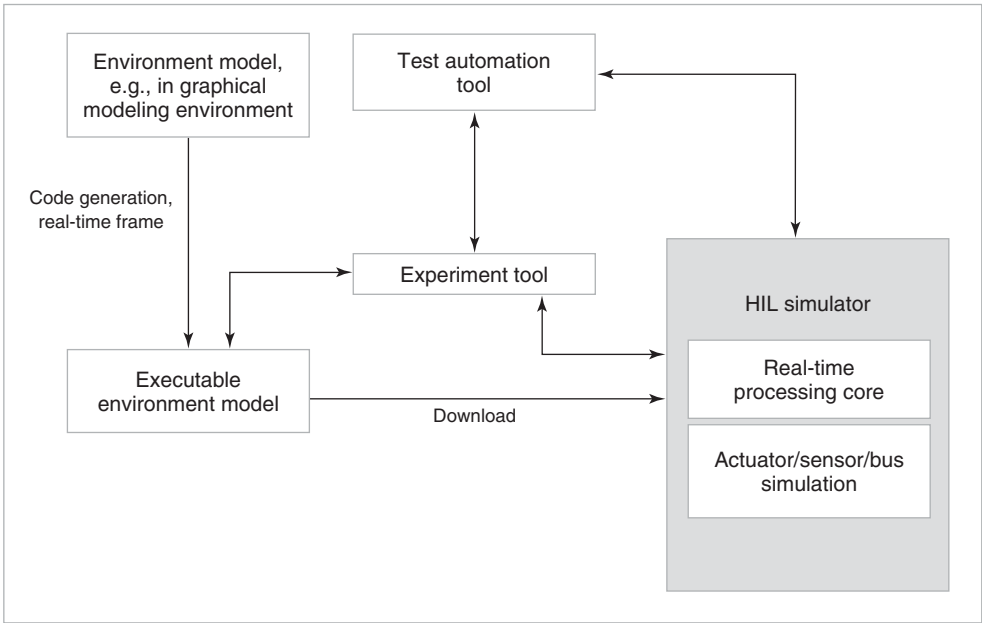

Figure 5. Software components in HIL simulation (Plöger and Köhl, 2006). (Reproduced by permission of Springer Vieweg.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

other traffic participants, such as oncoming traffic or pedestrians.

To test comfort functions, often all that is needed is quite simple functional, nonphysical behavior models for simulating the controlled system.

More precise models typically need higher processing power. Obviously, there is also more effort involved in parameterizing the models in these cases.

The controlled system models are usually available in a block-oriented graphical simulation environment. The currently most widely used tool for this is MATLAB®/Simulink®. Tools such as SimScape, SimulationX, and Dymola are used to design acausal models.

If very fast models are required, model calculation is transferred to FPGA. These are implemented in hardware description languages (HDLs). To avoid manual HDL programming, higher level tools are available to generate the HDL code directly from MATLAB, Simulink, and so on.

Many models are already available from offline simulation. As it is now increasingly possible to give the HIL systems enough processing power for complex modeling, models from offline simulation can often be reused in HIL simulation. Alternatively, parameters are exchanged via standard interfaces between the complex and the more simple models to allow maximum continuity within the virtual development process (Plöger and Köhl, 2006).

3.2.2 *Model implementation and hardware configuration, including I/O and restbus simulations, and interprocessor communication*

In addition to the actual controlled system models, the real-time processor also computes all the I/O functions including restbus simulation. All communications involved in multiprocessor operation can of course be implemented transparently for the user in high quality graphical form.

From the behavior model, which is graphically modeled, C code is typically generated automatically. The hardware configuration and the connection to the interfaces of the behavior model are performed in a simulator-specific configuration and implementation tool (such as ConfigurationDesk). This tool allows the signal path between the ECU or load pins and the behavior model interfaces to be configured and displayed. Besides simulator configuration, the tool also implements the behavior model code (from MATLAB/Simulink/Simulink Coder™) and I/O function code (from ConfigurationDesk) on the HIL hardware. The entire build process for a real-time application is handled by the configuration and implementation tool.

In addition to the I/O functionality, the allowed failure cases per channel are also configured at this stage.

If necessary, settings for partitioning the model to several cores or processors are also made in this context.

Comprehensive documentation options and graphical displays provide project transparency, especially in large-scale HIL projects. In addition to the model and the I/O configuration, external devices such as ECUs and loads, including their signal properties (descriptions, electrical properties, failure simulation settings, and load settings) can be defined and documented. Dedicated tools such as ConfigurationDesk allow the documentation to be generated in Microsoft® Excel® files (as required when testing according to ISO 26262).

To support distributed teamwork, it is essential that the required HIL hardware for a specific project can be assembled and configured offline as a "virtual system," in other words, as a purely software-based configuration. A real-time application needs to be executed for test runs even if parts of the necessary (and configured) I/O hardware are not physically available.

3.2.3 *Real-time software in general*

As mentioned earlier, the software running on the real-time processor is usually C code generated from the block-based graphical simulation environment or the physical acausal graphical simulation environment by means of automatic code generation. The currently most widely used tool for graphical simulation is MATLAB®/Simulink®. However, physical models are also becoming more important.

As a rule, the programs run in a real-time frame that should enable real multitasking as well as supporting timer, software, and hardware interrupts (Plöger and Köhl, 2006).

3.2.4 *Human–machine interface*

The manual operation of the test system, visualization and storage of real-time variables, and adjustment of model parameters are usually done on a host PC with the help of graphical front-end tools as the simulator's interactive experiment and visualization interface. These graphical user interfaces (such as ControlDesk Next Generation from dSPACE) are used for managing experiments, projects, and platforms. Virtual instruments allow visualization of a virtual instrument panel and access to the parameters of the real-time simulation model for manual or automatic modifications. The important issues include synchronous measurement and/or recording on all data sources (i.e., HIL simulator and ECU), and integrated measurement data analysis.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Typically, the same tool is used for layouting, logging, monitoring, and replaying the bus communication. CAN messages, LIN frames, and FlexRay PDUs (protocol data units) can be handled with modules such as the Bus Navigator from dSPACE. Instruments are available to view RX messages/frames/PDUs and to configure TX messages/frames/PDUs. For detailed tests on the control unit's bus communication, the messages, frames, and PDUs can be manipulated before transmission, or excluded from being transmitted.

The failure insertion unit of the HIL simulator is also remote-controlled via the experiment software. Failures in the wiring of an ECU such as an ECU pin short-circuited to the ground or the battery voltage are enabled and disabled.

Purely numeric displays and simple plotter instruments are no longer sufficient, particularly for testing vehicle dynamic functions or adaptive cruise control (ACC) functionality. A 3-D real-time animation tool (such as MotionDesk from dSPACE) is a far better way to visualize a vehicle's movements and assess them at a glance.

3.2.5 Software support for automated tests

The potential of HIL simulation cannot be fully harnessed without systematic, complete automation of all components. Development of the necessary test specifications begins with ECU or function specifications and system specifications (Sax and Schmerler, 2004). Thus, the HIL testing of ECUs is usually requirements-based testing and uses functional or black box tests.

The tasks involved in HIL simulation are extremely varied and require flexible and versatile means of test description. The past few years have, therefore, seen the arrival of numerous tools and solutions that address the issue of test description in different ways.

Script languages are very widely used in connection with automated testing on HIL simulators. For example, there are numerous libraries (APIs, application programming interfaces) for automating HIL simulators with the Python script language (www.python.org). Test scripts can be implemented in Python to access the different test system components such as the real-time model, failure simulation hardware, diagnostics, and calibration systems, via the APIs.

In 2009, the ASAM (Association for Standardization of Automation and Measurement Systems) Board released version 1.0 of the HIL API as a common standard to access HIL systems from test automation systems (http://www.asam.net/).

Script languages are extremely flexible to use, but a comparatively long time is required to learn them. Thus, they are usually suitable for test developers but not for testers. For this reason, several solutions have been developed to provide easier user access to specific test types. This means that testers do not have to bother with the script language itself, but can parameterize their tests conveniently with the input options provided by the front end.

Nowadays, however, even test development does not have to be performed exclusively by scripting. Modern tools such as AutomationDesk (dSPACE GmbH, 2004) provide graphical test description, like that from the Unified Modeling Language (UML) (www.uml.org), as an additional option.

The exact, automatable reproduction of test scenarios is the basic reason why HIL simulation boosts efficiency (Wallentowitz and Reif, 2006).

4 INTEGRATION INTO THE ELECTRONICS DEVELOPMENT PROCESS

For numerous car manufacturers, successful tests on the HIL simulator are one of the preconditions for a vehicle's release approval.

4.1 Goals

The later in the development process that an error is found, the more it costs (Figure 6). Problems can be detected and solved at an early stage by systematically using HIL test systems as early as possible. In the development process. In this way, the greatest possible vehicle maturity can be achieved quickly (Honisch, Hutter, and Schmid, 2004).

As a precondition for speedy error remedies, the development, commissioning, and verification of the ECUs must be closely interlinked. For example, when new software versions come along, information on the implemented changes has to be passed on, so that tests can be restricted to essential features, and also be extended if required (Plöger and Köhl, 2006).

4.2 HIL process

For efficient integration into the overall development process, HIL simulation must be treated as a subprocess. This subprocess begins by specifying the required HIL system based on the information that is available on the vehicle and the ECUs installed in it. Following preparatory assembly of all the ECU-independent components, the simulator can be adapted to the ECUs without losing time as soon as the ECU specifications are available. This includes activities such as implementing load simulations

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

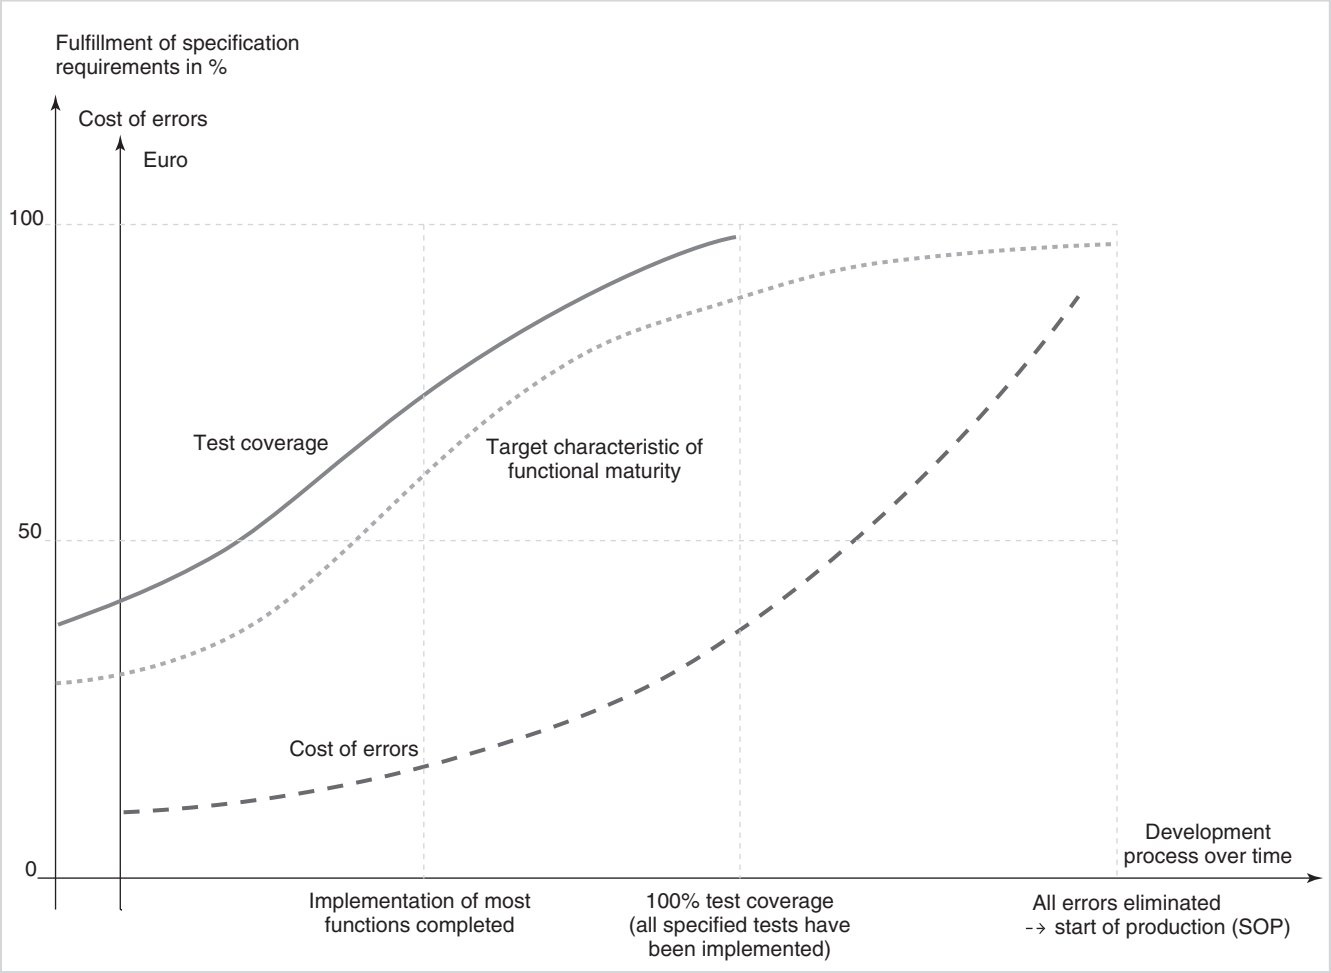

Figure 6. Functional Maturity in the electronics development process (Plöger and Köhl, 2006). (Reproduced by permission of Springer Vieweg.)

and preparing ECU mounts. It is still possible to perform iterations when ECU specifications change. After being put into operation with the defined number of ECUs, the simulator is ready and the test objects can be tested. The tests to be executed later can be developed in parallel to construction of the test system, using the ECU specifications as a basis.

When an ECU is updated, the simulator is once more put into operation (after any necessary adaptation has been performed) and regression tests are executed.

Test schedules and test cases are developed on the basis of the ECU/function specifications. In addition to the requirements documents, constant extension of the test suite also comes from test cases that were already implemented for predecessor ECU or vehicle models and from the developers' experience. Feedback from trials or service dealers is also used. Test coverage is not 100% in relation to the defined requirements until the second half of the development cycle (Figure 6) (Plöger and Köhl, 2006).

4.3 HIL testing in the context of ISO 26262

ISO 26262 will become the generally and globally accepted, automotive-specific standard and define what is "state of the art." Thus, it is highly relevant for the HIL testing of software for automotive ECUs, namely functionality, functional safety, diagnostics, and communication. ISO 26262-6 recommends HIL testing as a test method but does not state how to verify that a specific HIL system is suitable for testing safety-related functions.

Appropriate measures must be taken to ensure the proper operation of a HIL system. These measures can be based on detailed knowledge in HIL systems and procedures agreed

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto193
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

upon with long-term experienced users of HIL systems. The suitability of a HIL system for use in a specific safety-related project is verified by testing the entire system. This is required for the first time after system assembly and recurrently for a system in use.

The suitability of a tool and its automotive safety integrity level (ASIL) classification can be verified in consultation between customer and tool vendor. This is always carried out for a specific safety-related project.

It is not necessary to verify the suitability of software tools for a HIL system according to ISO 26262.

4.4 Integrating HIL simulation into the development and test process

Vehicle development generally begins 30 months before the planned SOP (start of production) date or earlier. Software development often begins at the same time as function specification, so it is a frontloaded design and preparation phase within the vehicle development process. HIL testing in software development is a firm component in ECU integration and release tests. Car manufacturers who have incorporated HIL simulation into their processes in this way have numerous HIL simulators constantly in action, testing subsystems and systems for the product range in active development. These systems typically work 24 h a day, 7 days a week (Plöger and Köhl, 2006).

Figure 6 shows the targeted functional maturity over the period of a development cycle. Functional maturity means the percentage of specification requirements that were tested "OK." When production begins, there should be no more errors present (100% maturity). If all the specified tests have been implemented for the defined requirements (100% test coverage), a high level of automation can be achieved. Now, all errors are eliminated in succession until there are no more known errors at the time of production start-up.

4.5 Connecting to requirements management

Tools such as DOORS or TestDirector are frequently used to collect and manage requirements and specifications. They are also very good for managing test specifications and results. The same applies to test plans and test execution. Direct connection to the HIL test environment (as is available with AutomationDesk) is, therefore, a logical step in process integration (Plöger and Köhl, 2006).

5 OUTLOOK

As electronics and software continue to grow, advanced, new systems will be developed. Also, complexity is constantly growing. One well-known way to prevent complexity leading to chaos is to use methods and tools, particularly HIL tests and model-based designs. These fields have witnessed an enormous amount of change over the past 10 years (Hanselmann, 2012).

Nowadays, whole vehicles are tested thoroughly using network simulators, and HIL tests for single ECUs and subsystems have been standard procedures for a long time. Entire ECUs are now developed using model-based design, and the ECU code is largely generated automatically (Hanselmann, 2012).

It is no longer individuals who perform these tasks, but whole departments and separate teams both within one company and, partly, in more than one company. Those in charge report having to handle up to 100,000 HIL test cases, 40,000 calibratable ECU parameters, or 400 vehicle variants. The volume of data generally created during ECU development, especially when methods and tools are used, is immense and still increasing. The ability to reuse this data in other projects, by other people or for other variants of the functions or systems under development, is a major factor in efficient development and also helps ensure quality (Hanselmann, 2012).

The precondition for reliable reuse is the central management of models, tests, parameters, and architectures, and of development results and statuses in general, including the underlying requirements. The numerous interdependencies and connections between all these data also have to be considered. It is no longer possible to master this management task solely using central file storage or configuration management systems: file-based management is not only too coarse-grained, it also does not provide sufficient traceability for observing dependencies (Hanselmann, 2012).

In practice, at dSPACE, we see tasks such as test management, model management, central parameter and signal management, and HIL hardware configuration management, in the context of the numerous variants that are created in the automotive industry, and in conjunction with the associated requirements (Hanselmann, 2012).

5.1 Test management

We understand test management not only as the general management of tests, test scripts, and test results but also test planning and the representation and analysis of test results. It also includes connecting to test execution, for example, by directly coupling test automation tools in the HIL environment (Hanselmann, 2012).

Test management must also create links to models, parameter sets, and variants.

5.2 Model management

In the development of complex systems, constructing giant, monolithic models quickly proves to be a dead end. That is why modularity is particularly important. It is a precondition for teamwork and the reuse of (sub)models in other projects, by other people, or for new variants. However, all this inevitably produces an even larger number of models that have to be handled together with their interrelationships.

Clean descriptions of the interfaces are also necessary to achieve modular structures and reuse individual submodels. The descriptions must, therefore, not be created from a local viewpoint, but coordinated on a global level (Beine, 2012).

Model management involves the central management of function models and plant models for real-time and offline simulations alike. It is closely connected with central parameter and signal management. The managed parameters are used to provide values to functions, models, and ECU code. The interfaces of systems, functions, models, and ECUs can be described by means of signals, laying the foundation for integrating individual submodels in an overall model (Hanselmann, 2012).

5.3 Data management

However, viewing these topics separately, mastering the individual stages in the development process and increasing the quality and productivity of each stage, is not enough. The overall goal is efficient, integrated management of the enormous volumes of complex and interdependent data (Hanselmann, 2012).

This management must cover all the process steps and all the individuals and teams who are users and producers of the data. In practice, however, it is often the case that only solutions for individual issues and for small teams are needed initially. In such cases, it is important to select a solution that is scalable and usable for other tasks. It must also be capable of being extended to cover the entire development process, and in connection with this, entire departments and companies (Hanselmann, 2012).

Using our years of experience and knowledge from countless ECU development projects, we (dSPACE) aim to give teams distributed worldwide the support they need throughout the entire E/E development cycle, based on an established data management platform. We will support the relevant standards and build a bridge to established development tools from dSPACE, and from other vendors as well (Hanselmann, 2012).

5.4 Virtual ECU testing

Another issue that we are intensively focusing on is frontloading, in other words, testing virtual ECUs.

Today's ECU software comprises numerous SWCs with intensive interactions. In the large ECU networks frequently installed in current vehicles, the number of SWCs can easily reach the thousands (http://www.dspace.com/en/inc/home/products/systems/virtual_ecu_testing.cfm).

In addition, because the task of developing ECU components is usually shared by several departments or even different companies, not only the SWCs themselves have to be tested and validated but also the interactions between them. The earlier in the development process that errors and inconsistencies are found, the quicker and cheaper it is to correct them (http://www.dspace.com/en/inc/home/products/systems/virtual_ecu_testing.cfm).

Virtual ECU testing means implementing early verification strategies in the ECU development process by means of more intensive virtualization—the current trend. At the heart of these verification strategies are the so-called virtual electronic control units (V-ECUs), which despite being pure software prototypes can realistically simulate the functional behavior of real ECUs including the operating system, task scheduling, and hardware-independent basic software parts. These V-ECUs can be used for initial (and automatable) integration testing by offline simulation on a PC very early in the development process, for high quality restbus simulation on a HIL simulator, as substitutes for ECU hardware prototypes that are not yet available during commissioning, and even in integration testing itself (Krügel, Geburzi, and Krisp, 2011; Krügel and Schulze, 2012; Krügel *et al*., 2012).

6 CONCLUSION

Vehicle electronic systems are becoming more advanced and complex. HIL simulation for testing electric/electronics has played an important role in the development process for many years and will continue to do so. In the same way as software and model complexity is growing, so is users' need for well-engineered procedural methods for handling large models and comprehensive software structures. HIL tests and model-based design are meanwhile being supplemented by the frontloading of tests, which means performing HIL tests earlier in the development process and also virtualizing HIL tests. Both these aspects enable users to reduce development time in spite of increasing complexity, while at the same time maintaining or even enhancing the quality of the electronics.

Vehicle Safety, Functional Safety, OBD Diagnosis

Stefan Kriso, Matthias Klauda, and Reinhold Hamann
Robert Bosch GmbH, Abstatt, Germany

1 INTRODUCTION

With a significantly increasing number of electrical and electronic systems within road vehicles, the complexity of such systems dramatically increases. To prevent these increasingly complex systems from becoming more and more fault-prone is one of the most important challenges of the future. Systems have to be intrinsically safe whereby owing to the cost pressure within the automotive industry, it is not possible just to double or triple the systems, as it is usual in the avionics industry. This chapter describes the general concept of vehicle safety—especially with regard to functional safety that came into focus within recent years with the advent of a new standard for functional safety of road vehicles—the ISO 26262.

2 DEFINITIONS

2.1 Risk

Combination of the probability of occurrence of harm and its severity.

2.2 Safety

Absence of unreasonable risk, which is judged to be unacceptable in a certain context according to valid societal moral concepts.

2.3 Functional safety

Absence of unreasonable risk due to hazards (potential source of harm) caused by malfunctioning behavior of electrical/electronic systems.

3 SAFETY OF ROAD VEHICLES

3.1 Safety relevant systems in road vehicles

The number of software intensive systems in road vehicles is increasing and becomes more and more important for future innovations. Today, they can be found everywhere in a modern car, for example, powertrain, entertainment, driver assistance, stability control, body applications, and passive safety. Many electrical/electronic systems within road vehicle can be assumed as safety relevant, that is, a malfunction of such a system can lead to harm of an involved person. Some examples for such malfunctions are

- stability control: unintended brake force up to almost locking pressure of one front wheel;

- engine management: unintended vehicle acceleration;
- airbag: faulty activation during driving;
- electric window lift: unwanted closing of a window; and so on.

A systematic determination leads to more than 1000 safety-relevant functions of electrical/electronic automotive systems.

3.2 Trends

3.2.1 E-mobility

The most upcoming trend today is e-mobility, that is, the electrification of the powertrain. This leads to new and partly unknown aspects of the safety of a vehicle:

- An electronic control unit of a conventional vehicle has about 10,000 operating hours, which corresponds to the driving hours of the vehicle. In an e-vehicle, the operating time is dominated by charging, which takes about 30,000–50,000 h. So new risks come up from the charging procedure and energy storage.
- High voltage within a car brings new risks for people maintaining and repairing the vehicle. This will lead to requirements for occupational health and safety procedures as well as for operating, service, and decommissioning of vehicles.
- Not only risks from electrical or electronic systems may arise, but also chemical risks from the battery ("thermal runaway") or risks for the environment (e.g., acid disposal) arise.

3.2.2 Miniaturization

Owing to the miniaturization of electronics devices, technology might reach its limits regarding capability to produce fault-free devices in a cost-effective way under given automotive quality requirements:

- Reliability may decrease with decreasing structure size;
- Amount of embedded logic and memory per device will increase, which may lead to an increase of the failure rate of the device (as the failure rate per bit is—in the best case—constant);
- Operating hours will increase (e-mobility).

In the end, the faults of semiconductors might become more and more common. But, as the safety on system level has to be reached anyway, the system design has to deal with this situation to ensure the overall level of system safety.

3.2.3 Variants

The number of variants of modern vehicles is more and more increasing. Software intensive systems allow vehicles to be individually customized, for example, just by activating/deactivating functionality (e.g., driver drowsiness detection is pure software function that can be located on different electronic control units in the vehicle). Vehicles provide more and more open interfaces to "external" systems, so that functions can be downloaded by the user (like a Smartphone app). This leads to huge number of variants with a lot of possible combinations of features. It must be ensured that all these possible feature combinations are safe and reliable. In this area, we see a correlation to the area of security that needs to provide measures to ensure the integrity of vehicle systems against malicious IT attacks and thereby safeguard the vehicle.

3.3 Special constraints of the automotive industry

To ensure safety of road vehicles, the special boundary conditions of the automotive industry have to be considered.

3.3.1 Driving cycle

A typical driving cycle of a road vehicle consists of three phases with different possibilities to ensure the safety of the system:

- Start-up: enhancing testing possible, increased test coverage. Can include "destructive" tests like memory checks.[1] The start-up time is strongly limited, for example, 50 ms for communication tests. Typically, all safety relevant measures are to be checked during start-up.
- Driving: often only limited nondestructive tests are feasible. The functionality of the system must be maintained and monitored, functional restrictions like interrupt blocking times must be considered.
- Shut-down: similarly to start-up, some safety functionality tests may be shared between start-up and shut-down. The shut-down cycle may be interrupted at any time.

3.3.2 Cost structure

The automotive industry is very cost sensitive because of the high production volume with small margins. Low unit cost for electronic control units translates into restricted memory size and limited computing capacity (Schäuffele and Zurawka, 2005). Consequently, strong reliance on

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

redundancy on system level as a safety concept (e.g., doubling or trebling of electronic control units) found elsewhere for example, in airborne systems, is not feasible within automotive systems.

3.3.3 Maintain and repair, field observation

Cars are sold to end customers, where it cannot be foreseen which kind of maintenance and repair strategy they have. So it is very difficult (or impossible) for a vehicle manufacturer to influence the maintenance and repair behavior of the user. Systems must be safe even if the end customer is not willing to maintain and repair their car regularly. Preventive maintenance as can be found in airborne systems is normally not very successful, as it cannot be ensured that all vehicles in the field will be included.

In addition, it is nearly impossible to get statistically significant data from field observation, even during the warranty time of the car. So, an evaluation of the safety of a vehicle system based on commonly recognized industry data basis would lead to overdesigned systems, as the data basis contains safety margins so that the data are normally too pessimistic.

3.3.4 Education and training

Vehicle users (drivers) are mostly educated and trained once—at the beginning of their "driver's career" when they earn their driver's license. Training with malfunctioning equipment such as in airborne industry does not take place. In most cases (except, perhaps, drivers of buses or similar), there is no requalification foreseen. The safety concept of a vehicle must consider this and different capabilities of drivers. In ISO 26262, this is directly mapped to the controllability of malfunctions (Section 4.4.3). This is not easy to determine as the capabilities of the "average driver" especially in highly critical situations are not well known and may differ regionally.

4 FUNCTIONAL SAFETY

4.1 ISO 26262: new standard for functional safety of road vehicles

ISO 26262 was published in November 2011 and addresses the functional safety of road vehicles. As it is the automotive specific adaptation of the IEC 61508 (functional safety of electrical/electronic/programmable electronic systems) it is going to become the most important safety standard within the automotive industry. Its introduction [*] states:

> *ISO 26262 is the adaptation of IEC 61508 to comply with the needs specific to the application sector of electrical and/or electronic (E/E) systems within road vehicles. This adaptation applies to all activities during the safety life cycle of safety-related systems comprised of electrical, electronic, and software components.*
> *[Functional] safety is one of the key issues of future automobile development. With the trend of increasing technological complexity, software content, and mechatronic implementation, there are increasing risks from systematic failures and random hardware failures. ISO 26262 includes guidance to avoid these risks by providing appropriate requirements and processes. ISO 26262*
>
> 1. *provides an automotive safety lifecycle and supports tailoring the necessary activities during these life cycle phases;*
> 2. *provides an automotive-specific risk-based approach to determine integrity levels [automotive safety integrity levels (ASILs)];*
> 3. *uses ASILs to specify applicable requirements of ISO 26262 so as to avoid unreasonable residual risk;*
> 4. *provides requirements for validation and confirmation measures to ensure a sufficient and acceptable level of safety being achieved; and*
> 5. *provides requirements for relations with suppliers.*
>
> *Figure* 1 *shows the overall structure of ISO 26262. It is based on a V-model as a reference process model for the different phases of product development.*

As ISO 26262 is very complex and addresses a lot of different issues, we focus only on some key issues of this standard in the following sections.

4.2 Legal point of view of ISO 26262

4.2.1 Introduction

The summary given here refers to the specific legal situation in Germany. Nevertheless, it may help to gain a better understanding of the legal background of ISO 26262, as the basic principles on product liability are very similar worldwide.

Technical standards are recommendations drawn up by acknowledged experts to be used as technical, best-practice solutions for sector- or product-specific problems. These recommendations also establish minimum safety requirements for the products in question. The fact that technical standards are to be regarded as pure recommendations without binding legal force does not in any way mean that they are of no legal consequence. On the contrary, compliance with a legally nonbinding recommendation is a crucial yardstick for all four areas of law dealing with liability for defective products:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

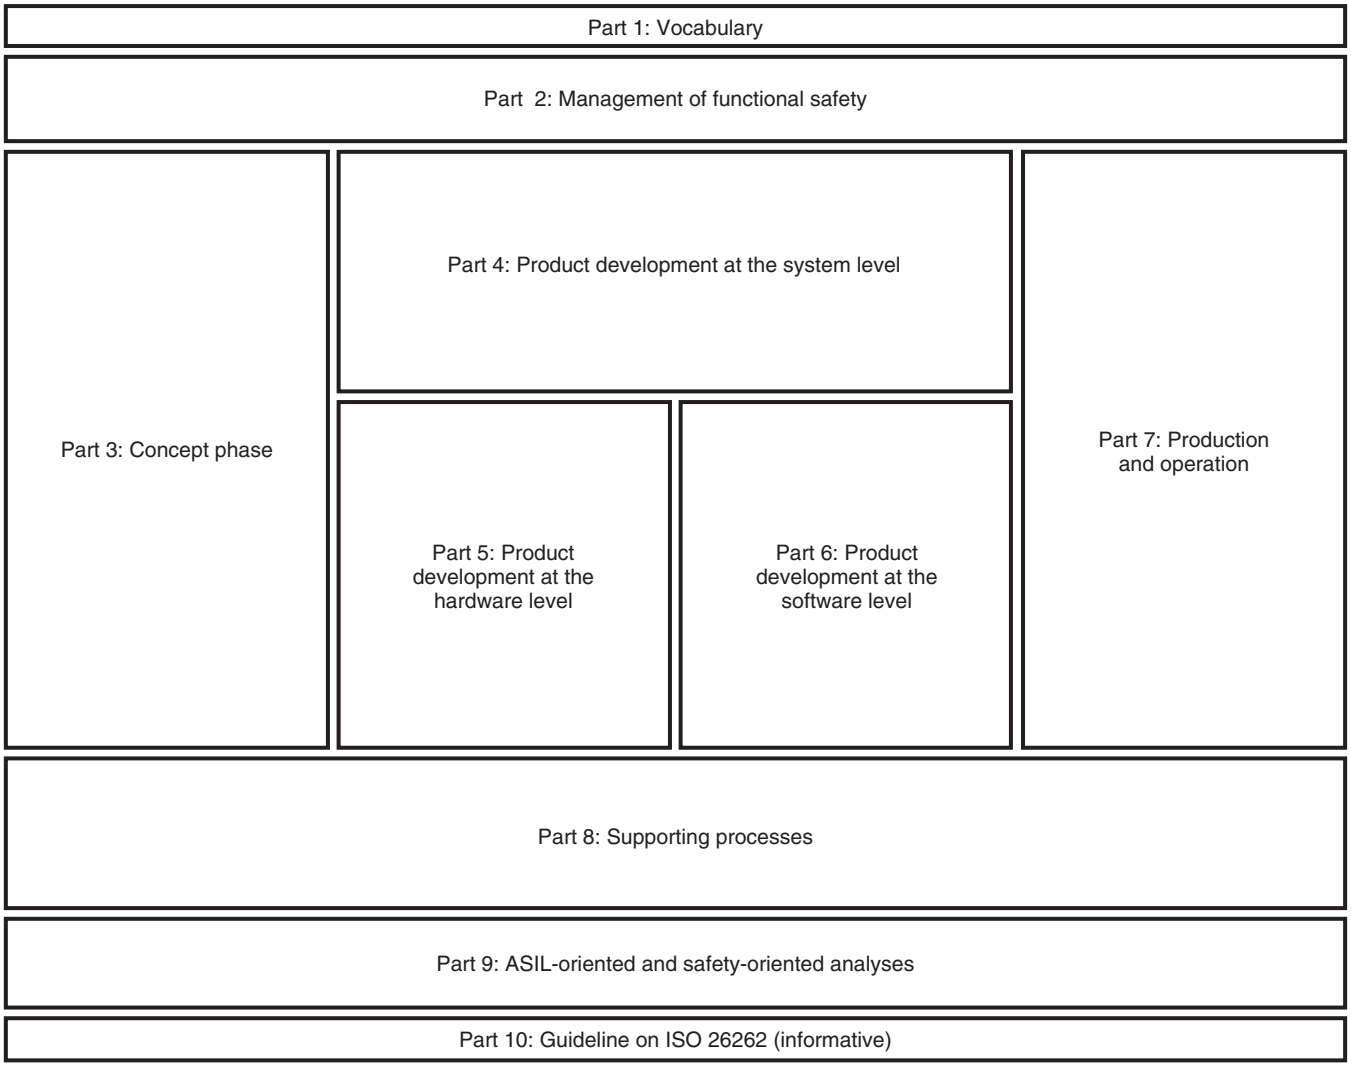

Figure 1. Overview of ISO 26262 [*]. (Reproduced by permission of DIN Deutsches Institut für Normung e.V.)

4.2.2 *Contract law—warranty*

Whether the obligations of the seller under a sales contract have been properly met initially depends, under Section 434 I of the German Civil Code (BGB, Bürgerliches Gesetzbuch), on whether the product sold has the properties as agreed between the seller and the purchaser. The terms of tender and/or the general conditions of purchase within the automotive industry regularly contain an obligation on behalf of the supplier to comply with all the technical standards relevant to the delivered item. This makes ISO 26262 one of the agreed properties once the contract has entered into force—even if this standard was not expressly mentioned in the tender. Even if compliance with the applicable standards has not been explicitly agreed as a requirement, ISO 26262, in its capacity as the key standard on functional safety in the automotive industry, becomes an integral part of the supply contract via Section 434 I No. 1 or 2 of the German Civil Code. If the supplier is unable to prove that he or she has met the requirements arising from ISO 26262, the product concerned is deemed to be nonconforming. As it is virtually impossible to meet the requirements of ISO 26262 after the fact, the OEM (original equipment manufacturer) customer may reject corresponding deliveries as noncompliant. The supplier is then liable without limitation for all subsequent costs caused by the deficient delivery.

4.2.3 *Product liability*

The legal duty to maintain safety, as far as product liability is concerned, requires (in accordance with established

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

case law) that the manufacturer employs due diligence in keeping with the state of technology at the time the products are brought into circulation, so as to ensure that the products are as safe as might legitimately be expected. In the event of an accident involving personal injury, the manufacturer of the product that caused the accident must prove that he or she has exercised due diligence in the normal course of business. If the manufacturer cannot even prove that he or she has at least fulfilled the minimum requirements of applicable technical standards, then the manufacturer has no realistic chance of defending himself or herself.

4.2.4 Public safety

The authorities are responsible for ensuring that public safety is not endangered by unsuitable products. The German Equipment and Product Safety Act give the authorities wide-ranging powers to intervene in order to fulfill this obligation, up to and including the closure of companies. An important criterion for the authorities in determining whether to intervene or not is whether the manufacturer has complied with the applicable standards. If he or she is unable to prove that he or she is in compliance when problems emerge in the market, then this would be grounds for action on the part of the authorities.

4.2.5 Criminal proceedings

If a product defect has led to an accident that caused severe injuries or even death, the public prosecutor's office must check whether a criminal offense has been committed. If the product that caused the accident does not meet the minimum requirements of the applicable standards, then this can be the trigger for criminal proceedings against the manufacturer's employees responsible.

In summary, it therefore can be said that technical standards indeed might not be legally binding in that they are nothing more than recommendations. However, they develop enormous legal significance as a yardstick for the care due in the normal course of business.

4.3 Key concept of ISO 26262

Goal of the activities that are addressed in ISO 26262 is the prevention of malfunctioning behavior of electrical and electronic systems. After defining the "item" (system or function under consideration), its malfunctions have to be determined and their impact on the safety of the involved persons (driver, passenger ...) has to be evaluated. This is done during the hazard analysis and risk assessment (Section 4.4) and leads for each malfunction to an "ASIL".

In a mathematical notation, the safety relevance of a function or a system can be expressed by the following term:

$$\text{Safety relevance} \in \{\text{QM}, \text{ASIL} | \text{ASIL} \in \{\text{A}, \text{B}, \text{C}, \text{D}\}\}$$

The higher the ASIL is, the higher will be the necessary risk mitigation, that is, for an ASIL D malfunction more risk mitigation measures are necessary than for an ASIL A malfunction. Not safety-related malfunctions are classified as "QM," that is, a standard quality management for example, according to ISO/TS 16949 is sufficient for the development of this function. In this case, there are no further requirements by ISO 26262.

In case of a given safety relevance of the item (safety relevance $\neq$ QM), the risk has to be reduced to a reasonable level. The measures to reach this are described in ISO 26262; the requirements in ISO 26262 and the proposed methods are dependent on the ASIL and therefore dependent on the initial risk outgoing from the item.

There are two kinds of sources of risks: systematic failures and random hardware failures. Both have to be considered in the development of the item. As systematic failures are mainly introduced during the development of the item, ISO 26262 defines a safety life cycle with requirements for the management of functional safety (for the project independent organization as well as for the project developing the item and for the phases after release for production), for the development process of the item, for the production, operation, service, and decommissioning phases, and for the supporting processes (e.g., interfaces within distributed development, requirements management, configuration management, change management, verification, and documentation).

Not all potential systematic failures can be avoided with the mentioned requirements for the safety life cycle. So, the product must be able to control the remaining systematic failures (e.g., errors in a piece of software) as well as random hardware failures. So, ISO 26262 gives requirements for development and test on system level, on hardware level (e.g., introduction of redundancies), and on software level (e.g., diagnosis).

In the end of the development phase of the item, an overall safety validation ensures the achieved functional safety of the system at vehicle level. This includes for example, the controllability of the malfunctions of the item and the effectiveness of safety measures for controlling random and systematic failures. In addition, measures to evaluate the implementation of the process requirements are introduced, see Section 5.1.

Figure 2 summarizes the key concept of ISO 26262.

In addition to the requirements, ISO 26262 gives a lot of recommendations for the development of functionally

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

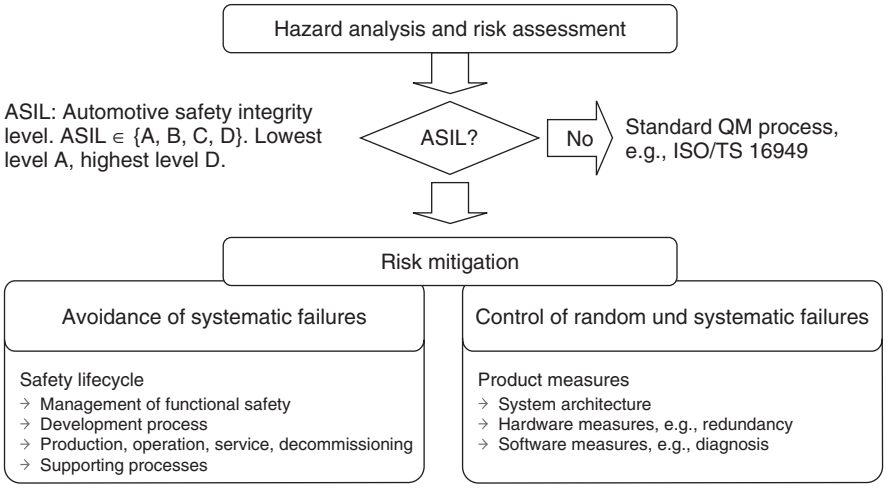

Figure 2. Key concept of ISO 26262.

safe products. These helpful recommendations may be implemented, but they are not necessary to proclaim conformance with the standard. Also, the requirements itself are not fully obligatory, as it is allowed to omit them based on a documented justification: "*When claiming compliance with ISO 26262, each requirement shall be complied with, unless one of the following applies: [. . .] b) a rationale is available that the noncompliance is acceptable and the rationale has been assessed in accordance with ISO 26262-2*." [*]

As a result of this, a one-to-one implementation of ISO 26262 is not required, and different organizations will find different ways of implementation of the standard.

4.4 Hazard analysis and risk assessment, ASIL classification

4.4.1 Introduction

Hazard analysis, risk assessment, and ASIL determination are used to determine the safety goals of the item such that an unreasonable risk is avoided. The scheme of ISO 26262 for hazard classification recognizes that a hazard in an automotive system does not necessarily lead to an accident. The outcome will depend on whether the persons at risk are actually exposed to the hazard in the situation in which it occurs, and whether they are able to control the outcome of the hazard. Figure 3 gives an example of this concept applied to a failure that affects the controllability of a moving vehicle.

The item is evaluated with regard to its potential hazardous events. Safety goals and their assigned ASIL are determined by a systematic evaluation of hazardous events. The ASIL is determined by considering the estimate of the

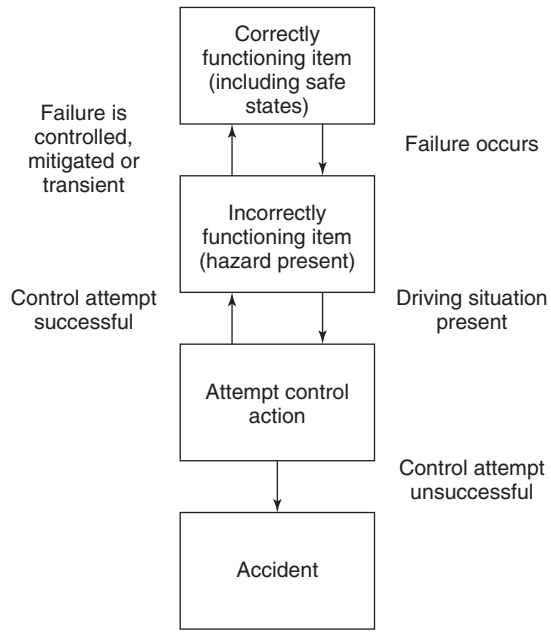

Figure 3. State machine of automotive risk [*]. (Reproduced by permission of DIN Deutsches Institut für Normung e.V.)

impact factors, that is, severity, probability of exposure, and controllability. It is based on the item's (i.e., system's) functional behavior; therefore, the detailed design of the item does not necessarily need to be known.

The detailed process to determine the ASIL is described in ISO 26262, part 3, Chapter 7. Figure 4 summarizes this procedure.

For each item (system under consideration), the potential malfunctions have to be determined. In a situation analysis,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

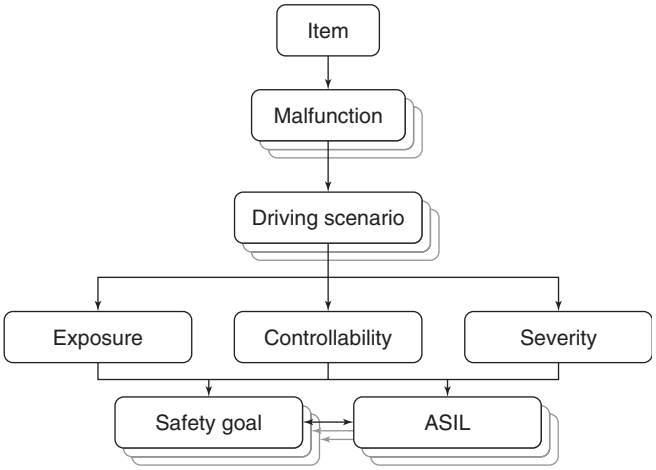

Figure 4. Hazard analysis and risk assessment according to ISO 26262.

the operational situations and operating modes in which the item's malfunctioning behavior will result in a hazardous event shall be described. These driving scenarios shall consider the correct usage of the vehicle and its incorrect usage in a foreseeable way.

In the subsequent hazard identification, the hazards are described and classified in a systematic way. For the classification of hazards, the following parameters are used:

4.4.2 *Exposure (E)*

To answer the question "How often does the driving situation occur?" the probability of hazardous driving scenario has to be estimated and classified into one of five probability classes according to Table 1.

It is important to know that only the probability of the situation is of interest, independent from the probability of the malfunction itself. For instance, the malfunction "unwanted deployment of an airbag" has a very low probability, but the driving scenario "driving on a highway," where the malfunction could become hazardous, has—according to ISO 26262, part 3, table B.2—a very high probability and therefore the exposure E4.

4.4.3 *Controllability (C)*

The next question is how the malfunction within the driving scenario can be controlled by the driver or by any other involved person. This controllability parameter shall be classified using Table 2.

It is assumed that the driver of the vehicle is in an appropriate condition to drive (e.g., he or she is not tired), has the appropriate driver training (he or she has a driver's license), and is complying with all applicable legal regulations, including due care requirements to avoid risks to other participants. Reasonably foreseeable misuse has to be considered, for example, driving at 60 km/h when the speed limit is 50 km/h.

4.4.4 *Severity (S)*

If a malfunction occurs and it cannot be controlled, then it is the question about the severity of the resulting hazardous event. The severity parameter is classified according to Table 3.

The focus is on the harm to each person potentially at risk, including the driver or the passengers of the vehicle causing the hazardous event, and other persons potentially at risk such as cyclists, pedestrians, or occupants of other vehicles.

4.4.5 *ASIL determination*

After determining the parameters E, C, and S, the ASIL can be simply determined using Table 4.

Table 1. Classes of probability of exposure regarding operational situations (ISO 26262-3, Table 2).

	Class				
	E0	E1	E2	E3	E4

The ASIL is defined within the range from ASIL A to ASIL D, where ASIL A is the lowest safety integrity level and ASIL D the highest. In addition, the class QM denotes that there are no requirements to comply with ISO 26262.

QM classified malfunctions are not safety relevant in the means of ISO 26262, what does not mean, that the system is not safety relevant at all. The classification QM assumes that there is a functioning QM system implemented, for example, according to ISO/TS 16949, and that this is sufficient to develop such a QM classified system.

Table 5 gives some examples for the ASILs of some malfunctions in road vehicles.

As the determination of the parameters E, C, and S are very subjective, the resulting ASIL cannot be objective. Currently, there are activities within the automotive industry to harmonize the method to determine the ASIL. A detailed harmonization of the ASIL itself is not possible as it depends on the concrete vehicle configuration (e.g., number of airbags that influence the severity of a malfunction of another system).

4.5 Safety element out of context [*]

The automotive industry develops generic elements for different applications and for different customers. These generic elements can be developed independently by different organizations. In such cases, assumptions are made about the requirements and the design, including the safety requirements that are allocated to the element by higher design levels and on the design external to the elements. Such a safety element out of context (SEooC) is not developed in the context of a particular vehicle.

An SEooC can be a system, an array of systems, a subsystem, a software component, or a hardware component or part. Examples are system controllers, ECUs, microcontrollers, software implementing a communication protocol or an AUTOSAR software component, and so on. Thus, the development of the SEooC is based on assumptions; on an intended functionality and use context that includes external interfaces. These assumptions are set up in a way that addresses a superset of items, so that the SEooC can be used later in multiple different, but similar, items.

Figure 5 shows the relationship between assumptions and SEooC development. The development of a SEooC can start at a certain hierarchy level of requirements and design. The correct implementation of the requirements for the SEooC will be verified during the SEooC development. The validation of these requirements and assumptions are then established during the development of the item.

Table 5. Exemplary ASIL classifications of some possible malfunctions of electrical/electronic vehicle systems[a].

System	Malfunction	Driving Scenario	Exposure	Controllability	Severity	ASIL
Electronic stability program (ESP ®)	Unintended brake force up to almost locking pressure of one front wheel	Country road, oncoming traffic, or obstacles on the side	E4 (according to ISO 26262-3, Table B.2)	C3 The majority of the drivers will not be able to keep the vehicle in the lane	S3 Because of asymmetric braking the vehicle will be destabilized, accidents with road users/objects may lead to life- threatening or fatal injuries	D
Airbag	Unintended airbag deployment during driving	Country road, oncoming traffic, or obstacles on the side	E4 (according to ISO 26262-3, Table B.2)	C3 (according to ISO 26262-3, Table B.4)	S3 Life-threatening injuries (survival uncertain) or fatal injuries cannot be excluded.	D
Engine management	Unintended acceleration	Country road, oncoming traffic, or obstacles on the side, driving in a curve at high speed, vechicle close to destabilization	E2 Significant amount of time for the critical scenario where an acceleration can result in leaving the lane is <1%	C3 Only a few drivers can handle this, as exceptional reaction is required	S3 Leaving the lane may lead to life-threatening or fatl injuries	B
	Sudden unwanted loss of vehicle acceleration	Country road, passing with oncoming traffic, "vehicle slows down to zero"	E1 Critical distance to oncoming traffic during passing very seldom	C2 Normally controllable, also by other traffic participants	S3 Passing can not be finalized, collision with oncoming traffic leading to life-threatening or fatal injuries	QM
Electric window lift	Unintended closing of window	Parking not belted passengers (children) leaning out of the window	E2 Parking with open window and children leaning out	C2 Adequate reaction possible in most cases, also by other traffic participants	S3 Can cause pinching of extremities or other parts of the body (head, cervix, etc.)	A
Turn indicator	Side-inverted activation	Country road, vehicle 1 wants to turn left (without a turn off lane in a small crossway), actuates indicator to turn left, but flasher indicates the wrong direction (i.e., indicates turning right) The following vehicle 2 wants to drive past left to the vehicle he is expecting to turn right	E2 Country road, crossroad without a traffic light, no turn off lane, intended overtaking in the area of turn off	C2 Following road traffic sees braking vehicle with wrong direction indication. This calls increased attention to most drivers, therefore they will abandon from driving past left	S3 Side collision, Delta-v > 35 km/h. Life-threatening injuries (survival uncertain) or fatal injuries cannot be excluded	A

[a] The current classifications for engine management lead to an ASIL B for the malfunction "unwanted vehicle acceleration" and QM for "sudden unwanted loss of vehicle acceleration." However, in the automotive community, we recognize the beginning of a trend toward ASIL C/ASIL A for these malfunctions; therefore, in future, the common understanding of these ASIL classifications may remain on this higher level.

For further information and detailed examples of the concept of SEooC refer to ISO 26262 part 10.

4.6 Confidence in the use of software tools

4.6.1 Introduction

The goal of the qualification of software tools is to get confidence that the use of a software tools does not lead to the violation of a safety goal (i.e., that an erroneous output could not lead to safety critical behavior of a product) by maintaining quality assurance for certain tools and their utilization. To this end, the ISO 26262 provides for the following measures:

- appropriate measures that can be introduced during the product development phases and that keep a tool from generating faults in and of itself;
- faults generated by a tool can be identified and eliminated in a subsequent process step or by means of organizational measures.

The term *software tool* used in the ISO 26262 context not only refers to the tools that are used in software development but also describes the application programs that are used in hardware development and ECU calibration or deployed at the system level (e.g., for requirements management). It comprises the huge range from commercial tools to small scripting enhancements.

Thus, development organizations may often have a huge number (typically more than a thousand) of tools. It is obvious that the qualifying tools according to ISO 26262 may lead to a high effort and in an extreme case may prohibit tool use. The challenge is to handle this immense number of tools adequately without degrading safety conditions. For that, we provide a methodology that is based on a fine granular tool classification that is based on a detailed use cases analysis. In addition, this section introduces a two-stage tool qualification that is based on generic uses cases and sample processes.

4.6.2 Tool classification

The first step for providing confidence in the use of software tool addresses the *classification of all use cases* for which a given tool is deployed during the development process. Basis for all further activities is a detailed use case analysis. In the case that a use case is not safety relevant, no further qualification measures are required and the qualification process is finished for this case (tool impact, TI). The other case calls for an investigation into the degree of probability with which faulty contents issued by the tool in a subsequent development step may be discovered, for example, through reviews or testing (tool error detection, TD). Quality control measures can be introduced through the deployment of an additional tool, or by superimposing a process step (e.g., plausibility checks). If it is not possible to insert suitable verification steps into the development process to exclude tool-induced errors with a high degree of probability (i.e., to increase the TD), measures suited to tool qualification are called for. The result of the classification (Figure 6) essentially depends on the context within which a software tool is deployed in the product development process.

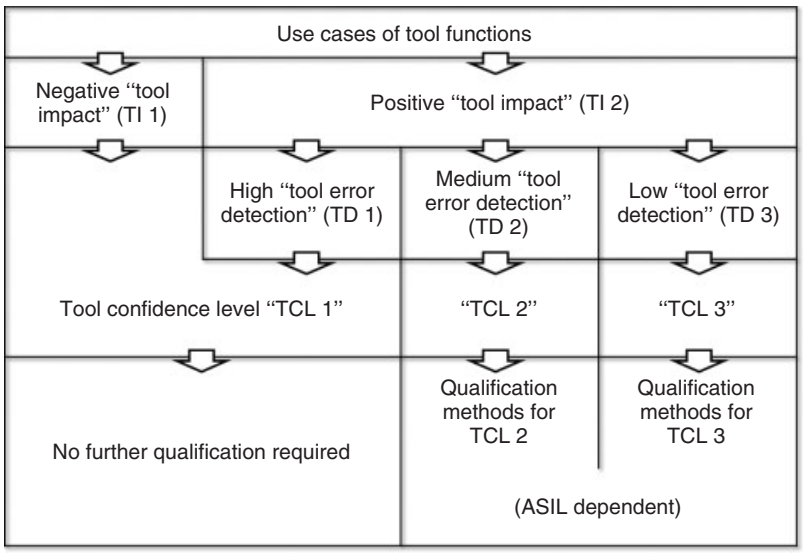

Figure 6. Two-staged process for qualification of software tools in accordance with ISO 26262-8.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 6. Methods for qualification of software tools classified TCL3 in accordance with ISO 26262.

Methods		ASIL			
		A	B	C	D
1a	Increased confidence from use in accordance with 11. 4.7	++	++	+	+
1b	Evaluation of the tool development process in accordance with 11.4.8	++	++	+	+
1c	Validation of the Software Tool in accordance with 11.4.9	+	+	++	++
1d	Development in accordance with a safety standard[a]	+	+	++	++

[a] No safety standard is fully applicable to the development of software tools. Instead, a relevant subset of requirements of the safety standard can be selected.
Example: Development of the software tool in accordance with ISO 26262, IEC 61508, or RTCA DO-178.
Reproduced by permission of DIN Deutsches Institut für Normung e.V.

4.6.3 Tool qualification

Tool qualification can be carried out in accordance with one of the four available methods. According to ISO 26262, they are

- increased confidence from use,
- evaluation of the development process,
- validation of the software tool, and
- development in compliance with a safety standard.

The recommendation for the usage of these alternative measures is to be determined considering the ASIL classification of the product to be developed, and from the result of the tool classification. Table 6 shows an overview of the qualification methods recommended for tools classified with "TCL (tool confidence level) 3" for the different ASILs.

4.6.4 Use case analysis based fine granular tool classification

Efforts during the tool qualification phase may reach an enormous level because of the typical use of an immense number of tools. For example, the Automotive Technology Business Sector of Robert Bosch GmbH covers approximately 1500 tools within 56 organizational units. The question is how to handle tool qualification adequately with this amount of tools.

In attaching importance to a fine granular tool classification, it is possible to contain the efforts that may be caused during the tool qualification phase.

At first sight, this seems to be contradictory as a use case's refinement and an increase of detail level are accompanied by an increase in the number of use cases, and thus it could be expected to result in an effort increase and just not an effort reduction. Therefore, the gain of a fine granular tool classification is not directly obvious.

But, this perspective is too simplistic. The increase of number of use cases is undisputed. As a reward for this, a detail level will be reached that is already located in software documentations, technical specifications, user guides, development manuals, former use cases analysis, and—what matters most is—descriptions for development processes.

Today's development processes currently reflect quality control measures. The intrinsic feature is that a tool chain will be described as a network of cooperating tools and not as a set of stand-alone tools whereby output from a predecessor tool may serve as input for a successor tool. This allows us to group relevant tools in terms of their data flow and not in terms of logical or physical borders. On the other hand, successor tools often provide safety as a precondition for further processing. It is to exploit this for ensuring tool correctness and improving functional safety.

Using this methodology, the Robert Bosch GmbH could demonstrate that the majority of tools embedded in a tool chain are protected within a development process and thus contain mostly use cases with TCL1. Hereby, only 2% of all use cases are classified as TCL2 or TCL3. In absolute numbers, that means, only 31 tools (from a total amount of 1500 tools) have to be considered in the subsequent qualification phase where the real efforts are estimated (e.g., in a validation). In this way, the increased effort in the first classification phase is more than compensated by a very slender second qualification phase.

As a spin-off of this methodology, it becomes clearly evident that critical tools in terms of ISO 26262 tool qualification are mainly located at the development process' periphery (concept phase and transition to production and operation), because further quality control measures with the scope of development process are very difficult to implement there.

This conspicuity has not been necessarily expected and can be approved by our experience over time—in the early beginning of tool qualification; there have been compilers and code generators that seemed to be the most critical tools. Thus, it is necessary to turn one's attention to tools that are located at the immediate beginning or at the end

of a development process, the top section of the V-shape process flow.

4.7 Random hardware faults and hardware metrics

4.7.1 Fault classes [*]

In general, the combination of faults that are considered are limited to combinations of two independent hardware faults, unless analysis based on the functional or technical safety concept has shown that n point faults with $n > 2$ are relevant. Therefore, for a given safety goal and a given hardware element, a fault can be classified in most cases as either one of the following fault classes:

- Single-point fault: this fault can lead directly to the violation of a safety goal and is a fault of a hardware element for which no (not one) safety mechanism prevents some of the faults of the hardware element from violating the safety goal.
- Residual fault: this fault can lead directly to the violation of the safety goal and is a fault of a hardware element for which at least one safety mechanism prevents some of the faults of the hardware element from violating the safety goal.
- Detected dual-point fault: this fault contributes to the violation of the safety goal, can only lead to a safety goal violation in combination with one other independent hardware fault that is related to the dual-point fault and is detected by a safety mechanism that prevents it from being latent.
- Perceived dual-point fault: this fault contributes to the violation of the safety goal but will only lead to a safety goal violation in combination with one other independent hardware fault that is related to the dual-point fault and is perceived by the driver with or without detection by a safety mechanism within a prescribed time.
- Latent dual-point fault: this fault contributes to the violation of the safety goal but will only lead to the violation of the safety goal in combination with one other independent fault and is neither detected by a safety mechanism nor perceived by the driver. Until the occurrence of the second independent fault, the system is still operable and the driver is not informed about the fault.
- Safe fault: safe faults can be faults of one of the two categories:
  - all n point faults with $n > 2$, unless the safety concept shows them to be a relevant contributor to a safety goal violation or
  - faults that will not contribute to the violation of a safety goal.

For further information about the hardware faults and a flow diagram for fault classification and fault class contribution calculation, please refer to ISO 26262 part 5 and part 10.

4.7.2 Hardware metrics

In the development of safety-related systems according ISO 26262, quantitative requirements for the above-mentioned fault classes have to be calculated. These quantitative requirements are ASIL dependent. For example, target values for the probabilistic metric for random hardware failures are $<10^{-7}\,\mathrm{h}^{-1}$ for ASIL C and $<10^{-8}\,\mathrm{h}^{-1}$ for ASIL D.

It is important to know that (other than in other safety standards) these quantitative requirements do not have any absolute significance. This means that these values do not correlate with real failure rates in the field. The quantitative requirements can be calculated based on a commonly recognized industry source, for example, IEC/TR 62380, EN 50129, and SN 29500. The quantitative requirements are only useful to compare a new design with an existing one or to compare two new alternative solutions. So, there is no necessity to align these results with real field data.

5 SIDE ISSUES OF SAFETY

5.1 Quality assurance

5.1.1 Quality gates

To assure the quality of a product, during the development of the product, there are several milestones defined where the product quality is checked using checklists. These so-called quality gates are typically defined as follows:

- QG0: project started
- QG1: release of technical specification
- QG2: completion of production planning
- QG3: scope of delivery is available from serial equipment
- QG4: product and process approval
- QG5: project completion.

Figure 7 shows a simplified process model with the mentioned quality gates.

The achieved level of product safety (together with other product and process quality criteria) is evaluated within quality gate meetings using checklists.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto194
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

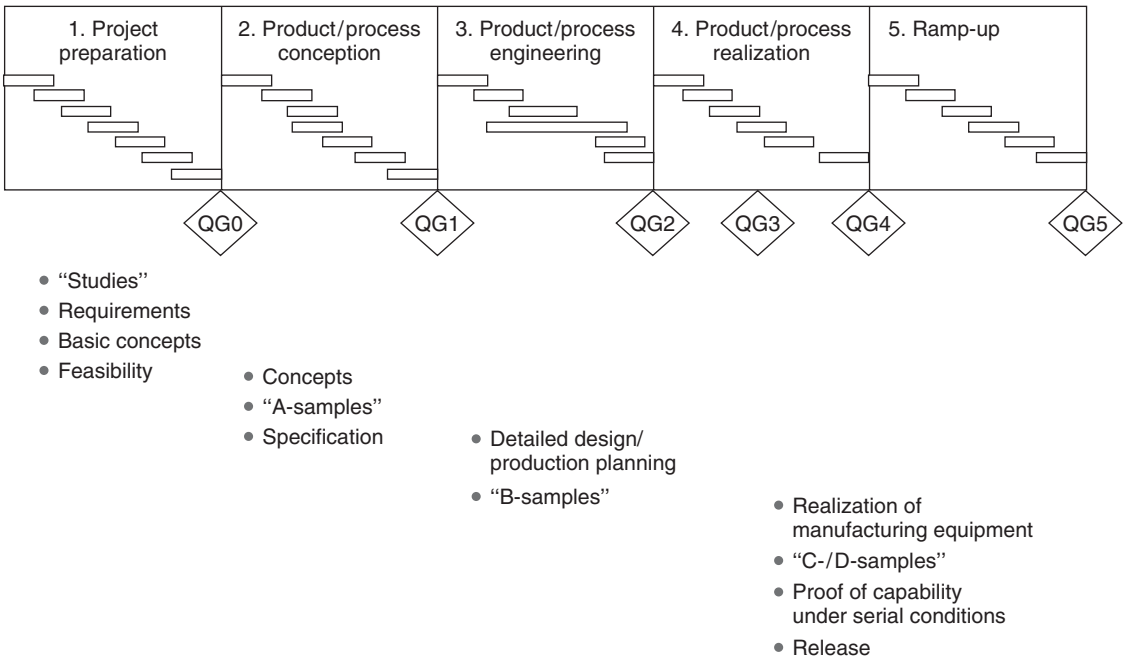

Figure 7. Quality gates of automotive development process.

5.1.2 Confirmation measures according to ISO 26262

ISO 26262 requires some further confirmation measures that are independent from the quality gates, but that are normally linked to them:

- Functional safety audit: evaluation of the process required for functional safety.
- Functional safety assessment: evaluation of the achieved functional safety of the item.
- Confirmation review: evaluation of the compliance of work products with the corresponding requirements of ISO 26262.

An overview of the subjects for evaluation, expected results, responsibilities of persons performing the confirmation measures, timing during the safety life cycle, scope, and depth is shown in Table 7.

In typically large organizations within the automotive industry, the process landscape is defined as follows (see also Figure 8).

On corporate level, directives and process definition define boundaries for the implementation on organizational level. These processes are evaluated within organizational safety audits if the definition of the processes on this level is compliant to ISO 26262.

On product engineering level in a functional safety audit, it is checked whether the product has been developed according to the defined processes. In parallel functional safety product assessments evaluate the achieved level of product safety. Questionnaires in mandatory quality gate meetings ensure that functional safety audits and functional safety assessments are done in each project.

Normally functional safety audits and functional safety assessments can be done internally, that is, it is possible to ensure the required independency of functional safety auditors or functional safety assessors without certification by an external party.

5.2 On-board diagnosis

5.2.1 Introduction

In case that a safety-related system is not able to guarantee its safety performance adequately and this could lead to a hazard of the system, it is necessary to mitigate this increased risk by safety measures. For this, it is necessary to have a detection mechanism for the system's faults, failures, and malfunctions.

5.2.2 Monitoring and fault recognition

Malfunctions or failures of a system can lead to deviations from the "normal" system status. So, the system status is subject of monitoring to recognize such deviations as early as possible as a trigger for mitigation activities, for example,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

reboot or switch off of the system. Goal is to prevent that a fault lead to a safety critical system status by bringing the system into its safe state, for example, switching off the engine to prevent the vehicle to accelerate unintentionally.

Examples of fault recognition methods, which can be used for monitoring purposes, are:

- reference value check
- redundant value check
- monitoring communication links
- handshake
- monitoring physical properties
- monitoring program execution.

For a deeper discussion of these examples, see Schäuffele and Zurawka (2005).

5.2.3 System classes

5.2.3.1 Fail-safe system (FS). On systems capable of assuming this type of safe state, such as the defined emergency shutdown (also frequently called *emergency stop*), a safety response may consist of the initiation of this state. It must be ensured that a safe state of this kind may be exited only in a controlled manner, that is, not as a consequence of additional faults, malfunctions, or failures. A system featuring this type of safety response is also known as a *fail-safe system* (*FS system*).

5.2.3.2 Fail-reduced system (FR). In some cases, the adoption of a safe state is naturally followed by the transition into a degraded operating mode. Whenever this result is continued—albeit restricted—system serviceability, such as the limp-home operating mode, this is termed *fail-reduced system* (*FR system*). There may be situations in which the degraded operating mode is deliberately introduced because of a scarcity of resources or with a view to risk minimization.

5.2.3.3 Fail operational system (FO). Sometimes introducing a safe state is not possible because of technical obstacles. This applies, for example, to many vehicle functions that are mandatory while driving. If a system happens to fail, the adverse effect of the system failure on the behavior of the vehicle must be neutralized, and a fallback switchover to a suitable backup system will be required. In principle, the implementation of the referred backup system may be similar to, or different from, the type of system suffering in failure. A system featuring this type of safety response is known as a *fail-operational system* (*FO system*).

For example, system requirements in terms of safety logic are frequently specified in the form of FO/FO/FS or FO/FO/FR. This means that a system meeting these specifications must remain fully operational, regardless of two successive internal failures. It is the occurrence of a third that would permit the system to transition into a safe state and/or enter the limp-home operating mode.

6 SUMMARY AND CONCLUSION

Safety of road vehicles becomes more and more important, as the vehicle systems get more complex in future. Managing this complexity leads directly to the challenge of managing the safety of such a complex system. The most important standard in this field is the newly released ISO 26262, a standard for functional safety of road vehicles. To reduce the risk in case of a product liability issue, it is necessary to implement the ISO 26262, as it contributes to the definition of the existing state of the art. Nevertheless, its implementation is not sufficient to reach the state of the art, as this could include much more than the contents of the standard. Key concept of ISO 26262 is a risk-based assessment and implementation of processes and product measures to reduce the residual risk to a reasonable level. The ISO 26262 requires several issues that seem to be new for the automotive industry, for example, the qualification of software tools and the application of hardware metrics. To evaluate the achieved functional safety of the product and the implemented processes, functional safety assessments and audits are performed. The results of these confirmation measures are typically checked at certain quality gates. To enable systems to tolerate faults and to reach and to stay within safe states, monitoring and diagnostics functions are used. This leads normally to FS systems, whereas in future, FO systems may come more into focus.

Interfaces between Sensors and ECUs

Hiroaki Hoshika and Shinya Igarashi

Hitachi Automotive Systems, Ltd., Hitachinaka, Japan

1 INTRODUCTION

Nowadays, automotive electronics systems use a lot of Electronic Control Units (ECUs) and sensors. In general, multiple sensors are connected to one ECU. They are connected with various interfaces. We are going to describe several types of interfaces that connect sensors to ECUs as well as their characteristics and synopsis.

2 REQUIREMENTS NECESSARY FOR INTERFACES BETWEEN SENSORS AND ECUS

Sensors convert some physical quantity, displacement, and/or the like into electric signals. The signals are used as an input to control an ECU. Therefore, various types of interfaces are used that are able to suppress deterioration and time lag to surely transmit sensor-collected information to an ECU. In automotive environments, various types of external electric disturbances can happen. This is why various measures are taken, for example, to minimize the influence of such disturbances, surely let an ECU know a failure of the sensor for a prompt failsafe process if a sensor fails, and transfer information to an ECU with some low cost communication means even from a sensor located at a distance from the ECU. Conventional interfaces have only such functions that transmit sensor-collected information to ECUs. In recent years, however, the needs are high for bidirectional information exchanges involving direct connections to vehicle networks such as LIN (local interconnect network) and CAN (controller area network).

3 CLASSIFICATION OF INTERFACES

Table 1 lists some of the typical interfaces that connect sensors and ECUs.

4 ANALOG INTERFACES

This is one of the interfaces that have been used for the longest time, and is still widely in use nowadays. The physical quantity detected by a sensor is replaced by a voltage or amperage for transfer. In automotive systems, the voltage type is frequently in use.

Analog interfaces convert the voltage acquired on the side of ECU into another physical quantity. Therefore, the relationship between voltage and physical quantity needs to be interrelated as the output characteristics of a sensor in advance. These characteristics do not necessarily need

Table 1. Typical interfaces

Classification by hardware	Classification by information transfer methods	Characteristics
Analog interface	Voltage	Physical quantity is transferred through voltage signal. This is one of the most common methods and is still applied in wide fields. This method, however, is under influence of voltage drops, external noises, grounding voltage, ECU's reference voltage, and so forth and, therefore, tends to cause errors. This is why precautions are necessary at the stage of designing wiring and signal filters
Analog interface	Current loop	Physical quantity is transferred through current in the signal lines. A current loop is formed with a sensor and an ECU. Consequently, this method is not susceptible to signal deterioration or external noises. However, electric circuits are somewhat more complicated than those of voltage methods
	Differential voltage	Physical quantity is transferred through voltage difference of two signal wires. This method is not susceptible to external noises that are not often in phase with two signal wires simultaneously. This method, however, has a complex electric structure and, therefore, is not usually used for automobiles
Pulse interface	Frequency modulation	Physical quantity is transferred in linkage with the frequency of pulse signals. This method is not susceptible to the fluctuation in signal voltage if some appropriate threshold is selected. This method has been in use with sensor signals for a long time but is not free from errors in modulation and demodulation caused by errors in frequency sources
	PWM modulation	Physical quantity is transferred in linkage with the duty ratio of a pulse signal. Duty ratio is acquired by dividing a high or low level time by the periods of pulse signals. This method, therefore, is not susceptible to errors in frequency sources, but obscure waveforms processed by a noise removal filter can be an error factor
	Frequency and PWM modulation	Frequency modulation and PWM modulation are processed simultaneously to link two types of physical quantities with one signal wire. Two types of signals are transferred with a single wire. Therefore, it is possible to reduce the wiring cost to connect an ECU
Serial communication interface	SENT (SAE-J2716)	This is the unidirectional communication with the pulse time modulation of 4 bits per pulse and 2 bytes per message. This method is seen as a replacement of analog signal communications. This method, however, supports IDs and CRCs in transfer data; therefore, multiple channels and error detections are compatible. Circuit configurations are simple enough to use LSIs. This method is used for angle sensors and so forth
	DSI/PSI5	Only two wires are used to enable power supply and signal transfer. Multiple sensors can be connected in parallel. Amperage readings are processed in Manchester encoding for data transfer. This method is suitable for an environment where you need to position a large number of sensors with relatively low power consumption. This method is used in, for example, airbag systems
Network nodes	CAN(ISO11519-2) (ISO11898)	This is a two-line differential type and enables multimaster bidirectional communications of 1 Mbps at the maximum. This method is widely used for inter-ECU communications. This method is one of the international standards but is rarely applied to sensors because of its cost of circuits. For more information, see Section 7.2
	LIN (LIN 2.x) (SAE-J2602)	This is a single-line type and enables single-master bidirectional communications (semiduplex communications) of 20 Kbps at the maximum. As the circuits are not expensive, this method is used for sensors that do not require very high response performance. For more information, see Section 7.1

to take a linear form. Contrarily, these characteristics can take various forms depending on the detection principle of such a physical quantity and/or the range of significant measurements (Figure 1).

When an analog interface is in use, signals are transferred from a sensor by way of a wire harness. On the side of an ECU, there is a filter to remove any intrusion of signal noises that may be caused by external electrical disturbance. Generally speaking, a low pass filter (LPF) is provided to cut off high frequency elements equal to or higher than the cut-off frequency (f_c). Figure 2 shows an example of such LPFs.

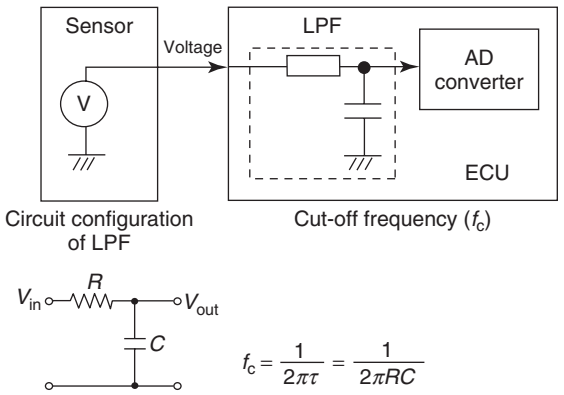

Figure 2. An example of low pass filters. (Reproduced by permission of Hitachi Automotive Systems.)

4.1 Precautions for using analog interfaces

If the voltage at the input terminal is different from the output of the sensor signal, the ECU causes an error in the physical quantity recognized on its side. Therefore, some measures should be taken to prevent any difference from being generated at the sensor output signal and the terminal voltage on the side of ECU. Such measures can differ depending on the situations. For example, a wire harness generates resistance. Accordingly, the current flowing down a signal wire or a grounding wire causes a voltage drop. Further, an overshoot can be generated in a grounding wire. As countermeasures, for example, the amperage in signal wires is reduced, and/or the grounding current is separated using a dedicated grounding wire. If, moreover, the reference sources are different between the side of a sensor and its corresponding ECU, such a configuration can cause errors. For this reason, when some high precision is required with respect to voltage, a ratiometric-type output circuit may be used where a reference voltage is provided from the side of the ECU to the sensor. Figure 3 shows some elements that tend to cause problems while a voltage-type analog interface is used.

5 PULSE INTERFACES

When analog interfaces are used, absolute voltage and absolute amperage are susceptible to various types of external disturbances. When pulse interfaces are used, on the other hand, external disturbances are not so influential because only two levels of voltage, a high level and a low level, need to be transferred as signals. This means that it is only necessary to reach and exceed the threshold of each level. On top of that, in this method, it is possible to replace the AD converter in an ECU with a timer circuit. Furthermore, it is also possible to simplify the signal output circuit on the side of the sensor. It is, more often than not, analog signals that are detected by a sensor. Consequently, these signals are converted into pulse signals in a modulation circuit.

The pulse frequency modulation is the so-called FM modulation; that is, the signals detected by a sensor are replaced with the frequency of pulse signals. For example, the analog voltage signal acquired on the side of a sensor is converted into the frequency with a VCO (voltage-controlled oscillator). On the side of an ECU, a counter circuit counts the number of pulses in pulse signals with regular intervals to acquire the counts in proportion to the average frequency in one period. VCO circuits are not too complicated. This is why they are widely in use as automotive sensors, which are mostly analog circuits. They, for example, are used to acquire output signals from an airflow sensor.

The PWM (pulse-width modulation) modulation is a type of information transfer where the ratio (the duty ratio) between the high and the low level times is used. The pulse frequency from one rising pulse to the next rising pulse (called a *carrier frequency*) is always constant, whereas the ratio between the high and the low level times of signals is varied. The ECU includes a timer circuit to detect each of the high and the low level times. If you divide the high or the low level time by the period of signals (the sum of the high and low level times), you can obtain the duty ratio. The PWM modulation does not change the duty ratio even if the period of pulses fluctuates. This is an advantage that enables the signal transfer with little errors, not requiring a stable oscillator on the side of the sensor. Figure 4 shows

a schematic view of a PWM modulation circuit based on an analog circuit (Kumagai, 2011).

PWM modulation pulses are also easily generated by a digital circuit. Therefore, microcomputer-equipped sensors, in general, use PWM output units without any alteration. As for ECUs, they usually include a built-in microcomputer equipped with a timer/counter unit that provides an operation mode suitable for acquiring a duty ratio from these PWM signals.

The ratio between the high and the low level times is significant for PWM modulation pulse signals. The time duration necessary for a level transition generates an error. Therefore, only a minimum number of processing units such as an LPF, necessary for noise reduction, should be inserted in the signal I/O circuit, depending on the carrier frequency. We ought to pay attention in order to avoid increasing transition time.

Both the frequency and the PWM modulations require one signal wire for one piece of analog information. On the other hand, complex PWM modulation is also used, which varies the carrier frequency of the PWM modulation to transfer two pieces of analog information via one signal wire. For example, analog signal A varies the frequency of pulse signals, whereas analog signal B varies its duty ratio. This modulation reduces the number of wires, which means a cost reduction.

6 SERIAL COMMUNICATION INTERFACES (PULSE CODE MODULATION)

Serial communication interfaces use AD converters or similar to encode analog signals from sensors. After this, they transfer such signals one by one by the unit bit. A clock synchronization type processes the transferring timing of each of such bits with a dedicated clock line, whereas a start–stop synchronization type has a fixed duration of transmission time for each one bit and controls only starting points. Of these two types, the start–stop synchronization type is more commonly used in automotive systems. In the broad meaning of the word, network communications such as CAN and LIN belong to serial communications. In this section, however, we classify as serial communication interfaces those that do not establish mutual communications between sensors and ECUs and, besides this, that mainly use signal transfer from sensors to ECUs.

SENT (Single Edge Nibble Transmission) and DSI/PSI5 (distributed system interface–peripheral sensor interface), for example, are among the ones that are standardized and already spread.

6.1 SENT

SENT is one of the communication standards based on SAE-J2716. The widths of 5-V amplitude pulses are defined and classified into 16 levels. Every one pulse transfers 4-bit information (called a *nibble*). Every one message transfers 8-nibble information (32 bits). Among the information, two nibbles convey a status and CRC (cyclic redundancy check). To sum up, a sensor practically transfers 24-bit data. The smallest unit of pulse widths is a tick. One tick is equivalent to 3 μs. The pulse width varies depending on data transferred. One message takes 152–272 ticks (456–816 μs) to complete a transfer. In the field of automobiles, analog signal sampling periods are approximately 1 ms per signal at the shortest. Therefore, the performance of this interface, able to transfer two-channel signals (24 bits in total) with the accuracy of 12 bits in one wire in 816 μs or shorter, is sufficient. As the pulse widths are controlled, a reference clock is required on the side of a sensor. The fluctuation of the reference clock on the side of a sensor is allowed within the range of 20%, as the pulse widths are classified into no more than 16 levels and synchronized pulses are measured on the side of an ECU to correct pulse-width information. Accordingly, even a simple oscillator can work as a sensor. In addition, you can use a timer with a small number of bits as a pulse-generating timer. No communication-receiving functions are available from an ECU. The signals are something like what you would obtain by replacing conventional analog signals with serial communication signals to improve the reliability in information transfer. This interface has already been applied to the interface of angle sensors (Figure 5).

6.2 DSI/PSI5

As of now, these two are not international but noninternational standards under management of consortiums joined by parts suppliers, semiconductor manufacturers, and so forth. These two are different communication standards. However, they, besides both being a two-wire-type sensor interface, share several common features as described later. Figures 6 (DSI Consortium, 2011) and 7 (PSI5 Consortium, 2011) show their connection topologies.

(1) Operation requires only two wires for the power supply and for signals.
(2) Communications are based on master–slave interactions. The master sends a command and the slave returns a response.

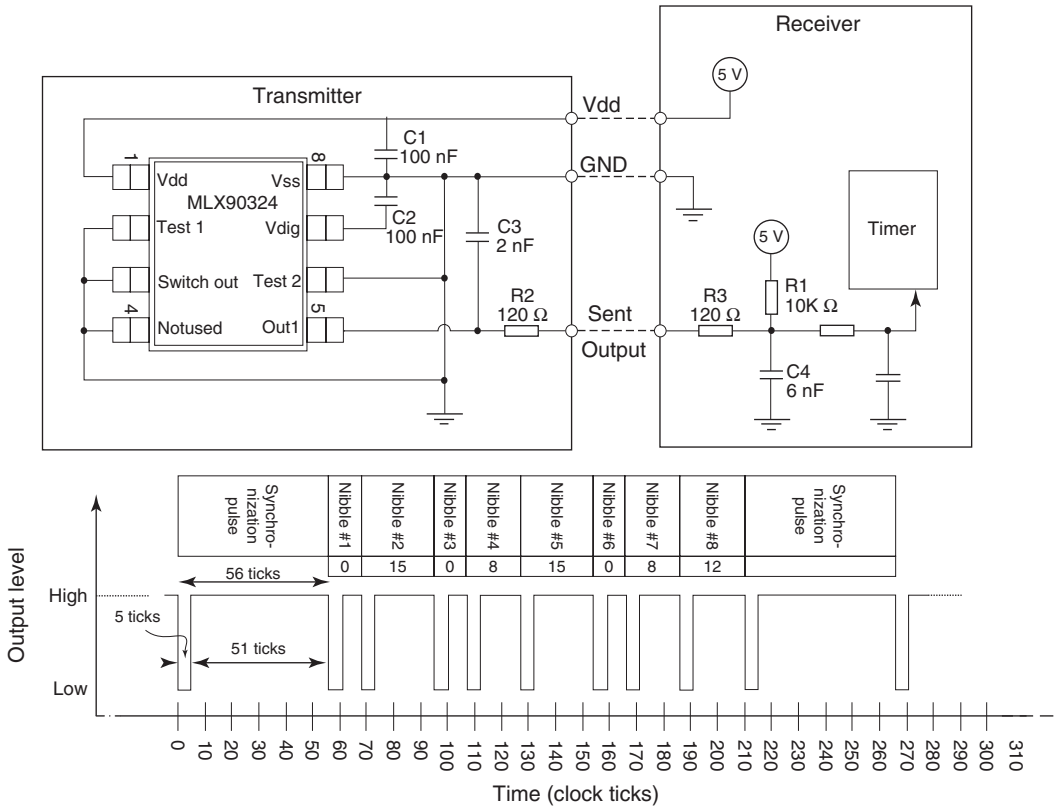

Figure 5. An example of interfaces based on SENT. (Reproduced by permission of Hitachi Automotive Systems.)

(3) Supported connections include topologies such as separate connections, bus connections, and daisy-chain connections.
(4) The master (ECU) controls the voltage of the power supply line. The slave (sensor) manipulates electricity for its own consumption to process communications.

These two look alike as types of interfaces. They, however, do not have any compatibility. DSI, for example, supports the commands of Manchester encoding based on voltage (it is not a level but a direction of transition that has logical significance). In its logic, responses are in the unit of nibble (4 bits) with which the electric current of a slave is controlled to one of three levels. PSI5, on the other hand, supports the commands based on the logic of voltage, whereas the responses are generated with Manchester encoding based on current C amperage. Their communication rates are also different from each other. DSI has a function that supports the power function class, an operation of an actuator. It is possible to operate an actuator by temporarily raising the voltage and amperage. These two standards are already in practical use in applications that require multiple sensors arranged in a wide range on one vehicle such as airbag systems.

7 NETWORK NODES

In recent years, there has been growth in the needs for sensors that support connections with networks. Automobiles use networks of various standards that correspond to their purposes. In this section, we are going to describe LIN and CAN, two typical communication standards generally used for sensors.

7.1 LIN (local interconnect network)

This was, at its origin, a network standardized by automobile manufacturers and parts suppliers in Europe, as a network they were able to configure with low cost hardware that did not require very fast communication speed such as small actuators and ECUs. Nowadays, this network is under management of a consortium joined by automobile manufacturers and parts suppliers from all over the world. This network has the characteristics described later. In general, this network is used as a subnetwork of a CAN.

The physical layer consists of single wires, which is the same as the standard of ISO9141 (International Organization for Standardization). The network has a bus structure

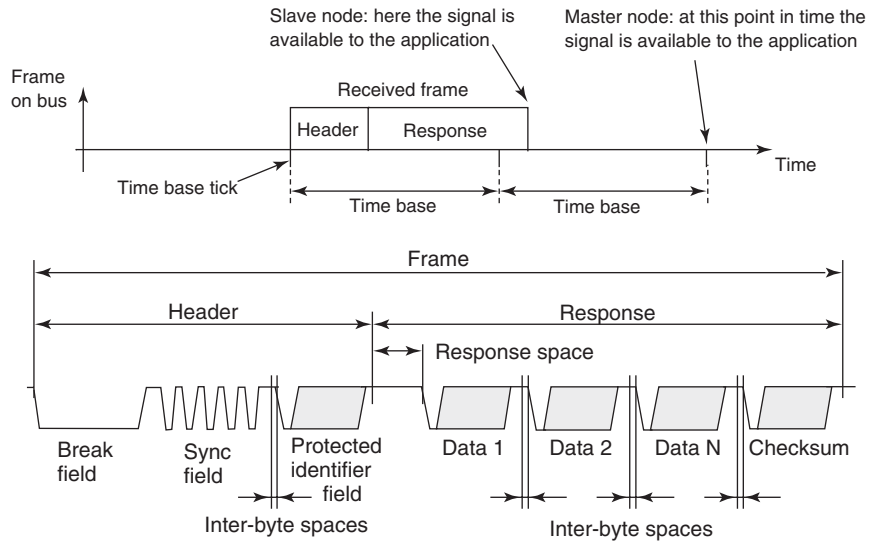

Figure 9. Configuration of the LIN communication frame. (Reproduced by permission of Hitachi Automotive Systems.)

of a linear type. There is only one master that sends tokens, which are received by a plurality of slaves at the same time. As message addressing is used, only the slave with the corresponding ID sends back a response to the master. In networks with sensors, the ECU works as the master, while the sensors work as the slaves. During communications, a time trigger protocol is used. Communication timings are all controlled by the master. The data transfer rate is 20 kbps at the maximum (10.4 kbps according to SAE-J2602), which is not suitable for transferring the signals in high speed responses. Figures 8 and 9 show a schematic view of tokens and the configuration of a communication frame (ITmedia Inc., 2010; Lin Consortium, 2006).

These serial communications make use of the UART (universal asynchronous receiver/transmitter) interface (start–stop synchronization). Slaves are synchronized based on the synchronization signal included in the message sent from the master. Therefore, slaves do not need any high accuracy oscillator. Messages are as short as 8 bytes at the maximum, including parity bits and checksums for protecting transferred data.

The transport protocol is based on ISO15765. Diagnoses and standard transport mechanisms are available. Therefore, various types of bidirectional communications are possible.

7.2 CAN (controller area network)

The specifications of CAN were published by Robert Bosch in Germany in 1986. Afterward, the specifications were standardized (ISO11898/ISO11519). As of now, this bus-type network is applied to almost all vehicles. Figure 10 shows an example of CAN connection and its data frame

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto195

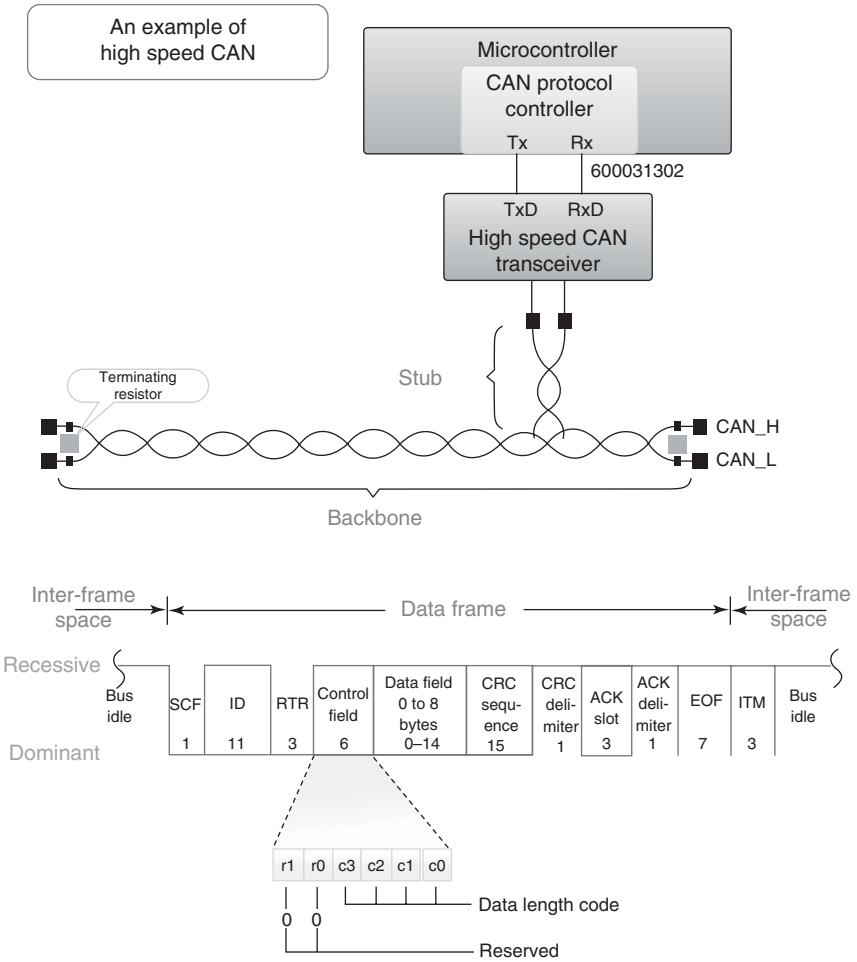

Figure 10. An example of CAN connection and its data frame configuration. (Reproduced by permission of Hitachi Automotive Systems.)

configuration (ITmedia Inc., 2008). This network is roughly classified into two types; that is, low and high speeds. The low speed CAN is mainly used for vehicle body systems, whereas the high speed CAN is mainly used for power train systems. Besides these, the single-wire CAN is also standardized. The high speed CAN is based on the two-wire voltage operation with twisted pair wires. This network is highly reliable. The standard maximum communication speed is 1 Mbps. However, the communication speed of 500 kbps is used for high speed CAN. Any node can start communications when the CAN bus is open. If, on the other hand, two or more nodes are trying to start communications at the same time, the node with the smallest ID number is given the right to start communications. This system makes it possible to control communication priorities.

This system requires a microcomputer. In most cases, a microcomputer equipped with a CAN controller is used. In addition, a CAN transceiver is used for the physical layer of CAN. As circuits are necessary for the network communication processing as well as a high performance microcomputer, this network is not suitable for small-scale sensors. This network is used for sensors and/or sensing systems with high reliability and complex functions. On top of that, this is a multimaster network, and it is easy to add CAN nodes. For example, if you want to add a sensor to a system for the purpose of control, and if it is difficult to modify the ECU, you only have to modify the software to add a sensor to a CAN bus.

8 CONCLUSION

As a trend of electrical interface between sensor and ECU, signals are generally shifting to digital transmission type such as SENT, LIN, DSI, and PSI5. It brings less cost of total vehicle electrical systems, higher safety redundancy,

and shorter development time of vehicle. In the future, it is expected that some of simple sensors will be managed by multifunction sensor-integrated communication unit to link vehicle network system. This maybe makes optimized sensor information topology.

Various Types of Sensors

Shinya Igarashi, Junji Onozuka, Hiroaki Hoshika, and Masahide Hayashi

Hitachi Automotive Systems, Ltd., Hitachinaka, Japan

1 INTRODUCTION

Automotive electronics systems make the best possible use of multiple types of sensors and sensing technologies for each and every function. The required amount of detected physical quantity depends on the purposes and means for control and information processing. The selection of sensors depends on how best to materialize the purposes and means with an excellent cost performance. Therefore, when developing automotive sensors, the purposes and effectiveness of the system should be considered in relation to the interrelationship with other systems and the influence of the technology.

Automotive electronic systems were started to reduce the toxic gases in the engine exhaust and to try to achieve high engine efficiency and a reduced fuel consumption rate. As next stage, the system development went on to improve ride comfort and operability. These purposes have been spreading to safe driving performance, preventive safety, information communications, traffic system linkage, and autonomous and/or automatic driving.

The details of specific sensors are described in the following sections. Sensing systems can take various types and forms and their technologies have evolved to apply the advanced technologies. The discussions in the following sections cover only a part of such systems and technologies. Automotive electronic systems have been expanding and requiring more physical quantity detection or information collection. When the form of the system is determined, the sensor specification will be clear such as what physical quantity detection is needed with what level of accuracy and the environment conditions. However, the sensors suitable for the system are varied. There are many principles of detection and different materials are used. There is some difficulty in selecting the best sensor for the system.

The next point of consideration should be how to materialize the system with the lowest possible cost. From an opposite viewpoint, it is necessary to find a way to materialize the system with a selected sensor to propose and/or create the system with high performance and high functionality, which all automobiles should follow thereafter. Developing sensors and sensing technologies with low costs requires consideration from various standpoints, such as the following:

1. pursuit of new sensors and sensing technologies based on new materials and new theories;
2. sensor types and structures oriented toward size reduction and high mass productivity;
