3. sophisticated information processing and communication technology such as sensor fusion based on digital conversion and intelligence deployment;
4. improvement in electronics systems oriented toward fewer sensor allocations or no sensor allocations.

These standpoints may include some elements that are incompatible with each other, yet designers and developers are constantly trying—from different viewpoint—to achieve the lowest cost system possible and the necessities of such a system for controlling and information processing, which ought to be common objectives among them. As a result, only the best combination at the time can be found.

Table 1 lists the needs that should be fulfilled by sensors in automotive systems. These are selected as combinations and/or means for achieving the purposes of control and information processing systems. In recent years, the automobile driving systems involving electric motors in place of engines are applied to electric vehicles (EVs) and hybrid electric vehicles (HEVs), for example. For such applications, different sensing technologies are required. These are very different from conventional engine control and the needs expected from the sensors in such systems will become clear in the future. Furthermore, the viewpoints of driver information, safety control, automatic driving, and communication-related processes vary reflecting the times. Table 1 shows general trends.

2 AIRFLOW SENSOR

Airflow sensors are major sensors for electronics control fuel injection systems used for measuring the rate of airflow into cylinders. Electronics control fuel injection systems enable optimal fuel supply and ignition by operating fuel injection valves and ignition systems on the basis of intake of air signals. The air–fuel ratio, the weight ratio between air intake and fuel, is one of the most important factors that determine the exhaust and fuel-efficiency characteristics of engines. In recent years, high accuracy and long-term reliability are required from the air–fuel ratio control for emission improvement. Therefore, high accuracy is required of airflow sensors. Furthermore, the selection of airflow measurement methods causes a great to input configurations of computer systems. To satisfy the new functional requirements of future engine control systems, the manufacturers of parts and automobiles have been developing a large number of airflow detection methods.

2.1 Specifications of airflow sensors

Table 2 lists some of the specifications needed from airflow sensors in electronics control fuel injection systems. To materialize highly accurate air–fuel ratio control, airflow rate ought to be expressed in terms of mass flow rate. This requires a wide range of measurement coverage as well as high accuracy. Airflow, while operating with an almost fully opened throttle valve, becomes large-amplitude pulsating flow with the frequency of 20–200 Hz, which results from the reciprocating motion of a piston. In some extreme cases, such pulsating flow can be accompanied by reverse flow. Sensors are supposed to take highly responsive measurements of such pulsating flow in order to acquire an average flow rate. On top of that, the above-mentioned requirement needs to be satisfied in such a severe environment as is characteristic of automobile engines, where there may be backfires, dust in intake airflow, oil drops (blow-by gas), and a wide range of air temperature changes.

Table 2. Specifications of automobile airflow sensors.

Item	Specification
Measurement accuracy in mass airflow rate	±2%
Measurement range	1 : 100 or larger
Response time	10 ms or less
Pressure loss	5 kPa or less
Measurement environment	Air temperature: −40 to 130°C
Durability	Mileage: 150,000 km
Vibration resistance	20 G 20–200 Hz

Reproduced by permission of Hitachi Automotive Systems.

In addition, long-term reliability is required as well as compactness, lightness, and low cost. Currently, there are no such airflow sensors that satisfy all these specifications. In practical use, lacking aspects are supplemented with control systems.

2.2 Types of airflow sensors

Airflow sensors have been applied to practical use in the form of the moving vane type, the Karman vortex type, and the thermal type, named in chronological order.

The moving vane type represents the flow rate sensors applied in the earliest days (Figure 1). The kinetic pressure from airflow is received with a moving vane (a rotatable plate). The moving vane opens, opposing the force from the return spring. This opening angle is measured to obtain the volume flow rate in this type.

The opening angle of the moving vane is measured on the basis of its sliding resistor position. The value of the sliding resistor's measurements is matched with the area of air passage formed by the moving vane. Thus, the signals from the flow rate instrument are interrelated with

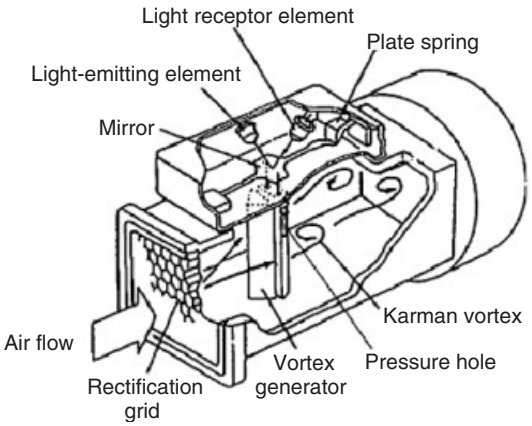

Figure 2. Karman vortex-type flow rate instrument. (Reproduced by permission of Hitachi Automotive Systems.)

the airflow rate values by means of logarithmic functions. There are, however, some boundaries with respect to durability and reliability that are brought by moving parts and sliding parts. Specifically, moving vanes are used with air damper chambers that suppress vibration. They make moving vanes larger in external dimensions and somewhat slower in response. In addition, there are some more shortcomings. For example, air pressure and temperature need to be compensated or corrected to obtain the mass flow rate.

Afterward, the Karman vortex type was applied in practical use. This type makes use of the fact that Karman vortices pass the downstream side of a vortex generator with regular intervals in proportion to the airflow rate. The frequency of the Karman vortices is measured to obtain the volume flow rate. As the means for detecting Karman vortex frequencies, the following methods have been adopted:

1. In the first method, an ultrasonic wave oscillator and a receiver oppose each other in the downstream of a vortex generator. Vortices are detected with synchronized modulation of ultrasonic frequencies generated by such vortices.
2. In the second method, the pressure variance resulting from vortex generation is led to a mirror by way of pressure holes on both sides of the vortex generator to vibrate the mirror. The vibration cycle of the mirror is detected with a light coupler (Figure 2).
3. In the third method, the pressure variance is measured with a micromanometer in the same manner as the above-mentioned method.
4. In the fourth method, vortices are measured with thermal wires.

This generation of Karman vortices, however, tends to be unstable at the time when they are with pulsating flow or low speed airflow. Therefore, it is not easy to measure large-amplitude pulsating flow or ultra-low flow rates. In addition, atmospheric pressure and temperature need to be used for compensation and correction to obtain mass flow rate, to name but a few disadvantages.

Following this method, thermal wire-type airflow sensors were applied. It is possible to directly detect the mass flow rate of air. If compared with the two methods mentioned earlier, the measurable range is wider than those of the above-mentioned methods. This type of sensor does not involve any moving parts; they are small and are manufactured at a low cost. This is why most of the airflow sensors are of this type nowadays.

Besides the above-mentioned types, there are corona discharge types, ultrasonic wave types, swirl vortex types, and so forth, which were not applied to engine control but were once considered for such applications. Other than the airflow sensors mentioned earlier, the speed density type, which acquires airflow rate indirectly from intake pipe pressure and engine revolution speed, and the throttle speed type, which acquires airflow rate indirectly from throttle valve opening angle and engine revolution speed, are applied to practical use. The former has a disadvantage; that is, the measurement accuracy of airflow rate deteriorates when exhaust air returns. Thanks to its low cost and high reliability; however, this type has been widely applied to such fuel injection systems that have a small rate of exhaust return and have no influence over measurement accuracy. The latter, on the other hand, are not so widely applied so far firstly because high accuracy is required of the throttle valve opening angle and secondly because the measurement accuracy of airflow rate deteriorates if atmospheric pressure varies. However, it is possible to compensate by Electronic Control Unit (ECU), so that the trend is variable.

2.3 Thermal wire-type airflow sensor

2.3.1 Principle of thermal wire-type airflow sensors

Thermal wire sensors supply electric current to a heat resistor made of platinum wire or platinum thin film in order to heat the resistor. This type makes use of the fact that the amount of heat transmitted to the air depends on airflow speed. As shown in Figure 3, a thermal wire probe, which detects airflow rate, and a temperature probe, which detects air temperature, are on the sides of a bridge circuit. The electric current supplied to the thermal wire probe is increased or decreased to regulate the temperature difference between the thermal wire probe and the air temperature probe regardless of airflow rate. At this time, the electric current supplied is converted into an airflow rate signal in this method. The interrelationship between the airflow rate and a signal is expressed by the following equation:

$$I^2R = A + B\sqrt{G_a} \tag{1}$$

where I is the electric current supplied, G_a is the airflow rate, and A and B are constants. In this method, the electric current is measured, and the above-mentioned equation is used to acquire airflow speed, G_a. When flow rate is low, electric current I, the measurement to be converted into a flow rate signal, varies a great deal, getting closer to showing logarithmic characteristics.

In Figure 4, the rectifying cylinder in the intake air passage contains the platinum wire of 70 μm in diameter spanned across the rectifying cylinder as the thermal wire

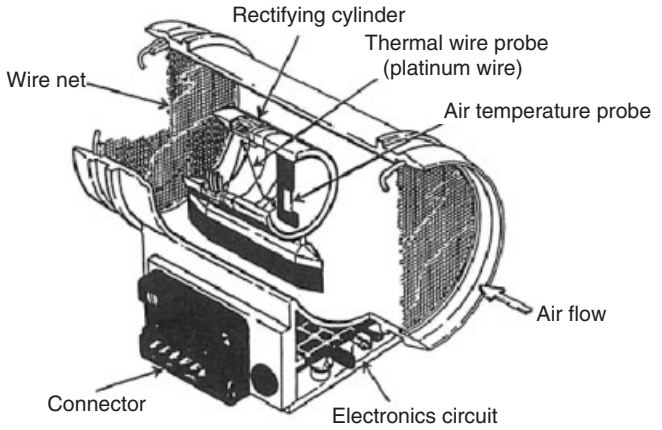

Figure 4. Thermal wire-type flow rate instrument. (Reproduced by permission of Hitachi Automotive Systems.)

probe. Further, the platinum thin film resistor formed on the ceramic plate is used as the air temperature probe. After the engine key is turned off, electric current flows to the thermal wire probe to heat it up to approximately 1000°C, thus burning and removing any adhering dust particles. This burn-off circuit is provided to prevent any adhering dust particles from degrading accuracy.

Figure 5 shows a bypass type, in which a thermal wire probe and an air temperature probe are disposed in a bypass passage branching from the intake air passage. The purposes of this bypass type are to take highly accurate measurement of pulsating flow and protect the thermal wire probe against the backfire at the time of engine disorder. Both the thermal wire and the air temperature probes are of a wire wound type, which have a platinum wire wound in

the shape of a coil around the cylindrical ceramic bobbin that is covered with glass.

Figure 6 shows a hot film type, which has a rectifying cylinder in the intake air passage containing a hot film plate filmed with a platinum thin film resistor on a thin ceramic plate. The hot film plate is inclined by approximately 30° with respect to airflow, letting airflow go along the plate. This is an attempt to reduce the noises emitted from flow rate signals triggered by the disturbance in airflow.

Figure 7 shows an insert type, which can be attached in any position in an intake air passage. The thermal wire probe, the bypass passage, and the electronics circuit are configured all in one and inserted into the sidewall of the intake air passage. The purpose of this type is to make the intake air pipe compact, including the airflow sensor. The differences in the cross-sectional areas of intake air pipes are automatically compensated by the air–fuel ratio closed-loop control with an air–fuel ratio sensor and the memory of the compensation values of this closed-loop control.

2.3.2 Structure of thermal wire-type airflow sensor

2.3.2.1 External shapes of sensors. Among those that have been applied to practical use, there are, from the structural viewpoint, the hot wire type, which directly spans a platinum wire in airflow; the wound wire type, which has a ceramic bobbin wound with a platinum wire; and the hot film type, which contains a platinum thin film resistor on a ceramic substrate. The hot wire type uses a platinum thin wire. Therefore, its thermal capacity is small and its response is excellent. However, the dust particles accumulating on a thin wire tend to result in some deterioration in the accuracy of flow rate measurement. On the other hand, the wire wound type and the hot film type have a large thermal capacity and, therefore, their responsiveness is inferior. Yet, the advantage of these types is that the influence of dust particle accumulation is much less and, therefore, the accuracy is less deteriorated.

The accumulation of dust particles on a thermal wire probe is affected—besides the shape of the probe—by the temperature of the thermal wire probe. While dust particles accumulate on the surface of a probe, it is mainly the moisture and the oil in the dust particles that attract the dust particles to one another. With this problem considered, the temperature of the thermal wire probe is raised to 200–250°C to vaporize the moisture and the oil on the surfaces of the dust particles, reducing the amount of accumulating dust particles. The wire wound type has a wire wound-type probe with some smaller surface area. Accordingly, it is practically easy to raise the temperature as mentioned earlier.

2.3.2.2 Electronics circuit. The temperature difference between a thermal wire probe and an air temperature probe is constantly controlled to a prescribed level, thus compensating any variance in air temperature. Besides the conventional electronics circuit shown in Figure 3, another

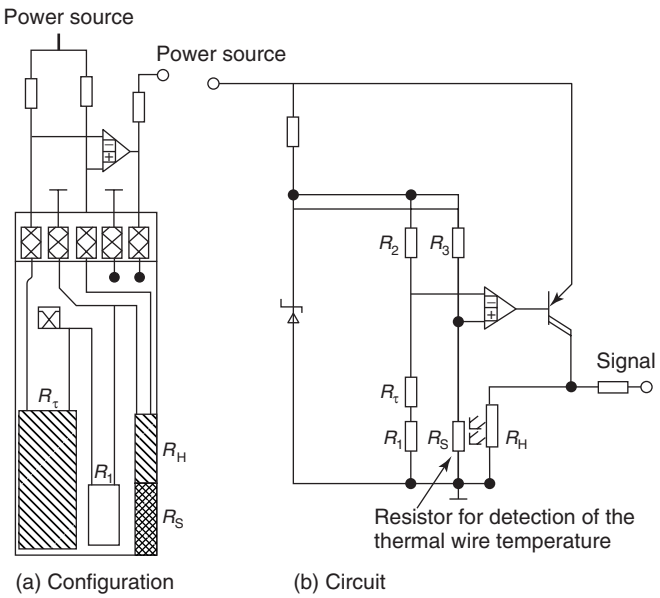

Figure 9. (a,b) Electronics circuit of a hot film-type flow rate instrument. (Reproduced by permission of Hitachi Automotive Systems.)

new electronics circuit has been developed as described later.

Figure 8 shows a circuit where another amplifier is added to a conventional circuit to make it possible to use probes having the same resistance for the air temperature probe and the thermal wire probe. As opposed to conventional ones, this air temperature probe causes less resistance and is more compact. Consequently, even if the air temperature changes suddenly, it is detected with no delay, and, therefore, it is possible to compensate the temperature change. Moreover, when it is assumed that the heat conduction from the probe-fastening end deteriorates the accuracy, identical shapes can be given to both the air temperature probe and the thermal wire probe, offsetting the influence from the heat conduction and hence reducing such influence.

Figure 9 shows a hot film-type circuit, in which a resistor is added to detect the temperature of the heat element to omit a fixed resistor having been supposed to be connected to the heat element in series. The sensor module is somewhat complicated, as the heat elements and the temperature-detecting resistors are stacked and disposed

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto196
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

there. Nevertheless, there is an advantage. As no fixed resistors that require cooling means are built-in, the electronics circuit is simplified compared to the circuits that come with a heat element emitting a great amount of thermal energy.

2.3.2.3 Bypass passage. The bypass type measures the flow rate in a bypass passage that branches off from an air passage. This type reduces the error in average flow rate measurement of pulsating airflow. When pulsating flow is measured with a thermal wire-type flow rate instrument, the following two problems could be faced.

2.3.2.3.1 Averaging the average flow rates of pulsating flow. As far as pulsating flow is concerned, the average of flow rate signal is smaller than the actual average airflow rate. One cause of this is, as shown in Figure 3, that the signals from a thermal wire-type flow rate sensor show nonlinear characteristics with respect to airflow rate. The larger the pulsating flow amplitude is, the slower the response is and the smaller the measurement will be than the actual value.

Another cause is that the amplitude is large enough to be accompanied by small reverse flows. When this happens, and if the air heated up by the thermal wire probe flows back in the opposite direction, then the air covers the thermal wire probe once again. Thus, the power supply to the thermal wire probe becomes higher, which means that the flow rate signals become higher. The bypass type uses the effect of the increase in the average flow rate, brought about by the inertia of the airflow in the bypass passage, in order to correct the error mentioned earlier. Airflow rate u in a bypass passage is acquired as follows:

$$\Delta P \sim \frac{u^2}{2} + \ell \frac{\mathrm{d}u}{\mathrm{d}t} \tag{2}$$

Here, ΔP is the pressure difference added to the inlet/outlet of the bypass passage that is generated by the airflow in the intake air passage, u the flow rate in the bypass passage, and ℓ the length of the bypass passage. The length of the bypass passage, ℓ, is determined such that the increase in the average flow rate in the bypass passage offsets the error mentioned earlier.

2.3.2.3.2 Reverse flow compensation. Normally, thermal wire-type airflow sensors cannot detect the direction of the flow. These sensors, even if the airflow travels in the reverse direction, will output the same signals as those at the time of the airflow traveling in the forward direction. Therefore, when an average airflow rate is acquired on the basis of actual measurement, reverse flow is measured in the same manner as forward flow. Consequently, the measurement can be larger than the actual average.

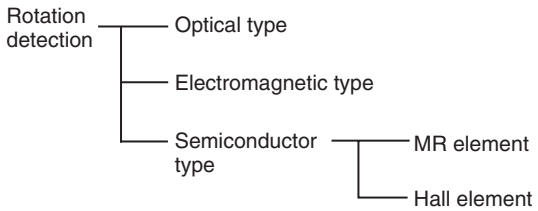
The bypass sensor type makes use of a strongpoint of fluid diodes to prevent airflow from traveling in a bypass passage in the reverse direction. As a result, the error is reduced to a half of the conventional one. To avoid the measurement error resulting from such reverse flow, you must subtract the flow rate of reverse airflow from that of the forward airflow, thus obtaining an actual flow rate. In order to take highly accurate measurements of average flow rate of the pulsating flow, including reverse direction flow, a thermal-type flow rate sensor is applied to a practical use, which acquires the direction and the flow rate of the flow at the same time. This type of sensor is described in a separate section about microelectromechanical systems (MEMS) airflow sensors (Section 6.4.7), together with semiconductor sensors.

3 ROTATION SENSOR

The purposes of rotation sensors range over various things such as detection of engine rotational angles, rotational speed of transmissions, and rotational speed of tires. In this section, examples such as crank angle sensors and cam angle rotation sensors used for the ignition timing of gasoline engines are described.

3.1 Types and principles of detection

Described below is a familiar detection method of rotation sensors.



3.2 Optical type

This is a type of rotation sensor used in the earlier days of electronic sensors. The optical type has a basic structure in which a distributor and a base component supply an ignition plug with power and the crank angles are detected with a light-emitting diode and a photodiode across a slit plate. Figure 10 shows a schematic view of its structure.

3.3 Electromagnetic type

Electromagnetic induction is used based on the detection principle. A coil and a magnet work in combination with

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto196
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

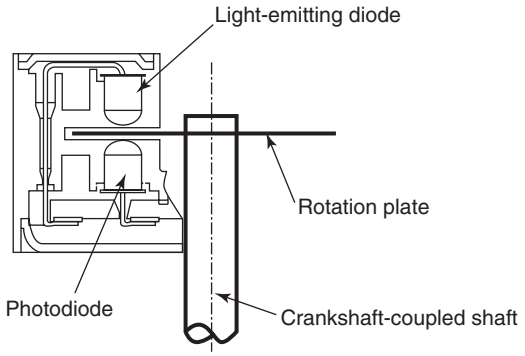


Figure 10. Optical-type rotation sensor. (Reproduced by permission of Hitachi Automotive Systems.)

each other. As a magnetism detector (gear or the like) moves, the magnetic flux varies, which enables the coil to generate electromotive force. The following equation expresses the relationship between the electromotive force and the rotational speed.

$$E = \frac{\Delta B}{L^2} \times N \times v$$

Here, E is the electromotive force, ΔB the change in the magnetic flux generated with a detection tooth, L the distance of the gap from the detection tooth, N the number of coils, and v the rotation speed of the detection tooth.

The electromagnetic type has several advantages in that the structure is simple and no power supply is necessary. There are, on the other hand, several disadvantages, for example, detection is not easy when the rotative object is standing still, the phase with respect to the rotative object varies depending on the rotational speed, and the temperature characteristics vary in a wide range.

Figures 11 and 12 show the structure and output characteristics of the electromagnetic type.

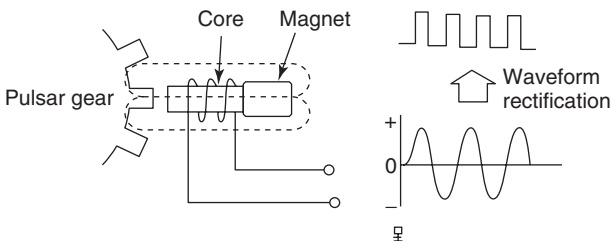

Figure 11. (a,b) Electromagnetic-type rotation sensor. (Reproduced by permission of Hitachi Automotive Systems.)

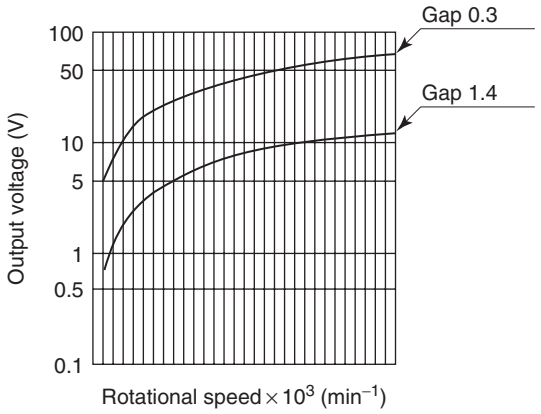

Figure 12. Output characteristics of the electromagnetic-type rotation sensor. (Reproduced by permission of Hitachi Automotive Systems.)

3.4 Semiconductor type

The advantage lies with its sensing element. MR and Hall elements are used for sensing. The mainstream applications contain one chip, which includes signal-processing circuits based on LSI (large scale integrated circuits) for compensation of temperature characteristics of elements, correction of rotation phases, and so forth.

Figure 13 shows the detection principle of a Hall element.

Figures 14 and 15 show an example of IC circuit structures (Sanken Electric Co, Ltd, 2007) and a block diagram (Sanken Electric Co, Ltd, 2007).

3.5 Structure

Rotation sensors are used in an environment where it is hot and oil is scattering. Therefore, housings are made with resin materials, which are resistant to high temperatures.

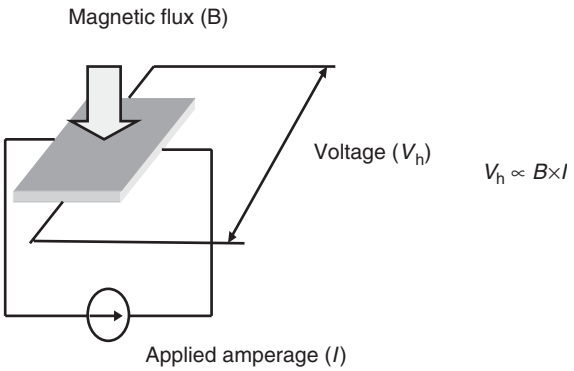

Figure 13. Detection principle of the Hall element. (Reproduced by permission of Hitachi Automotive Systems.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto196
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

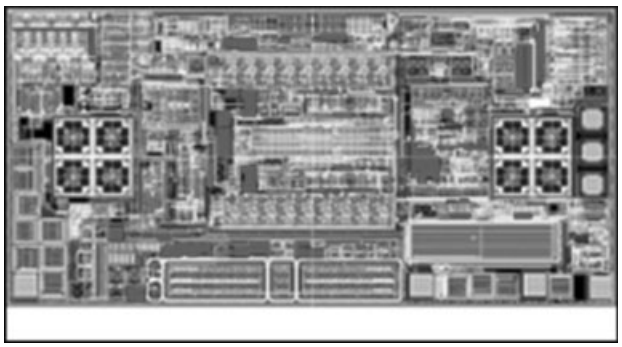

Figure 14. An example of the circuit structure of a semiconductor-type rotation sensor chip. (Reproduced by permission of Hitachi Automotive Systems.)

Figure 16. Examples of rotation sensors. (Reproduced by permission of Hitachi Automotive Systems.)

In addition, to be fit for the environment with scattering oil drops, housings are often equipped with an O-ring. Furthermore, to prevent erodent substances from infiltrating into the electronic circuit, duplicated housing structures may be formed, for example, with laser welding on interface surfaces to ensure reliability (Kato, 2010). Figure 16 shows examples of the external shapes of rotation sensors (Kato, 2010).

3.6 Characteristics of rotation sensors

Rotation sensors do not make contact with a rotating body to detect rotation. Therefore, the larger the distance (gap) from a rotating body, the more freedom is available for installing those sensors. As the distance (gap) depends on the magnetic flux density of the magnet, the sensitivity of the Hall IC, and the tooth shape of the rotating body,

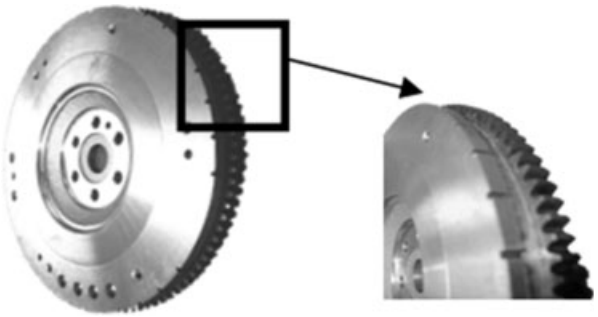

Figure 17. An example of pectinate teeth for detecting crank angles. (Reproduced by permission of Hitachi Automotive Systems.)

appropriate designs need to be made. In general, the distance (gap) is approximately 1 mm.

Figure 17 shows an example of the tooth shapes for the detection of crank angles.

4 KNOCK SENSOR

Knock sensors detect the vibration generated by abnormal combustion in a cylinder when knocking occurs in the engine. These sensors are used for engine control (ignition advance control). Knocking occurs in engines, varying depending on factors such as compression ratio, spark advance angles, fuel octane numbers, intake air temperature, humidity, or engine load. Therefore, an appropriate advance angle control needs to be performed to suppress knock generation.

4.1 Detection principle

Knock sensors use piezoelectric elements [lead zirconate titanate ($Pb(Zr, Ti)O_3$)] to detect vibration, which is subject to the piezoelectric phenomena. Knock sensors can be one of the two types: the resonance type, which has the same vibration frequency as that of the engine, and the nonresonance type, which does not have such vibration frequency. The resonance type has different resonance frequencies depending on engine types. Accordingly, the resonance of sensors needs to be adjusted for specific engine types. Nowadays, nonresonance type is in the mainstream.

4.2 Structure

To convert the vibration energy into pressure (physical force) to transmit it to piezoelectric elements, the piezoelectric elements have a structure in which appropriate weights are stacked. Its electromotive force is generated basically according to the following equation:

$$E = \alpha \times G \times W$$

Here, E is the electromotive force, α the vibration acceleration, G the piezoelectric constant, and W the mass of a weight.

When knocking occurs, the frequency is as high as 10 kHz or even higher. Consequently, the elasticity of the

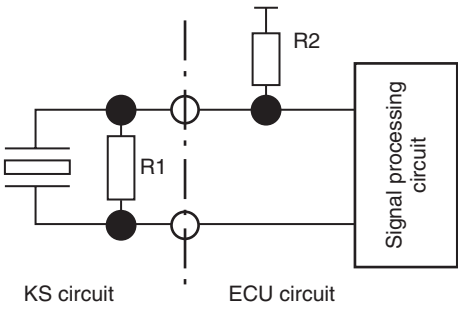

Figure 21. Electric circuit of a knocking sensor. (Reproduced by permission of Hitachi Automotive Systems.)

materials constituting the sensor tends to have an influence on that sensor. The resin material of the housing, in particular, is selected such that it does not have an influence on the frequency characteristics. Figures 18–21 show the structure and the electric circuit of a knock sensor.

5 TEMPERATURE SENSOR

The purposes of temperature sensors cover a wide range of applications such as the measurement of water temperature, engine-oil temperature, intake-air temperature, and EGR (exhaust gas recirculation) recirculating gas temperature. Temperature sensors for exhaust gas are under influence of high temperature. Therefore, platinum thermometers and thermocouples are applied.

5.1 Detection principle

To detect temperature, NTC (negative temperature coefficient)-type thermistors are mainly used. The characteristics of the thermistors depend on temperature ranges and detection sensitivity.

Thermistors vary their electric resistance exponentially with respect to temperature. Accordingly, it is necessary to make conversion into such signals that are easy for the ECU to process. In general, partial pressure circuits with series resistors (Figure 22) are widely applied. The relationship between a thermistor and the resistance is expressed by the following equation:

$$R_T = R_0 \times \exp\left\{B \times \left(\frac{1}{T} - \frac{1}{T_0}\right)\right\}$$

Here, R_T is the thermistor resistance at temperature T, R_0 the thermistor resistance at reference temperature T_0, and B a constant.

Figures 23–25 show examples of the characteristics of intake-air thermistors (Mitsubishi Materials Corporation, 2008), the characteristics of a partial pressure circuit with resistors, and its structure.

6 HUMIDITY SENSOR

6.1 Introduction

There is a growing awareness of global warming and resource saving. The endeavors for the improvement of car fuel mileage seem to be a never-ending challenge. Besides powertrain management, the energy management

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

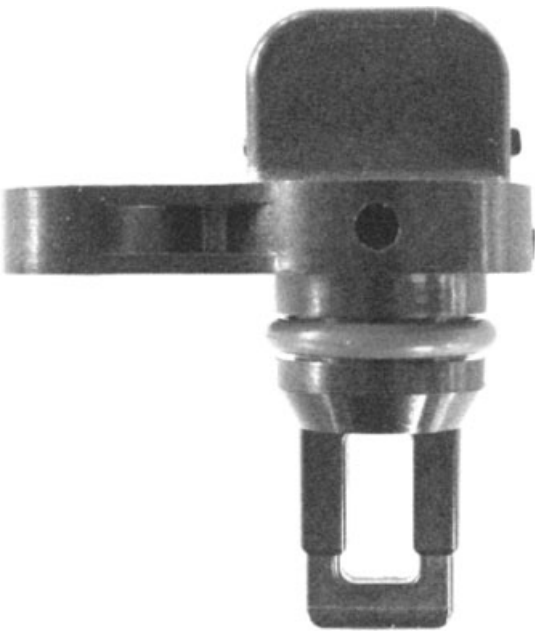

Figure 25. An example of an external view of a temperature sensor. (Reproduced by permission of Hitachi Automotive Systems.)

of air-conditioning systems and controls for minimizing front/rear glass frosting are also among the purposes of the improvement of the balance between the safety and the comfort. In recent years, more and more specific control is required for vehicles and powertrain systems. The relative humidity of the atmosphere is measured to improve the fuel mileage and reduce the cost of vehicles as well as to improve the safety and the comfort. All these efforts are picking up. In this section, we discuss the humidity sensors installed on vehicles for such purposes as mentioned earlier.

6.2 Overview of humidity sensors

Among the humidity sensors in practical use as of today, most are for the purpose of measuring the relative humidity of the atmosphere. They can be independent products or integrated with some other sensors for an application of practical use. Several major purposes are listed as follows.

6.2.1 Air-conditioning/cabin systems

Relative humidity is an important application. This is the detection of the humidity of the atmosphere let in from the outside, the humidity control in a cabin, the prevention of the front glass from being frosted (the temperature of the glass and the humidity in the cabin are detected to control dehumidification and/or rear-glass heaters before glass frost is formed), and so forth.

6.2.2 Power units and relevant components

Absolute moisture content is determined, usually to compensate the mixture ratio for moisture in the intake air to an engine. This is for ignition advance compensation/control, EGR rate control (the EGR rates that make combustion unstable will vary depending on humidity), estimation of combustion temperature, estimation of emissions of harmful substances in the exhaust (the combustion temperature varies depending on humidity, generating a different amount of harmful substances in different compositions, which are to be estimated), compensation of engine-generated torque, and so forth. Besides these, there are various purposes of use.

6.2.3 EV and so forth

A humidity sensor is disposed in a battery unit. This is for the safety management, for minimizing the energy consumed by the air conditioner system to improve the cruising range, and/or for some other purposes.

6.3 Classification of humidity sensors

In the household sector, various types of hygrometers and humidity sensors are used. In the automotive field, the humidity sensors should satisfy the requirements such as

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 3. Principles, use purposes, and characteristics of typical humidity sensors.

Classification	Principle of detection	Use purpose and characteristics
Macromolecule capacitance type	Polyimide system polymer materials have dielectric constant ε varying due to moisture absorption, forming a condenser structure. Its capacity variance is measured to detect the relative humidity	Engine control, air-conditioning systems, and so on This type is widely used in the household sector and the automotive field, providing the accuracy sufficient for the practical use in a wide temperature range. With some ingenuity in the electrode structure, some sensors are resistant to dew condensation. Others have a sensing module, temperature sensor, correction circuit, and so forth integrated on a conductor chip and are already in practical use. This type reacts to some types of volatile gases. An adequate check is necessary
Macromolecule resistor type	The wet and dry polymers with additives are coated on a pair of electrodes. The free ions from the additives vary the AC resistance, which is measured to detect the relative humidity	Air-conditioning systems This type is less costly and has made achievements in a wide range of fields in the household sector. Its accuracy in the low temperature and low humidity range, however, is not very good in general. As the characteristics vary due to dew condensation, an antimoisture coating needs to be applied, or this type should be used in an environment where dew condensation does not occur

the operation in a wide temperature range and the long-term reliability, so much so that the sensors with inherent durability are used. In addition, it is necessary for humidity sensors to be used in consideration of a variety of factors such as a waterproof structure, the availability of signals for external components, and the integration with some other functions. Table 3 lists typical humidity sensors in practical use for automobiles.

There are various kinds of forms to implement these sensors. Small ones are widely used. When absolute moisture is used in particular, it is necessary to calculate saturated vapor pressure. Therefore, you need to dispose a temperature sensor very close to a relative-humidity detecting component. Figure 26 shows several examples of automotive humidity sensors in practical use.

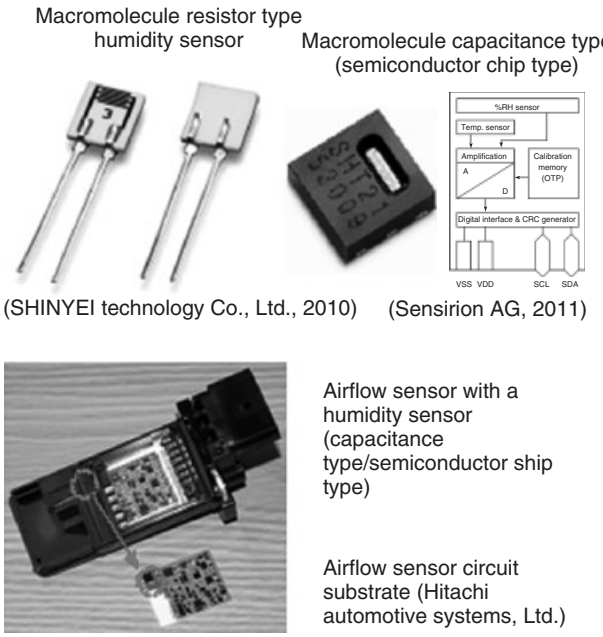

Figure 26. Examples of humidity sensors. (Reproduced by permission of Hitachi Automotive Systems.)

6.4 Characteristics of humidity sensors

For the evaluation of the performance of automotive humidity sensors, the following items, in general, can be included among the criteria.

6.4.1 Detection range of relative humidity

Normally, it is necessary to guarantee operation, in general, in the temperature range from −40 to 125°C for powertrain systems and from −40 to 85°C in a cabin. The functions should work at any temperature within these temperature ranges.

6.4.2 Accuracy of relative humidity

In the field of household products, the tolerance in the measurement of relative humidity is determined, usually, within the temperature range 20–25°C. In the field of automobile-related products, on the other hand, one needs to know the real-world tolerance across the entire temperature

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto196
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

range of the guaranteed operation. You should make use of a humidity generator or the like at low and high temperature ranges to take highly accurate measurement.

6.4.3 *Responsiveness*

An automobile can be under influence of radical temperature/humidity changes while driving and the responsiveness varies depending on the humidity. Therefore, a sufficient preparatory study of the application of a sensor is required before using it. Not only must the humidity sensor per se be considered but also the response lags caused by an antimoisture coating. Moreover, if absolute moisture is going to be acquired, the balance with the temperature sensor is important, too.

6.4.4 *Hysteresis*

Some minor amount of hysteresis is observed as a result of changes from a low humidity to a high humidity and vice versa.

6.4.5 *Over-time changes*

As macromolecules are used, the characteristics change over time, although such change is small. Automotive sensors ought to be subject to such changes only within a sufficiently limited area from a practical viewpoint.

6.4.6 *Characteristics of recovery from dew condensation or freezing*

Some sensors have an antimoisture coating, and others have detection macromolecules directly exposed. They are different in characteristics. An adequate examination of whether the characteristics change after the sensing module is under influence of dew condensation, or whether it has been frozen if the sensor has detection macromolecules exposed directly, is needed.

6.4.7 *Durability*

It is necessary to adequately assess whether the sensor is resistant to various types of gasses and chemicals that could be generated in the automotive environment such as high temperature and high humidity, thermal shock, vibration, temperature cycles, dew condensation, and exhaust gas durability.

6.4.8 *Miscellaneous*

When it is necessary to acquire the amount of moisture, for example, for the calculation of the dew point or the mixture ratio, the temperature around a humidity sensor is extremely important. Therefore, a thermometer is normally disposed in the vicinity of the humidity sensor. Particularly, when the temperature is high, attention should be paid to the accuracy of the temperature sensor and where the temperature sensor should be located as well as the accuracy of the humidity sensor.

7 COMBINED INERTIA SENSOR (ACCELERATION AND ANGULAR RATE SENSOR)

7.1 Outline and application of sensors

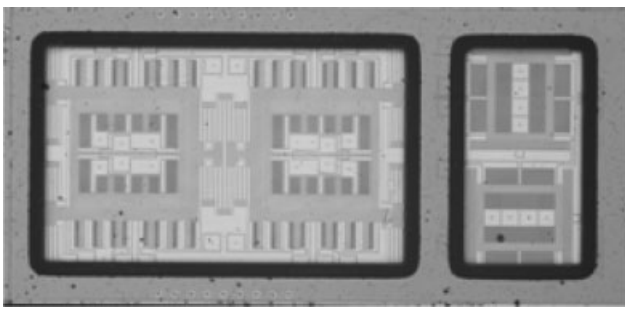
Combined inertia sensors take measurement of angular rate (rotation) and acceleration. These sensors have been already applied in some considerable amount to those systems that prevent vehicle skids. In the future, it is expected that the field of application will be expanding to such fields as suspension and rollover controls.

The MEMS semiconductor micromachining technology is used to integrate angular rate sensors and acceleration sensors on one SOI (silicon on insulator) substrate in two or more parts (Figure 27).

7.2 Principles of operation

7.2.1 *Angular rate sensor*

Figure 28 shows the operation principle of the angular rate sensor. Drive force F_d is generated by the electrostatic



(a) Angular rate sensor (b) Acceleration sensor module

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

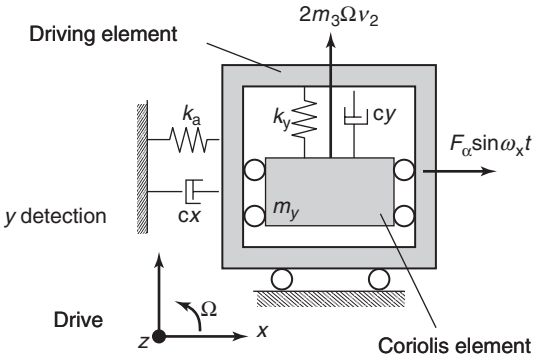

Figure 28. Operation principle of the angular rate sensor. (Reproduced by permission of Hitachi Automotive Systems.)

force. It excites the driving element in the drive direction (in the *x* direction). At this time, as the driving element is excited, the Coriolis element, which is connected with the driving element by the spring, starts to vibrate, too. While this is happening, an angular velocity around the *z*-axis is added. The Coriolis force is generated in the driving element being vibrated and the Coriolis element in the detecting direction (in the *y*-axis direction) orthogonal to the drive direction (in the *x*-axis direction) and the axis with the angular rate impressed (to the *z*-axis). As a result, the Coriolis element shifts itself in the detecting direction (in the *y*-axis direction) in proportion to the degree of the impressed angular velocity. The distance of such shift is detected as the variance in capacitance. As this variance is output as a signal, the impressed angular rate is detected (Hayashi, 2009).

7.2.2 Acceleration sensor

Figure 29 shows the operation principle of the acceleration sensor. As the acceleration is added, moving part m_y shifts. Two differential capacitance detection electrodes C1 and C2, disposed in the detecting direction, change their capacitances. Such change is output as an electric signal representing the acceleration.

7.3 Signal processing circuit

Figure 30 shows the constitution of a signal processing circuit. The MEMS element, connected with the analog end of the signal processing circuit, sends a signal, which is converted into a digital signal by the ΔΣ converter. This signal is processed by the Digital Signal Processor (DSP) for synchronous detection and feedback (Jeong, 2011).

7.4 Structure

Combined inertia sensors are installed in various places such as the inside of an engine compartment or the inside of a passenger compartment. Therefore, depending on the location in the vehicle, their structures are selected for implementation, for example, from ceramic packages, plastic packages, and transfer mold packages (Figure 31).

8 CONCLUSION

Sensors and sensing technologies, which have been developed and improved over long period of time, are now essential elements for improving the performance, safety, and

environmental compatibility of automobiles. New sensing technologies that add new functions to automobiles, new sensor structures that realize sensor cost reductions, and new sensor usages that improve the performance of automobiles will be developed continuously in the future.

1 MEMS AIRFLOW SENSOR

1.1 Introduction of MEMS airflow sensor

From the point of view of global environmental conservation, the regulations on automotive emission reduction are getting stricter year by year. To comply with such strict regulations, it is essential to make the air fuel ratio control highly accurate. It is required to take highly accurate and reliable measurement of intake air rate in a wide measurement range (Sasayama, 1997; Ishikawa, 2006).

In recent years, the emission regulations have been enhanced, and improved fuel mileage is wanted. Under these circumstances, DI (direct injection) systems, in which the fuel is directly injected into cylinders, are being applied. So are diesel engines, variable displacement functions, and so forth. Accordingly, a larger number of engines are coming up with larger pulsations in the intake air, thus letting the intake air flow back into the intake port. Such pulsating flow can be extreme. The flow rate of the air coming into a cylinder needs to be measured accurately. Thermal wire type airflow sensors, however, cannot adequately detect the direction of airflow. It was, therefore, necessary to develop the MEMS (microelectromechanical system) airflow sensor to make possible accurate measurement of intake airflow rate with such reverse flows and extreme pulsating flows (Figure 1) (Hayashi, 2009; Matsumoto, 2010).

1.2 Principles of the MEMS airflow sensor

The MEMS airflow sensor has a diaphragm structure formed by etching the rear surface of a silicon substrate. On this diaphragm, a heater resistor and, at both sides of the heater resistor, two temperature sensor resistors are disposed. The power is supplied to the heater to heat and control it to a certain temperature. The amount of heat emission and distribution to the air, and to the sensors on both sides, depends on the airflow rate. This is the principle utilized. The heater resistor and the temperature sensor resistors are treated as extremely thin diaphragms of several micrometers. Their heat capacities are so small that high speed response, with the response time of several milliseconds, is made possible.

Figure 2 shows the principle of the airflow rate detection. When no air current is coming, the temperature distribution on the silicon diaphragm makes a line symmetry image with the heater as the axis. When an air current occurs, the temperature at the downstream temperature sensor increases as much as ΔT, depending on the direction and the flow rate of the air current.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto197
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

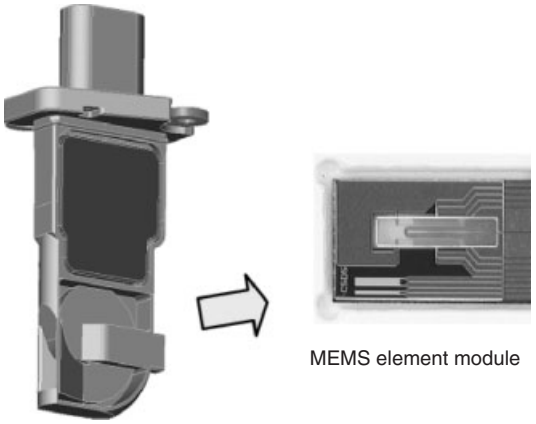

Figure 1. External view of a MEMS airflow sensor.

If a reverse flow occurs, the temperature at the upstream temperature sensor increases by ΔT. Temperature difference ΔT is determined based on the difference in the resistances between the two temperature sensors disposed on both sides of the heater, thus making it possible to acquire the flow rate and the direction. This temperature difference ΔT is processed with the constant temperature difference bridge circuit and the temperature difference detecting circuit and, thereby, is converted into a signal corresponding to the flow rate.

The heater and the temperature detection resistors are made with metal films such as platinum or polysilicon membrane. Figure 3 shows an example of sensing elements made with polysilicon membrane. The upper and lower sides are covered with the polysilicon membrane and the oxide films with excellent adhesive properties. Furthermore, to prevent moisture intrusion, the silicon nitride membrane is deposited in this structure.

1.3 Manufacturing processes of the MEMS airflow sensor

Figure 4 illustrates several manufacturing processes of a sensing element. To manufacture a sensing element, a monocrystal silicon substrate is covered with the silicon nitride membrane, the oxide film, and the polysilicon membrane in a prescribed order. The polysilicon membrane is treated in the patterning process to form the heater and the temperature sensors. On top of that, the oxide film, the silicon nitride membrane, and the polyimide membrane

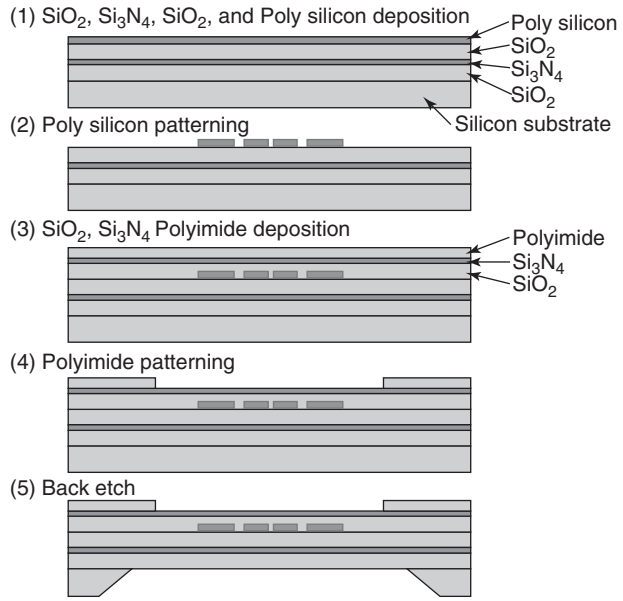

Figure 4. Manufacturing processes of a sensing element.

are formed. The polyimide membrane on the heater and the temperature sensors is removed. Then, the rear surface of the monocrystal silicon substrate is removed by alkali etching or the like. Thus, a diaphragm is formed with the thin films that provide excellent thermal insulation.

1.4 Possible problems and preventive actions for automotive application

1.4.1 Protection against floating foreign substances

The sensing elements of MEMS airflow sensors have a thin film structure. It is important to protect the thin films when a MEMS airflow sensor is applied to an automotive engine.

The intake air flowing into an automotive engine contains dust, rain drops if it is raining, oil evaporating from the engine, and the like, which are all accelerated with

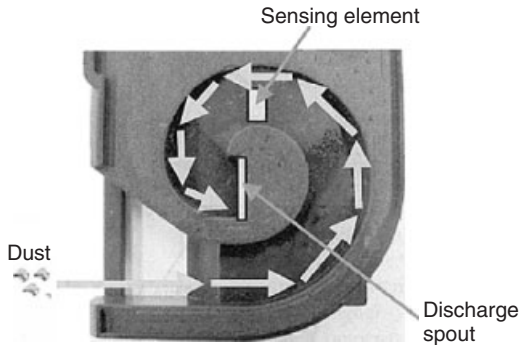

Figure 5. Structure of a cyclone type bypass passage.

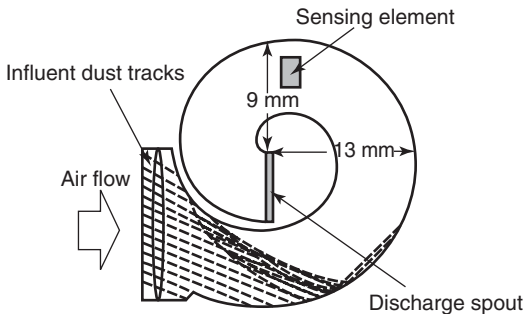

Figure 6. An example of particle tracking simulations of the dust.

the air current. The sensing element should be protected against these substances. To protect the sensing element, in particular, from the dust accelerated with the airflow, a bypass passage structure such as the one shown in Figure 5 is adopted.

This bypass passage is in the shape of a spiral. The dust accelerated with the airflow will be separated by the centrifugal force. Consequently, the dust flows along the wall of the bypass passage. As disposed in a position distant from the wall, the sensing element is free from collision with the dust.

Figure 6 shows an example of the result of particle tracking simulation of the dust. The dust is 10 μm in diameter and is accelerated to 50 m/s. In this simulation, the airflow of 50 m/s was generated around the bypass passage shown in Figure 5. Then, the speed distribution of the airflow inside and outside the bypass was acquired with fluid simulation. Finally, a plurality of tracks of the dust currents in the airflow was obtained.

The result of this tracking simulation shows that the dust, having flowed into the bypass passage, traveled to the wall of the bypass passage. The dust, when getting closer to the sensing element, traveled only along the wall. After this, the dust flowed out of the vent to the outside.

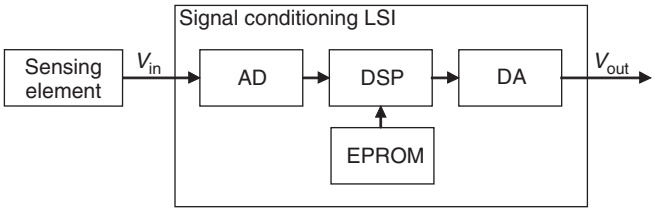

Figure 7. Signal processing LSI.

1.4.2 Catching up with high precision

The MEMS element makes fast responses and has a function to detect reverse flows. Furthermore, the element shows high affinity with semiconductor processes. Besides the conventional technologies for analog circuits, mixed signal technologies have been advancing in combination with digital technologies.

Figure 7 shows an example of implementation of a signal processing LSI. This LSI converts externally input signals provided from the sensing module into digital signals using the AD (analog-to-digital) converter. The individual adjustment information of each sensor is stored in the EPROM (erasable programmable read-only memory). On the basis of this information, the DSP (digital signal processor) makes digital calculation. Finally, the DA (digital-to-analog) converter outputs analog voltage out of this structure. In addition, the DSP has a built-in function that can compensate complex error curves provided from the sensing module.

Moreover, the MEMS type element, which has a fast response and is capable of detecting reverse currents, and the digital signal processing technology can be combined to make possible the compensation for the reverse current errors generated with pulsating flow.

Figure 8 shows the characteristics of the MEMS airflow sensor in the flow range of reverse currents. It is understood that the actual air pulsations are detected more accurately than those detected by the conventional thermal wire type under the conditions that generate reverse currents.

MEMS airflow sensors are manufactured with the semiconductor-manufacturing processes. This can be an advantage firstly because it is possible to make the sensors compact and secondly because these processes are highly suitable for mass production. At this moment, an accurate air fuel ratio controlling technology is under development, in which, besides airflow rate, EGR (exhaust gas recirculation) flow rate is measured and a plurality of information sources are utilized such as pressure sensors and open throttle angle sensors.

It is expected that the sensors will be made more compact and more intelligent with digital signal processing in the future. Besides these, it is also expected that they be going to be more accurate and have more functions.

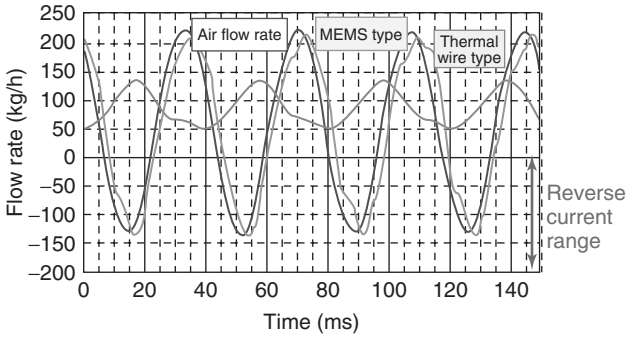

Figure 8. Flow rate characteristics of the thermal wire type sensor and the MEMS type sensor.

2 SEMICONDUCTOR PRESSURE SENSORS

2.1 Introduction of semiconductor pressure sensors

When electronic control began to be used in respect to automobiles, semiconductor pressure sensors were used as absolute pressure sensors at an intake manifold to control combustion in engines. Since then, a wide range of use has been seen in the middle pressure area such as hydraulic pressure applications including transmissions and suspensions, in the low pressure area that detects vaporized gasoline, and in the high pressure area in which fuel pressures are measured from gasoline DI engines and diesel common rail fuel injection systems (Sasayama, 1997; Kato, 2010).

This section describes the purposes of semiconductor pressure sensors as well as their technologies.

2.2 Purposes of semiconductor pressure sensors

Figure 9 shows some purposes of semiconductor pressure sensors.

The negative pressure of an intake manifold is measured to calculate the airflow, and thus control an appropriate mixture ratio with the gasoline. In these processes, the intake pressure is used. Furthermore, the intake pressure is also used for the measurement of boost pressure of turbo engines. Moreover, there are also such pressure sensors that can be integrated with temperature sensors.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto197
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

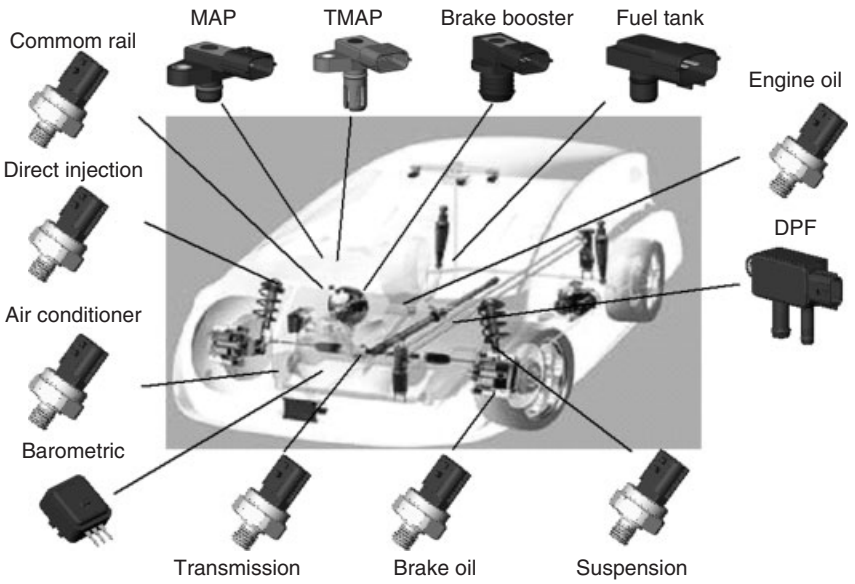

Figure 9. Purposes of semiconductor pressure sensors.

Atmospheric pressure sensors correct the air pressure during driving at high altitudes to control engine combustion to an optimal level.

The negative pressure in a brake booster is measured to acquire a brake booster pressure. In recent years, in particular, the brake booster pressure is used to control restarting an engine in an engine with stop/start capability.

The tank pressure was introduced with OBDII (on-board diagnostic II) to monitor the leakage of vaporized gasoline.

The oil pressure is used to take measurement of transmissions, engine oil, suspensions, and brake oil.

The fuel pressure is used to measure the pressure on the fuel for injecting gasoline directly into an engine as well as the pressure of the fuel for a common rail fuel injection system of a diesel engine.

Besides these, sensors are used for exhaust pressure, clog detection of diesel particulate filters on diesel engines, coolant pressure of air conditioners, and so forth.

Figure 10 shows the interrelations between some purposes and usable pressure ranges of semiconductor pressure sensors.

The pressure covers as wide a range as 5 kPa to 200 MPa.

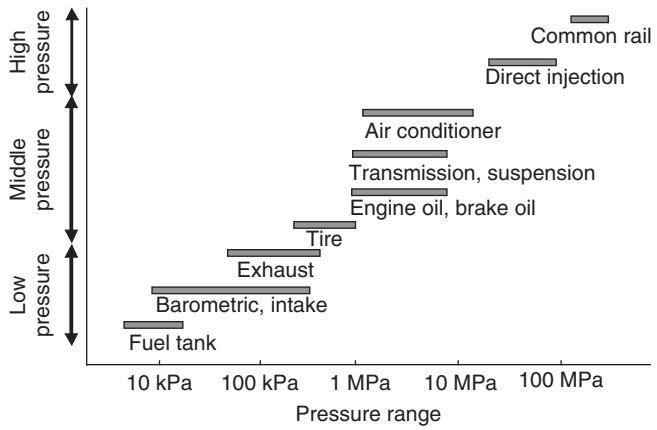

Figure 10. Purposes and usable pressure range.

2.3 Overview of pressure sensors

Semiconductor pressure sensors make use of the excellent characteristics of silicone for the elastic body. They, with micromachining technologies, form a thin film called a *diaphragm*, enabling the elements to convert pressure changes into electric signals.

Semiconductor pressure sensors are based on detection principles that can be generally classified into a piezo-resistor type and a capacitance type.

Figure 11 compares the detection principles of pressure sensors.

2.3.1 Detection principles

2.3.1.1 Piezo-resistor pressure sensors. Figure 12 shows the principle of piezo-resistor type pressure sensors. There is a diaphragm at the center of a silicon monocrystal. The diaphragm is formed thin in this structure, in a part of which a piezo-resistor gauge is spread and formed.

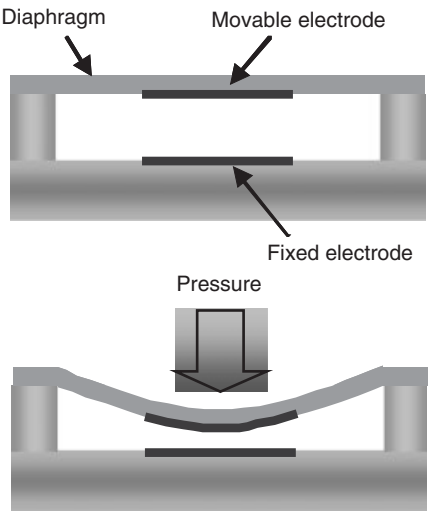

Figure 13. Detection principle of a capacitance type (Saito, 2009). (Reproduced with permission from CMC Publishing, Ltd.)

When some pressure is applied on the diaphragm, the strain generates stress (σ), causing resistance change (ΔR) to the gauge resistor.

$$\Delta R = \frac{1}{2} \bullet R \bullet \Delta\sigma \bullet \pi$$

ΔR resistance change to the gauge resistor
R initial gauge resistance
$\Delta\sigma$ stress generated in the gauge
π piezo-resistor coefficient.

A Wheatstone bridge output is expressed by the following equation:

$$\mathrm{Vo} = \frac{(Ra \bullet Rd) - (Rb \bullet Rc)}{Ra + Rb + Rc + Rd} \bullet I$$

Accordingly, the voltage signals are output in proportion to voltage.

2.3.1.2 Capacitance type pressure sensors. Figure 13 shows the detection principle of the pressure sensors of capacitance types. A silicon diaphragm is used as a movable electrode. On an insulated substrate, two opposing electrodes are formed in this structure.

When pressure is applied on the diaphragm, the shape and position of the diaphragm are transformed.

$$w = k \bullet P$$

w transformation of the diaphragm
k pressure/transformation coefficient of the diaphragm
P pressure.

The relationship between capacity variance ΔC and transformation w is expressed by the following equation:

$$\frac{\Delta C}{2C} = \frac{w}{d}$$

d electrode aperture

$$P = \frac{d}{k} \bullet \frac{\Delta C}{2C}$$

From the two equations above, the relationship between pressure P and capacitance variance ΔC is expressed by the following equation:

If this variance in the capacitance is converted into a change of voltage, voltage signals are output in accordance with pressure.

2.3.2 *Processing circuit*

Piezo-resistor type signal processing circuits consist of a temperature compensation circuit, an adjustment circuit, and an electric noise protection circuit.

In this section, we discuss temperature compensation circuits and adjustment circuits. A bridge is constituted with a P type Si piezo-resistor element, which is as impure as $10^{20}/\mathrm{cm}^3$. Here is the reason. The P type Si resistor of this density has a positive temperature coefficient. On the other hand, the piezo-resistor coefficient (π), which determines the sensitivity, has the negative temperature characteristics; that is, the coefficient decreases as the temperature rises. These characteristics are used to form a self-temperature compensation circuit. The principle figure of a self-temperature compensation circuit and adjustment circuit is shown in Figure 14.

The error characteristics of pressure sensors include the primary element errors such as offset voltage, temperature characteristics of the offset voltage, sensitivity, and temperature characteristics of the sensitivity as well as the secondary element errors such as nonlinearity of the temperature characteristics offset voltage, nonlinearity of the temperature characteristics of sensitivity, and nonlinearity of pressure characteristics. There are several methods to correct and reduce these errors in circuits; for example, (i) a method of using a laser to trim a thin film resistor and (ii) an electric trim method that uses an EPROM.

In the early days of commercialization, the gauge and the circuits, which formed an amplifier circuit and an adjustment circuit, were separately constituted. After that, the gauge was integrated with the circuits when those sensors were productionized later. Currently, the technology for integration of semiconductor circuits is in full use

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

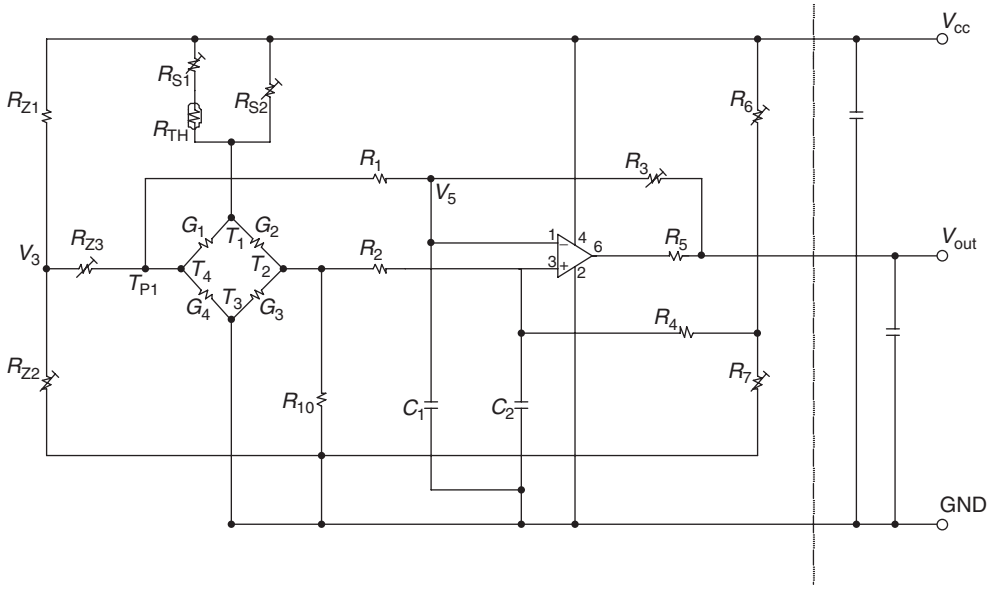

Figure 14. The principle of self-temperature compensation circuits.

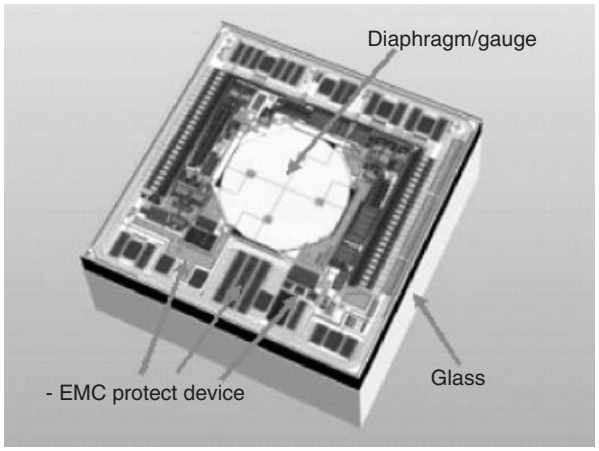

Figure 15. An example of integrated pressure sensors (Saito, 2009). (Reproduced with permission from CMC Publishing, Ltd.)

for small-sizing, cost cutting, and high reliability. Consequently, an EMC (electromagnetic compatibility) protection circuit is also integrated on one chip.

Figure 15 shows an example of integrated pressure sensors.

2.3.3 Production processes

Figure 16 shows an example of the production process flow of integrated pressure sensors (one-chip type).

2.3.3.1 Circuit formation process. The gauge resistor and the circuit elements are spread and formed. The electrodes are formed by evaporation. Furthermore, a passivation film is formed as a protection film.

2.3.3.2 Rear side polishing process. The rear side of the wafer is mirror-finished in the back grind process and the polish process.

2.3.3.3 Diaphragm formation process. Wet etching and/or plasma etching are used to process a concave cross section and to form a diaphragm.

2.3.3.4 Vacuum base chamber formation process. The electrostatic bonding is used to bond the silicon wafer and the glass wafer and thus to form a vacuum base chamber.

Figure 17 shows the principle of electrostatic bonding.

In the electrostatic bonding, a voltage is applied on the silicon and the glass. As the Na ion in the glass transfers, the electric charge moves. The glass in the vicinity of the silicon interface loses Na from its layer. Thus, the glass and the silicon bond to each other.

2.3.4 On-board installation (packaging) and types

In this section, we discuss typical intake pressure sensors and common rail pressure sensors.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto197
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

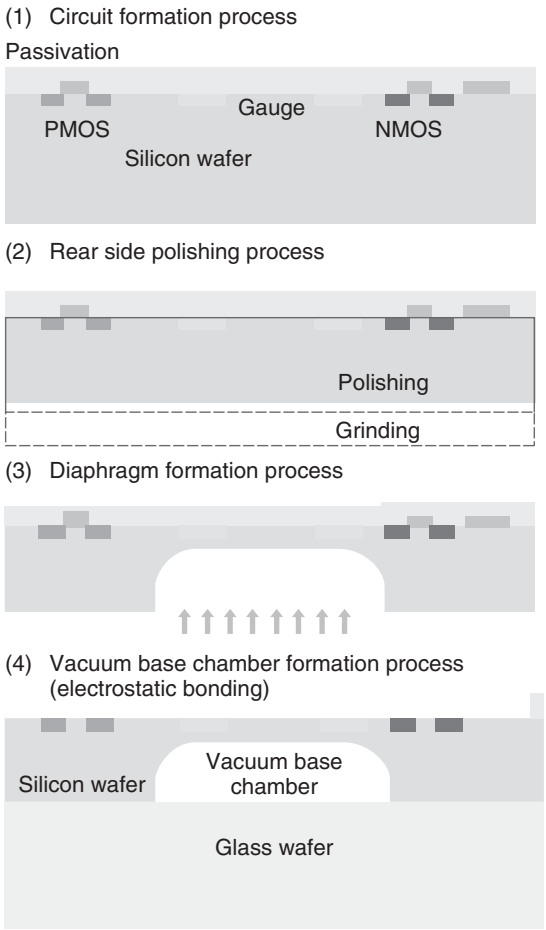

Figure 16. Production process flow (Saito, 2009). (Reproduced with permission from CMC Publishing, Ltd.)

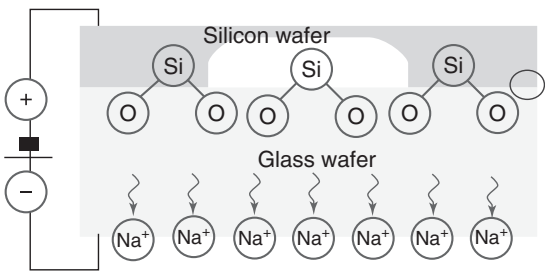

Figure 17. Principle of electrostatic bonding (Saito, 2009). (Reproduced with permission from CMC Publishing, Ltd.)

2.3.4.1 Intake pressure sensors. Figure 18 shows the structure and a picture of an intake pressure sensor of a surface pressure receiving type.

Intake pressure sensors form a sensor module for sensing pressure, a pressure guide module, and a connector. The sensor module is held by the housing and is fastened and air-sealed by the encapsulant. In addition, an O-ring ensures the air-tightness with the intake manifold in this structure.

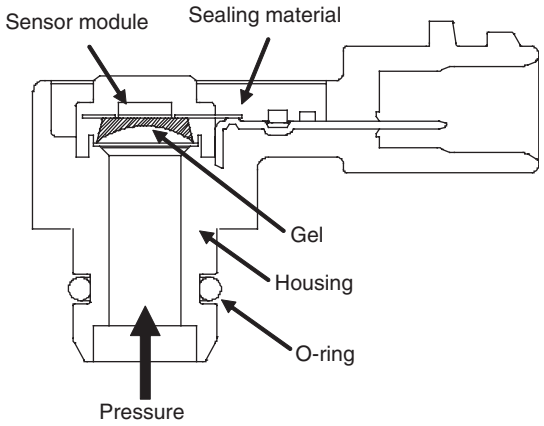

Figure 18. Structure of an intake pressure sensor.

As this is a surface pressure receiving type, the surface of the sensor chip may be directly in contact with foreign substances. This is why the sensor chip is covered with a gel material in this structure. The gel material protects the sensor chip against foreign substances included in a pressure medium. The gel material is made of such raw materials that have high elasticity (or low elastic modules) in order to minimize the stress to the diaphragm.

Furthermore, these materials have excellent chemical-resistant characteristics.

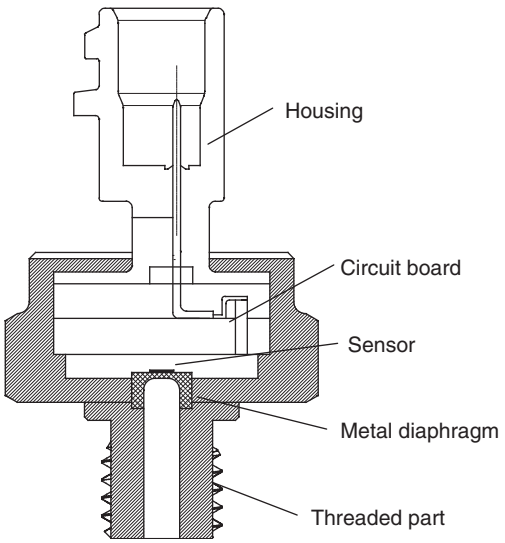

Figure 19. Structure of a common rail pressure sensor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto197
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.3.4.2 Common rail pressure sensor. Figure 19 shows the structure of a common rail pressure sensor. The pressure medium (fuel) for the super high pressure of 200 MPa receives the pressure directly with the thin wall metal diaphragm. The metal diaphragm and the threaded part are fixed by welding. To detect the pressure, the stress generated to the thin wall metal diaphragm is sensed by the Si piezo-resistor element connected on the diaphragm.

3 CONCLUSION

MEMS airflow sensors and semiconductor pressure sensors are already widely used in automotive applications. Moreover, the increase in demands for MEMS airflow sensors with high performances is expected because of the increase in needs for the accurate measurement of the intake airflow volume for increasing performance of automotive engines. On the other hand, the semiconductor pressure sensors will be used in a wider range of applications because of their high applicability to various systems for improving fuel mileage, emission reduction, and the safety in automobiles. Moreover, multifunctional sensors integrating a plurality of sensing functions, such as airflow, pressure, and humidity sensing functions, will be in greater demand in the future.

Advics Co., Ltd, Kariya, Japan

1 INTRODUCTION

Brake control systems experienced a rapid evolution in the 1970s with antilock brake system (ABS) as a technology to improve automotive active safety. ABS technology prevents wheels from locking and maintains vehicle steerability and stability under braking conditions. ABS was followed by traction control system (TCS), which prevents wheel spin at start-up or acceleration, and then electronic stability control (ESC) system, which prevents vehicle instability because of abrupt steering. Additional features, such as adaptive cruise control (ACC), use the ESC pressure control and have been widely adopted. In addition, brake pressure control plays an important role not only in active safety but also in regenerative brake coordination. This is an important technology for gas-mileage improvement of ecologically friendly cars such as hybrid and pure electric vehicles (EVs). This chapter describes the configuration of the sensors; electronic control unit (ECU); actuator; and control of ABS, ESC, and regenerative braking systems as a new technology.

2 ANTILOCK BRAKE SYSTEM

ABS prevents wheels from locking to maintain optimum brake force during abrupt braking or on slippery road surfaces. It also aids vehicle stability and steerability by maintaining cornering force.

Equation 1 shows the relationship among the slip rate (S), coefficient of friction (μ) between the tire and road surface, and cornering force, which are ABS control standards. The maximum coefficient of friction is obtained when the slip rate is approximately 20%. When the slip rate is 100%, wheels are in the locked state and cornering force is close to zero. The less cornering force there is, the more stability and steerability become deteriorated. In order to maintain sufficient brake force, control, and stability, it is necessary to control the brake hydraulic pressure of each wheel so that the slip rate is approximately 20%.

$$\text{ABS slip rate } (S) = \frac{\text{Vehicle speed} - \text{Wheel speed}}{\text{Vehicle speed}} \times 100\% \quad (1)$$

2.1 System

The basic system configuration of ABS is shown in Figure 1. Generally, ABS is comprised of four-wheel speed sensors provided for each wheel, ECU, and brake actuators. The integrated configuration of the ECU and actuators is largely industry-wide. In the case of four-wheel drive vehicles, they may include a longitudinal acceleration sensor to make the vehicle speed more accurate. The incorporation of a longitudinal acceleration sensor into the ECU has recently

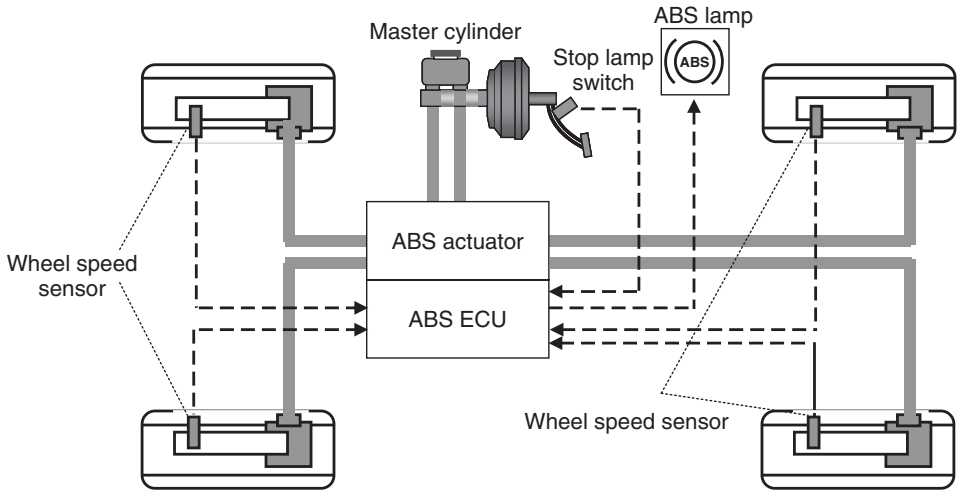

Figure 1. Example of ABS system configuration.

increased. The ECU judges the slip condition of each wheel from the input wheel speed sensor signal and uses the actuators to control the brake hydraulic pressure of each wheel.

2.2 Electronic control unit

A typical ECU configuration in the ABS is shown in Figure 2. It is mainly comprised of a CPU (central processing unit), which performs operations; an ABS interface IC, which performs inputs and outputs; a motor relay, which drives the motor; a solenoid relay, which supplies or cuts off power to the solenoid; a CAN (controller area network) driver, which drives the lamp; and an EEPROM (electrically erasable programmable read-only memory), nonvolatile memory. The mainstream CPU is usually a 16- or 32-bit microcomputer. The ABS interface IC controls the basic system inputs and outputs. It monitors wheel speed sensor signals and controls the solenoid outputs to the actuator. The motor relay is a semiconductor relay to drive the motor, and the solenoid relay is a fail-safe relay to cut off the power to the solenoid. The driver is notified of a system error by the illumination of a warning lamp. The lamp is

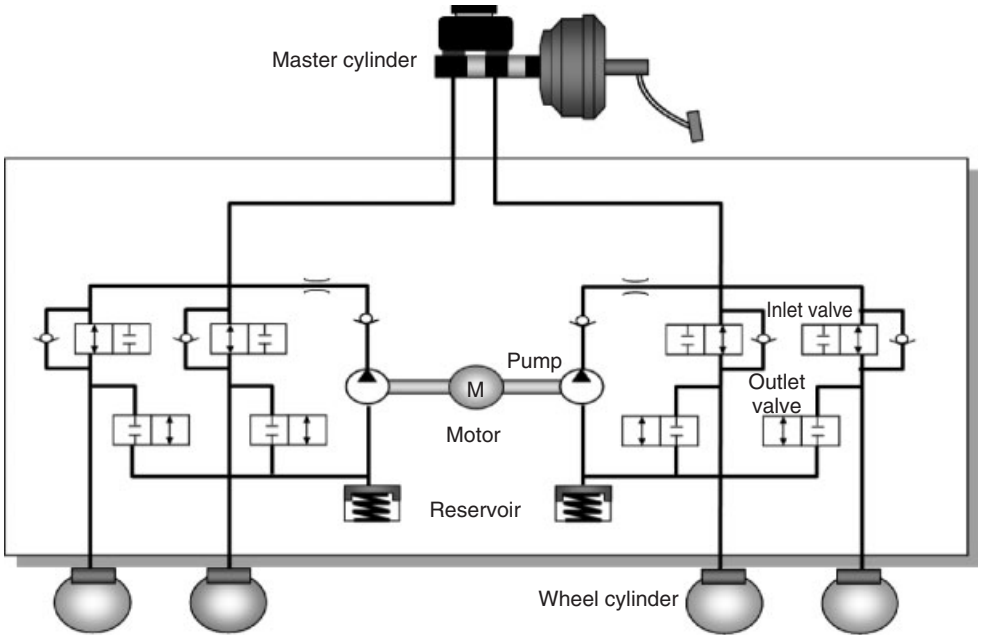

Figure 3. Example of ABS hydraulic circuit—ADVICS "ADS-A2."

controlled electronically by the instrument cluster or meter ECU. The ABS–ECU and meter ECU use CAN communication to report the system status. Failure information is stored in the EEPROM to avoid its loss even if the ignition switch is turned off.

2.3 Sensors

The wheel speed sensor is a sensor that detects the wheel rotational speed. It detects the speed of the rotor rotating in synchronization with the wheel by the electromagnetic pickup system and converts it to a voltage as an input to the ECU. Use of a hall element in the semiconductor system is now industry-wide.

The acceleration sensor is a sensor that detects the vehicle longitudinal acceleration. In the early years of ABS, a pendulum optical switch, mercury switch, and other types of sensors were used. A semiconductor system that can linearly detect vehicle acceleration is now the industry standard.

2.4 Actuator

The ABS actuator is an equipment that adjusts the brake hydraulic pressure of wheel cylinders according to the control command from ABS–ECU. The actuator has various configurations, and one example of the hydraulic circuit is shown in Figure 3. Each wheel has two solenoid valves (inlet valve and outlet valve). Three hydraulic patterns (apply, hold, and release) are created through on/off driving of those solenoid valves to control the brake hydraulic pressure of the wheel cylinder on each wheel. In the case of release, brake fluid is stored in the reservoir and pumped up from the reservoir to the master cylinder by running the motor. Recently, the common system has reduced noise, vibration, and harshness during ABS operation by performing motor speed control or solenoid valve current control.

2.5 Basic control of ABS

ABS control is performed by using individual wheel speed and wheel acceleration. This is obtained using the signal from the wheel speed sensors. These wheel speed sensors are also used to estimate the vehicle speed. An overview of ABS control is shown in Figure 4.

When the brake pedal is pressed, the hydraulic pressure in the wheel cylinder is increased, thus decreasing the wheel speed and increasing the slip rate. The wheels tend to lock abruptly when the slip rate exceeds the maximum coefficient of friction. The slip rate causing the wheel lock is continuously monitored using the wheel speed or wheel acceleration, and then the hydraulic pressure is released accordingly. The slip rate of the wheel speed or wheel acceleration is further monitored in order to avoid excessive release and the process is optimized by switching between hold and release judgment.

DOI: 10.1002/9781118354179.auto200
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

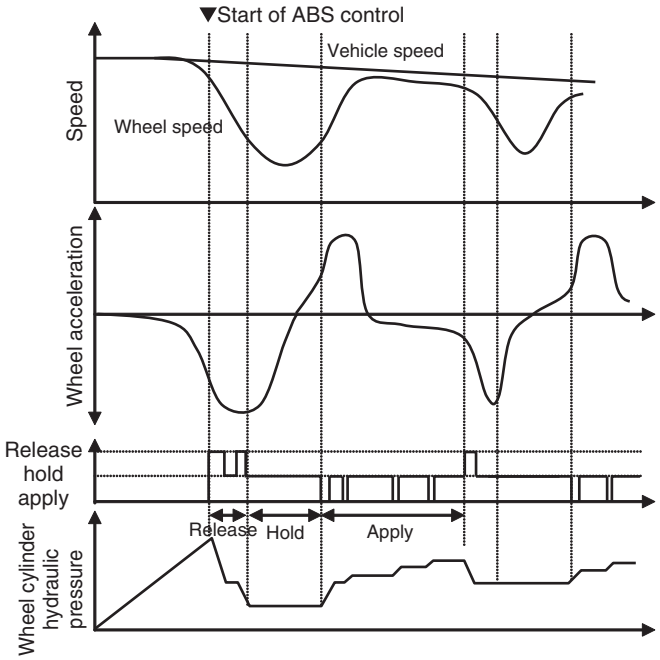

Figure 4. Overview of ABS control.

As the wheel speed increases and the slip rate decreases, a command is given to immediately apply brake hydraulic pressure to the wheel cylinders. When a sufficient hydraulic brake pressure is restored, the pressure pattern is switched to a relatively slow increase. Thus, high brake hydraulic pressure is maintained on the wheel. The above process is repeated to provide sufficient brake force and maintain stability and steerability of vehicle during braking.

The tendency of a wheel to lock differs on rough road surfaces such as gravel, dirt roads, potholes, manholes, and snowpacked roads. To avoid ABS malfunction on these road types, appropriate measures are taken for the calculation of slip rates of wheel speeds and wheel accelerations used in the judgment of wheel lock.

2.6 ABS application control

Electronic brake force distribution (EBD) is an ABS application function that controls the hydraulic pressure on rear wheels using the ABS actuator. Brake force distribution varies in cases of different loading conditions and because of a longitudinal load shift while braking. This causes an increased wheel slip on the rear wheels compared to the front wheels and results in vehicle instability. Brake hydraulic pressure on rear wheels used to be limited to the ideal brake force distribution by using a proportioning valve. These were replaced by EBD with the installation of ABS units.

EBD starts on the rear wheels with smaller amount of wheel slip than ABS. Stability of the vehicle is maintained by temporarily holding the brake pressure of the rear wheels. The hydraulic pressure on the rear wheels is thus controlled to limit the rear-wheel slip. Sufficient brake pressure is reapplied while continuously monitoring the rear-wheel slip. Intermediate pressure increase is performed during holds, considering the pedal feeling. The hydraulic pressure on the rear wheel can be reduced if the amount of slip increases excessively (Figure 5).

3 ELECTRONIC STABILITY CONTROL

Vehicles corner according to the driver's steering operation under normal conditions. However, a rear-wheel skid (oversteer) or front-wheel skid (understeer) may occur because of a sudden change in the road surface condition or sudden operations such as emergency avoidance (Figure 6).

The ESC detects vehicle behavior by various sensors such as the yaw rate sensor, steering angle sensor, longitudinal acceleration sensor, and lateral acceleration sensor. Skids are controlled to maintain vehicle stability by controlling the hydraulic pressure of each wheel and engine torque.

Analysis of data, both domestically and abroad, has shown a significant reduction in vehicle accidents among vehicles that have ESC systems installed. The benefits of ESC have become clear and it is a safety system that should be promoted for a safe automotive society. The installation of ESC has become mandatory in various parts of the world and its use has progressed rapidly.

Each vehicle manufacturer refers to ESC in its own way [ESP (electronic stability program), VDC (vehicle dynamic control), VSC (vehicle stability control), VSA (vehicle stability assist), etc.], but this chapter refers to it only as ESC.

3.1 System

An example of the ESC system configuration is shown in Figure 7.

The ESC system includes many sensors such as those which detect vehicle behavior (yaw rate sensor, longitudinal and lateral acceleration sensors) and those which detect a driver's operation (steering angle sensor, brake pressure sensor), in addition to each wheel speed sensor equipped with the ABS system. The ECU controls the brake actuator, which can automatically distribute brake pressure for four-wheel independent control. The ESC–ECU communicates with engine and meter ECUs on a vehicle

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

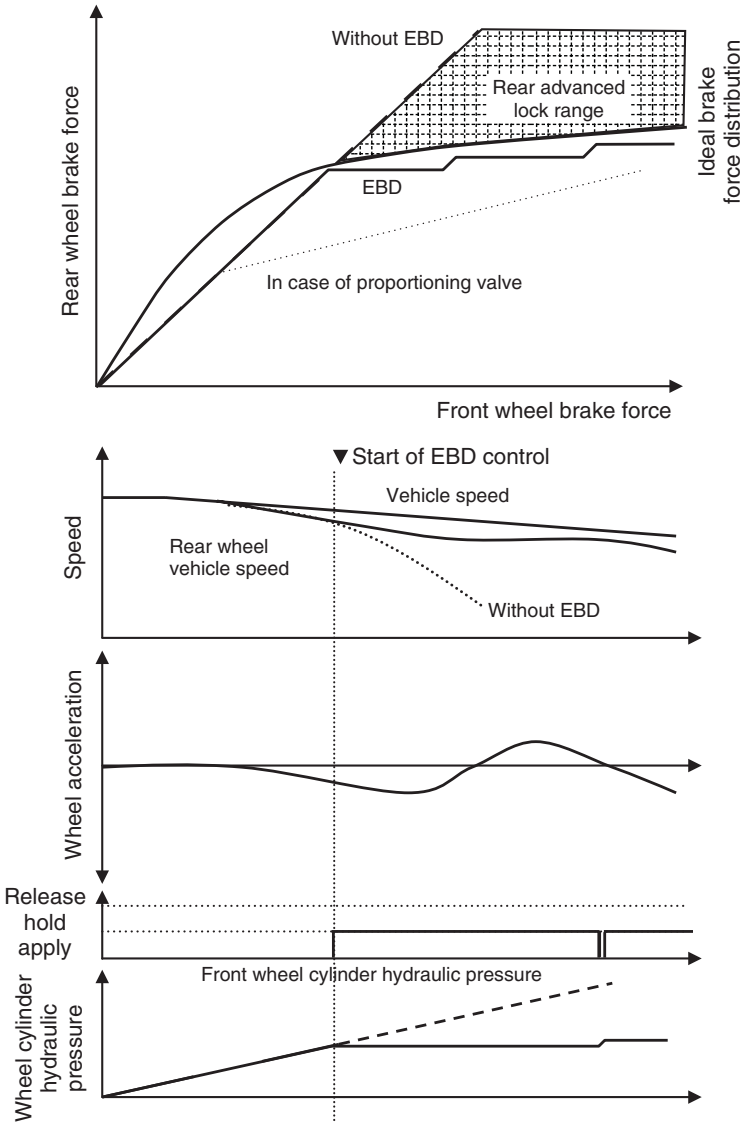

Figure 5. Overview of EBD control.

network, such as CAN, to control torque and lamp status.

3.2 Electronic control unit

The typical ECU configuration in the ESC system is shown in Figure 8. The main differences with ABS–ECU are as follows. The mainstream CPU is a 32-bit microcomputer. The linear solenoid driver for automatic brake pressure distribution for ESC is added. It is connected to other systems such as the engine and sensors over the CAN communication. In some cases, the yaw rate sensor and G sensor are incorporated into the ECU. Failure information and the sensor zero-point learning values are stored in EEPROM nonvolatile memory.

3.3 Sensors

As stated earlier, the ESC system includes many sensors such as those which detect vehicle behavior (yaw rate sensor, longitudinal and lateral acceleration sensors) and those which detect a driver's operation (steering angle sensor, brake pressure sensor), in addition to the wheel speed sensor used in ABS.

The yaw rate sensor detects the vehicle rotational speed by a gyro with the rotary inertia used, or a tuning fork

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

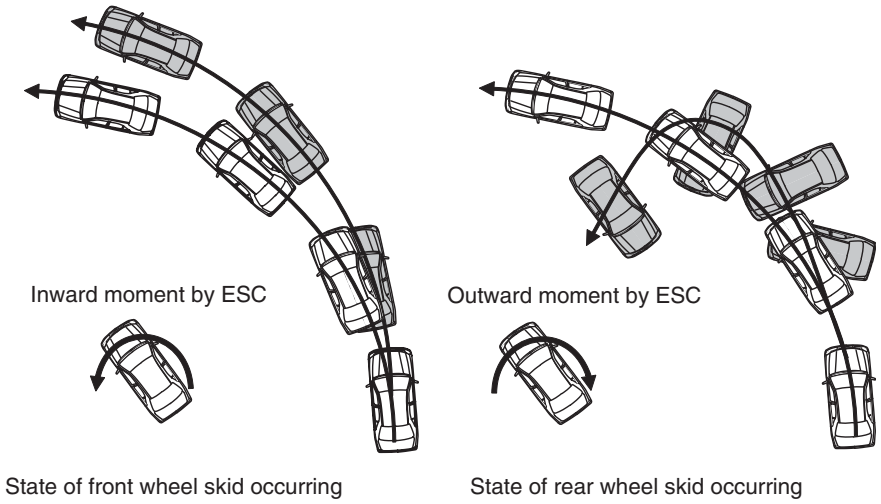

Figure 6. Effects of ESC.

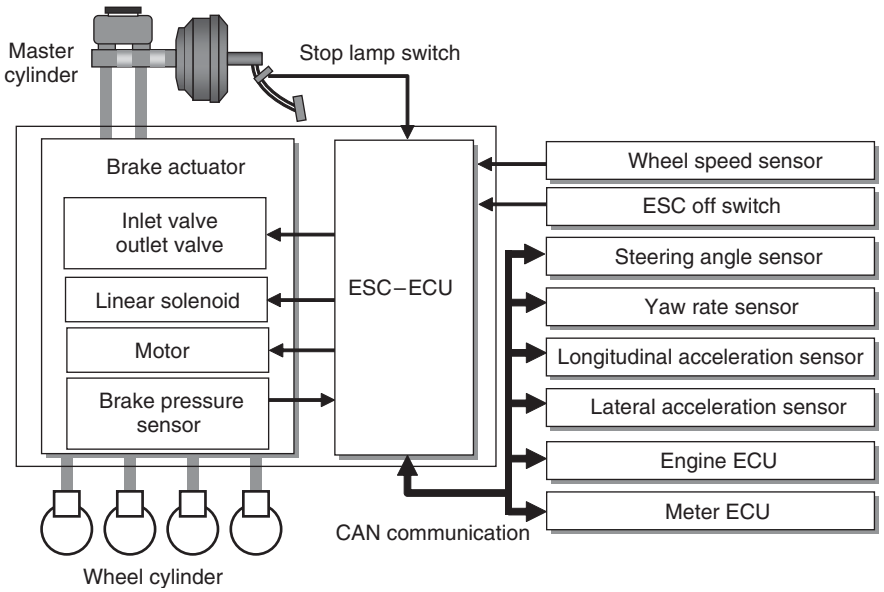

Figure 7. Example of ESC system configuration.

using a coriolis force. It converts that speed to a voltage and outputs it to the ECU.

There are two acceleration sensors mounted in total (longitudinal, lateral) to detect the acceleration in vehicle longitudinal and lateral directions. The acceleration sensors detect the acceleration by a semiconductor element, convert it to a voltage, and output it to the ECU. As a detection system, the piezo element system and capacitance system are mainly used.

The steering angle sensor is a detection element mounted on the steering column. It detects the steering rotational pulse and converts the steering angle calculation result to a voltage to output it to the ECU. It is used to detect the driver's steering speed and steering direction. As the detection system, there is an optical system as well as systems with an magnetic resistance (MR) element or hall element used.

The brake pressure sensor is a piezo element mounted on the master cylinder pressure input of the unit. It converts the master cylinder pressure to a voltage and outputs it to the ECU. It is used to detect the driver's demanded braking condition. The piezo elements for detection include the

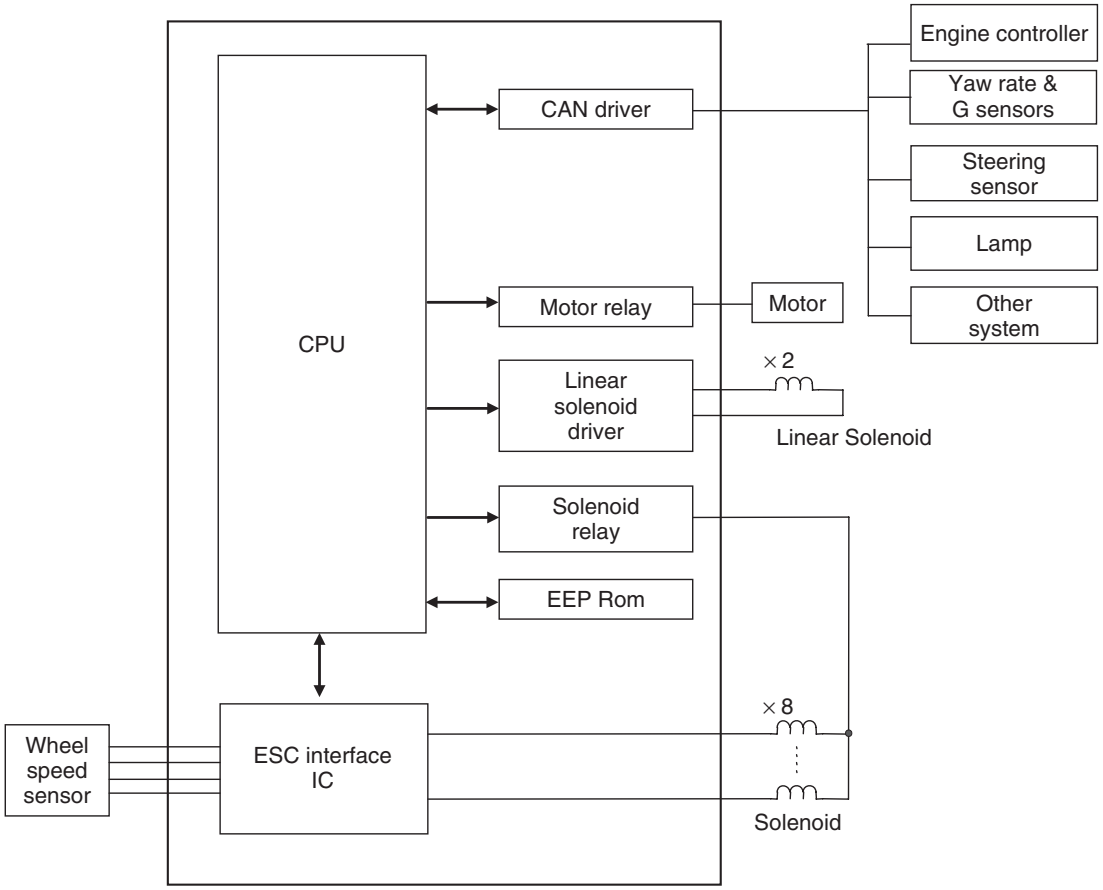

Figure 8. Example of ESC–ECU circuit configuration.

alloy wire resistance strain gauge system, semiconductor strain gauge system, and capacitance system.

3.4 Actuator

An ESC brake actuator must have the ability to apply pressure very quickly to control vehicle behavior. An ESC actuator requires additional hydraulic channels, solenoid valves, and a brake pressure sensor, as well as improvements in the capacity of the pump and motor to achieve the high performance that is required.

An example of the hydraulic circuit of the ESC brake actuator is shown in Figure 9. A linear solenoid is added upstream to the inlet valve for pressurization to make the pump-generated pressure linearly adjustable according to the current command from the ECU. In addition, the reservoir is equipped with the function of forming an inflow path from the master cylinder to the pump when the driver does not press the brake pedal. The ESC–ECU is generally integrated into the ESC actuator and installed in the engine compartment similar to the ABS–ECU and actuator.

3.5 Basic control of ESC

ESC detects the skids of front (understeer) or rear wheels (oversteer) to control the brake hydraulic pressure of each wheel and engine torque to stabilize the vehicle. The ESC–ECU compares the driver's intended direction (control target) detected from the steering angle sensor, accelerator position, and brake pressure with the vehicle condition detected from the yaw rate sensor, acceleration sensor, and wheel speed sensor (Figure 10).

When there is a tendency for a front-wheel skid (understeer) to occur, brake pressurization is commanded mainly to the turning inside rear wheel to give an inward moment to the vehicle. When there is a tendency for a rear-wheel skid (oversteer) to occur, brake pressurization is commanded to the turning outside front wheel to give an outward moment to the vehicle. The vehicle is controlled in a stable

direction by combining these brake pressurization controls and engine torque control.

3.6 ESC application control

Additional functions such as TCS, brake assist system (BAS), and ACC take advantage of the ESC systems automatic pressurization function and engine torque control function. The TCS and BAS are described here.

3.6.1 Application control (1): TCS

TCS is a brake control system that maintains vehicle stability and acceleration by preventing driven wheel

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto200
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

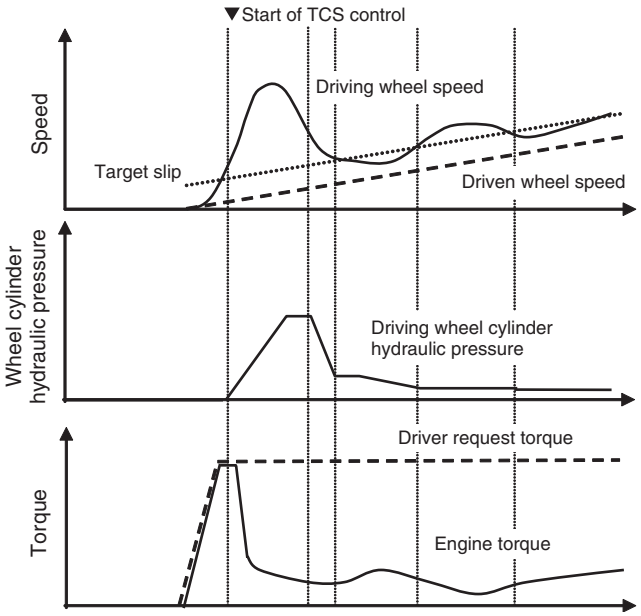

Figure 11. Overview of TCS control.

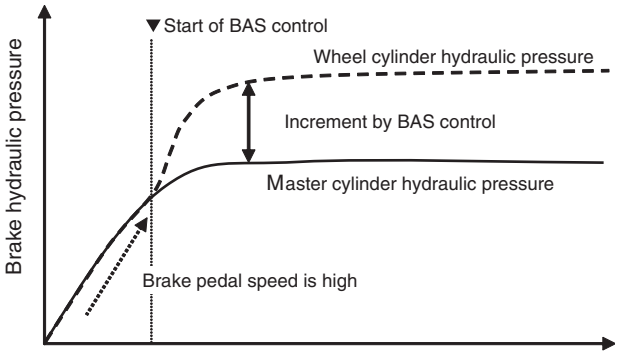

Figure 12. Overview of BAS control.

spin-up generated by slippery road surfaces or excessive driving force. As is the case with the $\mu-S$ characteristic in ABS, there is a relationship among the wheel slip rate, coefficient of road-surface friction, and tractive force. TCS calculates the wheel slip rate from the wheel speed of driven wheels and vehicle speed. The drive torque is controlled so that a proper slip rate, which can ensure a sufficient driving force and cornering force, can be maintained.

TCS performs control to limit the torque of driven wheels based on wheel slip. It judges slip by comparing the driven wheel speeds to the estimated vehicle speed. Estimated vehicle speed is calculated by using driven and non-driven wheel speeds as well as wheel acceleration. Control is performed by combining requests for engine torque reduction and controlling brake pressure of driven wheels (Figure 11).

When the driver presses the accelerator pedal, the force of the driven wheels increases with the increase in the engine output torque. When the driving force is higher than the friction force generated between the tires and the road surface, the driven wheel speed suddenly increases and a wheel slip occurs. When the wheel speed of driven wheels exceeds the control start threshold level, TCS control starts.

During TCS, brake pressure control is continued so that the wheel slip rate will come closer to the target slip threshold level. When the wheel speed of driven wheels decreases and falls below the TCS control completion threshold level, brake pressure control and engine control are gradually completed. The TCS system is designed to maintain vehicle stability and acceleration by controlling the slip rate of driven wheels. If the road has a different coefficient of friction between the right and left driving wheels, the wheel cylinder hydraulic pressure of driving wheels is controlled independently between the right and left.

3.6.2 Application control (2): BAS

In case of emergency, the pressure applied by many drivers on the brake pedal may not be sufficient for braking. In this situation, the pressurization function of ESC is used to increase the brake force in addition to the pressure from the driver. Over the last few years, the installation of BAS is mandatory in a number of regions to improve pedestrian safety.

Brake pedal speed and brake stroke are used by BAS to determine an emergency situation. The brake pedal speed and stroke are obtained from the pressure change gradient. Brake pressure is obtained from the brake pressure sensor equipped with the ECS brake actuator. BAS increases the hydraulic pressure of each wheel using the pressurization function of ESC when an emergency situation is determined (Figure 12).

Pressurization can be performed by driving the motor and linear solenoid within the ESC brake actuator (Figure 9).

4 REGENERATIVE-FRICTION BRAKE COORDINATION

Brake systems in hybrid vehicles and pure EVs are expected to have a function that contributes to a reduction of exhaust gas emission in addition to safety and comfort as in the case of conventional vehicle brake system (hereinafter called the *conventional braking system*). The coordination

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto200
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

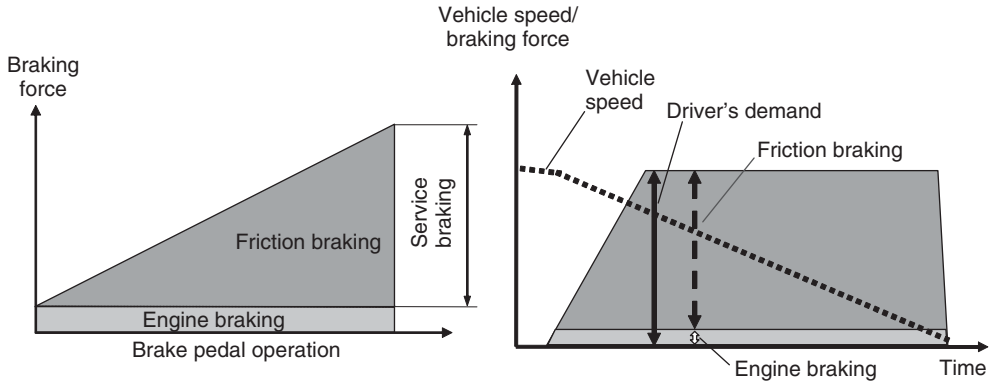

Figure 13. Sharing of braking force in conventional brake system.

of regenerative and friction brake should feel as natural as a conventional system while recovering the maximum kinetic energy during deceleration. This energy is known as the *regenerative energy* and is an effective technique for gas-mileage improvement.

4.1 Regenerative brake method

In a conventional braking system, vehicle deceleration is obtained by engine braking and service brakes (Figure 13). In this process, the kinetic energy of the vehicle is converted to heat energy in the engine and the wheel cylinders. This heat energy is thus released in the atmosphere.

Regenerative brake systems are broadly divided into two types; the first is with the simple regenerative-friction brake coordination method and the other with the more advanced regenerative-friction brake coordination method. In the first method with simple regenerative-friction brake coordination, the regenerative brake force is produced by the engine brake to recover some of the kinetic energy of the vehicle. As there is no coordination with the fiction brake system, the amount of kinetic energy recovered is limited to engine braking only. In this method, once the regenerative braking is no longer available from the kinetic energy corresponding to engine brake, vehicle deceleration is acquired by actual engine braking. Thus, the regenerative braking in this method does not require compensation from the service brake. Therefore, braking with the service brake delivers a natural brake feeling similar to conventional braking system, while still recovering some kinetic energy (Figure 14).

The second method recovers even more kinetic energy by coordinating regenerative-friction braking (Figure 15). This method recovers kinetic energy not only from the engine braking but also from the service brake by using regenerative brake. As the kinetic energy recovery amount is more than the simple regenerative-friction brake coordination method, lower fuel consumption is expected from this method. To allow maximum recovery of kinetic energy, maximum regenerative brake torque is developed within the range of brake force required by the driver. The remaining

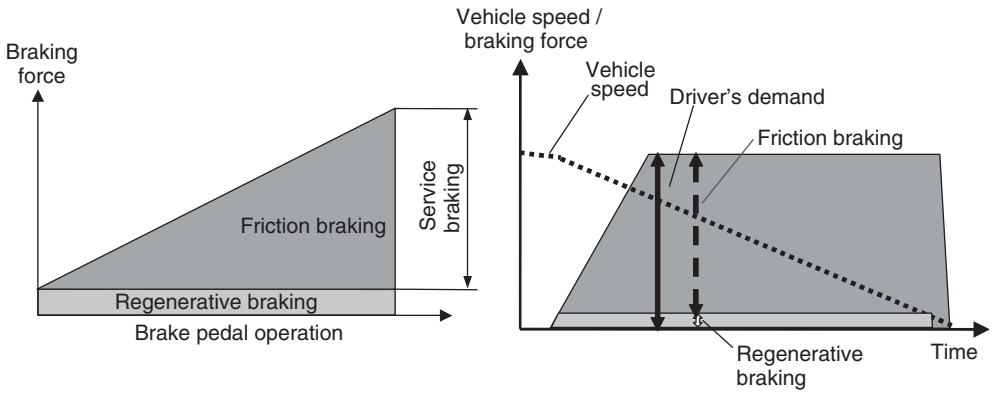

Figure 14. Simple regenerative-friction brake coordination method.

DOI: 10.1002/9781118354179.auto200
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

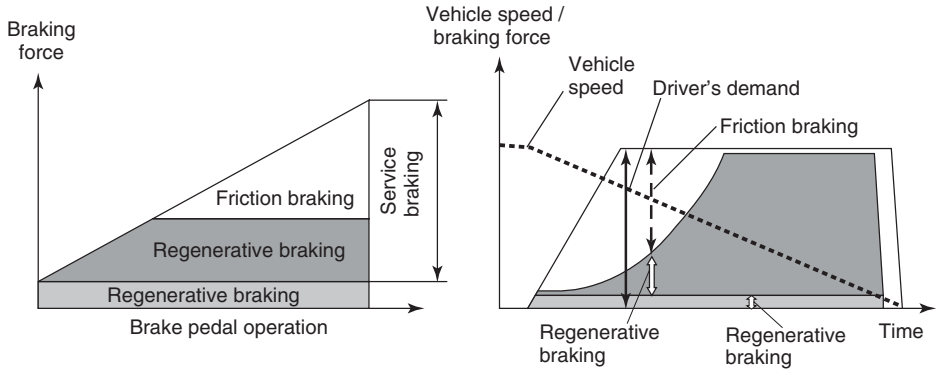

Figure 15. Advanced regenerative-friction brake coordination method.

brake force required by the driver is compensated by the friction brake torque. Advance regenerative-friction brake coordination method requires the friction brake torque to be controlled independently from the brake pedal operation amount by the driver.

4.2 Technology of friction brake torque control required for regenerative-friction brake coordination

With regard to friction brake torque adjustment methods, various techniques have been proposed. The following are typical methods:

4.2.1 Control of wheel cylinder pressure by active vacuum booster

In this method, an active vacuum booster is used to adjust the required friction brake torque during regenerative-friction coordination. This helps adjust the hydraulic pressure in the master cylinder, which helps achieve desired hydraulic pressure into the wheel cylinder (von Albrichsfeld and Karner, 2009) (Figure 16).

4.2.2 Control of wheel cylinder pressure by electric motor

In this method, the required friction brake torque is adjusted by driving an electric motor. The electric motor adjusts the hydraulic pressure in the master cylinder to introduce the desired hydraulic pressure into the wheel cylinder (Hano and Hakiai, 2011; Obata *et al*., 2011) (Figure 17).

4.2.3 Control of wheel cylinder pressure by linear solenoid valve

This method uses the linear solenoid valves to adjust the required friction brake torque during regenerative-friction coordination. This uses the high pressure brake fluid stored in the accumulator to directly introduce the desired pressure into the wheel cylinder (Nakata *et al*., 2009) (Figure 18).

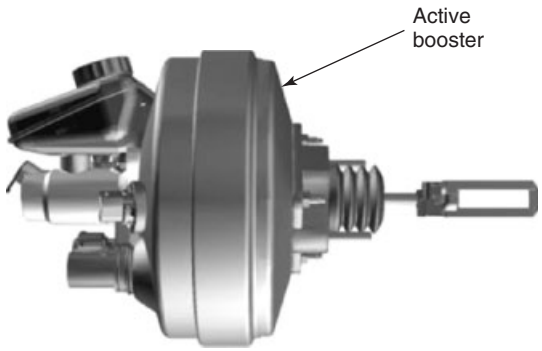

Figure 16. Adjustment of friction brake torque by control of servo-assisted vacuum. (Reproduced from von Albrichsfeld and Karner, 2009. © SAE International.)

4.2.4 Direct control of friction brake torque by electric motor

This method uses an electric motor directly mounted on the wheel cylinder to adjust the friction brake torque and achieve the required brake force.

4.3 Isolation technology of brake pedal stroke and brake pedal force from the friction brake torque

A natural brake feeling is required during the coordination of regenerative brake torque and conventional friction brake torque. To achieve natural brake feeling, the regenerative brake coordination with friction brake torque should not have any effect on the brake pedal stroke and brake pedal

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto200
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

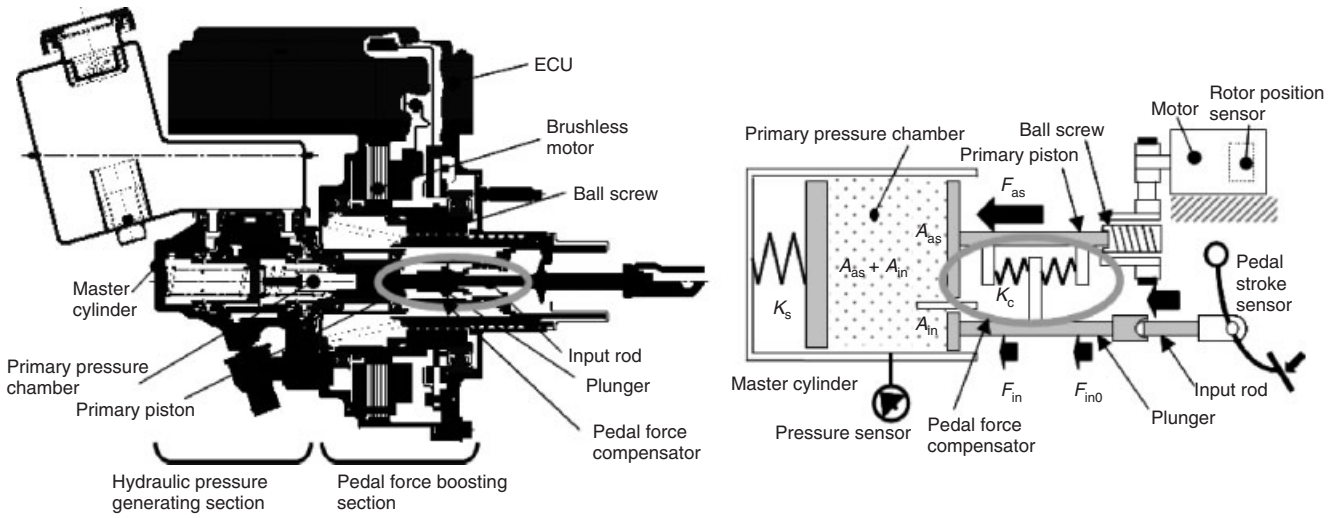

Figure 17. Adjustment of friction brake torque by electric motor control. (Reproduced from Hano and Hakiai, 2011 © SAE International.)

force. This should simultaneously perform coordination of the regenerative-friction brake torque according to the required driver's intended vehicle deceleration.

In order to avoid brake pedal feedback due to the friction brake torque adjustment, use of pedal stroke simulator is common. This creates a natural brake pedal feeling (Nakamura *et al.*, 2002; Nakata *et al.*, 2009). This adjustment in the friction brake torque can be separated from the brake pedal feeling by controlling the variation in pedal stroke and pedal force.

The pedal stroke simulator uses the brake pedal stroke and reaction force generated by the consumption of brake fluid to recreate a natural brake pedal feeling that feels similar to a conventional braking system. The consumption of brake fluid in the wheel cylinder reacts to the coordination of regenerative-friction brake, and the pedal feeling does not depend on this pressure. This method can be explained by visualizing a spring and piston assembly to recreate the reaction force characteristics corresponding to wheel cylinder (Figure 19).

5 FUTURE CONTROL BRAKES

The benefits of ESC in vehicles have been socially recognized. The effect on accident reduction has prompted various regions around the world to change laws and regulation to make ESC mandatory on all new vehicles. These changes mean the installation of ESC is no longer limited to only luxury vehicles but has also increased to compact

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

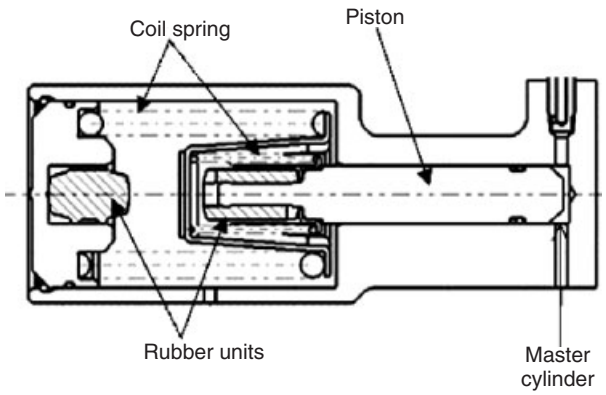

Figure 19. Example of pedal stroke simulator using springs and piston. (Reproduced from Nakamura *et al*., 2002. © SAE International.)

cars. Technology has advanced with demands for more lightweight, compact, and low cost ESC. In addition, there is a focus on collision mitigation, which can be realized by using the automatic brake function of ESC. This functionality can be realized by combining a sensor that detects an obstacle ahead (millimeter wave sensor, camera, etc.) and ESC. With the advances in this technology, there is a lot more attention being brought to the area of collision mitigation. It is expected that this will expand laws in many areas to make ESC standard on vehicles. The evolution into safer brake control technology is expected by linking with information over vehicle-to-vehicle communication or road-to-vehicle communication as well as perimeter monitoring sensors mounted on vehicles.

The role of the brake control has been increasing in the field of environmentally friendly vehicles. Advancements in engine technology to improve fuel efficiency have caused a reduction in engine vacuum levels. The utilization of brake control to reduce brake pedal force for low vacuum situations or for regenerative braking in the case of hybrid electric vehicle (HEV) and EV has been pursued. This means the brake control would not operate only during emergency situations but under normal braking conditions as well. Consequently, this drives the demand more than ever to advance the technology to produce ESC units that operate quieter than ever before.

Body ECU Cluster

Isamu Sakurai
Yazaki Parts Co., Ltd, Shizuoka, Japan

1 INTRODUCTION

A body electronic control unit (ECU) cluster (hereafter called *cluster*) is a device that is located at an easy-to-see position within a driver's line of sight and displays the conditions of a vehicle including information required by laws and regulations such as the speed of a vehicle. The information that the cluster displays allows the driver to not only monitor the conditions of the vehicle but also recognize that the vehicle may be in trouble. Consequently, the driver can take preventive measures before an accident happens. The most common location of the cluster is such that the meters or gauges can be viewed through the steering wheel. However, in some vehicles, the cluster is located at the center of the dashboard or at the position where the driver's line of sight for viewing the meters or gauges is over the steering wheel. How the cluster displays the information varies from one vehicle model to another. Therefore, this chapter focuses on the most popular cluster configuration that is introduced in vehicles released until 2011. The subsequent sections provide a detailed explanation of the history and development of the cluster, types of gauge readings, and components that form the general cluster.

2 GENERAL METERS AND GAUGES IN THE CLUSTER

This section describes the key meters and gauges included in the modern cluster and the information that they display.

2.1 Speedometer

A speedometer is a meter that displays the speed of a vehicle (hereafter called *speed*). Speeds are expressed in either of the two units: kilometers per hour (km/h) or miles per hour (MPH). In countries where miles are used to measure distance, the speedometer displays speeds in both MPH and km/h, though MPH is used as the primary unit and km/h as the secondary unit. On the other hand, in most of the countries where the metric system is used to measure distance, speeds are expressed only in km/h. In Canada, speeds are expressed in both the units (km/h is used as the primary unit and MPH as the secondary unit). Many of the regions including Europe, China, Japan, the Middle East, and South Africa comply with Regulation No. 39 of the Economic Commission for Europe of the United Nation (ECE39) in terms of tolerances of the measuring mechanism of the analog cluster. In these regions, the speedometer has a plus tolerance so it is designed to read a little faster than the actual speed.

2.2 Tachometer

A tachometer is a meter that displays the number of revolutions of the engine (hereafter called *engine RPM*).

The engine RPM is expressed in the unit r/min, 1/min, or revolution per minute (RPM). Particularly, the analog cluster gives readouts in the unit $\times 1000$ r/min, 1/min $\times$ 1000, or RPM $\times$ 1000. As a result, the number of digits on the dial is minimized to present readouts as simply as possible. In addition, many of the tachometers have redlining to indicate that the engine is being revved up to the maximum safe limit.

2.3 Fuel gauge

A fuel gauge is a gauge to display the amount of fuel remaining in the tank at present. Many of the fuel gauges show the ratio of the full amount of fuel to the remaining amount. The pointer points to "F" or "1" indicating that the tank is filled up, or to "E," "0," or "R" indicating that the tank is empty. The typical fuel gauge has tolerances of the measuring mechanism. To be more specific, when the tank is filled up, the fuel gauge has a plus tolerance so it reads past "F" or "1." On the other hand, when the tank is empty, the fuel gauge has a minus tolerance so it reads past "E," "0," or "R." In addition, an increasing number of modern clusters have a fuel gauge symbol with an arrow indicating on which side the filler is located.

2.4 Coolant temperature gauge

A coolant temperature gauge is a gauge to indicate that the engine coolant temperature is at an appropriate level. Overheating or overcooling of the engine coolant may adversely affect the function of the engine of a vehicle. Therefore, the coolant temperature gauge helps the driver check to see that the engine coolant temperature falls within a safe range while driving.

2.5 Odometer/tripmeter

An odometer is a gauge that displays the total distance traveled by the vehicle over its life. A tripmeter is a gauge that displays the distance traveled by the vehicle up until the present moment since it was last reset to zero. As is the case with the speedometer, distance traveled is expressed in the unit km in many countries, but miles are also used in countries such as the United States or Britain. In addition, a switch is used to switch the display between odometer mode and tripmeter mode or to reset the tripmeter to zero. (Note that some tripmeters contain multiple pieces of data.)

2.6 Additional driving information

An increasing number of modern vehicles are equipped with a cluster that displays additional driving information besides odometer and tripmeter distance, such as instantaneous or average fuel economy, average speed of the vehicle, traveling hours, and distance that a vehicle can cruise until the next tank fill.

2.7 Information displayed by the cluster on a hybrid electric vehicle (HEV), electric vehicle (EV), or plug-in hybrid electric vehicle (PHEV)

Many of the hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), or electric vehicles (EVs) are equipped with a cluster that displays the amount of power consumed or the state of the battery charged by the regenerative braking system. Moreover, the indicators in the cluster assist the driver in monitoring his or her contribution to environmental conservation while driving in an eco-friendly manner. Such contribution is presented in visual form using a bar graph indicator or eco-driving symbols. In addition, EVs and PHEVs have indicators to show the remaining battery power available or the charger cable being attached to the charger.

2.8 Indicators

The driver can be informed about the operating state or failure of the systems in the vehicle by turning on or blinking the symbols arranged in the cluster. Some of the symbols illuminate with a beep sounded as a warning. In most countries, laws and regulations concerning vehicles define required indicators, symbols, and their colors. For instance, vehicles are mandated by law to have a brake warning indicator indicating that the brake is in trouble or a seatbelt warning indicator indicating that the seatbelt is not fastened.

2.9 Other information

Today, a wide variety of ingenious ideas are incorporated into clusters equipped with monochrome dot-matrix displays or color thin-film transistor (TFT) liquid displays, which may also differ from region to region or from vehicle to vehicle. For instance, such clusters are capable of

- prompting the driver to take a break based on the collected data about his or her driving behavior or continuous driving for longer hours than specified;
- assisting the driver in identifying the orientation of the wheels when starting the vehicle;
- informing the driver about preset calendar dates such as anniversaries as soon as the engine starts.

3 HISTORY AND DEVELOPMENT OF CLUSTERS

The first automotive meter was a governor-type speedometer introduced in Oldsmobile in 1901 (Figure 1). In recent years, a multiplex communication system has been introduced so a large amount of data required to display the information (e.g., speeds, engine RPM, and warnings) is transmitted as an input to the cluster from ECUs. Such data is processed in the microcontroller unit (MCU) built into the cluster, and consequently presented in either analog or digital form.

Now we consider the history and development of analog speedometers in the last 50 years as an example. An approach to signal conveyance and gauge reading is being developed to ensure higher accuracy. In early speedometers, a speedometer cable was used to mechanically convey the rotational speed of the axles to the speedometer. As the cable rotated, the magnet spun. The spinning magnet produced eddy currents, and the pointer turned in response to the strength of the produced eddy currents. Later on, an approach of converting the rotational speed of the axles into electric pulse signals was invented. The produced electric pulse signals were input to the speedometer. A current was passed to cross coils according to the input signals, and then the pointer turned in the direction of the generated magnetic field. Today, a multiplex communication system is used to convey speeds to the speedometer in accordance with defined protocols. A stepper motor moves the pointer at an angle so as to read speeds according to the input signals (Figure 2).

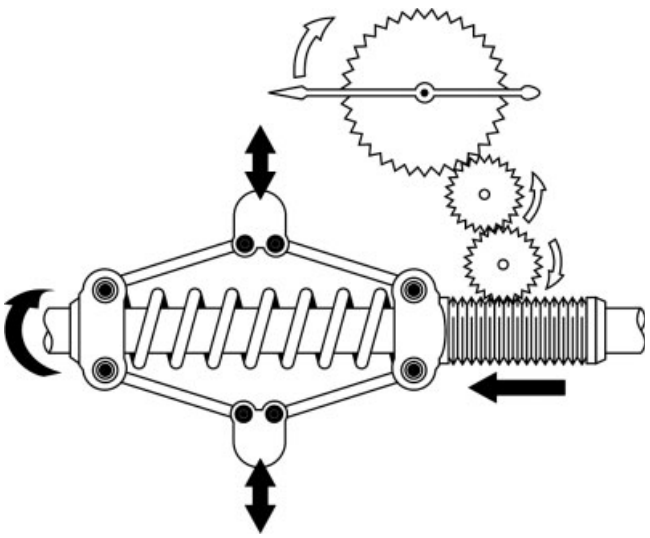

Figure 1. Simplified diagram of a governor-type speedometer.

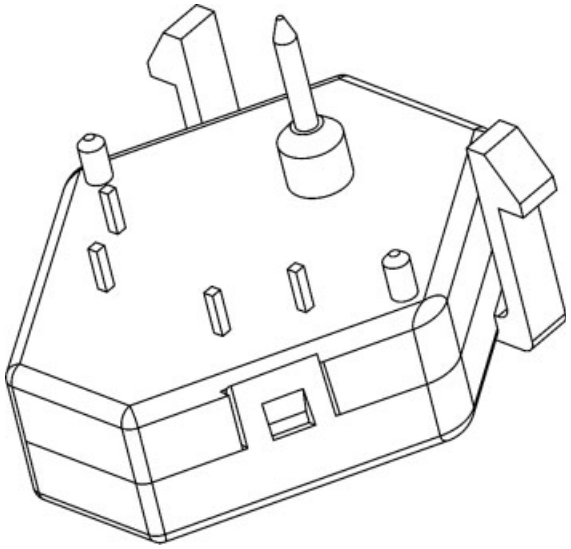

Figure 2. Simplified diagram of a stepper motor.

The cluster design has also been changing. Almost all the meters or gauges were separately enclosed in round housings, but now they are combined into in a single enclosure, which is called a *cluster*.

Next, the material that the meter, gauge, or cluster housings are made out of has changed from metal to general-purpose resin. A transparent material that the cluster front glass is made out of has changed from inorganic glass to transmissive resin such as polymethylmethacrylate (PMMA) or polycarbonate (PC).

An approach to illuminating the cluster has also undergone many changes for higher visibility especially at nighttime. An indirect lighting system was popular, where the dial and the pointer were irradiated with light from the front or side of the cluster. However, such system was replaced by a transillumination system to illuminate the dial, or by a self-luminous system to illuminate the pointer. The transillumination system is designed to illuminate the dial by allowing the transmission of light from the back. In the self-luminous system, the pointer seems to illuminate itself by light emitted from the light emitting diode (LED).

Moreover, the light source has changed from a bulb to a LED. Since the emergence of the digital cluster in the late 1970s, a dot-matrix display or a high definition display has taken the place of a segment display. In addition, a monochrome display has been replaced by a color display.

4 TYPES OF GAUGE READINGS

4.1 Use of a movement

Movement-equipped clusters are capable of indicating continuous and variable readings (e.g., speeds) by moving the pointer to point to an appropriate mark or number printed on the dial. Many of the clusters include movement-equipped meters or gauges such as a speedometer, a tachometer, a fuel gauge, and a coolant temperature gauge. This type of cluster usually comes with a small display unit that indicates odometer and tripmeter distance in digital form. This type of cluster is hereafter called *analog cluster*. Figure 3 illustrates an external view of a typical analog cluster.

4.2 Use of a display unit

In general, a cluster that employs a display unit is designed to convert measured values (e.g., speeds) into numbers and display discrete values in numeric or segment form on a liquid crystal display (LCD) panel or a vacuum fluorescent display (VFD). This type of cluster is hereafter called *digital cluster*. In this chapter, the term *digital cluster* refers to the cluster that shows key driving information (e.g., speeds) on the display, though some of the digital clusters use indicators rather than the display unit to indicate particular information. Figure 4 illustrates an external view of a typical digital cluster.

Figure 4. External view of a typical digital cluster.

As shown in Figure 5, an increasing number of digital clusters present graphic images on the color display unit that look exactly like the analog cluster.

4.3 HUD (head-up display)

Recent years have seen more vehicles equipped with a head-up display (HUD). The HUD system consists of a

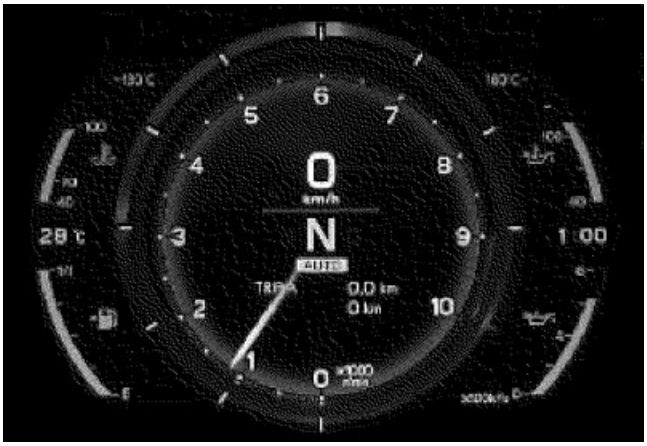

Figure 5. "Faux-analog" digital clusters.

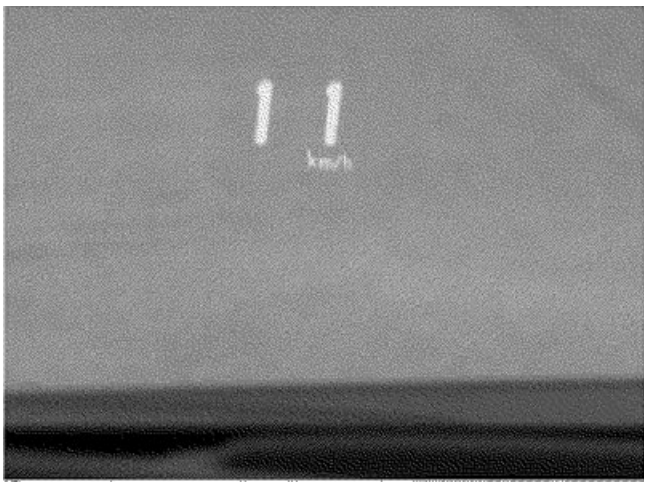

Figure 6. HUD that projects information on the windshield.

display projector, which is installed inside the dashboard and hidden from the view of the driver. Driving information on the display projector is projected on a transmissive and reflective panel either on the windshield (Figure 6) or on a specific reflector panel (Figure 7) pulled up from the dashboard. The information is projected in such a way that it appears a little farther away from the driver than it actually is. This allows the driver to get the projected information into his or her sight in less time. The HUD system also reduces the number of times the driver moves his or her eyes up and down. Therefore, the driver can recognize the projected driving information at a glance with his or her eyes kept on the road. These features of the HUD system are of great benefit to safe driving. Figure 8 illustrates the mechanism of the HUD system.

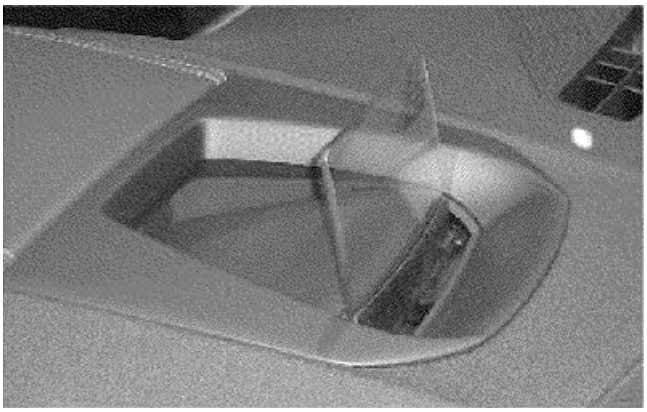

Figure 7. HUD that projects information on a specific reflective panel.

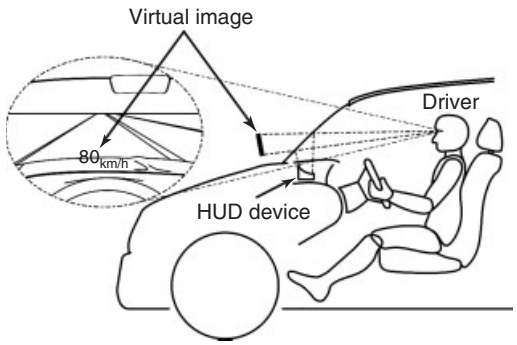

Figure 8. Mechanism of a HUD.

5 COMPONENTS THAT FORM A GENERAL CLUSTER

5.1 Parts breakdown

Figure 3 shows the external view of the general analog cluster, and Figure 9 its parts breakdown. This section, taking the speedometer as an example, describes the basic structure of the meters and gauges that gives the driver readouts using the pointer. A range of numbers and marks are printed on the dial plate (d in Figure 9). The pointer (c in Figure 9) is located at the center of the dial, surrounded with the printed numbers or marks. Once the movement (i in Figure 9) has been driven, it moves the pointer to read speeds. The light sources (k in Figure 9) are located inside the speedometer so as to illuminate both the dial and the pointer at nighttime (or at anytime of the day or night). The

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

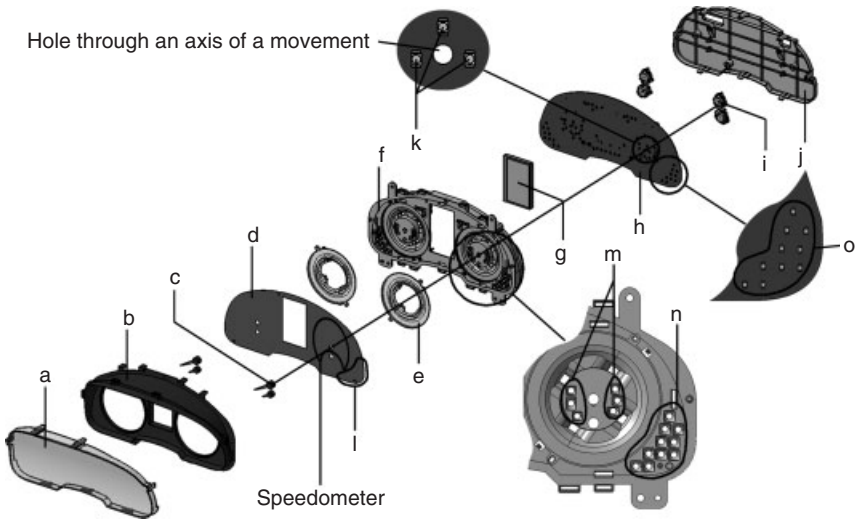

Figure 9. Parts breakdown of a typical analog cluster.

tachometer, fuel gauge, and coolant temperature gauge are structured in the same manner as described above.

There is space reserved for mounting the indicators (l in Figure 9). Below such space are individual lamp cases (n in Figure 9), in which the light sources (o in Figure 9) to illuminate the indicators are housed. As an increasing number of indicators are included in the cluster in recent years, more space needs to be reserved for them. Therefore, some of the indicators may be placed within available open areas located inside the individual gauges (m in Figure 9). In addition, the small display unit (g in Figure 9) is provided to show text or numeric information such as odometer or tripmeter distance.

Besides the above components, the cluster is composed of the following basic components: the transmissive front glass (a in Figure 9) to cover the cluster, the housing (b in Figure 9) to hold the front glass, the case (f in Figure 9) to secure the printed circuit board (PCB) (h in Figure 9) to the dial plate, and the rear cover (j in Figure 9) to protect the PCB. Some of the clusters contain prisms (e in Figure 9) immediately below the dial plate in order to maintain high brightness uniformity on the dial.

Next, Figure 4 shows the external view of the general digital cluster, and Figure 10 its parts breakdown. A wide variety of display units are introduced in the digital cluster as described in Section 5.2. Figure 10 shows the

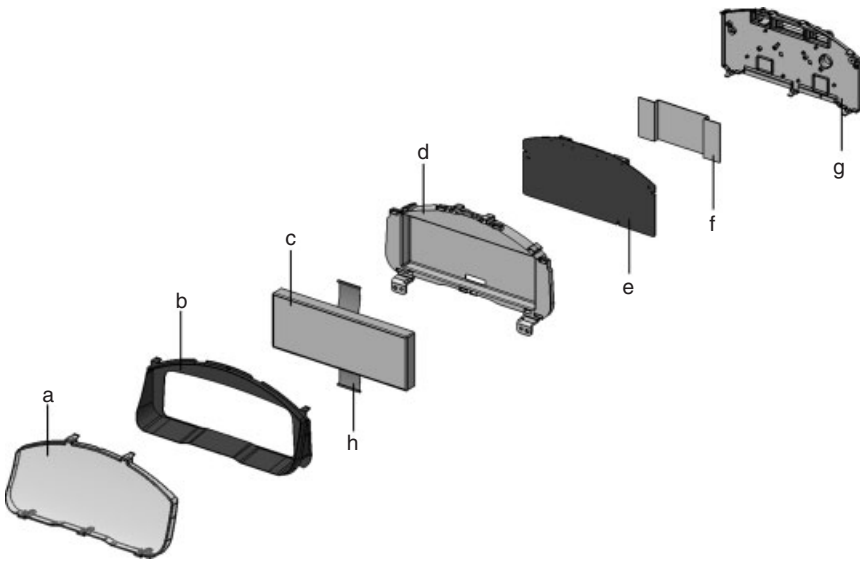

Figure 10. Parts breakdown of a typical digital cluster.

DOI: 10.1002/9781118354179.auto201
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

components of the cluster equipped with a color TFT-LCD module (hereafter called *display module*). The display module (c in Figure 10) is secured in front of the case (d in Figure 10). The PCB (e in Figure 10) is mounted behind the case. The flexible printed circuits (FPCs) (h in Figure 10) connector, which is mounted on the display module, is electrically connected to the PCB. As is the case with the analog cluster, the front of the display module is covered with a transmissive front glass (a in Figure 10). The front glass is secured with the housing (b in Figure 10). At the back of the cluster is the rear cover (g in Figure 10), which is used to protect the PCB. If a controller (graphic display controller or GDC) that operates on a high clock frequency of 100 MHz or over is used to display graphic images, the cluster may be equipped with a noise-suppressing shield case (f in Figure 10).

5.2 Display types

Display types included in the cluster range widely, from a small display in the analog cluster to indicate odometer or tripmeter distance to a large full-color display in the digital cluster that looks exactly like the analog cluster. Display types vary in panel type or size and driving system depending on the cluster type in use. Therefore, the subsequent sections list some of the typical display types available in the clusters today.

5.2.1 *Monochrome segment display*

A monochrome segment display, which typically uses an LCD, consists of seven character-forming segments for displaying numeric information in odometer or tripmeter mode, a unit of distance (e.g., km), fixed icon patterns, and a bar graph indicator to present a fuel level in visual form. There are two types of segment displays: positive display and negative display. The image on the positive display becomes opaque when the segment is turned on, but becomes transparent when the segment is turned off. Conversely, the image on the negative display becomes transparent when the segment is turned on, but becomes opaque when the segment is turned off. A twisted nematic (TN) display is commonly used for the positive display. On the other hand, a vertical alignment (VA) display is commonly used for the negative display, featuring a high contrast and a wide viewing angle. In addition, in some of the display units, the entire display area or only the specific segment patterns are colored for better looks. They are usually colored by affixing a printed sheet to the LCD or by color printing on the inner surface of the glass plate of the LCD.

5.2.2 *Monochrome dot-matrix display*

A monochrome dot-matrix display, which typically uses an LCD, is designed to form text and numeric characters or graphics from a matrix of small dots. The dot-matrix display is useful in displaying text or numeric information including speeds in the font that cannot be formed by the seven-segment display. In addition, the monochrome dot-matrix display is capable of visually representing an increase or a decrease in a level using a bar graph indicator or messages in much greater details than the seven-segment display. A dual scan super twisted nematic (DSTN) display or a temperature compensation film super twisted nematic (TC-FSTN) display is a commonly used type of monochrome dot-matrix display. In the DSTN display, a compensated cell is affixed to a driving cell to compensate for optical property variations caused by changes in temperature. In the TC-FSTN display, an inexpensive compensation film is used as an alternative to a compensated cell.

5.2.3 *Full-color display*

A full-color display, which typically uses a TFT, allows more flexible graphical expression, and is capable of presenting high resolution images or animations. One pixel is composed of three subpixels: red, green, and blue. Detailed color representation is provided pixel by pixel as a result of controlling a gradation of levels of each subpixel. Compared with the monochrome dot-matrix display, the full-color TFT display features a higher resolution, a higher contrast, and a higher responsivity at low temperatures.

5.2.4 *Other types of display*

In addition to the display types described in the preceding sections, a VFD or an organic electroluminescence (EL) display is often introduced in the cluster. Both of the display types show speeds using segments and the engine RPM or fuel level using the bar graph indicator. In addition, a matrix of lights are arranged in such a way to express text and numeric characters or graphic images by turning selected lights on or off. Both of the display types feature a high contrast, a wide viewing angle, and high responsivity, thanks to their self-luminous system.

5.3 Hardware

Many of the modern clusters are designed to cover all of the basic circuit functions on a single PCB. For instance, the analog cluster has a circuit configuration as shown in Figure 11. It is the MCU (a in Figure 11) that is responsible

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto201
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

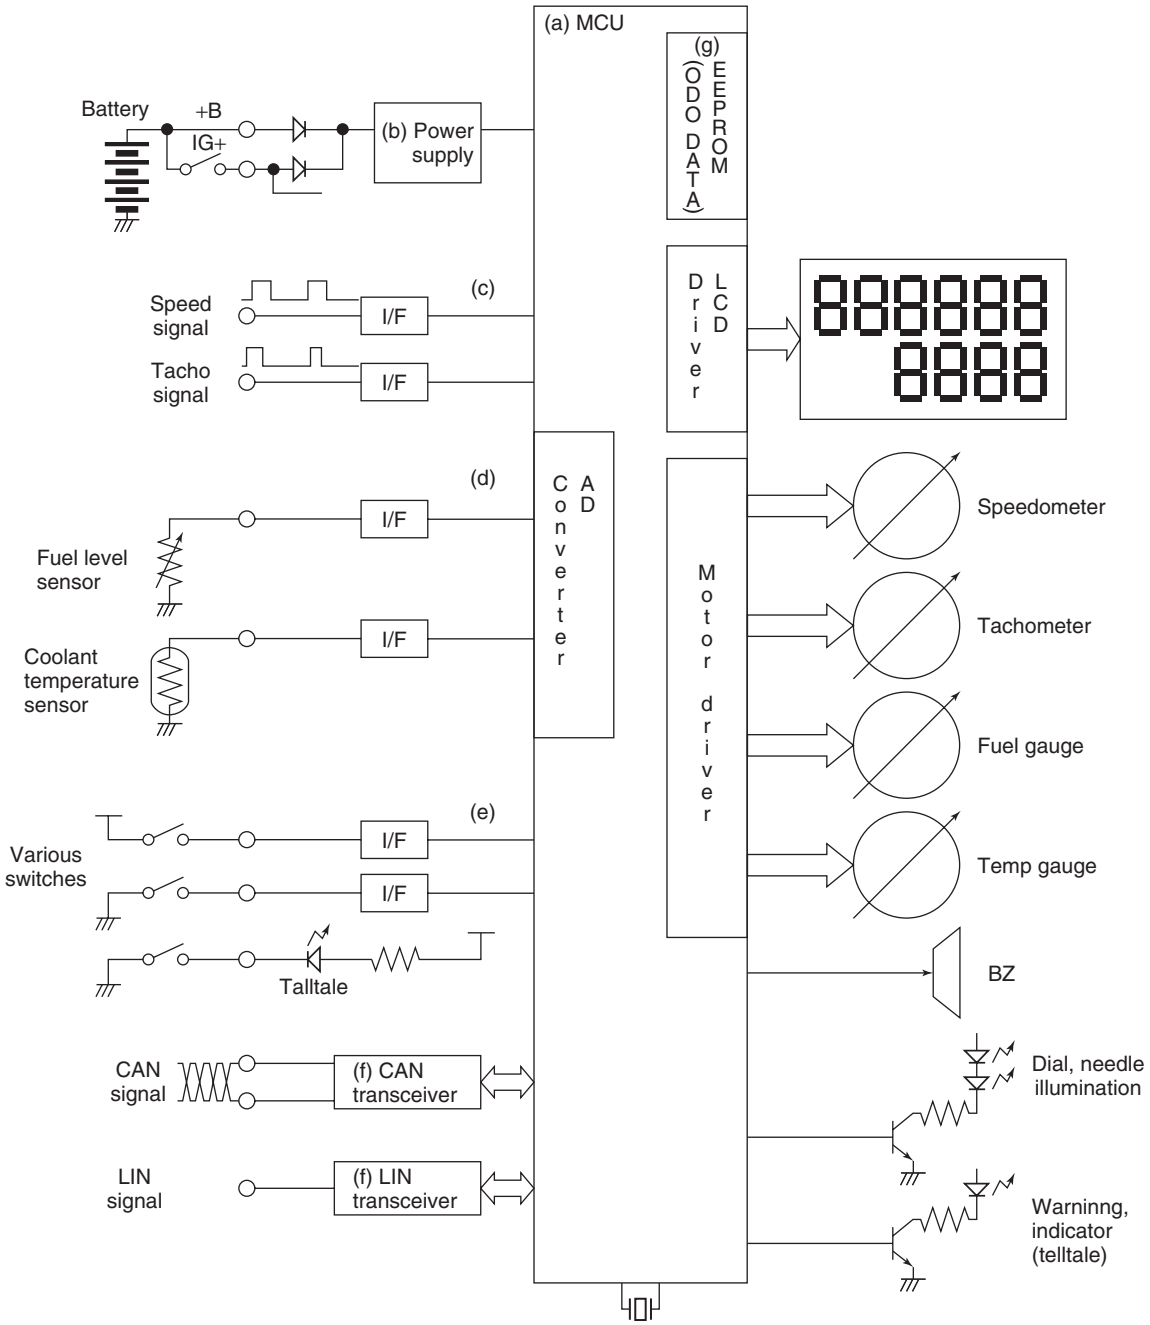

Figure 11. Example of a circuit diagram.

for almost all cluster functions. Power, specifically for the MCU, which is generated on the power integrated circuit (IC) (b in Figure 11), is derived from 12 V (or 24 V) supplied from the battery. Power is supplied to the MCU and the peripheral circuits. Such signals, as the speed signal and the engine RPM signal (c in Figure 11), which are transmitted to the cluster, need to be measured periodically. The voltage signals (d in Figure 11) from the fuel gauge sensor (the amount of fuel remaining) or the coolant temperature gauge sensor (coolant temperature) are captured into the analog to digital (A/D) converter. The switch signals (e in Figure 11) detect the on/off level of the brake, lighting switch, or A/T (automatic transmission) shift position. These signals are captured into the MCU via the specific interface (I/F) circuit, and undergo necessary processing within the MCU.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto201
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The produced output signals drive the stepper motor for gauge reading, the LCD to display odometer or tripmeter distance, the LEDs for the indicators, the buzzers to give warnings, or the LEDs to illuminate the dial or pointer. Some drivers are included in the MCU and capable of driving the stepper motor, LCD, or LEDs directly, and others are provided external to the MCU.

Odometer distance must be retained even when the battery is removed. Therefore, the data is stored in the nonvolatile electrically erasable and programmable read-only memory (EEPROM) (g in Figure 11).

Many signals are transmitted using a multiplex communication system such as controller area network (CAN) or local interconnect network (LIN). Such signals are captured into the MCU via the specific transceiver (f in Figure 11), and input/output processing is performed. As a communication system is more multiplexed, multiple signals are included in a CAN or LIN signal and transmitted together at once. This leads to a reduction in the number of circuit components required for the input I/F as well as simplification of the system. In recent years, an increasing number of clusters utilize a multiplex communication system to transmit not only the speed signal and the engine RPM signal but also the fuel level, the coolant temperature, and the switch signals to detect the on/off level.

5.4 Software

In modern clusters equipped with the MCU, the data input into the cluster is processed by software (or a program) contained in the MCU at any time. The meter or gauge readings (e.g., speedometer, tachometer, and indicators) are controlled in real time and kept updated. The C language or assembler is a commonly used program language. In digital clusters with a large full-color display unit, an authoring tool is also used because it allows a screen layout to be visually designed without in-depth knowledge of software.

As an example of processing performed by software in the analog cluster, the stepper motor is software controlled for smoother moving of the pointer instead of just being controlled according to the input signals from the vehicle. In addition, in the fuel gauge, where the input signals largely vary, filtering is performed. Filtering allows the gauge to display the current fuel level based on not only the instantaneous input signal but also averaging of the multiple input signals sampled. Such software control increases accuracy and provides the driver with an easy-to-view display. It applies to all software-processed gauge reading in both analog and digital clusters.

5.5 Illumination

In the analog cluster, both the dial and the pointer are illuminated in order to ensure high visibility of the cluster even at nighttime. Many clusters use LEDs as light sources. Printing on the dial plate divides the dial plate into two areas: transparent areas, which allow the transmission of light (e.g., printed marks or numbers), and opaque areas, which do not allow the transmission of light (areas other than the printed marks or numbers). High visibility is ensured by a contrast between these two areas when the dial plate is irradiated with light from the back. Light emitted from the LED reaches the hot-stamped section of the pointer. The light is reflected diffusely there and causes the pointer to be illuminated.

In some clusters with a dial plate made with authentic metal, an indirect lighting system is applied to illuminate it because it does not allow the transmission of light. Moreover, using an indirect lighting system in combination with such a dial plate can create a more luxurious appearance. Some clusters are illuminated at all times. In this case, they have a mechanism to dim the light at nighttime compared to daytime. Others allow the driver to adjust the brightness on his or her own. The digital cluster is typically illuminated at all times, and dimmed at nighttime.

5.6 Movement

In many analog clusters, the pointer is moved by the stepper motor. The stepper motor is capable of turning the pointer accurately in accordance with the output signals from the MCU because the rotational angle of the motor shaft is in proportion to the number of pulses input to the motor. Pulse signals can be used as input to the motor. In addition, the circuit configuration between the MCU and the motor can be simplified. For these reasons, use of the stepper motor has become the mainstream way of moving the pointer in the modern MCU-controlled analog cluster.

5.7 Decorations

The cluster is located in the driver's line of sight when he or she takes the driver's seat. Therefore, the cluster plays an important role as not only a display device but also a part of the interior design. Modern clusters are more stylized than ever before, including a stylish dial, pointer, or illumination. The dial is decorated with a ring. Moreover, finishing touches are added on the housing or ring with ornamental patterns, coating, plating, or printing for a more attractive appearance.

DOI: 10.1002/9781118354179.auto201
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6 CONCLUSION

Since the beginning of the twentieth century, when a cluster basically had only a speedometer, modern clusters have made such great strides that they can now accurately provide all the information (as described in Section 2) to the driver in a manner that is easy to see and understand. It is likely that more and more information will be provided to drivers by various means in the vehicle. In addition, it is likely that the amount of information that drivers demand will grow steadily. In conclusion, clusters are sure to play even more important role in the future in presenting accurate, legible, and intelligible information to drivers.

Car Navigation

Shouji Yokoyama
Aisin AW Co. Ltd, Okazaki, Japan

1 INTRODUCTION

Car navigation systems help drivers determine current location, search for destinations, and provide pinpoint guidance. They gained popularity in the 1990s and current usage has spread around the world. Before car navigation systems achieved mass market production, many earlier systems helped evolve the technologies behind the current systems. This section describes a brief history of these evolutions.

In 1909, one year after the launch of the first mass market automobile, the Ford Model T, J. W. Jones invented "Jones Live Map" in the United States. His equipment showed the real-time direction and distance to the destination using a turntable connected to a vehicle wheel. Chadwick's "Automatic Route Guide" and Rodes' "Route Indicator" are also known as *primitive route guidance systems* with predefined route data. These systems disappeared soon after printed road maps became widespread.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

In the late 1960s, Rosen *et al*. proposed the electronic route guidance system (ERGS), which realized route guidance according to the information from terrestrial beacons. Similar systems were investigated in Japan and West Germany in the 1970s. Although these systems achieved good results, none of them were realized due to the huge infrastructure costs required to deploy the systems.

The world's first inertial car navigation system is said to be the Honda Electro Gylocator launched in 1981 for the Japanese market. This system mainly consisted of a Gyroscope, CRT display, and replaceable printed maps on transparent films. The system calculated the current location from the gyroscope data and vehicle speed data. Then, it superimposed a bright dot indicating current location on the CRT overlaid by the map film. In 1985, Etak in the United States launched the world's first digital-map-based system, "Navigator" with map matching function. The car navigation system did not achieve mass market production until the 1990s when the Navstar GPS constellation became fully operational.

GPS was developed by US Department of Defense and one of the signals is freely accessible to anyone. The first GPS satellite was launched in 1978. Since then, many GPS-based car navigation systems were studied. For example, Mitsubishi Electronic showed a GPS and inertial car navigation system prototype at the 1983 Tokyo Motor Show and GM announced a GPS, inertial, and Loran-C hybrid system in 1984.

In March 1990, Mazda and Mitsubishi Electronics launched a GPS and inertial car navigation system for the Japanese market. Soon after, Pioneer launched an aftermarket system in June 1990. Car navigation systems gained popularity in Japan where the population is crowded into densely populated plains and the road structure is extremely complicated. Although the first generation systems only showed current location on the map, many companies

joined the market and technical innovations such as route guidance functions accelerated. In 1992, Toyota and Aisin AW launched a Voice Navigation System with fully automatic route planning and voice guidance. This system realized all the basic functions of current navigation systems.

In Europe, BMW and Philips launched a car navigation system in 1994. Mercedes and Bosch followed with "Auto Pilot" in 1995. Turn by Turn navigation systems without map display function gained initial popularity in Europe where road structure and road signs are well organized and driving speeds are higher than that in other regions. In 1997, the RDS-TMC traffic information service was launched and has grabbed an almost de facto standard position in the current traffic information service worldwide.

In the United States, Visteon launched "Avis Satellite Guidance" for rental cars in 1994. Although many car-navigation-related technologies were developed in the United States, safety- and security-oriented communication services such as GM's "OnStar" spread earlier than car navigation systems.

Location accuracy was advanced by methods such as using an accelerometer to detect slope, image recognition for precise positioning, and so on. In 1998, Toyota and Aisin AW realized an automatic transmission control system based on the function of the car navigation system.

Paralleling the mobile phone technology evolution, wireless-communication-based car navigation system technologies have been actively developed. In 1996, Denso launched its in-car communication information terminal "MUIT". Since then, various car-navigation-related communication services such as internet-based destination search, traffic information delivery and sharing, map data update delivery, route delivery, and so on have been realized by many service providers.

In 2000, "Selective Availability" was discontinued and GPS positioning accuracy was greatly improved. Simple location systems with only a GPS receiver could now obtain sufficient accuracy, so portable navigation device (PND) development accelerated. In 2004, TomTom in the Netherlands launched "TomTom Go". These types of PNDs exploded in popularity due to the high performance to cost ratio and excellent usability. Recently, mobile phone technologies have reached a level sufficient to realize navigation functionality. In 2009, Google launched a free navigation service with advanced voice recognition function for its Android smartphone.

The following sections mainly describe basic technologies of in-car navigation systems.

2 SYTEM OVERVIEW

Figure 1 shows the overall configuration of the car navigation system. A car navigation system consists of a navigation unit installed on the vehicle, a satellite positioning system, and a traffic information service.

The navigation unit consists of input sensors, processing, map database, and output devices.

2.1 Input sensors

The input sensors consist of a satellite signals receiver, distance travelled sensor, travel heading sensor, traffic information receiver, and user input device. Positioning is the most important function of the car navigation system. Position is calculated using a satellite positioning system as an absolute positioning sensor on the earth and using information from a distance travelled sensor and travel heading sensor as relative positioning sensors where no satellite signal reception is available. Relative positioning sensors are also used to adjust for positioning error. Owing to cost, simple car navigation systems in many cases do not use relative positioning sensors and instead only use the satellite positioning system.

2.1.1 Satellite positioning system (Absolute positioning sensor)

The US NAVSTAR GPS system and the Russian GLONASS are current satellite positioning systems, with others planned such as the European Union Galileo. This section explains the principle of widely used GPS positioning.

A GPS receiver calculates the time of signal transmission from GPS satellite "" by checking the difference between the time the satellite transmits the GPS signal and the time the GPS receiver receives it. The distance from the satellite r_i is calculated by multiplying message transit time by the speed of the light c, where the subscript i is the satellite number.

Since the GPS signals contain their orbital (absolute position) information, as shown in Figure 2, it is theoretically possible to determine a receiver position (x, y, z) on the earth if the receiver receives the signals from at least three satellites. In reality, the GPS receiver's clock information contains a significant error δ. So, messages from at least four satellites are needed to be received in order to solve the equations with unknown values x, y, z, and δ. By assuming the true distance from satellite i is the calculated distance r compensated by the clock error δ, the equations for each satellite are as follows;

$$(x - x_1)^2 + (y - y_1)^2 + (z - z_1)^2 = (r_1 + \delta c)^2$$
$$(x - x_2)^2 + (y - y_2)^2 + (z - z_2)^2 = (r_2 + \delta c)^2$$
$$(x - x_3)^2 + (y - y_3)^2 + (z - z_3)^2 = (r_3 + \delta c)^2$$
$$(x - x_4)^2 + (y - y_4)^2 + (z - z_4)^2 = (r_4 + \delta c)^2$$

The absolute receiver position (x, y, z) and the clock error δ can be derived by solving these equations. When the vehicle is in motion, it is also possible to calculate the absolute vehicle speed and the absolute vehicle heading by detecting and synthesizing the carrier frequency deviations of the GPS signals caused by the Doppler effect.

The positioning accuracy of current GPS receivers is around 10 m under open sky conditions. The accuracy is degraded by multipath reflection from the building, terrain, and road surfaces. The largest cause of GPS positioning error in an open sky condition is the unpredictable delay through the ionosphere.

Although technology that can compensate for ionosphere delay by using correction data from fixed stations (D-GPS or RTK-GPS) has been realized, current car navigation systems do not use them because of the additional cost. It is also possible to correct for ionosphere effects by checking the difference between at least two signals from a satellite. The US government is planning to add new civil signals in different frequencies. Because of this, the expectation is for positioning accuracy to be improved in the future.

The road surface reflection can be suppressed by installing the GPS antenna on the metallic roof, or putting a metallic plate (or specially designed rings known as a *choke ring*) under the antenna. It is also possible to filter the deteriorated reflection signals while the vehicle in motion.

2.1.2 Distance travelled sensors

The vehicle wheel speed sensor is often used as a distance travelled sensor. Owing to slip occurring at the drive wheels, the non-driven wheel speed is preferable. Some car navigation systems use integration of the accelerometer output for easier installation, but care is needed about significant accumulated errors.

2.1.3 Travel heading sensors

There are two ways to detect travel heading: absolute direction detection and integration of relative direction movement. Geomagnetic field detection is the typical method to get absolute direction, but the magnetic field has a tendency to be affected by the surrounding environment such as bridges or railroads, magnetization of the vehicle body, and the magnetic field inside the vehicle system. While

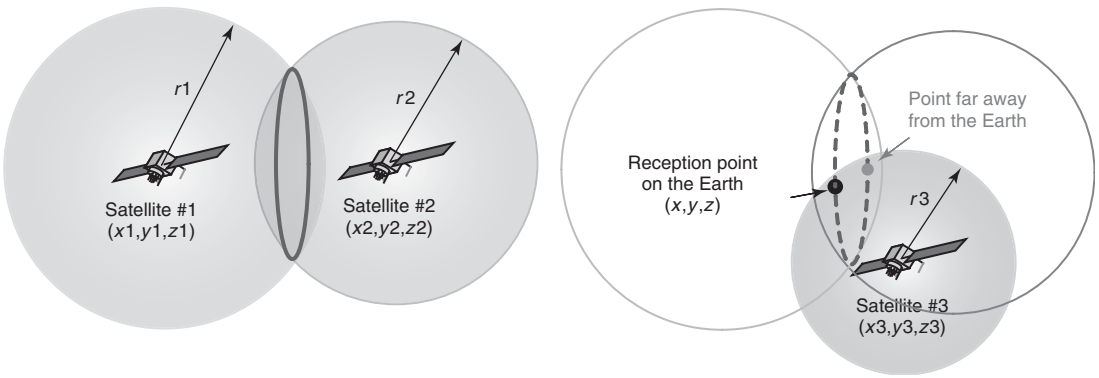

Figure 2. GPS positioning. (Reproduced with permission from Aisin AW Co. Ltd.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the vehicle is in motion, the above-mentioned GPS-based absolute heading method is more accurate and stable.

A gyroscope is generally used for measuring heading. Car navigation systems use low cost and compact Coriolis Vibratory Gyroscopes instead of fiber optic gyros that are typically for aviation use. It is also possible to detect vehicle heading from the wheel speed difference between the left and right wheels or steering angle information, but few systems use these methods.

The car navigation system determines the heading of the vehicle by a combination of absolute and relative headings. In many cases, systems mainly use the GPS-based absolute heading and compensate using the gyroscope during low speeds or when there is no GPS signal reception.

2.1.4 *Traffic information service*

By utilizing traffic information on the car navigation system, the driver can understand the real-time road situation, alternate routes to avoid congestion, and a more accurate estimated time of arrival.

Traffic information is generally generated at public or private traffic information centers and is based on roadside sensor data, communication terminal data in vehicles (Probe Car Data), local police department information, and so on.

There are several traffic information transmission protocols. For example, the widely used TMC (Traffic Message Channel) protocol is standardized as ISO-14819. Also used in car navigation systems in some regions are the Japanese VICS, VICS-based Chinese RTIC, and TMC's next generation protocol, TPEG (Transport Protocol Expert Group) that can also deliver other information such as fuel price and public transport information.

The car navigation system acquires the traffic information via broadcast or wireless communication such as FM subcarrier (radio data system (RDS), data radio channel (DARC)) broadcast, digital broadcast, roadside beacon, or mobile phone. The system then displays the traffic situation on a map, provides congestion guidance by either voice or display, recalculates the route considering the congestion, and shows the updated estimated time of arrival.

Some car navigation systems or traffic information services store historical traffic patterns and utilize it for future traffic estimation according to the time of day, day of the week, and so on.

2.1.5 *User operation input*

Touch screen displays and control methods such as a rotary switch or joystick are widely used user operation input methods. Numerous systems display software keys on a touch screen where a user can enter information by touching the screen, operating a rotary switch, and so on.

Resistive and capacitive touch screens are widely used in car navigation systems. A resistive touch screen consists of two thin transparent electrically resistive layers facing each other with a thin gap. One layer applies electrical voltage, and the system detects the touch location by analyzing the associated voltage on the other side. Capacitive touch screens detect the position by measuring the change in capacitance between the transparent conductor-coated screen and the finger.

Since the user only needs to directly touch the software key on the screen, the touch screen is intuitive and easier to use. On the other hand, the screen has to be installed close to the driver seat so that the driver can reach it.

Remote control methods such as a rotary switch or joystick are less intuitive than the touch screen method and the user has to become acclimated to operating them. Since the screen and the operation control are separated, it is possible to install the screen far from the driver so that the driver's eye movement is reduced, and the operation control is close to the driver.

Some systems add a microphone for speech input. In many cases, speech input is integrated with a touch screen or remote control. Speech input is usually used for complicated inputs such as address or POI (point of interest) input.

2.2 Map database

A map database is the digital data representation of required information for the car navigation system. The data consist of background data, road data, index data, and other data. The background data are used for map display. The index data are used for destination search. The road data are used for positioning, route planning, and map display. Reference tables in the other data are used for traffic information display.

2.2.1 *Background data*

The background data represent areas (ocean, lake, pond, river, building footprint, wooded area, forest, farm, etc.) in polygons, lines (railroad, narrow stream, etc.) in polylines, and the location of texts or symbols in map lettering information (Figure 3).

The polygon or the polyline data contain the category of the shape and its drawing rules (conditions to show or not show the shape, etc.). The map lettering information also contains the category of the text or the symbol and its drawing rules (drawing the text along the road shape, etc.).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

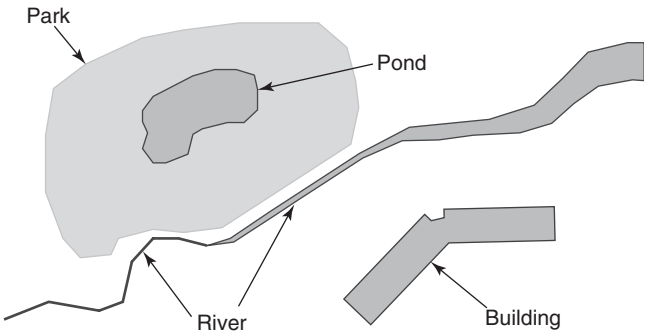

Figure 3. Background data. (Reproduced with permission from Aisin AW Co. Ltd.)

2.2.2 *Road data*

The road data are polyline representations of the centerlines of the corresponding roads. In some cases, both directions of a single road are represented by separated polylines or some portions of the lanes are represented by individual polylines. Crossroads are represented by points, which are connected to the polylines of the corresponding roads. The above-mentioned polylines and points are defined as links and nodes. A node represents an intersection point of the road network such as a crossroad, and a link represents the road portion between the nodes (Figure 4).

The road representative polyline has attributes such as the road administrator information, the function of the road (main line, ramps, service road, etc.), structure (highway, bridge, tunnel, etc.), width, number of lanes, one-way or two-way, speed limit, and so on. The node has attributes such as traffic signals existence, stop sign locations, traffic regulations, and simplified maps for the route guidance function. The road data also often contain a main road network data set in order to reduce the calculation time in long distance route planning.

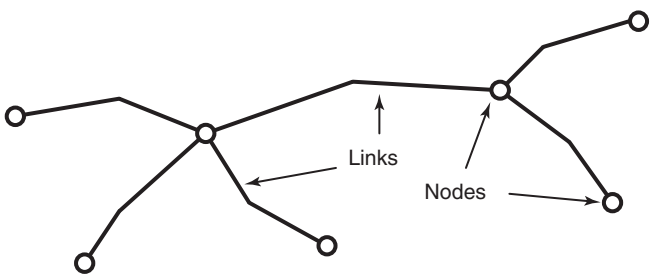

Figure 4. Links and nodes. (Reproduced with permission from Aisin AW Co. Ltd.)

2.2.3 *Index data*

The index data correspond to the location coordinates of a polygon of an area (or a building, or a point when there is a representative point). The index data can consist of a name of the area, an address, a postal code, a name of the intersection, a name or category of the POI, more detailed information such as business hours, and so on.

2.2.4 *Other data*

Other data mainly consist of a data for linking external information to the map database of the car navigation system. One example is a reference table for linking the external traffic information to the roads in the map database. Voice data for the route guidance function are also categorized as other data.

2.2.5 *Storage format*

The storage format of the database should follow a standard in order to reduce the development cost and time for designing or updating the map database for the car navigation system.

As an example standard, this section includes an abstract of the logical data storage format of the Japanese JIS-D0810 format proposal for ISO/TC4/WG3 international map database standardization working group (Hamada, 2002). The logical format portion was published as TS20452 in 2007.

Data structure describes the real world by shape, attribute, and connection-related information. They are represented by background data, road data, network data, and index data (Figure 5). The area is divided by the rectangular-shaped "parcel" data for map display, positioning, route guidance, and so on, and by the arbitrary-shaped "region" data for route planning. Both the parcel data and the region data have a layered structure in order to realize quick indexing in certain situations.

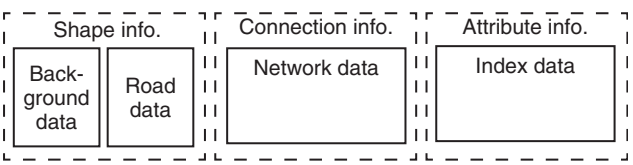

Figure 5. Data structure. (Reproduced with permission from Aisin AW Co. Ltd.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.3 Processing

The processing consists of a positioning module that determines the vehicle position, a destination setup module that supports the user to set the destination, a route planning module that calculates the route to reach the destination considering various conditions, a guidance module that generates the route guidance via both voice and image at the appropriate timing, a map display module, and a traffic information display module that superimposes the traffic information on the map.

2.3.1 Positioning

Positioning can be realized by a hybrid navigation method, which is a combination of inertial navigation, map matching methods, and GPS positioning.

An inertial navigation is a simple method to estimate the current location by integrating the above-mentioned distance travelled sensor and travel heading sensor information. It has a drawback of accumulated error due to integration of the detection errors.

A map matching method can compensate the problems of inertial navigation. Map matching is a method to compare the inertial navigation trace and the corresponding road shape on the map and determine the most probable current location. The combination of these methods is useful as long as an initial location is determinable, the map data are accurate, and the vehicle is traveling on a mapped road (Figure 6).

GPS positioning is a method to obtain the vehicle's latitude, longitude, altitude, and traveling direction. Although it is a discrete value, the system can estimate the absolute position as a circle (sphere) with a specific probability. Many simple car navigation systems only use GPS positioning as it can derive an absolute position and direction very simply. On the other hand, they cannot identify the location when there is no GPS satellite signal reception such as in tunnels, in urban canyons, on roads under highway overpasses, in underground car parking lots, on sides of steep mountains, and so on.

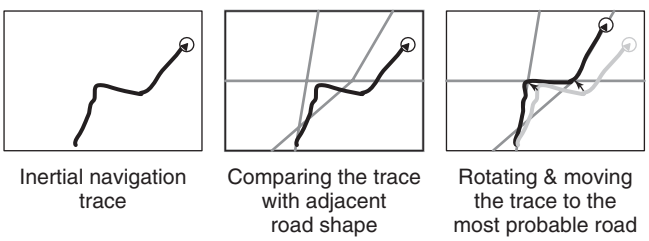

Figure 6. Map matching. (Reproduced with permission from Aisin AW Co. Ltd.)

Many car navigation systems use a hybrid navigation method that combines the inertial navigation, map matching, and GPS positioning. The system modifies the current location based on the GPS location when there is no inertial navigation trace data at the system initial setup, or when the estimated position is not located inside the GPS's probability circle. The inertial navigation and map matching are used when there is no GPS satellite signal reception such as in a tunnel.

2.3.2 Destination setup

The destination setup module supports the user to set the destination (latitude, longitude) interactively using the user input devices. The car navigation system provides various ways to support destination inputs: pointing to the destination directly from the map, searching the map database by inputting the name of the destination or address, selecting from the category list, and combinations of the above-mentioned methods. Some of the methods differ from country to country, region to region, and language to language.

2.3.3 Route planning

The route planning module derives the appropriate route to reach the destination from the road network data consisting of nodes and links.

As nearly all roads lead to the destination indirectly, there are almost infinite paths in the real road network. It is time-consuming and not practical to check all the possible paths. Several algorithms have been proposed to simplify the calculation. A Dijkstra's algorithm is one of the classic methods and often used in car navigation systems.

Furthermore, the road network should be layered in order to reduce calculation time for effective route planning. In the general case, people select the main network roads rather than the minor streets when the travel distance is long. So, the database structure is layered so that the upper layer, which only contains main network road data, is used in longer distance route planning (Figure 7).

In order to calculate the appropriate route, the road data contain various additional information called *costs*. In addition to the length, the link data contain various costs according to category, number of lanes, toll road status, speed limit, and so on. The node data contain traffic signal cost, left-turn cost, right-turn cost, going-straight cost, and so on. When the user defines the route planning preference (e.g., allowing or avoiding toll roads), the system selects the costs to be considered in order to calculate the route that takes the user's preference into account.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

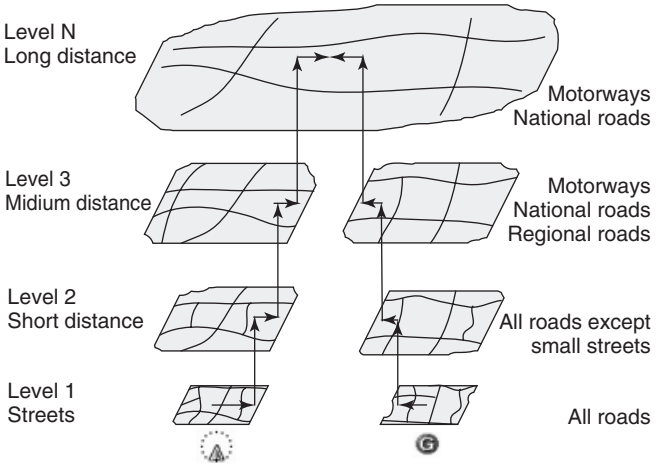

Figure 7. The layered road network database for route planning (Region data). (Reproduced with permission from Aisin AW Co. Ltd.)

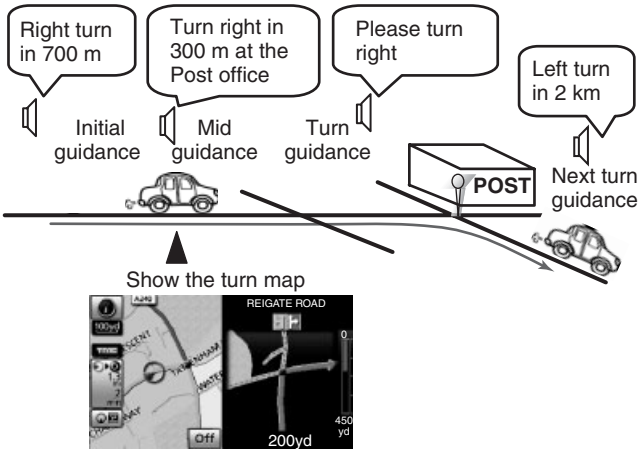

Figure 8. Route guidance example. (Reproduced with permission from Aisin AW Co. Ltd.)

The real-time traffic information can be considered in order to derive the "quick" route that considers congestion, road closures, road work, and so on. In this case, the system increases the cost of the links with traffic problems according to the situation.

Some systems have begun to utilize wireless communication to provide "quicker" routes that consider precise and wide area coverage traffic information, region-specific routes, fuel-efficient routes, scenic routes, and so on.

2.3.4 *Route guidance (simplified turn map, voice guidance)*

The route guidance module shows the necessary information for reaching the destination such as turn directions, landmarks, and the like to the user by voices and images at appropriate timing while the vehicle is traveling along the planned route.

The system determines at which turns or crossroads along the route to provide guidance from the relationship among the entrance link, exit link, and other links; the connection angle among the links; the road category; the road name; the road width; and so on. In some very difficult cases, additional field surveys alone can determine the necessity of guidance.

Turn guidance timing is determined according to the road category, road width, road shape, and so on. Some systems adjust the timing according to the vehicle speed in order to make guidance at appropriate timings.

A basic route guidance example is shown in Figure 8.

There are other kinds of guidance functions along with the basic route guidance. For example, a "turn by turn list" shows the list of turns with distances and directions, a "simplified highway map" shows the list of highway facilities and infrastructures with their names, distances, and estimated times of arrival (Figure 9).

Some systems use a secondary display inside the instrument panel or the heads up display (HUD) that can project

Figure 9. Turn by turn list and Simplified highway map. (Reproduced with permission from Aisin AW Co. Ltd.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

various types of information such as direction, distance to the next turn, lane information, and the like on the windshield (Figure 10).

The route guidance differs from region to region. For example, a crossroad is defined by the combination of the street names in Europe and the United States, whereas a crossroad is directly defined by the crossroad name in Japan. There are also regionally specific turn types such as Michigan lefts in the United States and P-turns in South Korea (Figure 11). Consideration is also needed due to ideal route guidance timing and display also differing from region to region.

Some systems capture the front view image by a windshield mounted camera and superimpose the route guidance on a live image. In the future, guidance images will be integrated with above-mentioned HUD or displayed inside the instrument panel.

The ultimate route guidance is something like a passenger very familiar with the area who recognizes the situation with their eyes (cameras) and brain (ECU), then shows the direction by voiced instructions (speakers) and gestures (displays) at the appropriate timing, and adjusts according to the driver's skills and surrounding environment.

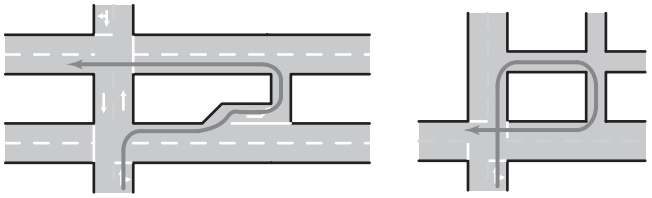

Figure 11. Michigan lefts and P-turns. (Reproduced with permission from Aisin AW Co. Ltd.)

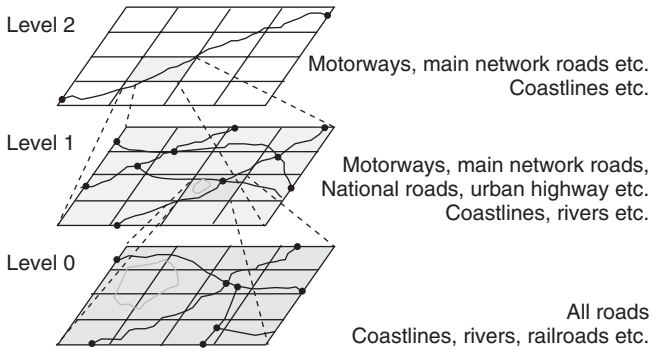

Figure 12. Layered map database structures (parcel data). (Reproduced with permission from Aisin AW Co. Ltd.)

2.3.5 *Map display*

The map display module provides location information to the user by showing the adjacent background, road data, and so on, stored in the map database (Section 2.2), then superimposing the current location, route information, destination, and so on.

The map database has a layered structure. Each layer corresponds to a certain scale of the map and stores background and road data according to the level of layer as a "parcel" of information (Figure 12).

First, the system determines the area to be displayed from the desired map scale, position, display size, and drawing orientation of the map. After reading the corresponding parcel data, it transforms the coordinates and draws the transformed data.

Since the map database has a layered structure, the system can realize quick zooms in and out, and wide area drawing while keeping the data size small.

The user can select the drawing orientation from north-up, heading-up that changes orientation according to the travel heading, or bird's-eye that can show more nearby detail, and so on. Each orientation can be realized by transforming the coordinates. For example, the coordinate transformation equation for heading-up is as follows:

$$\begin{bmatrix} X' \\ Y' \end{bmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \begin{bmatrix} X \\ Y \end{bmatrix}$$

where $[X,Y]$ is the value on the original coordinates, $[X', Y']$ is the value after the transformation, and θ is the transformation angle (Figure 13).

Some systems show an intuitive and attractive 3D terrain map display using altitude information and 3D image transformation (Figure 14).

Figure 13. North-up map and heading-up map. (Reproduced with permission from Aisin AW Co. Ltd.)

Figure 14. Bird's-eye map and 3-D terrain map. (Reproduced with permission from Aisin AW Co. Ltd.)

Future map displays will obtain more up-to-date information from external resources and show relevant and desired information in more intuitive ways.

2.3.6 Traffic information display

The traffic information display module provides traffic information such as congestions, hazards, and so on to the user by displaying the information by text, simplified image, or superimposition on the map.

The navigation system translates the location format of traffic information from the traffic information centers into the road data format of the navigation system's map database in order to superimpose the information on the map. The location format of the traffic information is defined by each traffic provider (VICS link numbers are used for VICS, location codes are used for RDS-TMC). The system stores location reference tables in the map database (Section 2.2.4), and refers the location of the traffic information to the corresponding road information, then superimposes the traffic information on the map. An example of the VICS traffic information display is shown in Figure 15

The Japanese VICS has three types of methods to display the traffic information: text, simplified image, and superimposition on the map (Figure 16).

For RDS-TMC, the traffic information is superimposed as icons and arrows that show the traffic flow situation

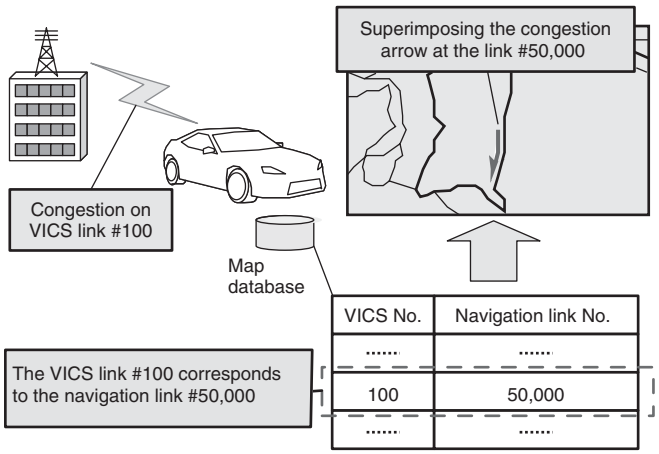

Figure 15. Traffic information display. (Reproduced with permission from Aisin AW Co. Ltd.)

on the map. The RDS-TMC also expresses the traffic situation in text list format. The driver can understand the traffic situation details by selecting items from the text list (Figure 17).

2.4 Output

The output devices consist of displays to show various types of information and a speaker to provide information by sound and voice.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 16. VICS simplified image and superimposition on the map. (Reproduced with permission from Aisin AW Co. Ltd.)

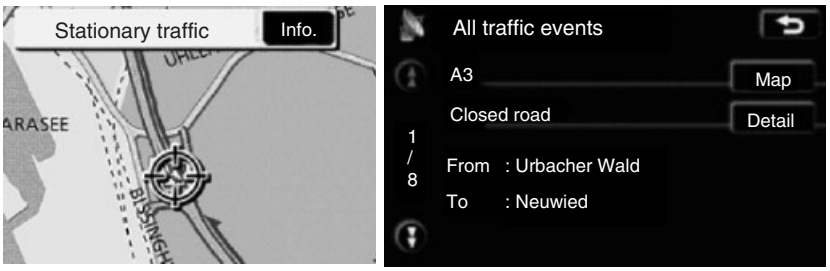

Figure 17. RDS-TMC superimposition on the map and text list. (Reproduced with permission from Aisin AW Co. Ltd.)

2.4.1 Display

A display provides the map and information such as various menus on high resolution screens installed around the cockpit. Some systems have a twin display (main display and secondary display) configuration, and others have an ultrawide display.

2.4.2 Speaker

The car navigation system normally shares the speaker for voice output with the car audio system. Only a subset of speakers is used for the voice guidance or the guidance voice is superimposed over the audio sound so that the user can notice the guidance voice of the car navigation system while continuing to listen to the sound from the car audio system.

3 CAR NAVIGATION-BASED SYSTEM INTEGRATION WITH OTHER SYSTEM

Car navigation systems can support realizing innovative systems by connecting to the cellular communication network or the vehicle system network.

3.1 Telematics

The car navigation system can get external information and send the information from the vehicle to the external world by incorporating a wireless communication function such as a cellular phone module. Various functions such as phone, emergency call, operator assistance, remote vehicle diagnosis, and destination search from the internet have been realized in this area. This section describes some parts of such functions.

3.1.1 Probe car data

Some navigation systems integrate a probe car traffic information technology, in which the car sends the measured position or speed data to the traffic information center and the center sends back traffic information on the roads beyond the coverage areas of current traffic information services such as VICS or RDS-TMC.

There are various methods to implement probe car traffic information: upload current position as determined in the positioning module, upload speed, or upload congestion information determined by the car navigation system. Uploading the congestion information can reduce the communication cost, while a simple method of uploading the current position has an advantage in expanding the usefulness because of its flexibility. Some systems also

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

implement uploading the fuel consumption data for fuel-efficient route planning.

The probe car system is also effective for supporting the recovery from disaster. Honda, Toyota, Nissan, Pioneer, and ITS Japan integrated their probe car data after the massive earthquake on March 11, 2011, and provided a "passable road map" of the disaster area.

3.1.2 Map update

The car navigation system needs to use the latest map database in order to maintain good performance. Off-board navigation systems and onboard navigation systems with incremental map update functions have been realized using wireless communication.

The off-board navigation system has the map database on the server side, and only the necessary portion of information is transmitted via wireless communication. Off-board solutions are widely used in cellular-phone-based navigation systems. They become useless outside the coverage area of the wireless communication, although some systems solve this issue by downloading the necessary information in advance.

An onboard navigation system with an incremental map update function can keep the latest map database with low communication cost by downloading only the updated portion of the map database and synthesizing inside the car navigation system. The synthesizing process is a background task, so performance reduction needs to be taken into account when the incremental map update function is designed.

3.2 Collaboration with the vehicle system

By connecting the car navigation system to the in-vehicle network, the car navigation system can utilize various vehicle sensor data and support the vehicle control system.

3.2.1 Car-navigation-system-based driver support system

Car navigation systems can predict the oncoming road conditions from road shape data in the database, current position, speed, and the planned route. They can support improving vehicle system control by providing feed-forward information.

For example, an automatic transmission control system can detect the driver's intention to decelerate from the upcoming corner shape information, driver's accelerator pedal operation, and brake pedal operation, and then the system can prevent unnecessary upshifting. It can also downshift based on the driver's accelerator or brake pedal operation before a downhill corner so that the vehicle can accelerate smoothly after passing the corner.

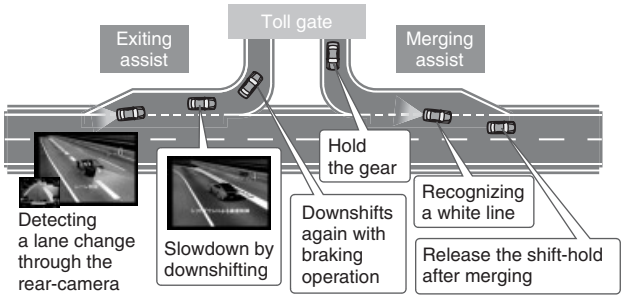

Figure 18. Camera-based automatic transmission control on a highway. (Reproduced with permission from Aisin AW Co. Ltd.)

3.2.2 Collaboration with the in-vehicle camera

Recently, rearview cameras and forward view cameras are beginning to be installed on vehicles to improve safety. Some car navigation systems can recognize road paint patterns (lane marker, stop line, pedestrian crossing, etc.) from the captured images and compare with map data in order to improve positioning. This precise vehicle position is used for advanced navigation system functions such as lane change guidance or for driver assistance systems such as automatic transmission downshifting to support deceleration while the vehicle is exiting a highway (Figure 18).

There is also image recognition technology to acquire the speed limit information from traffic signs and then display the speed limit information on the car navigation system screen.

4 FUTURE OF THE CAR NAVIGATION SYSTEM

Thanks to the automobile, people can freely move to distant places with relatively low cost. On the other hand, people have to concentrate on their location and finding the directions to their destination when driving in unfamiliar places. Some people may enjoy exploring places. However, sometimes it may lead to unsafe distracted driving.

Car navigation systems can support the driver by identifying the current location on the map and guidance to the destination. So, they have realized safer and more comfortable driving, meeting driver's demands. Since they can enhance the freedom of movement, car navigation systems have gained worldwide popularity.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto202
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In the future, the car navigation system will become a standard function of the rapidly evolving mobile phone and will incorporate public transport and pedestrian navigation functions for supporting the total movement of people. In-vehicle terminals will also incorporate wireless communication, sharing various types of information between vehicles, and so on. The driver will be able to have safer and more satisfying driving experiences on demand.

On the other hand, the driver will be provided with tremendous amounts of information, including the entertainment functions, while driving the vehicle. So the in-vehicle system will need to allow through filtering only the necessary information, just like an internet search engine selects the most useful information from the oceans of internet data, and then provides the information with easy-to-use interactive interfaces. Car-navigation-system-based autonomous driving functions may also support safer driving so that the driver can manage a large load of information in some situations.

Series Hybrid Electric Vehicles (SHEVs)

Joeri Van Mierlo and Omar Hegazy

Vrije Universiteit Brussel (VUB), Brussels, Belgium

1 INTRODUCTION

Electric vehicles (EVs) can be an alternative to the internal combustion engine vehicles (ICEVs). EVs are powered by electric batteries, which need to be recharged with electricity from the grid. Furthermore, the EVs can provide an ideal solution to reduce the environmental impact of transports and reduce the energy dependency because they have low energy consumption and zero local emissions. In other words, battery electric vehicles (BEVs) are zero-emission vehicles (ZEVs) (Chan, Bouscayrol, and Chen, 2010; Van Mierlo and Maggetto, 2001). However, the BEVs still have some challenges, which need to be solved. These challenges are limited driving range, long charging time, battery lifetime, and high initial cost. Therefore, the concept of the series hybrid electric vehicles (SHEVs) can be a viable solution to overcome the disadvantages of the BEVs.

SHEVs comprise two or more energy sources to drive the vehicle, normally one is the main source [such as internal combustion engine (ICE) or fuel cell (FC)], and another is an auxiliary source [such as battery, supercapacitor (SC), or flywheel]. These energy sources can be arranged in different topologies and can cooperate in different ways. Recently, most hybrid vehicles in automotive market are hybrid electric vehicles (HEVs) with an ICE or FC and at least one electrical machine. The commercialization of HEVs has mainly been possible due to the advances in the battery packs, power electronics interfaces (PEIs), and control strategies (Emadi, Lee, and Rajashekara, 2008; Emadi, Williamson, and Khaligh, 2006; Hegazy, Van Mierlo, and Lataire, 2011c).

In the recent years, many research studies in the control strategy (CS) of HEVs have been proposed (Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011; Hegazy, Van Mierlo, and Lataire, 2011c; Chan, Bouscayrol, and Chen, 2010; Van Mierlo and Maggetto, 2001). As reported in these studies, the main objectives of the power CS are to improve fuel economy, reduce the exhaust emissions, and maintain the battery packs in their desired state of charge (SoC) while ensuring seamless operation of the powertrain. Therefore, the major challenge for the development of SHEVs is the CS of multiple energy sources and PEIs. This necessitates the utilization of an appropriate CS to achieve high performance SHEVs and relatively many references can be found (Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011). Furthermore, the development of the PEIs and the electrical machines has been investigated in the literature (Hegazy, Van Mierlo, and Lataire, 2011a; Van Mierlo and Maggetto, 2001; Emadi, Williamson, and Khaligh, 2006; Emadi, Lee,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto203
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

and Rajashekara, 2008). In other words, the proper selection of the power electronics technologies (such as DC/DC converters, inverters, and chargers) is essential for the successful development of efficient and high performance SHEVs. In addition, the electric machines are another key component required for the emergence and acceptance of high performance SHEVs.

This chapter presents a comprehensive review of the SHEVs to give a clear picture on their powertrain and power management strategy for the next-generation SHEVs. It should be pointed out that the SHEVs have significant potential to not only improve fuel economy and the performance of the vehicle but also reduce the emissions.

2 CONCEPT OF SERIES HYBRID ELECTRIC VEHICLES

Compared to BEVs, SHEVs are potentially capable of extending the driving range and battery lifetime and reducing the battery size. The SHEVs comprise an ICE/generator, electric motor (EM), single or multiple energy storage systems (ESS), power electronic converters, and controllers. In a SHEV configuration, the tractive effort (or traction power) comes only via an electric drive, which obtains electricity from either the ICE/generator (called *GENSET*) directly or from the battery packs with/without power electronics converter. In other powertrains, an auxiliary power unit (APU) is also used as an alternative to GENSET.

In addition, the SHEV has the ability to operate the GENSET on high power when the power demand from the driver is low, which implies a high efficiency for the powertrain. The extra power generated can be stored in the ESS (such as batteries) for future use. Furthermore, the overall efficiency can be significantly improved by operating the electrical machine as a generator during deceleration of the vehicle (called *regenerative braking mode*). Therefore, the SHEVs have the possibility to recover this energy during regenerative braking mode instead of losing the kinetic energy as heat in mechanical brakes as in conventional vehicles (CVs). On the other hand, if the power demand of the EM is higher than the output power of the GENSET, the required power is supplied from the battery packs (called *hybrid traction mode*). Figure 1 illustrates the schematic diagram of the concept of the series hybrid configuration.

The SHEVs have many advantages compared to the CVs, which are represented as follows (Chan, 2007; Chan, Bouscayrol, and Chen, 2010; Bayindir, Gozukucuk, and Teke, 2011):

1. There is a mechanical decoupling of the ICE and the wheels; thus, the GENSET can be located anywhere. Moreover, it is possible to operate the ICE very close to maximum efficiency.
2. SHEVs are relatively the most efficient during stop-and-go city driving.
3. The ICE can operate in a narrow revolutions per minute range (its most efficient range), even when the vehicle changes the speed.
4. SHEVs are easy to control; thus, ICE can operate at maximum efficient point by controlling the output power of the battery to satisfy the required power of vehicle.

However, the SHEVs have some drawbacks, which are given as follows (Chan, 2007; Chan, Bouscayrol, and Chen, 2010; Bayindir, Gozukucuk, and Teke, 2011):

1. The GENSET and the EM must be large enough to satisfy the performance of the vehicle. Consequently, the total weight, cost, and volume of the powertrain can be excessive compared to BEV powertrain.
2. During the highway driving cycle, the overall efficiency is less optimal because of the many energy conversions

occurring in the different series-connected components of the propulsion system.

3 SERIES HYBRID ELECTRIC DRIVETRAINS

3.1 Powertrain based on ICE

There are several possible configurations of SHEVs. For example, as shown in Figure 2a, the ICE drives a three-phase electric generator (called EM_1) and a three-phase rectifier (named PEI_1) instead of directly driving the wheels, whereas a high-voltage battery system (HV-BS) is directly connected to the DC-bus. The EM (called EM_2) is the only means to provide the power to the wheels. This configuration is the simplest and is of lowest cost. However, this configuration comprises a heavy ESS (i.e., battery) because a large number of battery cells are connected in series to reach the voltage of the high voltage DC-bus (Figure 2a). It is important to point out that this configuration has a low regenerative braking capability, especially at low speed. At low speed, the voltage generated by the EM is less than that generated by the DC-bus, where the DC-bus generates battery voltage. For this reason, the regenerative braking capability is limited at low speed. To improve the performance of the powertrain during regenerative braking, the low-voltage battery system (LV-BS) is connected to the DC-bus through bidirectional DC/DC converter (*buck/boost*), as shown in Figure 2b. In this configuration, the low-voltage battery has the ability to recover more energy from the DC-bus during regenerative braking. To achieve this operating mode, the bidirectional DC/DC converter works as buck converter to transfer the power from DC-bus to battery system.

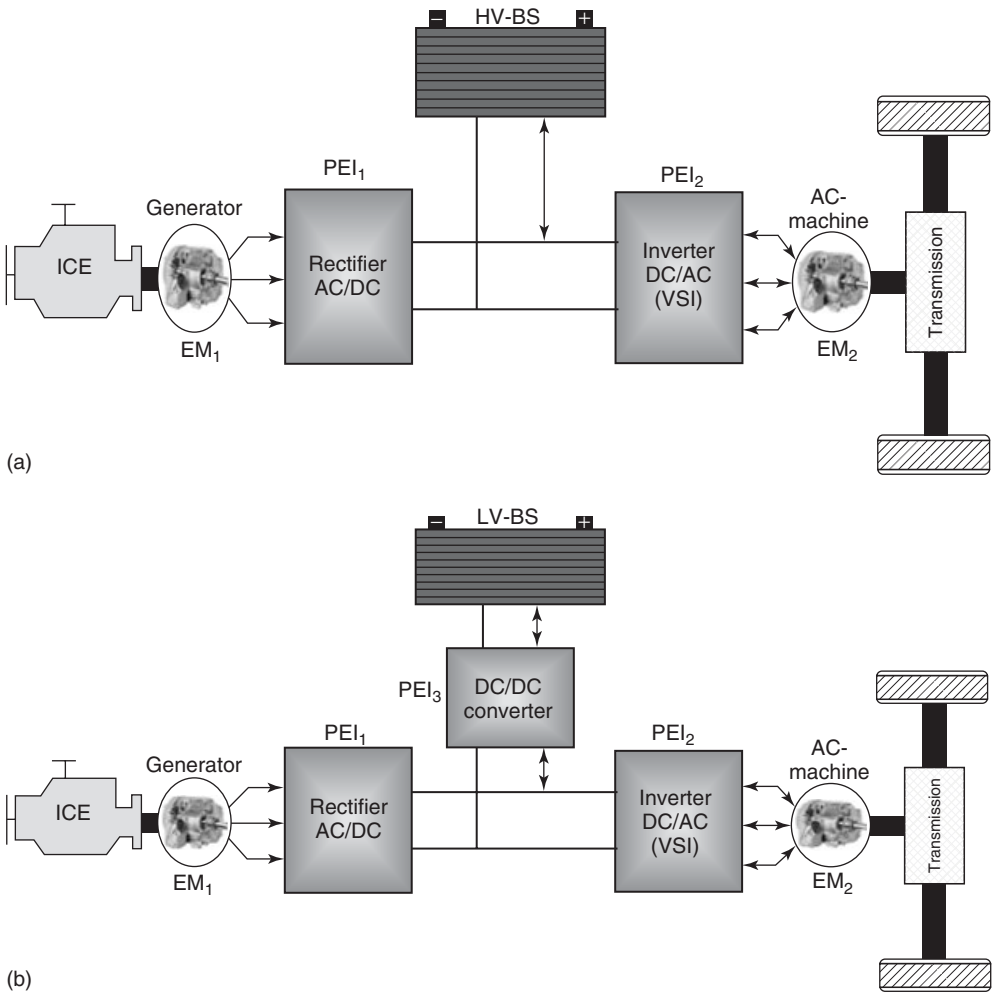

Figure 2. Different powertrain configurations based on ICE. (a) High-voltage battery (configuration I) and (b) low-voltage battery with bidirectional DC/DC converter (configuration II).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

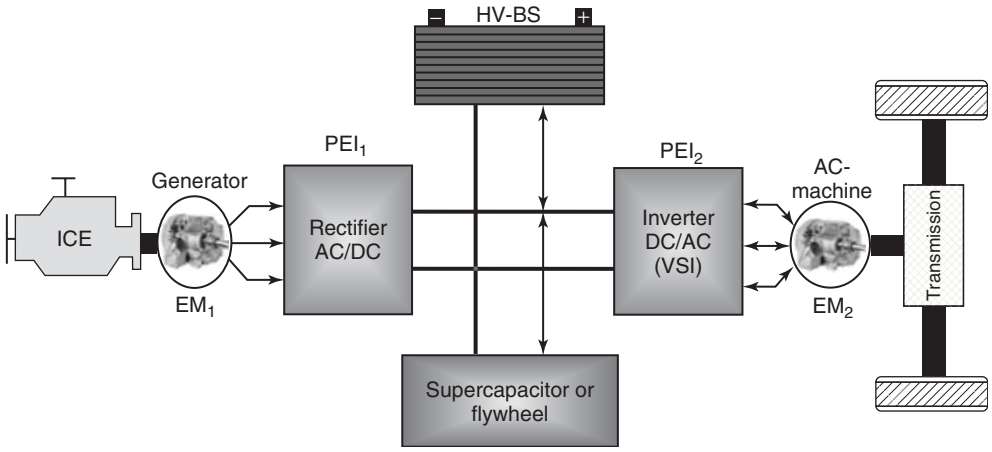

Figure 3. SHEVs with peak power source.

In addition, SHEVs can be assisted by SCs (or flywheels), which can improve the efficiency by minimizing the losses in the battery. They deliver peak power during acceleration and recuperate the regenerative energy during braking (Van Mierlo and Maggetto, 2001; Bayindir, Gozukucuk, and Teke, 2011). Therefore, the SCs are kept charged at low speed and almost empty at maximum speed. In this configuration, the SCs not only improve the performance of the powertrain but also extend the lifetime of the battery. Figure 3 shows the SHEVs with peak power source. In addition, for low-voltage ESS (batteries and SCs), the DC/DC converter should be placed between the ESS and the DC-bus, which may lead to features such as light ESS, less cost, and high regenerative braking capability, especially at low speed.

3.2 Powertrain based on FC

A special SHEV has an FC hybrid structure. In this structure, the engine/generator group is replaced by an FC system producing electric energy starting from stored hydrogen or from a fuel tank feeding a reformer to produce hydrogen. The FCs have emerged as one of the most promising candidates for fuel-efficient and emission-free vehicle power generation. In particular, the proton exchange membrane fuel cells (PEMFCs) have received much attention for automotive applications because of their solid electrolyte, low operating temperature, and high power density. However, the high cost and its slow dynamics are the major challenges for the commercialization of fuel cell electric hybrid vehicles (FCHEVs) (Feroldi, Serra, and Riera, 2009; Van Mierlo, Van den Bossche, and Maggetto, 2004; Hegazy, Van Mierlo, and Lataire, 2011b; Van Mierlo and Maggetto, 2001; Chan, 2007; Chan, Bouscayrol, and Chen, 2010; Feroldi, Serra, and Riera, 2009). To improve the transient performance of FCs and recover energy through regenerative braking, as mentioned in Section 1, FC systems should be typically hybridized with ESS, such as batteries or SCs to form the FCHEV powertrain. In other words, it is important to hybridize an FCHEV with an ESS for the following reasons:

1. To provide a fast dynamic response for the powertrain.
2. To enable recovery of regenerative braking energy, and to improve the overall efficiency of the vehicle.
3. To reduce the size of the FC, where an FC of lower rated power can be significantly lighter and cheaper than an FC of higher rated power.
4. Improvement in the CS allows the FC to operate more often in the high efficiency region.

As illustrated in Figure 4, one or more high-power DC/DC converters are commonly required within an FCHEV powertrain. The major challenge of multiple DC/DC converters is the CS, which would be complicated. In other words, for these applications, a high-power DC/DC converter is a key component that interfaces the FC or ESS to the DC-bus in the powertrain of the SHEVs (Emadi, Williamson, and Khaligh, 2006; Emadi, Lee, and Rajashekara, 2008; Hegazy, Van Mierlo, and Lataire, 2011a). Therefore, the design of high-power DC/DC converters and their controller would play an important role in the future powertrain system to control the power regulation, particularly for a common DC-bus. Several topologies of DC/DC converters based on the count of their components, advantages, and disadvantages are discussed and compared in the literature (Solero *et al.*, 2005; Hegazy, Van Mierlo, and Lataire, 2011a, 2011c). Moreover, for high

power applications, multiphase interleaved converters have been proposed for use in HEV applications to improve their efficiency and reliability. As is clear from previous studies, the selection of PEI is based on some significant factors such as lower cost, higher efficiency, electrical isolation, free ripple, and reliable operation.

In addition, the fuel consumption, driving range, emissions, and powertrain efficiency are the major issues when comparing SHEV based on ICE and SHEV based on FC. The SHEV based on FC can provide zero emissions, high fuel economy, high efficiency, and satisfied driving range compared to SHEV based on ICE. However, SHEV based on FC has a high cost, and it is still under development. Table 1 summarizes the major characteristics of the SHEV based on ICE and the SHEV based on FC (Chan, Bouscayrol, and Chen, 2010; Bayindir, Gozukucuk, and Teke, 2011).

4 HYBRIDIZATION RATE OF SERIES HYBRID ELECTRIC VEHICLES

There exist three definitions of the hybridization rate for the SHEVs. These definitions are (i) electric hybridization rate (EHR), (ii) combustion hybridization rate (CHR), and (iii) rate of hybridization (RoH) (Maggetto and Van Mierlo, 2000; Van Mierlo and Maggetto, 2001).

4.1 Electric hybridization rate (EHR)

The EHR gives an indication of the SHEV performance. The EHR is the ratio between the electric power and the total traction power as seen in Equations 1 and 2. Moreover, the EHR is expressed in percentage. The high percentage illustrates that the vehicle tends to a pure BEV.

$$\mathrm{EHR} = \frac{\text{electric power}}{\text{traction power}} \tag{1}$$

In SHEVs, the traction power corresponds with the nominal EM power as the EM is the only means to provide the power to the wheels. Consequently, the EHR for SHEV is given by

$$\mathrm{EHR} = \frac{\text{battery power}\,(P_{\mathrm{bat}})}{\text{electric motor power}\,(P_{\mathrm{mot}})} = \frac{P_{\mathrm{mot}} - P_{\mathrm{gen}}}{P_{\mathrm{bat}} + P_{\mathrm{gen}}} \tag{2}$$

where P_{gen} is the GENSET power.

4.2 Combustion hybridization rate (CHR)

To obtain an idea of the relative contribution of the ICE, the CHR is to be defined as the ratio between the thermal power and the total traction power, as indicated in Equations 3 and 4. Furthermore, CHR is expressed in percentage, and a high percentage indicates that the vehicle tends to be a pure thermal vehicle.

$$\mathrm{CHR} = \frac{\text{thermal power}}{\text{traction power}} \tag{3}$$

For SHEV, the thermal power is the rated GENSET power (P_{gen}). Therefore, the CHR is defined by

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto203
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$\mathrm{CHR} = \frac{P_{\mathrm{gen}}}{P_{\mathrm{mot}}} = \frac{P_{\mathrm{mot}} - P_{\mathrm{bat}}}{P_{\mathrm{bat}} + P_{\mathrm{gen}}} \tag{4}$$

It should be pointed out that the sum of EHR and CHR is always equal to 1 and each concept is just an indication of whether the vehicle tends toward a pure BEV or a pure thermal vehicle.

4.3 Rate of hybridization (RoH)

To investigate the relative contribution of each energy source, the rate of hybridization (RoH) has to be defined. If both energy sources have an equal contribution to the traction power, the RoH is defined as equal to 1 (for maximum value). If the contribution of the ICE system is higher than the electric battery system, the RoH ($\mathrm{RoH_{th}}$) is the ratio of the battery power (P_{bat}) to the thermal power (P_{gen}) and vice versa of the $\mathrm{RoH_{el}}$ (Equations 5 and 6).

$$\text{If } P_{\mathrm{bat}} < P_{\mathrm{gen}}, \quad \text{then} \quad \mathrm{RoH_{th}} = \frac{P_{\mathrm{bat}}}{P_{\mathrm{gen}}} \tag{5}$$

$$\text{If } P_{\mathrm{gen}} < P_{\mathrm{bat}}, \quad \text{then} \quad \mathrm{RoH_{el}} = \frac{P_{\mathrm{gen}}}{P_{\mathrm{bat}}} \tag{6}$$

Figure 5 illustrates the hybridization rate of SHEVs.

5 OPERATING MODES

In SHEVs, the power flow control can be illustrated by seven operating modes, as shown in Figure 6. Seven possible operating modes exist for the SHEVs:

1. *Mode 1* (called *pure GENSET drive*): the GENSET only supplies the required power.
2. Mode 2 (named *zero-emission driving*): in this mode, the GENSET is turned off and the vehicle is only supplied by the batteries. This mode can be applied in urban driving.
3. *Mode 3* (called *hybrid drive*): the traction power is supplied by the GENSET and the batteries. This mode is used when the power requirement is high.
4. *Mode 4* (named *engine traction and battery charging*): the GENSET provides the energy needed for charging the batteries and the propulsion of the vehicle.
5. *Mode 5* (called *battery charging and no drive*): in this mode, the GENSET charges the batteries, whereas the traction motor is not used.
6. *Mode 6* (named *regenerative braking*): during braking or deceleration, the GENSET is turned off and the traction motor is operated as generator to charge the battery.
7. *Mode 7* (*hybrid battery charging*): both the GENSET and the traction motor operate as generator to charge the batteries.

Furthermore, these operating modes of SHEVs are summarized in Table 2.

As a result, these various power flow paths can provide a tremendous flexibility of vehicle operation compared to CVs. With proper CS, applying a specific mode for a special operating condition can significantly improve the overall performance, efficiency, and emissions. In the following section, a general overview of the control strategies is presented.

6 ENERGY/POWER MANAGEMENT CONTROL

Owing to the multiple energy sources and PEIs, there exist several powertrain configurations and different control strategies to control the energy source, resulting in different operating modes. The aim of the energy/power management strategies is to satisfy a number of objectives for HEV. The main objectives are represented as follows:

1. Low fuel consumption
2. Low emissions
3. Low noise
4. Good drivability
5. Minimum propulsion system cost
6. Acceptable performance.

The concept of sharing the requested power between the ICE and ESS (i.e., battery packs) for traction mode during vehicle operation is referred to as *vehicle supervisory control* or *energy/power management control*. Therefore, there are a number of energy/power management strategies

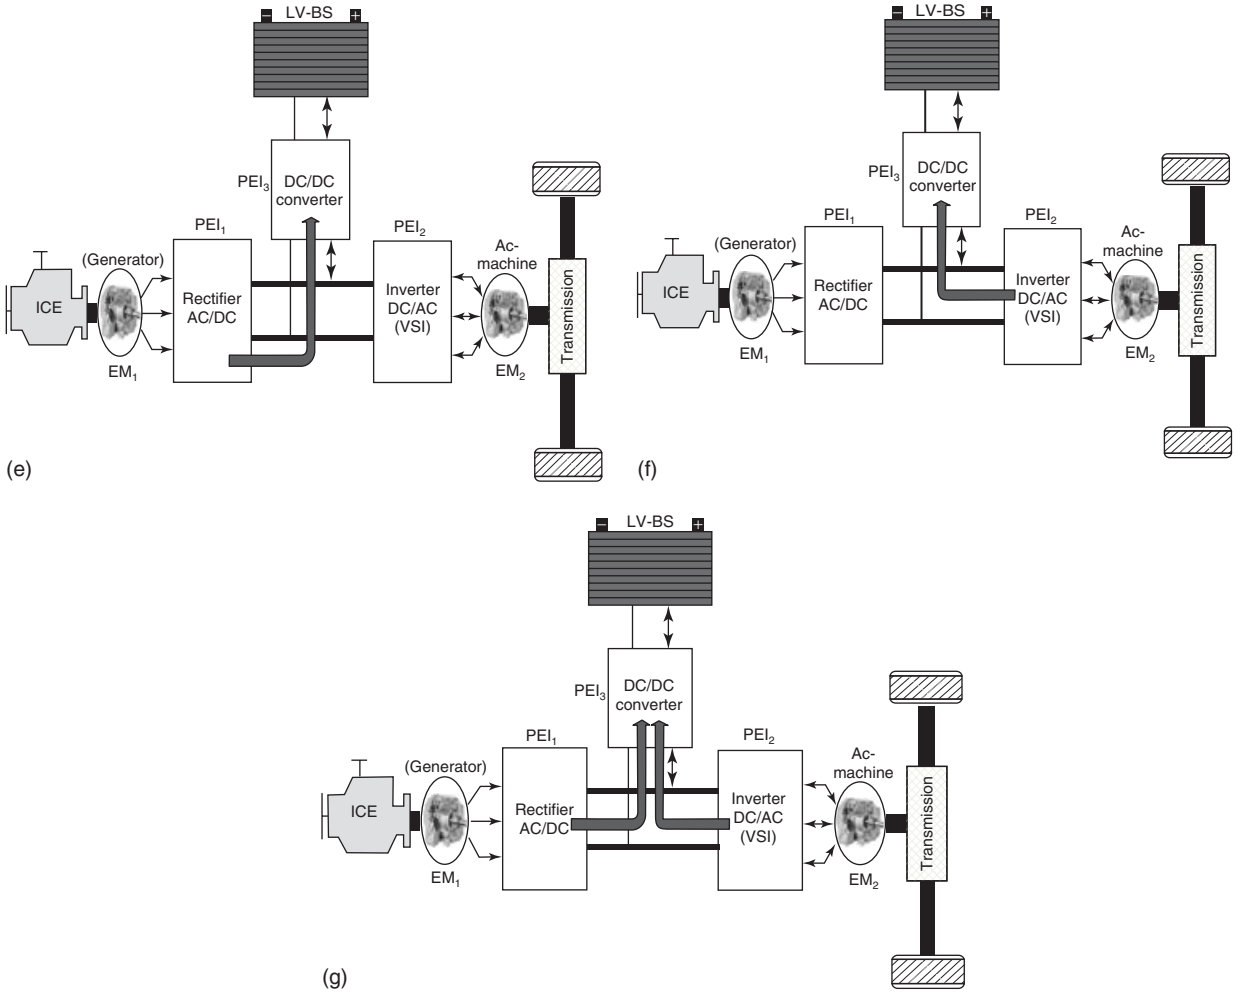

Figure 6. (*Continued*)

proposed in the literature of hybrid vehicles to minimize the fuel consumption and reduce the emissions (Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011; Barrero *et al*. 2009). As illustrated in Figure 7, the energy/power management control strategies can be classified into two main categories: rule-based control strategy (RBCS) and optimization-based control strategy (OBCS) (Salmasi, 2007; Hegazy, Van Mierlo, and Lataire, 2011b). These control strategies will be presented in more detail in Energy Management Systems of HEVs.

It is clear that different control strategies are possible to control the power flow in a hybrid powertrain, as shown in Figure 7. Majority of the proposed solutions for the power CS can be classified into two types: (i) RBCS and (ii) OBCS. RBCSs consist of deterministic and fuzzy logic-rule-based methods, while OBCSs are typically utilized global optimization and real-time optimization when determining the CS. The following subsections provide an overview of the commonly used control strategies.

6.1 Rule-based control strategies (RBCSs)

The main aspect of the RBCSs is their effectiveness in real-time supervisory control of power flow control in a hybrid powertrain. The rules are determined based on heuristics, human expertise, and mathematical models without a prior knowledge of a predefined driving cycle. These strategies can be classified into deterministic and fuzzy rule-based methods, as shown in Figure 7 (Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011; Barrero *et al*. 2009). The main concept of RBCSs is commonly based on "IF-THEN" type of control rules, which determine, for example,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

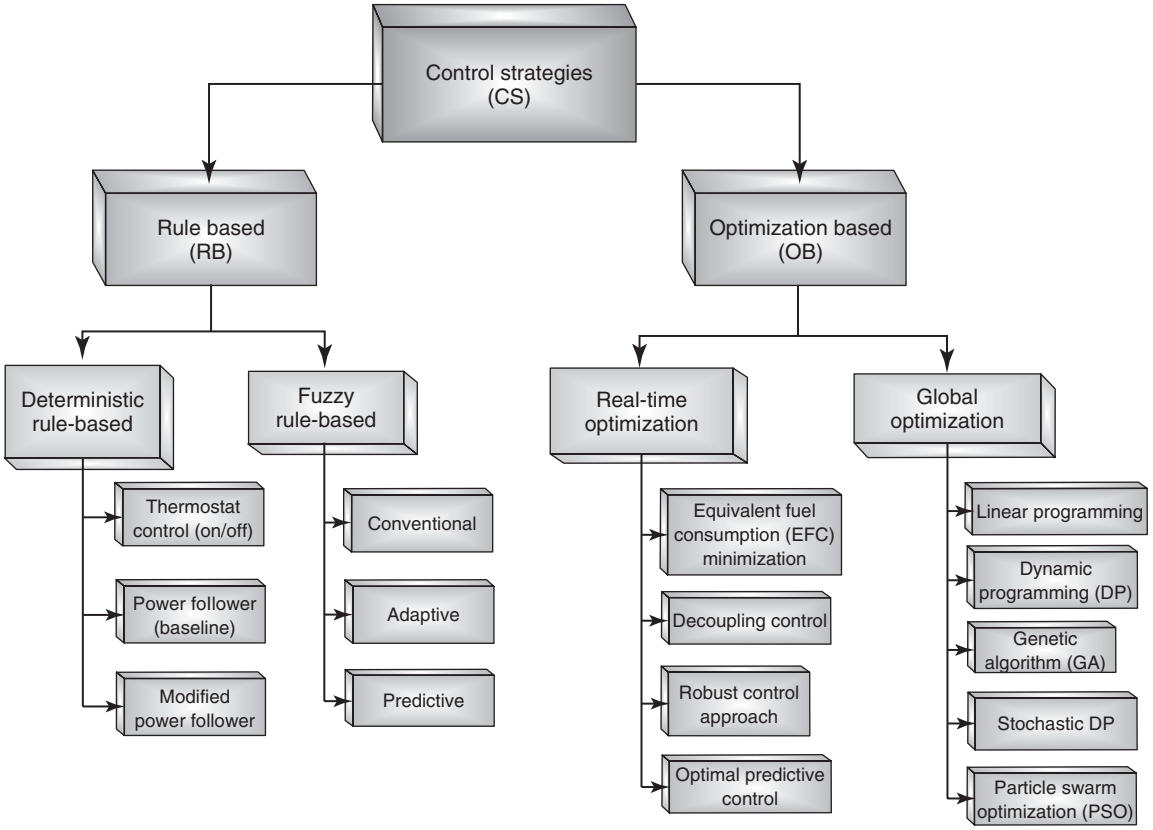

Figure 7. Classification of the hybrid electric vehicle control strategies.

when to shut down the ICE or the amount of electric charging/discharging powers. These control strategies perform load leveling or balancing within vehicle operation. The idea behind load leveling is to move the ICE operation point as close as possible to optimal region of fuel economy, efficiency, and emissions at particular ICE speed. However, for this type of system, a high fuel economy can be found at lower ICE torques, while the efficiency may not be the best value. Thus, small acceleration demand can result in higher fuel economy. The difference between the power demand and ICE-generated power will be compensated by the EES or utilized to charge the EES.

6.1.1 Deterministic rule-based control strategies (DRBCSs)

To realize these control strategies, the rules are designed with the aid of power flow in a hybrid powertrain, efficiency/fuel maps of ICE, and driving experience. Furthermore, these rules are generally implemented via lookup tables in order to split the requested power between the ICE and ESS.

6.1.1.1 Thermostat (ON/OFF) control strategy. Thermostat (ON/OFF) CS is a popular strategy for energy management in current hybrid powertrains (Barrero *et al*., 2009). This strategy attempts to obtain the maximum efficiency of the ICE. For this purpose, the ICE runs at the most efficient point of the efficiency map, providing a constant power. The difference between this set point and the power needed is absorbed by the ESS. In this simple CS, the battery SoC is always maintained between predefined high and low levels by simply turning on or off the ICE. In addition, the benefits of this strategy are an optimal ICE efficiency and almost no inertial losses. The drawbacks are that a larger ESS is needed so that the engine's ON-and-OFF cycles are not too short. In addition, high losses are produced on the ESS as the power flow is very high. The operation of the thermostat (ON/OFF) CS is illustrated in Figure 8.

6.2 Optimization-based control strategies (OBCSs)

These control strategies are used to maximize the fuel economy and the efficiency of the powertrain while

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto203
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

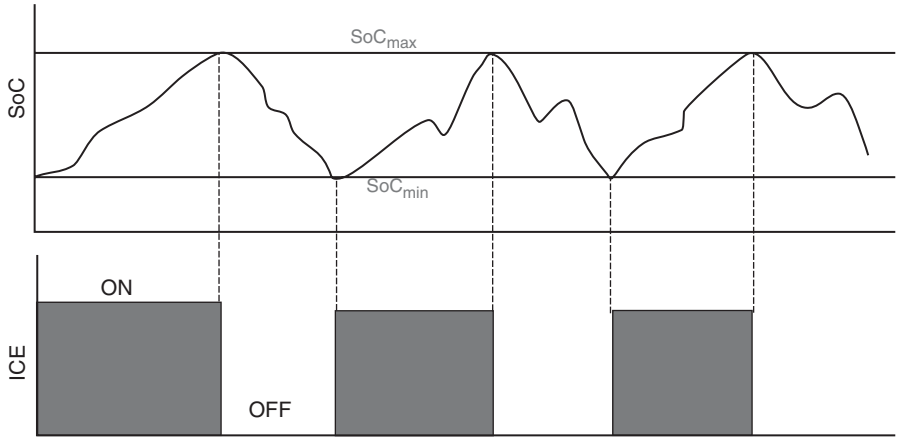

Figure 8. Operation of thermostat (ON/OFF) control strategy.

minimizing the losses in powertrain. The optimal reference torques/currents for the power converters and the optimal hybridization degree are calculated by minimization of a cost function generally representing the fuel consumption or emissions. If this optimization is implemented over a given driving cycle, a global optimum solution can be found. Indeed, the global optimal solution is inherently noncausal, in that it provides a minimum fuel consumption using knowledge of future and past power demands. However, these approaches cannot be directly utilized for real-time energy management and they are not easily implementable for practical applications. The classification of the OBCS is depicted in Figure 7.

6.2.1 Global optimization

There exist several presented solutions to achieve performance targets by optimization of a cost function representing efficiency, fuel consumption, and emissions over a drive cycle, yielding to global optimal operating points. These techniques are not applicable because of their preview nature and computational complexity (Salmasi, 2007; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011). Some control algorithms for global optimization, based on a priori knowledge of a scheduled driving cycle, have been proposed to achieve fairly fuel economy with minimum cost. A commonly used technique for determining the globally optimal energy management in hybrid powertrain is dynamic programming (DP) technique. The DP technique yields the minimum but has the disadvantage of its high computational load and the need for high memory storage capacity. It is a memory- and computational-intensive algorithm, especially when dealing with large-scale optimization problems. Recently, the particle swarm optimization (PSO) algorithm is used to achieve the global optimization for hybrid powertrain. PSO algorithm is a member of the wide category of swarm intelligence (SI) methods (Hegazy, Van Mierlo, and Lataire, 2011b). Compared to genetic algorithms (GAs) and DP, the PSO is simpler and requires less memory and less computational time. Moreover, the PSO algorithm has no evolution operators such as crossover and mutation. In addition, the PSO can reliably solve this complex constrained optimization problem easily and quickly.

7 CONCLUSION

This chapter has presented a comprehensive review of the SHEVs to give a clear overview on their powertrain and energy management control strategies for the next-generation SHEVs. Moreover, the benefits and the drawbacks of the SHEVs are provided. In this chapter, the different operating modes of the SHEVs are investigated. Furthermore, a comparative study between SHEV based on ICE and SHEV based on FC has been presented in this study. It is noted that the SHEV based on FC is a very promising topology for improving the fuel economy and achieving zero emissions. Furthermore, it is important to point out that the SHEVs can have predominance in many applications, such as city vehicles and urban buses.

Parallel Hybrid Electric Vehicles (Parallel HEVs)

Joeri Van Mierlo and Omar Hegazy

Vrije Universiteit Brussel (VUB), Brussels, Belgium

1 INTRODUCTION

Owing to the concerns about the environmental and energy issues, many research studies have been carried out to enhance the performance of the internal combustion engine vehicles (ICEVs) and launch new-generation vehicles. Furthermore, it is widely accepted that the fuel consumption improvements of ICEV are reaching their limits. To improve the performance of the ICEVs and recover energy through regenerative braking, the vehicle should be hybridized with energy storage systems (ESSs), such as batteries, supercapacitors, or flywheels (Van Mierlo and Maggetto, 2001; Van Mierlo, Van den Bossche, and Maggetto, 2004; Chan, 2007; Chan, Bouscayrol, and Chen, 2010). Nowadays, hybrid electric vehicles (HEVs) have become an interesting alternative to ICEVs because of their ability to reduce the fuel consumption and achieve zero-exhaust emissions. HEVs can significantly provide high performance and flexibility over conventional vehicles.

In general, HEVs consist of an internal combustion engine (ICE) and one or more electric motors (EMs). In other words, HEVs comprise two or more energy sources to drive the vehicle, normally one is the main source (called *ICE*) and another is an ESS (such as battery and supercapacitor). In HEV configuration, the ESS can be connected to DC power bus through a bidirectional power electronics interface (PEI) (called *DC/DC converter*), whereas the EM is connected to DC power bus by means of a motor controller, which is a bidirectional DC/AC inverter. Conceptually, it is inherently an EM that assists the ICE for achieving lower emissions and fuel consumption. Furthermore, the ESS can improve the dynamic performance of the vehicle and recuperate the energy during regenerative braking.

On the basis of different combinations of connecting EM, transmission system, and ICE, HEVs are generally classified into two basic configurations: series hybrid electric vehicles (SHEVs) and parallel hybrid electric vehicles (parallel HEVs). Recently, with the combination of the features of both SHEVs and parallel HEVs, the classification has been extended to three arrangements: series, parallel, and series–parallel or power-split hybrid vehicles (Van Mierlo and Maggetto, 2001; Van Mierlo, Van den Bossche, and Maggetto 2004). As described in the previous chapter (see Series Hybrid Electric Vehicles (SHEVs)), SHEVs can provide a viable solution to extend the range of the battery electric vehicles (BEVs).

This chapter provides an overview of common parallel HEVs and gives a comprehensive review on their powertrains and power management strategies. In this chapter, different transmission systems are presented. Furthermore,

the hybridization rate of parallel HEVs is explained in this chapter.

2 CONCEPT OF PARALLEL HYBRID ELECTRIC VEHICLES

Parallel HEVs comprise an ICE and at least one EM, which are both mechanically connected in parallel to drive the wheels. Figure 1 shows the schematic diagram of the concept of the parallel HEV configuration, where the output torques of the ICE and the EM are mechanically connected through a torque coupler or speed coupler. As illustrated in Figure 1, the power relationship can be expressed as follows:

$$P_{\text{req}} = P_{\text{ICE}} + P_{\text{EM}} = P_{\text{ICE}} + \begin{cases} \eta_{\text{EM}} P_{\text{ESS}}, & \text{if } P_{\text{EM}} \geq 0 \text{ (motor mode)} \\ \frac{P_{\text{ESS}}}{\eta_{\text{EM}}}, & \text{if } P_{\text{EM}} < 0 \text{ (generator mode)} \end{cases} \quad (1)$$

where

P_{req} the required power
P_{ICE} the ICE power
P_{EM} the electric motor power
P_{ESS} the ESS power
η_{EM} the electric motor efficiency.

Thus, the overall powertrain efficiency is increased because of low power transmission losses compared to the SHEV powertrain. The parallel HEV powertrain is compact because the generator is not needed and the EM size is small compared to the EM of the SHEV. In addition, the parallel HEV offers more freedom to select the combination of the traction source. For example, the EM can be connected to the powertrain in different ways and can be located at different positions along the transmission (see the subsequent text).

In parallel HEV configuration, both ICE and EM can propel the vehicle, either independently or simultaneously, thanks to the use of clutches. The main advantage of parallel HEV is that the vehicle can recuperate the energy from the regenerative braking instead of losing the kinetic energy as heat in mechanical brakes as in ICEVs. Moreover, the parallel HEV allows to utilize the EM as starter motor, which allows to switch off the ICE when the vehicle is standing still at a red traffic light.

The parallel HEVs have some benefits compared to the ICEVs, which are summarized as follows (Van Mierlo and Maggetto, 2001, 2004):

1. The ICE can be operated in a region (in the torque–speed engine map) where it has a good efficiency. In conventional vehicles, the ICE can sometimes be operated at working conditions where the efficiency drops below 20% (see the dark gray line in Figure 2).
2. Both the ICE and EM are directly connected to the wheels. Consequently, the energy loss may be low, which increases the overall powertrain efficiency. In other words, the parallel HEV has fewer energy conversion stages than the SHEV.
3. The EM allows stop–start functionality: switching off the ICE when the vehicle is standstill.
4. Braking energy can be recuperated into the battery because of the fact that the EM works as a generator during vehicle deceleration.
5. Owing to the absence of the electric generator, the parallel HEV is more compact than the SHEV.

However, the parallel HEVs have some disadvantages, which are represented as follows:

1. The mechanical transmission system is complex.
2. The control of parallel HEV is more complicated than SHEV because of the mechanical coupling.
3. The mechanical coupling of the ICE to the wheels leads to a limited choice of operating points of the ICE in a narrow speed and torque range.

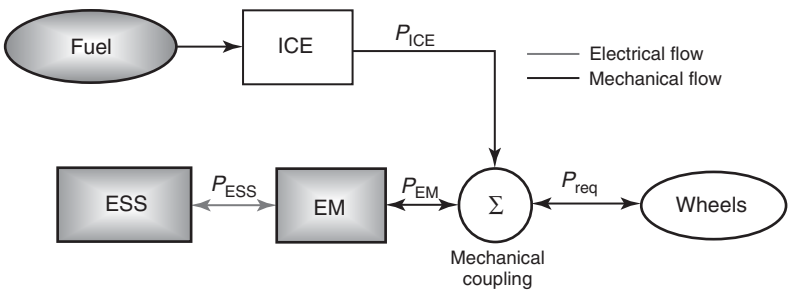

Figure 1. Schematic diagram of parallel HEV.

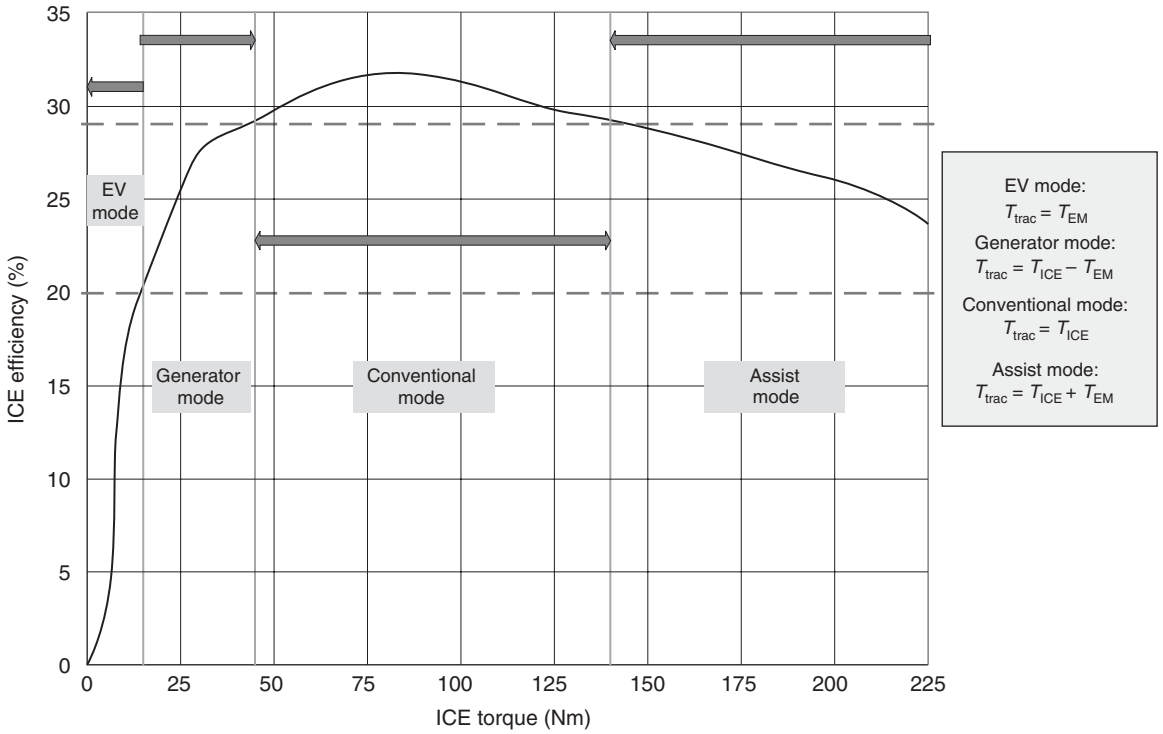

Figure 2. Different operating modes based on ICE torque and ICE efficiency at a given speed. T_{trac}, the traction torque; T_{EM}, the EM torque; T_{ICE}, the ICE torque.

Figure 2 presents the operating modes depending on the ICE torque and ICE efficiency at a given speed (Debal *et al*., 2009). This figure clearly demonstrates the ability of a parallel HEV to optimize the fuel consumption to operate the ICE in a region where it has a high efficiency. This is possible only during the presence of the EM.

Indeed, at low requested torque, the parallel HEV will operate in electric vehicle mode (EV mode). Only the EM will drive the wheels.

At a higher requested driving torque (example shown in Figure 2 between 17 and 40 Nm), the parallel HEV will be operated in generator mode. This means that the EM will function as a generator, demanding a higher power to the ICE than needed for driving. Hence, the ICE is operated at efficiency higher than 20% (in this example). In this generator mode, the battery is charged.

Above 40 Nm, the vehicle will work as a conventional vehicle (conventional mode). Only the ICE drives the wheels.

Above 140 Nm, the parallel HEV will be operated in power assist mode (assist mode). This means that the ICE and EM are driving the wheels. This mode not only achieves higher fuel economy, but also keeps the vehicular emissions low. The gray dashed lines indicate the ICE efficiency at beginning of each operating mode.

3 PARALLEL HYBRID ELECTRIC DRIVETRAINS

There exist different parallel HEV propulsion topologies. The parallel HEV drivetrain configurations comprise a conventional drivetrain (ICEV) with an electrical drivetrain (ED) in parallel. On the basis of the location of the transmission system relative to the ICE and EM, the parallel HEV drivetrains can be further classified as pretransmission (Figure 3) or posttransmission parallel HEV (Figure 4). The stop–start functionality is easier to implement in a pretransmission parallel HEV. Furthermore, the requested EM maximum torque is smaller than in the case of a posttransmission parallel HEV. On the other hand, the posttransmission parallel HEV has the advantage that the power does not need to pass through the transmission (while driving as well as braking), which reduces the losses. The challenge of the posttransmission parallel HEV is the required high starting torque of

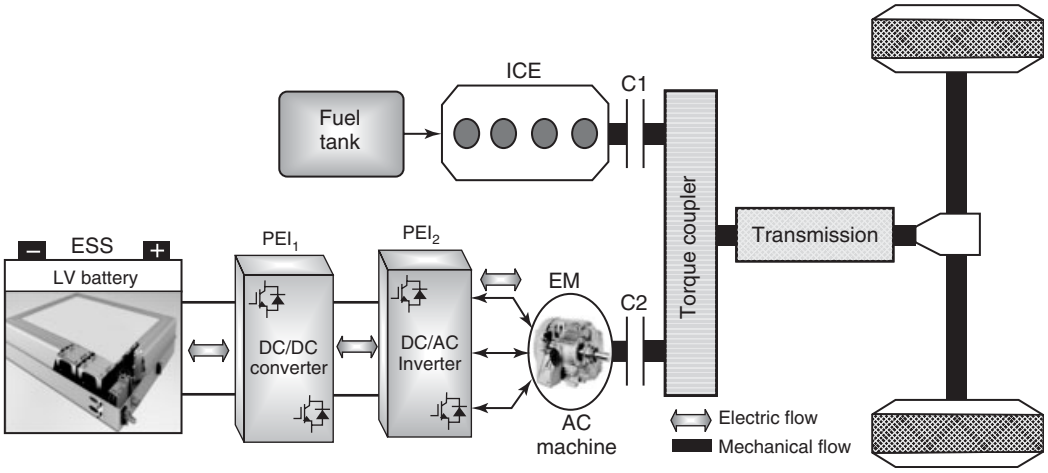

Figure 3. Pretransmission parallel HEV configuration.

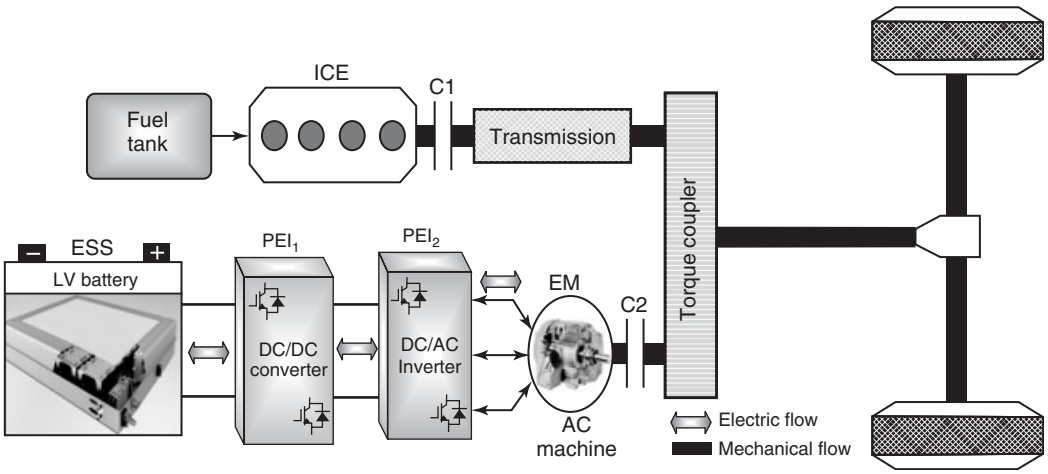

Figure 4. Posttransmission parallel HEV configuration.

the EM. A third solution is the split-transmission parallel HEV, which is also known as *separated axle configuration* (Figure 5).

In a pretransmission parallel HEV, the transmission system is located on the main drive shaft after the torque coupler, as shown in Figure 3. Hence, the gear speed ratios apply on both the ICE and the EM. The mechanical power flows are summed at the transmission system. In other words, the generated torque from the EM is added to the generated torque from the ICE at the input shaft of the transmission system. In addition, there are two clutches (C1 and C2), which are used to disconnect the ICE or the EM from the drivetrain, as illustrated in Figure 3. Therefore, this configuration can provide an independent use of the ICE and the EM, thanks to these clutches.

On the other hand, in a posttransmission parallel HEV, the transmission system is located on the ICE shaft before the torque coupler, as depicted in Figure 4. Hence, the gear speed ratios only apply on the ICE. In a posttransmission parallel HEV, the generated torque from the EM is added to the generated torque from the ICE delivered on the output shaft of the transmission system (Gao and Ehsani, 2006). The transmission system is used to adapt the operating point of the ICE in order to improve the vehicle performance. Furthermore, the posttransmission parallel HEVs can be used in HEVs with a higher degree of hybridization. To further improve the ICE efficiency, a continuous variable transmission (CVT) can be used.

As can be seen in Figures 3 and 4, a low-voltage (LV) battery system can be used to recover more energy from the DC link during regenerative braking. To achieve this operating mode, a bidirectional DC/DC converter is needed to work as a buck converter in order to transfer the power from DC link to LV battery system.

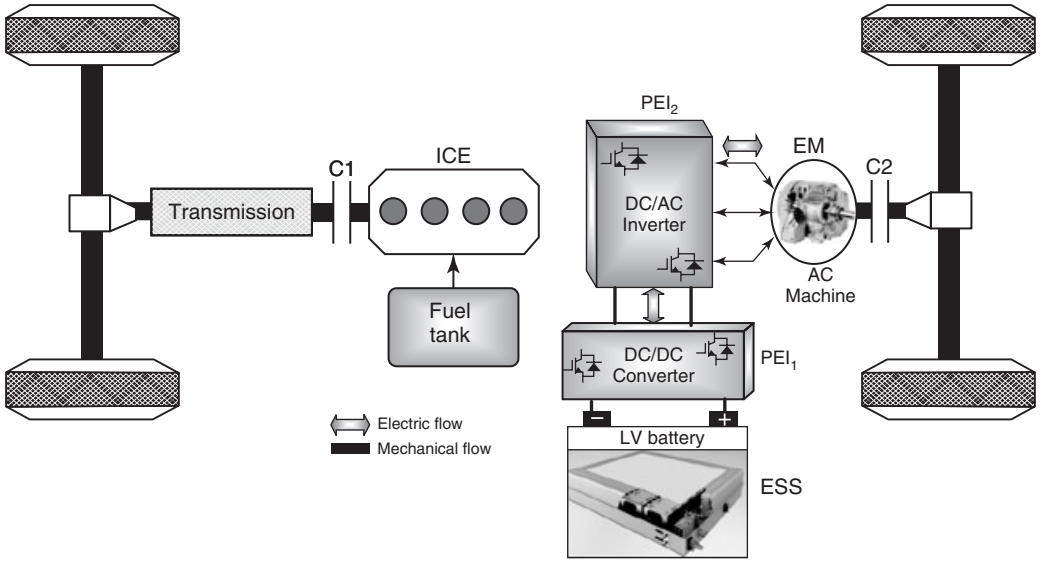

Figure 5. Through-the-road parallel HEV configuration.

As demonstrated in Figure 5, the ICE and the EM can drive on an all-wheel drive vehicle, which is known as *through-the-road configuration* or *separated axle configuration* (Ehsani, Gao, and Emadi, 2010). In this configuration, the ICE and the EM can separately provide the propulsion force to the wheels. The implementation of this configuration is to connect the ICE to the rear wheels, while the EM is connected to the front wheels. In this way, more power can be recuperated during the regenerative braking mode because the major weight is located on the front wheels during braking. Furthermore, this configuration is effective on slippery surfaces by providing vehicle longitudinal stability control that is not as easy with other types of parallel HEV configurations. However, in this configuration, the battery packs cannot be charged from the ICE when the vehicle is in a standstill mode. Furthermore, in the driving mode, the battery is charged by the ICE through an inefficient power path, where the power is transferred from the ICE via the road wheels to the battery system.

Most operating modes described in the SHEVs are still effective for parallel HEVs (see Series Hybrid Electric Vehicles (SHEVs)). It should be pointed out that the SHEVs may be considered as an extension of a purely BEVs with a small ICE, while the parallel HEVs can be considered as an improvement of the ICEVs with small ESS and EM. However, the control strategy of the parallel HEVs is more complicated than the control of the SHEVs because of the mechanical coupling between the ICE and the EM. As mentioned in SHEVs section, one or more PEIs (such as DC/DC converter and DC/AC inverter) are commonly used in parallel HEV powertrain (Emadi, Lee, and Rajashekara, 2008; Van Mierlo and Maggetto, 2001). Furthermore, one or more EMs are required in parallel HEV powertrain. Therefore, the major challenges of the development of the parallel HEV are PEIs, EMs, mechanical coupling systems, and control strategies.

4 HYBRIDIZATION RATE OF THE PARALLEL HEV

The concept of the hybridization rate of the parallel HEV is mainly classified into three basic definitions: (i) electric hybridization rate (EHR), (ii) combustion hybridization rate (CHR), and (iii) rate of hybridization (RoH) (Maggetto and Van Mierlo, 2000; Van Mierlo and Maggetto, 2001). As explained before in the previous chapter (see Series Hybrid Electric Vehicles (SHEVs)), the EHR indicates as to which extent the propulsion system tends toward a BEV. In general, the EHR is the ratio between the electric power and the total traction power. In the case of a parallel HEV, the EHR is equal to the ratio of the EM power to the total traction power, as illustrated in Equation 2.

$$\text{EHR} = \frac{\text{power of the electric motor}}{\text{power of the ICE} + \text{power of the electric motor}} = \frac{P_{\text{EM}}}{P_{\text{ICE}} + P_{\text{EM}}} \quad (2)$$

On the other hand, the CHR is the ratio between the ICE power and the total traction power, as shown in Equation 3.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto204
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Furthermore, the CHR can be expressed in percentage, and a high percentage indicates that the vehicle tends to be an ICEV. The CHR can be written as follows:

$$\mathrm{CHR} = \frac{\text{power of the ICE}}{\text{power of the ICE} + \text{power of the electric motor}} = \frac{P_{\mathrm{ICE}}}{P_{\mathrm{ICE}} + P_{\mathrm{EM}}} \quad (3)$$

To investigate the relative contribution of each energy source to another, the RoH can be defined. Hence, if both energy sources have an equal contribution to the traction power, the RoH will be 1 (or 100%). As was described for SHEVs, if the contribution of the ICE power is higher than the EM power, the RoH ($\mathrm{RoH_{ICE}}$) is the ratio of the EM power (P_{EM}) to the ICE power (P_{ICE}) and vice versa of the $\mathrm{RoH_{EM}}$, as demonstrated in Equations 4 and 5.

$$\text{If } P_{\mathrm{EM}} < P_{\mathrm{ICE}} \Rightarrow \text{Then} \quad \mathrm{RoH_{ICE}} = \frac{P_{\mathrm{EM}}}{P_{\mathrm{ICE}}} \quad (4)$$

$$\text{If } P_{\mathrm{ICE}} < P_{\mathrm{EM}} \Rightarrow \text{Then} \quad \mathrm{RoH_{EM}} = \frac{P_{\mathrm{ICE}}}{P_{\mathrm{EM}}} \quad (5)$$

Figure 6 presents the hybridization rate of the parallel HEVs. In the following section, the operating modes of the parallel HEV are described.

5 THE OPERATING MODES OF THE PARALLEL HEV

Owing to the multiple sources and coupling systems, the parallel HEV has different operating modes in general. These operating modes are illustrated in Figure 7. In addition, these operating modes are described in detail as follows:

1. In *mode 1* (pure electric drive mode), as shown in Figure 7a, the ICE is switched off and the parallel HEV only runs on its EM, which receives the energy from the battery pack. This mode occurs when the parallel HEV speed is low.
2. In *mode 2* (hybrid drive mode), as illustrated in Figure 7b, when the traction power is higher than the maximum power of the ICE, both ICE and the EM are operated to drive the parallel HEV.
3. In *mode 3* (hybrid battery-charging mode), as shown in Figure 7c, the battery pack can be charged by the energy that delivered from the ICE and regenerative braking, when the battery has a very low state of charge (SoC), and the regenerative braking energy is not enough to recharge the battery.
4. In *mode 4* (regenerative braking mode), as depicted in Figure 7d, the braking energy can be recuperated to charge the battery pack by using the EM as a generator.
5. In *mode 5* (pure ICE drive mode), as shown in Figure 7e, the ICE is switched on to drive the parallel HEV, when the battery is fully charged, and the required power is less than the ICE power that can deliver in its optimal operating line.
6. In *mode 6* (engine traction and battery-charging mode), as demonstrated in Figure 7f, the ICE is turned on to propel the parallel HEV and charge the battery, where the battery SoC is below the upper limit, and the required power is less than the ICE power. In this mode, the ICE can operate in

its optimal operating line to improve the powertrain efficiency.

6 MECHANICAL COUPLING

In parallel HEV powertrain, the main goal of the mechanical coupling, irrespective of the type of transmission, is to keep the ICE speed and torque within its operating point regardless of the speed and torque requirements at the wheels, as explained Section 2 (Van Mierlo and Maggetto, 2000, 2001). This adaptation of speed can be achieved in different ways for manual and automatic transmission systems. In other words, the two energy sources may be coupled together by either torque or speed coupling.

In the torque-coupling system, the speed values of the ICE and EM have always the same relation to each other. Furthermore, the torque coupling sums the generated torques of the ICE and EM and delivers the total torque to the wheels. As shown in Figure 8, the typical torque coupling is a shaft-fixed gear set. The speed relation between the inputs and outputs can be expressed as follows (Gao and Ehsani, 2006; Van Mierlo and Maggetto, 2000, 2001, 2004):

$$\omega_3 = \frac{1}{i_{g1}}\omega_1, \quad \omega_3 = \frac{1}{i_{g2}}\omega_2, \quad \text{and} \quad \omega_2 = \frac{i_{g2}}{i_{g1}}\omega_1 \tag{6}$$

In the traction mode, the torque relation between the inputs and outputs can be given by

$$T_3 = T_1 \cdot i_{g1} \cdot \eta_1 + T_2 \cdot i_{g2} \cdot \eta_2 \tag{7}$$

However, in the regenerative braking mode, the torque relation between the inputs and outputs can be calculated as follows:

$$T_3 = \frac{T_1 \cdot i_{g1}}{\eta_1} + \frac{T_2 \cdot i_{g2}}{\eta_2} \tag{8}$$

where

η_1	the efficiency of the ICE shaft to the output shaft
η_2	the efficiency of EM shaft to the output shaft
T_1	the ICE torque
T_2	the EM torque
T_3	the output torque
i_{g1}	the gear ratio of the ICE shaft to the output shaft
i_{g2}	the gear ratio of the EM shaft to the output shaft
ω_1	the speed of the ICE shaft
ω_2	the speed of the EM shaft
ω_3	the speed of the output shaft.

7 POWER FLOW CONTROL STRATEGIES

Owing to the mechanical coupling, the control structure of parallel HEV is more complicated than SHEV. The main objectives of the control strategies are to satisfy the requirements of the vehicles (Van Mierlo and Maggetto, 2000, 2001) and improve the performance of the parallel HEVs. In the parallel HEV configuration, the supervisory control strategy comprises energy management rules to split power requirements between the ICE and the EM as well as to determine the transmission gear ratio. Consequently, the

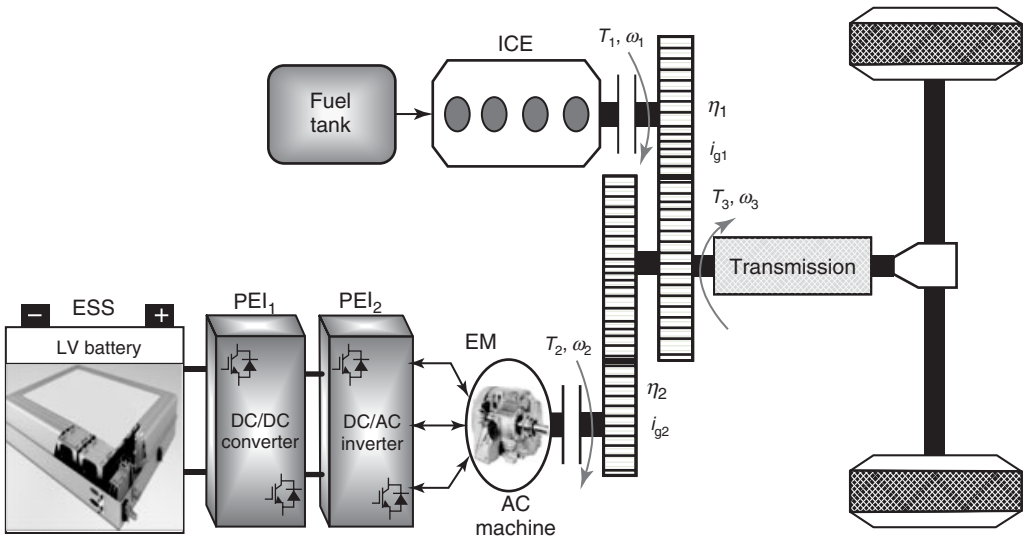

Figure 8. Gear set as the torque coupling for parallel HEV.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto204
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

main objective of the power control strategy is to operate the ICE along its optimal operating line, that is, where the highest efficiency is achieved for every given power level (see the dark gray line in Figure 2). In order to achieve this target, it is important that the correct number of gears and the correct individual gear ratios would be chosen.

Recently, different control strategies in the literature have been reported for parallel HEVs to improve the fuel economy, reduce exhaust emissions, and maintain the battery packs in their desired SoC (Gao and Porandla, 2005; Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011; Sciarretta, Back, and Guzzella, 2004; Salmanx, Schouten, and Kheir, 2000). These energy management strategies can be generally classified into two kinds and they are as follows:

1. rule-based control strategies
2. optimization-based control strategies.

The rule-based control strategies consist of deterministic and fuzzy logic rule-based methods, while optimization-based control strategies are typically utilized global optimization and real-time optimization when determining the control strategy.

Furthermore, the main concept of rule-based control strategies is commonly based on "IF-THEN" type of control rules. These control strategies only operate the main energy source (i.e., ICE) when it can operate at a high-efficiency region because of high power demands or low SoC of the ESS (such as batteries). The rule-based control strategies can be used to operate the parallel HEV in purely electrical mode from standstill to a low vehicle speed. When the vehicle speeds up from this speed, the ICE will turn on and operate based on optimal operating line. Thereby, the fuel consumption and the exhaust emissions can be reduced, and the total efficiency of the parallel HEV powertrain can be improved. However, as in all HEV propulsion systems, the SoC of the ESS should be controlled as well.

On the other hand, the optimization-based control strategies are used to minimize the fuel consumption and maximize the efficiency of the powertrain. In fact, the global optimal solution is inherently noncausal, in that it provides a minimum fuel consumption using knowledge of future and past power demands. However, these control strategies cannot be directly used for real-time energy management and they are not easily implementable for practical applications (Gao and Porandla, 2005; Salmasi, 2007; Gao *et al*., 2009; Bayindir, Gozukucuk, and Teke, 2011; Shen, Shan, and Gao, 2011; Sciarretta, Back, and Guzzella, 2004; Salmanx, Schouten, and Kheir, 2000).

Nowadays, the Honda Insight, Honda Civic, Ford Escape hybrid SUV, and Honda Accord are some examples of parallel HEVs, which are commercially available in the market.

8 CONCLUSIONS

This chapter presents an overview of the parallel HEV powertrains. Moreover, the advantages and the disadvantages of the parallel HEV are presented. In this chapter, the different operating modes of the parallel HEVs are provided. Furthermore, different mechanical coupling systems that used in parallel HEV powertrains are described. It should be pointed out that parallel HEVs can have predominance in many applications, such as city vehicles and trucks.

Series–Parallel Hybrid Electric Vehicles

Joeri Van Mierlo, Omar Hegazy, Jelle Smekens, and Cedric De Cauwer

Vrije Universiteit Brussel (VUB), Brussels, Belgium

1 INTRODUCTION

In general, hybrid electric vehicles (HEVs) can be classified into series hybrids, parallel hybrids, and series–parallel hybrid vehicles. The series–parallel hybrid electric vehicles (series–parallel HEVs) incorporate the features of both series hybrid electric vehicles (SHEVs) and parallel hybrid electric vehicles (parallel HEVs). This powertrain comprises an additional mechanical link as compared with the SHEVs and also an additional generator as compared with the parallel HEVs. Because of the fact that series–parallel HEVs can operate in both parallel and series modes, the fuel economy and drivability can be optimized based on the operating condition of the vehicle. However, due to increased components and complexity, the series–parallel HEVs can be more expensive than a series or parallel HEV.

The series–parallel HEV is also known as a *combined hybrid electric vehicle* (*CHEV*) or *power-split HEV* (Liu and Peng, 2008; Chan, 2007; Chan, Bouscayrol, and Chen, 2010; Bayindir, Gozukucuk, and Teke, 2011; Van Mierlo and Maggetto, 2000, 2004). The Toyota Hybrid System (THS) is a series–parallel drivetrain, which was developed and used on Toyota Prius in 1997 in Japan (Liu and Peng, 2008). As is reported in the literature, the series–parallel HEVs are investigated and developed to overcome the drawbacks of series and parallel architectures (Grammatico, Balluchi, and Cosoli, 2010).

This chapter reviews the state of the art of the series–parallel HEVs, and gives an overview on their powertrain and power management strategy. In this chapter, different transmission systems [such as continuous variable transmission (CVT) and electric variable transmission (EVT)] are described. In addition, the operating modes of the series–parallel HEVs are explained in detail.

2 CONCEPT OF SERIES–PARALLEL HYBRID ELECTRIC VEHICLES

There are a number of variations of series–parallel HEV configurations. The series–parallel HEV contains an internal combustion engine (ICE) and one or more energy storage systems (ESSs), as illustrated in Figure 1. Configurations 1 and 2 also consist of two electric motors (EMs) and a power-split device. The power coupling contains a torque and/or speed coupling and possibly one or more single- or multigear transmissions. With the invention of EVTs, a third configuration has been made possible in which the EVT fulfills coupling, motor, and generator

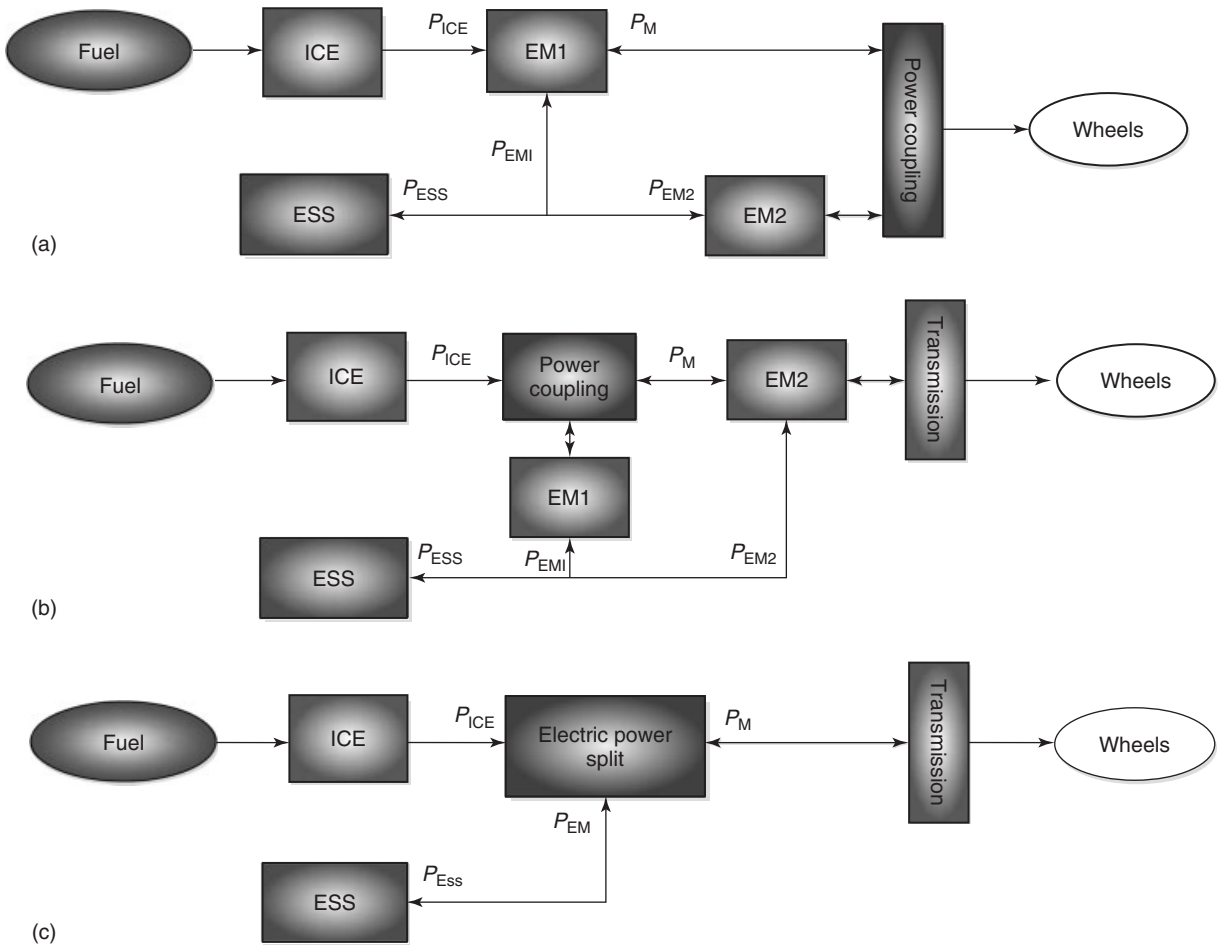

Figure 1. Schematic diagram of series–parallel HEVs. (a) Configuration 1; (b) configuration 2; (c) configuration 3.

functions. In configuration 3, the EVT is contained in the electric power split together with a single- or multigear transmission. Because the EVT fulfills multiple functions, it is convenient to introduce the concept of a power split to compare with the other configurations. In Section 2, the power split is introduced, and we will see that the combination of power coupling device and two electric machines can realize the same power conversions as a power split. In the schematic diagrams in Figure 1, no electronic power converters or controllers are depicted, but it is presumed that they are implicitly present.

The advantage of a series–parallel HEV is that it has several more operation modes than those of an SHEV or parallel HEV separately and thus can benefit from the advantages of both, as described in the previous chapters (see Series Hybrid Electric Vehicles (SHEVs) and Parallel Hybrid Electric Vehicles (Parallel HEVs)). Furthermore, one can observe the differences between the three topologies from the point of the view of the design of a drivetrain.

- In an SHEV, the rated power of the traction motor is directly determined by the design requirements of the vehicle. So, there is no degree of freedom (DoF) in downsizing the EM. However, the ICE can be downsized compared to the conventional ICE-powered vehicle. In addition, the ICE can run in its high-efficiency operating point when charging the battery.
- In a parallel HEV, there is more liberty in downsizing the ICE or the EM because their power is added to deliver the power to the wheels. However, the mechanical coupling of the ICE to the wheels makes it impossible to choose the operation of the ICE independent of the speed. The total power of the ICE and the EM is equal to the traction power. So, depending on the control strategy of this drivetrain, the ICE can be operated in its optimal region.
- In a series–parallel HEV, the power distribution among the ICE, EM1, and EM2 can be controlled to give more DoF compared to SHEV and parallel HEV powertrains.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Moreover, the power split allows the rotational speed of the motor to be decoupled from the speed of the vehicle.

With a series–parallel HEV, the carmaker has more DoF to look for an optimal powertrain relative to SHEVs and parallel HEVs. However, the disadvantage of the series–parallel HEV is that control strategies are more complex because of the increase in subsystems.

In the following section, the concept of a planetary gearbox, which functions as speed coupling, is explained in detail.

3 TRANSMISSION SYSTEMS

To realize the concept of a series–parallel HEV, a particular power conversion is required: the mechanical power (P_{ICE}) from the ICE and the electrical power (P_E) from the battery are considered to be power inputs and have to be summed up to deliver the traction power (P_T) transmitted to the wheels. As shown in Figure 2, this apparatus should have a bidirectional electric power input (P_E), an unidirectional mechanical power input for the ICE (P_{ICE}), and a bidirectional mechanical power output to connect the wheels of the vehicle (P_T). The output should be bidirectional for regenerative-braking purposes. The operating modes this device should deal with are the same, as specified in Section 3. It is convenient to call such a transmission system a power split. As mentioned earlier, a power split can be realized by the combination of a power coupling (i.e., a speed or torque coupler) and two electric machines or by an EVT. Below a speed coupler is introduced as a particular power coupling.

Analogous with the torque coupler that is introduced in the chapter on parallel HEVs (see Parallel Hybrid Electric Vehicles (Parallel HEVs)), we can define a speed coupler. A torque coupler signifies a three-port power transmission of which the output torque is a linear combination of the input torques, whereas a speed coupler signifies a three-port power transmission of which the output speed is a linear combination of the input speeds as written in Equation 1.

$$\omega_T = S_{ICE}.\omega_{ICE} + S_E.\omega_E \tag{1}$$

where S_{ICE} and S_E are constants associated with the design of the speed coupler. ω_{ICE} and ω_E are, respectively, the rotational speed of the ICE and the rotational speed that can be associated with the electrical input. ω_T is the rotational speed of the output shaft. By introducing energy conservation and neglecting the losses, we see that this power converter offers two degrees of freedom: ω_{ICE} and ω_E. The torques are linked together by the following equation of which the lowest torque determines the other two (Ehsani, Gao, and Emadi, 2010).

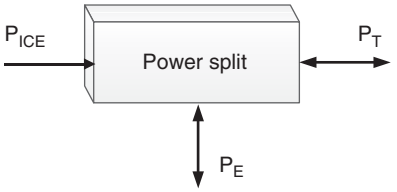

Figure 2. The block diagram of the power split.

$$T_T = \frac{T_{ICE}}{S_{ICE}} = \frac{T_E}{S_E} \tag{2}$$

where T_T, T_{ICE}, and T_E are, respectively, the torques related to the input and two output shafts. In the Toyota Prius, the speed coupling is realized using a planetary gearbox.

3.1 Planetary gearbox

A speed coupler can be realized using a planetary gear in which the torque values of all the shafts have a constant relation to each other. Planetary gearing is widely used in many HEVs as a speed coupling (Gao and Ehsani, 2006; Van Mierlo and Maggetto, 2000, 2001). It features a compact structure, high load ability, and a high efficiency. Figure 3 illustrates the section drawing of the planetary gear. It includes three parts, a sun gear, a ring gear, and several planet gears connected by a gear carrier. The sun gear, the ring gear, and the carrier gear are the three shafts a planetary gear set connects to the outside. The planetary gear set is often utilized in an automatic transmission. Such a gear set can produce one or two gear reductions and reverse based on simultaneously engaging or locking various elements of the planetary systems. For example, the gear reduction can be produced in the planetary gear set by turning the sun gear and holding the ring gear. The speed relation between the inputs and outputs can be expressed as follows (Van Mierlo and Maggetto, 2000, 2001):

$$\omega_c \cdot (1 + \rho) = \rho \cdot \omega_s + \omega_r \tag{3}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto205
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

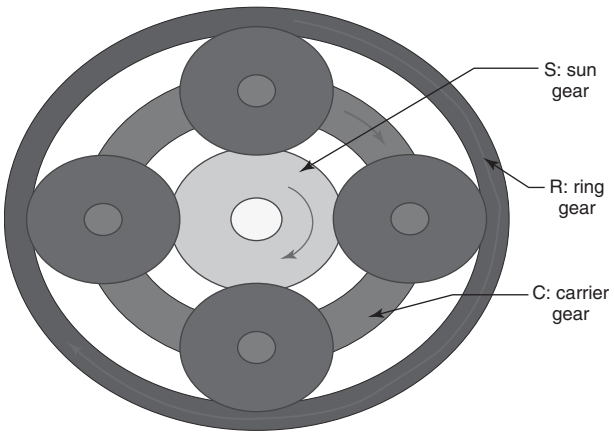

Figure 3. Planetary gearbox for speed coupling.

The torque relation between the inputs and outputs can be expressed by the following equation (Van Mierlo and Maggetto, 2001):

$$T_C = \frac{(1+\rho)}{\eta_S \cdot \rho} \cdot T_S = \frac{(1+\rho)}{\eta_R} \cdot T_R \qquad (4)$$

where

T	torque
η_S	efficiency from sun to carrier
η_R	efficiency from ring to carrier
ω_s	sun gear angular speed
ω_r	ring gear angular speed
ω_c	carrier angular speed
ρ	planetary gear ratio (number of the sun gear teeth/number of ring gear teeth)

As an example, we will explain the operational modes for a configuration 2-type series–parallel HEV. In the Toyota Prius II powertrain, the generator is mechanically connected to the sun gear, the motor to the ring gear, and the ICE to the carrier. The relation between the angular speeds of the three gears is described in Equation 5.

$$\omega_s = \left(1 + \frac{n_r}{n_s}\right) \times \omega_c - \frac{n_r}{n_s} \times \omega_r \qquad (5)$$

where in this particular case,

n_s	number of teeth of the sun gear
n_r	number of teeth of the ring gear
ω_s	sun gear angular speed equal to the generator angular speed
ω_r	ring gear angular speed equal to the motor angular speed
ω_c	carrier angular speed equal to the ICE angular speed

Additionally, the vehicle speed is linked to the motor speed by means of a gearbox (Figure 9, Section 3). Equation 5 is illustrated by a nomogram in Figure 4. In this figure, one can see three vertical lines representing all possible values of, respectively, the generator speed, the ICE speed, and the motor speed (or sun, carrier, and ring gears). The relative spacing between these vertical lines is related to the planetary gear ratio. The lines given in different colors represent the speed relation for different operational modes, which are discussed later. For example, with a generator speed of 2000 rpm and the ICE turned off (i.e., zero angular speed), the motor speed is determined by the intersection of the third vertical line with the straight line through these two points (generator speed of 2000 rpm, ICE of zero speed).

Operational modes as represented in Figure 4 are listed in the following:

- *Stand still* is represented by a red line, where all three speeds are zero.
- *Zero-emission driving* is represented by a yellow line. At low speeds, the ICE is turned off. Therefore, the ICE speed should be zero.
- *Reverse driving* is represented by a skin-colored line. Reverse driving is a particular form of zero-emission driving where the motor speed is negative.
- *Cranking aid* is represented by a purple line, where the ICE is driven by the generator, while the motor speed is zero. When the vehicle speed increases to a nonzero speed, the ICE's speed increases and it provides additional power, illustrated by the purple line migrating toward the position of the upper green line, which represents hybrid driving.
- *Hybrid driving* is represented by the green lines. In the upper line, the generator has a nonzero speed, while in the lower line, the generator is standing still. If the vehicle speed is set, the generator speed fixes the ICE speed. To preserve the freedom in choosing the operating point of the ICE, the generator must turn accordingly. This means that the generator must work on idle (no torque) to obtain the hybrid drive mode, that is, no battery charging with hybrid driving when ICE speed requirements fix the generator speed to a nonzero value.

3.2 Electric variable transmission

As described in the beginning of Section 3, the EVTs are contained in the electric power split in configuration 3 (Figures 1c and 10). Here, we will go in more detail on this device and give a review on the latest developments. An EVT equipped with the proper electric converters is

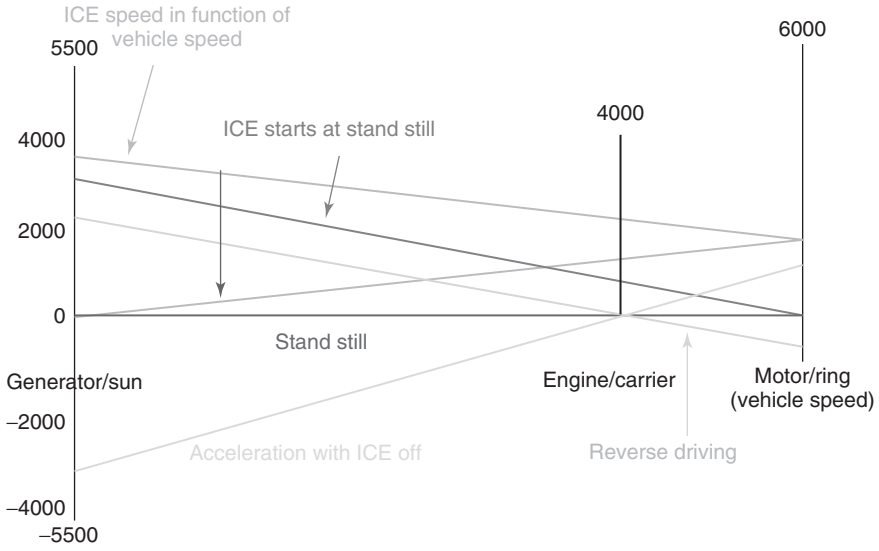

Figure 4. Nomogram of the Toyota Prius.

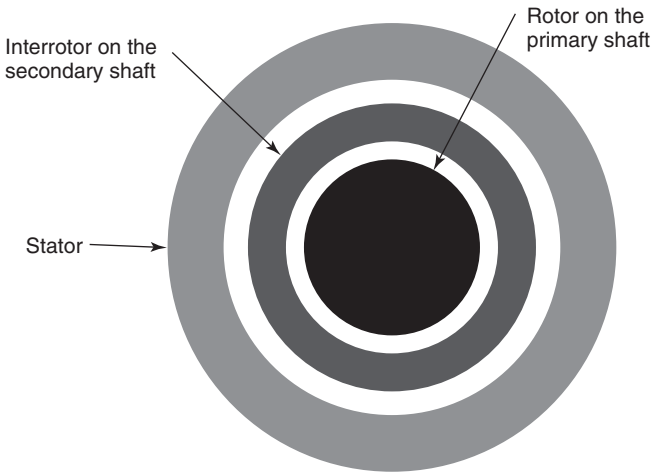

Figure 5. Two concentrically arranged electric machines.

capable of the same power conversions as a power split, hence the name electric power split.

The basic concept is to combine two electric machines concentrically based on magnetic coupling (Figure 5). As indicated in Figure 5, this concept is realized using two rotors and one stator. The rotor, which is fixed with the secondary shaft and is rotating between the rotor and the stator, is called *interrotor*. The electric power is exchanged via two power electronics converters with the DC-bus. The result is a power split with two mechanical ports and one electrical port (Miller, 2006).

One mechanical connection, the primary shaft, is connected to the ICE and the secondary shaft is connected to the driveline. For the inner machine (rotor and interrotor), we can write the following energy balance (Figure 6) (Kessels and van den Bosch, 2009).

$$P_{ICE} = T_{ICE}.\omega_{ICE} = P_{IM} + P_D \tag{6}$$

where P_D is the direct mechanical power, which is transferred to the secondary axis, and P_{IM} is the electrical power involved in this power transfer. For the outer machine, one can write the mechanical power as follows:

$$P_D = P_{EM} + P_M \tag{7}$$

where P_M $(= T_M \cdot \omega_M)$ is the mechanical output power and P_{EM} is the electrical power involved in this power transfer. The net electrical power is the sum of the electrical power from the power converters. This power is given by Equation 7:

$$P_E = P_{E1} + P_{E2} \tag{8}$$

where

- P_E includes the sum of the power from the electric converters and this power is accumulated in the battery.
- P_{E1} and P_{E2} are the electrical powers that are transferred to the inner and outer rotors, respectively. They are given by the following two equations.

$$P_{E1} = \begin{cases} P_{IM}\eta_1, & \text{if } P_{IM} \geq 0 \\ \frac{P_{IM}}{\eta_1}, & \text{if } P_{IM} < 0 \end{cases} \tag{9}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto205
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

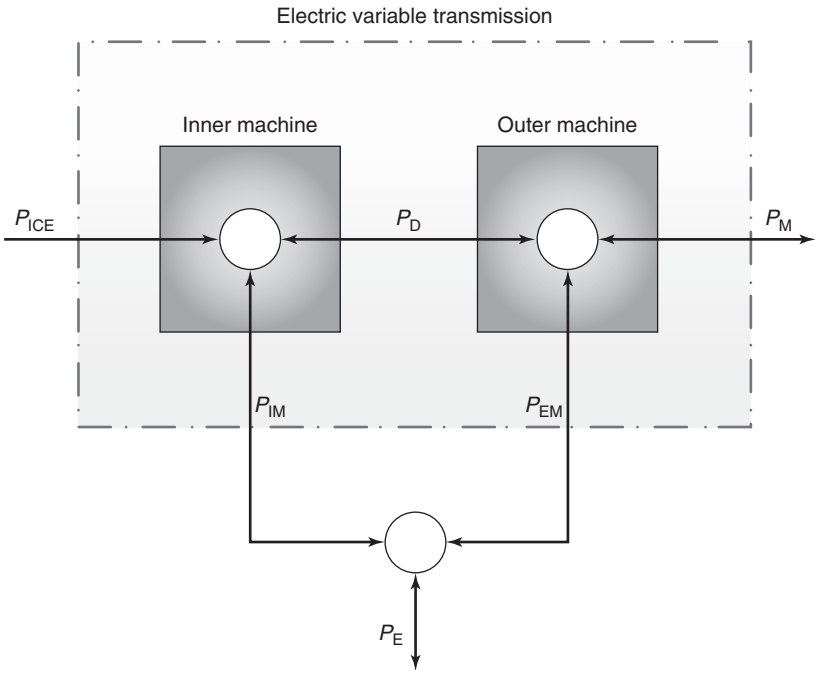

Figure 6. Power flows in an EVT.

$$P_{E2} = \begin{cases} P_{EM}\eta_2, & \text{if } P_{EM} \geq 0 \\ \frac{P_{EM}}{\eta_2}, & \text{if } P_{EM} < 0 \end{cases} \tag{10}$$

where η_1 and η_2 are the efficiencies of the electrical machines and the electronic power converters.

Although there is a direct power exchange, there is no mechanical link between the primary and secondary shafts. Furthermore, the two rotational speeds of the inner and outer rotors are independent. Figure 6 illustrates the power flows in an EVT. To understand how the ICE and battery are coupled to this apparatus, we refer to Figure 10 (Section 3).

Hoeijmakers and Rondel (2004) and Hoeijmakers (2003) proposed an EVT for HEVs. It was composed of two concentrically arranged induction machines (IMs): the outer machine is a common squirrel-cage induction machine (SCIM) with three-phase windings on the stator and the squirrel-cage on the interrotor. The inner machine is also an SCIM but with the three-phase windings on its inner part, the rotor, and its squirrel cage is on the outer part, the interrotor. The interrotor is made thin to make the machine light and compact, the fields of both machines turn with the same speed and the slip frequency is the same. The behavior of the two SCIMs cannot be separated and thus is not the same as two individual IMs. This is explained as follows (Figure 7): when the current in the rotor increases, the flux of the inner machine may saturate the interrotor material. Consequently, a part of the flux passes through the air gap of the external machine. In case a current passes in another direction of the stator windings, an electromechanical torque will be produced between the rotor and stator.

Another interesting way of accomplishing the variable transmission and the power split is the combination of two permanent magnet (PM) machines. Many configurations are possible depending on where the PMs are placed: on the rotor, interrotor, or stator (Xizheng *et al.*, 2009; Chen, Quan, and Zhu, 2011). PM machines offer the advantage of high power density and good efficiency, but it is difficult to weaken the magnetic field and they are relatively expensive because of the scarce materials used for PMs. Especially for

higher speeds, their inability for field weakening control is a drawback.

A third way that is being researched to make an EVT is the implementation of two switched reluctance machines (SRMs). SRMs are simple, reliable, have a lower manufacturing cost than IMs, and show superior thermal and mechanical robustnesses. They can accept high rotation speeds and high temperatures but they are noisy and produce a large torque ripple (Van Mierlo and Maggetto, 2001; Chen, Quan, and Zhu, 2011).

With the PM machines and SRM solution, the magnetic coupling between the inner and outer machines can be ignored. With SCIM, this is not the case, presenting an extra difficulty in the controllability of this machine.

As reported in the literature, the EVT can achieve all operating modes, which are required for the series–parallel HEV (Hoeijmakers and Ferreira, 2006; Hoeijmakers and Rondel, 2004).

4 SERIES–PARALLEL HYBRID ELECTRIC VEHICLE CONFIGURATIONS

In general, power can flow from the ICE completely and directly to the wheels (traction power), completely to the battery (charging power), or can be split in traction power and charging power. Electric power can flow from (traction power) and to the battery (braking or charging power). Combinations of these power flows result in eight practical operating modes, which are discussed in Section 4.1. As seen in Section 2, three configurations are possible to realize all the power flows. They are discussed later. In configuration 1 (Figure 8), the power from EM1 ($\eta_{EM1} \cdot P_{EM1}$) is added with the power from the ICE (P_{ICE})—they are on the same axis to deliver the mechanical power P_M. P_M is added to the mechanical power from EM2 ($\eta_{EM2} \cdot P_{EM2}$)

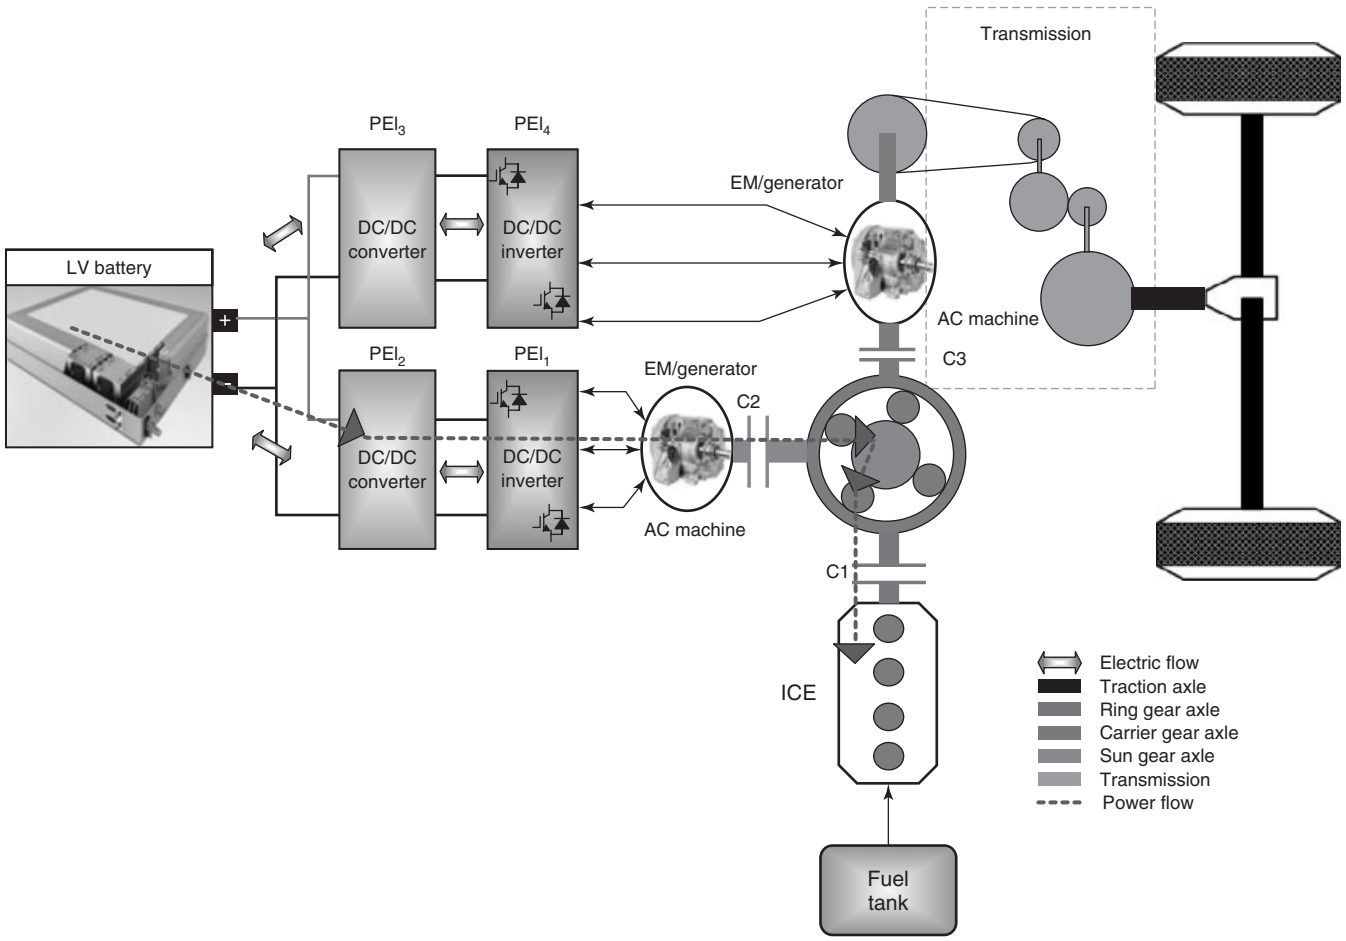

Figure 12. Operational mode 1: cranking aid.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

by a mechanic coupling. An example of this configuration is the Opel Ampera/Chevrolet Volt. When the vehicle is driving at low speeds, the pure electric mode is most efficient. In this case, only EM2 is generating traction power, and clutch 3 (C3) and clutch 4 (C4) are closed, while clutch 2 (C2) is opened to decouple EM1. At higher speeds, more traction power is required; C4 is opened, while C2 is closed. Consequently, EM1 can be operated to deliver the additional traction power. C1 is opened to limit the inertia and friction losses from the ICE. When the battery is almost depleted, the ICE is turned on to extend the range of the vehicle. EM1 is used as a starter-motor (cranking aid) to start the ICE. C1 is closed to realize this effect. Then, EM1 can be used as a generator. At low speeds, all the power from the ICE is converted into electric power (C2 open and C4 closed; cf. mode 6 in Section 4.1), and at high speeds a part of this power is transferred to the wheels (C2 closed and C4 opened; cf. mode 5 in Section 4.1).

In configuration 2 (Figure 9), the mechanical power from the ICE (P_{ICE}) is added with the output of EM1 ($\eta_{EM1} \cdot P_{EM1}$) by a power split device. The output axis of the power split is the same as the rotor of EM2. An example of this configuration is the Toyota Prius II, where the power split is also a planetary gearbox. Note that in both configurations, the electric machines EM1 and EM2 can be operated as a generator or motor to make all modes possible (Section 4.1). Note the absence of clutches in this powertrain.

As demonstrated in Figures 8 and 9, configurations 1 and 2 can both be accomplished with the same number of components: an ICE, an ESS, two EMs, a planetary gearbox, and transmission and electronic power converters for the EMs. Consequently, these configurations are comparable in complexity, size, and weight. In the case of configuration 3, the EM1, EM2, and the mechanic coupling are replaced by one electric machine, an EVT (Figure10). This configuration is lighter and likely to be more efficient.

4.1 The operating modes of the series–parallel HEV

All operating modes described for the SHEV and parallel HEV (see Series Hybrid Electric Vehicles (SHEVs)and Parallel Hybrid Electric Vehicles (Parallel HEVs)) are still valid for the series–parallel HEVs, but the realization of the operating modes can be different from the SHEV because of the specific architecture of the series–parallel HEV, that is, a mechanical connection between the EM and the ICE. Moreover, the mechanical connection between the EM and the ICE allows another operating mode: it allows the ICE to be driven by the EM when starting up the car. Therefore, eight possible operating modes exist for the series–parallel HEVs.

The different operational modes are illustrated by means of the power flow in an example of a configuration 2-type series–parallel HEV. The power split device is planetary gearbox, with the ICE connected to the carrier, the generator to the sun wheel, and the motor to the ring wheel. The implementation of the series–parallel HEV architecture for this example is depicted in Figure 11.

The different operating modes of the series–parallel HEVs are described as follows:

1. *Mode 1* (cranking aid): the motor/generator is used to drive the ICE for start-up of the ICE, as illustrated in Figure 12.
2. *Mode 2* (*pure ICE drive*): only the ICE supplies the required power. This mode can either be achieved through the mechanical connection between the ICE (see Parallel Hybrid Electric Vehicles (Parallel HEVs)) and the wheels or through the numerous electrical conversion steps (see Series Hybrid Electric Vehicles (SHEVs)). Both power flows are shown in Figure 13. The power flow strategy will determine which of the both can be used according to the circumstances.

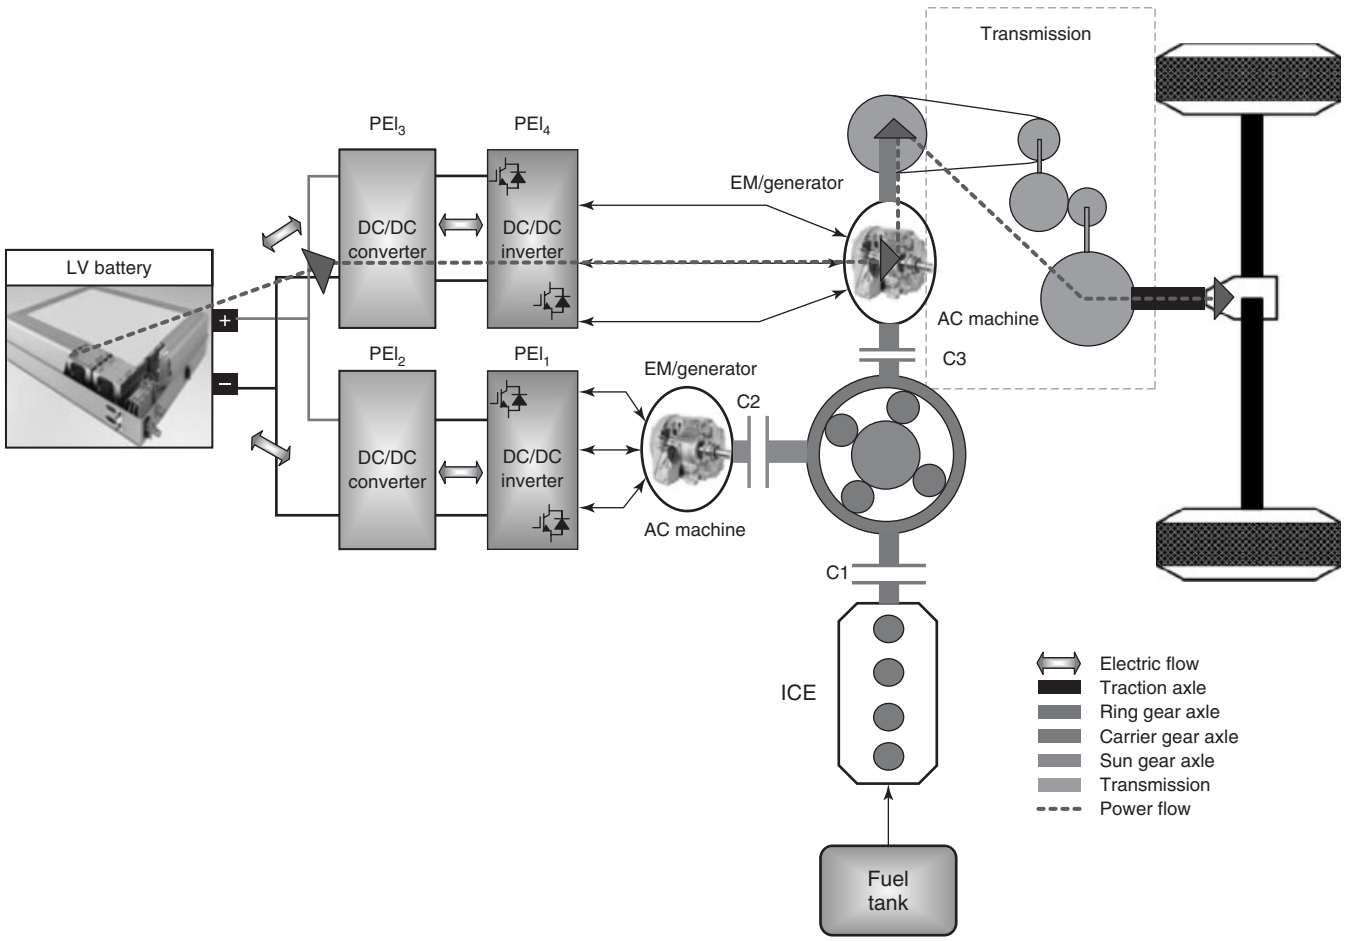

Figure 14. Operational mode 3: electric mode.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

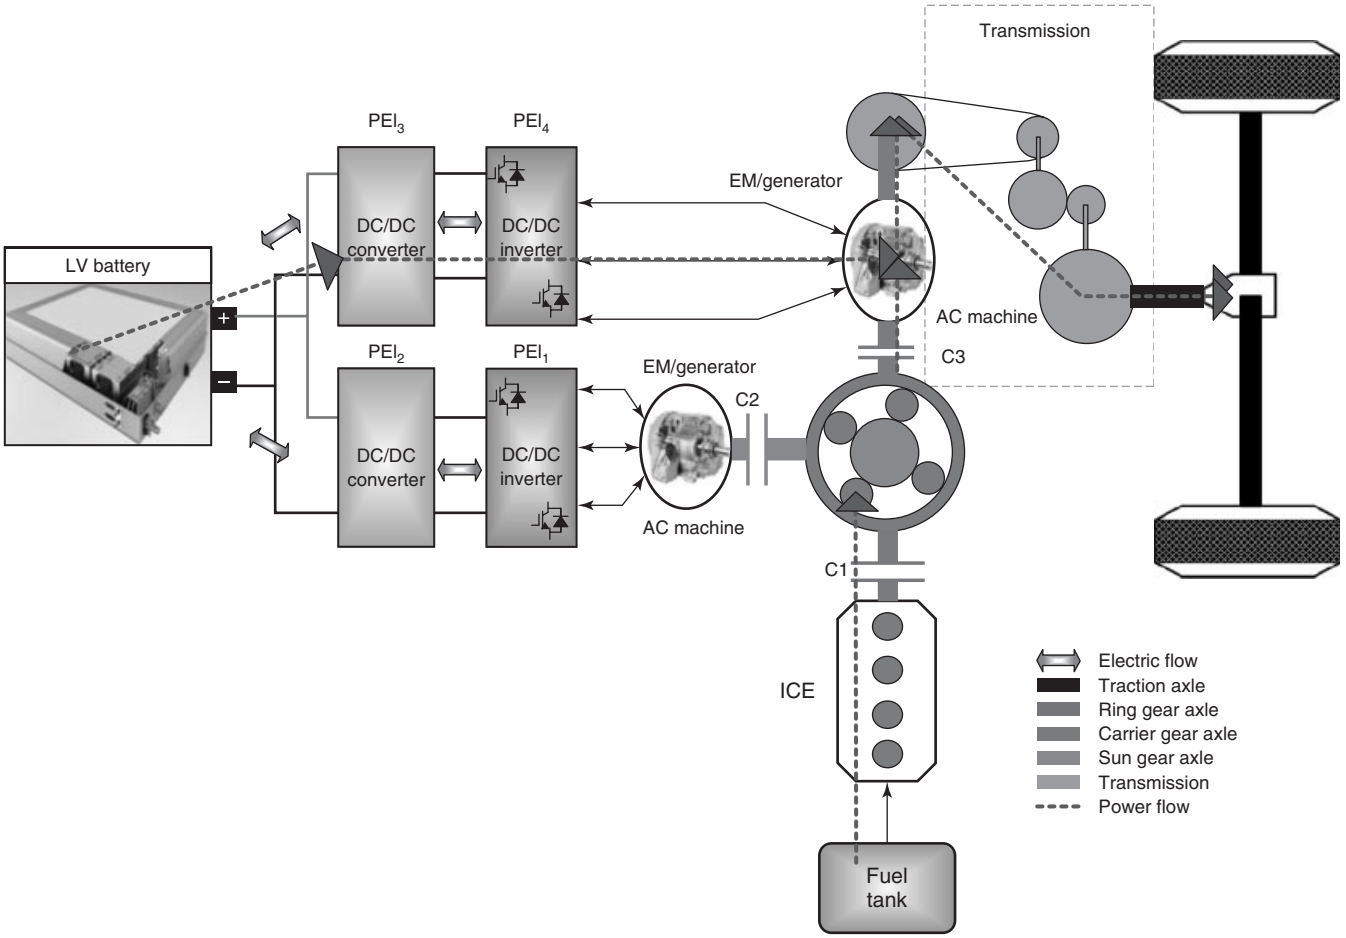

Figure 15. Operational mode 4: hybrid drive.

3. *Mode 3* (*electric mode*): in this mode, the ICE and generator are turned off and the vehicle is only supplied by the batteries (Figure 14).
4. *Mode 4* (*hybrid drive*): the traction power is supplied by the ICE and the batteries. This mode is used when the power requirement is high (Figure 15).
5. *Mode 5* (*engine traction and battery charging*): the ICE provides the energy needed to charge the batteries and drive the vehicle (Figure 16).
6. *Mode 6* (*battery charging and no drive*): in this mode, the generator transfers mechanical power from the ICE to electrical power to charge the batteries (Figure 17).
7. *Mode 7* (*regenerative braking*): during braking or deceleration, the ICE is turned off and the traction motor is operated as generator to charge the battery. Because of the speed coupling, during regenerative braking, the speed of both generators should be such that the ICE speed is zero, or the ICE must be unclutched (Figure 18).
8. *Mode 8* (*hybrid battery charging*): both the ICE and the traction axle provide power to charge the battery (Figure 19).

5 POWER FLOW CONTROL STRATEGIES

The power flow control strategies consist essentially in using the vehicle in a combination of the operational modes to obtain or optimize the objectives for a HEV specified in the previous chapter (see Series Hybrid Electric Vehicles (SHEVs)). A series–parallel HEV can combine the features of the SHEV and the parallel HEV for its power flow control strategies. In an SHEV, the ICE operating point can be set independently of the vehicle speed, but the power flow from the ICE to the drive axle has numerous power conversion steps, accumulating losses at each conversion step. This can be disadvantageous in some driving conditions. In a parallel HEV, there exists a direct

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto205
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

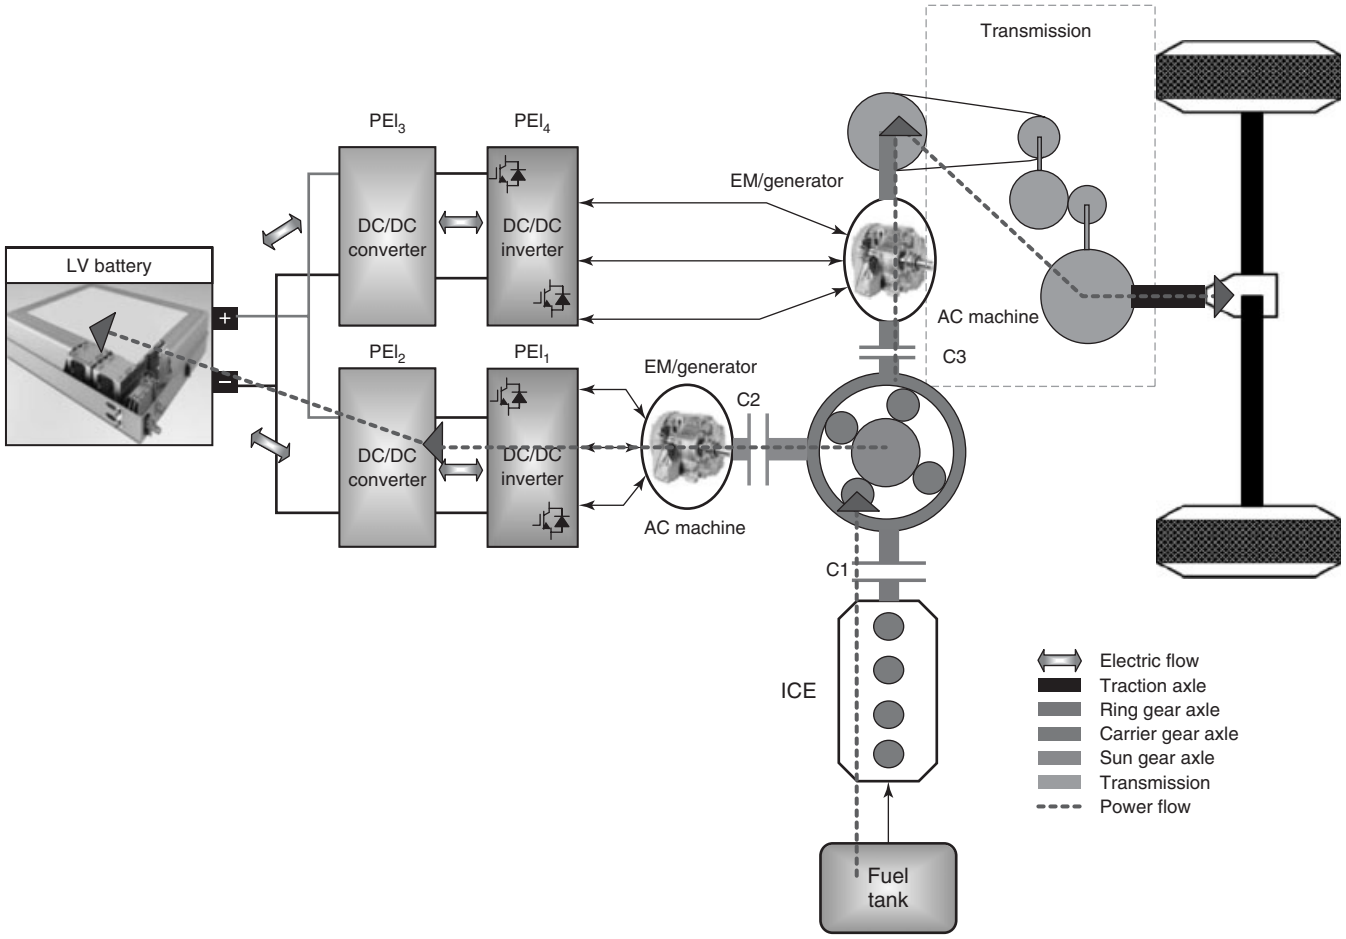

Figure 16. Operational mode 5: engine traction and battery charging.

mechanical coupling between the ICE and the drive axle. As a result, the power from the ICE can be directly transmitted to the drive axle with less power conversion steps than that in an SHEV. This is likely to result in a higher overall efficiency compared to an SHEV if the driving conditions allow the ICE to work in an operating point with a high efficiency. But the direct mechanical coupling also fixes the ICE speed according to the vehicle speed such that the overall efficiency can be lower than that of an SHEV if the driving conditions force the ICE to operate in operating points with low efficiency.

Series–parallel HEVs have the ability to combine these features of an SHEV and a parallel HEV. The series–parallel HEV's speed and torque coupling make it possible to let the ICE work in a fixed working point, regardless of the vehicle speed (Van Mierlo and Maggetto, 2000, 2001), but still has a direct mechanical coupling between the ICE and the drive axle.

One approach is to keep the ICE operating in its highest efficiency point. Keeping the ICE in a constant working point, that is, the working point corresponding to the lowest fuel consumption, does not necessarily mean the lowest fuel consumption of the complete drivetrain. While the average power is delivered by the ICE, acceleration peaks are covered by the EM (Section 4.1, mode 4) and with power demands lower than the average power, the surplus of ICE power recharges the battery (Section 4.1, mode 5). This can result in frequent charging and discharging and possibly lower overall efficiency.

Another strategy is to target maximum overall efficiency. As indicated in Section 3, the operational mode 2 has multiple paths for the power flow, and overall efficiency is determined by the power requirement (driving conditions), power distribution, and the power flow pathway. By calculating the power distribution that minimizes overall losses for each torque and speed value (driving conditions), maximum overall efficiency can be obtained (Van Mierlo and Maggetto, 2001).

In every control strategy, the control of the state of charge (SoC) of the ESS must be incorporated and limited

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto205
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

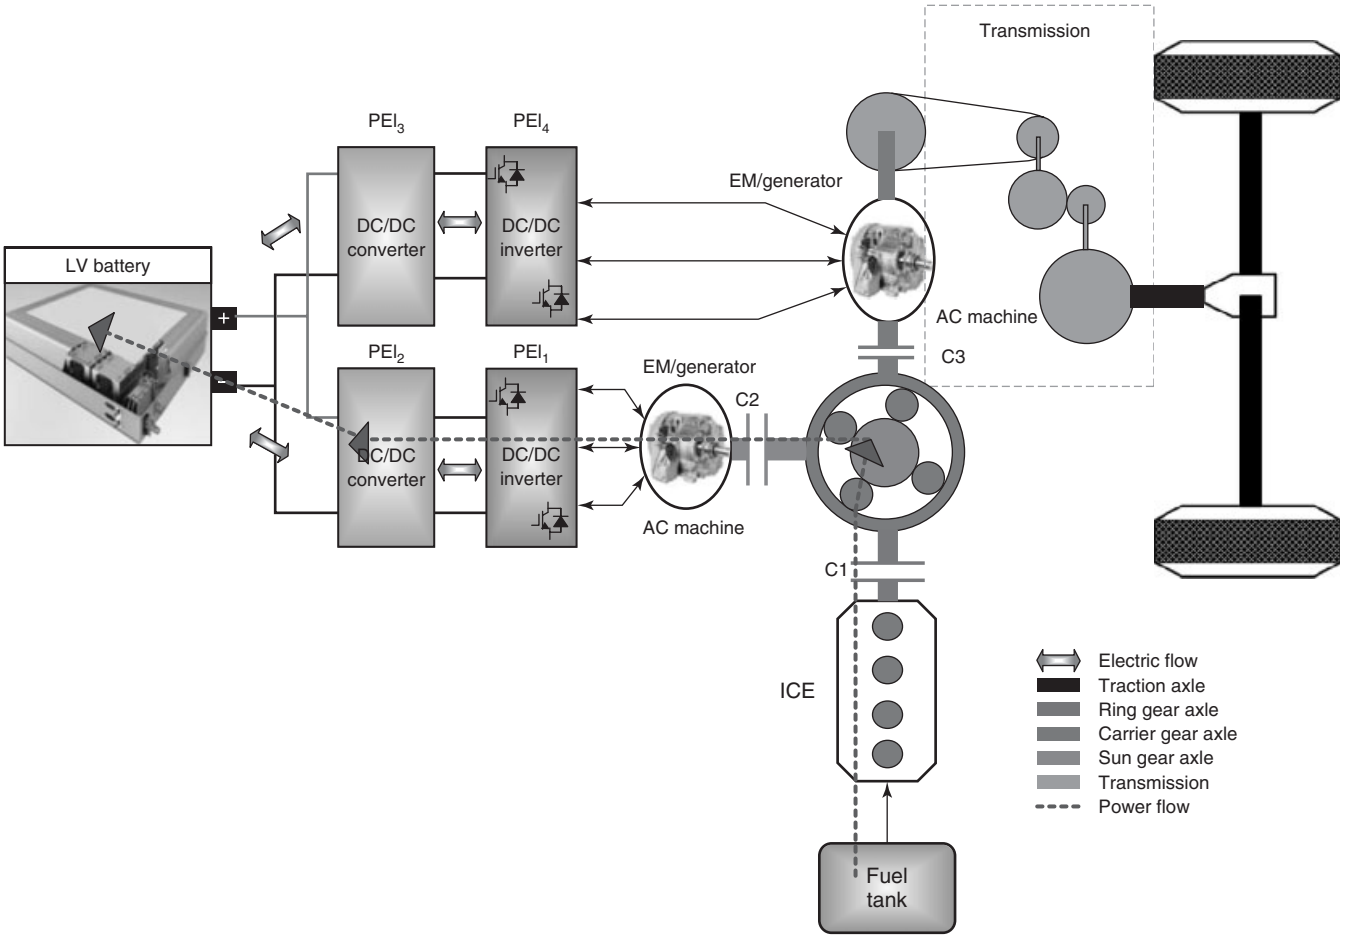

Figure 17. Operational mode 6: battery charging and no drive.

battery capacity can have an impact on the strategy (Van Mierlo and Maggetto, 2001, 2004; Van Mierlo et al. 2004; Salmasi, 2007; Barrero, Van Mierlo, and Tackoen, 2008). Battery capacity ranges from close to 1 kWh for a hybrid with almost no all electric range (AER), to a multiple or even an order of magnitude higher than that of the capacity for a plug-in hybrid vehicle, depending on the target AER (Abkemeier and Mize, 2012; Axsen, Burke, and Kurani, 2008; US Department of Energy, 2010).[1] The ESS SoC operating range in the case of a battery is generally between 80% and 40% charged, where 20% is considered as a minimum SoC to limit the battery degradation. To maintain the SoC, it can be necessary to impose a power demand for battery charging in certain drive cycles. This limits the freedom in which other strategies, such as that mentioned earlier, can be applied as the power distribution will depend on not only the driving conditions but also the power demand for battery charging. An SoC-maintaining strategy will provide battery power in the case of high or low power demand. The high power demand will be provided by the battery and the ICE together (Section 4.1, mode 4), while in the case of a low power demand, only the battery will provide the required power and the ICE is switched off (Section 4.1, mode 3). For moderate power demands, the ICE will drive the wheels and charge the battery through the generator with a charging power as a function of SoC (Section 4.1, mode 5) (Van Mierlo and Maggetto, 2001). SoC-maintaining strategies are applied in vehicles with limited battery capacity, such as the Toyota Prius, as well as in vehicles with considerable battery capacity (such as plug-in hybrid vehicles such as the Opel Ampera/Chevrolet Volt) when the battery depletion is near to its limit or at the driver's request. Figure 20 illustrates the SoC-maintaining strategy for a hybrid vehicle with limited battery capacity and a plug-in hybrid vehicle.

As was explained in the previous chapter (see Series Hybrid Electric Vehicles (SHEVs)) for SHEV, for series–parallel HEV, the power flow strategies can also generally be classified into two kinds: (i) rule-based control strategy and (ii) optimization based control strategy.

6 CONCLUSIONS

This chapter has presented an overview of series–parallel HEV powertrains, which are known as *CHEVs*. The main concept of the series–parallel is presented, followed by the introduction of the different operating modes of the series–parallel HEV. In addition, the transmission systems such as CVT and EVT are introduced as they are essential for state-of-the series–parallel HEV. As can be observed from the series–parallel HEV architectures, the series–parallel HEV has the features of both series and parallel topologies. Compared to series and parallel HEVs, the series–parallel HEVs can provide a good solution for better fuel economy and low emissions for both city and highway driving cycles. The Toyota Prius, Lexus, Opel Ampera/Chevrolet Volt, and Ford Escape are some examples of series–parallel HEVs, which are commercially available.

LIST OF ABBREVIATIONS

Series–parallel HEVs	series–parallel hybrid electric vehicles
Parallel HEVs	parallel hybrid electric vehicles
SHEVs	series hybrid electric vehicles
CHEVs	combined hybrid electric vehicles
ESS	energy storage system
ICE	internal combustion engine
HEVs	hybrid electric vehicles
EM	electric motor
CVT	continuous variable transmission
EVT	electric variable transmission
C1 & C2	clutches
SoC	state of charge
DoF	degree of freedom
SCIM	squirrel-cage induction machine
PM	permanent magnet
AER	all electric range

UHC and CO Formation and Models

Miroslaw L. Wyszynski
University of Birmingham, Birmingham, UK

1 SOURCES OF UHC AND CO IN AN ENGINE

Unburned hydrocarbons (UHCs) and carbon monoxide (CO) are products of imperfect, that is, either partial or incomplete, combustion. As shown in Figure 1, other products of partial or incomplete combustion can include aldehydes and particulate matter. In addition, oxides of nitrogen are some of the most important by-products of high temperature combustion. Particulate matter is dealt with in Particulate Formation and Models and oxides of nitrogen in NO_x Formation and Models.

Ideally, products of stoichiometric combustion should be those of complete combustion as shown in Figure 1, while products of combustion of lean mixtures would also include unused oxygen. However, it is known that products of combustion in engines of a charge which on average is lean will include some UHCs and CO. This is partly due to the fact that for increasingly lean mixtures (even homogeneous), there will be an increasing occurrence of misfires as the mixture becomes leaner (Figure 2).

The other important reasons for UHC and CO emissions are (i) that mixtures are rarely completely homogeneous, (ii) that there are regions in the combustion chamber where temperatures will be much lower than average, and (iii) that some of the new combustion technologies, particularly the homogeneous charge compression ignition (HCCI) and similar technologies, are designed to lower the combustion temperature, largely in order to reduce nitrogen oxide emissions.

The first factor, that is, nonhomogeneity of mixtures was always the main source of emissions of particulate matter (that includes absorbed and adsorbed UHCs) from diesel engines. Recently, this problem also includes spark ignition (SI) engines with fuel injection, particularly, the gasoline direct injection engines. Problems with fuel droplet size distribution, spray penetration, evaporation, and mixing are increasingly solved by increasing the fuel injection pressures.

The second factor, that is, high production of UHCs and CO in regions of the combustion chamber where there is significant quench of flame or significant enrichment of the mixture, is best illustrated by the existence of regions such as shown in Figure 3.

A good example of evidence that UHC emissions in spark-ignited engines are caused among other factors by quenching near the walls was provided in an experiment by Tabaczynski, Heywood, and Keck (1972), with an explanation and results presented in Figure 4, quoted here after Ferguson (1986).

2 MODELS

There can be several levels of modeling of the quantity and formation mechanisms of UHC and CO, starting with (i) stoichiometric models that may include simple chemical equilibria for CO and NO*x*; through (ii) zero- and quasi-dimensional thermodynamic models of engine cycles with simple or detailed chemical kinetics for CO and numerous hydrocarbons (HCs); and ending with (iii) hugely computing-intensive computational fluid dynamics (CFD) models, including engine thermodynamic processes and detailed chemical kinetics in each cell of the domain; (iv) less-demanding simplified kinetics in CFD; or (v) probabilistic models.

2.1 Stoichiometric models with chemical equilibria

Low temperature (below 1000 K, as in the exhaust) equilibrium products of combustion of HC or oxygenated HC fuels with air at different mixture strengths yields mainly water and carbon dioxide as products, alongside the untouched nitrogen from air, as quoted below after Ferguson (1986), pp. 109–110.

For rich mixtures, there is some CO in the combustion products, and for high temperatures, formation of nitrogen oxides (covered in NO_x Formation and Models) has to be considered.

$$\phi\varepsilon C_\alpha H_\beta O_\gamma N_\delta + (0.21O_2 + 0.79N_2) \rightarrow \nu_1 CO_2 + \nu_2 H_2O + \nu_3 N_2 + \nu_4 O_2 + \nu_5 CO + \nu_6 H_2$$

where ε is the stoichiometric fuel/air ratio in molar terms,

$$\varepsilon = 0.21\left(\alpha + \frac{\beta}{4} - \frac{\gamma}{2}\right)$$

for example, for CH_4

$$\varepsilon = 0.21\left(1 + \frac{4}{4}\right) = 0.21 \times 2$$

ϕ is the fuel/air equivalence ratio (which is the reciprocal of air excess ratio λ, thus $\phi = 1/\lambda$), and molar coefficients ν_i give the product composition.

For lean and rich combustion, one can reasonably approximate as a first attempt:

$$\text{lean}: \quad \phi < 1, \quad \nu_5 = \nu_6 = 0$$
$$\text{rich}: \quad \phi > 1, \quad \nu_4 = 0$$

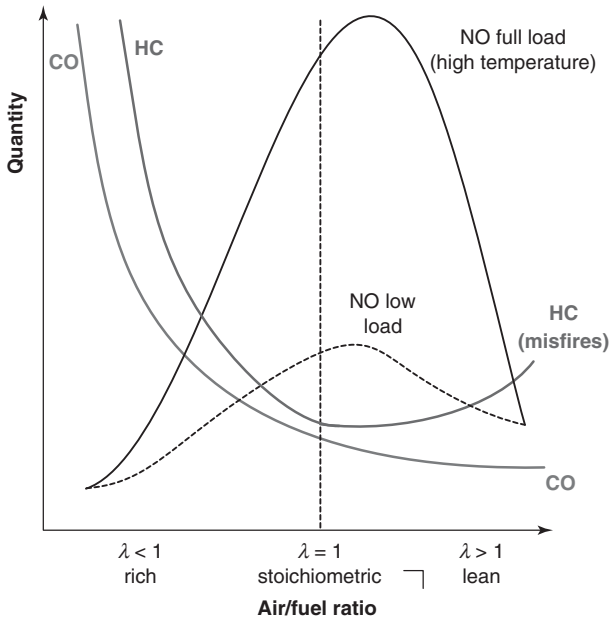

Figure 2. Relative quantities of emissions at different values of air excess coefficient λ.

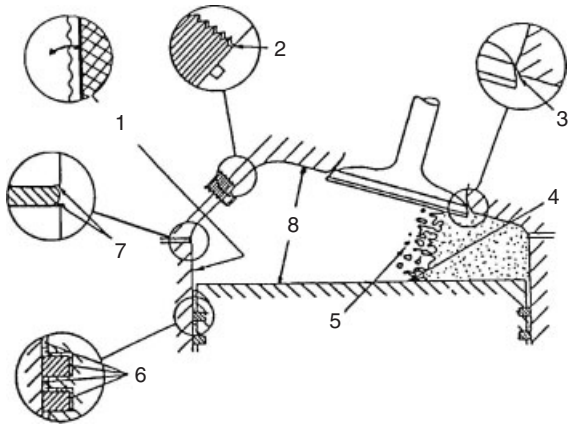

Figure 3. Sources of unburned hydrocarbons and carbon monoxide in a spark ignition engine (1) adsorption/desorption in/from lubricating oil, (2) space around the thread of spark plug/fuel injector, (3) space around the seat of inlet/exhaust valve, (4) flame quench near the walls, (5) flame quench in the area of flame front, (6) species trapped between the piston rings, (7) gaps around the head gasket, (8) adsorption/desorption from deposits on walls. (Adapted from Rychter and Teodorczyk, 2006. © Wydawnictwa Komunikacji i Łączności Sp.z.o.o.)

For the lean and stoichiometric cases, one can determine the product composition from atom balance as given in Table 1.

Rich combustion conditions are assumed as reasonably rich, that is, when there is enough oxygen so that solid carbon does not form, and all oxygen is divided in products between carbon dioxide and CO. In such cases, an important factor to consider is the equilibrium of the so-called *water gas reaction*.

For the rich case, the equilibrium constant K_{wg} of the water gas reaction:

$$CO_2 + H_2 = CO + H_2O$$

will give one more equation needed to determine the product composition:

$$K_{wg} = \frac{\nu_2 \nu_5}{\nu_1 \nu_6}$$

Molar coefficient of CO in the products ν_5, when the combustion reaction is written for 1 mol of air (as above) can then be calculated from:

$$\nu_5 = \frac{-b + \sqrt{b^2 - 4ac}}{2a}$$

where:

$a = 1 - K_{wg}$

$b = 0.42 - \phi\varepsilon(2\alpha - \gamma) + K_{wg}[0.42(\phi - 1) + \alpha\phi\varepsilon]$

$c = -0.42\alpha\phi\varepsilon(\phi - 1)K_{wg}$

The equilibrium constant fitted to the JANAF table data is given by:

$$\ln K_{wg} = 2.743 - \frac{1.761}{\left(\frac{T}{1000}\right)} - \frac{1.611}{\left(\frac{T}{1000}\right)^2} + \frac{0.2803}{\left(\frac{T}{1000}\right)^3}$$

where T is in degrees Kelvin (absolute temperature), with the fit applying to $400 < T < 3200$ K.

Having calculated the ν_5 coefficient for CO, the basic six components of combustion products (without taking into account the high temperature formation of nitrogen oxides) can now be explicitly determined from the available equations, and are summarized in Table 1.

Table 1. Low temperature (until 1000 K) combustion products (Hires *et al.*, 1976), as quoted below after Ferguson (1986), pp. 109–110.

i	Species	Lean and stoichiometric combustion $\phi \le 1,\ \lambda \ge 1$	Rich combustion $\phi > 1,\ \lambda < 1$
1	CO_2	$\alpha\phi\varepsilon$	$\alpha\phi\varepsilon - \nu_5$
2	H_2O	$\beta\phi\varepsilon/2$	$0.42 - \phi\varepsilon(2\alpha - \gamma) + \nu_5$
3	N_2	$0.79 + \delta\phi\frac{\varepsilon}{2}$	$0.79 + \delta\phi\frac{\varepsilon}{2}$
4	O_2	$0.21(1 - \phi)$	0
5	CO	0	ν_5
6	H_2	0	$0.42(\phi - 1) - \nu_5$

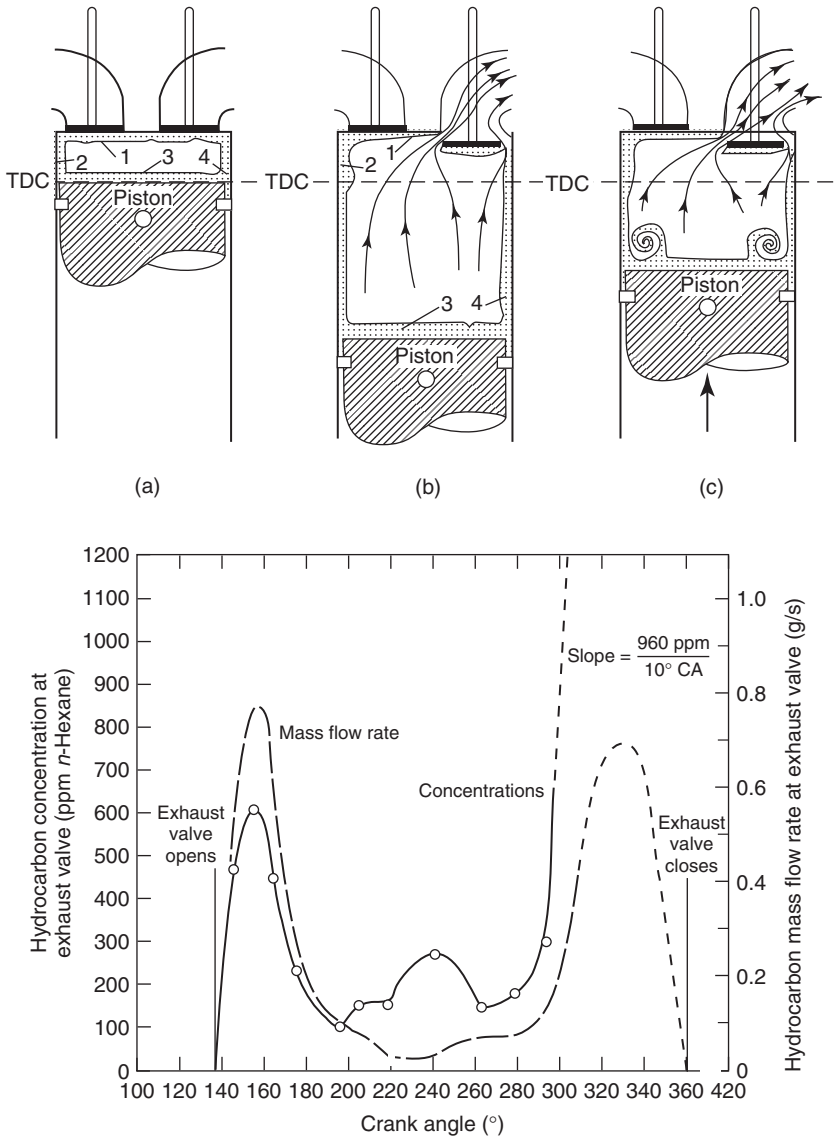

Figure 4. Important processes in hydrocarbon emissions. Unburned fuel is near the walls at (1), (2), and (3) and in the piston crevice area (4) as a result of flame quenching and absorption by oil layer (a). During the expansion in work, stroke hydrocarbons are desorbed and spread near the wall (b). During the exhaust stroke (c), hydrocarbons from regions (1) and (2) exit the cylinder with the main flow, and those from regions (3) and (4) roll up into a vortex which leaves at the end of the exhaust stroke. This is confirmed in the time-resolved measurement of hydrocarbon flow rate and concentrations during the opening of exhaust valve, as shown in the second diagram—large flow on opening the exhaust valve at 140–170° CA, just before BDC, and large flow again toward the end of the exhaust stroke near TDC at 300–340° CA.

Equilibrium combustion products involving consideration of many more chemical species and wider range of temperatures are now routinely performed using public domain software such as STANJAN (this seems to recently have gone commercial, but there are plenty of earlier free versions circulating in the engine community) or some other programs currently available online. There is an open-source code CANTERA http://code.google.com/p/cantera/, http://www2.galcit.caltech.edu/EDL/public/codes.html, and links to several equilibrium programs can be found at http://www.gaseq.co.uk/eqlinks.htm.

These programs are based on seeking a minimum of the Gibbs function, which is the basic thermodynamic condition of chemical equilibrium. Number of moles of individual atoms in the reactants (for combustion in engines, these normally include C, H, N, and O) and all the expected species in products have to be declared. The iterative solution then can proceed assuming

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

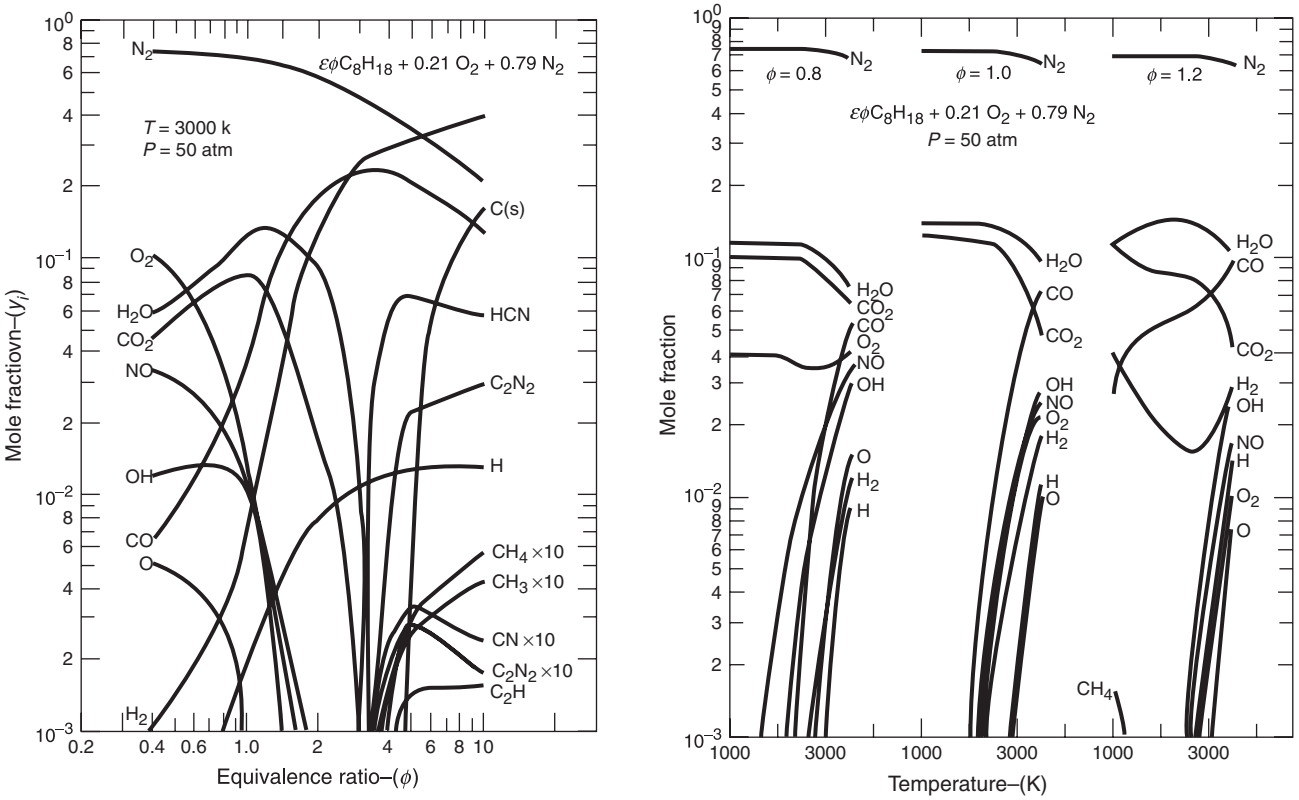

Figure 5. Equilibrium products for combustion of isooctane with air. (a) Temperature 3000 K and pressure 50 atm for a range of equivalence ratios, and (b) Pressure 50 atm, three values of equivalence ratio, and a range of temperatures in each case.

two of the defining thermodynamic properties such as temperature, pressure, enthalpy, and so on. The solutions shown in Figure 5, reproduced from Ferguson (1986) for combustion of isooctane with air are shown at (i) temperature 3000 K and pressure 50 atm for a range of equivalence ratios, and (ii) pressure 50 atm, three values of equivalence ratio, and a range of temperatures in each case.

Bearing in mind that vertical axes (mole fractions) are presented in Figure 5 on logarithmic scales, it is quite clear from Figure 5a that even at pressure and temperature typical for combustion in engines, there is very little CO predicted for lean mixtures (with equivalence ratio 0.4, it is 0.6%). For stoichiometric mixtures, CO is predicted around 3% and then it rises quickly to 30% at rich equivalence ratio of 2 and even to 30% at high equivalence ratios of 6 and beyond. UHCs appear with predicted equilibrium fractions over 0.1% for rich mixtures of equivalence ratio equal 3 and beyond. In addition, for very rich mixtures with equivalence ratio of 5 and beyond, there is predicted solid carbon C(s) forming. This partly explains the formation of soot in the rich regions of mixture, particularly around the core of evaporating and mixing liquid fuel sprays.

Figure 5b shows a very similar picture in a different configuration: for a lean mixture (equivalence ratio $\phi = 0.8$), the equilibrium-predicted CO starts to rise beyond 0.1% only at temperatures around 2200 K; for a stoichiometric mixture (equivalence ratio $\phi = 1.0$), this happens at temperatures over 2000 K and the fractions reached at higher temperatures are now larger; while for even a moderately rich mixture (equivalence ratio $\phi = 1.2$), several percent of CO are predicted at temperatures starting from 1000 K.

One HC predicted at noticeable equilibrium quantities is methane CH4 dropping to below 0.1% for temperatures rising above 1000 K (notice that most of the HCs predicted for very rich mixtures at 3000 K in Figure 5a are shown with values amplified 10 times).

2.2 Zero- and quasi-dimensional thermodynamic models of engine cycle with simple or detailed chemical kinetics for carbon monoxide and numerous hydrocarbons

Kinetics submodels take into account the progress of combustion reactions in time (as opposed to chemical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto206
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

equilibrium models discussed above which assume that sufficient time is available for the reactions to reach their equilibria). In case of some very fast reactions, such as CO oxidation, there is little difference between the equilibria- and kinetics-controlled compositions. Quantities of some other species, particularly the oxides of nitrogen, have to be computed using the kinetics-controlled approach, as the time of residence at high temperatures is hugely important. Formation of oxides of nitrogen is covered in NO_x Formation and Models.

Reaction rates are usually described for the various reactions using the Arrhenius type relations:

$$k = C\,p^a\,T^b\,\mathrm{e}^{-E/RT}$$

where:

p is pressure, T is absolute temperature,
E is activation energy, and R is the gas constant
C, a and b are coefficients defined for the given reaction.

All these are in units defined in the individual data for a given reaction.

This approach requires the knowledge (or assumption based on an informed model) of the mechanisms of reactions for combustion of different fuels. These mechanisms can be hugely complicated and involve hundreds or even thousands of intermediate steps. Thus, the efforts of modelers for the last decades have been directed at two approaches: (i) generating (from first principles of physical chemistry) and setting up comprehensive chains of reactions that can be used in computer-intensive modeling, where computing time and effort is not of primary concern, and (ii) simplifying these models so that they contain as few reactions as possible without losing too much accuracy. The latter approach is useful in the combustion and emissions submodels of the thermodynamic models of engine cycles and in some more advanced CFD models of reactive flows within engine combustion chambers.

3 CARBON MONOXIDE OXIDATION KINETICS

CO oxidation is a very fast reaction, much faster than the time scale of gas-dynamic processes in the combustion chambers of piston engines. Because the detailed mechanisms of combustion are not well known, usually one can assume that concentrations of CO are determined by the equilibrium calculations as presented above.

3.1 Single global equation

If kinetics calculations for CO are to be conducted, it is recommended to use the following data for CO kinetics representing various burners and reactors, fuels, equivalence ratios, and pressures, which have been considered to be adequately correlated for practical purposes over the temperature range 840–2360°K by the global equation (Howard, Williams, and Fine, 1973):

$$-\frac{\mathrm{d[CO]}}{\mathrm{d}t} = k_0[\mathrm{CO}][\mathrm{O_2}]^{1/2}[\mathrm{H_2O}]^{1/2}\exp\left(-E/RT\right)$$

where [CO], [O_2], [H_2O] are molar fractions, with

$$k_0 = 1.3 \times 10^{14}\ \mathrm{cm^3/(mol \times s)}, \text{and } E = 30\ \mathrm{kcal/mol}$$

3.2 Comprehensive reduced 14-reaction model

A comprehensive 36-reaction kinetics model for CO combustion was developed and implemented into the ISIS thermodynamic engine model by Raine (2001). He has also presented a reduced 14-reaction scheme shown in Table 2.

The forward rate coefficients are presented in the form:

$$k_\mathrm{f} = A \times T^n \times \exp\left(-\frac{B}{T}\right), \text{ where } B = \frac{E_\mathrm{a}}{R_\mathrm{u}}$$

where A is the pre-exponential factor, n is the temperature dependence exponent, E_a is the activation energy, and R_u is the universal gas constant.

Units are:

$$[A] = \left[\frac{\mathrm{cm^3}}{\mathrm{mole \times s \times K}}\right] \text{ and } [B] = [\mathrm{K}]$$

Values of the kinetic coefficients have been taken from Peters and Rogg (1993), where further details such as third body (M) efficiencies can also be found.

The backward reaction rates can be calculated through determining the equilibrium constants:

$$k_\mathrm{b} = \frac{k_\mathrm{f}}{K_\mathrm{eq}}$$

with equilibrium data taken from CHEMKIN (Kee, Rupley, and Millar, 1990) and JANAF (Chase *et al*., 1985) sources.

Initial CO concentration is calculated based on all carbon from the fuel being present as CO, even for stoichiometric and lean conditions.

The results of the CO kinetic modeling by Raine suggest that at very lean mixtures and with a homogeneous charge, the bulk gas will be only a small contributor to engine-out CO emissions.

However, it is likely that with nonhomogeneous charge, the bulk gas will be a significant source of CO emissions from rich zones.

4 KINETICS OF HYDROCARBON COMBUSTION

For HCs, the situation is much more complicated for reasons of their complexity (normally typical gasoline or diesel fuel will have up to several dozen or several hundred components) and the multi-step reactions with mechanisms that can involve several hundred reactions even for simplest HC such as methane. For practical purposes of modeling combustion of HCs in engines and employing these models in a thermodynamic model of engine processes (including emissions of UHCs), there is a need to create a much simplified model, preferably involving just one global reaction. An early attempt is represented by the following rate equation, applicable to alkane HCs quoted here after (Rychter and Teodorczyk, 1990):

$$-\frac{\mathrm{d}[C_nH_m]}{\mathrm{d}t} = 6 \times 10^4 \times \gamma\, T\, p^{0.2} \exp\left[-\frac{12,200}{T}\right] [C_nH_m][O_2]^{0.5}$$

Where T [K] is temperature, p [atm] is pressure, $\gamma = 1$ for plug flow, and $\gamma = 80$ for fully stirred flow.

More complex set of mechanisms involving two-step reactions were formed based on observations that typical HC fuels burn in a somewhat sequential manner, that is, the fuel is partially oxidized to CO and H2, which persist until all of the HC species are consumed (Westbrook and Dryer, 1984). Thus, for methane, the two reactions model would be based on:

$$CH_4 + \frac{3}{2}O_2 = CO + 2H_2O$$

$$CO + \frac{1}{2}O_2 = CO_2$$

Similar considerations for other HC fuels with addition of other reactions lead to quasi-global reaction mechanisms which combine a single reaction of fuel and oxygen to form CO and H_2 together with a detailed mechanism for the $CO–H_2–O_2$ system. A table giving the coefficients for the two-step and quasi-global mechanisms is quoted here after Westbrook and Dryer (1984) (Table 3).

These values are to be used in single-rate expressions of the type:

$$k_{ov} = AT^n \exp\left(-E_a/R_uT\right) \ [\text{Fuel}]^a[\text{Oxidizer}]^b$$

with values of E_a in kcal/mol and quantities of fuel and oxidizer as molar fractions.

More detailed models and mechanisms have been presented in numerous studies that have been published over the decades on the subject of comprehensive modeling of HC combustion (and thus also formation of UHCs) (see Fundamental Chemical Kinetics). Some more recent examples of implementing the detailed chemistry into engine models include work from Cambridge (Coble *et al*., 2011), Aachen (Pitsch and Peters, 1998), and Lawrence Livermore (Curran *et al*., 1998) groups as well as numerous others published constantly. A comprehensive review of the detailed models was published by Simmie (2003). Recent approach to measurements and modeling of UHC and CO from a light-duty diesel engine was presented by Ekoto *et al*. (2009)

Such detailed chemistry simulation technologies provide enhanced robustness and predictive power for modeling of combustion. Specifically, they strive to make it possible to predict the onset of ignition, low and high temperature heat release, local extinction, knocking, exhaust gas emissions including the formation CO and UHC, and so on. However, the adoption of detailed chemistry comes at a much greater computational cost. One of the methods that make it possible to retain computational robustness and ease of use while reducing computational timescales is the proposed use of the PDF (probability density function) model based on the stochastic reactor model (SRM) (Pitsch and Peters, 1998). It offers capabilities to account for in-cylinder processes such as chemical kinetics, fuel injection, turbulent mixing, heat transfer, and so on, while retaining in-cylinder stratification of mixture composition (i.e., fuel equivalence ratio) and temperature. Results equivalent to a non-PDF/SRM detailed chemistry model can be achieved with a reduction in computational time from 28 days to 10 min. In addition, modest parallelization of computing algorithms, requiring only 8–16 processor cores, can substantially speed up simulations using detailed chemistry. Reduced chemistry models dramatically cut the computational time, but only provide trends for emissions results. Parallelization is not really beneficial with reduced chemistry models, as these models can already be solved very quickly on a single-core PC.

When it is assumed that the ignition of diesel fuel can be described by using the single component model fuel *n*-heptane, a detailed chemical reaction scheme with about 1000 reactions among 168 chemical components could be replaced by a skeletal mechanism consisting of 98 reactions and 40 components, which is still capable of describing the autoignition process and concentrations of NO. Applying a flamelet model, it has been shown (Curran *et al.*, 1998) that the influence of the flow field and in particular the turbulence on the ignition process can be described by a single parameter, the scalar dissipation rate. Since the scalar dissipation rate can easily be evaluated from CFD calculations, if equations for the mean value and the variance of the mixture fraction are solved, the approximation formula can be used to estimate the departure of ignition in diesel engines from the homogeneous ignition delay times.

The key to understanding the reaction mechanisms is a careful and accurate description of the major chain-branching reaction paths and those kinetic processes that compete with the chain-branching paths. For example, it has been shown that low temperature chemistry is very sensitive to the formation of stable olefin species and to the chain-branching (Simmie, 2003).

The ultimate goal of chemical kinetic modeling is to develop an ideal set of thermodynamic data and a "perfect" reaction mechanism that will describe all the essential details of the physical reality, specifically the combustion of a HC in the gas phase. Great strides have been made of late in the computation of rate constants but it can be an acronymic nightmare for the unwary (Ekoto *et al.*, 2009). Initiatives that provide online computations of rate constants are most welcome and are a signpost for the future. Since a variety of experimental techniques is rarely, if ever, available in one laboratory, it reinforces the notion that cooperative research is essential. Modeling just your

own experiments with your own mechanism is scientifically worth very little (unless there is no other data of course) and one would hope that journal editors and referees would discourage researchers from such excessive introspection (Ekoto *et al*., 2009).

5 TYPICAL ENGINE EMISSIONS

Standard emissions of CO from engines are usually measured using nondispersive infrared instruments (NDIRs), whereas emissions of total UHCs are typically measured in engine research laboratories using the flame ionization detector (FID) method or the simpler NDIR geared to measure HCs based on a propane base (C_3H_8). The FID method relies in reality on measuring carbon atoms in HCs, whereas the NDIR method must be declared and calibrated to a specific base HC (usually propane). Typically, at the same time, emissions of nitrogen oxides are quoted and illustrate the trade-offs between good oxidation at high temperature (low UHC but high NO_x) and low temperature combustion at lower loads with higher HC emissions. The example below in Figure 6 (Zhong *et al*., 2010) compares three SI fuels—gasoline, ethanol, and the new experimental biofuel—2.5 dimethyl furan studied at Birmingham. One can see that emissions of CO and HC are lowest for the oxidated fuels, while emissions of NO_x are also lower for ethanol on account of its high evaporation enthalpy and lower combustion temperatures. It can also be seen from various literature sources reporting emissions from HCCI engines that the lower temperature combustion process leads to very low nitrogen oxides emissions, but higher HCs and CO emissions. These, however, are very easy to cope with in modern exhaust aftertreatment systems.

6 SPECIATION OF HYDROCARBON EMISSION

Speciation of the numerous emitted UHCs is a different and much more difficult matter. Much more sophisticated methods of separation and identification of individual HC are needed. This can be achieved by various techniques, all of those requiring extensive experience in chemical analysis. Probably, the oldest technique is the separation of HC on a gas chromatographic column and measurement on the standard flame ionization detector (called *GC-FID*), with the difference that now individual HCs can be measured as they elute from the column. With good calibration technique, a series of standard HCs in exhaust gases can be quantified. A new technique supposedly not requiring too

much experience is the fourier transform infrared (FTIR) detector, whereby individual spectra of HCs can be identified and with a good set of calibration gases can be quantified. These instruments have reached some maturity now and are increasingly used in different research laboratories, but still there are questions of stability, effect of water contamination, and so on. Perhaps, the most versatile method is the gas chromatograph–mass spectrometer (GC–MS) tandem, which allows identification of unknown compounds as they elute from the column on the basis of their mass spectra by comparison with vast libraries of chemical compound offered by the GC–MS vendors. After identification and selection of important species, a suitable set of calibration gases makes it possible to quantify the amounts. This method is, however, very much reliant on experience of the chemical analyst operator in selecting the GC columns and procedures and in the skill of separating and identifying the mass spectra. Heavy HCs in the exhaust, bound to particulate emissions and/or condensing from the exhaust gas, can also be separated by filtering, capturing on adsorption and absorption media, and extracting them to feed to a GC–MS procedure.

A number of the online and off-line speciation studies have been published, perhaps starting with the online GC–MS and real-time MS-only method pioneered in Birmingham in the early 1990s for measurement of individual aromatic HCs in the exhaust (Lehrle, West, and Wyszynski, 1995) and their changes under the effect of replacing some fuel with the equivalent energy fed in reformed fuel consisting largely of hydrogen and CO (Lehrle *et al*., 1993). Figure 7 presents the effects of improvement of combustion cleanliness demonstrated by the dramatic decrease in aromatic HCs selected for real-time observation using mass spectrometer fed directly with the exhaust gas (bypassing the gas chromatograph). The changes are quantified relative to the (assumed constant) argon content in the exhaust. The datum is the top left corner where no reformed gas has been introduced, and on replacement of even a small part of gasoline fuel with the equivalent calorific supply of the reformed gas fuel, one can see very large decrease in emissions of the most toxic aromatic HCs—benzene and methylbenzenes.

Recently, the particularly harmful vapor-phase and particulate-bound aromatic HCs, polycyclic aromatic hydrocarbons (PAHs), generated by a V6 gasoline engine working in SI and HCCI modes were collected and analyzed (Elghawi *et al*., 2010). All data were obtained during steady-state, fully warmed-up operation at different engine power levels (low and medium loads and mid-speed), and two different engine operation modes (SI

BDL—below detection limit.

and HCCI). The fuel used in this study was winter grade commercial gasoline fuel.

The vapor-phase exhaust gases were passed through stainless steel cartridges containing XAD-2 resin to capture PAHs. The PAHs were extracted from the resin with dichloromethane in an ultrasonic bath, and the obtained extracts were later analyzed qualitatively and quantitatively by GC–MS. The vapor-phase PAHs compounds observed from HCCI mode operated in low load were naphthalene, acenaphthylene, and acenaphthene only, whereas that obtained from SI mode under low load were naphthalene, acenaphthylene, acenaphthene, fluorene, anthracene, phenanthrene, fluoranthene, and pyrene.

The PAHs bound to particulates were trapped by using a complex of dilution tunnels with filter papers.

The soluble organic fractions (SOF) of the trapped particulates were separated from the insoluble fraction (ISF) with the help of ultrasonic elution, and analyzed by GC–MS method. The most abundant PAHs detected under selected operation conditions for HCCI mode was benzo[a]anthracene, followed by chrysene, then pyrene, and pursued by benzo[b]fluoranthene; in SI mode, under same operation condition, the highest PAH detected was benzo[a]anthracene followed by pyrene, benzo[b]fluoranthene, and chrysene. Probable mechanisms for the production of some of the pyrosynthetic PAH are discussed in Daniel *et al*. (2012).

Table 4 presents the list of poly-aromatic HC compounds found in the exhaust gas and selected for this study, with their molecular weight and number of aromatic rings. Table 5 presents the concentrations of the most abundant PAHs found in the exhaust gas from an engine fed with commercial grade gasoline and operated in two different modes (HCCI and SI) at two loads. It becomes clear that the HCCI mode (although it is generally believed to be prone to produce increased HC emissions) leads to greatly reduced emissions of PAH, which are lower than those from SI mode of operation even when comparing medium load HCCI with low load SI.

Another recent work (Daniel *et al*., 2012) presents the key individual HCs and carbonyls that have been identified using GC–MS and quantifies the emissions of 13 different carbonyls as specified by the California Air Resources Board (CARB) Method 1004 using high performance liquid chromatography (HPLC). The tests were conducted on a single cylinder direct-injection spark ignition (DISI) engine having compression ratio 11.5 at 1500 rpm, $\lambda = 1$, and

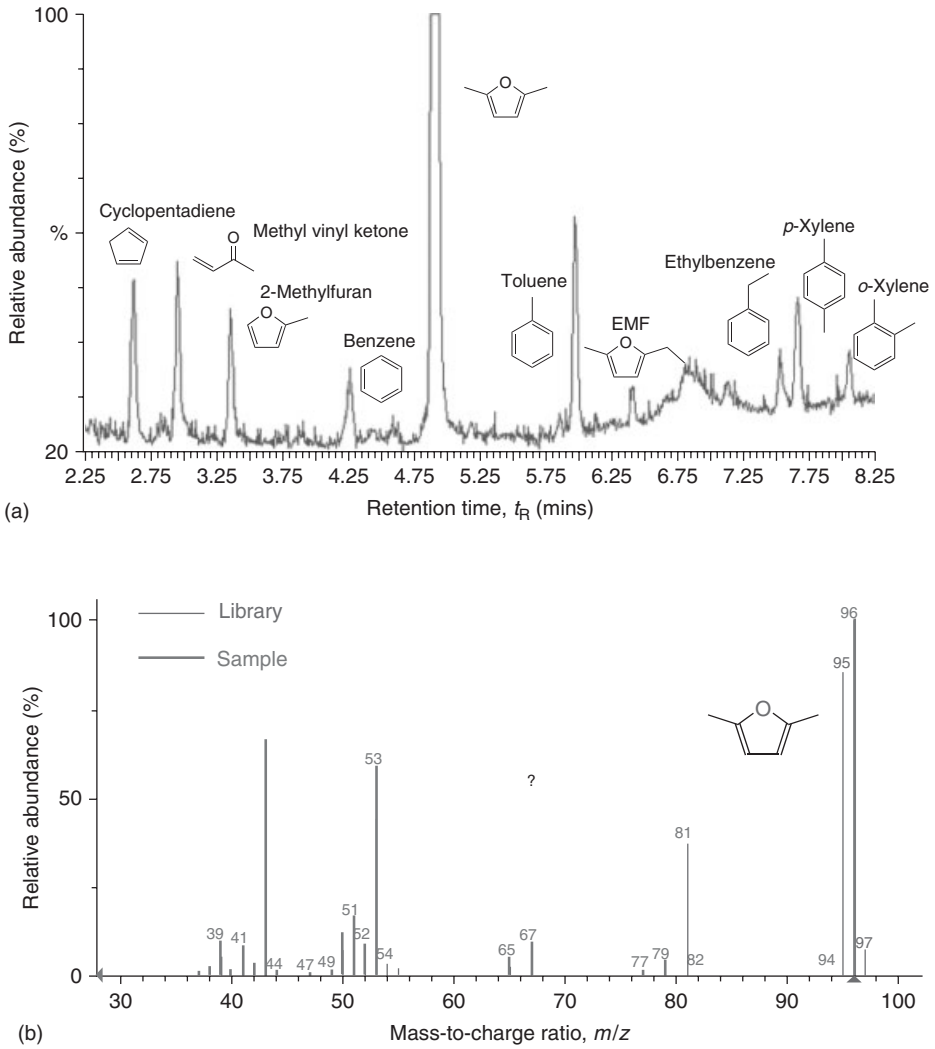

Figure 8. (a) Chromatogram of engine-out emissions using DMF (2,5-dimethyl furan as fuel. (b) Library and sample spectrum of DMF.

constant ignition timing. The fuels included 2,5-dimethyl furan (DMF), gasoline, *n*-butanol, ethanol, and methanol. For the GC analysis, the midrange HCs were identified using the mass spectra. Figure 8 shows a chromatogram of the engine-out emissions when the engine was fueled with DMF and the spectrum library used to identify the DMF. The results show that when DMF was used as fuel, unburned DMF dominates the emissions. Other main emissions include cyclopentadiene, methyl vinyl ketone, 2-methylfuran, and aromatics. There was no evidence of the emissions of linear alkanes except methane.

Figure 9 presents the individual carbonyl emissions when the engine was fueled with different fuels—2,5 DMF, gasoline, *n*-butanol, ethanol, and methanol. A carbonyl compound contains a functional group composed of a carbon atom double-bonded to an oxygen atom: C = O. A carbonyl group is present for example in the following types of compounds: aldehydes, ketones, carboxylic acids, esters, amides, and so on. A comprehensive analysis of carbonyls, their chemistry, and toxicity is beyond the scope of this work, but can readily be found in organic chemistry texts.

DMF produced the lowest overall low carbonyl (formaldehyde and acetaldehyde) emissions compared with methanol, ethanol, *n*-butanol, and gasoline and, more importantly, as seen in Figure 9, the lowest emissions of formaldehyde.

Figure 10 presents the higher carbonyl engine-out emissions for the cases of engine fueled with the three main fuels—ethanol, DMF, and unleaded gasoline. It should be noted that the levels of concentrations are an order of magnitude lower than those for low carbonyls presented in Figure 9. Here, the picture is more varied—ethanol generally produces lowest emissions and DMF is in most cases worse than gasoline. This may be caused by the

composition of DMF which was not of a very high grade. An example of the variation of carbonyl proportions in engine-out emissions when fueled with the three main fuels is shown in Figure 11. It can be seen that formaldehyde and acetaldehyde are dominating the carbonyl emissions in all cases, with acetaldehyde being hugely dominant in the case of ethanol fueling.

One more modern example of experimental study of UHC and CO emission sources is presented in Ekoto *et al*. (2009), where an optical, light-duty diesel engine operating under low load and engine speed was used, while employing a highly dilute, partially premixed low temperature combustion (LTC) strategy. The progression of in-cylinder mixing and combustion processes is studied using ultraviolet planar laser-induced fluorescence (UV PLIF) to measure the spatial distributions of liquid- and vapor-phase HC. A separate, deep-UV LIF technique is used to examine the clearance volume spatial distribution and composition of late-cycle UHC and CO. In-cylinder UHC and CO imaging highlights the differences that changes in dilution and load have on the main UHC source regions: (i) The cylinder center region contains intense near-injector fluorescence indicative of late-cycle fuel addition, whereas diffuse fluorescence is present from UHC and CO that is embedded in the surrounding fuel-lean bulk gases; and (ii) Squish volume UHC and CO principally results from the partial oxidation of lean mixture, although UHC from piston top fuel films and crevice flows is also observed (Ekoto *et al*., 2009).

7 SUMMARY

An introduction to understanding the origins of emissions of UHCs and CO from internal combustion engines, followed by a short review of the methods of modeling the formation of those pollutants has been presented. These modeling methods ranged from simple thermodynamics models involving stoichiometry and chemical equilibria through chemical kinetics of reactions to detailed chemistry of reactions, particularly for CO and some representative HCs. In the latter case, simplified reaction schemes, parallel multicore computing, and novel approaches such as probability density function analyses are particularly important to reduce the computation times while maintaining chemical accuracy and usefulness of the modeling. Some basic experimental methods of measuring engine-out emissions were introduced, while emphasis was put on determining the individual chemical species in engine-out emissions of HCs, particularly for the noxious and toxic aromatic and poly-aromatic HCs and carbonyls.

1 INTRODUCTION

The product of engine test facilities is data; the quality and relevance of which depends on the standard of the test instrumentation, the design of the experiment (DOE), the degree to which control and measurement systems are matched and integrated, and the environment in which both instrumentation and the unit under test (UUT) operate. The test environment and the engine's loading must emulate, as closely and as repeatedly as possible, the real life or the legislatively prescribed conditions of the engine during any test sequence. The increasing industrial requirement to share and correlate experimental results across different test locations requires that all uncertainty in test variables having a material effect on engine performance and its measurement must be minimized.

The modern test facility is full of sensitive electronic devices that may have to operate in the same electromagnetic environment as powerful variable-speed electrical drive systems. This imposes an absolute requirement for the highest possible standard of electrical system layout design and detailed insulation. Problems caused by inappropriate cable routing, shielding, and the lack of equipotential (ground) bonding within the facility are difficult and time-consuming to cure postinstallation.

The international nature of engine development means that test data has to be shared and compared around the world; therefore, the subject of correlation of test results from different test facilities should be mentioned here. The empirical rules of test result correlation that the authors suggest are as follows:

- Repeatability of test results, while a good characteristic, is not a proxy for accuracy of results.

- The "golden engine" concept of checking test cell performance is a fallacy. No engine however well sealed and programmed can be used as a standard torque or gas-producing device; there are too many variables. The results of "round-robin" testing, whereby an engine is subjected to the same tests in many cells, are always disappointing. This holds true unless the engine is moved on a pallet on which it is completely prerigged with its fluid control systems and all mounted transducers, then tested with the same reference fuel and conditioned combustion air. Even then, the time wasted in chasing the causes of smaller and smaller variations in results will probably render the exercise a waste of time.
- Nothing is more important than regular and careful instrument calibration and diligence in avoiding physical or post-processing signal corruption.

2 THE TEST CELL STRUCTURE, ITS SAFETY, AND ENVIRONS

The engine test cell is subject to a wide range of safety and environmental regulations that vary only in detail worldwide. In addition to long established best operating practices, a test cell under all modern legislation is built and operated as a "hazard containment box." As an example, the European Union (EU) has enacted legislation that directly (*if sometimes unintentionally*) impacts on the design of engine test facilities, the most important of which may be the ATEX (EU 94/9/EC): (HSE) directives (Section 3). The New Machinery Directive (2006/42/EC) (European Commission) goes further with the concept of hazard containment, in that the cell structure tends to be treated as a "machine" the access to which has to be controlled, and guards within the cell (shaft guards) are treated as secondary protection.

Moreover, the walls and roof of the test cell should be of a substantial construction, providing attenuation of the engine noise at the adjoining workspaces and having at least a 1-h fire rating that is achieved by inclusion of automatic fire dampers fitted at all points of major cell penetrations (ventilation ducts).

Building codes and their local interpretation, covering the construction of engine test cells, varies around the world. In the United States, it has been a common practice to fit "blast panels" within an outside wall of the cell; whereas, in Europe, such features are only incorporated in cells using gaseous fuels; even then the panels are usually only in the exhaust ducting.

Environmental considerations on the test facility location concern both the effect of the facility on the environment and the environment on the facility. Depending on the type of testing being carried out, the location can cause deleterious effects on testing. Thus, proximity of emission laboratories to air pollution from traffic or industrial processes or noise, vibration, and harshness (NVH) facilities to major sources of vibration such as railroads is inadvisable. The impact of the facility on the local environment of a low number of engine test cells is minimal compared with the traffic densities surrounding them; however, an environmental hazard from a facility that can result in penal costs is fuel leakage into the ground water. Every precaution against such occurrences must be taken in the design and operation of bulk fuel storage and reticulation. Modern best practice dictates that buried fuel lines are of a double-walled design equipped with interstitial monitoring. Within facility buildings, fuel lines, made in welded stainless steel, are now run above head level where they can be easily monitored.

2.1 Size of test cells

Table 1 shows the typical sizes of four types of engine or powertrain test cells taken from actual European examples. Generally observed best practice is that a cell should be sized such that an operator has a clear walkway at least 1 m wide around the installed plant, although commonly this is not possible at the rear of the cell because of exhaust pipes running out of the cell. It is particularly important to leave sufficient clear space for calibration equipment, particularly for the dynamometer.

Table 1. Listing of the actual internal dimensions of different types of engine test cells.

Dimensions	Cell Category
6.5 m long × 4 m wide × 4 m high	Quality assurance (QA) test cell for small automotive diesels fitted with eddy-current dynamometer.
7.8 m long × 6 m wide × 4.5 m high	Engine control unit (ECU) development cell rated for 250 kW engines, containing work bench and some emission equipment
6.7 m long × 6.4 m wide × 4.7 m high	Gasoline engine development cell with AC dynamometer, special coolant, and intercooling conditioning
9.0 m long × 6 m wide × 4.2 high (to suspended ceiling)	Engine and transmission development bed with two dynamometers in "tee" configuration. Control room runs along 9 m wall.

2.2 Bedplates and seismic blocks

For normal development or quality assurance test cells, running engines in the light vehicle range, it is rarely thought necessary to employ vibration isolation techniques that require significant building excavation work, such as seismic blocks. The general best practice is to use cast-iron bedplates that are mounted on self-leveling "air springs" giving the combined mass system a natural frequency of around 3 Hz. Large bedplates fitted with a matrix of "tee slots" have the additional advantage over conventional bedplates of allowing the repositioning of both dynamometer(s) and the UUT to cater for different layouts, such as changing from in-line to transverse engine and exhaust layouts. Figure 3 (presented later in this chapter) will show such a facility.

2.3 Fire suppression

In spite of improved working practices over the years, fire remains a significant risk in test cells running engines, whatever their fuel. Indeed, the advent of common rail and direct injection engines has increased the occurrence of cell fires. On the detection of fire, the test cell control system should

- cut off the supply of fuel at the entry into the cell;
- shut down the ventilation system(s) and close fire dampers in the ventilation ducts;
- bring engine rotation to a stop and then shut off electrical power to the dynamometer.

Triggering of the extinguishing system often requires manual intervention in order to reduce disruptive false alarms. Systems based on CO_2 or conventional water sprinklers are not recommended anymore and several gas-based extinguishants are banned by environmental legislation. The system recommended in modern test cells is based on "water-mist," sometimes known as *micro-fog* technology. Not only do such systems have a very fast "knockdown" of fire, but importantly, they tend to wash the free-carbon particles out of the smoke and make subsequent cleaning a matter of days rather than weeks. Any chosen system will need to meet local regulation and building codes.

3 THE TEST ENVIRONMENT: AIR

The prime functions of airflow within the test cell are as follows:

- The removal of heat generated by the test equipment and the UUT. A "rule of thumb" for the airflow Q_A in cubic meters per second required to reduce the cell temperature by ΔT in degree Celsius where the estimated heat input is H_L in kilowatt is

$$Q_A = 0.84 \frac{H_L}{\Delta T} \quad (1)$$

- The prevention of the buildup of an explosive atmosphere by removal of hydrocarbon vapors. The design and operation of air-handling subsystems are prescribed under European ATEX regulations and represent worldwide best practice, as they form part of the test facility's primary safety system. This requires that the low point(s) of the test cells are purged of hydrocarbon vapor via an individual (nonsparking) purge fan for a set time before the engine is activated; this is achieved by interlocking with the cell control system. The cell must also be fitted with a hydrocarbon detection system made up of explosion-proof sniffers and connected to the primary alarm/safety system (Section 12). Note that the sniffers are the only explosion proof rated devices normally fitted, or required to be fitted in engine test cells. At a preset "alarm level" of hydrocarbons, the cell ventilation is increased, and at a higher level, the engine is shut down and a full purge sequence is activated.
- Combustion air for the engine under test is supplied by either
  - the engine ingesting the cell ventilation air or
  - a treated air supply independent of the cell ventilation system (Section 4).

To maintain consistent test results, particularly when the engine is ingesting cell air, the flow paths of air within the test cell should be consistent. The most common cause for inconsistence test results due to the variable influence of the test cell is the poorly controlled use of mobile "spot-cooling" fans. It is a best practice to control the ventilation within the test cell through balancing the inlet and outlet flows, such that the temperature within the cell is maintained below 40°C and the pressure below ambient by 50 Pa. The slightly negative pressure ensures that fumes from the cell are not forced into the control room. Using variable-speed fans on both the inlet and the outlet, the control system can control the outlet fan to control temperature and the inlet fan to control cell pressure. With this arrangement, when the air temperature rises, the speed of the outlet fans rises creating a cell pressure drop. The inlet fan then speeds up to balance the outflow. This control method ensures that during transient conditions of rising temperature, the cell pressure tends to be negative

rather than positive; thus, minimizing fumes being expelled into other work areas. Even with a pressure differential of only 50 Pa large, outward opening cell doors may be difficult to open and pressure surges because of badly adjusted systems constitute a hazard to staff because of doors either bursting open or effectively being locked shut.

4 COMBUSTION AIR TREATMENT AND MEASUREMENT

Variability in the content (pollutants), temperature, and pressure of the air ingested into the combustion chamber of an engine will produce commensurate variability in both power output and gaseous emissions. Therefore, high fidelity testing at most sites requires that combustion air is pretreated. *If correlation of test results is required, it is essential that all tests be carried out with common, standard conditions, at least, of air temperature and purity*.

Automotive Combustion analysis (CA) treatment units are widely commercially available that provide air at "standard conditions" of 25°C, fewer will control humidity of that air to 30% RH and fewer still will also control engine inlet air pressure. Best practice dictates that before specifying a CA treatment system, the required engine-test operating points of temperature and humidity are marked on a psychometric chart in order to describe the full operating envelope. It should be appreciated that the wider the operating envelope and the wider the range of ambient conditions are, the greater will be the capital and energy cost of the treatment module. Pressure control of CA adds a further level of complexity dependent firstly on the set point settling time following a change in engine state and secondly whether it is required to run at air pressures below local barometric.

While correction codes such as SAE J1349 are valuable for standardizing engine power outputs, to repeat or correlate engine emission measurements requires standardized air.

5 FUEL TREATMENT AND MEASUREMENT

The handling and treatment of liquid and gaseous fuels in bulk are subject to national and local safety and environmental protection regulations worldwide; facility management must take cognoscente of them. Best practice and regulation dictate that at the entry point of fuel into a test cell, fuel flow must be controlled by a "normally closed" solenoid valve that is interlocked with the emergency stop and fire alarm systems. The fuel consumption of modern engines, fitted with a variety of "spill-back" systems, cannot be measured by recording the mass or volume of liquid fuel supplied to the engine, as in the past, but rather the volume or mass of fuel leaving the metering system and before the engine's recirculation loop must be measured. A difficulty that arises is due to the heat picked up by the fuel in the pressure rail system and vapor that may have been created—both changing the volume and unit mass of the liquid. Figure 1 shows the type of circuit required to maintain temperature and degas fuel.

6 ENGINE EXHAUST HANDLING

The modern automotive exhaust system with its post-combustion gas treatment modules and in one of the intended vehicle configurations has to be considered an integral part of the engine system as rigged in any test cell carrying out homologation and mapping work. The need to rig engines with a variety of exhaust configurations has led to a general increase in the size of cells. For such cases, the cell system must provide an extract duct working under negative pressure into which the last section of the exhaust pipe discharges. The fan that withdraws the exhaust, diluted with a proportion of cell air, should ideally be placed so that its discharge ducting, under positive pressure, is outside any enclosed workspace. Where a vehicle exhaust is not used, then the gasses are removed by direct coupling to pipework forming part of the cell system. This will include a short flexible section at the engine and suitable silencers (mufflers).

For both safety and operational reasons, modern best practice dictates that cells are provided with individual exhaust systems of whatever type, rather than using shared ducting. In the case of direct-connected exhaust systems, the practice is to provide oversized pipework fitted with a valve to regulate backpressure.

Finally, diluted exhaust ducts act as condensers and can produce highly corrosive condensates. The ducts must therefore be made from suitable stainless steel. Spiral wound galvanized duct must never be used in this situation. (*Note*: exhaust emission analysis equipment and operation are discussed in Exhaust Emissions).

7 ENGINE MOUNTING

7.1 Engine support mechanism

The support mechanism provided for the engine UUT depends largely on the frequency of unit change (the rig/run ratio). The requirement to obtain maximum possible use from increasingly expensive test facilities has meant that most operations prerig the UUT in support workshops on specially designed pallets (fork-lift transported) or trolleys. By providing a workshop rigging-stand that emulates the positions of critical interfaces (shaft height, exhaust flange, etc.) of test stand, unproductive installation time in the cell is minimized.

Vehicle-type engine mounts are widely used on pallet-rigged engines. However, owing to the different system dynamics, it should be noted that they do not always provide the correct degree of support or damping.

7.2 Connecting shaft

The connecting shaft is the rigging component that creates most frequent problems; shaft vibration may occur in a particular engine/dynamometer configuration when ranges of engines are tested with the same shaft. Connection shaft selection may require a detailed analysis of the system, a subject covered in detail in specialist publications such as "Engine Testing" fourth edition (see recommended Further Reading). The results of shaft failure, due to incompatibility with the torsional regime or poor quality of installation, are serious and will cause significant consequential damage unless properly controlled. Shaft guarding must be designed to retain shaft components in the case of failure and also prevent accidental human contact with rotating parts. However, it must be possible for the engine to flex on its mountings to the normal extent during running without making contact with any part of its enclosing guard; the presence of such clearance must be a standard prerun check. Modern safety practice requires that shaft guards are hinged for access but that the state of the guard system is interlocked with the cell control system.

7.3 Transducer cables

The transducer cables should be bunched and supported so far as is possible during the prerigging so that in the cell they are simply plugged into the cells transducer box. Transducer boxes (Section 8) that are close to, or above, the test engine are frequently force ventilated to keep internal temperature below 40°C.

8 ENGINE SERVICES BOX

The out of vehicle running of engines requires that the test cell is fitted with an *engine services box*, installed close to the UUT in order to provide electrical power to the engine control unit (ECU), power to the starter motor when required and other auxiliary units such as diesel heater plugs. A typical set of connections is shown in Figure 2. Note: KAP (keep alive power) terminals are for providing some ECUs with an unswitched 12 V DC supply, for preventing loss of datasets in volatile memory.

It should be noted that in addition to some ECUs requiring continuous power, it is highly advisable to fit the test cell control computer with an uninterrupted power supply (UPS) unit with a 1 h capacity.

9 DYNAMOMETERS

All dynamometers absorb and measure the torque produced by the connected engine while recording rotational speed of the dynamometer shaft. Thus, they can be considered as power measurement devices. Test routines require that the dynamometer both absorbs and contributes torque to the test system and is able to respond to demands for speed/torque changes quickly enough to simulate the quasi-real life drive cycles encoded in legislation and the requirements of control mapping.

AC motor-based dynamometers of low rotational inertia coupled with fast reaction pulse width modulating (PWM) drives have become the standard technology used in modern automotive test cells. It should be noted that, in addition to produce noise in the radio-frequency (RF) band (see later), AC drives contain expensive and delicate electronics; therefore, care should be taken in their position within the test facility and in their clean and reliable ventilation.

Less common, but still used dynamometers include direct current (DC), eddy-current, and water brake dynamometers. DC dynamometers are used in electromagnetic compatibility (EMC) test cells, where their lower RF signature is valued. The proven, absorb only, dry-gap, eddy-current dynamometers still retain a role in engine testing, where cost-effective running of engines under load is required such as in catalytic aging and endurance work. Water brake dynamometers are used for engines having power outputs beyond the economic range of AC machines such as use with medium speed diesels.

Torque measurement by modern dynamometers is achieved by one of the following two possible methods:

- By mounting the absorbing body of the dynamometer in trunnion bearings (cradle mounting) and measuring the torque reaction against the floor-fixed frame using a stiff solid-state strain gauge.
- By fitting a torque-measuring transducer at the dynamometer end of the shaft system connecting the engine. Such devices take the form of either a torque shaft fitted with its own bearings or a torque flange.

There are a number of subtleties in the choice of torque measurement systems but all must be capable of on-site calibration, usually using weights that apply a known force on an arm of known length.

Rotational speed is measured either by a toothed wheel and proximity pick-up, as is commonly used on eddy-current dynamometer, or, in the case of AC machines, by optical encoders. The engraved disk on the optical encoders can be produced so as to record not only instantaneous speed but also shaft position and direction of rotation.

10 THROTTLE ACTUATION

Almost all modern automotive engines are “drive-by-wire” meaning that the fueling control (for diesel engines) or “throttle” (for gasoline engines) is achieved by sending an electrical demand to the ECU. While it is possible to simulate that demand signal via an analog output from the test bed control computer in the test cell, it is rarely done this way. Owing to the complexity of this safety critical vehicle system, it is best practice and easier to use a complete vehicle accelerator pedal system directly wired into the engine loom, as in a vehicle. The pedal unit, rigidly mounted in a support frame, is operated via a Bowden cable by a fast-acting actuator under the control of the test bed controller. Setting up the zero to wide open throttle (WOT) position during engine rigging should be straightforward in a well-designed system and the shifting force should be mechanically limited. In all cases of engine rigging, particularly when intermediate linkages are used between actuator and pedal unit, backlash must be eliminated; otherwise, stable control will never be achieved.

11 ELECTROMAGNETIC COMPATIBILITY OF THE TEST CELL

The automotive powertrain test cell contains a number of powerful emitters of electromagnetic energy encompassing a very wide frequency spectrum. Such an environment is capable of corrupting both data and control systems unless the greatest possible care is taken in the design, particularly in the installation of all cables within the test facility. Radiation in the RFs is an inherent feature of the pulse-width-modulating drives associated with AC dynamometers. This source of interference has replaced the harmonic distortion of the AC supply associated with older DC dynamometer systems and is commonly dealt with by powering the machines through a dedicated isolating transformer of the correct capacity.

The two key EMC requirements of a test facility are as follows:

- The whole building—all its services and all the installed test equipment should be connected to an equipotential grid; meaning that the earth (ground) potential is common throughout the facility and at the lowest possible impedance.
- The upmost care is paid to the layout and separation of data, control, and power cables. Signal corruption, through inductive, capacitive, or conductive coupling interference is very difficult to correct in carelessly installed sites, where underfloor trays are full of coils of over-sized or inappropriately bunched cables (Figure 3).

Figure 3. An AC dynamometer-equipped engine test cell containing a large cast-iron tee-slotted bedplate that is supported on air-springs, allowing multiple configurations of test equipment. Engine supported within a wheeled trolley allowing extensive prerigging outside the cell. Low level, rectangular "purge duct" can be seen on the right hand side of the photo next to an, circular section, exhaust dilution and extract duct. (Photograph reproduced by permission of AVL List GmbH.)

12 TEST CELL AUTOMATION

The engineer working within a test cell facility will have to understand the functions and interactions of four separate but interlinked control systems:

- the building management system (BMS);
- the test bed control and data acquisition systems;
- control systems embedded within "intelligent" devices such as AC drives and instrumentation such as combustion analysis and emission analysis equipment;
- the engine or powertrain control unit (ECU). Communication hardware with ECU can range from simply providing the "missing" digital I/O required to run the engine (wireless ignition key signal) to access required to map the control parameters.

12.1 Building management system

The BMS is a programmable logic controller (PLC)-based control system through which all of the facility services are started in a predetermined sequence, monitored, and shut down. Such systems range from the simple operation of the motor control panel, providing power to ventilation fans and fluid pumps, to highly complex building energy control systems. However, the correct interaction logic between the BMS and the test cell control system is vitally important to avoid test work being ruined by inappropriate shut downs triggered by building conditions irrelevant to the test cell in question. A key design and operational document for a test facility is the safety interaction matrix (SIM), parts shown in Table 2

The creation of a SIM is a key task in the system integration process because it requires the design team and cell operator to consider, record, and codify the system reactions in the case of every defined change of state or alarm condition of connected modules. Every SIM has to meet the operational preferences of the owner, within the restraints of safety legislation, and will be specific to the system for which it is designed.

12.2 Test bed control and data acquisition systems

The test bed control and data acquisition systems are based on powerful personal computers running specialized

Table 2. Parts of a typical safety interaction matrix that designates the interaction between control systems during normal and alarm states within the test facility.

Test cell safety matrix	Cell control system (CS)	400 V AC electrical supply	Test cell power sockets	Ventilation fans	Ventilation fire dampers	Combustion air system	AC dynamometer	Engine control	Test cell incoming fuel solenoids	Compressed air system	Other systems
Controlled by	CS	ESR	ESR	BMS	BMS	BMS	CS	ESR	ESR-DO	ESR-DO	
Event											
Main building fire alarm	No reaction	Enabled	Enabled	Manual shutdown of test cell, via "fast (regen) stop," before facility evacuation							
Test cell fire system (automatic)	Stop	Enabled	Disabled	Disabled	Closed	Disabled	Stop	Stop	Closed (off)	Closed	
Level 1 HC/CO gas alarm	Message display	Enabled	Enabled	Purge sequence	Open	Enabled	Power on	Enabled	Open (on)	Open	
Level 2 HC/CO gas alarm	Fast stop	Enabled	Enabled	Purge sequence	Open	Power off	Regen stop	Stop	Closed (off)	Open	
Manual emergency stop (remote from desk)	FAST STOP	ENABLED	Disabled	Disabled	Closed	Disabled	Regen stop	Stop	Closed (off)	Closed	
Other events											
Test cell doors opened during engine test	Fast stop or idle[a]	Enabled	Enabled	Freeze vent	Open	Enabled	Stop or idle[a]	Stop or idle[a]	Open	Open	
Test sequence stage alarm	Message display	Enabled	Enabled	Enabled	Open	Enabled	Power on	Enabled	Open	Open	
Other events											

Abbreviations: BMS, building management system; CS, (cell) control system; DO, digital out (from control system); and ESR, emergency stop relay.
[a]The action taken when the cell door is opened during engine running has to be determined by the operator via a risk analysis; the default options are either "engine stop" or "engine to idle." Ventilation freeze means that the system is held at the running status at alarm tripping.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto207
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

software. The prime functions of the test bed controller are to provide the following:

- A suitable mechanism to write and execute automated test sequences, control and record the engine's speed, and load together with all of the controlled variables provided by the cell's services control systems. Systems must be at least capable of running and recording the data required by modern legislated tests, such as the FTP75 and the NUDC drive cycles. Typically, the control loop times of modern digital systems will be >1 kHz. The data acquisition rates can be of the same order but should be adjustable to rates appropriate to the measurement being made.
- The ability to control the power produced by the engine by controlling the throttle (fueling) and load imposed on the engine by the dynamometer. This must be done so that the demanded parameters are achieved, within the capability of the engine, which may itself exhibit unstable characteristics, both during steady-state running and transient conditions between demand points. In addition, most modern controllers should be capable of direct PID or PI control of external devices such as coolant temperature control units. A suitable interface and system for connection and marshaling of sensors and transducers measuring temperatures, pressures, and other analog values around and within the UUT. Many of the raw data streams will have to be subjected to signal conditioning, such as analog to digital conversion, with the minimum possible data degradation before being transmitted via an error-tolerant high speed bus. The most common high speed bus is currently CAN (controller area network), as defined by ISO 11898.
- Recording (storage) of computer data in a suitable electronic file format for subsequent data analysis, display and retransmittal, and unique labeling of each data channel from transducer to stored data. Note that without a consistent channel identification convention being imposed by test engineers, over all cells involved in a common exercise, there is no possibility for realistic comparison or correlation of test results.
- Suitable interfaces for appropriate "intelligent" measurement devices, their remote control, monitoring, and data recording.
- A calibration system for all of the directly coupled transducers that provides a certification audit trail that meets the requirements of an ISO 9001 quality system.
- An interface that meets the conventions laid down by ASAM (Association for Standards in Automation and Measurement). These interface specifications, such as ASAP-3, ASAM MCD3, are widely adopted in automotive industry.
- A primary programmable safety system interfacing with any BMS fire and gas alarm circuits. The continuous monitoring system should be designed to react to at least two levels of alarm state: warning level and shut down level. The primary alarm levels should be set to protect the integrity of the equipment and the secondary alarms (test stage specific) to protect the UUT or the integrity of the test sequence.
- A mechanism for management and storage of test sequences and cell settings to allow for reuse and traceability of test sequences and cell settings.

At the leading edge of development work, the hardware and software forming powertrain test cell control and data acquisition systems are the signature product of a few internationally known companies. Such systems are of necessity, complex and continually updated as user requirements and experience is embodied in updates. The choice of which system to use has important implications to the efficiency of the facility. However, training in the use of such complex and expensive systems, both at basic operator and advanced engineer levels, is a fundamental requirement if full return on the investment is to be made.

12.3 Engine or powertrain ECU

The engine or powertrain ECU that controls all modern units requires calibration (mapping) in the engine's development phase such that the powertrain performance meets the requirements of the chosen user profile while at the same time meeting all the relevant legislative requirements. In addition to the basic task of controlling ignition and fueling over the full range of operational and environmental conditions within a permitted legislative envelope, the ECU also has to be loaded with the logic required by the on-board diagnostic (OBD) systems.

Once calibrated, the production version of the ECU sets a problem for all test engineers downstream of the calibration cells that have to run the engine when some of the ex-vehicular components required by the software are lacking. In these situations, various levels of communication with the ECU are required. The ECUs used in vehicles are made by a limited number of manufacturers worldwide who do not permit access to the lowest levels of the embedded software within, even to their OEM customers. Therefore, calibration engineers, who require the ability to read and write data to the control maps of the ECU, have to work with specially prepared, development versions of the ECU and use one of the software tools supported by various specialist companies.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto207
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The software tool is generally known as an *ECU application system* and allows access to measurement and calibration data from within the ECU processor and memory for the purpose of online optimization of calibration data variables. For the calibration task, the development ECU must be equipped with two important features:

- Additional memory for handling calibration variables during run time, known as *CalRAM*;
- An interface that will allow manipulation of these variables online, as well as access to measurement dataset variables from within the ECU processor. This is the interface to the application system and is defined by ASAM standards (ASAM) (MCD 1 and 2).

The development ECU also facilitates "switching off" of production-related functions—for example, operation of the ECU outside the connected vehicle network, disabling of on-board diagnostic functions, and disabling of related functions within the ECU (allowing "flat" maps to start the calibration process).

The physical interface (or connection) to the development ECU can be executed with one of the following two methods:

- *Emulator*—an additional processor board, often installed inside the ECU case, that has direct access to the ECU memory and data bus. This device has additional calibration memory on-board, as well as a high speed interface to the application system via a signal processor.
- *CCP* (*CAN Calibration Protocol*)—using an additional driver in the development ECU processor, allows access to measurement and calibration data via a CAN port on the ECU (either the existing vehicle CAN port or a dedicated calibration CAN port). The ECU must also be equipped with additional memory space, or "ring-fenced" memory, for manipulation of calibration data online, that is, CalRAM.

The emulator is more difficult and expensive to implement; however, where many levels of map and measurement values need to be manipulated, the emulator provides more memory and much faster communication to the application system. It is therefore more often applied to development ECUs that will be employed earlier in the development process of the UUT. CAN-based interfaces have memory and bandwidth limits, but are cheaper and simpler to implement, and are therefore more appropriate to the later stages of the development process.

13 DATA ACQUISITION FOR SENSORS AND TRANSDUCERS

One of the primary requirements for the test bed system is to acquire and store data from a wide range of types of sensors and transducers on and around the UUT. Table 3 lists the common measurements made in automotive test cells and the type of transducers used.

Most, but not all, of the transducers listed can be calibrated against a reference signal by the operators of the test facility as is required by any quality certification system.

Many operators who give a great deal of thought about the specification of individual transducers may tend to ignore the inherent changes to such specification wrought by the systems in which they are installed. Calibration has to include the complete measurement chain, from transducer to the input of the data store.

14 DISTRIBUTED I/O SYSTEMS

The low levels of many transducer outputs in their path to recording medium are vulnerable to corruption by external electromagnetic fields. Therefore, it is necessary that such signals are conditioned, digitized, converted, or amplified as close to the transducer as possible. The conditioned signal can then be passed via a high speed communication link, such as CAN-bus or Ethernet based interfaces to the data acquisition computer external to the cell. Signals are best marshaled and conditioned within the cell, within a "transducer box" into which run the multiple transducer cables or pressure lines. While the transducer box must be close to the engine as the source of the signals, it must also be protected from overheating by either positional shielding or/and forced ventilation.

The transducer box can be considered as one node in a distributed I/O system. Distributed I/O provides a very flexible, scalable concept for test data acquisition. It would normally consist of modules that are "daisy chained" together via a digital bus; the system can be extended by simply adding more modules to the I/O chain. Each module may have multiple input channels and its own local processing capability and intelligence, allowing it to measure the value from the connected sensor, convert it to a physical value by applying the correct calibration information, and then transmit the value back to the bus "host" with a defined response time, or data acquisition frequency. All data values are acquired with a time stamp and can hence be synchronized with the overall system data acquisition frequency.

In addition to analog signals, the test bed controller needs to be capable of reading and producing digital signals;

Table 3. A listing of the most common measurement channels used within the engine test system together with the type of signal produced.

Measurement	Principle applications	Method or transducer	Signal produced
Time interval	Rotational speed	Tachometer Single impulse trigger, starter ring gear, and pickup Optical encoder	Incremental pulses, analog sine wave or digital square edges
Force, quasi-static	Dynamometer torque	Strain gauge load cell	Analog signal, voltage, or current, to be amplified and linearized
Force, cyclic	Stress and bearing load investigations	Attached strain gauges plus wireless transmitters Strain gauge transducer Piezoelectric transducer	Analog signal, often complex, for detailed analysis May need additional signal conditioning/processing
Pressure	Fluid flow systems, gas or liquid	Liquid manometer Bourdon gauge Strain gauge pressure transducer	Analog voltage or current. Digital, pulse width modulated or variable frequency, also digital message (via CAN) for intelligent sensors
Pressure cyclic	In-cylinder, inlet, and exhaust events, fuel rail	Toughened strain gauge transducer Capacitive transducer Piezoresistive or Piezoelectric transducer.	Analog signals, used in conjunction with external signal conditioning to provide analog voltages for measurement
Position	Throttle and other actuators	Mechanical linkage Linear variable displacement transducer (LVDT) Rotary optical encoder	Analog voltage or current as a linear function of position
Displacement cyclic	Needle lift Crank top dead center (TDC)	Eddy-current or hall effect transducer, Inductive or Capacitive transducer	Requires external conditioning system to produce analog voltage for processing (absolute position not always necessary)
Acceleration	NVH investigations Shaft balancing	Strain gauge accelerometer Piezoelectric accelerometer	Analog signal, often complex, for processing and detailed analysis
Temperature	Fluids, air, and gases, mechanical components, in-cylinder	Liquid in glass Several types of Thermocouple PRT Thermistor Electrical resistance Optical pyrometer	Analog as a function of temperature, each type needs specific conditioning for amplification and linearization suitable for measurement

Table 4. Giving typical numbers of measurement channels specified for modern powertrain test cells in three generic types of industrial facilities.

Channels and I/O interfaces for measurement and data acquisition (excluding engine and dynamometer controls)	Base systems for QA and typical tier 1 and 2 testing	Engine calibration testing	Advanced powertrain development testing
Digital inputs (inc. PW and frequency)	16	16	32 or more
Digital outputs	16	16	32 or more
Analog inputs	Until 100	100–250	250 upward
Analog outputs	8–12	8–16	16–32
Interfaces to intelligent measurement devices (hybrid and digital)	4	8	8–16
Typical data acquisition speed (fastest channel sampling rate)	1–10 Hz	10–100 Hz	From 100 Hz to >1 kHz

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto207

typical applications include simple state bits (logic 0 or 1), binary input ports, counter–timers, pulse width, and duty cycle signals. Table 4 shows the typical I/O requirements for a range of test automation systems.

The choice of transducer, the speed at which its data is sampled and the accuracy to which it is digitized, should always be appropriate to the use. High speed acquisition and high resolution digitization of the signal from a K-type thermocouple is at best a waste of computing power and produces an allusion of precision beyond reality. The transducers serving those channels connected to primary safety systems, such as engine oil pressure, or critical control systems, such as the coolant temperature control unit, must be the most robust available (e.g., a PRT rather than K-type thermocouple).

15 INTEGRATION OF INTELLIGENT INSTRUMENTS

In addition to the analog and digital signals acquired directly from the transducers and interfaces described earlier, test cell automation has to support various special measurement devices within a test environment. These are devices with some local intelligence and are capable of data acquisition, signal conditioning, and calculation of derived data. The interface between the control computer and the device generally performs a remote control and data transfer function, communicating with the device via a digital interface. A commonly used interface is the so-called AK serial protocol that uses RS232 as the physical hardware layer. There are several other communication interfaces used and technology development in this area is in a state of evolution.

Measurements that were taken 10 years ago by long established techniques and basic instrumentation are now the subject of advanced study using increasingly complex digitally controlled devices, examples being:

- *Engine blow-by measurement* by instruments capable of detecting and integrating pulsating or inverted blow-by flows.
- *Oil consumption measurement*, which can involve instruments capable of detecting and measuring low levels of nuclear isotopes in exhaust gasses to calculate lubricating oil combustion in near real time.
- *Emission devices—gaseous and particulate*. These are sophisticated devices, containing several internal measurement modules using complex technologies covered elsewhere in Exhaust Emissions. The task of the test controller is to trigger their internally programmed processes when they are required to measure, purge, or calibrate themselves. Emission measurement units of the type used in research work have self-monitoring capabilities and are capable of flagging operation and error states. All this control and information need handling over an interface, as well as the transfer of data values, either online or as statistical values after a measurement procedure; therefore, a reliable digital interface is required. Several technologies can be encountered including general-purpose interface bus (GPIB, a parallel interface technology), RS232 (serial), and, increasingly, TCPIP (standard network technology).

16 COMBUSTION ANALYSIS

High speed measurement of combustion pressure-related parameters, in the crank-angle domain, is a common requirement employed throughout the engine development process. An overview of engine speed and cylinder pressure-related measurements is discussed in the following sections. We will consider the practical aspects of using this measurement technique later in the engine development process at the test bed. More details can be found in specialist publications such as “Engine Combustion Pressure Measurement” (see recommended Further Reading). Detailed analysis of the pressure data for information such as heat release rate is also discussed in Pressure and Heat Release Analysis. In order to implement any CA work, the engine must be prepared with additional instrumentation specific to this task, namely, an engine angle encoder and a combustion pressure sensor.

16.1 The angle encoder

This instrument facilitates recording of engine absolute position, from which the instantaneous engine volume can be derived. Its specification has to be carefully matched with the requirements of the system into which is to be integrated. The most commonly used encoder for CA applications generates square wave signal, on an incremental basis, giving the crank degree marks (a fixed number of marks per revolution) and a reference signal (one mark per revolution).

The encoder, mounted directly to the engine, operates in an environment with significant heat and vibration. In extreme situations, such as for some high performance engine test applications, the usual etched glass encoder disk has to be replaced by one made of metal. Mounting has to be carried out with care and precision so that the dynamic effects of misalignment are avoided.

16.2 The engine combustion pressure sensor

The ECPS has to be mounted in the engine cylinder(s) to enable pressure data sampling and acquisition until 1 MHz. ECPS is manufactured with different properties to meet a wide range of test and engine monitoring applications that no sensor will fulfill. There will always be trade-off between durability, temperature range, and accuracy. An example is the knock measurement task; this will require a sensor of high durability and natural frequency rather than the highest pressure measurement accuracy.

The modification of a cylinder head required for the installation of a pressure sensor can present considerable practical challenges to a machine shop and must not be underestimated. In order to help with this task, some suppliers provide cutting tools specifically for the job. It must also be remembered that the installation should not affect the combustion chamber with respect to volume, charge motion, or thermal properties, neither must permanent installation compromise cooling fluid nor oil flow passages in the engine cylinder head.

An important part of the specification of any ECPS is the maximum temperature that the measuring element can withstand. Many water-cooled units have been produced, while the maximum temperature range of uncooled units continues to rise. A popular misconception is that water-cooled transducers must be more accurate and stable; this misconception is based on legacy issues with quartz piezoelectric transducers. Cooling of transducers requires extra equipment, and does not always mean greater accuracy or stability. The movement of water mass around the sensor element inside the transducer can create noise and crosstalk. Note also that cooled transducers are generally larger and more difficult in integrate in modern combustion chambers of production engines. Uncooled transducers are generally smaller but can have lower sensitivity.

The temporary installation of an ECPS can be achieved by using special, uncooled, or hybrid spark-plug sensors or those sized to use diesel glow-plug ports, but such installations generally trade-off convenience with ultimate accuracy (Figure 4).

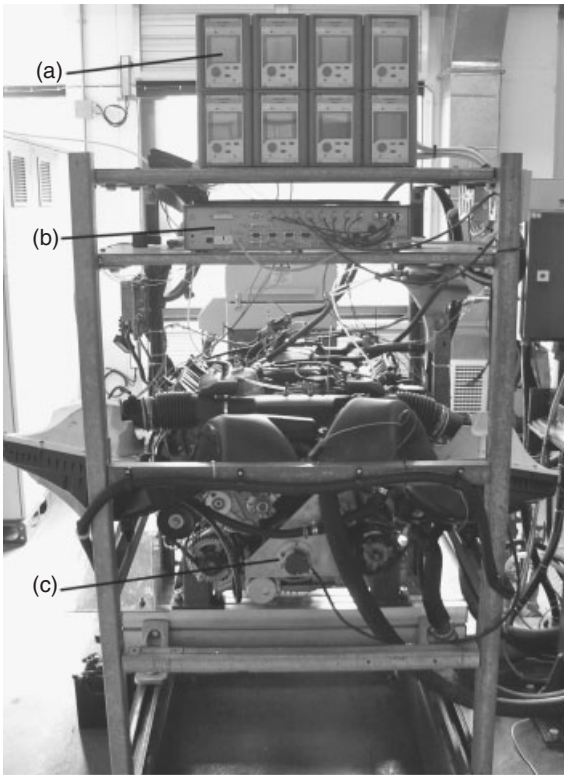

Figure 4. View of an engine fully rigged for combustion analysis work with the listed instrumentation shielded from direct engine heating by frame mounted shelving. A = signal conditioning rack and charge amplifiers; B = combustion pressure measurement and analysis system; and C = engine front pulley mounted encoder. (Photograph reproduced by permission of University of Bradford.)

17 CONDITIONING OF CYLINDER PRESSURE SIGNALS

The raw signal from engine combustion pressure transducers is not generally suitable for direct connection to the data acquisition device. The signal often needs a combination of conversion, amplification, and filtering in order to be usable. These functions are carried out by specific signal conditioning hardware, which can be physically integrated into the measurement system, but is more often positioned externally, close to the transducer.

Specific details of amplifier technology, operation, and integration are beyond the scope of this chapter and covered in detail within general texts (Randolph, 1990; Lancaster, Krieger, and Lienesch, 1976; Brown, 1967; Davis and Patterson, 2006; Kuratle and Balz, 1992) and proprietary literature from manufacturers. However, some general comments to consider in the interest of producing high quality data are listed.

- As a rule of thumb, the amplifier rack should be mounted as close as possible to the transducer, but it needs to be kept in at a stable temperature, so unnecessary switching on and off should be avoided and they must be shielded from heat sources.
- Interface panels and connectors for all cabling should be maintained clean as per laboratory instrumentation standards.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto207
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- Cable routing must be considered very carefully, avoiding all other power and signal cables in the test environment.
- The amplifier setting must be optimized with respect to sensor sensitivity and expected signal range. This will provide the optimum digital conversion quality.

18 SPECIAL PURPOSE TEST CELLS

The majority of this chapter has covered the choice, integration, and some of the uses of hardware installed within engine test cells designed for general research work on automotive engines. Many of the components and practices of these cells are also appropriate to the more common types of specialist test cell used in engine and powertrain development. The following sections cover special constructional and operational features of cells designed for climatic, NVH, or EMC research.

18.1 Climatic engine test cells

Climatic engine test cells range between those designed to run legislative "cold-start" test sequences, currently requiring the UUT to be at $-7\,^{\circ}$C, to those capable of exposing the UUT to temperature ranges of $+50\,^{\circ}$C to $-40\,^{\circ}$C. Such thermal changes demand considerable electrical energy for refrigeration plant and a great attention to the detailed construction. It is most advisable to only use refrigeration contractors with the appropriate industrial experience for the construction of such facilities, as those without will not appreciate or cater for the fluctuating energy outputs within the cell. While whole vehicle climatic chambers reduce the temperature of the complete cell, it is possible for engine testing to encase the UUT within a thermally insulated "tent" while circulating cold air around and cold fluids within the engine. Such systems greatly simplify the cell construction and reduce the energy required.

18.2 Anechoic cells

Anechoic cells of significantly different construction are required for EMC and NVH testing. In both cases, the site location has to be chosen so that there is a minimum of the type of background "noise"' in the location that would interfere with the measurements being made.

18.2.1 Anechoic cells for NVH

Anechoic cells for NVH work on engines are normally of a semianechoic (also called *hemi-anechoic*) design that can be thought of as simulating the sound regime of a vehicle sitting on a road in still air in the middle of the flat Arizonian desert. Full anechoic chambers are most commonly met in the smaller sizes required for component testing. The key specification of such cell is their "cut-off" frequency, which is the lowest frequency that sound can be emitted at the center of the cell while still obeying the inverse square law of sound energy decay. Typically, for modern engine test cells, this is around 60 Hz. These cells are fitted with sound-absorbing linings, the most common types of which take the form of cones whose apex protrude into the cell. Such cells require specialist designers experienced in dealing with the particular design and construction restraints that include

- the need to keep ventilation airflow as quiet as possible by the use of high volume, low velocity ducts whose entry termination is below the last row of cone lining and outlet is above or in the cell top corners.
- fluid control valves that create random noise, as they operate, have to be outside the chamber, which increases the thermal inertia of the system and gives control problems.
- the shaft connection to the engine needs to bridge an unusually large gap to maintain the engine position near the cell center. A pedestal bearing is usually mounted just inside the cell in order to divide the shaft to the dynamometer (outside the cell) into two sections.
- color CCTV using zoomable and steerable cameras need to be part of the cell system, as no (sound reflecting) windows can be included.

18.2.2 Anechoic cells for EMC work

Anechoic cells for EMC work are rarely constructed simply for engines but rather they are sized for whole vehicles. This is because the interference caused by the engine and powertrain and their vulnerability to electromagnetic energy sources can only be tested correctly as part of the total system of modules and their interconnecting wiring looms. The cell structures have to form a Faraday cage and they are lined with either or both:

- closed cell polyurethane foam molded into a steep pyramidal shape impregnated with carbon;
- ferrite tiles that are made from a sintered iron/nickel material usually measuring $100 \times 100 \times 6$ mm thick.

The need for certified EMC test facilities increases with the new generation of hybrid and electrical vehicles producing a whole range of new potential interference problems with their variable-speed drive systems.

19 DATA MANAGEMENT, QUALITY, AND SECURITY

The product of all the expensive equipment within an automotive test facility is data and the empirically gained experience of its staff. In order to derive the maximum value from test data, it has to be protected from loss and corruption and be made readily available, in an appropriate form, to a range of authorized users. The greater the degree of homogeneity in the data sets, the easier will be the task of later correlation and research. This requires discipline to be imposed on the DOE on channel naming, storage of raw data, and auditing of postprocessing work.

The chosen software of the data acquisition and postprocessing suites can impose such discipline, but it must also be a part of the quality assurance procedures of the test facility. Differential access to levels of test controller software is a sensible precaution to prevent casual alteration of alarm limits; similarly, the veracity of original (raw) test data should be protected through protected archiving from post-processing.

There are a few major suites of software produced by companies, such as AVL List GmbH and MTS®, designed specifically for handling the work-flow and data-flow of automotive test facilities, but there is no substitute for diligent and supportive management of trained staff.

Trends—Compression Ignition

Zissis Samaras, Ilias Vouitsis, and Savas Geivanidis

Aristotle University, Thessaloniki, Greece

1 INTRODUCTION

On the evening of 29 September 1913, Rudolf Diesel (born in 1858), George Carels (an industrialist and Diesel's close friend, who would stand by him in times of need), and his chief engineer Luckmann sailed from Antwerp bound for Harwich on the Great Eastern Railway steamer *Dresden*. It would be a beautiful, calm, and clear night. The route was ideal because the English port lay only a few miles from Ipswich where a factory visit had been scheduled before the first annual meeting of Consolidated Diesel Engine Manufacturers in London on October 2. The three men had a pleasant dinner aboard and retired to their staterooms about 10 o'clock. It was agreed to gather for an early breakfast before going ashore the next morning. The ever punctual Diesel did not appear as planned, and in due course his stateroom was checked. They saw his bed turned down but not slept in, all personal baggage intact, his watch by the bedside, and keys hung from his handbag. A search of the ship before allowing passengers to disembark found no trace of him (Cummins, 1993).

One century after this fatal night, the compression ignition (CI) engine (popularly known by his name) is the standard solution for almost all heavy-duty applications, either commercial or military (buses and trucks, ships, engines for industry, power generation, construction, and agriculture). This is due to its reliability, durability, and fuel efficiency. In recent years, owing to the rapid increase in specific output with simultaneously very high torque when used with a turbocharger, it has become very popular for passenger cars (PCs) and sport vehicles as well, especially in Europe (Figure 1). Modern diesel PC offers an outstanding driving experience, while at the same time consuming very little fuel.

Future CI powertrains for both light- and heavy-duty applications have to fulfill a set of requirements determined by a combination of social, economic, environmental, technological, political, and infrastructural constraints (Figure 2). The importance of each component depends on the application but the general scheme is the same. The technological evolution of all engines in the near future will be driven mainly by environmental requests: "near zero" "toxic" emissions by the 2030 time frame and substantial reductions of greenhouse gas (GHG) emissions. Figure 3 shows the main technology trends for the light-duty powertrain over the next 20 years.

In the following, the technology status and future trends of CI engines are discussed. We begin with fuel injection equipment (FIE) and proceed with turbocharging and downsizing, flexible engine systems, friction losses and thermal management, advanced combustion modes and reduction of emissions, alternative fuels, and hybrids. We end with a brief comparison with spark-ignition (SI) engines and with the conclusions.

2 TECHNOLOGY: THE STATE OF THE ART AND FUTURE TRENDS OF CI ENGINES

CI engine system design is a highly specialized technical field, which integrates the performance of various subsystems and properly matches them with optimization approaches to achieve precise and accurate system (Xin, 2011). It covers injection system design, thermodynamic cycle simulation and air system design, valvetrain system design, engine friction, brake performance, combustion, heat rejection and cooling, emissions, and electronic controls.

2.1 Fuel injection

Fuel injection affects heavily the process of mixture formation and combustion as well as the emission formation. Modern high speed direct injection (HSDI) CI engines are capable of reaching levels of performance and refinement that were implausible some years ago, mainly because of the availability of very advanced fuel-injection

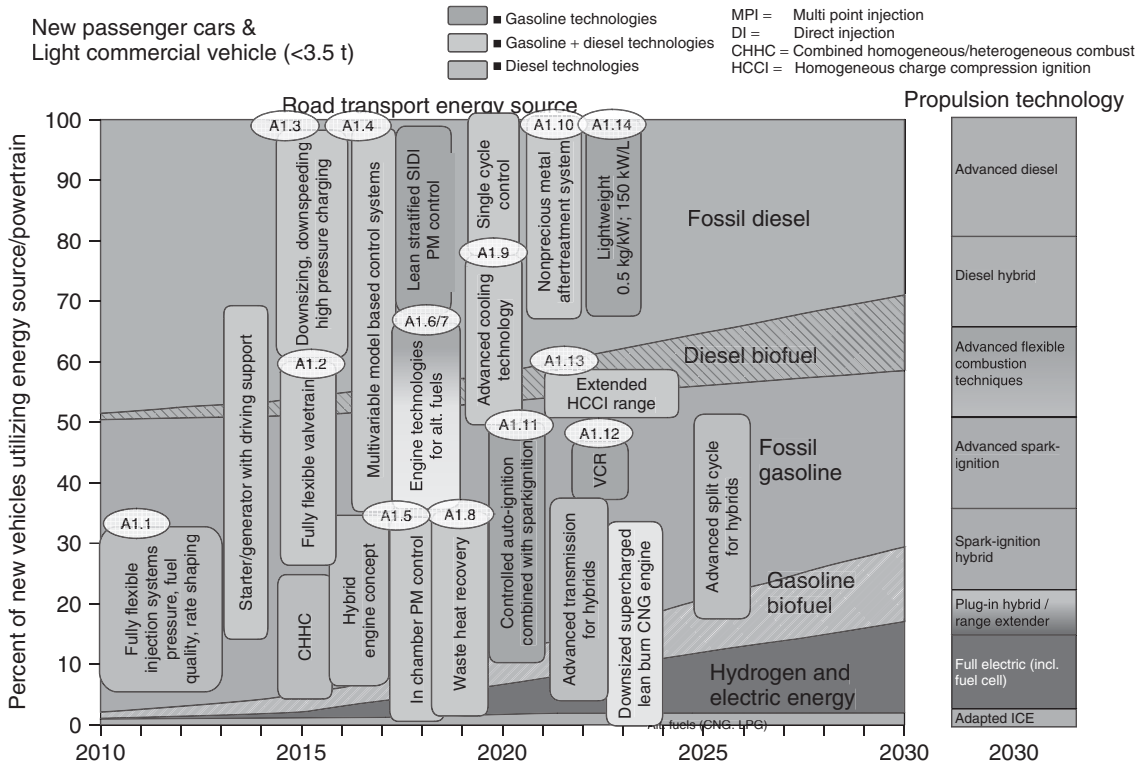

Figure 3. Technology trends and research needs for light-duty ICE powertrains to 2030. (Reproduced by permission of ERTRAC.)

technologies. In a high pressure common rail (HPCR) fuel injection system, pressure generation and fuel injection are separate events; the injection pressure is not dependent on engine speed, allowing thus highly flexible injection strategies at pressures above of 2000 bar and up to five injections per cycle per cylinder, allowing significant reductions in engine-out emissions, noise, and fuel consumption (Dober *et al*., 2008; Kimberley, 2005).

Modern FIE offers the possibility of performing multiple injections (Figure 4). In this case, the injection event consists of three parts, pre-, main, and postinjections. The multiplicity of injections gives the possibility for lower engine noise by reducing explosiveness and vibration and simultaneous reduction of particulate and nitrogen oxide (NO*x*) emissions by optimizing injection timing and quantity for variations in fuel quality, cold starting, and so on (Mittal *et al*., 2009; Baumgarten, 2006; Mahr, 2002).

The latest generation common-rail FIE incorporates piezoelectric-controlled injectors (Figure 5) that are capable of extremely rapid switching and as such the possibility of shorter injection durations, very small injection quantities, and multiple injections per cycle. The piezo element can be made to act directly on the nozzle needle without the need for an intermediate hydraulic system, unlike Figure 5,

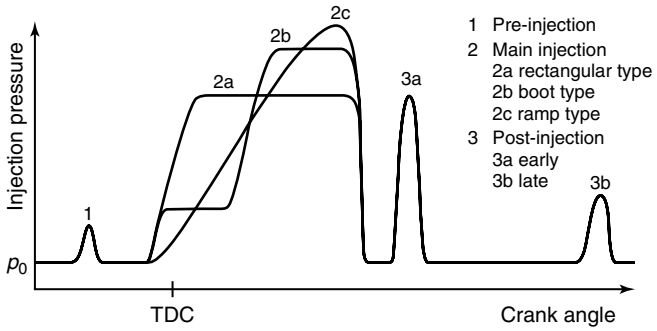

Figure 4. Schematic diagram of a multiple injection. (Reproduced from *Mixture Formation in Internal Combustion Engines*, 2006, G. Baumgarten. With kind permission of Springer Science+ Business Media.)

allowing more precise control of the degree and length of the time the injector is open. This allows the option of injection rate shaping as an alternative to the usual multiple injection method used so far, which places severe mechanical demands on the injection system. For the direct acting piezo design, the piezo actuator simultaneously acts as a sensor by reporting the precise position of the nozzle needle to the electronic control unit. The result is a self-contained

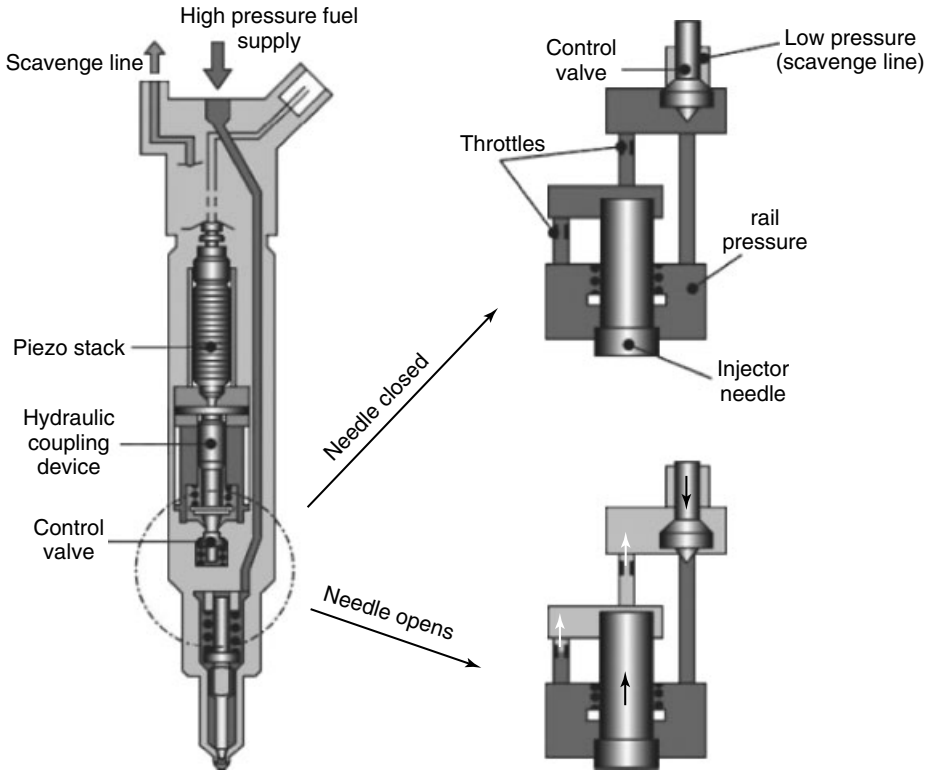

Figure 5. Piezo in-line injector from Bosch. (Reproduced from Mixture Formation in Internal Combustion Engines, 2006, G. Baumgarten. With kind permission of Springer Science+Business Media.)

flow rate control system; the control unit detects any variations in flow rate while the vehicle is being driven and individually adjusts each injector. This produces the best possible figures for NO_x emissions and fuel consumption. Improvements to the hydraulic design will optimize the performance of the already proven technology behind the millions of piezo common rail systems currently in use, enabling the fuel return flow to be reduced by 40%. This measure alone will reduce the CO_2 emissions from a typical diesel PC by 1 g/km. In addition, a fuel pump with a lower delivery rate is needed, which reduced costs still further.

In future, very flexible high pressure fuel injection systems with multiple injection and rate shaping capabilities as well as increased injection pressures, matching of the fuel spray by means of variable nozzle geometry and multihole nozzles and optimized control strategies are necessary in order to realize the optimum rate shaping and injection timing for each single point of the engine map and to get the best compromise between emission trade-off and fuel consumption. The more the injection pressure is increased, the more the efficiency of the injection system itself becomes important for achieving a low overall fuel consumption for an engine.

2.2 Turbocharging

The purpose of turbocharging has in the past been to increase the power-to-weight ratio of the engine. By increasing the amount of air available for the combustion process, more fuel can be burned effectively. Nowadays, the primary goal to use turbocharging for heavy-duty applications is still to raise the power-to-weight ratio; however, it is more and more used as a help to optimize the engine to obtain lower emissions in order to meet future emission legislation while maintaining or even improving fuel efficiency. Turbochargers and details of their performance and operation are discussed in detail in Intake Boosting. The turbocharger itself has become a mature product. Improvements on the turbomachine will, therefore, be rather incremental and the focus for development has turned more toward the turbocharger application. New complex systems to improve exhaust energy utilization over a wide engine operating range will be more frequently incorporated into the engine design such as variable geometry turbines (VGTs), multistage turbocharging, electric turbocompounding, or various additional mechanically driven compressors (Eichhorn, Boot, and Luijten,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto208
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2010; Brockbank, 2009; Plianos and Stobart, 2008; Knecht, 2008; Uchida, 2006; Hopmann and Algrain, 2003).

2.2.1 *Variable geometry turbines*

The VGT (Figure 6) is an effective approach to the turbocharger to engine matching problem. By varying the inlet turbine geometry, it is similar to having a finite range of turbine sizes in one unit. At low engine speeds, the VGT is kept closed to raise the pressure upstream the turbine, thus the isentropic energy from the exhaust increases. At high engine speeds, the inlet area is increased to avoid overboosting and high engine backpressure. The inlet area is mainly adjusted in two ways, by a sliding nozzle ring mechanism or by pivoting nozzle blades. The sliding nozzle ring mechanism keeps the nozzle blades fixed and changes the inlet area because of an axial movement of the sliding wall. By pivoting the nozzle blades, the area between the blades changes as well as the vane angle.

2.2.2 *Two-stage turbocharging*

Two-stage turbocharging (Figure 7) is an effective way of overcoming the limitations imposed on boost pressure by current compressor materials and to improve transient response. In a two-stage turbocharging system, an intercooler can be used between the compressor stages, which reduces inlet air temperature to the high pressure stage, thus it is possible to reach higher boost pressures with the standard impeller material. Increased air density also implies that a smaller compressor can be used and that less power is needed to reach the desired pressure raise. In a sequential turbocharger arrangement, two or several different sized turbochargers can be used where the flow can be switched, so that the best-suited turbocharger for that operational point is used. Sequential turbocharging can improve low end torque, response time, and/or operational range.

2.2.3 *Electric turbocompounding*

A further development is the use of turbochargers with electric motor/generators on the turbocharger shaft (Figure 8). This may offer (Knecht, 2008)

- increased boost pressure at low engine speeds where exhaust flow to drive the turbine is limited;
- maintained turbocharger speed during gearshifts;
- reduced turbocharger speed under high engine power conditions, using the electrical machine to apply a restraining torque to that exerted by the turbine;
- recovered exhaust energy using the electrical machine in generator mode, converting excess shaft power to electrical power.

2.3 Downsizing, downspeeding, and cylinder deactivation

Engine downsizing is the most important indirect fuel-economy measure in the powertrain. Downsizing means the reduction of displacement—either by making the specific cylinder displacement smaller or by reducing the number of cylinders. Compared with the reference engine, the downsized engine has a smaller displacement, which reduces friction, moving mass, and thermal loss. The increased specific maximum power because of engine downsizing is made possible by the appropriate redesigning of the air system (turbocharger and intercooler), combustion chamber (piston and cylinder head), and FIE (high pressure pump, injector and nozzle, and sensors and actuators).

By downspeeding, the engine is operated at low speeds but with higher torque (same power produced). The speed change can be achieved by changes to the gear ratio. Recent research (Ostrowski *et al*., 2012; Narayanan, 2011) has shown that downspeeding proves to be efficient. The fuel economy improvement is a result of three main factors: reduction of friction, relative heat transfer, and increase of fuel conversion efficiency.

Cylinder deactivation (Flierl *et al*., 2012) is a method used to create a variable displacement engine that is able to supply the full power of a large engine under high load conditions as well as the fuel economy of a small engine for cruising. By deactivating half of the cylinders, the remaining active cylinders operate at twice the load that the engine would normally operate at if all cylinders were active. This reduces the pumping losses and improves fuel consumption. Engines with cylinder deactivation can be found in several vehicles under various trade names such as multiple displacement system (MDS) and active fuel management (AFM). To date, cylinder deactivation has been applied to V6, V8, and V12 engines.

Strongly interlinked with downsizing is engine lightweighting (ERTRAC, 2010). The latter, however,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto208
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

presents substantial challenges for ultrahigh power-to-weight ratios. The higher the specific power output of an engine will be, the more the demand for high cylinder pressure exists. This in turn requires very high strength for components such as the crankcase, connecting rod, piston, and bearings, which currently does not exist in conventional turbocharged engines. Cylinder pressures of around 200 bar require special designs which in turn increase weight. The challenge is to make a step-out improvement compared to today's engine. The use of exotic materials and very smart design layouts, which are considerably different from today, is inevitable. Lightweighting will be especially important in hybrid vehicles to offset additional battery weight.

2.4 Flexible engine systems

Although a significant number of engine valve-actuation systems including cam-based and camless mechanisms have been already introduced by several researchers and companies, only a few types of these systems (mainly cam based) have been actually employed on commercial vehicles because of the liability, durability, and cost issues. Despite the fact that cam-based valve systems offer more reliable and durable functionality, the camless valvetrains can vary valve lift and timings to a greater extent compared to the cam-based types (Zheng, 2007). Several systems that allow flexible control are being assessed: variable valve actuation (VVA), variable swirl systems (VSSs), and variable compression ratio (VCR).

VVA gives the opportunity to have specific lift profiles for every operating condition and thus gives greater efficiency and power across a wider range of engine speeds. Camless-based VVA strategies offer great adjustability of valve timing and lift. The drawback is that these systems are often complex and expensive and mainly used in laboratory settings. Several different approaches have been proposed including electromagnetic, electrohydraulic, and electropneumatic systems (Figures 9 and 10) (Heinzen, Gillella, and Sun, 2011; Turner *et al*., 2004; Tai and Tsao, 2002; Schechter and Levin, 1996). VSSs fulfill the need of CI combustion systems for variable swirl levels dependent on load and speed (Kawashima, Ogawa, and Tsuru, 1998). This is true for conventional fuel systems with load- and speed-dependent injection pressure, but also for advanced common rail systems where there is freedom to choose the most appropriate injection pressure almost independently from the operating conditions.

VCR was originally developed for SI applications; however, it seems promising for CI engines as well

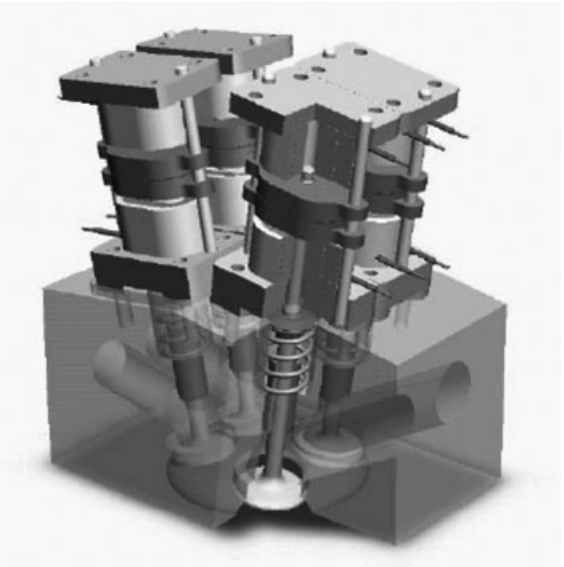

Figure 9. Electromagnetic fully flexible valve actuator. (Reproduced by permission of Engineering Matters, Inc.)

(Pesic, Milojevic, and Veinovic, 2010). A VCR engine is able to operate at different compression ratios, depending on the particular vehicle performance needs. The VCR engine is optimized for the full range of driving conditions, such as acceleration, speed, and load. At low power levels, the VCR engine operates at high compression to capture fuel efficiency benefits, whereas at high loads during turbocharging, its compression ratio is lower than that of a conventional engine, so that the temperature and pressure conditions remain at acceptable levels. One approach for realizing a VCR engine is with a variable combustion chamber volume enabled through a secondary piston in the cylinder head (e.g., Erlandsson *et al*., 1998). This design needs supercharging, because implementation becomes more difficult in engines with four valves per cylinder technology. Another possibility for the VCR engine is the repositioning of the cylinder or the cylinder head that has been put into practice by SAAB—Saab variable compression—SVC engine) (Bergsten, 2001). As an alternative to VCR, some approaches use late intake valve closing (LIVC) to further reduce the effective compression ratio (Patton, Manuel, and Gonlazez, 2010; Dec, 2009). LIVC has the advantage of allowing the effective compression ratio to be rapidly adjusted as part of the control system, while a high expansion ratio is preserved for good cycle efficiency.

VSS and VCR increase the engine complexity significantly and their cost/benefit is under investigation.

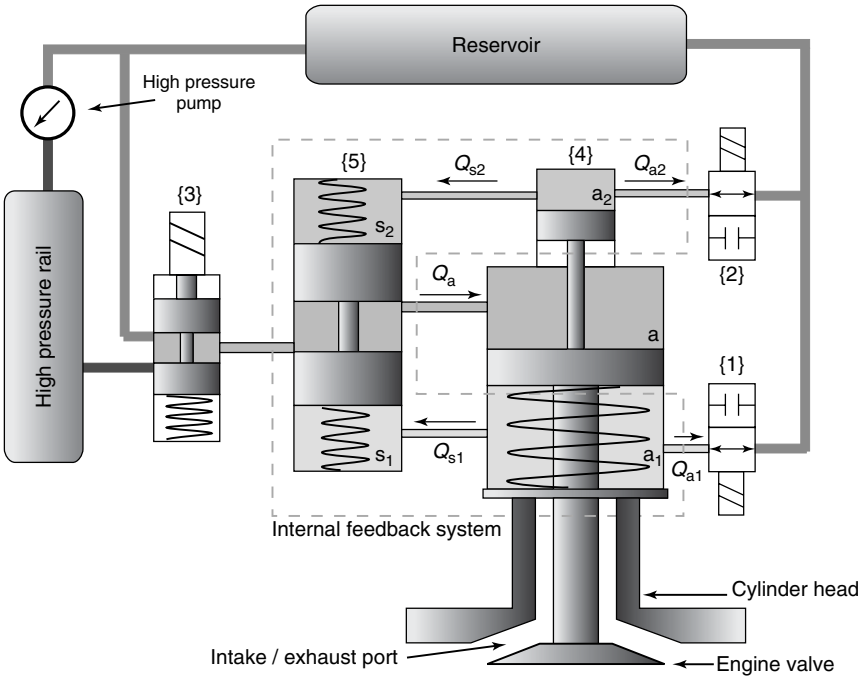

Figure 10. Electrohydraulic valve actuation system with internal feedback. (Reproduced from Heinzen, Gillella, and Sun, 2011. © Elsevier.)

2.5 Engine friction losses reduction

An area of interest to all engine developers is internal friction reduction. Insight into reduction of friction at part load (PC) or all loads (trucks) is increasing. Newer engines are showing a reduction of 40% in wall to piston ring friction by introducing new honing processes allowing the piston ring pretension to be reduced by 50%.

Losses in driving auxiliary systems are tackled by the introduction of variable cooling liquid and oil pumps that allow the precise balance between pump volume/pressure and engine condition to be controlled and thus not "waste" energy driving them. Better control of cooling liquid pumps also allows more advanced heat management. This allows the engine to warm up more quickly, which leads to a CO_2 emission reduction.

Current and future technologies needed to reduce friction and wear focus on (Automotive Technology Centre (ATC), 2011; Fenske *et al.*, 2009)

- development and application of mechanistic models of friction losses to predict parasitic losses as a function of engine and tribological conditions;
- evaluation/screening the potential of candidate surface treatments and additives to reduce boundary friction under lab conditions prototypical of engine environments;
- development of advanced surface treatments and additives that provide low friction and are robust, reliable, and durable;
- development of tools and theories to understand and model complex physical phenomena in tribological environments;
- development of advanced laser surface treatments;
- demonstrate efficiency improvements in multicylinder engines.

2.6 Thermal management

2.6.1 Advanced cooling and electric water pump

Advanced automotive thermal management systems can effectively maintain the desired temperature in internal combustion engines for enhanced performance (Figure 11). Automotive cooling systems can be upgraded to computer-controlled servo-motor actuated components rather than the conventional wax-based thermostat valve, mechanical water pump, and viscous clutch radiator fan (Chalgren and Barron, 2003). The latter action decouples the water pump and radiator fan from the engine crankshaft. Hence, the problem of having over/undercooling, due to the mechanical coupling, is solved, and parasitic losses reduced, which arose from operating mechanical components at high rotational speeds. The adjustment of thermal system operation

per driving condition can reduce fuel consumption, parasitic losses, and tailpipe emissions during transient and steady-state operation (Page, Hnatczuk, and Kozierowski, 2005; Chalgren and Barron, 2003).

Waste heat recovery systems (WHRSs) have been already used as possible solutions for improving the efficiency by converting the high amount of heat wasted in exhaust gases into usable mechanical or electrical energy. Different methods have been recommended, such as, thermoelectric, absorption refrigeration system, and organic Rankine cycle (ORC). In particular, the latter is often proposed as a very powerful means and it is extensively investigated by the automotive manufacturers (Edwards *et al.*, 2012). Various configurations have been presented for heat recovery using ORC. Some of them are simple, preheat, and regenerated Rankine cycles. The amount of recovered heat and, consequently, cycle output power for these configurations depend on their characteristics (Figure 12).

2.7 Advanced CI combustion modes

To achieve the needs of further emissions reduction, improved efficiency, and cost, significant research is currently being focused on alternative forms of CI combustion. Advanced combustion modes attempt with in-cylinder approaches to achieve high fuel efficiency and to either meet fully the emission standards, thus avoiding the need to use aftertreatment or, at the very least, lower the performance demands required from aftertreatment systems, thus reducing their cost and complexity (Jääskeläinen, 2010). These advanced combustion systems carry numerous names such as homogeneous charge compression ignition (HCCI) and premixed charge compression ignition (PCCI) that may or may not accurately reflect the combustion process. HCCI was one of the early CI combustion concepts to attract attention. As the name implies, the goal of early HCCI work was to achieve as homogeneous an air–fuel mixture as possible before ignition—much the same as in a conventional SI engine. This can be achieved by injecting fuel either in the intake port or directly in the cylinder and allowing sufficient time between injection and ignition to achieve complete mixing of air and fuel. The charge then autoignites, as it is heated by the compressed gases—no spark or other means of forced ignition is used. In order to address many of the challenges posed by HCCI such as limited load range, controllability, and knocking, a number of other concepts have evolved from this homogeneous charge approach; in many cases, charge stratification was introduced. As the term *HCCI* may no longer accurately describes many of these systems, the term *low temperature combustion* (*LTC*) can be used as a general term to refer to these and other advanced combustion concepts, because the primary goal is to lower combustion temperatures to advantageously alter the chemistry of NO_x formation while achieving air–fuel mixture conditions that also avoid soot formation.

As stated earlier, the underlying objective of LTC is to keep in-cylinder temperatures low (less than approximately 1900 K) through volumetric energy release via autoignition of dilute air–fuel mixtures, as opposed to the high temperatures created by, for example, flame propagation through stoichiometric mixtures in conventional SI engines (Foster,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

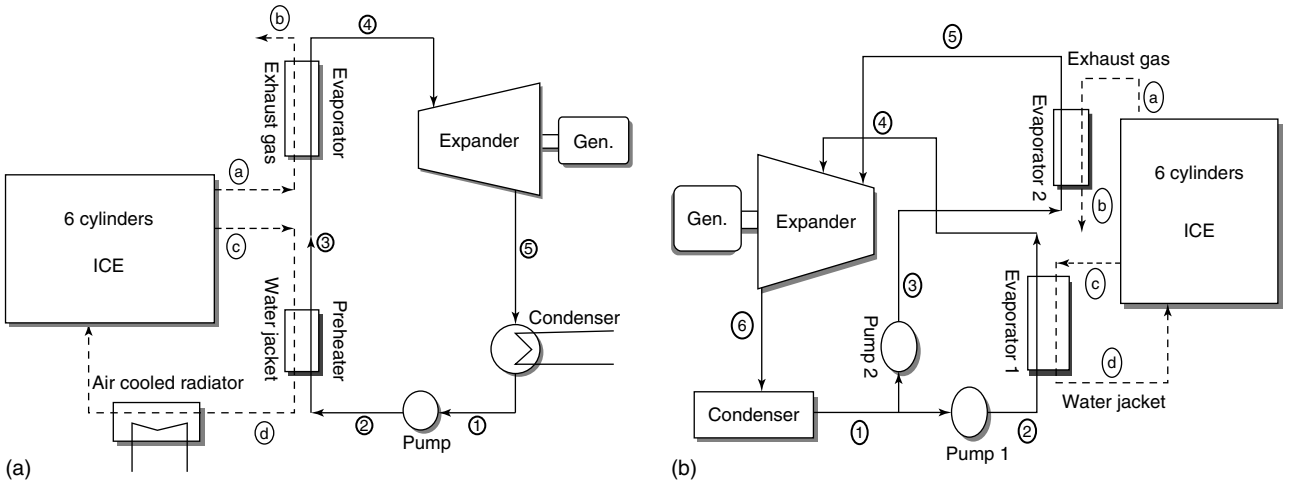

Figure 12. Configurations of Rankine cycle for waste heat recovery: preheat (a) and two stage (b). In the first one, a preheater was used for waste heat recovery from the coolant. The working fluid was preheated in this heat exchanger then entered the evaporator and was converted to saturated vapor by absorbing heat from the exhaust gas. After that, it entered the expander and generated mechanical power by expanding. Owing to working fluid mass flow rate limitation, this configuration is unable to absorb the total heat released by the coolant. Thus, an air-cooled heat exchanger should be used to reduce the temperature of the coolant before returning to the engine. In the second one, the working fluid flows in two different stages with different pressures after leaving the condenser. Low pressure stage relates to heat recovery from the coolant and the other stage relates to heat recovery from exhaust gas. Using this configuration, the total wasted heat of the coolant can be recovered and there is no need for an air-cooled heat exchanger. (Reproduced by permission of THERMAL SCIENCE, International scientific journal, ISSN 2334-7163.)

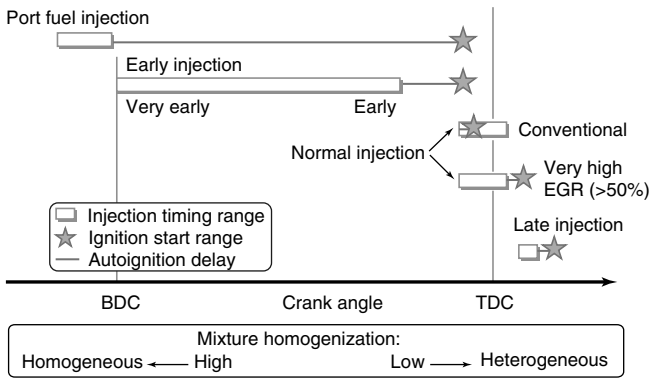

Figure 13. Classification of low temperature combustion strategies. (Reproduced with permission from Dieselnet, 2013. Source: Dieselnet.com © Ecopoint Inc., 2013.)

2012). LTC utilizes high levels of dilution (air or EGR) combined with flexible fuel injection strategies and strongly turbulent in-cylinder conditions to create conditions for reducing overall temperatures to levels below the critical temperature for NO*x* formation, and at the same time, air–fuel mixture conditions for reducing smoke formation. LTC strategies can be classified as (i) port mixing, (ii) early direct injection, and (iii) late direct injection. Some classification further breaks down the late injection systems into those that use "conventional" injection timing just before TDC and those with injection occurring after TDC. These strategies are summarized graphically in Figure 13. LTC has already demonstrated a significant potential to reduce PM and NO*x* emissions at part-load operation without major increase of fuel consumption and/or combustion noise excitation. However, an increase in hydrocarbons (HCs) and carbon monoxide (CO) emissions has been observed (Dec, 2009). Further, at higher loads, and especially at full load, it is challenging to achieve low temperatures. One approach to achieve high loads requires the development of new control strategies for transitioning between the LTC modes and a more conventional combustion mode at higher loads, such as SI. This approach will require conventional aftertreatment at high load and introduces the challenge of making the combustion mode transitions completely transparent to vehicle driver (Schulte and Wirth, 2010). Another approach to high loads that is emerging is the use of elevated levels of turbocharging with LTC. This approach does not require a combustion mode change but does drive the need for boosting/air-handling/EGR systems that effectively provide the right combination of the boost pressure and EGR rate under all load and speed conditions. Note also that because LTC depends on autoignition, the methods used to achieve it are dependent on the autoignition characteristics of the fuel being used. The various advanced CI combustion modes are discussed in more detail in Diesel and Diesel LTC

Combustion and Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot.

2.8 Reduction of emissions

The major challenge for the CI engine is meeting the tough near-future emission targets. For example, Euro VI standards for PCs are 0.08 g/km for NO*x*, 0.005 g/km for particle mass (PM), and 6×10^{11} particles/km for particle number (PN), and Euro VI standards for heavy-duty vehicles (HDVs) are 0.4 g/kWh for NO*x* and 0.01 g/kWh for PM (Dieselnet, 2012) at affordable cost, while further improving, or at least maintaining the diesel typical fuel economy advantages.

In contrast with SI engines, there is not just one key technology (such as the three-way catalyst for gasoline engines) that would provide sufficient potential to achieve these future standards. To overcome the inherent PM–NO_x trade-off, an integrated system approach is required. It includes two main areas:

- combustion system developments to reduce engine-out emissions;
- emission control technologies using exhaust gas aftertreatment.

2.8.1 *Combustion system developments*

These involve achieving highly premixed combustion and LTC in the directions already discussed in a previous section. Engines that utilize the conventional combustion mode at higher loads and LTC mode at moderate to light loads (mixed mode) are being investigated. Mixed mode operation combines the high efficiency, high load capabilities of conventional mode with the high efficiency, low emission capabilities of LTC mode to overcome deficiencies of aftertreatment system at low loads while dealing with the limited operating range of LTC.

Along with these developments, robustness control will become a critical issue (Galindo *et al*., 2011). For this reason, control system developments will be essential. This is likely to be achieved through a combination of new sensor technologies and improved processing capabilities. New sensors will provide direct feedback indicating combustion characteristics to the control system and, when coupled with model-based control of the air and EGR systems, will enable adaptive control of the engine variables. Such systems also provide improved onboard diagnostic (OBD) capability. This technology is at an early stage and further developments are required. Advances in model-based control will be an essential enabler for low NO*x* strategies, which operate much closer to engine combustion limits.

2.8.2 *Emission control technologies*

The exhaust emission standards for new cars have effectively required fitment of a diesel particulate filter (DPF) in the exhaust of PCs since 2009, when the Euro V standard came into force. Further, DPFs are expected to be necessary to meet the HDV Euro VI standard. DPFs usually remove 99% of the particles (Johnson, 2008). Details of PM control technologies are discussed in Solid/Condensed Phase Aftertreatment Systems.

Exhaust gas aftertreatment is one way to avoid the target conflict between NO*x* emissions and fuel consumption. Euro IV legislation launched the introduction of selective catalytic reduction (SCR) for NO*x* control by the majority of European HDV manufacturers. An alternative to SCR is an adsorber catalyst (lean NO*x* trap—LNT), which adsorbs NO*x* in "lean" exhaust gas conditions and desorbs it in short periods with "rich" exhaust gas (Johnson, 2008). Figure 14 gives an overview of emission reduction technologies for heavy-duty applications in Europe and the United States. Details of NO*x* and other gas phase emission control technologies are discussed in auto130.

While DPF (as well as diesel oxidation catalysts—DOCs) can be considered state of the art and an integral part of the CI engine, similarly to direct injection and turbocharging, this does not apply to NO*x* reduction catalysis. The development of LNT and SCR systems has not yet been successfully completed for light-duty diesel engines. SCR technology is much more mature, has a higher NO*x* reduction potential because of its wider temperature window with high conversion rates, and is less dependent on precious metal usage. The major SCR disadvantages result from the current need for onboard storage of the reductant, currently an aqueous urea solution, and the infrastructure, which is needed for the urea supply. In general, it is desirable to exploit possible synergies in the exhaust line. Typical examples of such synergies are the DOC/DPF CRT system, the "passive" LNT/SCR system, and the integration of DOC and/or deNO*x* functionality inside the DPF (Koltsakis *et al*., 2007, 2012). Figure 15 shows the structure of an advanced exhaust aftertreatment system and Figure 16 a model-based comparison of DeNO*x* performance of different exhaust system layouts. Advanced coating technologies employing multiple zones or layers may further contribute to the clever design of such systems. Designing and evaluating advanced multifunctional systems requires good understanding of the complex underlying phenomena and requires much effort, time, and experimental work, rendering the use

of advanced simulation tools a necessity. Improved SCR technology with improved reduction agents can reduce the cost of NO*x* aftertreatment systems. Nonprecious metal aftertreatment systems are the hope for future cost and resource savings. However, the pollutant transformation efficiency still needs intensive research work.

An important issue and challenge that arises from the applications described earlier is the increased fraction of NO_2 in the total tailpipe NO*x* emissions that are forecast to be measured at roadside. Bearing in mind the upcoming tightening of the NO_2 air quality limits and the steady increase of traffic volumes, excesses of the NO_2 limits have to be expected to an increasing extent during this decade.

2.9 Alternative fuels

Fuel robustness is a key for the future development of the engine system. Because of the unique, inherent energy efficiency and operating characteristics of the CI engine, diesel is well positioned as the fuel of choice. Introduction

of ultralow sulfur diesel fuels has been a central part of the new clean diesel system designed to meet present and future emissions standards. In Europe, fuel sulfur levels were reduced by 97% from 2000 (300 ppm) to 2009 (8 ppm).

Renewable fuels represent an opportunity to diversify fuels available for CI engines and reduce demand for conventional petroleum-based diesel fuel. CI engines are uniquely capable of operating on a range of renewable fuel feed stocks (algae, biomass, soy-based biodiesel, palm oil, and so on). Most new and existing diesel vehicles and equipment are compatible with biodiesel or renewable diesel fuel blends at ratios ranging from 5% to 20% depending on manufacturer warranties.

Owing to the increasing pressure of rising oil price, decreasing fossil reserves, and the imperative to minimize CO_2 emissions, future fuels will be characterized by the addition of or the substitution by synthetic components (International Energy Agency (IEA), 2010; European Commission (EC), 2006). Contrary to fuels distilled from crude oil, synthetic fuel offers the possibility to be tailored. Parameters relevant for engine combustion can be swayed with purpose, aiming toward lower emissions while optimizing the combustion in terms of efficiency and noise. Synthetic fuels such as gas-to-liquid (GTL), coal-to-liquid (CTL), and biomass-to-liquid (BTL) can be used directly in current engines, as their characteristics are even more favorable than today's diesel fuel. The development of process technologies for synthetic diesel, such as Fischer–Tropsch (FT) and hydrogenation of vegetable oils (HVOs) and of animal fats, enables a wider panel of combustion approaches; thanks to the specific fuel properties of these blend components, especially higher cetane number and low aromatics content. It should be noted, however, that with the increasing share of alternative fuels and vehicles, fuel supply chains diversify and emissions tend to occur further upstream; hence, the responsibility of car manufacturers should shift to maximizing tank-to-wheel efficiency. In addition, as well-to-tank emissions become increasingly relevant with alternative fuels, the capability to reduce emissions and hence responsibility shifts from car manufacturers to fuel and energy suppliers—including refineries and utilities—and these actors are accountable for the carbon content of their respective fuels. All the above need to be done in an efficient, cost-effective, and

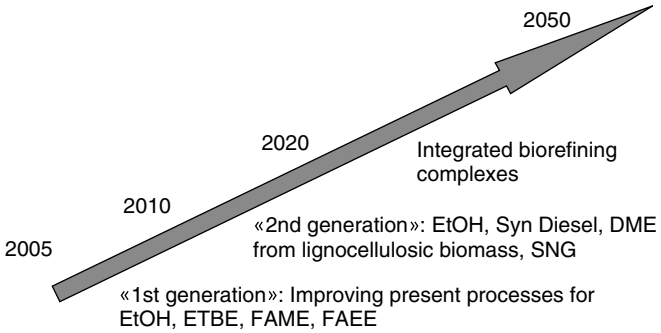

Figure 17. European Union's anticipated future roadmap. (Reproduced from EC, 2006 © European Communities.)

appropriate manner, such that instruments correspond to proper actors and set suitable incentives. Flexible and comprehensive solutions to regulate all GHG emissions and provide a level playing field across all fuels and technologies are currently being discussed.

Figure 17 shows the European Union's anticipated future roadmap for fuels. Also see Fuels for Engines and the Impact of Fuel Composition on Engine Performance for more extensive discussion on the characteristics of conventional and alternative fuels.

2.10 Hybrids

It is well understood that major reductions in GHG emissions in light-duty vehicle transportation sector are required to achieve significant reduction of the total GHG emissions in the mid-term future (Sandy Thomas, 2012; McKinsey & Company, 2007). The alternative vehicle options considered in this framework include hybrid electric vehicles (HEVs) and plug-in hybrid electric vehicles (PHEVs). By combining an internal combustion engine and an electric motor, HEVs have attracted increasing interest by the automotive industry. They are considered in the short term as the most viable alternative propulsion system for significantly improving fuel efficiency and emissions without sacrificing traditional vehicle performance criteria.

CI HEVs and PHEVs are not as common as SI HEVs, which are the mainstream choice. This is due to pollutant legislation issues (in the United States and Japan) and to cost advantages of advanced CI vehicles in Europe (Berggren *et al*., 2009), as well as due to construction nonlinearities. Some manufacturers in the European Union, however, do offer CI HEVS and PHEVs options (Volkswagen Golf TDI, Mercedes-Benz E-Class E300 BlueTEC, Peugeot 3008 Crossover HYbrid4, and Volvo V60 plug) and seem to be more interested in the long term, considering the concept as the very best of what an electric and diesel car can offer: very low fuel consumption and CO_2 levels, combined with long range and high performance.

2.11 Comparison to future SI engines

The development of both SI and CI engines is driven by meeting emission legislation while at the same time maintaining or even improving the efficiency of the CI engine. In spite of specific technical bottlenecks, advanced CI technologies offer better fuel economy over conventional SI technology under all driving conditions, and with no detriment to performance. Besides fuel economy and lower CO_2 emissions, advantages of CI engine include improved performance and towing, and high torque at low engine speed giving "fun-to-drive" characteristics. However, competing developments of advanced SI technologies are likely to erode diesel advantages.

SI engines despite their present drawbacks with respect to their diesel counterpart still offer two fundamental advantages:

- a robust and low cost emission control technology;
- an intrinsic cost advantage.

During the coming decade, the SI engine technology will be the major contributor to the CO_2 emissions reduction of the European vehicle fleet through

- downsizing by means of turbocharging and efficiency improvement by means of electronic valve control and DI of fuel (the feasible reduction in cylinder displacement is up to 40%, with a corresponding benefit in fuel consumption and CO_2 emissions of up to 20%);
- the progressive exploitation of their intrinsic capability to burn low carbon content fuels ranging from natural gas to hydrogen (if energy policy promotes these fuels into the marketplace, SI systems tailored to these fuels will emerge).

Regarding customer expectations, trends are very similar for CI and SI engines, especially in the volume segments and markets. Customers are focused on total cost of ownership, which is determined by such factors as price, resale value, fuel consumption (and fuel price), and maintenance cost, as well as safety, reliability, and durability. In current and future CI engines, there is almost a chemical factory on board and that comes at a price. At the same time, customer expectations regarding "fun to drive" are still increasing. This translates into a continuation of the "power and torque race" to further improve vehicle performance and drivability.

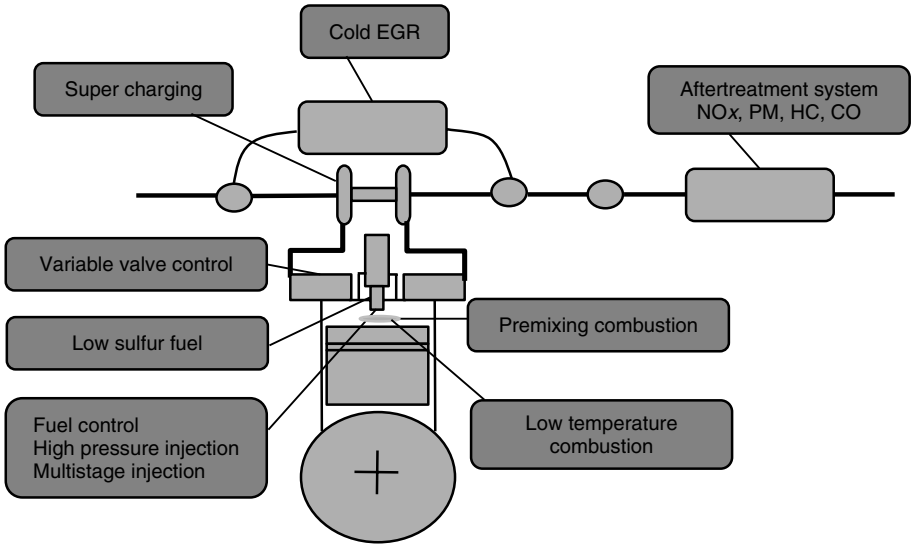

Figure 18. Advanced technologies in CI engine.

Last but not least, possible constraints in regional diesel fuel supply may also brake further expansion of the diesel market. There is indeed a limit as to how far the refinery fraction for diesel can be pushed, and Europe is already a net importer of diesel (and a gasoline exporter to the United States). If the United States begins to drive more CI vehicles, then the shortage of diesel in Europe will become even greater. As a large proportion of the diesel fuel is used by trucking to transport goods that are essential for society, it may well happen that the use of diesel for private motor cars will decline in the future (Lindstedt, 2012).

This growing imbalance in the diesel/gasoline demand ratio, particularly in Europe, initiates the need of additional out-of-the-box options. Research results generally indicate that a special fuel is not needed for advanced combustion CI engines and that future, but still practical hardware, will enable engines to be quite tolerant of a range of fuel properties (e.g., Rose *et al*., 2010). This indicates that multifuel concepts are increasingly necessary, including gasoline-in-CI concepts (Weall and Collings, 2009; Manente *et al*., 2009). Recent practical developments (such as the Mazda Skyactiv system) may be considered as stepping stones in this direction.

3 SUMMARY AND CONCLUSIONS

CI engine has made an outstanding development in Europe by giving the customer at the same time better fuel economy and more driving pleasure. From the society viewpoint, it has provided significant oil savings and CO_2 emission reduction and it has complied with even more stringent emission regulations. This evolution has been supported by a sustained technological improvement.

There are many advanced technologies for high performance engines (most of these are summarized in Figure 18). There are two ways to proceed: optimization and robustness. Flexible FIE, optimized turbocharging, variable geometry engine, reduction of engine friction losses, optimized thermal management, highly premixed and lower temperature combustion, and advanced and high sulfur resistance aftertreatment systems are candidates for the development of a highly efficient and robust CI engine, with near-zero emissions. In the next 20 years, technology innovations such as LTC are expected to play a role in the advancement of CI engines.

Increasing environmental awareness and oil supply tension put CI engines in a challenged position. On the one hand, fuel price increase and developments presented in this chapter can be considered as opportunities. However, on the other hand, diesel fuel shortage and future stringent emission regulations could make cost to customer benefit balance less favorable.

ACKNOWLEDGMENTS

We are indebted to Professor David Foster (University of Wisconsin—Madison) and Dr. Dennis Siebers (Sandia National Laboratories) for their careful and extensive review of our paper. Their corrections, comments, and suggestions for both the literary and scientific parts of our work (with emphasis on the part on LTC) were extremely useful for the overall improvement of our manuscript.

Induction Motor Drives

Ming Cheng[1], Zheng Wang[1], and Yuk Sum Wong[2]

[1] *Southeast University, Nanjing, China*
[2] *State Grid Energy Research Institute, Beijing, China*

1 INTRODUCTION

An induction (or asynchronous motor) is a commutatorless AC motor in which all electromagnetic energy is transferred by inductive coupling from a primary winding to a secondary winding, the two windings being separated by an air gap. The history of construction and application of induction motors (IMs) in electric drive dates back as far as over 100 years. At present, IM drives are the most mature technology among various commutatorless motor drives. The IM drives offer the advantages of robust structure, low cost, high reliability, and being free from maintenance as compared with the other types of electric motor drives. These advantages are particularly important for electric propulsion in electric vehicle (EV) applications. Hence, IM drives are popular choices for traction applications. However, as compared with permanent magnet (PM) motors, IMs have lower efficiency and less torque density.

There are two types of IMs, namely, wound-rotor and squirrel-cage motors. Owing to the high cost, need for maintenance, and lack of sturdiness, wound-rotor IMs are less attractive than their squirrel-cage counterparts, especially for electric propulsion in EVs. Hence, squirrel-cage IMs are loosely named as IMs.

An inverter is used to convert the energy from the batteries to the motor so that the desired torque can be delivered for a given driving condition at a certain speed. Advanced control methodologies, such as vector control and direct torque control (DTC), are popular in IM drives for electric propulsion applications.

IMs used for electric propulsion are principally similar to that used for other industrial applications. Nevertheless, these IMs should be specially designed with reference to the requirements of electrical drivetrain in EVs. Laminated thin silicon cores should be used for the rotor and stator to reduce the iron loss, whereas copper bars are preferred for the squirrel cage to reduce the winding loss. Reasonable high voltage low current motor design should be employed to reduce the cost and size of the power inverter, although the voltage level of the motor is limited by the number, weight, and type of EV batteries. High speed operation should be adopted to minimize the motor size and weight, although the maximum speed of the motor is limited by the bearing friction and windage losses. Low stray reactance is also necessary to favor flux-weakening operation. Concerning motor performances for EV operation, high torque at low speeds, low torque at high speeds, and instantaneous overloading capability are desired for hill climbing, highway cruising, and vehicle overtaking, respectively (Chan and Chau, 2001). The key differences between

Table 1. Key differences between EV IMs and standard industrial IMs.

Items	EV IMs	Industrial IMs
Ambient temperature (°C)	−40–+125	−20–+40
Coolant temperature (°C)	75–150	<40
Mounting base	Mobile	Stationary
Protection	Salt, spray, explosive	No special
Acceleceration/ decceration	Frequent	Most stable
Motor size and mass	Tight limited	Relaxed
System voltage	Isolated and varied	Stable network
Acoustic noise level	Very low	Low
Speed range (rpm)	0–15,000 or higher	<3600

Data taken from "Electric Machine Systems for Powertrains of New Energy Vehicles" presented in the 2nd China International New Energy Vehicle Forum 2013 by Dr. William CAI.

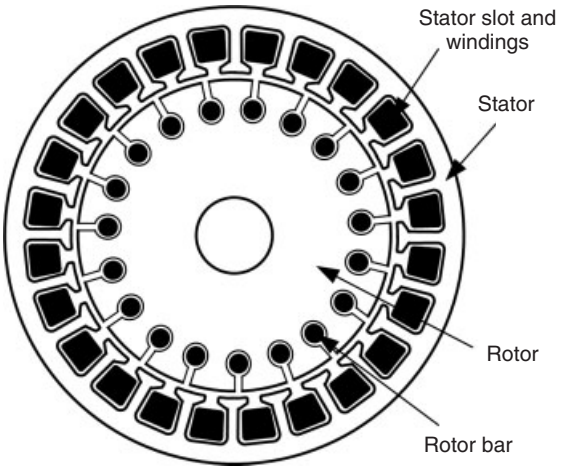

Figure 1. Cross section of an induction motor.

EV traction IMs and standard industrial IMs can be summarized as shown in Table 1.

2 STRUCTURE AND OPERATION PRINCIPLE

2.1 Structure

A cross section of an IM is shown in Figure 1. An IM is basically composed of two main parts, namely the stator and the rotor, between which there is a uniform air gap. Both the stator and the rotor are made of laminated silicon steel with thickness of 0.35, 0.5, or 0.65 mm. The laminated steel sheets are first stamped with slots and are then stacked together to form the stator and the rotor, respectively.

There are some additional components to make up the whole machine: the housing that encloses and supports the whole machine, the shaft that transfers torque, the bearing, an optional position sensor, and a cooling mechanism (such as a fan or liquid cooling tubes) (Mi, Masrur, and Gao, 2011).

It should be emphasized that the robust mechanical design and reduction of noise and vibration are indispensable for a traction motor because exposure to temperature change and external impact can result in mechanical fatigue on motor structure, and abnormal sound and movement of motor during driving can make people uncomfortable. In addition, it is required that a traction motor be of a compact size owing to the limitation in the installation space.

As shown in Figure 1, slots in the inner periphery of the stator are inserted with three-phase windings. The turns of each winding are distributed such that the current in the winding produces an approximately sinusoidally distributed flux density around the periphery of the air gap. The three-stator windings are displaced from each other by 120 electrical degrees in space around the air gap.

Figure 2. Rotor squirrel cage of an induction motor.

The most common types of IM rotors are the squirrel-cage rotors in which aluminum bars are cast into slots in the outer periphery of the rotor. The aluminum bars are short-circuited together at both ends of the rotor by cast aluminum end rings, which can also be shaped as fans (Ehsani, Gao, and Emadi, 2009). Figure 2 shows a rotor squirrel cage.

2.2 Operation principle

Figure 3a shows a simplified two-pole three-phase IM. The concentrated full-pitch coils, displaced from each other by 120° in space, are shown by coils a–x, b–y, and c–z, which may be considered to represent distributed windings producing sinusoidal magnetomotive force (MMF) waves on the magnetic axes of the respective phases.

The three-phase windings are excited by three-phase AC sinusoidal current as

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

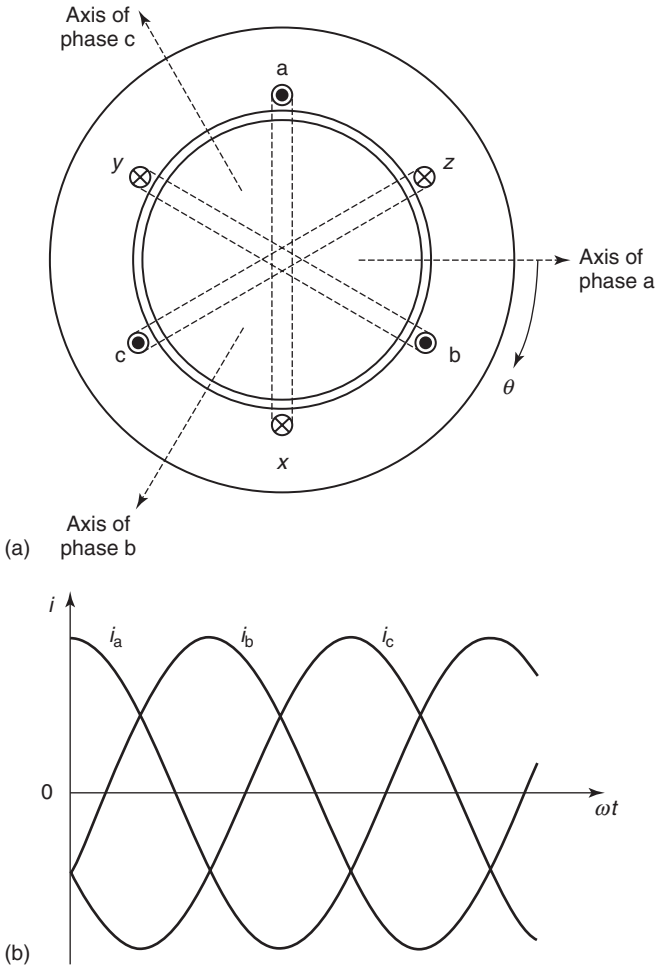

Figure 3. Simplified two-pole three-phase stator winding current: (a) spatially symmetric three-phase stator windings; (b) phase currents.

$$\left.\begin{aligned} i_a &= I_m \cos(\omega t) \\ i_b &= I_m \cos(\omega t - 120^\circ) \\ i_c &= I_m \cos(\omega t + 120^\circ) \end{aligned}\right\} \quad (1)$$

where I_m is the amplitude of the phase currents and ω the angular frequency of the current. The instantaneous currents are shown in Figure 3b. Each of the three-phase currents will generate an MMF, which is a space vector. As the three windings are located 120° from each other in space along the inside surface of the stator, the MMF generated by each phase can be written as follows:

$$\left.\begin{aligned} f_a &= F_{m1} \cos(\omega t) \cos(\theta) \\ f_b &= F_{m1} \cos(\omega t - 120^\circ) \cos(\theta - 120^\circ) \\ f_c &= F_{m1} \cos(\omega t + 120^\circ) \cos(\theta + 120^\circ) \end{aligned}\right\} \quad (2)$$

where $F_{m1} = \frac{2}{\pi}\frac{wk_{w1}}{p} I_m$ is the amplitude of the space-fundamental MMF of each phase, θ the spatial angle measured with respect to the rotor magnetic axis, w the turn number of phase winding in series, k_{w1} the fundamental winding factor, and p the number of pole pairs. Use of a common trigonometric identify permits Equation 2 to be rewritten in the form

$$\left.\begin{aligned} f_a &= \frac{1}{2}F_{m1}\cos(\omega t - \theta) - \frac{1}{2}F_{m1}\cos(\omega t + \theta) \\ f_b &= \frac{1}{2}F_{m1}\cos(\omega t - \theta) - \frac{1}{2}F_{m1}\cos(\omega t + \theta + 120^\circ) \\ f_c &= \frac{1}{2}F_{m1}\cos(\omega t - \theta) - \frac{1}{2}F_{m1}\cos(\omega t + \theta - 120^\circ) \end{aligned}\right\} \quad (3)$$

The three MMFs can be summed to form

$$f = f_a + f_b + f_c = \frac{3}{2}F_{m1}\cos(\omega t - \theta) \quad (4)$$

Equation 4 indicates that the magnetic field is rotating along the inner surface of the stator with the frequency of the angle velocity ω, and its magnitude is $3/2F_{m1}$.

Figure 4 graphically shows the stator MMF vectors at $\omega t = 0$, $\omega t = \pi/3$, and $\omega t = 2\pi/3$. At the moment $\omega t = 0$, the current i_a is at its maximum value I_m, and i_b and i_c are both $I_m/2$ in the negative direction, as shown by the dots and crosses in Figure 4, indicating the actual instantaneous directions. The corresponding MMFs are shown by the vectors F_a, F_b, and F_c, respectively, where $F_a = F_{m1}$ drawn along the magnetic axis of phase a, whereas F_b and F_c are both of magnitude $F_{m1}/2$ drawn in the negative direction along the magnetic axes of phase b and phase c, respectively. The resultant, obtained by adding the individual contributions of the three phases, is a vector of magnitude $F = \frac{3}{2}F_{m1}$ centered on the axis of phase a. It represents a sinusoidal space wave with its positive peak centered on the axis of phase a and having an amplitude 1.5 times that of phase a contribution alone. At a later moment $\omega t = \pi/3$, the currents i_a and i_b are a positive half maximum, and the current i_c is a negative maximum. The resultant MMF vector has the same amplitude as at $\omega t = 0$, but it has rotated clockwise by 60 electrical degrees in space. Similarly, at $\omega t = 2\pi/3$, the current i_b is a positive maximum, and i_a and i_c are a negative half maximum; the same resultant MMF vector is again obtained, but it has rotated clockwise by 60 electrical degrees still further and is now aligned with the magnetic axis of phase b. Obviously, as time passes, the resultant MMF wave retains its sinusoidal form and amplitude, but rotates progressively along the air gap. Thus, the net result is an MMF wave of constant amplitude rotating at a uniform angular velocity (Fitzgerald, Kingsley, and Umans, 2003).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

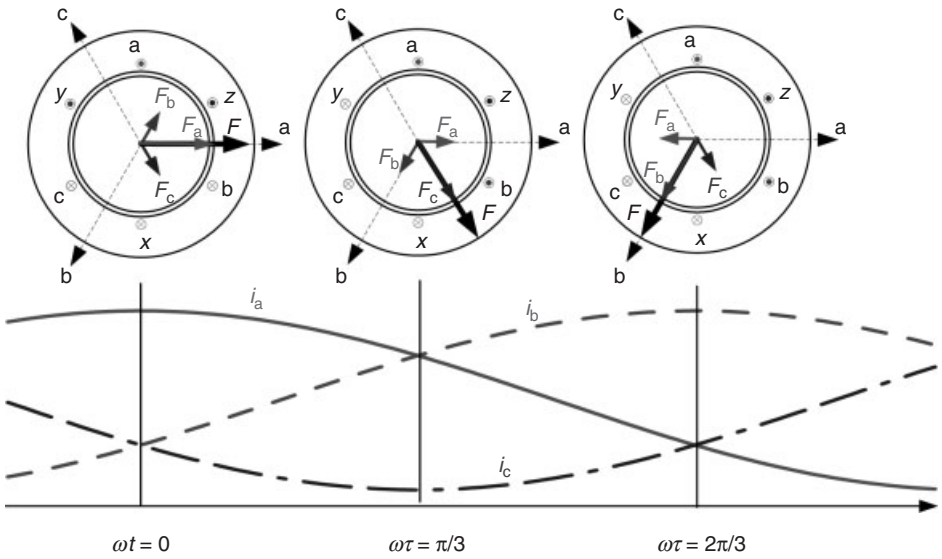

Figure 4. Rotating magnetic field produced by three-phase currents.

As $\omega = 2\pi f$, the rotating speed of the field will be the same as the supply frequency: f revolutions per second or $n_s = 60f$ revolutions per minute (rpm). Noting that the above derivation is based on one pair of poles, a more generic equation for the field speed (or synchronous speed) of an induction machine can be given as $n_s = \frac{60f}{p}$ and

$$\omega_s = \frac{2\pi n_s}{60} = \frac{\omega}{p} = \frac{2\pi f}{p} \tag{5}$$

If the rotor is turning at the steady-state speed of n rpm in the same direction as the rotating stator field, then the relative speed between the stator rotating field and the rotor is $n_s - n$. This difference between synchronous speed and the rotor speed is commonly referred to as *slip* of the rotor, which is more usually expressed as a fraction of synchronous speed

$$s = \frac{n_s - n}{n_s} \tag{6}$$

where s is slip. The rotor speed can be expressed in terms of the slip and the synchronous speed as

$$n = (1 - s)n_s \tag{7}$$

Assuming initially that the rotor is stationary, the rotating stator field will induce an electromotive force (EMF) inside the rotor bars of the squirrel cage. A current is therefore formed inside the rotor bars through the end rings. The reaction between the rotating stator MMF and the rotor currents will generate a torque on the rotor. If the torque is large enough, the rotor will start to rotate. The rotor accelerates until the magnitude of induced rotor current and torque balances the applied load. As rotation at synchronous speed does not result in any induced rotor current, an IM always operates slower than the synchronous speed. Typical slips of IMs are within 1–3% (Mi, Masrur, and Gao, 2011). When the load increases, the speed drops and the slip increases enough to create sufficient torque to turn the load, and vice versa. For this reason, IMs are sometimes referred to as *asynchronous motors*.

The essential character of an induction machine is that it is created solely by induction rather than being separately excited as in synchronous or DC machines or being self-magnetized as in PM motors.

An induction machine can be operated as an induction generator for regenerative braking in EV applications.

3 STEADY-STATE PERFORMANCE

3.1 Equivalent circuit

As the three phases are symmetrical, the equivalent circuit can be derived for one phase, with the understanding that the voltages and currents in the remaining phases can be found simply by phase shift of 120°. An IM is simply an electrical transformer in the magnetic circuit, in which the stator winding and the moving rotor winding are separated by an air gap and the transformer convention is used, as shown in Figure 5a. It is worth noting that the rotor and the stator quantities will have different frequencies except when the rotor is stationary.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

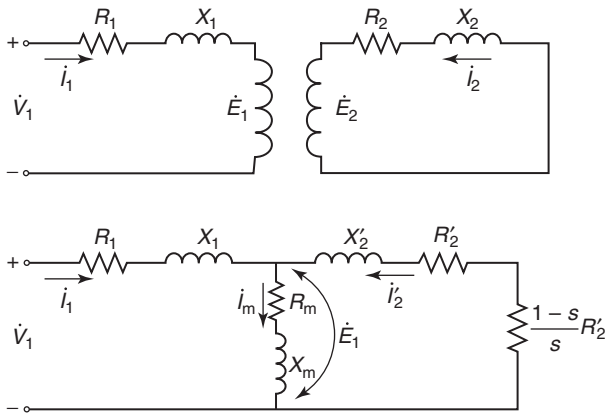

Figure 5. Equivalent circuit of an induction motor. (a) Stator and rotor circuits; (b) T-equivalent circuit.

The voltage equation of the stator and rotor circuit can be written as

$$\dot{V}_1 = \dot{I}_1 R_1 + jX_1\dot{I}_1 + \dot{E}_1$$
$$0 = \dot{I}_2 R_2 + jX_2\dot{I}_2 + \dot{E}_2 \tag{8}$$

where $\dot{V}_1$ is the stator phase voltage, $\dot{I}_1$ and $\dot{I}_2$ the stator and rotor currents, respectively, R_1 and R_2 the phase resistance of stator and rotor respectively, $X_1 = \omega_1 L_1$ and $X_2 = \omega_2 L_2$ the leakage reactance of stator and rotor respectively, and $\dot{E}_1$ and $\dot{E}_2$ phase EMF of stator and rotor respectively.

The circuit shown in Figure 5a is inconvenient for general use because of the presence of two frequencies, namely ω_1 in stator and $\omega_2 = s\omega_1$ in rotor. If both sides of the second equation in Equation 8 is multiplied by k and divided by s, it yields

$$0 = \left(k^2\frac{R_2}{s}\right)\frac{\dot{I}_2}{k} + j\left(k^2\frac{X_2}{s}\right)\frac{\dot{I}_2}{k} + \frac{k\dot{E}_2}{s} \tag{9}$$

By using the following, $R'_2 = k^2 R_2$, $X'_2 = k^2 X_2/s = k^2 s\omega_1 L_2/s = k^2\omega_1 L_2$, $I'_2 = X_2/k$, and $E'_2 = kE_2/s$, Equation 9 becomes

$$0 = \frac{\dot{I}'_2 R'_2}{s} + j\dot{I}'_2 X'_2 + \dot{E}'_2 = \dot{I}'_2\left(R'_2 + \frac{1-s}{s}R'_2\right) + j\dot{I}'_2 X' + \dot{E}'_2 \tag{10}$$

which suggests a single frequency equivalent circuit operating at stator frequency ω_1. By choosing k such that $\dot{E}_1 = \dot{E}'_2$, the equivalent circuit can be redrawn as shown in Figure 5b, where $\frac{1-s}{s}R'_2$ is the equivalent electromechanical power resistance representing the mechanical load, X_m the magnetizing reactance, and R_m the equivalent magnetizing loss resistance. The rotor primed variables are said to be referred to the stator side.

3.2 Torque characteristics

In the circuit shown in Figure 5b, for a given voltage supply, the current of the circuit can be derived as

$$\dot{I}_1 = \frac{\dot{V}_1}{R_1 + jX_1 + (R_m + jX_m)//(R'_2/s + jX'_2)} \tag{11}$$

To simplify the analysis, we can neglect $R_m + jX_m$. Under this assumption, $I_1 = I'_2$. Thus, the electromagnetic power transferred from the stator to the rotor is

$$P_{em} = mI_1^2\frac{R'_2}{s} = \frac{mV_1}{(R_1 + R'_2/s)^2 + (X_1 + X'_2)^2}\frac{R'_2}{2}$$
$$= \frac{mV_1^2}{(R_1 + R'_2/s)^2 + (X_1 + X'_2)^2}\left[R'_2 + \frac{1-s}{s}R'_2\right]$$
$$= p_{Cu2} + P_{mech} \tag{12}$$

where m is the number of phases. Note that electromagnetic power or rotor power can be divided into two parts: the first term p_{Cu2} is the rotor copper loss and the second term P_{mech} is the total mechanical power on the shaft. Thus, the electromagnetic torque of the motor can be written as

$$T_{em} = \frac{P_{mech}}{\omega_m} = \frac{m}{\omega_m}\frac{V_1^2}{(R_1 + R'_2/s)^2 + (X_1 + X'_2)^2}\frac{1-s}{s}R'_2 \tag{13}$$

where ω_m is the angular velocity of the rotor. Figure 6 shows the torque–slip characteristics of an IM with fixed voltage and frequency, in which the normal motoring region, the generating region, and the braking region are illustrated. In normal motor operation, the rotor revolves in the direction of rotation of the magnetic field produced by the stator currents, the speed is between zero and synchronous speed, and the corresponding slip is between 1.0 and 0. In the region of $0 < s < s_m$, where s_m is the slip corresponding to the maximum torque, the torque increases approximately linearly with the increase in slip until reaching its maximum at $s = s_m$, then it decreases with the further increase in the slip. At $s = 1$, the rotor speed is zero and the corresponding torque is the starting torque, which is less than its torque at $s = s_m$. In the region of $s > 1$, the rotor torque is positive and decreases further with the increase in slip, and the rotor speed is negative, according to Equation 7. Thus, in this region, the operation of the motor is reverse braking. The induction machine operates as a generator if its rotor is driven above synchronous speed, corresponding to the slip region of $s < 0$ or forward braking region. One such operation mode is that a vehicle goes

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

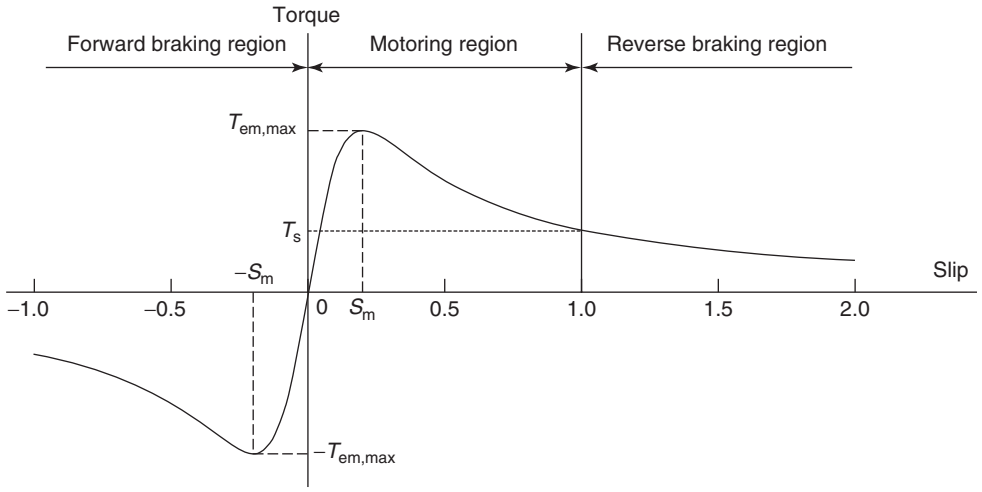

Figure 6. Torque–slip characteristic of induction motor with fixed stator voltage and frequency.

down a long slope and drives the induction machine speed higher than the synchronous speed.

Obviously, the torque–speed characteristic of an IM at fixed voltage and fixed frequency is not appropriate to vehicle traction applications because of the low starting torque, limited speed range, and unstable operation in the range of $s > s_m$, where any additional disturbing torque in the load will lead the machine to stop as the torque decreases with the speed decreasing characteristically. The high slip also results in high current, which may cause damage in the stator windings. Actually, the fixed voltage and frequency IM are usually operated in the narrow slip range of $0 < s < s_m$. Thus, for traction application, an IM must be controlled by an electronic inverter to provide proper torque–speed characteristics (Zhu and Howe, 2007).

3.3 Efficiency and losses

In the motor operation mode, the active power drawn from the supply can be expressed as

$$P_1 = mV_1I_1\cos\varphi_1 \tag{14}$$

where m is the phase number and φ_1 the phase angle between the stator voltage and the current. This power cannot be fully transmitted to the mechanical power on the shaft because of various losses in the IM. There are five types of losses in induction machine, namely,

(i) copper loss in the stator winding $p_{Cu1} = mI_1^2R_1$, which is the power dissipated as heat in the stator windings;

(ii) magnetizing loss in the stator iron (or core loss or iron loss) $p_C = mI_m^2R_m$, which is the power dissipated as heat in the stator core;

(iii) copper loss in the rotor winding $p_{Cu2} = mI'^2_2R'_2$, which is the power dissipated as heat in the rotor cage;

(iv) windage loss p_{fw} due to the rotation of the rotor and frictional loss in the bearing; and

(v) additional losses p_{ad}, which cannot be accounted for by the above components, also called *stray load loss*.

The power balance equations are

$$P_{em} = P_1 - p_{Cu1} - p_C \tag{15}$$

$$P_{mech} = P_{em} - p_{Cu2} \tag{16}$$

$$P_2 = P_{mech} - p_{fw} - p_{ad} \tag{17}$$

where P_2 is the output power to the load connected to the shaft. The power flow in an IM is shown in Figure 7. The

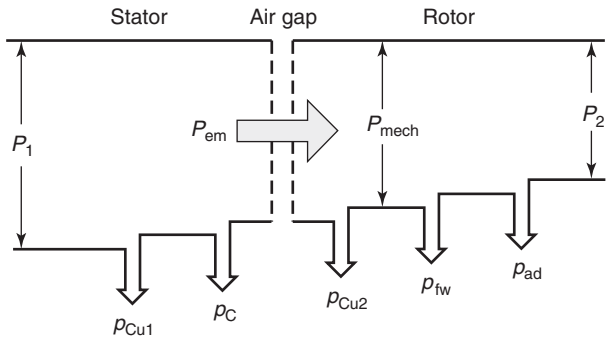

Figure 7. Power flow in an induction motor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

efficiency of an IM can be expressed as

$$\eta = \frac{P_2}{P_1} = \frac{P_2}{P_2 + p_{Cu1} + p_C + p_{Cu2} + p_{fw} + p_{ad}} \quad (18)$$

It should be noted that laminated silicon steel sheets were traditionally designed for use at low frequencies (50 or 60 Hz), and today's traction drives in modern HEV typically operate at about 6000–15,000 rpm. With four-pole machines, the operating frequency is 500 Hz. Some traction motors operate at frequencies as high as 800–1200 Hz. As eddy current loss and hysteresis loss are proportional to frequency or the square of frequency, the core loss will be significant at high frequencies. In order to keep the core loss within a reasonable range, the magnetic flux in the iron core has to be relatively lower than those used in low speed motors, and the thickness of the silicon steel sheets may have to be reduced as well.

Moreover, the IM used in vehicle traction applications is operated by inverter, which can result in harmonics in its voltage and current. These harmonics will introduce additional losses in the winding and iron core of stator and rotor. As is well known, the eddy current loss can be doubled in many IMs because of the pulse-width–modulation (PWM) supply. These additional losses may cause excessive temperature rise, which must be considered during the design and analysis of IMs (Mi, Masrur, and Gao, 2011).

In a word, more losses are generated in traction IMs than industrial IMs because of their high current density, increased harmonic components of current, and so on. This may cause insulation to become brittle and apply high mechanical stresses on the bars and end rings because of differential thermal expansion, if a motor is not properly cooled and operates above the threshold temperature of insulation with long time. This phenomenon can lead to motor failure. Particularly, it is known that insulation life decreases by 50% for every 10°C increase above the threshold temperature. Therefore, a totally enclosed liquid cooled system is usually adopted in traction IMs, and liquid cooling channels are located in the housing. Heat generated in the stator core and stator coil is cooled directly through cooling liquid in housing, and heat in the rotor part is also cooled through heat exchange of internal air (Kim *et al*., 2012).

4 POWER INVERTERS

The evolution of power inverter topologies follows that of power devices, aiming to achieve high power density, high efficiency, high controllability, and high reliability. The IM drives are necessary to offer the torque–speed requirements of the EV driving profile without involving variable gearing or gearbox. Besides, the EV motor drive should provide the capability of bidirectional power flow to recover the regenerative braking energy. The wish list of the power inverters driving EV motor includes efficiency over 95%, power density over 3.5 W/cm^3, switching frequency over 10 kHz, dv/dt below 1000 V/μs, zero electromagnetic interference (EMI), zero failure before the end of the vehicle life, and redundance with limp-home mode (Chau and Wang, 2005).

4.1 Voltage source inverters

The three-phase two-level voltage source inverter has been widely used in industry for many different applications. As shown in Figure 8, this power inverter is composed of six switches, with an antiparallel free-wheeling diode for each switch. The switches can be metal–oxide–semiconductor field-effect transistor (MOSFET) or insulated-gate bipolar transistor (IGBT) devices, depending on the power and voltage ratings of the converter. The two-level power inverters transform the fixed DC link voltage to a three-phase AC voltage with variable magnitude and frequency for satisfying the operating requirements of IM for EV.

The modulation strategies are used for the two-level voltage source inverters (VSIs) to transform the fixed DC voltage into the desired AC voltages. The sinusoidal pulse-width modulation (SPWM) and the space vector modulation (SVM) are the two widely used modulation strategies. Figure 9 shows the principle of the SPWM for the two-level VSIs. The switching signals of the three legs are generated by comparing the three-phase sinusoidal modulating signals v_{mA}, v_{mB}, and v_{mC} with a common triangle carrier v_{cr}. The waveforms v_{AN} and v_{BN} are the switching signals for upper switches in legs A and B. The conduction of the lower switches is complimentary to that of the upper switches in the same legs. v_{AB} is the line waveform between phases

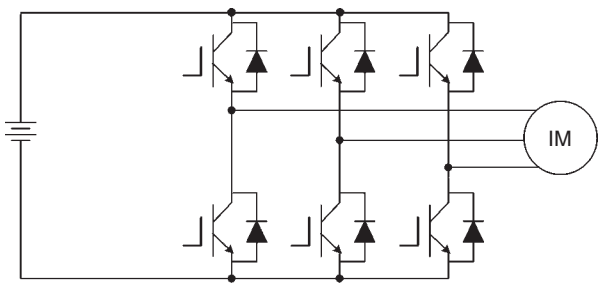

Figure 8. Configuration of three-phase two-level voltage source inverter.

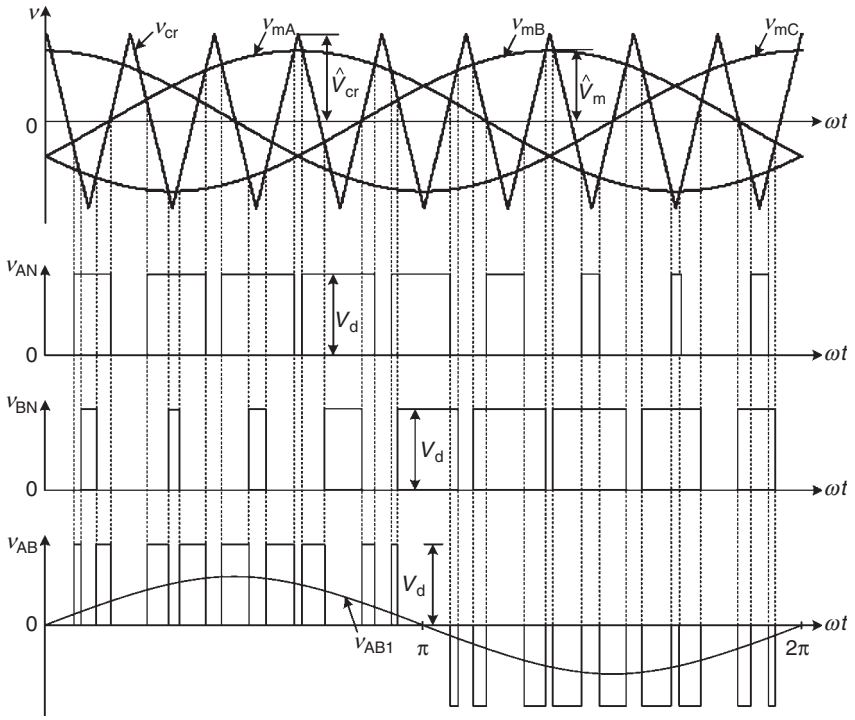

Figure 9. Principle of SPWM.

A and B. v_{AN} and v_{BN} in Figure 9 also show the two-level switched waveforms in each phase. The fundamental-frequency component in the inverter output voltage can be controlled by the amplitude-modulation index m_a, which is defined as the peak value of the modulating wave $\widehat{V}_m$ to the peak value of carrier wave $\widehat{V}_{cr}$. The frequency-modulation index m_f is defined as the frequency of the modulating wave to the frequency of the carrier wave.

Another popular modulating strategy for the three-phase two-level VSI is SVM. Figure 10 shows the vector diagram

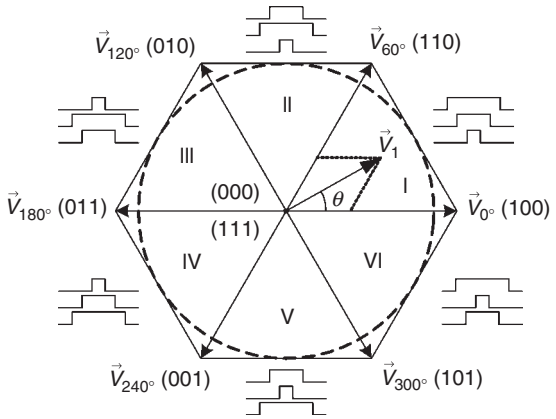

Figure 10. Vector diagram of SVM for two-level voltage source inverter.

of the SVM. The SVM is one of the real-time modulation techniques and is widely used for digital control of VSIs. There are eight switching states of the three upper-leg switches: $\vec{V}_0 = (0,0,0)$, $\vec{V}_1 = (1,0,0)$, $\vec{V}_2 = (1,1,0)$, $\vec{V}_3 = (0,1,0)$, $\vec{V}_4 = (0,1,1)$, $\vec{V}_5 = (0,0,1)$, $\vec{V}_6 = (1,0,1)$, and $\vec{V}_7 = (1,1,1)$. The three lower-leg switches have the complementary switching states. In each switching period, the sequence of the switching states is $\vec{V}_0(T_0/4) \rightarrow \vec{V}_A(T_1/2) \rightarrow \vec{V}_B(T_2/2) \rightarrow \vec{V}_7(T_0/2) \rightarrow \vec{V}_B(T_2/2) \rightarrow \vec{V}_A(T_1/2) \rightarrow \vec{V}_0(T_0/4)$, where $\vec{V}_A$ and $\vec{V}_B$ are the active switching states. The active switching states correspond to the two adjacent basic voltage vectors between which $\vec{V}_1$ locates. The dwell time for the switching vectors essentially represents the duty-cycle time (on-state or off-state time) of the chosen switches during a sampling period T_s of the modulation scheme. The dwell time calculation is based on "voltage-second balancing" principle. That is the product of the reference voltage $\vec{V}_1$ and the sampling period T_s equals the sum of the voltage multiplied by the time interval of chosen space vectors. The dwell times T_1, T_2, and T_0 are computed by:

$$T_1 = \frac{2|\vec{V}_1|T_s}{\sqrt{3}|\vec{V}_A|}\sin(60^\circ - \theta) \tag{19}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$T_2 = \frac{2|\vec{V}_1|T_s}{\sqrt{3}|\vec{V}_B|}\sin\theta \quad (20)$$

$$T_0 = T_s - T_1 - T_2 \quad (21)$$

where θ is the phase angle of $\vec{V}_1$ and T_s the switching period.

4.2 Multilevel power inverters

Compared to the two-level VSI, the multilevel power inverters can offer some unique advantages that are particularly beneficial to EV. Namely, they can generate near-sinusoidal voltages with only fundamental-frequency switching, produce less EMI, are suitable for high power motor drives, and fit well with battery-powered EV where floating DC sources are naturally available. There are three main types of multilevel inverters, namely the neutral point diode-clamping (NPC) type, the flying-capacitor (flying-source) type, and the cascaded H-bridge (CHB) type.

Figure 11 shows the configuration of the three-level NPC inverter. Each inverter leg is composed of four active switches with four antiparallel diodes. On the DC side of the inverter, the DC bus capacitor is split into two, providing a neutral point Z. The diodes connected to the neutral point, namely D_{z1} and D_{z2} are the clamping diodes. When the middle two switches in each leg conduct, the phase is connected to the neutral point through one of the clamping diodes. The terminal voltage of the corresponding phase is zero. Such switching state is represented by O. When the upper two switches conduct, the inverter terminal voltage is $+E$, and the switching state is represented by P. When the lower two switches conduct, the inverter terminal voltage is $-E$, and the switching state is represented by N. The switches S_{1A} and S_{3A} operate in a complementary manner, whereas the switches S_{2A} and S_{4A} operate in a complementary manner. The same operating principle works for phase B and C.

The SVM for the three-level NPC inverter is more complex. There are a total of 27 possible combinations of switching states (Feng *et al.*, 2004). Based on their magnitudes (length), the voltage vectors can be divided into four groups: zero vector with magnitude of zero, small vectors with magnitude of $V_d/3$, medium vectors with magnitude of $\sqrt{3}V_d/3$, and large vectors with magnitude of $2V_d/3$. Figure 12 shows the vector diagram of the

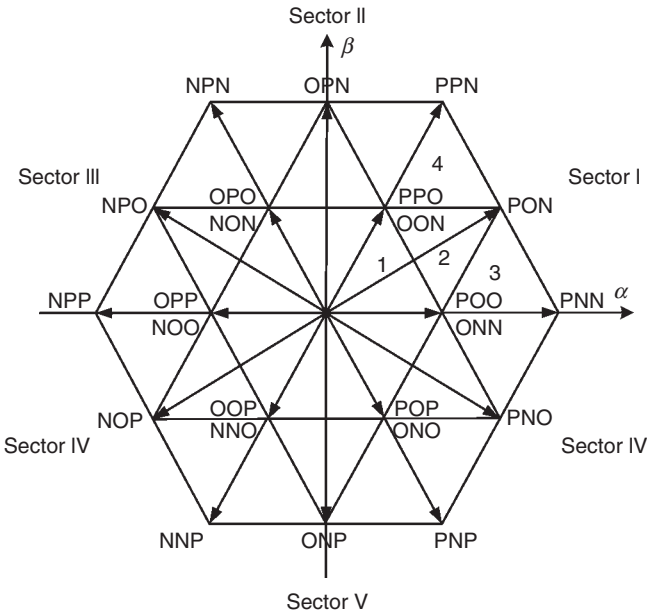

Figure 12. Vector diagram of three-level NPC inverter.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

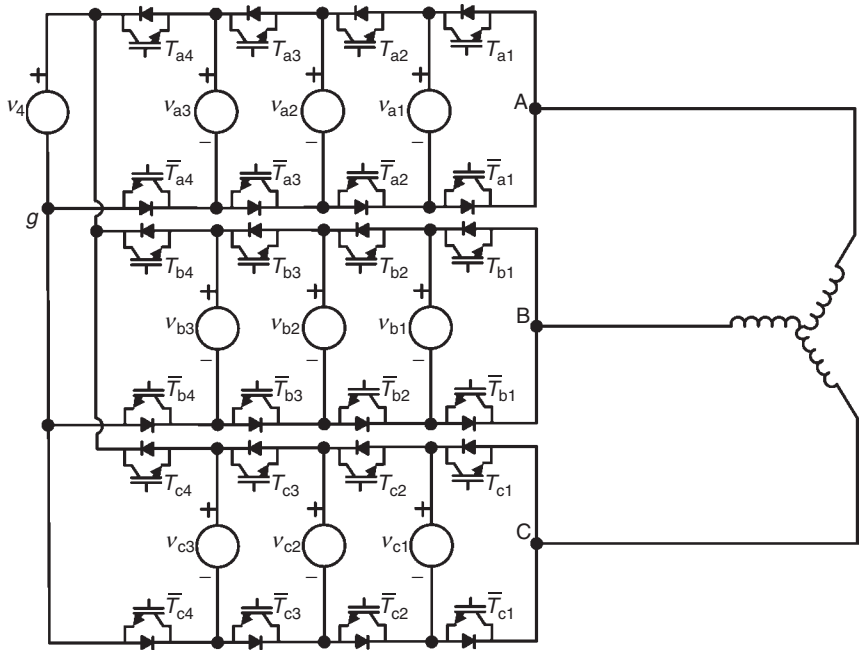

Figure 13. Configuration of a four-cell flying-capacitor multilevel inverter.

three-level NPC inverter, where the space is also divided into six triangular sectors (I–VI), each of which can be further divided into four triangular regions (1–4). For NPC inverter, the reference vector can be synthesized by three nearest stationary vectors. The dwell time calculation is also based on "voltage-second balancing" principle. The unbalance of the DC capacitor voltages can be mitigated by tuning the dwell time of small vectors.

Considering a large amount of battery sets existing in the EV, the multilevel inverter topologies with separate DC links are attractive. Figure 13 shows the configuration of a kind of four-cell flying-capacitor multilevel inverter. By replacing the floating capacitors with batteries and employing the full binary combination schema (Kou, Corzine, and Familiant, 2002), the number of voltage levels and the power quality of this inverter can be further increased. For conventional flying-capacitor multilevel inverter, the voltages of floating sources are 1 : 2 : 3 : 4, and there are only five voltage levels, namely 0, E/4, E/2, 3E/4, and E. The value of E refers to the DC voltage of v_4 in Figure 13. As the voltage step for the flying-capacitor voltages is uniform, the capacitors connected in series could provide the required flying sources. Conversely, the distribution between voltages of floating sources v_{a1}, v_{a2}, v_{a3}, and v_4 in Figure 13 is designed unevenly, in such a way that 16 voltage levels are available in the phase or line-to-ground voltages. The 16 voltage levels are 0, E/15, 2E/15, 3E/15, 4E/15, 5E/15, 6E/15, 7E/15, 8E/15, 9E/15, 10E/15, 11E/15, 12E/15, 13E/15, 14E/15, and E. There are other options of voltage ratios for the binary-combination-schema-based flying source multilevel inverter. For example, 1 : 3 : 7 : 15, 8 : 12 : 14 : 15, and 1 : 5 : 13 : 15. The batteries with different voltages in EV can provide the floating sources in Figure 13.

Figure 14 shows another multilevel inverter for IM drive of EV. It is a cascaded H-bridge-based inverter that consists of five floating DC sources per phase (Tolbert, Peng, and Habetler, 1999). This inverter takes not only the unique advantages of multilevel inverters but also the use of identical H-bridge inverter units, thus enhancing modularity and manufacturability. The CHB-based inverter requires separate DC links, and the battery sets are very suitable to provide such separate DC links. The multilevel carrier-based modulation technique is used widely for the CHB-based multilevel inverters. The multilevel carrier-based modulation includes the phase-shifted and the level-shifted PWM schemes. The multilevel inverter with m voltage levels requires $(m-1)$ triangular carriers. In the phase-shifted multi-carrier modulation, all the triangular carriers have the same frequency and the same peak-to-peak amplitude, but there is a phase shift between any two adjacent carrier waves. The shifted phase is $2\pi/(m-1)$. The modulating signal is usually a three-phase sinusoidal wave with adjustable amplitude and frequency. The switching signals are generated by comparing the modulating waves with the carrier waves.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

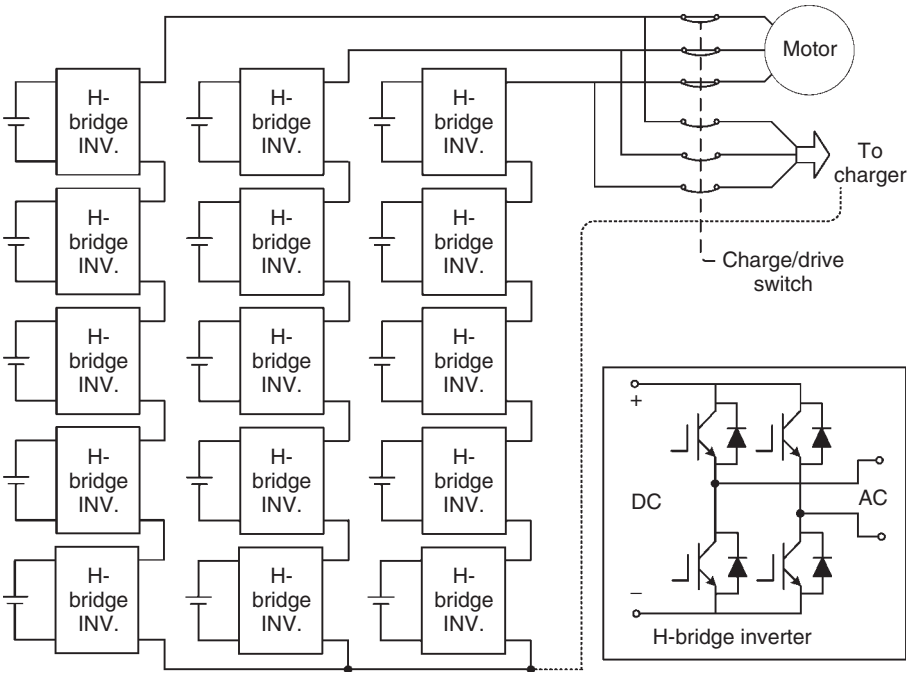

Figure 14. Configuration of CHB-based inverter.

The level-shifted modulation for CHB inverter uses $(m-1)$ level-shifted triangular carriers to construct an m-level CHB inverter (Malinowski *et al*., 2010). The $(m-1)$ level-shifted carriers all have the same frequency and amplitude. They are vertically disposed and the bands they occupy are contiguous. There are three level-shifted multi-carrier modulation schemes: in-phase disposition (IPD), where all carriers are in phase; alternative phase opposite disposition (APOD), where all carriers are alternatively in opposite disposition; and phase opposite disposition (POD), where all carriers above the zero reference are in phase but in opposition with those below the zero reference.

4.3 Soft-switching power inverters

In order to reduce the issues resulting from the high value of dv/dt such as the EMI and common-mode voltages in EV motor drives, soft-switching power inverters are invented to implement the zero-voltage transition (ZVT) or the zero current transition (ZCT) for the power switches. Figure 15 shows the configuration of a three-phase star-configured resonant snubber-based inverter, which is a kind of ZVT inverter for IM drives of EV (Lai, 1997). The resonant snubber-based inverter proposes to produce the zero voltage across the switching device using the resonant branch,

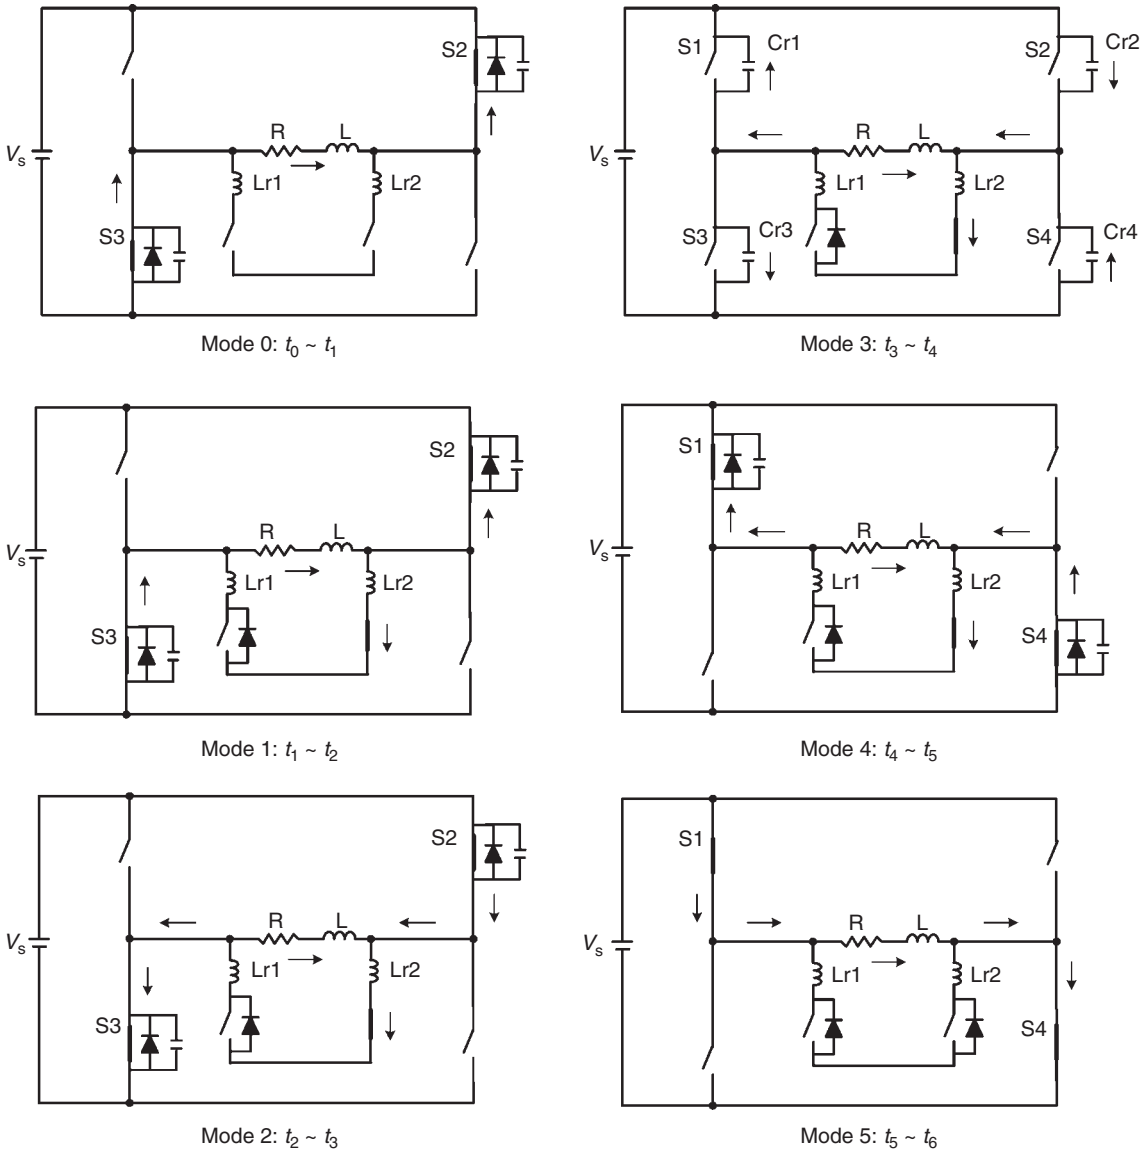

Figure 16. Working modes of phase-to-phase configuration of star-configured resonant snubber-based inverter.

which includes an auxiliary switch, a resonant inductor, and the stray capacitance of the switching device.

Figure 16 plots the working modes of the phase-to-phase configuration within the half cycle of positive load current. The initial condition is that a positive load current is freewheeling diode through D2 and D3, and the switched S2 and S3 remain on. At the time of t_1, the resonant switch S_{r2} is turned on. The resonant inductor current I_{Lr2} increases linearly. Thus, the current in switches S2 and S3 declines gradually and becomes zero at t_2. The resonant inductor current I_{Lr2} keeps increasing and exceeds the load current after t_2. Then, the devices S2 and S3 are turned off. Owing to the existence of the capacitors C_{r2} and C_{r3}, the zero-voltage turn-off operation is available for the main switches S2 and S3. After the turn-off of S2 and S3, the capacitors C_{r2} and C_{r3} are charged. Meanwhile, C_{r1} and C_{r4} are discharged to zero. The resonant current keeps decreasing, and the load current flows through D1 and D4. Thus, the switches S1 and S4 can be turned on at the zero-voltage condition. When the resonant inductor current is equal to the load current, the load current flows through the switches S1 and S4. The resonant current deceases until it becomes zero, and it is blocked by the diode across S1.

Figure 17 shows the configuration of a three-auxiliary-switches-based ZCT inverter (Li, Lee, and Boroyevich, 2003). The auxiliary switches functions to initiate resonance

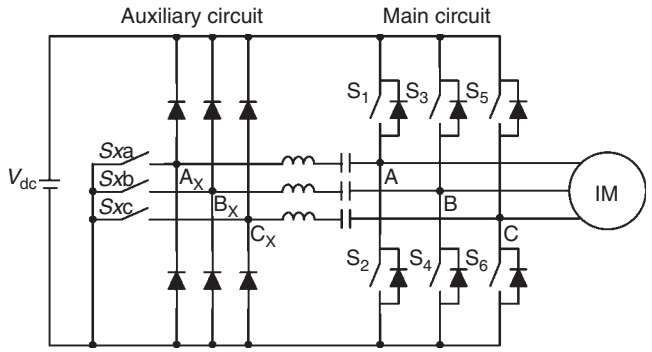

Figure 17. Configuration of three-auxiliary-switches-based zero current transition inverter.

and provide the flowing paths for the resonant current. Figure 18 shows the working modes of one-phase leg of the three auxiliary switch ZCT inverter. The operation of the circuit is not symmetrical for different load directions. The negative load current condition is used for exemplification. Therefore, the load is connected through S_2 and D_1. The initial status is that the load current flows through D_1. The turn-on of the auxiliary switch S_{xa} makes the L_x and C_x resonant. When the resonant current arrives at the peak value, close to the load current, the current flowing through D_1 approaches to zero at t_1. The turn-on of S_2 at this moment can avoid the diode reverse current and reduce the diode switching loss. The gating signal for S_1 should be removed before t_1. Otherwise, the shoot-through fault will occur. The resonant current i_x keeps decreasing to zero at t_2. After that moment, i_x is driven to the negative direction and D_{xa} conducts. Thus, the switch S_{xa} achieves the zero-current turn-off condition. When the resonant current i_x goes back to zero at t_3, the diode D_{xa} turns off and is blocked. The auxiliary circuit continues to resonate. The resonant current is then diverted to the diode D_{ca}. When the positive resonant current returns to zero, the diode D_{ca} turns off naturally and the load current flows through the switch S_2.

When S_2 is ready to turn off, the auxiliary switch S_{xa} is turned on at t_5. When the resonant current increases to the load current, the current through S_2 decreases to zero, and S_2 can be turned off at zero current condition. The resonant current continues to increase, and the surplus current flows through the diode D_2. After arriving at the peak value, the resonant current decreases back below the load current. D_2 thus turns off naturally. The load current flows only through the resonant tank and charges the resonant capacitor linearly. When the resonant capacitor voltage is charged to the DC link voltage, the diode D_1 begins to conduct. Then, the main switch S_1 can be turned on. At t_9, the resonant current i_x decreases to zero, and the resonant current will be carried by the diode D_{xa}. The resonant switch S_{xa} can be turned off with zero current. The resonant current will go back to zero and is blocked by the diodes D_{ca} and D_{xa}. Then, the load current flows through D_1.

4.4 Current source inverters

Unlike VSI, the current source inverter (CSI) adopts the inductor as the energy storage element in the DC link. Figure 19 shows the configuration of the CSI for IM drive of EV (Su and Tang, 2011). The CSI provides the following merits. First, it allows the shoot-through operation, where the upper and the lower switch in the same leg conduct meantime. Second, it can boost the DC link voltage and provide higher AC output voltage, which is suitable for the extended speed operation of EV motor. Third, the filter capacitors for current commutation of CSI can provide better output voltage waveforms.

For CSI, SVM is a very suitable modulation strategy as it offers high flexibility and controllability. Two switches are allowed to conduct at the same time in the CSI. One is in the top half of CSI and the other is in the bottom half of CSI. Therefore, they are totally nine switching states. Among them, six are active vectors and three are zero vectors. Figure 20 shows the vector diagram of the CSI (Wang *et al.*, 2012a, 2012b). Similar to the vector diagram of SVM for VSI, $\vec{I}_1$ to $\vec{I}_6$ are the active vectors and $\vec{I}_7$ to $\vec{I}_9$ are the zero vectors. The difference is that there is 30° shift between the vector diagram of CSI and that of VSI. The calculation of the dwell time for different vectors is also based on the "current-second balancing" principle to synthesize the reference current vector $\vec{I}_{ref}$. There are different switching sequences available for the SVM of CSI. Figure 21 shows a kind of switching sequence that has better THD performance under the same switching frequency (Wang *et al.*, 2012a, 2012b).

Figure 22 plots four operation modes of the CSI-based EV motor drives (Su and Tang, 2011). The CSI and the motor are represented by a voltage source V_{in}. In mode I, the switches S_a and S_b are both turned on. The battery charges the DC inductor. In mode II, the switch S_a is turned on while the switch S_b is turned off. On the contrary, the switch S_b is turned on while the switch S_a is turned off in mode III. In mode IV, both the switches S_a and S_b are turned off. In the low speed motoring operation region, the *V–I* converter operates between mode I and mode II or mode I and mode III. The DC link current is regulated by the *V–I* converter. In the low speed regenerative operation region, the converter operates between mode II and mode IV or mode III and mode IV. For the high speed motoring operation of EV, the switches S_a and S_b are kept on, and the DC link current is regulated by the CSI side. On the

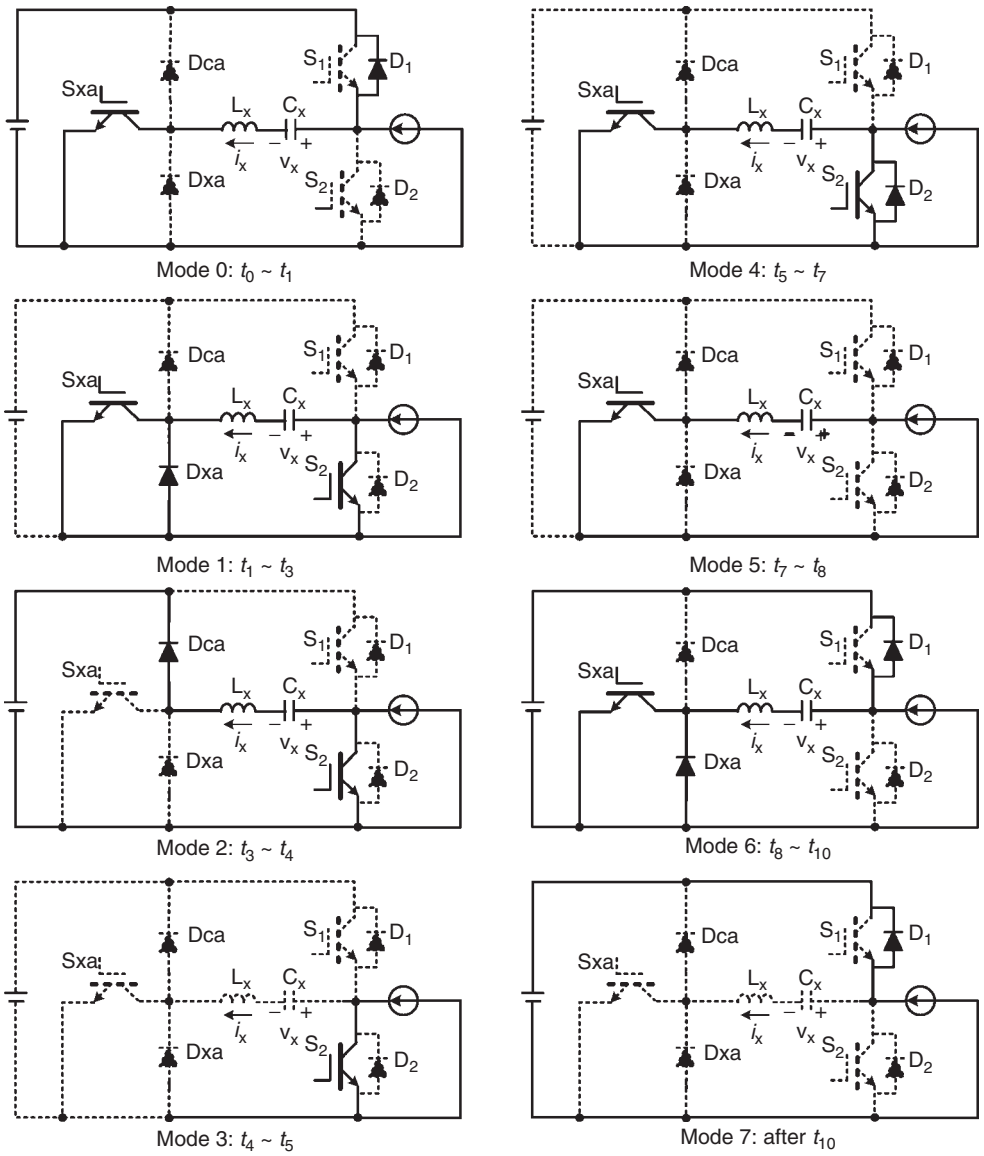

Figure 18. Working modes of one phase of three-auxiliary-switches-based zero current transition inverter under negative load current condition.

contrary, the switches S_a and S_b are kept off for the high speed regenerative operation of EV. Under this condition, the DC link current is also regulated by the CSI side.

4.5 Z-source inverters

The Z-source inverter provides a unique impedance network as shown in Figure 23. In the DC link, a two-port network consisting of a split-inductor L_1 and L_2 and capacitors C_1 and C_2 connected in X shape is employed. The unique feature of the Z-source inverter is that the output AC voltage can be of any value between zero and infinity regardless of the DC link voltage. Thus, the DC/DC converter used to boost the DC link voltage for extending operation of EV can be removed. Besides, the shoot-through operation induced by the EMI noise is allowed for the Z-source inverter. Different from the traditional PWM for VSI, a shoot-through zero states are inserted into the switching states. Hence, the equivalent DC link voltage to the inverter can be boosted effectively (Peng, 2003).

The relationship between the equivalent DC link voltage V_i and the input DC voltage V_o is (Peng, 2003)

$$\frac{V_i}{V_o} = B \tag{22}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

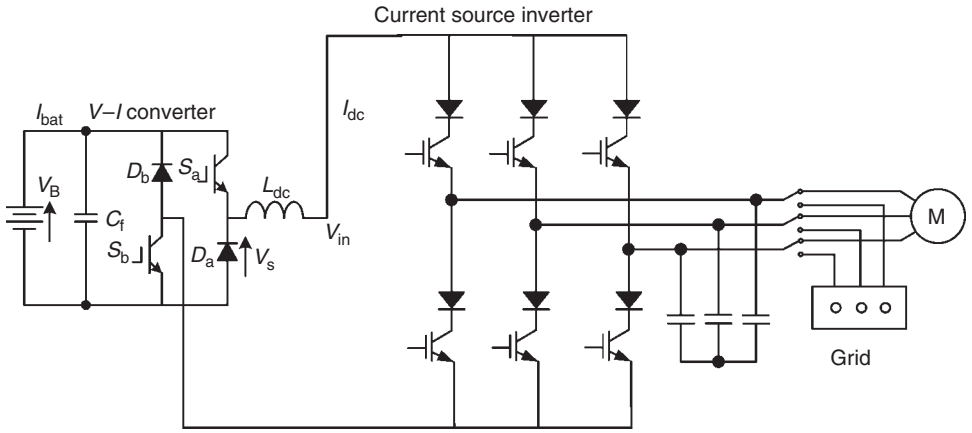

Figure 19. Configuration of current-source-inverter-based motor drive.

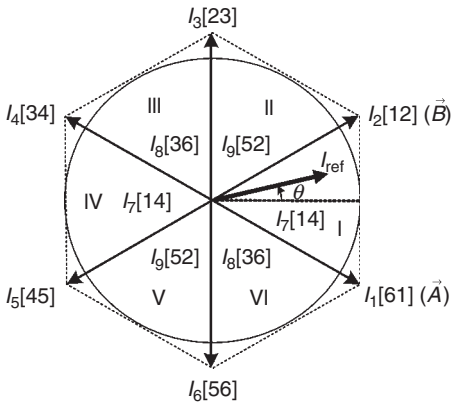

Figure 20. Vector diagram of current source inverter.

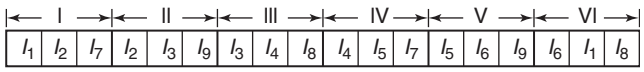

Figure 21. Switching sequence of current source inverter.

where B is the boost factor and is determined by:

$$B = \frac{1}{[1 - 2(T_{SC}/T)]} \tag{23}$$

where T_{SC} is the shoot-through time interval within a switching interval T. As $B \geq 1$, the boost operation is implemented.

Figure 24 gives 12 operation modes of the bidirectional Z-source inverter (Dehghan, Mohamadian, and Yazdian, 2010). Modes 1 and 2 correspond to the shoot-through operation of IM drive, where the switch S_7 is turned off, and its antiparallel diode is reverse biased. The DC link on AC side is short-circuited in modes 1 and 2. Modes 3 and 4 correspond to the zero states of IM drive, where the zero switching states are given at the inverter side. The DC link on AC side is thus open circuited. For modes 5, 6, 7, and 8, the inverter has an active vector for VSI, and its output current is positive. That means the active power is delivered from the battery at DC side to the IM at AC side. For modes 9, 10, 11, and 12, the inverter also has an active vector, but its output current is negative, which indicates the active power is delivered from the AC side to the DC side. This condition corresponds to the regenerative operation of IM drive in EV.

5 CONTROL STRATEGIES OF IM DRIVE FOR EV

Speed control in induction drive systems is more complex than that in DC drive systems because the IMs suffer from nonlinearity of the dynamic model with coupling between direct and quadrature axes. The basic equation of speed control of IM is governed by:

$$n = n_s(1 - s) = \frac{f}{p}(1 - s) \tag{24}$$

Thus, the motor speed can be controlled by f, p, and/or s.

As shown in Figure 25, the characteristics of the induction drive system can be divided into three operating regions (Chau and Wang, 2011). The first region is called the *constant-torque region* in which the motor can deliver its rated torque for frequencies below the rated frequency. In the second region, called the *constant-power region*, the slip is increased to the maximum value so that the stator current remains constant and the motor can maintain its

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

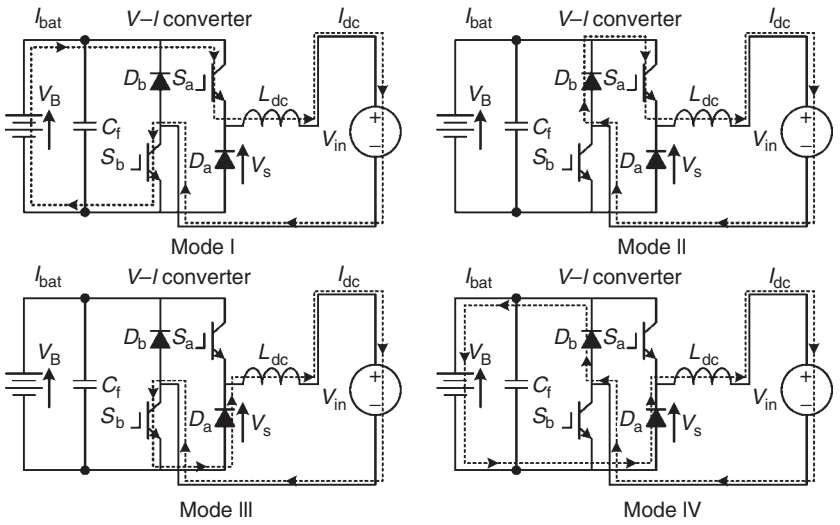

Figure 22. Operation modes of current-source-inverter-based induction motor drive for EV.

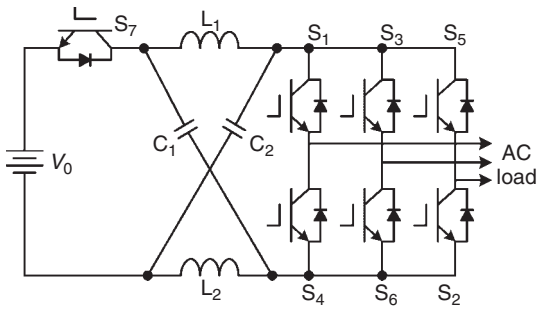

Figure 23. Configuration of bidirectional Z-source inverter.

rated power. In the high speed region, the third region, the slip remains constant while the stator current decreases. Thus, the torque capability declines with the square of speed.

5.1 Variable-voltage variable-frequency control

The variable-voltage variable-frequency (VVVF) control is a kind of open-loop control. Figure 26 shows its block diagram (Chau and Wang, 2011). This strategy is based on the constant volts/hertz control for frequencies below the motor-rated frequency and variable-frequency control with constant-rated voltage for frequencies beyond the rated frequency. For very low frequencies, voltage boosting is applied to compensate the difference between the applied voltage and the induced EMF because of the stator resistance drop.

In the VVVF control, the motor speed reference is constructed as a ramp shape to prevent the electrical and mechanical shock to the speed control system. There is no speed feedback for the VVVF control, and the motor speed is assumed to follow the output frequency. With the given voltage reference V and the frequency reference f, the PWM signals are provided for the power inverters to feed the IM. The current is usually fed back for the VVVF control mainly for protection.

As the VVVF control employs the open-loop control, it has the following drawbacks. First, the torque performance at low speed is poor because of the significant drop of stator voltage. Second, this control cannot provide high dynamic performance and torque response. Although the slip compensation strategy has been employed to regulate the frequency reference f to adapt to the change of load, the dynamic performance of the VVVF control is still worse than that of the closed-loop control strategies. Third, the IM drive with VVVF control cannot provide good operating performance under the shock loads, which are usually required by EVs. Therefore, the VVVF control strategy is less attractive for high performance IM drive systems.

5.2 Field oriented control

The field oriented control (FOC), also known as *vector control*, is proposed for IM drives to emulate the DC motor control. By using the proper field orientation, the stator current could be decomposed into a flux-producing component and a torque-producing component. Then, the two components can be controlled separately, which is very similar to that of DC motor drives. The FOC can be classified into three categories based on the synchronous

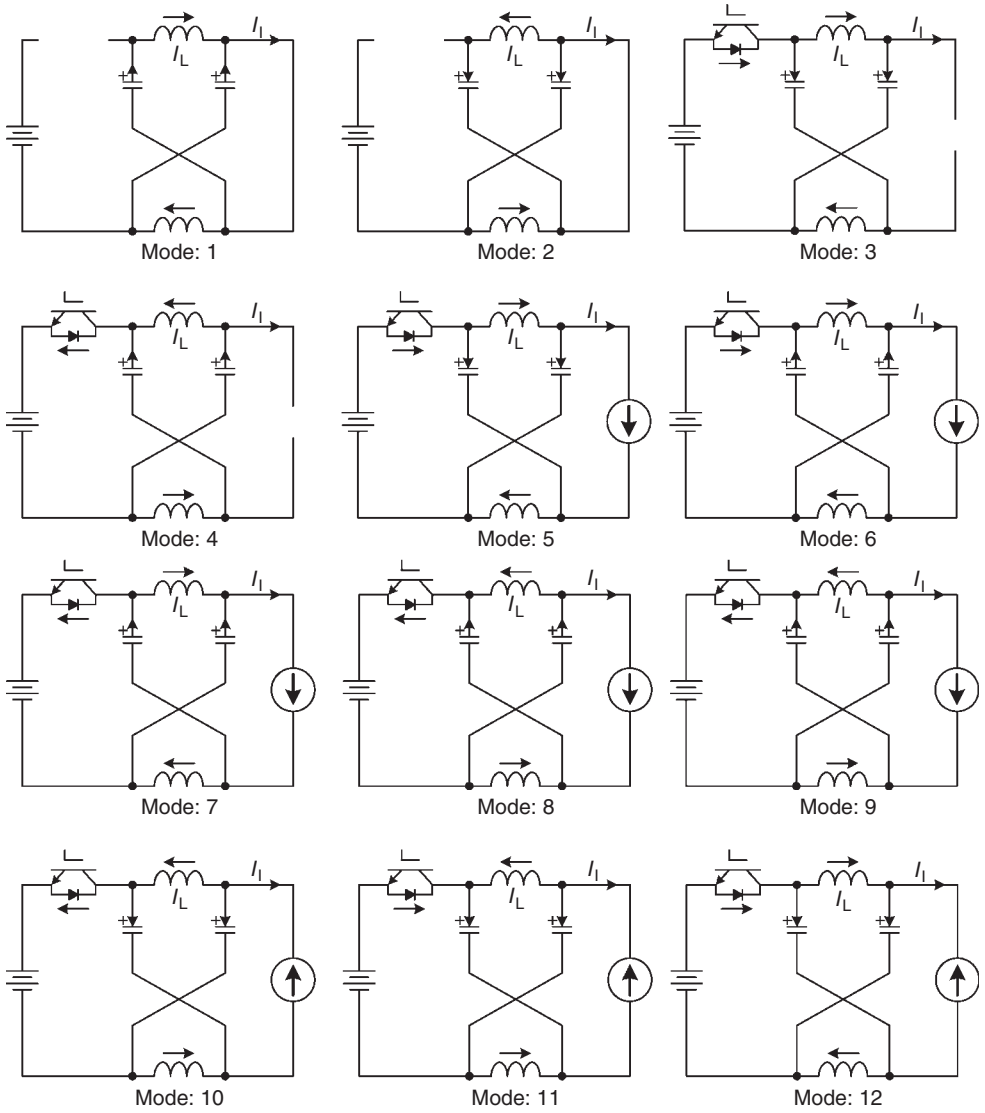

Figure 24. Operation modes of bidirectional Z-source-inverter-based induction motor drive for EV.

frame choice: the stator flux orientation, the air-gap flux orientation, and the rotor flux orientation. Among the different FOC strategies, the rotor flux orientation is most widely used. The principle of the rotor flux orientation is to align the *d*-axis of the synchronous reference frame with the rotor flux vector of IM.

Figure 27 shows the block diagram of FOC for IM drive (Chau and Wang, 2011). By using FOC, the mathematical model of IMs is transformed from the stationary reference frame ($\alpha-\beta$ frame) to the general synchronously rotating frame ($x-y$ frame) as shown in Figure 28. Thus, at steady state, all the motor variables such as supply voltage v_s, stator current i_s, rotor current i_r, and rotor flux linkage λ_r can be represented by DC quantities. When the x-axis is purposely selected to be coincident with the rotor flux linkage vector, the reference frame (d-q frame) becomes rotating synchronously with the rotor flux as shown in Figure 29, where i_{sd} and i_{sq} are the d-axis component and q-axis component of stator current, respectively. Hence, the motor torque T can be obtained as:

$$T = \frac{3}{2} p \frac{M}{L_r} \lambda_r i_{sq} \tag{25}$$

where M is the mutual inductance per phase and L_r the rotor inductance per phase. As λ_r can be written as Mi_{sd},

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

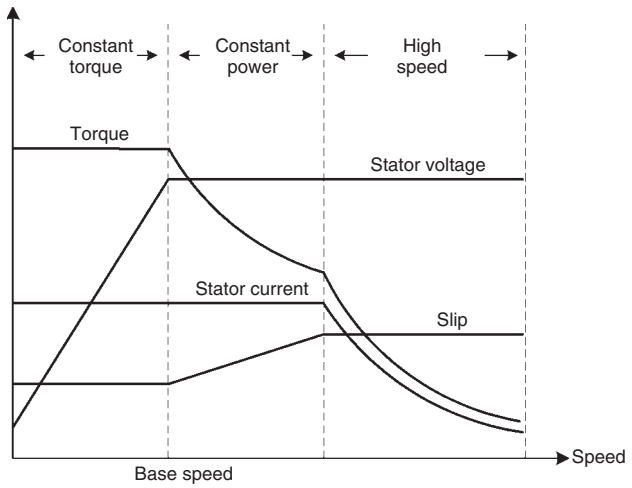

Figure 25. Characteristics of induction motor.

the torque equation can be rewritten as:

$$T = \frac{3}{2} p \frac{M^2}{L_r} i_{sd} i_{sq} \tag{26}$$

This torque equation is very similar to that of separately excited DC motors. Namely, i_{sd} resembles the field current I_f, whereas i_{sq} resembles the armature current I_a. Thus, i_{sd} can be considered the field component of i_s, which is responsible for establishing the air-gap flux. On the other hand, i_{sq} can be considered the torque component of i_s, which produces the desired motor torque. Therefore, by using this FOC, the motor torque can be effectively controlled by adjusting the torque component, and the field component remains constant. Hence, the IM drive can offer the desired fast transient response similar to that of separately excited DC drive systems. In order to attain the above FOC, the rotor flux linkage vector is always aligned with the *d*-axis. This criterion of the decoupling condition can be attained through slip frequency ω_{slip} control as given by:

$$\omega_{slip} = \frac{R_r i_{sq}}{L_r i_{sd}} \tag{27}$$

where R_r is the rotor resistance for each phase.

Since the advent of FOC, a number of methods have been proposed for implementation. Basically, these methods can be classified into two groups, namely direct FOC and indirect FOC. The direct FOC requires calculating the rotor flux and the motor speed with the measured motor voltages, currents, and the IM model. In contrast, the indirect FOC determines the rotor flux angle from the measured rotor speed and calculated slip angle based on motor parameters. Figure 30 shows the block diagram of the indirect FOC for IM drive (Chau and Wang, 2011). Although the FOC has been widely used for high performance induction drive systems, it still suffers from some drawbacks. Particularly, the rotor time constant L_r/R_r (which has a dominant effect on the decoupling condition) changes severely with the operating temperature and magnetic saturation, leading to deteriorate the desired FOC. In general, there are two ways to solve this problem. One way is to perform online identification of the rotor time constant and accordingly update the parameters used in the FOC controller. The other way is to adopt a sophisticated control algorithm to enable the FOC controller insensitive to motor parameter variations.

5.3 Direct torque control

The DTC is another advanced control strategy, which is widely used for IM drives (Buja and Kazmierkowski, 2004). It has the merits of simple control algorithm, fast torque response, easy digital implementation, and robust operation. The electromagnetic torque for an IM can be expressed as:

$$T = \frac{3P}{2}\frac{L_m}{\sigma L_s L_r}\lambda_s \lambda_r \sin\theta_T \tag{28}$$

where λ_s and λ_r are the magnitude (peak value) of the stator and rotor flux linkage vectors $\vec{\lambda}_s$ and $\vec{\lambda}_r$ and θ_T the angle between the stator flux and the rotor flux. Figure 31 shows the different reference frames in IM where d, q axes align with rotor flux $\vec{\lambda}_r$, x, y axes align with stator flux $\vec{\lambda}_s$, and α, β axes are stationary with α axis aligning with armature winding a. θ_T thus becomes the angle between $\vec{\lambda}_s$ and $\vec{\lambda}_r$.

In the stator flux control, the relationship between the stator flux $\vec{\lambda}_s$ and the stator voltage vector $\vec{v}_s$ is given as follows:

$$\frac{d\vec{\lambda}_s}{dt} = \vec{v}_s - R_s\vec{i}_s \tag{29}$$

The stator voltage $\vec{v}_s$ is the output voltage of the inverter, which can be controlled by the reference vector $\vec{v}_{ref}$ in the SVM. As $\vec{v}_{ref}$ can be controlled by the power inverter, the proper combination of the switching vectors could adjust the magnitude and angle of $\vec{\lambda}_s$ dynamically. The DTC is to control the electromagnetic torque by

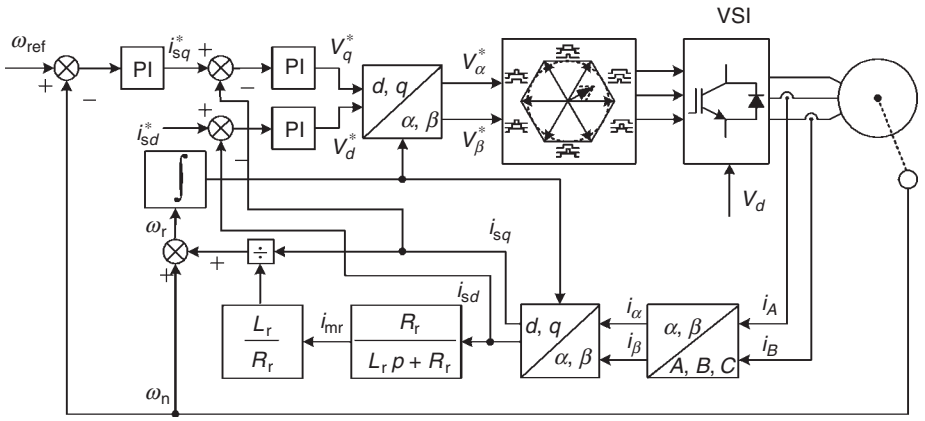

Figure 30. Block diagram of indirect FOC for induction motor drive.

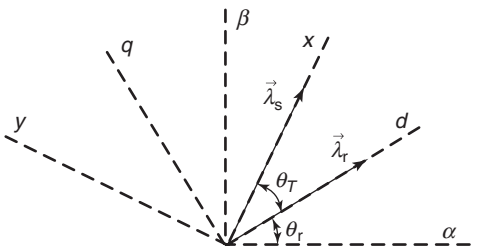

Figure 31. Different reference frames of induction motor.

adjusting the torque angle θ_T while keeping the magnitude of the stator flux at a constant value. Figure 32 shows the block diagram of DTC. The measured voltages and currents are transformed into α, β axes. Then, λ_s can be estimated with u_α, u_β, i_α, and i_β. Thus, the electromagnetic torque T is calculated with the estimated $\vec{\lambda}_s$ and the measured stator currents i_α and i_β. The reference torque T^* is generated by the speed controller. The magnitude and angle of the stator flux $\vec{\lambda}_s$ is calculated as:

$$\lambda_s = \sqrt{(\lambda_{s\alpha})^2 + (\lambda_{s\beta})^2} \tag{30}$$

$$\theta_s = \text{arctg}\left(\frac{\lambda_{s\beta}}{\lambda_{s\alpha}}\right) \tag{31}$$

As shown in Figure 32, the switching status in DTC is determined by the sector where λ_s locates and by the outputs of two hysteresis loops for torque and flux. Figure 33 shows the principle of choosing switching status for DTC. Figure 33a corresponds to the acceleration condition by defining the anticlockwise direction as

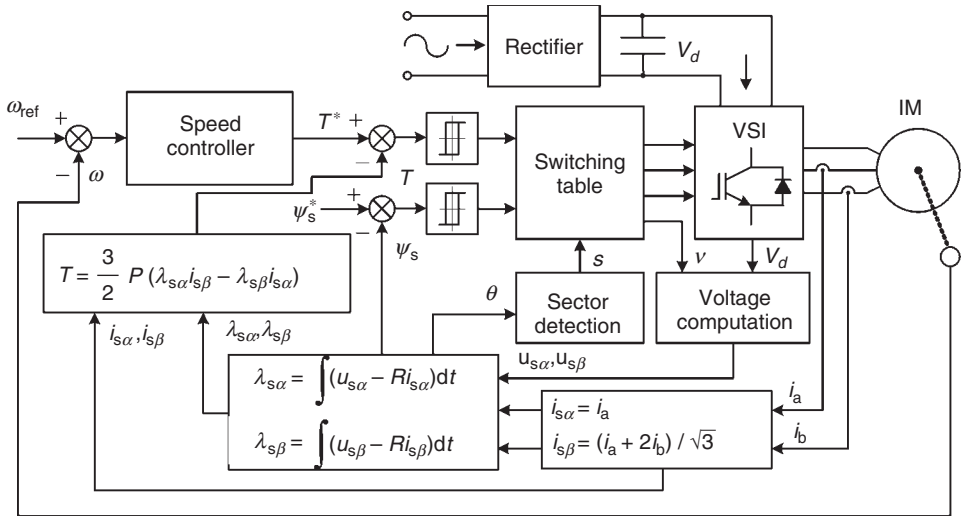

Figure 32. Block diagram of DTC for induction motor.

DOI: 10.1002/9781118354179.auto210
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

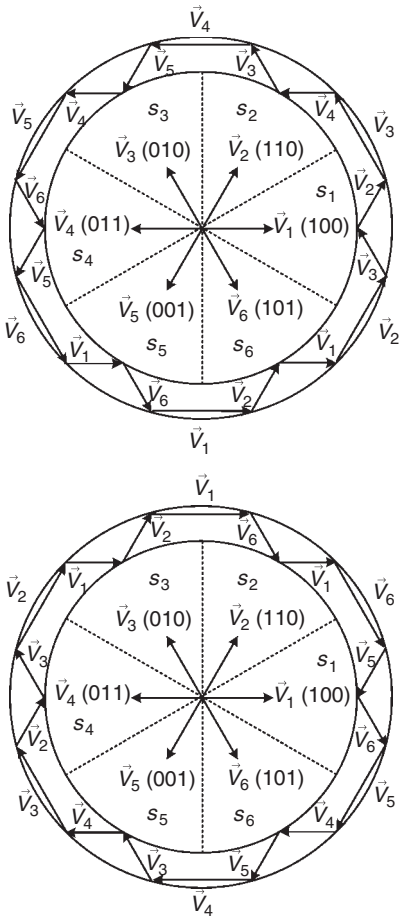

Figure 33. Choice of switching status for DTC: (a) acceleration condition; (b) deceleration condition.

the rotating direction of IM. Accordingly, Figure 33b plots the deceleration condition. The impact of the stationary voltage vectors $\vec{V}_1$ to $\vec{V}_6$ on $\vec{\lambda}_s$ and θ_T can be observed in Figure 33. The stationary plane for the stator flux $\vec{\lambda}_s$ is divided into six sectors from I to VI. For example, four switching vectors, namely $\vec{V}_2$, $\vec{V}_3$, $\vec{V}_5$, and $\vec{V}_6$ have the impact in sector I. The electromagnetic torque increases by selecting the vectors $\vec{V}_2$ and $\vec{V}_3$. On the contrary, the vectors $\vec{V}_5$ and $\vec{V}_6$ will reduce the torque and decelerate the motor. For the impact on the flux, the vectors $\vec{V}_2$ and $\vec{V}_6$ can enlarge the magnitude of stator flux $\vec{\lambda}_s$, whereas the vectors $\vec{V}_3$ and $\vec{V}_5$ can reduce the stator flux in sector I. The choice of the vectors for change of the torque and flux in other sectors are similar as in Figure 33.

It should be mentioned that the zero vectors of voltage source converter have no impact on the torque and flux. The two zero vectors, namely 000 and 111, could be used under the condition where the torque does not need changing. Thus, the smaller torque ripple can be available.

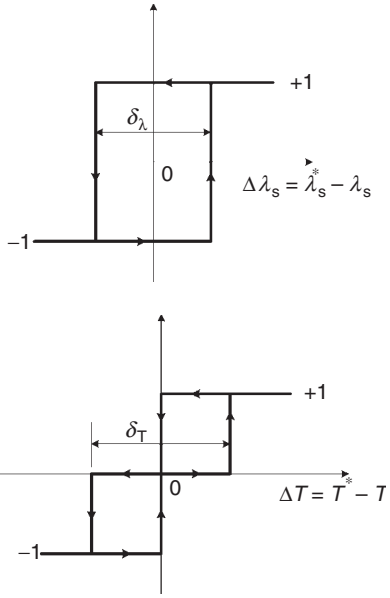

Figure 34. Characteristics of hysteresis loops: (a) flux loop; (b) torque loop.

The corresponding flux and torque hysteresis loops are shown in Figure 34, where δ_λ and δ_T are the boundaries for the flux and torque hysteresis loop, respectively (Wu, 2006). The key for choosing zero vectors is to minimize the switching times when the active vectors are switched. For example, the zero vector 111 is used when the torque does not change but the flux is increasing in sector I. On the contrary, the zero vector 000 is used when the torque does not change and the flux is decreasing in sector I. The choice of zero vectors in other vectors is similar.

6 CONCLUSIONS

The characteristics of IM drives and advanced control strategies are extensively discussed. The IM drive is the most mature technology among various commutatorless motor drives. The IM drives offer the advantages of robust structure, low cost, high reliability, and being free from maintenance, which are particularly important for electric propulsion in EV applications.

The power inverter for IMs is designed to achieve the torque–speed requirements of the EV driving profile without involving variable gearing or gearbox. Moreover, it should provide the capability of bidirectional power flow to recover the regenerative braking energy. Five mature power inverter topologies, VSIs, multilevel power inverters, soft-switching power inverters, CSIs, Z-source inverters, are elaborated and evaluated for EV applications.

Speed control of IM drive systems is more complex than that of DC drive systems because IMs suffer from nonlinearity of the dynamic model with coupling between direct and quadrature axes. Three speed control strategies, VVVF control, FOC, DTC, are also discussed and evaluated.

It should be noted that system efficiency optimization of IM drive is extremely desirable for EV because of limited energy. Hence, efficiency optimization control of IM drive, incorporated with various speed control strategies, have attracted more attention (Li, Zhang, and Cui, 2010; Sergaki and Moustaizis, 2011).

CVT Control—System Integration, Ratio Choice, Shift Strategy and Dynamics, Adaptive Features, Engine Calibration, Electric Motor Assist

Takashi Shibayama
JATCO Ltd., Fuji City, Japan

1 INTRODUCTION

In order to understand the basic concept and outline of continuously variable transmission (CVT) control, following topics are described. (i) CVT control system, (ii) ratio changing control of a CVT, (iii) shift schedule of CVT, (iv) CVT ratio changing control strategy, (v) other ratio changing control of CVT, (vi) engine and CVT integrated control, (vii) CVT clamping force control, (viii) CVT control in hybrid electric vehicle systems, (ix) control for CVT with auxiliary shifting system, (x) chain CVT control, and (xi) control of toroidal CVT. CVT ratio control with a stepper motor, CVT shift feeling improvement, and automatic engine braking by CVT ratio change control are also discussed.

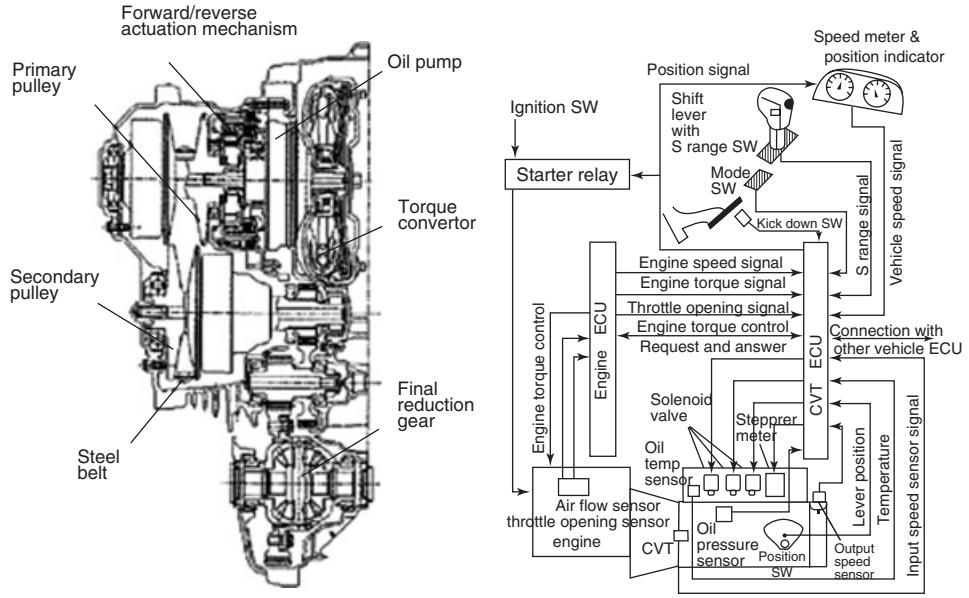
2 CVT CONTROL SYSTEM

Figure 1a shows a cross section of a typical belt CVT transaxle (Abo *et al*., 2003). Engine output is connected to the torque converter, which acts as a launching device. The forward/reverse actuation mechanism changes torque direction, and then by the adjustment of the primary and secondary pulleys, and steel belt system, a continuously variable ratio change is realized. The wheel driving torque is then derived through the final reduction gear.

Figure 1b shows a typical CVT control system, which has several sensors, actuators, and communicators. The most important sensor is the pressure sensor by which CVT ECU (electric control unit) can detect belt clamping force, which should be enough to prevent belt slipping.

Figure 1c shows a typical device combination for CVT control. The control system is similar to that of an Automatic Transmission (AT), which is described in (see AT Control—Actuation Methods & System Integration, Gear Choice, Gear Shift Strategy & Process, Adaptive Features) The main differences are the pressure sensor and stepper motor for controlling CVT ratio changing.



Category	Device	Major act of the device
Sensor	Pressure sensor	To detect damping force of pulley
	Engine speed sensor	To detect torque converter slipping ratio
	CVT input speed sensor	To detect speed ratio of CVT
	CVT output speed sensor	To detect gear ratio of CVT
	Vehicle speed sensor	To detect wheel slip
	Position sensor	To detect P.R.N.D.L opening range
	S range SW	To make special shift control, ex. sporty or normal
	Mode SW	To switch mode, ex. economy or normal
	Kick down SW	To detect drive's high intension for acceleration
	Engine throttle opening	To detect drive's intension for acceleration
	Engine airflow meter	To detect engine output torque
	Temperature sensor	To detect CVT Oil temperature to know viscosity of oil
	Other sensors	It depends on the purpose of some additional special control Ex. Hydraulic pressure sensor, SW, g sensor, ect.
Actuator	Stepper motor	To control CVT speed ratio
	Solenoid value	To control CVT hydraulic pressure
	Engine torque adjusting device	To adjust engine torque
	Indicator lamp	To indicate P.R.N.D.L range status to driver
	Starter relay	To allow engine starting during P.n range only
Communicater	Engine—CVT communicator	To agree engine torque adjusting
	Other vehicle ECUs—CVT communicator	To make communication with ABS, ASCD, NAVT, ect. for some additional special control
	*Recently both above communications are usually done by CAN network	

(c)

Figure 1. A typical CVT control system. (a) Cross section of typical belt CVT. (b) Typical CVT control system diagram. (c) Devices for CVT control. (Reproduced by permission of Jatco, Ltd.)

There are many kinds of CVT ratio changing controls. Some CVTs have stepper motors to control speed ratio with ratio control valves mechanically connected to the stepper motor. Some use pressure control devices for the ratio control of primary and secondary pulleys. Stepper motor control systems are popular traditional systems for CVT ratio changing control, so the example figure shows a stepper motor.

Communication between the engine and the CVT is very important for keeping enough torque capacity on the belt and the pulley systems preventing belt slipping. In addition, communication between engine and CVT, by engine torque control, helps engine speed changing during CVT ratio changing.

Vehicle CAN (controller area network) brings good communication with other vehicle ECUs such as ABS

(antilock brake system) and NAVI (automotive navigation system). The CVT ECU can modify the ratio changing schedule based on this information.

Figure 2a shows CVT hydraulic control diagram (Sugano *et al*., 2003, p. 22). Hydraulic power is supplied by an oil pump and its flow is delivered to the belt and pulley system, the forward and reverse clutches, and the torque converter with lockup clutches. Clutches are controlled by hydraulic and solenoid valves, as shown in Figure 2b.

In a CVT, the clutch function is very simple: that is, forward and reverse only make engagements at very low or vehicle stop conditions. On the other hand, the torque converter lockup clutch makes engagements at a variety of vehicle speeds. Therefore, usually, pressure

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

control linear solenoid valves are shared and "multiplexed" between garage shifting (shifting from P,N to D,R at vehicle stop condition) control and torque converter lockup clutch control. A selected s/w valve will switch the circuit from garage shifting clutch to torque converter clutch after launching.

3 RATIO CHANGING CONTROL OF CVT

As is described in detail in Article (see The variable pulley CVT), to prevent belt slipping and to keep some speed ratio, clamping force control is important. Ratio change is made by clamping force control. Figure 3a shows primary and secondary clamping forces.

Figure 3b shows a typical chart for indicating clamping force ratio to keep a required speed ratio. As shown, this changes with transmitting torque.

On the line shown in Figure 3b, the CVT does not change ratio, but maintains a constant speed ratio. However, if clamping force is changed on the primary or secondary pulley, the clamping force balance is broken and speed ratio change begins.

For example, to make shifting from A to B, the shift controller will increase primary pulley clamping force to high, then the speed ratio begins to change from A to B [i.e., toward over drive (OD)]. The shifting speed depends on how large the primary clamping force is and the hydraulic flow determines how fast the pulleys can move.

This is the basic concept of CVT shifting control.

In order to provide such clamping force control, several kinds of clamping force generation systems and control systems have been invented.

1. clamping by hydraulic power;
2. clamping by electric motor power;
3. clamping by loading cam.

Sometimes, these methods are combined together.

Figure 3c shows the principle of a loading cam. By this cam force, the transmitting torque can be obtained without any hydraulic or electric power. Some CVTs use this mechanism.

Hydraulic control is the most popular way. However, there are two approaches

1. Direct control:

Primary and secondary hydraulic pressures or flows are controlled independently by solenoid valves.

2. Stepper motor and ratio control valve system:

In this system, stepper motor provides speed ratio changing control, and mechanical linkage provides feedback to the ratio control valve.

There are two approaches to the direct control system: primary control system or dual control system. Figure 4a shows a typical example of primary pressure direct control system. Primary pulley actuating pressure is controlled for ratio changing. The line pressure control solenoid valve provides line pressure, which is applied to the secondary pulley, whereas the primary pulley pressure is controlled by the primary control solenoid valve. The difference between primary and secondary pressures can be made by the line pressure control solenoid valve and the primary control solenoid valve. The controller calculates the speed ratio detecting pulley speeds from speed sensors. Feedback control to primary pulley pressure is adapted to control the speed ratio.

Figure 4b shows another typical direct control system of pulley actuating pressure for ratio changing. It is almost the same as the system described earlier, the difference being the secondary pressure control method. A secondary control solenoid valve is added. By this additional valve, the controller can make secondary pulley pressure lower than its feed pressure (line pressure). As a result, operation during low engine torque conditions such as cruising can be accomplished with low clamping force and low friction loss in the belt and pulley systems for good fuel economy.

However, in this system, parts count and system cost increase. Speed ratio is again calculated by the controller by detecting primary and secondary speeds. Using the calculated speed ratio, the controller provides feedback control of both pulley pressures.

Figure 4c shows the stepper motor and ratio control valve system with a mechanical linkage (Abo *et al*., 2003; Singh *et al*., 2003). One end of the linkage is connected to stepper motor, which makes linear movement step by step. Another end of the linkage is connected to mechanical sensor, which is always slipping on the primary pulley back surface. If the primary pulley strokes to the right or left as described in the figure, the linkage end will move right or left along with the primary pulley movement.

In the control from UD (under drive) to OD, the stepper motor moves the linkage to the right, and the ratio control valve provides oil flow charge to primary pulley chamber, which initiates the ratio changing toward OD. When the OD shift is completed, the primary pulley back surface will move to the left and make the ratio control valve to stop charging the primary pulley chamber.

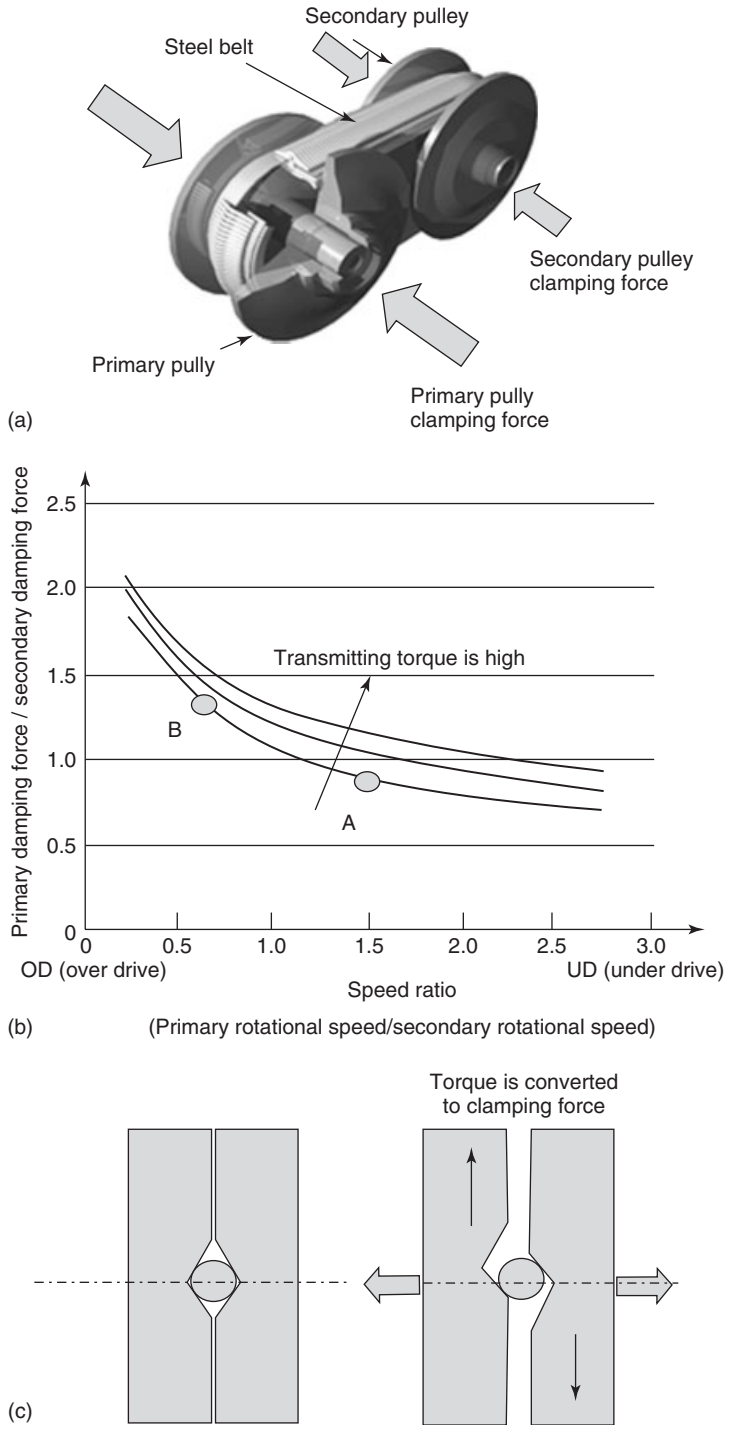

Figure 3. CVT ratio changing control by the clamping force control. (a) Clamping force. (b) Primary/secondary clamping force ratio characteristics. (c) Principle of loading cam. (Reproduced by permission of Jatco, Ltd.)

In this way, the linkage works as a mechanical sensor for hydraulic feedback control. The controller detects the speed ratio by speed sensors and makes adjustments of the stepper motor movement. In such a way, this system makes both mechanical and electrical feedback adjustments, thereby providing a more stable ratio changing system. Calibration is easier with this system than a direct control system, so many CVT designs adopt this control approach.

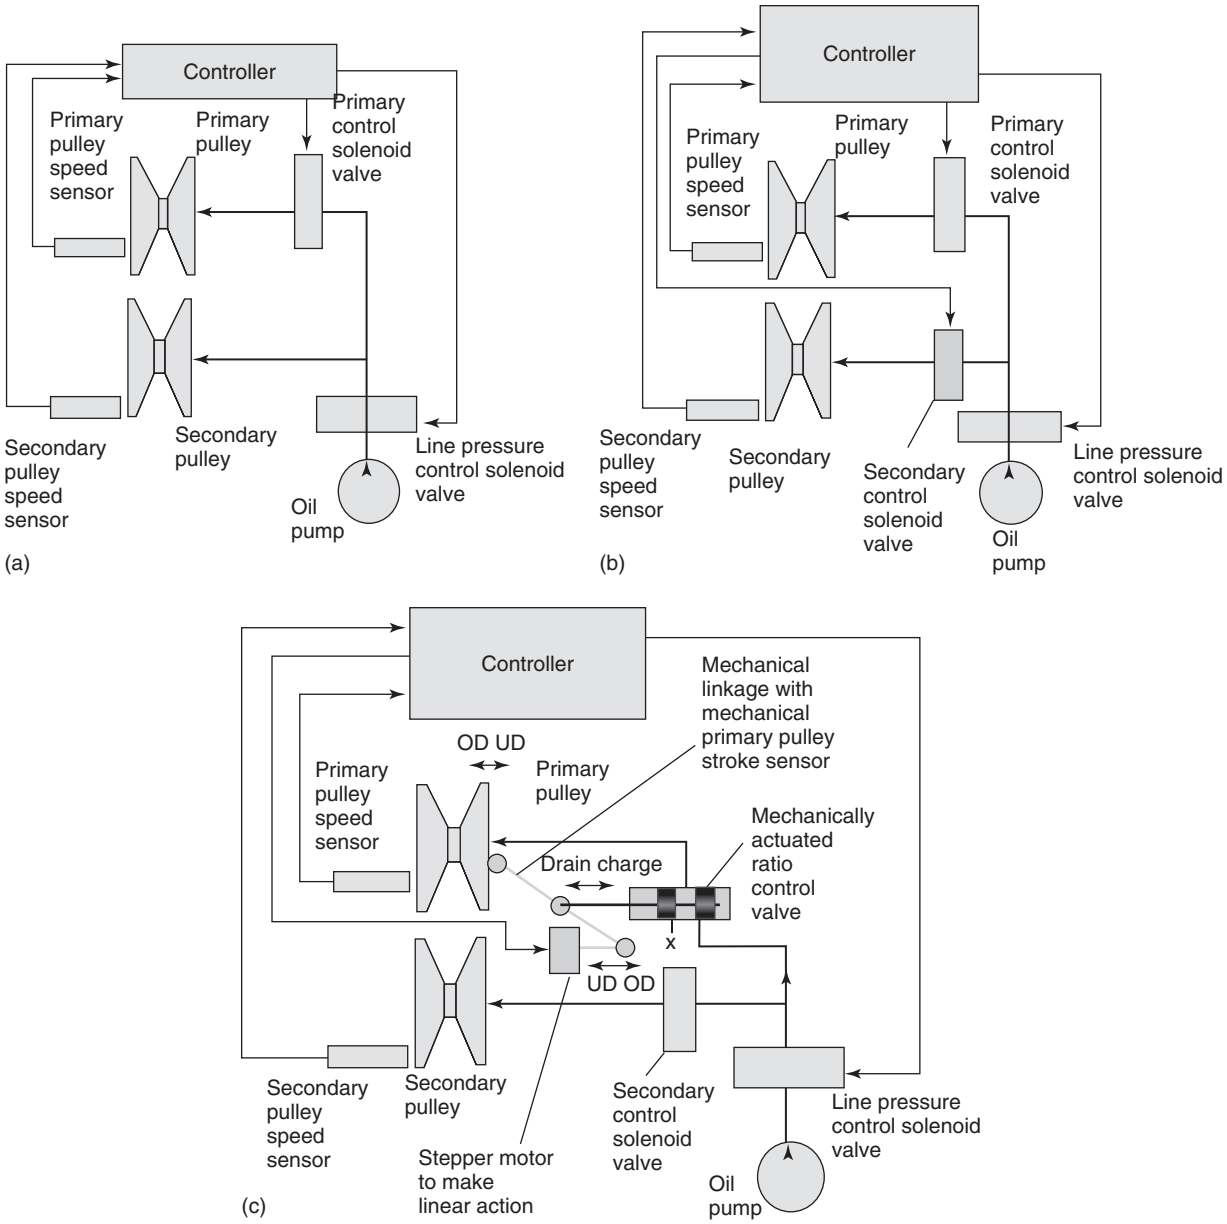

Figure 4. Various hydraulic systems for CVT ratio changing control. (a) Direct control system (primary control system). (b) Direct control system (dual control system). (c) Stepper motor and ratio control valve system. (Reproduced by permission of Jatco, Ltd.)

In CVT development, ratio speed change and accuracy are evaluated, as they have a large influence on vehicle response and drivability. Figure 5a shows various evaluation points for shift control performance. Various values are measured to evaluate the difference between target and actual ratios.

Rapidness of ratio changing is a critical evaluation point because it sets the requirement for oil pump capacity, and size of hydraulic channels and valves. These factors can influence space and cost issues as well as oil pump loss issues, which is a very important factor for fuel economy.

Figure 5b shows the explanation. Because pulleys are actuated by hydraulic flow and pressure, high capacity pumps, large valves, and flow channels need to be provided to ensure rapid response of the pulley system. The most severe operating condition need to be evaluated to determine those specifications. Kick down acceleration or rapid deceleration conditions often becomes the most severe condition.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto211
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 5c shows such an evaluation test example. At some defined vehicle speed, the driver presses the brake pedal strongly to give a rapid slowdown condition. With poor system performance, the speed ratio change will lag to the vehicle deceleration rate, and the subsequent relaunch of the vehicle will have slower acceleration because of not having completed the shift and achieved the required UD ratio. Usually, the result of such an evaluation requires a larger pump, and the designer often realizes a trade-off conflict between fuel economy and pick-up performance immediately following a slowdown event.

To solve such a trade-off situation, many ideas have been invented and are being studied. For using an electric motor--driven pump or loading cam, there are two approaches. Figure 5d shows another idea of reusing hydraulic power and flow. In shifting, oil flows from one pulley to another and can be controlled via a switching valve.

4 SHIFT SCHEDULE OF CVT

Figure 6a shows a typical shift schedule of a CVT. It is different from that of automatic transmission. The vertical axis is primary pulley speed instead of throttle opening. Throttle opening is a parameter; if throttle opening is held constant, primary pulley speed will move along the throttle opening line during acceleration. If the throttle pedal is kicked down, the primary speed will increase according to the established shift schedule. Multiple throttle opening shift lines can exist between OD and UD lines. Within this area, designers can make any line freely because a CVT can make any speed ratio between OD and UD. In a torque converter lockup condition, the primary pulley is equal to the engine speed; therefore, shift schedule decides engine speed changing behavior directly.

5 CVT RATIO CHANGING CONTROL STRATEGY

In CVT shifting control, prevention of the rubber band feeling is important. Figure 6b explains the meaning of "rubber band feeling." When a driver steps on the throttle, the CVT makes a rapid ratio change and the engine speed will increase rapidly. However, a too rapid engine speed increase provides a bad feeling to drivers, like both ends of a rubber band. Only engine speed increases, but vehicle speed does not increase concurrently and vehicle acceleration does not happen during this engine speed increase because of engine inertia consuming available output torque. After engine speed goes high, acceleration will come down. That feeling is really like stretching a rubber band. In making shift schedules and shift controls, software is often improved to avoid such rubber band feeling.

Figure 6c shows the improved control. Engine speed rising up is restrained by the control to enable earlier vehicle acceleration. The vehicle response feeling becomes much better. Furthermore, vehicle speed increasing with the increasing engine speed brings a good feeling to the driver as if the vehicle is really accelerating well. By such a control approach, linear acceleration feeling can be enjoyed by the driver.

Theoretically, such acceleration is not the fastest acceleration, but this control approach provides a better feeling to the driver. Therefore, such an approach has become very popular and is adopted by many CVTs.

Some CVTs adopt another shift schedule approach as shown in Figure 7a to obtain good acceleration feeling similar to an AT. In this control, the CVT makes ratio changes like a step AT. Rhythmical engine speed rising and falling repeatedly brings a sporty and active feeling to the driver. Such control is effective especially at wide-open throttle conditions. Therefore, usually, such an approach is adopted for wide-open throttle acceleration only. For light acceleration conditions, first priority is put on fuel economy in the shifting control strategy.

For best fuel economy, the first priority is the good operation point of the engine. As is shown in Figure 7b, the CVT control makes speed ratio adjustments to achieve the optimal operation point of the engine as much as possible. Because the CVT can make continuous speed ratio changes, it can adjust better than any stepped transmission. That is one reason why the CVT has fuel economy benefits compared with the step AT.

Another reason why the CVT has a fuel economy benefit is that an earlier lockup of the torque convertor can be employed. Torque converter lockup control can be made at lower vehicle speeds, just after launch. Therefore, the energy loss at the torque converter is less in a CVT. In step ATs, such an early lockup leads to hard NVH (noise, vibration, and harshness) issues when the driver steps into the throttle at low speed. However, in a CVT, it can make rapid ratio changes to avoid NVH issues. Such early

DOI: 10.1002/9781118354179.auto211
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

lockup control is one of the important strategies in CVT control.

Much longer utilization of fuel cut control is one more benefit of CVT. Figure 7c shows the explanation of the strategy. During deceleration, fuel can be saved by adopting fuel cut control by the engine controller. By continuous precise speed ratio adjustment ability of CVT, engine speed can be kept to a high enough level beyond the fuel recovery limit where engine stall would occur. By controlling its speed ratio continuously, a CVT can make a much longer fuel cut duration than a step AT.

In such a deceleration condition or on a downhill road, the CVT can automatically adjust engine braking. Figure 7d shows the strategy of automatic engine braking adjusting control. By detecting unusually large accelerations compared with a normal flat road, the controller can detect a downhill condition. Steepness can be calculated by watching vehicle acceleration, and adequate speed ratio can be determined by the CVT controller. On a steep downhill road, large engine braking force is obtained by shifting to more low, and on a slight slope downhill road, slight engine braking force is obtained by shifting less low. Here again, the benefit of CVT is smooth ratio changing. The CVT controller can provide a very slow ratio change at the beginning of automatic engine braking adjustment. If a step AT controller makes a similar automatic engine braking control, a sudden shift down will be occur and downshift shock will happen.

6 OTHER RATIO CHANGING CONTROL OF CVT

The automatic engine braking control described earlier is one of the adaptive control features of a CVT. There are many other adaptive control features, similar to those of a step AT control, which were described in Article 5.7. For various road conditions and characteristics of driver

operation, various shift schedules can be determined by the computer. Figure 8a shows an example of a block diagram of an adaptive shift schedule control.

Manual shift control can also be adopted, similar to a step AT. Figure 8b shows a typical manual shift schedule of a CVT. In such a manual mode, speed ratio is kept at the same value until another shifting change signal comes. Like a step AT, the CVT controller changes the speed ratio step by step.

For such a manual shift mode, quick response to shifting switch operation is very important. From this standpoint, the CVT system has theoretically a good feature. Figure 8c explains that in detail. When shifting is executed, the engaging clutch of a step AT has to make clutch stroke at first. On the other hand, the CVT can begin shifting immediately after deciding ratio change is desired. Therefore, theoretically initial response is different. CVT does not have an initial lag by clutch stroking like a step AT, so the CVT provides a quick manual shifting system. Gear ratio selection is free; therefore, in a CVT, making 8 speeds, 9 speeds, or manual shift control can be easily realized.

In manual mode, some protection control must be adopted. For example, engine speed will not go into overspeed zone, as automatic upshifting will occur. When vehicle speed decreases to a point at which the engine may stall, automatic downshifting will occur. This is also effective for the next launch to obtain enough driving force.

As is described in Article 5.7, the switch for manual mode has a lot of possibilities. However, the basic concept is exactly the same as an AT providing a +SW (steering wheel) and −SW is popular. Sometimes, a SW or paddle shift levers are provided.

The CVT has another benefit when the driver makes shift commands very frequently; that is, the CVT can make repeated shifts as frequently as the driver's commands without lag time, because there are no friction clutches making frequent disengagements and engagements, causing friction material heating issues.

7 ENGINE AND CVT INTEGRATED CONTROL

As is similar to the description of AT-integrated control in Article 5.7, engine and CVT-integrated control is often adopted. Engine control participates in adaptive controlling. Figure 8d shows an example of such an integrated control. Here, the engine throttle opening is controlled to provide optimal driving or deceleration forces for downhill or uphill driving. Another integrated control is engine torque control during up shifting or down shifting. As for step AT control, engine torque control helps engine speed changing during shifting.

8 CVT CLAMPING FORCE CONTROL

Clamping force control is important for both fuel economy and reliability of belt system. As shown in Figure 9, there

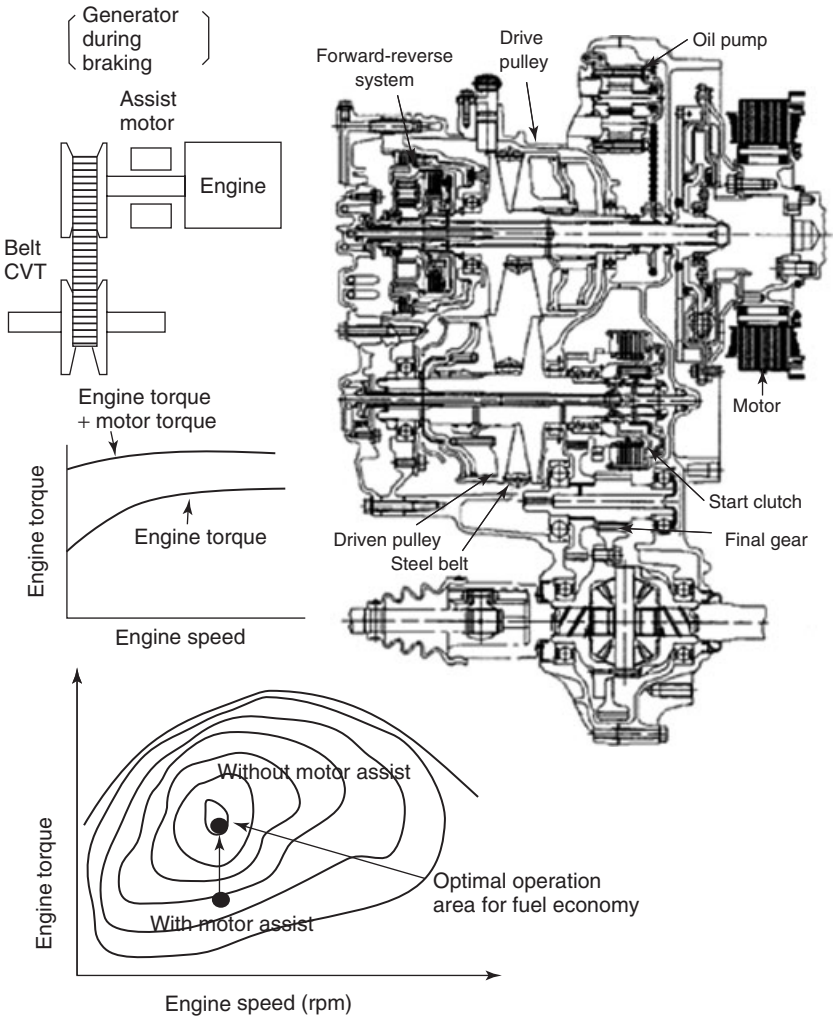

Figure 10. Honda CVT ratio changing control for HEV. (Reproduced by permission of Honda, Japan © Honda Motor Co., Ltd.)

are several contacting surfaces in a belt and pulley system at which friction loss is generated. The loss will increase as clamping force is increased. Therefore, clamping force should be kept as low as possible. On the other hand, torque transmitting capacity is related to clamping force, so clamping force needs to kept high enough to transmit torque without the risk of belt slip. That is trade off of clamping force control, if clamping force is not high enough, belt slipping will be caused. In actual CVT control, some margin is adopted on hydraulic pressure to provide enough clamping force to prevent belt slip. Engine torque signal is used for the clamping force control, along with the hydraulic pressure sensor. If hydraulic pressure cannot be achieved for some reason, the CVT controller will request the engine controller to reduce torque output. The clamping force should also be increased during engine braking because braking torque is added to the belt and pulley system. The CVT controller can detect various situations and make various control adjustments to keep optimal clamping force.

9 CVT CONTROL IN HEV SYSTEM

To obtain excellent fuel economy in a hybrid electric vehicle (HEV) system, a CVT is very effective in obtaining optimal operating condition. Figure 10 shows the Honda HEV system that has an electric motor and a belt CVT system (Ota and Eguchi, 2007, p. 183). The electric motor will act as power assistance during acceleration or as a generator during deceleration. In this system, motor torque and the CVT speed ratio are controlled to obtain optimal engine operating condition for achieving good fuel economy. For example, during slight acceleration, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

motor assist torque is not generated to make the engine torque higher as is shown in the figure. Thereby, the engine operation condition is moved to go into optimal operation area. CVT speed ratio is adjusted to obtain the driving force that the driver demands, and keeps these engine and motor states.

Honda is also adopting motor and engine integrated control. Motor assist torque is generated to make engine torque higher during high acceleration. During low speed cruising, the engine becomes idling and the valves of the engine stops their movement to reduce pumping losses, and only the motor torque is used for the vehicle driving.

10 CONTROL FOR CVT WITH AUXILIARY SHIFTING SYSTEM

Recently, a CVT with an auxiliary shifting system has been released to the market. Figure 11 shows the structure of this CVT (Nakagawa, 2012, pp. 23–30). It has a 2-speed shifting mechanism in D range. By adopting that system, ratio coverage has become much wider than a conventional CVT and pulley size has become smaller, thereby enabling weight reduction and stirring loss reduction because of fewer rotating parts in the oil sump. In this CVT, up shifting of the belt pulley system and down shifting of the auxiliary shifting system are simultaneously controlled.

Figure 11 shows such a simultaneously shifting control. At the same time the auxiliary shifting system makes an up shift, the CVT variator system makes a downshift. Therefore, the driver does not notice any ratio disturbance at this shift point. By this control, a continuous shifting feeling can be maintained.

11 CHAIN CVT CONTROL

Up to this section, the belt CVTs have been used for the explanation for CVT control because the belt CVT is the most popular system. However, there are other

popular CVTs that use a chain system. Figure 12a shows a typical chain CVT, which is also described in Article 3.5 (Englisch, 2010, pp. 139–151). This is Audi Multitronic®.

Figure 12b shows a variator component supplied by LUK. A chain is used instead of a steel belt. The chain has pins and the end of pins is in contact with the surface of the pulleys. Basically, the control approach is similar to the belt CVT. Clamping forces of pulleys are controlled to affect speed ratio changes. Because the contact between pin and pulley is completely different from the contact between belt element and pulley of steel belt, clamping force characteristic is not same as Figure 6.

Figure 12c shows the difference between the characteristics of a belt CVT and that of a chain CVT. Of course, the calibrator of the chain CVT has to be aware of this difference. As is shown in Figure 12b, the guide rail is used to reduce the string vibrations of the chain.

The LUK variator system adopts several unique hydraulic controls. Figure 13a shows the hydraulic system. The cylinders to obtain basic clamping force and to adjust the ratio changes are separated from each other. The ratio change control is achieved by the adjusting pressures 1 and 2. As the figure shows, the adjusting pressures are applied to the small cylinder of the pulley.

To achieve a rapid ratio change, it is best to have such a small chamber that responds rapidly because of reduced oil flow demand.

On the other hand, basic clamping force is obtained by the clamping cylinder as is shown in the figure. The applied clamping pressure is very important, for the fuel economy, because the oil pump loss depends on the clamping pressure magnitude.

To adjust and obtain optimal clamping pressure, the torque sensor system is used. Figure 13b and c shows the system. The torque sensor system consist ball, ramp, and a clamping pressure control orifice. The clamping pressure is adjusted by the orifice in order to apply the adequate pressure values according to the input torque.

The dual stage torque sensor control systems reduce the clamping pressure in OD as is shown in the Figure 13b.The oil passage for OD is open to exhaust when the pulley moves to the OD position, and the clamping pressure is then provided by another pressure chamber, thereby reducing the pressure value. In the OD pulley position, the clamping pressure will be reduced as is shown in the figure.

Figure 13c shows a further advanced system. The variable torque sensor control consists of balls and variable ramps as is shown in the figure. Clamping pressure is adjusted and reduced continuously as is shown in the figure. The clamping pressure is lower than that of dual stage torque sensor systems, thereby better fuel economy can be achieved by this system.

12 CONTROL OF TOROIDAL CVT

In Article (see Traction drive CVT), the toroidal principle and related techniques have been described. Here, control of the toroidal will be explained.

Figure 14 shows a cross section of a toroidal CVT and its schematic model. It is the first toroidal CVT model that was sold in the market. In this CVT, clamping force for the power roller was provided by a loading cam (Shimanaka *et al*., 2001; Hibi, Sumi, and Takeuchi, 2002; Kawaguchi

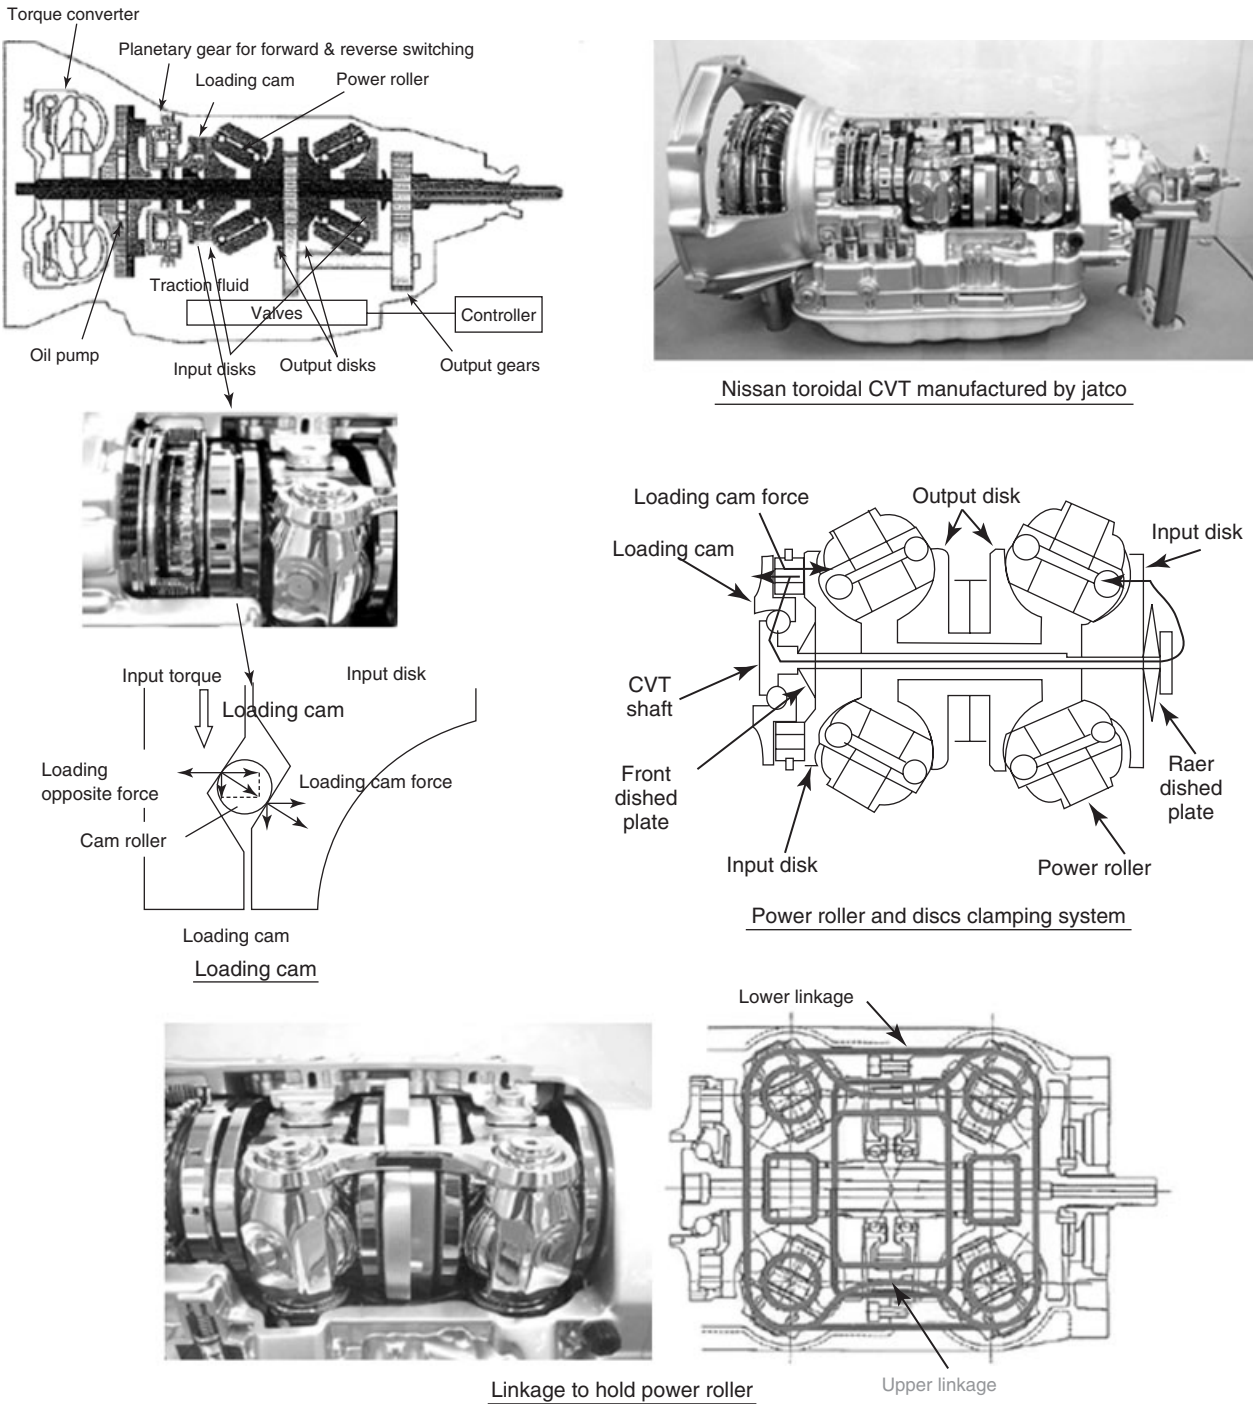

Figure 14. A cross section of a toroidal CVT and its schematic model. (Reproduced by permission of Jatco, Ltd.)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

et al., 2000; Toyoda, Imanishi, and Inoue, 2010, pp. 67–72). Figure 14 shows the loading cam profile and its picture. When engine torque comes from the engine, the loading cam converts that torque and makes an axial force to obtain provide force for the discs and power rollers. As is shown in figure, this axial force is transmitted through the CVT shaft, and all power rollers and discs in the two cavities are clamped by the same force. Therefore, in this system, high hydraulic pressure as with the belt CVT is not necessary. Clamping force can be generated

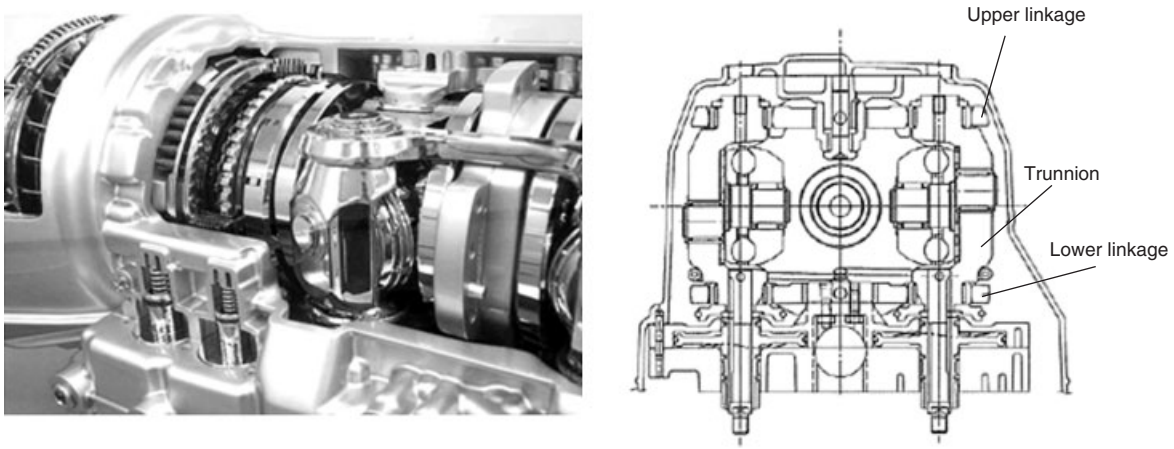
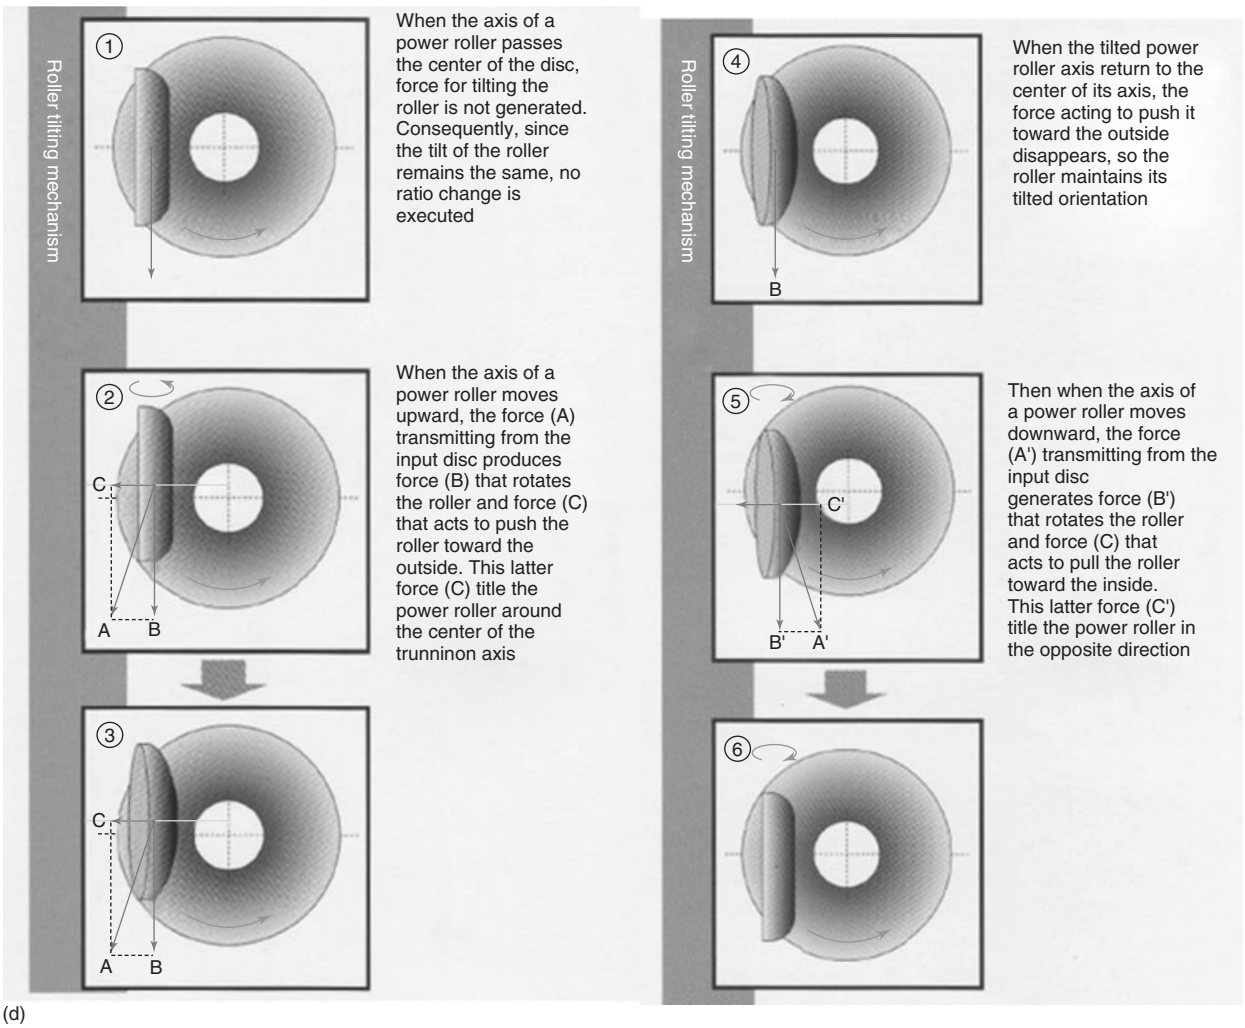
mechanically. Here, as is shown in Figure 14, linkage provides assistance for keeping the four power rollers in position.

Ratio changing control of toroidal CVT is slightly different from belt CVT control. Tilting trunnion control is adopted. Figure 15a shows roller and disc contact and



(c)



(d)

Figure 15. (*Continued*)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto211
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 15b shows the control system. The trunnion is moved up and down by hydraulic pressure. A hydraulic actuated piston is installed as is shown in Figure 15c and these pistons move trunnions up and down during shifting as is shown in Figure 15d. The detail control is indicated in the figure. When light movement up or down is made to the trunnion, self-rotating force in a caster action to rotate the axis of the power roller is caused at the contacting point between the power roller and the disc, because the contact point is moved slightly from the rotating axis. As the power roller makes a self-rotating behavior, ratio changing rapidness is sufficiently fast Figure 15e.

ACKNOWLWDGMENTS

The author wishes to thank Mr. Andreas Englisch and Dr. Markus Baumann from Schaeffler Group LUK Gmbh & Co.oHG, Mr. Akihito Oohashi, Mr. Yorinori Kumagai from Honda R&D Co., Ltd., and Prof. Nicolas Vaughan for their very helpful advice to improve the contents of this subscription, and also would like to thank all colleagues in JATCO and JATCO US.

Historical Overview of Electronics and Automobiles: Breakthroughs and Innovation by Electronics and Electrical Technology

Mitsuharu Kato
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

This chapter describes the relationship between automobiles and electronics. Figure 1 shows an outline of this history.

1.1 Vehicles (Casey, 2008)

The fledgling automotive technology that sprung up in Germany in the 1880s took shape as an industrial product in the form of the Model T Ford released in 1908, which went on to sell a total of 15 million units. According to Ford's internal records, the Model T was the first vehicle to be mass produced on a conveyor belt. This was state-of-the-art production line technology for the time and its basic premise is still in use today. In contrast, however, cars have completely changed. In 1908, cars were made up entirely of mechanical parts. Soon after, light bulbs began to be used in headlamps, and starter motors were introduced. Subsequently, automotive technology remained based on mechanical systems, supplemented by a small range of traditional electrical technologies, such as light bulbs, the starter, battery charger, battery, and spark plugs. At the time, the term *electronics* referred to vacuum tubes. By today's standards, the production of 15 million vehicles is an astounding feat and demonstrates the impressive evolution of mechanical engineering since the industrial revolution.

1.2 Semiconductors (Shockley, 1950)

The first practical semiconductor devices were invented in 1947, 40 years after the Model T. William Shockley was responsible for confirming the characteristics of diodes and amplification. Although already known based on solid-state physics and quantum mechanics theory, the practical verification of these characteristics was a major turning point. Soon after, p-type and n-type semiconductors were combined to form a rectifying diode, and the first transistor with an amplification function was developed. These new devices were achieved as a result of the advances in solid-state physics and quantum mechanics research that occurred in the twentieth century. In 1958, the integrated circuit (IC)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto212
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

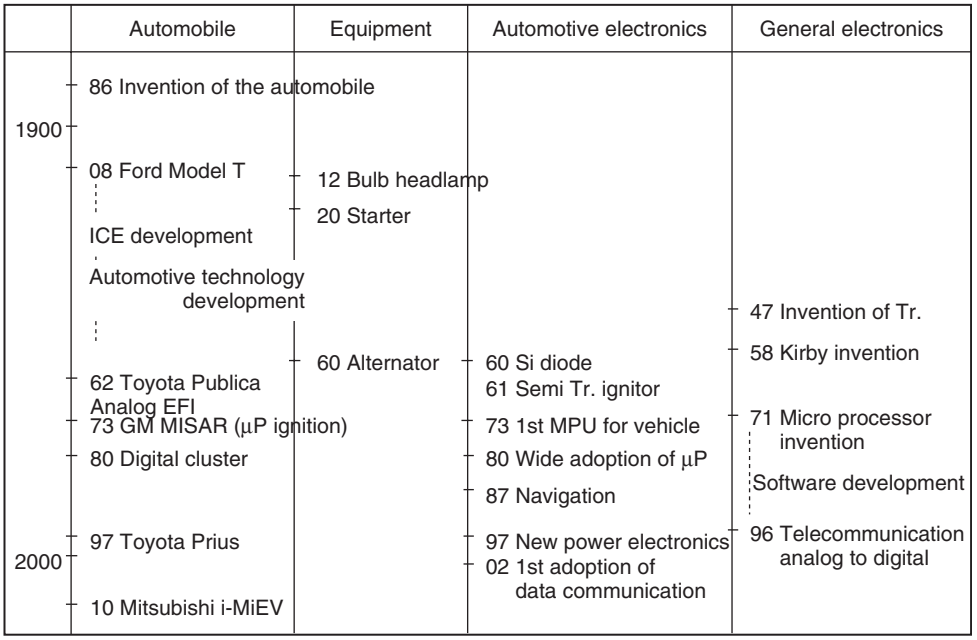

Figure 1. Automobiles and electronics (history). (Reproduced with permission from Kato, 2010 © Denso Corporation.)

that used multiple transistors was invented and patented by Jack Kilby. This invention heralded the launch of analog and digital ICs. The semiconductor device invented by Shockley in 1947 was the bipolar transistor, which used the amplification effect of a p-n junction. This was followed by the development of analog and digital ICs that used bipolar devices, which combined pnp and npn transistors. Operational amplifiers consisting of these devices in combination represented a major breakthrough as the basic components of analog ICs. In comparison to bipolar transistors, the practical application of metal-oxide-semiconductor (MOS) transistors took time due to the instability of the MOS interface. However, once these characteristics were stabilized, the simplicity of the MOS structure enabled large-scale integration (LSI) devices to enter mainstream use. Since then, the number of transistors mounted on a single IC has increased exponentially. Figure 2 shows the upward trend of device integration. As described by Moore's law, integration has roughly quadrupled every three years. This has been accomplished by the development of increasingly fine semiconductor manufacturing technologies and innovations in device structures.

1.3 Fusion of megatechnologies in the twentieth century

The vehicle is an example of a megatechnology, that is, a product in which many technologies intertwine to create a new easy-to-use technology that has the potential of helping realize the dreams of its users (Kato, 2010). As vehicles became more and more widespread, exhaust emissions created issues such as pollution, typified by the infamous smog of Los Angeles. The emissions regulations that were introduced in 1980 could not be met by conventional technology, and depended on the development of electronics, another megatechnology of the twentieth century. Figure 3 shows the principle configuration of the system developed at the time to meet these regulations.

The configuration shown in the figure is required to ensure complete combustion by optimizing the air/fuel (A/F) ratio and ignition timing, providing feedback control through O_2 sensors, and the like. This system is not entirely electronics-based. It also utilized the evolution of materials technologies such as three-way catalysts and the feedback system shown in the figure to greatly reduce emissions. It is no coincidence that the accelerated global spread of the automobile was sparked by the practical application of semiconductor technologies and the collaboration between automotive mechanical and electronics engineering to meet such regulations. This system may only represent a tiny step forward by today's standards, but it would have been unfeasible without the contribution of electronics. In this way, the negative effects on the global environment caused by the mass production and popularization of cars from 1910 were halted by the advent of electronic controls. These controls that overcame the limits of mechanical technology became feasible through the 1970s up until

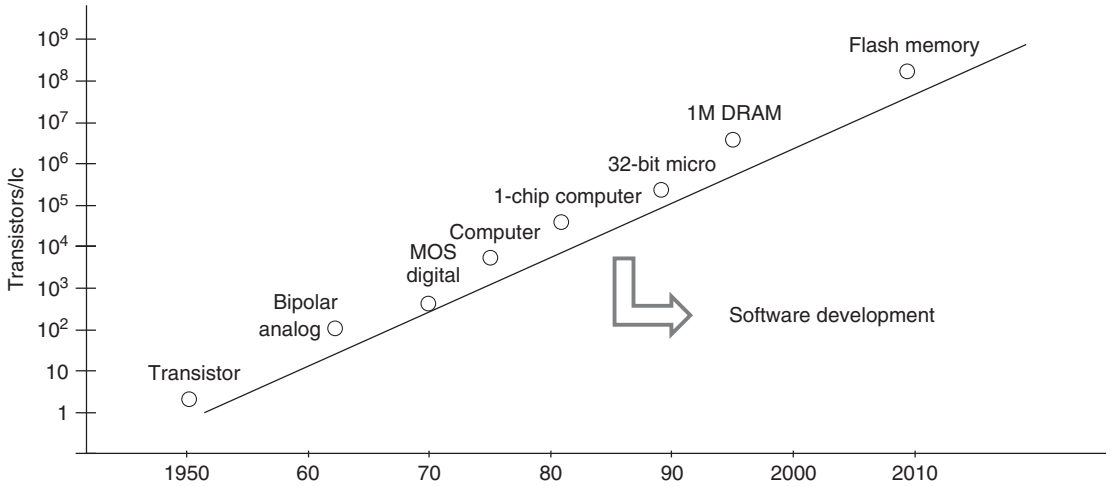

Figure 2. Integration trends.

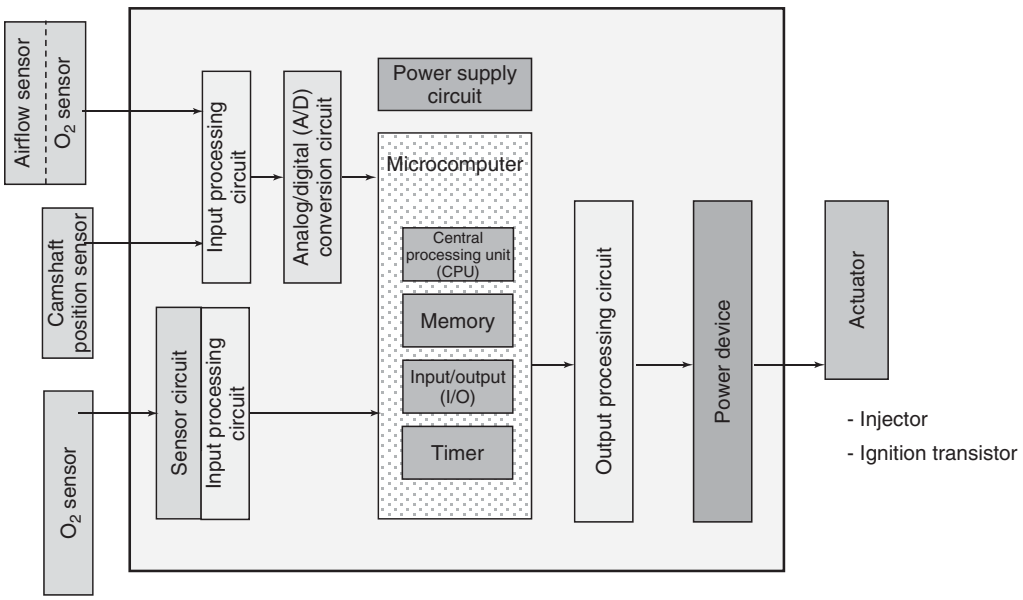

Figure 3. Basic ECU configuration.

around 1980. Modern electronics can be seen as a product of this era, in which solutions were presented to meet such regulatory requirements. This was the trigger for full-scale application of electronics to automobiles, and it inspired the development of various vehicle controls and products. In this era, the megatechnologies of automobiles and electronics finally came together.

2 ADOPTION: INITIAL PERIOD

The invention of semiconductor diodes enabled the development of solid-state rectifiers, which was a significant breakthrough because it allowed the adoption of more efficient alternating current (AC) generators in place of direct current (DC) generators. Figure 4a shows a rectifying diode. The principle of the rectifying function has not changed in the last 50 years. As shown in Figure 4b, the first transistors were used for ignition. Conventionally, a mechanical contact was used to shut off the current of the ignition coil. However, the high voltage generated by the coil would cause an arc, which limited the size of the generated voltage. Transistor ignition was capable of shutting off the current without using a contact. It enabled the generation of higher voltages and resulted in the development

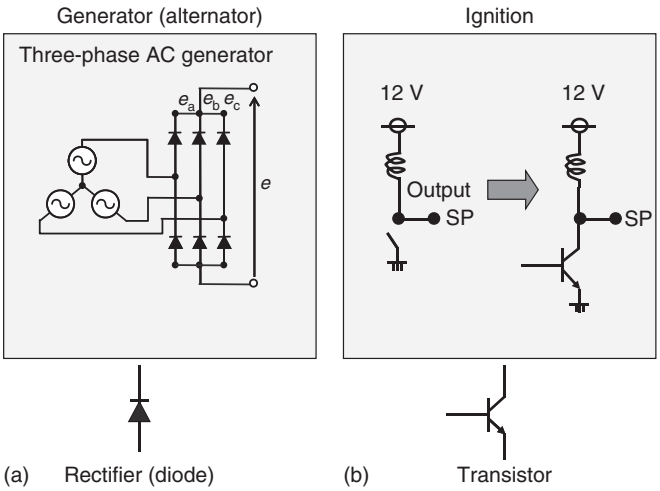

Figure 4. (a, b) Initial period of diode and transistor development (beginning of 1960s).

of gasoline engine ignition systems with high combustion efficiency.

2.1 Adoption to electronic fuel injection (EFI) (Manger, 1998)

The popularization of electronic circuits through analog circuits and analog computers, which combine operational amplifiers and make use of their functions, started in household appliances. However, when this trend began in the 1970s, such circuits were quickly adopted in vehicles as well. The first full-scale adoption of electronic circuits was in A/F ratio control systems that measured the amount of intake air in a gasoline engine with an airflow sensor and determined the optimum amount of fuel to be injected. This had been conventionally performed by mechanical systems that used the principle of atomization by a carburetor. In these systems, an amount of fuel commensurate to the airflow was mixed in the manifold and dispatched to the cylinders. In contrast, electronic control enabled the cylinder to combust the correct A/F ratio for the intake air volume. A/F ratio control was a major breakthrough because it allowed the calculation and control of engine conditions beneficial to ignition and torque output. The configuration of this system is shown above in Figure 3. Even today, the basic engine control unit (ECU) configuration of sensors, control circuits, actuator drivers, and a power source has not changed. Sensor signals include inputs such as the crankshaft, airflow, air temperature signals, and the like. This system controls parameters, such as the time that power is applied to the injectors, to determine the amount of fuel injection. Initially, this control used analog control ICs. Digital control was introduced after the invention of the microcomputer.

2.2 ECU development (Numazawa, 1998)

The development of a practical microcomputer opened the floodgates for the application of electronics to cars. Figure 5 shows the history of this application. Meter and body system microcomputers started to be adopted from around 1980. The first utilization in meter systems was in the form of digital meters that used fluorescent display tubes. Subsequently, higher performance systems started to be used as liquid crystal meters became more available. One particular use of high performance microcomputers was for

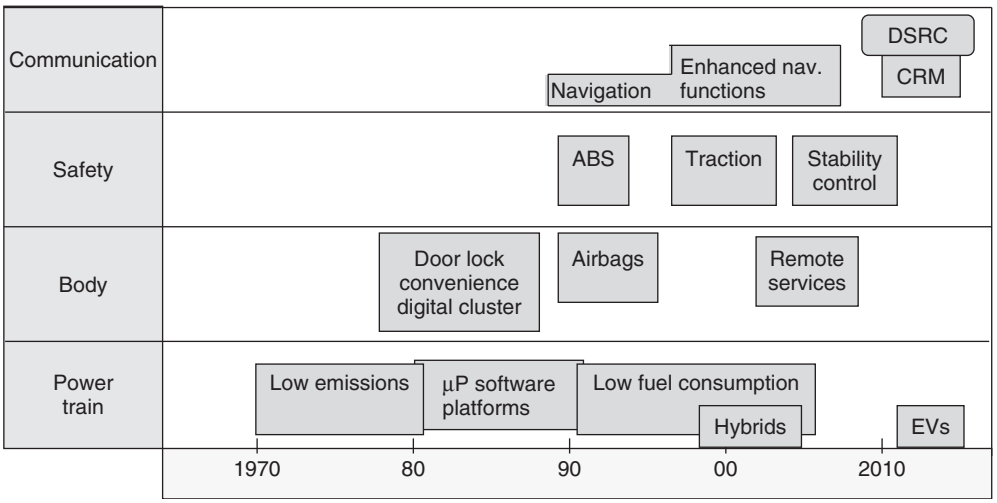

Figure 5. History of automotive electronics.

DOI: 10.1002/9781118354179.auto212
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

information display. Later in the 1980s, microcomputers were adopted in safety controls. This started with seat belt interlock functions, and then spread to airbags and antilock brake systems (ABSs). The development of these systems at this time all depended on microcomputer technology.

3 MICROCOMPUTERS

Intel developed the first 4-bit microprocessor in 1971. The first automotive application was in GM's MISAR ignition control system in 1973, which used a 10-bit microprocessor. In Japan, 12-bit microcomputers were used in fuel injection systems. Although the microcomputers invented by Intel are now available in 4-, 8-, 16-, and 32-bit configurations, the first microprocessor was only available in anomalous 10- and 12-bit configurations. This was because the performance of a general purpose microcomputer was insufficient. These anomalous bit lengths were adopted to increase calculation speeds through the use of integrated instruction and data sets. Although use of these 10- and 12-bit microcomputers was limited, the same basic configuration is still present. In particular, the free running timer and compare register configuration has become a basic circuit block for real-time control. A significant breakthrough was the use of special timers to compensate for inconsistencies between the microcomputer calculation speed and the speed required for control. The use of such circuit blocks to reduce the load of the microcomputer remains unchanged today.

3.1 Microcomputer configuration

The first microcomputers required various externally attached parts, such as ROM, RAM, I/O, and the like, centered on a CPU. A watchdog timer was also required to prevent microcomputer overrun. Modern microcomputers are now realized on a single chip with in-built ROM, RAM, I/O, and program monitoring functions.

3.2 Various types of microcomputer

In addition to fields that depend on control speed, microcomputers have also been developed to meet needs for programmability and diversity. One dominant example is the 1-bit microcontroller (see the image and configuration in Figure 6). The 1-bit microcontroller was cutting-edge technology when the cost of 4- and 8-bit microcomputers was too high for use with single functions and developers were consolidating peripheral parts onto a single chip. Although the 1-bit configuration limited their coefficient of performance, these microcontrollers could be used to control event chains in single bit increments. As a result, these were ideal for monitoring and controlling door

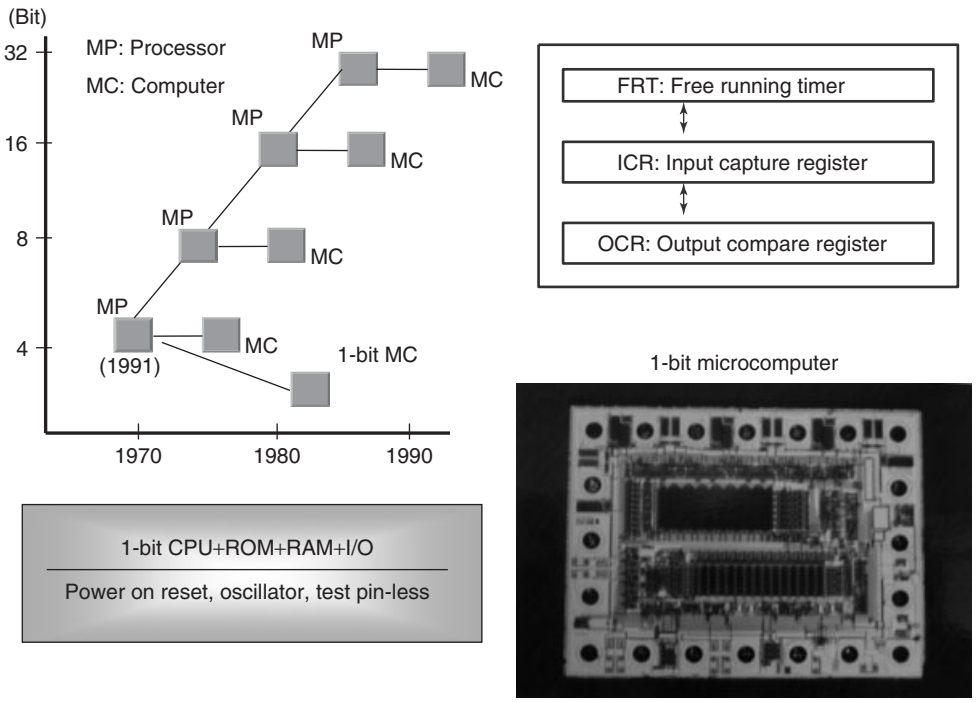

Figure 6. Microprocessor history.

opening/closing and switch on/off functions. 1-bit microcontrollers consolidated all peripheral parts onto a single chip and have evolved into today's embedded microcomputers. Mainstream microcomputers have adopted 16- and 32-bit configurations. Innovations unique to the automotive industry such as easy-to-program architectures and free running timers mean that the automobile has created a separate field of microcomputers.

4 ECU CONFIGURATION AND HARDWARE

Although the configuration of ECU hardware has not changed from that shown in Figure 3, the shape of functional parts has changed greatly in accordance with the cyclical changes of semiconductors. Figure 7a shows that early ECUs used printed circuit boards with through holes, which were used to attach parts such as capacitors, resistors, and ICs packaged with leads. The ECU in Figure 7a uses three analog ICs. Subsequently, parts become more compact and devices were mounted directly onto the surface of the circuit board. Excluding connectors, these boards had no through holes (Figure 7b). This figure shows an ECU with a 32-bit microcomputer. The vast increase in parts mounted on the circuit board is easily noticeable. As the performance of microcomputers increased, vehicles began to use the latest microcomputer technology.

4.1 Features of on-board ECUs (Kato, 2010)

The defining feature of automotive ECUs is their harsh operating temperature range, which may reach as high as 125°C in the engine compartment and fall as low as −40°C in winter. This is vastly different from the operating temperature range of household appliances. Figure 8 lists the features of automotive ECUs. To operate in these conditions, although ECUs in the occupant compartment use conventional printed circuit boards, ECUs in the engine compartment tend to use ceramics. Actuators have been integrated onto electronic circuits from the start, and devices used with ceramic circuit boards have adopted a bare chip configuration. In particular, systems such as generators and ignition devices that have always been installed in the engine compartment adopt special packaging. One of the characteristics of automotive ECUs is the high recovery rate of defective parts. As shown in Figure 8, if a defect occurs in the market, a system has been developed that returns the defective ECUs to the manufacturer through the dealer. This enables the location of the defect to be identified and helps understand issues, particularly

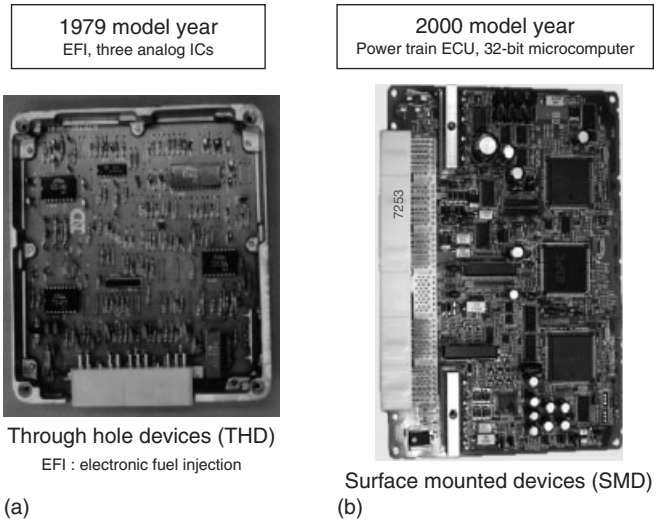

Figure 7. (a, b) Photographs of ECUs.

with semiconductors. Lessons from these steps have been reflected in improved semiconductor structures and manufacturing methods. As a result, this system has also been applied to household appliances as well as automotive semiconductors, thereby greatly helping improve the quality of the semiconductor industry as a whole.

4.2 Electromagnetic compatibility (EMC) and noise of on-board ECUs

One of the consequences of the proliferation of automotive electronics is the increase in the number of noise sources (Kato, 2010; CISPR 12; CISPR 25; ISO7637-1; ISO7637-2; ISO11451; ISO11452). As indicated in Figure 9, typical noise sources include radio frequency noise from the ignition system, surges, and electrostatic discharges. Power wiring voltages vary from 4.5 V used by 12-V systems when the starter is in operation to 17 V. Signal wiring may generate overvoltages of 200 V or more when switching parts with embedded inductance. Therefore, during ECU design, diodes and the like must be provided to protect electronic components from malfunction or breakage due to voltages transmitted through power or signal wiring. In recent years, the amount of high frequency noise emitted from ECUs has increased as microcomputer operation has speeded up. This is a potential cause of audiovisual (AV) system malfunction. Another major issue is ECU malfunction due to a reduction in signal levels caused by greater semiconductor integration. These issues are referred to as *electromagnetic interference (EMI)* and *electromagnetic compatibility (EMC)*, respectively. Measures for EMI include reducing the strength of electromagnetic

(1) Operating environment conditions
- Operating temperature range:
  −40°C to +85°C or +125°C
- Humidity: 60% to 90% RH
- Vibration resistance

(2) Traceability
- First-in first-out system on ECU production line
- Lot control of ECU production line
- Lot control of parts
- Supply chain control of parts
- Recovery system for defective ECUs
- Analysis system for defective ECUs
- Feedback to improve part quality

(3) 100% nondefective parts and the building of quality with responsibility
- Guarantee of 100% defective-free parts
- Adoption of systems to build quality with responsibility in ECU production (i.e., that prevent defective parts from moving to the next production process)

Figure 9. Sources and effects of ECU electrical and radio noise.

wave emissions as a part of electronic circuit design. EMC is a potential case of electronic circuit malfunction, and robust design measures are required to prevent electromagnetic interference. Various international test standards have been established with respect to these issues. Figure 10 shows some relevant examples. EMI and EMC will play an increasingly significant role when improving the performance of electronic products in the future.

5 SEMICONDUCTOR SENSORS (INA, 1988)

Semiconductors have another critical role in electronic systems as sensors. A glance at early electronic fuel injection (EFI) control shows that the airflow sensor played a key part. Rudimentary airflow sensors measure the angle of a damper to gauge the airflow. These evolved into sensors that measured the Karman vortex and then into the indirect measurement of intake air by monitoring the manifold pressure. The use of pressure sensors has greatly reduced the size of these systems. A dedicated semiconductor pressure sensor was developed to measure the manifold pressure, which signaled the start of the groundbreaking technique of semiconductor micromachining. The semiconductor sensor shown in Figure 11 uses the Piezo resistance effect. This provided the stimulus for the development of various sensors using different semiconductor properties (Figure 12). Semiconductors are now used in pressure, acceleration (G), photo, and magnetic sensors. Silicon plays a key role as the base material for micromachining. Angular acceleration sensors have

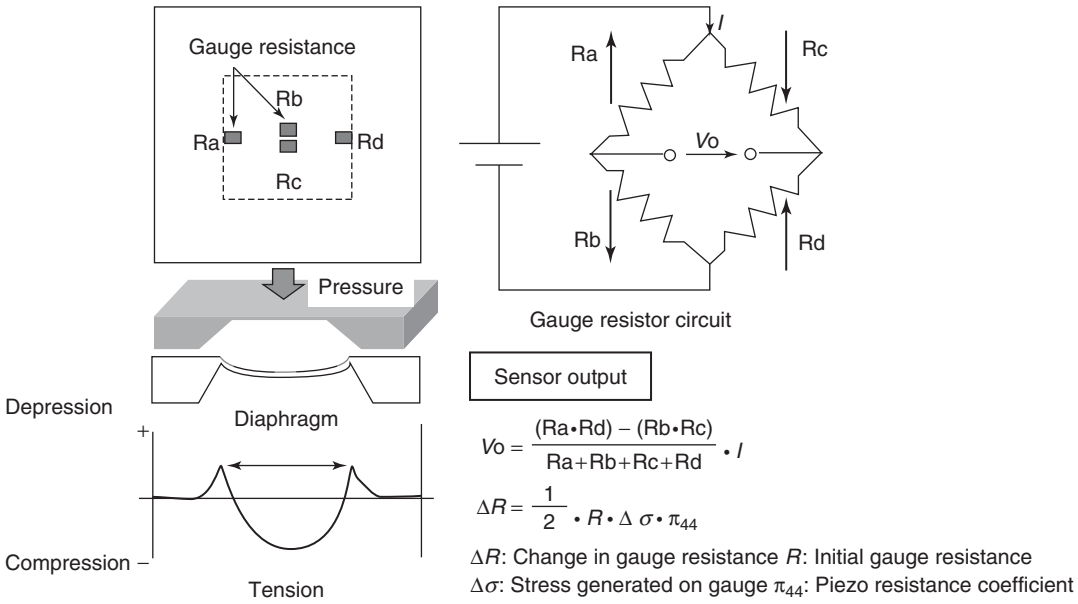

Figure 11. Pressure sensor. (Reproduced with permission from Kato, 2010 © Denso Corporation.)

also been practically adopted. Magnetic sensor devices that mount thin film magnetic resonance (MR) devices on an IC are a crucial part of proximity sensors that identify minute vector changes in magnetic fields. The feasibility of control systems depends on the enhancement of sensor performance as well as the microcomputer processing capability. For example, engine control systems are now capable of fine controls using linear sensors that monitor the oxygen concentration in emissions. Vehicle attitude control uses *G* and yaw rate sensors. The detection and control of states using sensors involves calculation by a microcomputer, and feedback of the results to actuator outputs.

6 SOFTWARE STORAGE PROGRAM MEMORY

The configuration of program memory has switched from mask ROM to EPROM, EEPROM, and electronically rewriteable flash memory. The usability of program memory has changed substantially. Writeable technology for program memory using masks required the details of the program to be determined a few weeks before the IC was packaged. Therefore, technology was developed to push the program writing step further back in the semiconductor manufacturing process to minimize the program creation lead time. The program still required four to six weeks,

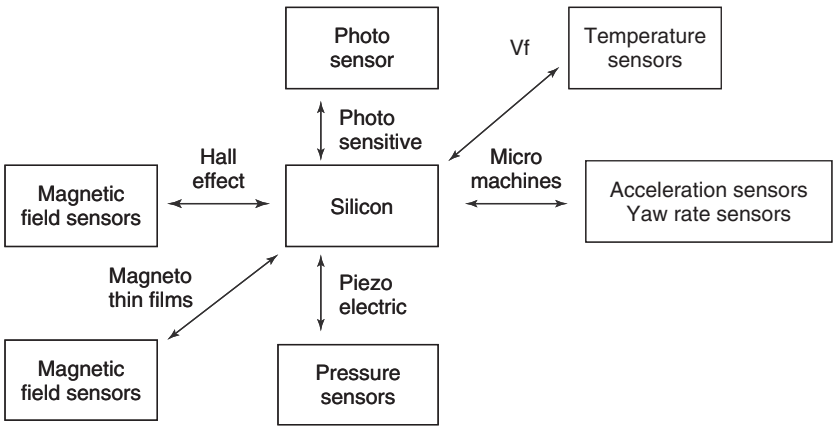

Figure 12. Semiconductor sensors.

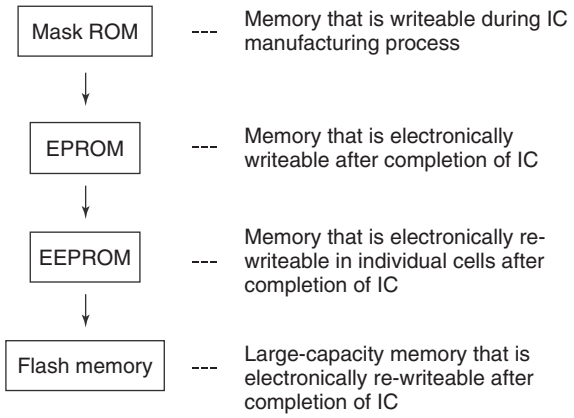

Figure 13. Program memory.

which became a major issue once software control became the mainstream control method. For this reason, the appearance of EPROM technology was a major breakthrough as it allowed the contents of the ROM to be electronically written. Electronic programming could then be set as the final step of ECU manufacture. Semiconductor technology continued to evolve and perfect the basic technologies for writing programs into memory electronically. Flash memory is a good example of this. It can be used to update ECU programs through a service connector while the ECU is mounted in the vehicle. This has helped further accelerate the pace of vehicle control development (Figure 13).

6.1 Importance of software technology

High performance ECUs that use microcomputers have given rise to new system controls, which have in turn spurred the development and introduction of even higher performance microcomputers. The scale of software has increased as a result of more sophisticated microcomputers and cheaper memory, making system controls more complicated. Consequently, the quality of software has become more important. Software program languages have evolved from assembly language to advanced languages such as C and C++. Programs now consist of between several tens of thousand to several hundreds of thousand lines of code. Advanced languages are a prerequisite for software creation productivity. Software developers are facing a growing burden, which means that software architecture is playing a more central role and a critical issue has become how to improve reusability rates. A capability to build architectures with individual software modules that have independent characteristics is the most important current issue for improving both productivity and quality. From a systems standpoint, detailed studies of control specifications are more important than ever, and software developers are driven by the need to build fault-tolerant systems (Figure 14).

7 ECU–ECU NETWORKS AND FUSION OF ECUS (KATO, 2010)

The number of wire harnesses (W/H) has increased in accordance with the spread of electronic systems. As a result, W/H weight and complexity is on the increase. This increase in W/H is the direct consequence of the importance of linking ECUs. Multiplex communication has also become more important as the number of W/H has exceeded 1500. Historically, ECU communication began with the controller area network (CAN) used by engine systems and spread with the adoption of J-1850 body control systems. More recently, low, medium, and high speed CAN systems have been adopted, and FlexRay has

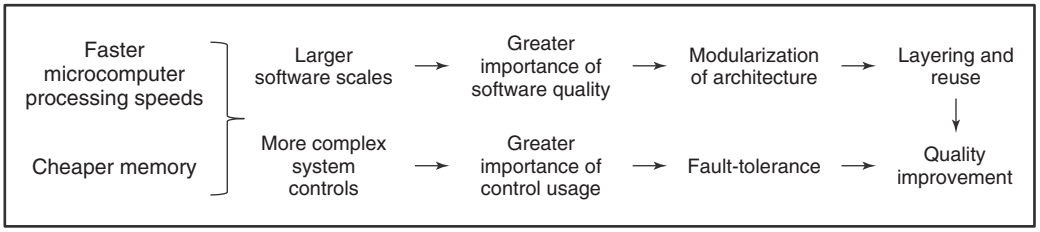

Figure 14. Software trends.

emerged as a feasible direction for sensor systems. Standard multimedia systems include Media Oriented Systems Transport (MOST). Although such systems are capable of eliminating several hundred W/H, increasing system complexity is causing the number of W/H to increase. ECU fusion is one basic method of suppressing system complexity and W/H increase. This aims to consolidate similar ECUs, thereby reducing their number as well as the connecting W/H. ECUs can be categorized into five main types: powertrain systems, chassis control systems, body systems, entertainment systems, and systems related to external information. However, the best way to consolidate each ECU type remains the key issue. Possible bases for combining ECUs include standard functions, differences in optional functions, and differences in development cycles. Furthermore, the growing popularity of hybrid vehicles is driving even greater ECU complexity by making control systems more complicated, further diversifying the information that must be communicated between ECUs, increasing the driving assistance functions that can be performed by connecting with external networks, and the like. The development of fault-tolerant systems is becoming even more crucial.

8 THE INFORMATION AGE (KATO, 2010)

In the 1990s, the application of electronic systems became further oriented toward information. Although the first navigation system was actually developed in 1987, the full-scale adoption of navigation systems began at the end of the 1990s. This was due to the spread of accurate position detection using GPS technology, the development of digital maps on compact discs (CDs), and the improvement in microcomputer performance. Figure 15 shows these trends. In addition, display technology was enhanced by the development of the liquid crystal display (LCD). As a result, it became possible to show other information rather than just maps on a multipurpose screen, such as information captured by rearview cameras.

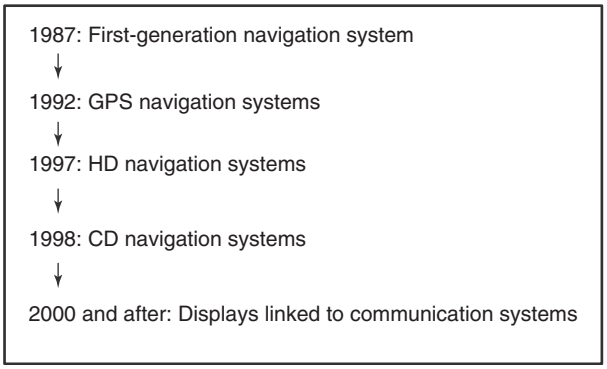

Figure 15. Information device trends.

The importance of multipurpose displays has increased further. The digitalization of communication has significantly speeded up rates of information transmission. As a result, communication technologies have become an indispensable aspect of vehicles in the 2000s. In addition to destination information as typified by navigation systems, emergency notification systems such as OnStar from GM and eCall from Mercedes have also been developed. Toyota's G-Book, Nissan's CARWINGS, and Honda's Internavi are other specific examples of enhanced communication systems. These developments highlight the growing significance of information communication in twenty-first century. Further progress will see the permanent connection of vehicles to communication systems and the adoption of more innovative communication applications.

8.1 The age of ITS

Improving the efficiency of communication, information, and traffic flow is a key part of modern vehicle development. Helping alleviate the congestion and negative environmental impacts caused by the popularization of the automobile and reduce the number of traffic accidents require comprehensive solutions. In the future, it is possible that automated vehicles will work as an ideal solution. Major short-term issues include reducing accidents by

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto212
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

alleviating driver burden and congestion avoidance. The navigation system plays an indispensable role in addressing these points. The identification of the vehicle's current location by GPS and vehicle speed sensors, and detailed maps that include traffic information can help guide the driver to target destinations, minimize congestion, and reduce energy consumption. Navigation software exceeds half-a-million lines of code, the most of all automotive systems. This field is likely to become even more important in the future to help improve usability and save energy, as well as to provide detailed road information and safety assistance.

8.2 Expansion of automotive communication technologies

Communication technologies will play an even more important role in the future. Radio waves, which were originally used for AM and FM radio systems, have also been adopted for remote entry systems and tire pressure monitoring systems (TPMSs), as well as for external communication functions such as the Vehicle Information and Communication System (VICS), electronic toll collection (ETC), and mobile telephones. Figure 16 shows the history and status of radio wave usage in Japan. Effective radio wave technologies have already evolved from AM modulation, FM modulation, time division multiple access (TDMA), and code division multiple access (CDMA) protocols. In the future, the long-term evolution (LTE) protocol is expected to be adopted. These advances have been made feasible by the greater integration and processing speed of semiconductor devices. In addition to helping boost the performance of microcomputers, the evolution of semiconductor technology has also contributed greatly to the advancement of communication technology, that is, the effective use of finite frequency resources. In the future, it is expected that 1-GHz broadband technology will become even more sophisticated and spread to vehicles by improving communication quality.

9 THE FUTURE OF COLLABORATION

Until now, control system ECUs and electronics have been able to overcome the limitations of mechanical technology. In turn, this has encouraged the evolution of mechanical systems, a synergistic effect that has accelerated the evolution of automotive controls. Figure 17 illustrates these trends. Taking ABS as an example, microcomputers spurred the evolution of hydraulic systems. Compact and high performance oil pumps were then integrated with electronic circuits, which have been further integrated with actuators. These systems have diverged from household applications where devices are mounted on printed circuit boards to form new derived technology. Packaging technology has advanced to the stage where devices can be mounted on ceramic boards with excellent heat resistance. Although this is only a single example, the growing complexity of controls is likely to require the development of even more

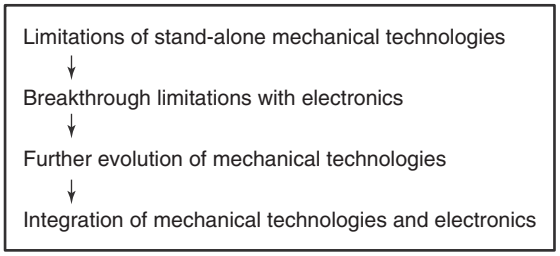

Figure 17. Collaboration trends (1).

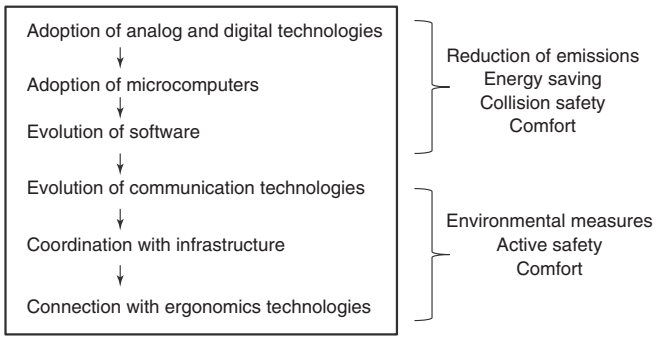

Figure 18. Collaboration trends (2).

unique technology. One possibility is the electronic correction and reduction of mechanical tolerances that exist in individual torque converters to improve the efficiency of automatic transmissions. It should be possible in the future to electronically adjust individual mechanical tolerances. This will require the integration of mechanical products and electronic circuits, which is dependent on the development of new packaging methods. Furthermore, although technology applications started with analog and digital technology, microcomputers have taken center stage and larger scale software has evolved. It is likely that wireless communication technology will become more advanced and find greater applications in the fields of environmentally friendly technology, safety, comfort, and the like. At the same time, this is likely to trigger further discussion about communication reliability. The introduction of CO_2 regulations as vehicles become even more widespread, safety concerns, and growing demands for active safety systems will usher in an age where image processing and recognition technologies, and technologies that incorporate aspects of ergonomics are as important as simple control systems. Figure 18 illustrates these likely trends. Thus, the role of electronics, software, and algorithms will continue to increase, placing even greater emphasis on collaboration between automotive and electronics technologies.

ECU Technologies from Components to ECU Configuration

Yukihide Niimi
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Since the 1960s, when the first radios and stereos equipped with transistors began to be installed in cars, electronics were seen very much as optional equipment. The full-scale introduction of electronics for vehicle control began in 1970 with the proposal of the Clean Air Extension Act (popularly referred to as the *Muskie Act* after its main sponsor, the United States Senator Edmund Muskie) to regulate harmful emissions (NO*x*, HC, and CO) from the engine. To comply with this Act, there was a trend for conventional carburetor fuel supply systems to be replaced with electronic fuel injection systems, which used injectors to control the amount of fuel injected into the engine intake system. This fuel system was controlled by an electronic control unit (ECU).

As electronic fuel injection systems became the mainstream means of supplying fuel, engine control systems began to evolve steadily. Initially, control simply judged the cleanliness of emissions to determine the optimum fuel injection amount. Once ECUs were introduced, automakers realized that various controls could be performed efficiently. Electronic circuits evolved from analog to digital (microcomputer control), and various controls were added to the engine ECU. These included ignition timing control, knock control, idling speed control, transmission control, and so on. At the same time, electronic control also spread quickly to functions such as the air conditioner, ABS (anti-lock braking system), and airbags.

Currently, controls are categorized in accordance with the field, such as powertrain, air conditioning, body, and dynamic and safety controls. There are many different control system variations within these categories. This chapter describes the internal structure and parts used in ECUs, using the engine ECU as a typical example.

2 ECU OUTLINE

Most car electronics contain an electronic control computer called an *ECU* (Kato, 2010a). This ECU functions to process inputs from sensors and the like to drive motors or other kinds of actuators. ECUs communicate with each other using the in-vehicle local area network (LAN). ECUs contain sensor and switch input processing circuits, analog–digital (AD) conversion circuits, microcomputers, a power supply, output processing circuits, and a communication circuit for interacting with other ECUs. The main components are semiconductors. Figure 1 shows a typical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto213
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

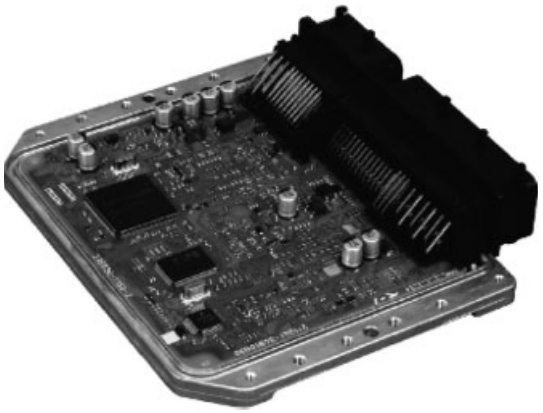

Figure 1. Typical ECU.

printed circuit board type ECU and Figure 2 shows the general functional blocks.

Each block in the ECU has the following roles. The power supply provides a stable voltage to each block (5, 3 V, and the like). It is connected to the battery (12 V) in the engine compartment. The power supply block must be highly accurate as it also uses the reference voltage of the AD conversion circuit (see below).

The input processing circuit converts digital input signals into signal levels that can be inputted into the microcomputers.

The AD conversion circuit (also known as the *AD converter*) converts analog input signals into digital values that can be inputted into the microcomputers. The microcomputers calculate the control amounts from each input signal and control the output signals in accordance with the results of these calculations. The output processing circuit converts the output signals of the microcomputers into signal formats capable of driving the actuators, amplifies voltages, and so on. The communication circuit contains a communication driver that converts data output from the microcomputers into communication signals that comply with communication standards. It also includes a communication receiver that converts signals transmitted from other ECUs into signal levels that can be input to the microcomputers.

3 ECU INSTALLATION LOCATIONS AND OPERATION CONDITIONS

3.1 ECU installation locations

The simple term *ECU* covers a wide range of ECU types that differ depending on the installation location. The structure of each ECU is designed in accordance with its installation environment (Kato, 2010b).

Electronic control systems comprise three types of devices: (i) an ECU that governs the system control, (ii)

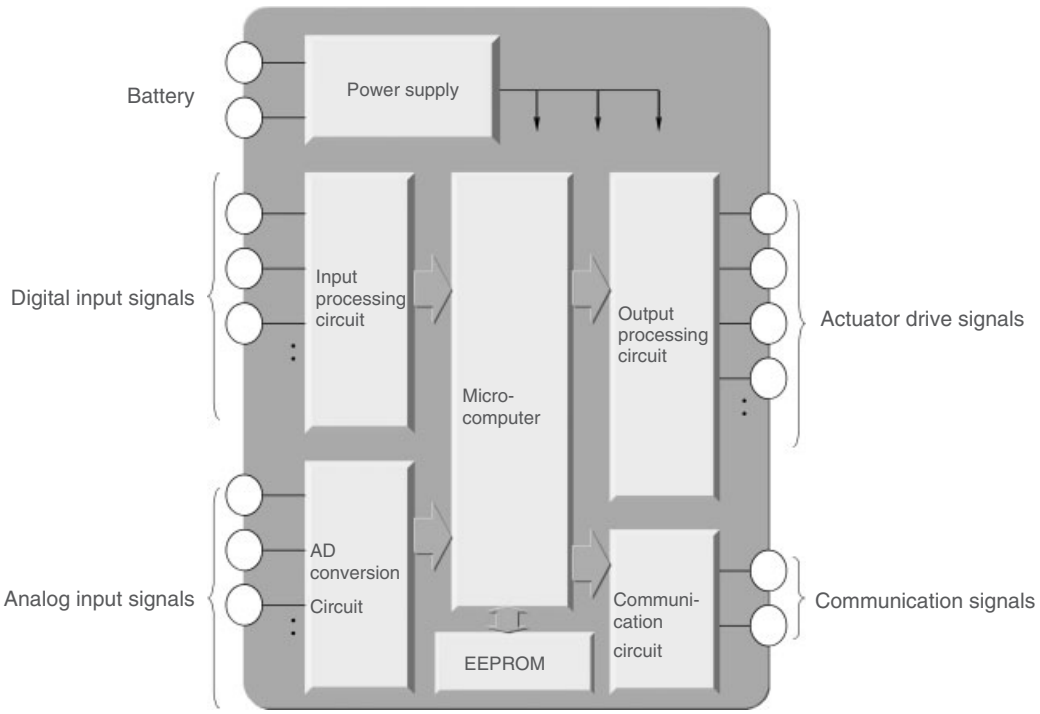

Figure 2. ECU functional block diagram.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto213

sensor groups that input the states and information relevant to the control into the ECU, and (iii) actuator groups that ultimately achieve the targeted control. Of these device types, the sensors and actuators have to be installed in certain locations to achieve the function. In contrast, the installation locations of ECUs have changed over the course of history. When the electrification of vehicles started, electronic parts were particularly vulnerable to heat, humidity, and vibration. For this reason, ECUs were installed inside the occupant compartment. Subsequently, as the reliability of circuit board-based electronic parts and packaging technology for electronic parts improved, it became possible to install ECUs inside the engine compartment, despite its severe heat, humidity, and vibration, and even directly attach ECUs to the engine itself. By making the appropriate considerations at the design stage, it is now possible to install ECU hardware anywhere in the vehicle. This is known as the *free-installation concept*.

However, ECUs, sensors, and actuators have to be connected together electrically using wire harnesses. It is clearly preferable to ensure that these wire harness connections are as short as possible. Short wiring lengths have the following merits.

- lower material costs, enabling cheaper wire harnesses;
- less copper used, enabling vehicle mass reduction;
- lower electrical resistance, enabling thinner wires to be used;
- less susceptibility to the effects of induced noise caused by wiring impedance, which is generated depending on the frequency of the signal. Shorter wires also emit less noise.

For these reasons, the transmission ECU is installed as close to the transmission as possible. In some vehicles, it may actually be installed inside the transmission itself. Furthermore, a growing number of electronic parts related to engine control are installed directly on the engine. Ignition induction coils are installed on the plug hole to minimize ignition noise by making the high voltage wiring as short as possible. Impedance is a restriction for the electric driver unit (EDU) that is used to drive the injectors in a direct injection gasoline engine, because of the large current flow and considering operation speed. Accordingly, these units are installed close to the engine in the engine compartment with as short a wiring length as possible.

The installation location is often determined from a functional standpoint. For example, acceleration (G) sensors are located in multiple locations throughout the vehicle in the airbag system. As the airbag inflator has to deploy multiple airbags, it is located close to the center of the vehicle. In addition, the navigation system display has to be in a position that is easily visible, which restricts its installation location. Recently, as electronic circuits become more compact, motor control circuits are becoming extremely small. These compact controllers are now being installed and integrated into the actual motors, further driving reductions in size. Car electronics are installed in locations that facilitate the target function. Installation methods are categorized in accordance with the installation location (Figure 3). Each installation

Typical maximum humidity exposure of automotive parts

Location	Maximum humidity
Engine compartment (close to engine)	38°C 95% RH
Seats	66°C 80% RH
Close to side doors	38°C 95% RH
Close to dash board	38°C 95% RH
Floor sheet	66°C 80% RH
Rear deck	38°C 95% RH
Luggage compartment	38°C 95% RH

Typical maximum temperature exposure of parts in engine compartment

Location	Maximum temperature (°C)
Engine cooler	120
Engine oil	120
Transmission oil	150
Intake manifold	120
Exhaust manifold	650
Alternator intake air	130

Typical maximum temperature exposure of parts in occupant compartment

Location	Maximum temperature (°C)
Top of dash board	120
Bottom of dash board	71
Floor	105
Rear deck	117
Headlining	83

Figure 4. Installation environments inside vehicle.

location has a different environment and ECUs are designed considering that environment. Figure 4 shows the typical environmental conditions of each installation location in a vehicle.

3.2 ECU operation conditions

Table 1 shows the different categories of operation conditions.

ECUs related to basic vehicle performance (the engine and dynamic ECUs) and ECUs related to occupant safety (the airbag ECU) operate under harsh conditions. In contrast, the operation conditions for the navigation system ECU are not set at the same level. This is because enabling an ECU to operate under harsher conditions than necessary generates excess cost and because the electronic circuits used in complex controls such as the navigation system are not yet able to operate in the harshest environments.

3.2.1 Operation conditions of parts used in ECU

Each part has different operating conditions (Kato, 2010b). Table 2 shows the temperature conditions for an electrolytic capacitor.

As the operation environment of automotive ECUs is harsher than those for home electronics, electrolytic capacitors are required to operate under more severe conditions. That difference is reflected in the higher purchase price.

Table 1. ECU operation conditions.

Application	Installation Location	ECU Type	Voltage (V)	Temperature (°C)	Vibration (G)
Engine	Engine compartment	Engine ECU	6–16	−30 to +95	4.4
Dynamics	Occupant compartment	ABS ECU	6–16	−30 to +80	4.4
Safety	Occupant compartment	Airbag ECU	6–16	−30 to +80	4.4
Body	Occupant compartment	Navigation system ECU	8–16	−30 to +80	4.4

Table 2. Operation conditions of electrolytic capacitor.

For Automotive Use		For Home Electronics

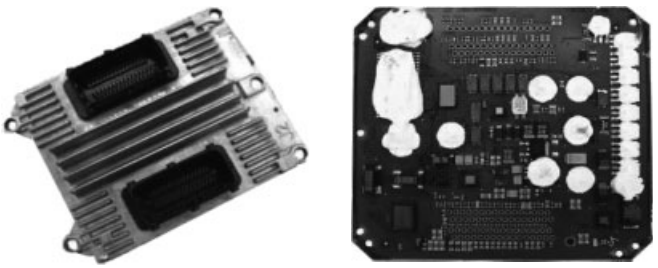
4 ECU EXAMPLES

4.1 Examples of printed circuit board-based ECUs

4.1.1 Engine ECU

The engine ECU is a standalone package and has only one internal control circuit board. As the number of control functions increased, some engine ECUs were developed with multiple boards. However, these functions have come to be collected together as integrated circuit (IC) devices, and modern engine ECUs have returned to a one-board configuration. Figure 5 shows an example of this type of ECU. It has a waterproof structure and its outside shape is designed to dissipate heat generated from the inside.



(a) (b)

The ECU case is provided with fins to improve heat dissipation. The white plastic portions in Figure (b) are made from a material called a thermally conductive gel, which is designed to improve heat transmission. These design points improve heat dissipation from the ECU and allow installation on the engine

Figure 5. Example of engine ECU. (a) Outside appearance of ECU. (b) Circuit board inside ECU.

4.1.2 Navigation system ECU

The navigation system ECU arranges components such as a display, DVD drive, and hard disc drive (HDD) in a compact package on the circuit board. Figure 6 shows a basic 2DIN type navigation system. Although it contains a built-in audio system and multiple circuit boards, the navigation system functions are collected on the same board. The navigation system uses a microprocessor with high functionality. To ensure efficient heat dissipation, a metal case is used that is punched with holes for ventilation.

4.2 Hybrid ECU

Hybrid ECUs are compatible with high functionality and large currents. In this type of ECU, bare chips are packaged on multilayered laminated ceramic circuit boards with high thermal conductivity. Figure 7 shows the example of a diesel engine hybrid ECU (Kato, 2010b). It contains a microcomputer, hybrid ICs, and power devices. Hybrid ECUs are usually adopted to meet requirements for size and weight reduction, and environmental resistance.

As shown in Figure 8, a hybrid ECU is structured with a control portion, power portion, large parts, and a connector. It uses multilayered laminated ceramic circuit control boards with high thermal conductivity, a bare chip type of chip scale package (CSP), conductive adhesive connections for the power ICs and chip parts, gold (Au) wire bonding, and silicon gel sealing.

Figure 9 shows an electric drive unit (EDU). A typical example of EDU application is as an injector drive controller. EDUs use a thick multilayered laminated ceramic circuit board. The ICs are bare packaged to help reduce the size of the circuit board. The largest parts on the

circuit board are the capacitors, which store accumulated energy for driving devices, and coils. EDUs are designed to be resistant against heat, vibration, and water. The bare chips are sealed in silicon gel to protect the bare packaged chips against the external environment.

5 ECU CONFIGURATION AND COMPONENT PARTS

5.1 ECU configuration

In broad terms, an ECU consists of a circuit board, a connector, and a case that protects these two portions from the external environment (Figure 10). Active, passive, and functional parts are arranged on the circuit board. Figure 11 shows the configuration of these parts. ECUs are increasingly being installed inside the engine compartment and on the engine itself, as well as in the occupant compartment. Figure 12 shows some typical examples of each.

5.2 Case

ECUs located inside the occupant compartment are open because water exposure is not considered likely. In contrast, ECUs installed inside the engine compartment or on the engine are designed with a waterproof case. The cases of ECUs attached to the engine are also designed to dissipate heat considering the harsh temperature environment. Most

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

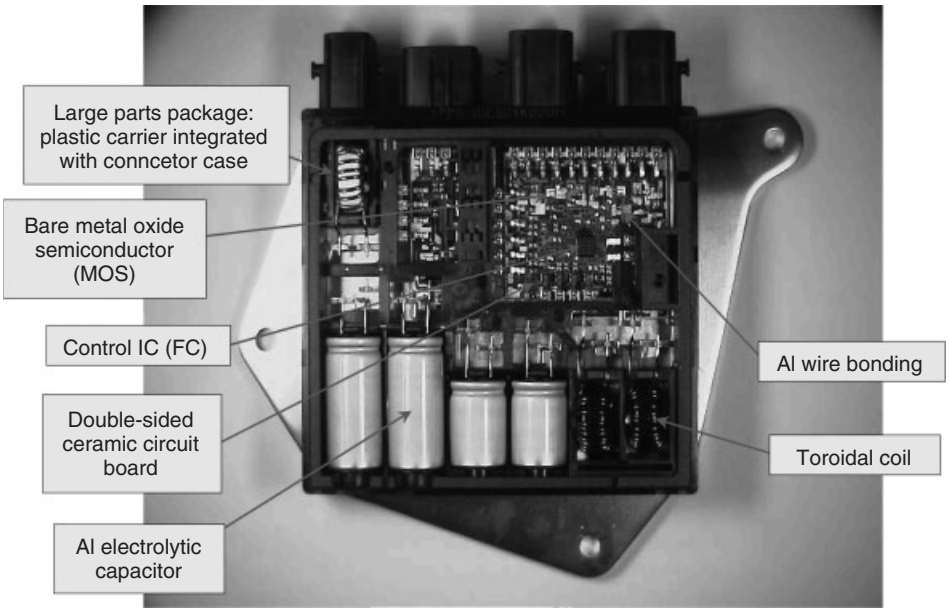

Figure 9. Electric driver unit.

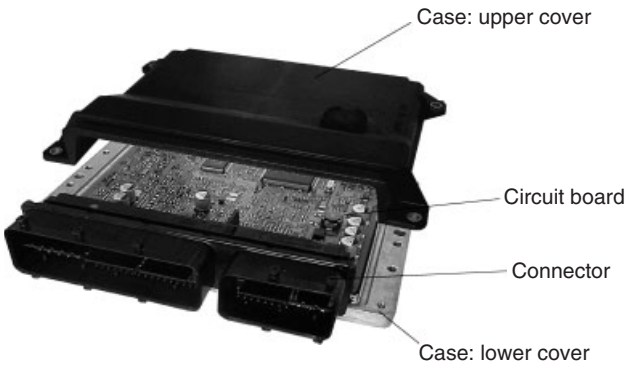

Figure 10. Configuration of typical ECU (waterproof type).

cases are configured in two sections with an upper and a lower part.

5.2.1 Non-waterproof case

The primary role of a non-waterproof case is to protect the circuits from the impact of external shocks. Non-waterproof cases that are not required to dissipate heat are often made of plastic. When heat dissipation (natural cooling) is required, metal cases are used, including Al die-cast, Al-stamped, and Fe-stamped cases.

5.2.2 Waterproof cases

Circuit assemblies in which the circuit board and connector are soldered together must be protected from water using upper and lower cases that have been designed accurately in accordance with the dimensional requirements. Accuracy is particularly required for the joining case surfaces, and shape around the connector, as these areas are closely related to waterproof performance. A waterproof sealing material is used to fill the gap between the cases. This material is generally a silicon gel with properties that do not change under temperatures as high as 150°C.

5.2.3 Waterproof type high heat dissipating cases

Cases installed in the engine compartment must be designed with resistance against heat, vibration, and water exposure. In addition to the waterproof design described earlier, the mechanical properties of the case material must be considered to withstand the vibration applied to the ECU from the engine. Most cases in engine compartment are also shaped to dissipate heat. This shape must be determined considering the surrounding airflow and recent developments use simulations to improve the efficiency of the shape design process.

5.3 Connector

Unlike conventional electrical products, which only have to perform a single function, ECUs are used for control based on signals measured by sensors with respect to a control target. ECUs identify the state of the control target, calculate the final control value with this built-in microcomputer, and transmit signals to drive actuators. Consequently, ECUs require a large number of signal

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto213
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

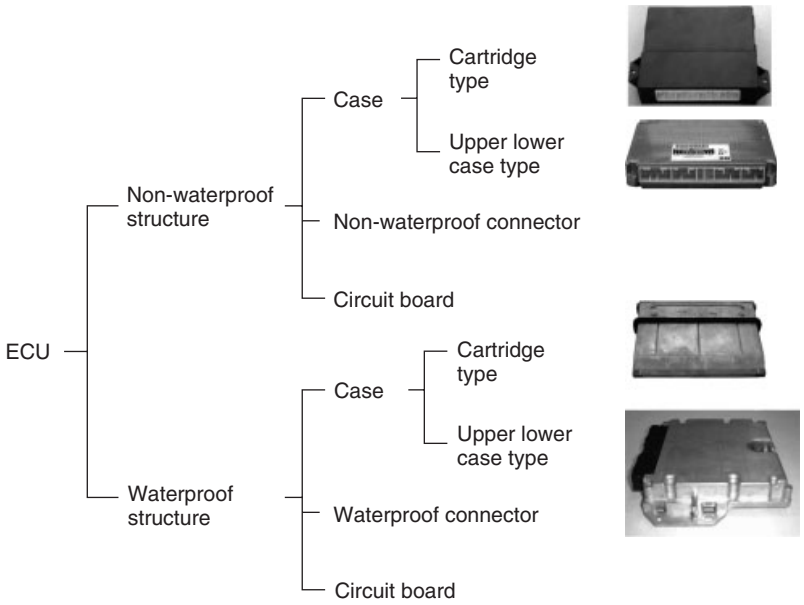

Figure 11. ECU component parts.

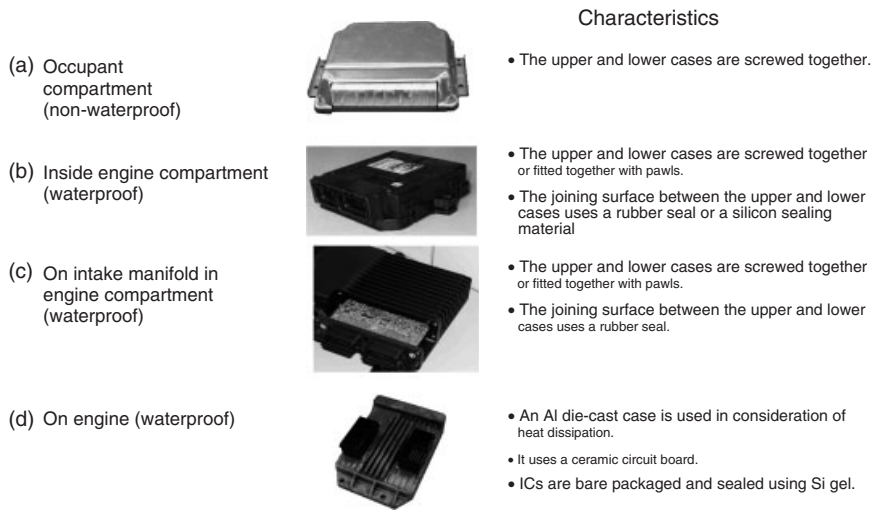

Figure 12. Appearance of ECU according to installation location.

terminals, such as sensor input terminals, actuator drive output terminals, power supply terminals, and terminals for communicating with other ECUs.

The part that collects these terminals into a single group is called the *connector* (Figure 13). The number of terminals in the connector is increasing as ECU functions become more sophisticated. Although advances in compact packaging technology have reduced the size of the circuit board, there has been no progress in making the connector smaller because of restrictions related to the diameter of the externally connected wires (i.e., the wire harnesses).

Waterproof and non-waterproof connectors are available. Waterproof connectors tend to be larger than non-waterproof connectors. Furthermore, non-waterproof connectors are divided into blocks of around 20 terminals. This is related to the maximum number of wires that can pass through a hole in the wall separating the engine and the occupant compartments (about 200). In contrast, waterproof connectors are designed with a split terminal layout, which is divided between wire harness groups used in the engine compartment and wire harnesses that transmit signals within the occupant compartment. In this

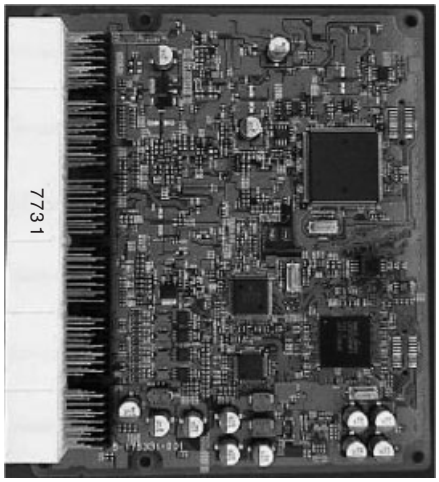
DOI: 10.1002/9781118354179.auto213
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5



Non-waterproof type connector

Figure 13. Connector circuit board inside ECU.

case, a 200-terminal connector often has two blocks of about 140 terminals for transmitting signals to the engine compartment and about 60 terminals for the occupant compartment. Figure 14 shows the housing (circuit board side) and plug (vehicle wire harness side) of a waterproof and a non-waterproof connector.

5.4 Circuit board

Figure 15 shows the two types of circuit board used in an ECU, which are fabricated from epoxy resin and ceramic, respectively. Circuit parts are installed on the circuit board and the packaging format of these parts differs greatly between the circuit board types. More specifically, IC parts are bare packaged on ceramic circuit boards because this type of board is more expensive.

The type of the circuit board also affects the forms of the packaged parts. The use of through-holes to package parts has given way to the use of surface mounted devices (SMDs). This is because electronic parts are becoming smaller because of constant demands to install more functions within a smaller case. The merits of SMD can be outlined as follows.

- Compared to insertion, eliminating the through-hole enables more efficient use of the circuit board surface, increasing the available area for packaging. Therefore, a circuit board with the same number of parts can be made smaller.
- The soldered portion of the through-hole can be eliminated, reducing the size of the soldering land pattern and increasing the density of the wiring pattern.
- Eliminating the through-hole simplifies the circuit board fabrication process, which helps to reduce costs.

5.4.1 *Epoxy resin printed circuit boards*

Automotive applications widely use laminated circuit boards (Japan Institute of Electronics Packaging, 2006) based on glass epoxy resin. This type of circuit board is widely categorized into through-hole circuit boards (double-sided, 4-layer, and 6-layer), blind via hole (BVH) circuit boards (a type of through-hole circuit board), and build-up circuit boards that have a build layer on both sides and a conventional layered structure in the center (Figure 16). Build-up circuit boards that have a single build layer on the sides and a core 4-layer center structure are called *1-4-1 build-up circuit boards*. Build-up circuit boards are used in the navigation system and other systems that require high functionality with dimensional restrictions, as well as parts where small size is important. 1-4-1 build-up circuit boards have also begun to be adopted in engine

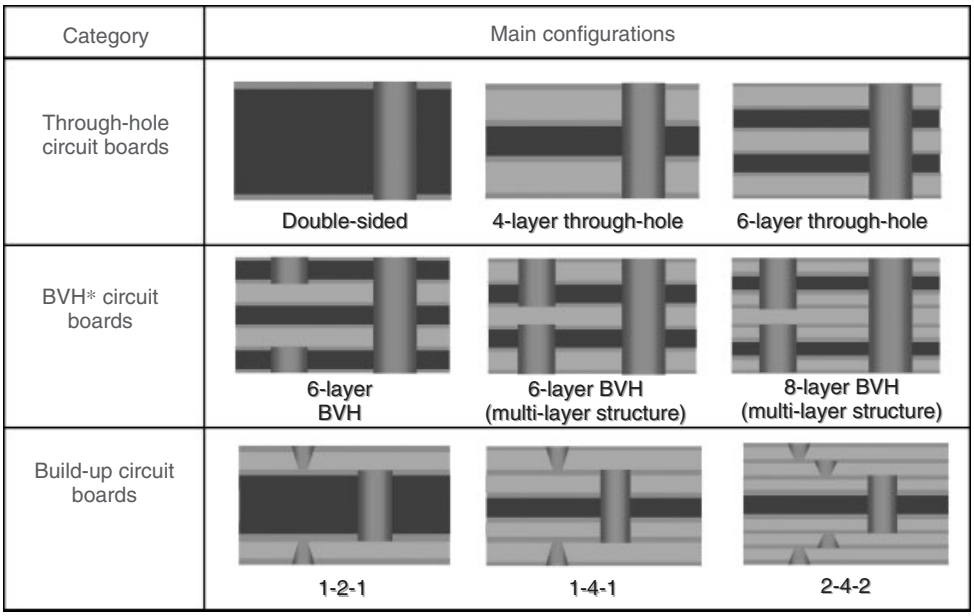

Figure 16. Categories and layer configurations of epoxy resin circuit boards.

ECUs installed in the engine compartment. Through-hole circuit boards are particularly widely used in ECUs that have severe restrictions on size.

5.4.2 Ceramic circuit boards

Types of ceramic circuit boards include single-sided, double-sided, thick multilayered laminated, and sheet-laminated. The type used depends on the application. Single-sided to thick multilayered laminated ceramic circuit boards are widely used in control circuit boards for driving actuators. These control circuit boards also include built-in power devices for driving the actuators, with an emphasis on heat dissipation performance and size reduction. Sheet-laminated circuit boards are used in ECUs that operate under harsh temperatures and vibrations, such as those directly installed in the engine. These circuit boards include bare packaged ICs such as microcomputers and power

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

devices. The configuration of sheet-laminated circuit boards is useful in achieving high wiring densities and size and weight reduction.

5.5 Categories of circuit parts

The parts (Japan Institute of Electronics Packaging, 2006) installed on a circuit board can be categorized in terms of function and shape. From the standpoint of function, these parts can be divided into general electronic and functional parts (Table 3). General electronic parts can be further categorized into passive parts, functional parts, connection parts, and conversion parts. Functional parts include individual semiconductors, ICs, and hybrid ICs. From the standpoint of shape, categories include inserted, surface mounted, and bare chip parts (Figure 17).

5.5.1 Inserted parts

These parts include axial lead parts, radial lead parts, irregular lead parts, and various types of packages, such as single inline packages (SIPs), dual inline packages (DIPs), and pin grid arrays (PGAs).

5.5.1.1 Axial lead parts. These parts have a transverse shape with two lead wires in the direction of the device. Lead wires are generally made of copper with a round cross section and use solder plating. These parts are inserted onto the circuit board and the lead legs are bent into an "L" shape. Typical axial lead parts include carbon film resistors, cylindrical ceramic capacitors, diodes, and so on.

5.5.1.2 Radial lead parts. These parts have a vertical shape with two or three lead wires protruding in parallel. Radial lead parts may be formed by processing the leads of axial lead part. As radial lead parts are created to match the pitch of the insertion holes in the printed circuit board, there is no need to bend the lead legs after insertion. In addition, the vertical shape of these parts means that a narrow interval can be set between leads, allowing denser packaging than with axial lead parts. More radial lead part types are available than axial lead parts, and these include Al electrolytic capacitors, transistors, ceramic filters, crystal oscillators, and the like.

5.5.1.3 Irregular lead parts. These are parts that cannot be categorized as either axial or radial lead parts. The shape, layout, and number of wires can be freely set, which means that there are various types of irregular lead parts. Typical examples include connectors, switches, variable resistors, and the like. Transistors and other devices that have an amplification action include ICs, power devices, and so on.

5.5.2 Surface mounted parts

These can be categorized into general electronic parts and active parts. General electronic parts can be further categorized by shape into flat, cylindrical, and irregular types. Flat parts are currently the mainstream type of surface mounted parts. Active parts can be categorized according to package type. These include mini-mold packages, small outline packages (SOPs), quad flat packages (QFPs), ball grid arrays (BGAs), and CSPs.

Table 3. Circuit part function categories.

Part Categories		Functions	Applications
General electronic parts	Passive parts	Controls voltage and current without changing the input signal characteristics	Resistors, capacitors, etc.
	Functional parts	Changes the input signal characteristics such as the frequency and time axis	Crystal oscillators, LC filters, etc.
	Connection parts	Mutually connects and switches parts and circuit devices	Switches, connectors, etc.
	Conversion parts	Converts input signals into different forms of energy	Speakers, sensors, etc.
Active parts	Individual semiconductors	Has active functions such as input signal amplification control, and memory. Standalone devices	Transistors, diodes, LEDs, etc.
	ICs	Collects and integrates multiple semiconductors.	Analog ICs, microcomputers, etc.
	Hybrid ICs	Collects active, passive, and film devices on a printed circuit board, and has active functions	Thick film hybrid ICs, thin film hybrid ICs, etc.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto213
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

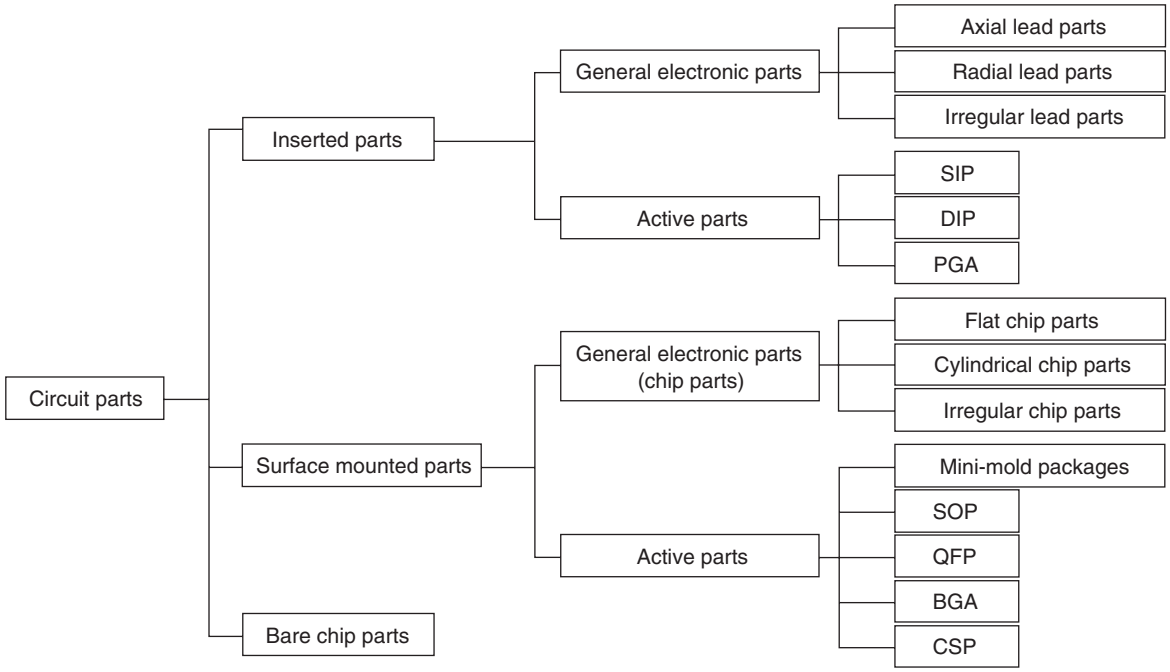

Figure 17. Circuit part shape categories.

5.5.2.1 Chip parts. Surface mounted general electronic parts are called *chip parts*. Flat chip parts are rectangular. These parts generally have no leads and have portions referred to as *terminals* that are located on the bottom or side surface of the solid shape. Fixed resistors, ceramic capacitors, laminated inductors, and the like use printed or laminated ceramics materials, which are formed to match the shape of the chip. These are formed into the flat shape by molding or enclosing the rectangular chip in a case. Typical flat chip parts include tantalum electrolytic capacitors, molded wound inductors, and the like.

Unlike flat chip parts, cylindrical chip parts have no directionality and can be used effectively in a package. However, the cylindrical shape is a disadvantage when packaging on a surface with various other parts. For this reason, there are not many parts with this shape. Irregular chip parts are those parts that are neither flat nor cylindrical. Typical examples include Al electrolytic capacitors, inductors, and the like.

5.5.3 Surface mounting semiconductor packages

5.5.3.1 Mini-molded packages. These packages enclose individual semiconductors such as transistors and diodes. The lead wires protrude to the outside of the package.

5.5.3.2 Small outline packages. SOPs are compact DIPs, with the leads processed for surface mounting. The lead pitch for automotive applications is between 1.27 and 0.5 mm, but consumer applications may have a lead pitch of 0.4 or 0.3 mm.

5.5.3.3 Quad flat packages. QFPs have lead wires that protrude in four directions from the package. QFPs are designed for high density packages with more leads than SOPs. The lead pitch for automotive applications is between 0.8 and 0.5 mm, but consumer applications may have a lead pitch of 0.4 or 0.3 mm.

5.5.3.4 Ball grid arrays and chip scale packages. Providing connection terminals for more than 500 pins on a QFP results in a large package. A countermeasure for this is to provide terminals on the back surface, opposite to the package front surface where the semiconductor devices are installed. The name BGA is derived from the round solder balls of these terminals. CSPs have the same structure as BGAs, but have a smaller package of virtually the same size as the semiconductor devices. CSPs attached with solder balls in the rewiring semiconductor fabrication process performed are sold under the names wafer process packages (WPPs) or wafer level packages (WLPs).

6 ECU AND MICROCOMPUTER TRENDS

6.1 ECU evolution

Figure 18 illustrates how ECUs have evolved. Figure 18a (Kato, 2010a) shows an electronic fuel injection device ECU with an analog circuit, which was used before the practical application of microcomputers. This is an analog ECU formed by discrete devices and used in 1973. This evolved into ECUs comprised of analog ICs, such as that shown in Figure 18b. This ECU is from the DIP era of ICs. Figure 18c is a digital engine ECU configured around a microcomputer. The custom microcomputers used in 1978 adopted software that was programmed using a 12-bit assembly language. The program used read-only memory (ROM), which was built in as a wafer during the microcomputer fabrication process. The photo shows the most complex engine ECU installed in 1983 models. Figure 18d is a modern powertrain ECU with two 32-bit microcomputers. Excluding the connectors, all the ECU parts used in 2006 were mounted on the surface. The software is written in C language. It uses flash memory and can read information from external terminals. As this shows, in addition to the scale of ECUs, the component parts, package shapes, and software languages have all evolved with the times.

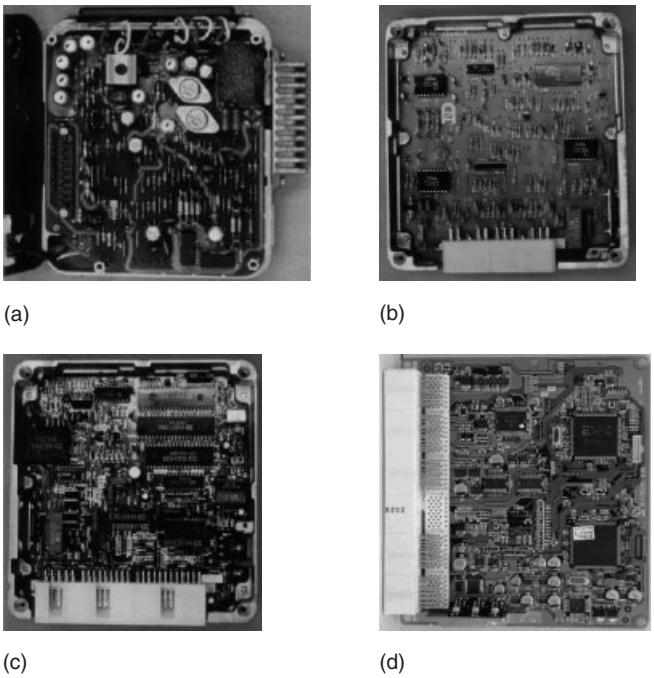

Figure 18. ECU evolution. (a) Analog ECU using discrete devices (1973 model). (b) Analog ECU using custom ICs (1979 model). (c) Digital 12-bit microcomputer (1983 model). (d) Digital 32-bit microcomputer (2006 model).

6.2 Microcomputer evolution

6.2.1 Function

This section describes the basic configuration of a microcomputer used in an ECU (Figure 19).

As the configuration of automotive microcomputers is no different from general-purpose types, a detailed description of general microcomputer characteristics is omitted in this section.

ROM has been adopted in recent years for regulatory compliance, and memory in modern microcomputers is configured to allow changes (i.e., flash memory) in block units within the ROM.

The timer controller performs time and time interval control. These devices have a compare function that changes an existing output when the set interval matches the internal timer value, and a capture function that memorizes the input time interval of external signal edges. The compare function is used to determine injection signal output timings and the like. The capture function is used to measure the engine speed signal input timing in combination with the interruption controller.

The communication interface is used to interact with input/output expansion ICs inside the ECU and with other ECUs. A growing number of microcomputers have an in-built CAN (controller area network) function for compatibility with the in-vehicle LAN.

6.2.2 Microcomputer evolution

The ROM capacity of microcomputers has rapidly increased to comply with new and more stringent regulations. This trend is likely to continue in the future, necessitating further miniaturization and increases in speed. Microcomputer types have also changed from 8- to 16-, to 32-bit configurations to meet requirements for greater processing speeds. As the pace of development has speeded up, the time to market introduction has grown shorter. In accordance with this trend, the type of ROM has switched from mask ROM to one-time programming (OTP) to flash ROM. Figure 20 shows an example of an engine control microcomputer. The details are described elsewhere.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6.2.3 *Software trends*

Engine control by microcomputer began in the period from 1970 to 1980 in response to emissions regulations. Since then, microcomputers have spread to the transmission, airbags, navigation system, automatic air conditioner, and so on. As car electronics particularly the software is responsible for adding value to modern vehicles, this trend is likely to continue in the future. In the 1970s, the length of an engine control ECU program was about 4,000 lines of code. As a result of the recent explosive growth of electronic controls, which is rooted in the growing demands to improve the environment by reducing emissions and fuel consumption and to enhance vehicle safety through systems such as the airbags and seatbelts, a luxury vehicle may contain more than 80 ECUs that are larger in scale and far more sophisticated than ever before. Excluding the navigation system ECU, the total amount of program (software) code now exceeds 7 million lines, leading to a huge jump in developmental work hours.

6.3 Other ICs

Custom ICs designed to combine required functional blocks, such as operational amplifiers, comparators, and power supplies, and semi-custom ICs that make changes to existing blocks have also been developed. In the same volume, custom ICs are most expensive, followed by semi-custom ICs, and the lowest cost general-purpose ICs. The specifications of custom and semi-custom ICs are generally not disclosed to parties other than the customer. Another type of IC mixes digital and analog circuits on a single semiconductor chip.

In accordance with the configuration of the ECU, various single-chip custom ICs have been adopted that combine power devices with function blocks such as the power supply and in-vehicle LAN. As power devices are a cause of heat generation, these custom ICs use power packaging with a high heat dissipation performance instead of standard packaging to reduce the size of the ECU.

7 THE FUTURE OF ECU TECHNOLOGIES

This chapter described ECUs, focusing on their installation environment, operation conditions, common structures, component parts, and circuit parts, using the engine ECU as a typical example. ECUs contain sensor and switch input processing circuits, AD conversion circuits, microcomputers, a power supply, output processing circuits, and a communication circuit for interacting with other ECUs. This chapter detailed the parts provided on the circuit boards of ECUs, categorized in accordance with function and shape. It also included a brief outline of ECU trends.

In the past, ECUs operated independently, but ECUs today communicate with each other, and this has evolved into a networked system of ECUs. Recently, cooperation and integration with network applications have been seen. In the future, these systems will develop into cooperative autonomous systems that autonomously respond to the user's needs. So, as you can see, ECUs will continue to become more complex and larger in scale.

In addition, the ability to develop ECUs for which software and hardware in a short time frame is becoming crucial. It also goes without saying that functional safety must be considered at all times. We are in an age in which it is necessary to create frameworks for developing ECUs that can respond to a diverse range of needs.

Diversification of Electronics and Electrical Systems and the Technologies for Integrated Systems

Yukihide Niimi
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Until recently, cars were a collection of mechanical parts. Electronic control began in the 1970s with the engine, and now extends to the brakes, steering, suspension, instrument cluster, climate control, airbags, door locks, power windows, and the navigation system. In fact, virtually every device used in a modern vehicle is subject to electronic control. The human body works as a metaphor for an electronic control system. Sensors play the roles of the eyes and ears, actuators replace the hands and feet, and the brain becomes the electronic control unit (ECU). Signals measured by the sensors are transmitted to ECUs, where they are used to calculate control signals. The signals to and from the ECU are transmitted via wire harnesses and the like. An ECU consists of hardware such as a microcomputer, peripheral ICs, a power supply, printed circuit board, and connectors, as well as software that controls the calculation procedure.

A typical example of electronic control is the electronic control system in a gasoline engine. The engine ECU functions as the brain to calculate the fuel injection amount and ignition timing. As shown in Figure 3, the engine control ECU is connected with the in-vehicle network to exchange information with other ECUs. For example, the engine coolant temperature is transmitted to the instrument cluster for display on the temperature gage. Another example is in vehicles with adaptive cruise control (ACC), which functions to maintain a set distance with the vehicle ahead. If the vehicle-to-vehicle distance increases, the in-vehicle network is used to request the engine ECU to accelerate. In addition, when the cooling capacity of the climate control is insufficient in hot weather while the vehicle stops, the climate control ECU transmits a signal to the engine ECU to increase the engine speed. For details of automotive control systems, see Robert Bosch GmbH (2008, 2011), Denton (2004), Jurgen (1999), Mizutani (1992).

Figure 1 illustrates the change from independent standalone vehicle systems for engine control, brake control, climate control, and the like to integrated vehicle control systems that perform complex functions in cooperation with multiple control systems. There is also a growing trend for coordinated control with infrastructure outside the vehicle. Conventional vehicle electronics systems consisted of collections of individual ECUs installed separately to perform independent control. However, to achieve the type of complex and versatile control required by modern vehicles, these ECUs are being connected to the in-vehicle network (Figure 3). As the number of connected ECUs

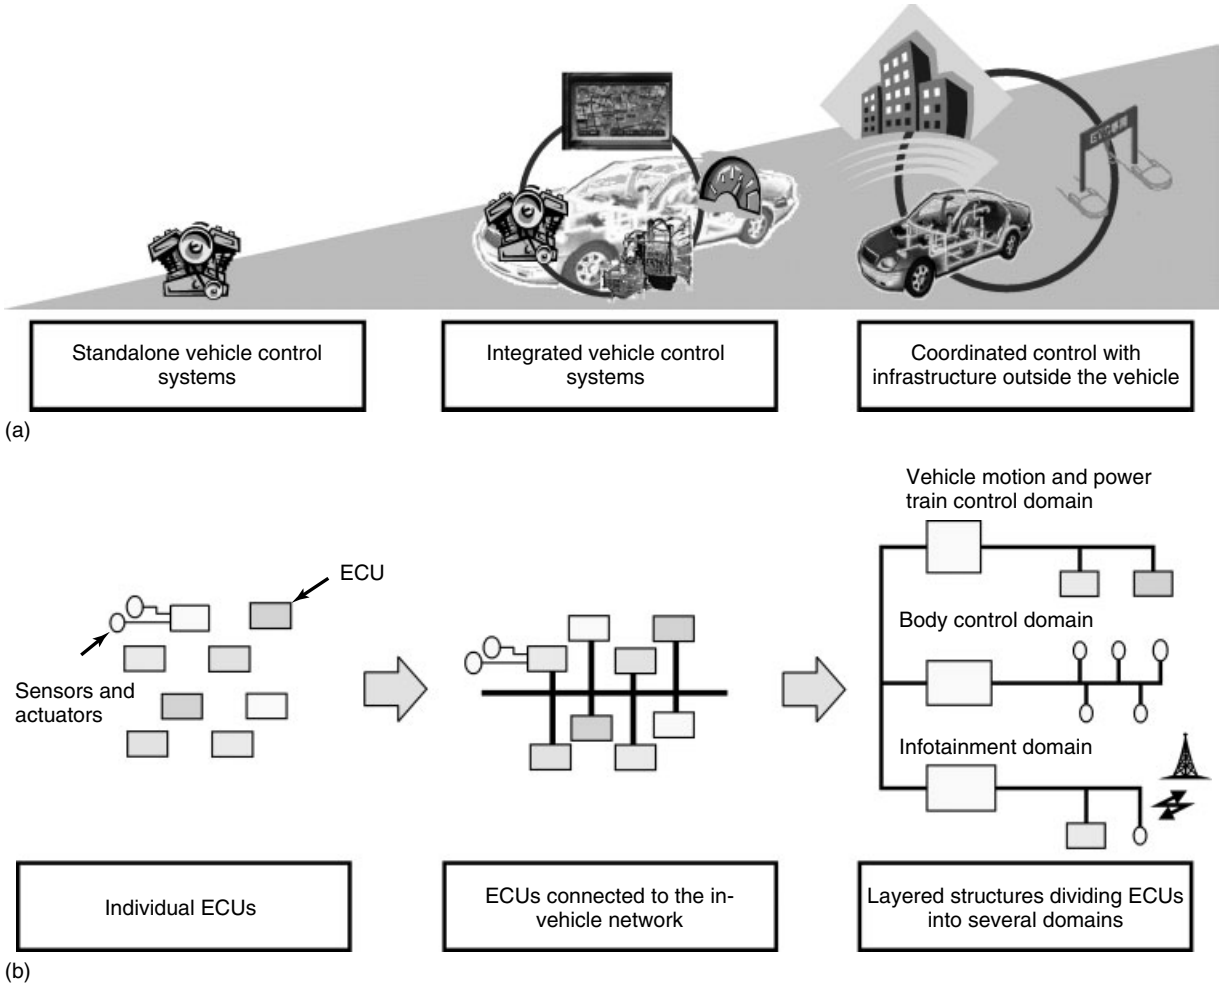

Figure 1. Evolution of automotive electronics systems. (a) Vehicle control systems. (b) Vehicle electronics systems.

increases, it is likely that layered structures will be created that divide these ECUs into several domains (Schäuffele, 2005a).

In the 1970s, the length of an engine control ECU program was about 4000 lines of code. As a result of the recent explosive growth of electronic controls, which is rooted in the growing demands to improve the environment by reducing emissions and fuel consumption and to enhance vehicle safety through systems such as the airbags and seat belts, a luxury vehicle may contain more than 80 ECUs that are larger in scale and far more sophisticated than ever before. Excluding the navigation system ECU, the total amount of program (software) code now exceeds 7 million lines. Figure 2 shows the trends for ECUs installed in luxury vehicles since 1995 (Schäuffele, 2005b).

Consequently, it is becoming more difficult to secure enough space to install electronic system components, particularly ECUs. As a result, ECUs are being made smaller and integrated with sensors and actuators. The commonization and standardization of parts, including software for configuring electronic control systems is also becoming more prevalent to help achieve major improvements in development efficiency.

The control systems of modern vehicles mutually connect the control functions of the power train, chassis, and body (i.e., the fundamental driving, turning, and stopping functions of a vehicle) with service functions that support the driver through information and communication. By doing so, modern vehicles are safer, more comfortable, easier to use, and more environmentally friendly than ever before. The scale of such systems is likely to increase in the future in response to the needs of society, which means that their functions will become even more sophisticated and versatile. New control, information, and communication technologies will be required to achieve such large-scale systems, and it will be necessary to design the optimum systems while ensuring high quality and reliability for both hardware and software.

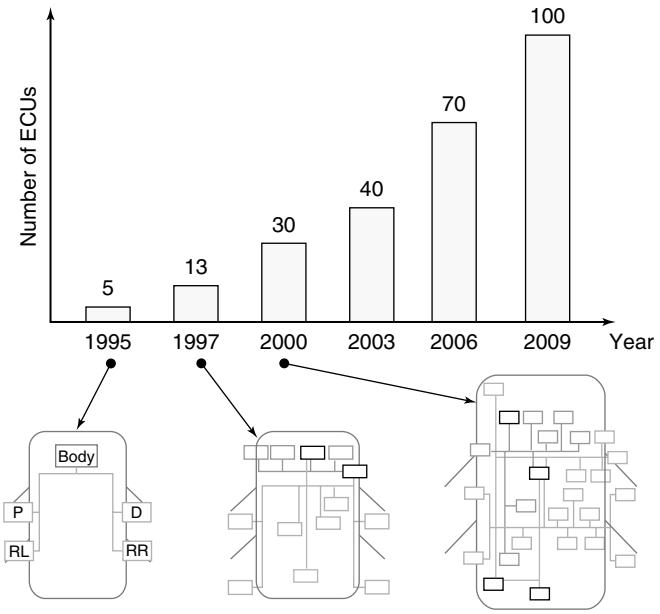

Figure 2. Number of ECUs installed in luxury vehicle.

2 LAYERING, STRUCTURING, AND FUNCTIONAL ALLOCATION

As shown in the example in Figure 3, the ECUs in a modern vehicle are connected to an in-vehicle network. The free exchange of data between the ECUs as well as between the sensors and actuators enables the vehicle system to determine which ECUs should be allocated with which functions from the standpoint of overall optimization. This stands in contrast to the conventional method in which the processes performed by the ECUs were automatically determined for each function.

However, as the number of ECUs in a vehicle increases, it is becoming more difficult to secure enough installation locations. Individual functional ECUs of standard functions that have no variations depending on the region of sale or vehicle grade are gradually giving way to integrated control. The integration of similar or mutually closely related functions is one way of reducing the number of ECU cases, ECU power supplies, component devices, connectors, and wire harnesses required. In other words, reducing these parts is a way of reducing costs. Under this strategy, nonstandard functions, new functions that have not yet found universal application, and functions for certain regions or vehicle grades are not subject to integration. These remain carried out by individual functional ECUs.

As the number of functions in each vehicle increases, another issue that has emerged is how to organize functional relationships and reconfigure the functional structure in the vehicle as a whole. In other words, this means determining how to most efficiently distribute functions throughout a vehicle.

Figure 4 analyzes each type of support function installed in a vehicle. This example shows three layers (the objective control layer, state control layer, and equipment control layer). The relationship between the three layers is as

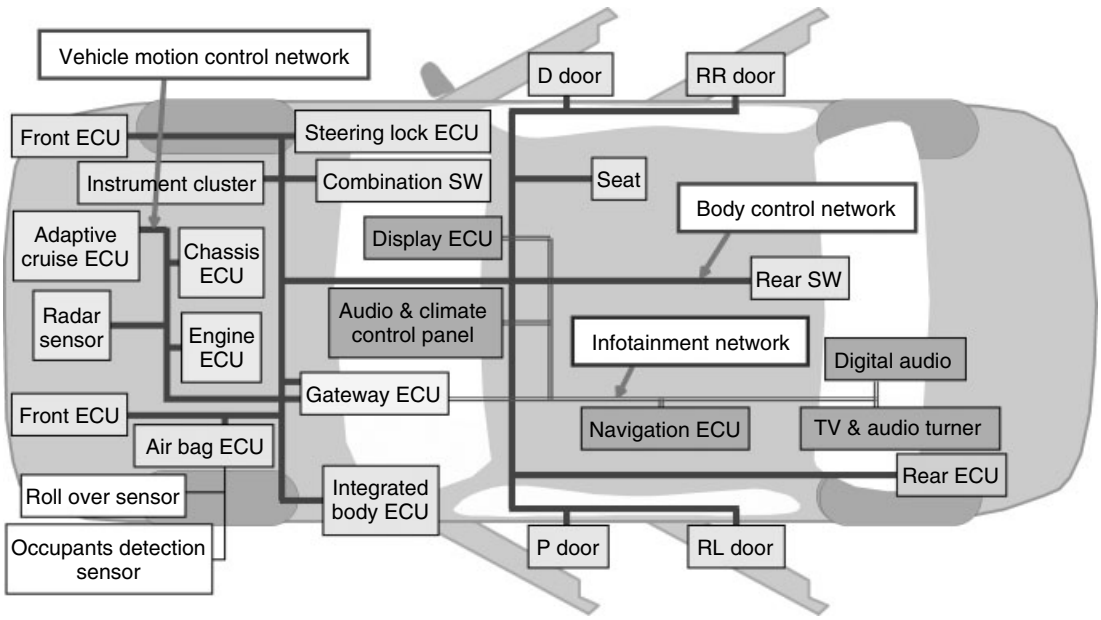

Figure 3. Example of in-vehicle network.

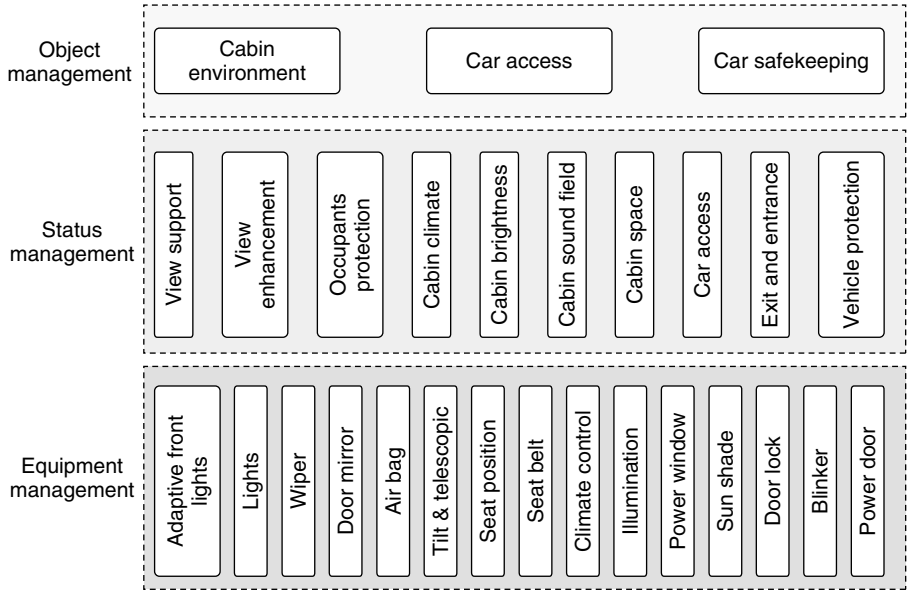

Figure 4. Example of layering of support functions.

	Role of layers	Interfaces of layers
Objective management layer	To obtain target value of required state to achive objective	Interface of objective management and state management: target value of required state
State management layer	To select the optimum equipment for achieving the state requested by the objective management, and to request drive to that equipment	Interface of state management and equipment management: target value of equipment control
Equipment management layer	To drive the actuators based on the required equipment control	

Figure 5. Role and interfaces of layers.

follows. The upper layer acts as the objective for the lower layer, and the lower layer acts as the means for the upper layer. As Figure 5 shows, the role of the objective control layer is to judge the required state and to set a target value that achieves the objective. The role of the state control layer is to select the optimum device for achieving the state requested by the objective control, and to request drive to that device. The role of the device control layer is to drive the actuators based on the required device operation.

For example, electronic keys are one type of support function that helps the driver enter the vehicle. If the driver approaches the vehicle carrying something bulky, the security control detects the key, temporarily deactivates the warning mode system, unlocks the door, and illuminates the interior with foot lamps. The driver can then open the door simply by gripping the door handle. Then, when the driver acts to close the door, the system drives the door closer and sets the driver's seat to the optimal position. Other examples are the climate control that controls the temperature and humidity of the vehicle interior to ensure the comfort of the occupants, and the view support functions such as the windshield wipers, mirrors, and glass defoggers.

Figure 1 illustrated that the scale of electronics systems will continue growing, particularly in luxury vehicles.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Layering and structuring is a key theme in these vehicles. In the future, a domain controller is likely to be provided for each system to enable sophisticated process function integration of these systems. Another likely trend is the integration of input/output processes with sensors and actuators, regardless of vehicle type. As these trends progress, it is also likely that the in-vehicle network will become layered with small-scale local networks between ECUs, sensors, and actuators, networks within domains for each system or domain, and a backbone network between domain controllers (Bertram *et al*., 1998; Dieterich and Schröder, 1998; Lang *et al*., 2008; Stolz, Kornhaas, and Krause, 2010).

3 INTRODUCTION OF COMMON STANDARDIZED PARTS AND REUSE

At present, one of the largest issues in vehicle development is how to establish an efficient process for designing the myriad of electronics systems concurrently and in a short space of time. This process has to cover a range of vehicle types from mass-market vehicles, which contain only an electronic instrument cluster and engine control ECU, to luxury vehicles that have large-scale electronics systems. This is achieved by maximizing the reuse of parts that have already been designed and developed through commonization and standardization, and newly designing only those parts that are required to achieve new functions. These two types of parts can then be combined to create versatile automotive electronics systems.

A structure of commonized and standardized parts and technologies may be called an *electronics platform*. Vehicle platforms generally refer to shared body and chassis designs. For computers, although the term generally relates to hardware or operating systems (OSs), the meaning and objective are the same from the standpoints of organizing systems, structures, commonized and standardized parts, and technologies to enable the efficient combination of a wide range of variations.

3.1 ECU software structure

This section describes the structure of the software in the ECU as a practical example. Figure 6 shows the relationship between the hardware and software in an ECU, and the software structure.

The electronic control system in an ordinary vehicle consists of sensors, actuators, and ECUs. Each ECU contains hardware such as a microcomputer, peripheral ICs, a power supply, and connectors, as well as software that performs the control procedure.

Conventionally, software was created in a structure that fitted with the characteristics of each individual ECU. More recently, software has been divided into two major categories: the application portion and the common portion, which does not rely on the vehicle type or function. Both are increasingly adopting structures that group together reusable parts. In principle, this structure can be used to form real-time OS, local area network (LAN) communication, device driver, and diagnostic driver software that allows common use across functions (such as engine control, brake control, steering control, and so on), vehicle models, and microcomputer types. It also facilitates the reuse of application component units.

In addition, creating the software for each ECU using the same structure may also enable the reuse of particular application components across ECUs. For example, application components installed in the engine ECU may be used in the climate control ECU. When adding a new function, only the application component that achieves that function has to be created. As a result, the function can be placed in the software platform with minimal changes to the platform, enabling fast and efficient development.

3.2 Other electronic platforms (commonized and standardized parts and technologies)

Obviously, the hardware parts of an ECU also require some form of platform. In the initial phase of electronic system adoption, it was acceptable to make optimal designs for each specific application. However, today, it is becoming increasingly important to achieve the standardization and common use of virtually all ECU hardware parts, such as microcomputers, power supply ICs, communication circuits, connectors, passive components, and so on.

Figure 3 illustrated that modern vehicles have an in-vehicle network system that connects ECUs by communication and exchanges data over the communication paths. This system enables cooperative control of vehicle behavior to assist the driver. For example, by sharing sensor data and using the navigation ECU to predict corners in advance, the engine ECU can command the transmission to generate engine braking by automatically changing gear. This in-vehicle network is utilized by something called a *communication platform*. This refers to a standard configuration of ECU groups connected to the network, a standard communication procedure, standard drivers, and standard interface signals for communicating between the ECUs.

This type of coordinated navigation system control means that the functional structure of the vehicle electronics system is becoming more complex. For example, in the case of longitudinal vehicle motion control, requests for engine

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto214
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

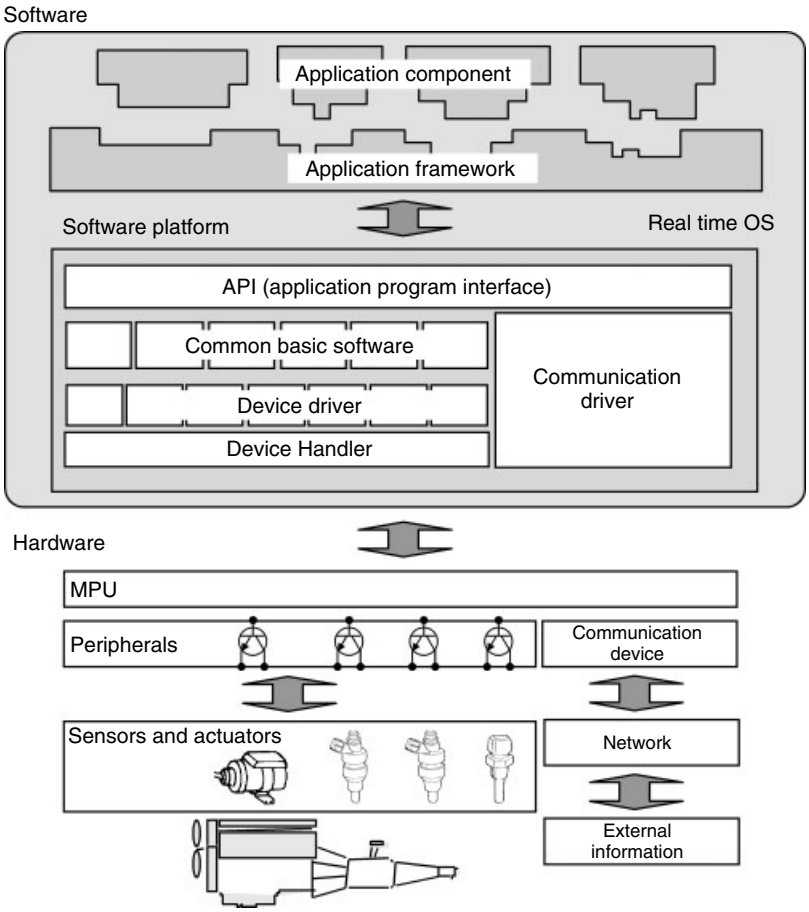

Figure 6. Software structure.

braking do not involve simply the conventional aspects of acceleration and braking. Other ECUs that are relevant to this control include the ACC ECU, which uses millimeter wave sensors and cameras to maintain a set distance to the vehicle ahead, the vehicle stability control (VSC) ECU that ensures stable vehicle handling on rough or dangerous road surfaces, the parking assist ECU that helps the driver parallel or reverse park, the precrash ECU that detects the potential of collision with objects, and the like. Torque commands from all these ECUs are transmitted through the in-vehicle network. Arbitration control prioritizes these signals is an indispensable part of the system and is an important element in the control platform.

Figure 7 shows a vehicle motion control platform. If the vehicle ahead is moving away, the ACC ECU will issue an acceleration request. Similarly, if the vehicle-to-vehicle distance is narrowing, the ECU will issue a deceleration request. The vehicle motions control platform factors in requests from other ECUs (e.g., a deceleration request from the precrash ECU will be prioritized) and calculates a target torque by prioritizing and judging information about the vehicle state to determine how the vehicle should react. This torque is then distributed to the engine and brakes. If gradual deceleration is required, it will reduce the engine request. If sudden deceleration is required, it will issue a braking torque request to the brakes.

The vehicle motion control platform also facilitates the reuse of functions such as these with other functions. By adopting the control structure shown in Figure 7, the high-speed ACC function (i.e., its control logic) developed for use on highways can also be used in principle without modification in vehicles with six-cylinder gasoline or diesel engines, or in hybrid or electric vehicles, as well as in the original four-cylinder gasoline engine vehicle. The development of new functions, such as full-speed ACC that includes start and stop control, can be separated from the development of other engines and carried out independently at the same time. Control platforms are also required for prioritizing vehicle behavior in the lateral and vertical directions as well as longitudinally (AUTOSAR, 2009).

DOI: 10.1002/9781118354179.auto214
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

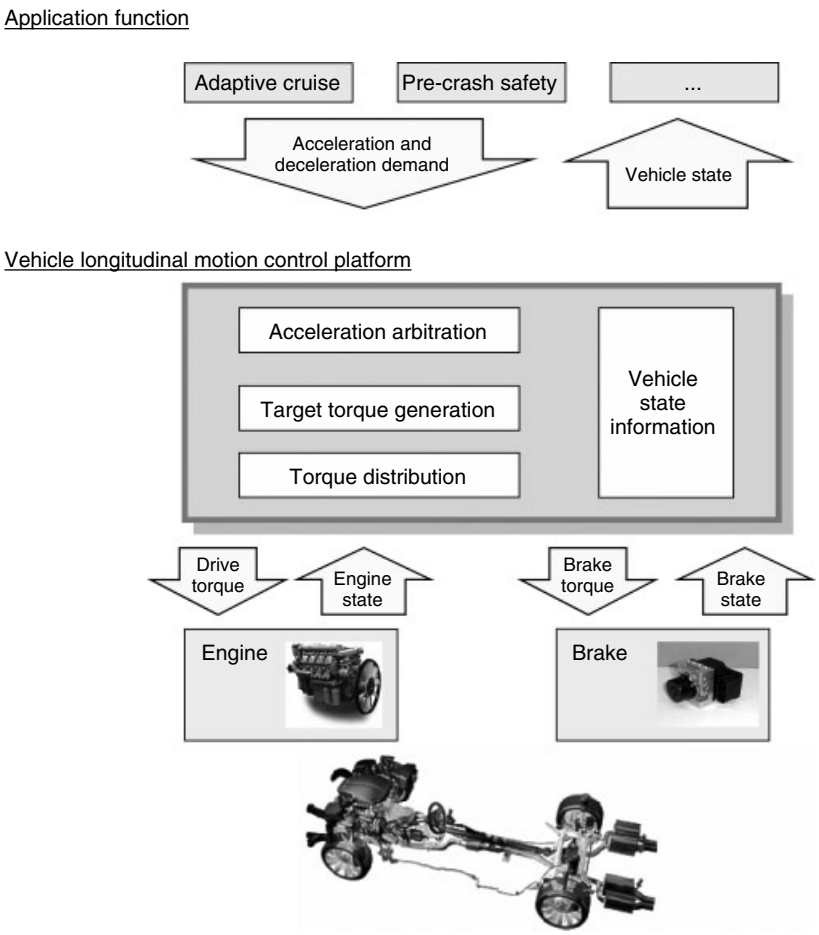

Figure 7. Structuring of vehicle motion control.

Another example of a control platform is the system for prioritizing displays of information to the driver. Since a vehicle only has one driver, it is not possible for that person to simultaneously process large amounts of information. A luxury vehicle has functions to display more than 10 different types of warnings as well as the operation states of various devices. This control platform prioritizes the displays in accordance with the constantly changing driving conditions and shows them in the proper sequence.

This section has described the details of electronic platforms (i.e., commonized and standardized parts and technologies) through various examples. In addition, electronic platforms are a wide-ranging concept in development that also encompasses vehicle power supply systems, types of vehicle control structures, and tools for designing ECUs. These platforms are also seen as the key concept for efficiently developing high quality automotive electronics systems that will continue evolving into the future. All electronic platforms have an interdependent relationship, and it will be necessary to find optimal solutions for the best way to combine such platforms into automotive electronics systems.

4 INTERNATIONAL STANDARDIZATION

The parts and technologies that are being popularized and standardized as described above contain many examples that require standardization on a global basis, irrespective of the industry standards of each country. A typical example is communication procedures, which are a basic technology for constructing the in-vehicle network. This has been the subject of international standardization efforts for some time. These efforts have recently spread to in-vehicle OS, ECU software structures, common basic software, the languages used for specifications, functional safety design methods, design and development tools, evaluation methods, and so on.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto214
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Conventionally, standardization in this field has been carried out internationally through the International Organization for Standardization (ISO) and International Electrotechnical Commission (IEC). Although these organizations dominated standardization efforts in the past, the speed of technological and market changes means that recent efforts have mainly been carried out through consortiums that make contracts with the main stakeholders to eliminate time-consuming deliberations on a country level. Although consortiums are in charge of establishing new standards that require speedy response, items that have legal and certification ramifications are still carried out by the ISO. These include the operation and maintenance of established standards, functional safety design methods, interfaces between ECUs and failure diagnostics tools, and procedures to dispose of airbags in scrapped vehicles.

As a typical example, the following sections describe the approach of functional safety design methods, which are formulated by AUTOSAR (automotive open system architecture) and established as ISO standards. Other main consortiums are LIN (local interconnect network) (http://www.lin-subbus.org/) and MOST (http://www.mostcooperation.com/home/index.html), which are related to communication procedures. OSEK (http://portal.osek-vdx.org/) deals with in-vehicle OS related to software, GENIVI (http://www.genivi.org/) works to reduce costs and to shorten development lead times in the fields of multimedia, telematics, and human machine interfaces, and the Association of Standardization of Automation and Measuring Systems (ASAM, http://www.asam.net/) is related to calibration and measurement.

4.1 AUTOSAR (automotive open system architecture)

In 2003, this consortium was founded, centering on German automakers and several major parts suppliers. AUTOSAR is working to standardize software structures, common basic software, software design tools, interfaces between application components, and certification test methods. As of June 2009, there were a total of 158 participating members: nine companies with voting rights (BMW, Daimler, VW, Toyota, PSA, GM, Ford, BOSCH, and Continental), 85 premium associate members with proposal rights (including Honda, Nissan, Mazda, DENSO, Hitachi, NEC, Fujitsu, and Renesas), another 85 associate members, and 8 development members. The work of AUTOSAR is being carried out through 26 working packages.

AUTOSAR has specified the common basic software and proposals for globally standardized specifications that transcend individual functional ECUs, vehicle types, manufacturers, and countries have been made with regard to in-vehicle network drivers such as CAN (controller area network) drivers, LIN drivers, and FlexRay drivers, systems services such as the ECU State Manager and Watchdog Manager, and software models including those related to input/output. For details of AUTOSAR activities, see AUTOSAR (2008), Ataide (2007), and Heinecke *et al.* (2004).

4.2 Functional safety standards

ISO 26262, an international standard for road vehicle functional safety was published in 2011. The standard covers automotive electronic systems relating to safety, and includes subjects such as definitions of concepts for determining safety levels such as the automotive safety integrity level (ASIL), risk assessment and other safety evaluation methods, and approaches to safe lifecycles.

ISO 26262 consists of 10 parts (Gräter, 2011). Part 1 begins with a definition of terminology, part 2 covers the requirements of organizations and people related to safety functions, and part 3 describes the procedure for developing functional safety concepts after setting safety targets. Parts 4–6 describe development and design procedures for systems, hardware, and software (in that sequence). Part 7 covers procedures related to production and market servicing. Part 8 describes guidelines for configuring and managing products developed to support these procedures, guidelines for managing modifications, guidelines for verification, guidelines for managing documentation, guidelines for certifying tools, guidelines for certifying components, and the like. Part 9 deals with guidelines related to ASIL. Finally, part 10 describes reference information to be used as guidelines for parts 1–9.

5 CONCLUSIONS

This chapter described the layering and structuring methods used in basic development of complex and large-scale vehicle electronics systems of today, the standardization and reuse of common parts in these systems, and activities to develop related international standards. Layering and structuring were outlined through a description of software structures and a motion control platform for longitudinal vehicle behavior. International standardization was covered in sections about AUTOSAR and functional safety standards. We expect these technologies will contribute to the higher level of improvement of the function and the performance in the field of fuel economy and vehicle safety in the near future.

ECU Design and Reliability

Joji Yoshimi
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

There are increasing calls to make vehicles more environmentally friendly, safe, convenient, and comfortable. To meet these demands, onboard engine control units (ECUs) have grown more sophisticated in terms of function and performance. As a consequence, the scale of hardware and software has dramatically increased compared to the 1970s when the widespread use of automotive products with electronic applications first began. Drivers are also more sensitive to quality and now demand ECUs with higher reliability. This chapter describes the use of simulations for efficiently designing a large-scale ECU and methods for evaluating whether the ECU achieves a required level of quality.

2 ECU DESIGN

With the advancement of onboard electronics technology in recent years, luxury vehicles are now installed with around 100 ECUs, which cooperate with each other through an onboard LAN connection (Ookura, 2005). In the future, ECUs will have more functions that will also become increasingly sophisticated, and the interaction between the different functions is likely to become more complex.

2.1 ECU design process

Figure 1 shows a general design flow for an ECU. The requirement definition step consists of defining all requirements throughout the ECU life cycle relating to reliability, regulations, and the ECU manufacturing process, in addition to defining requirements for the functions and performance demanded. This can reduce reworking at subsequent steps.

At the step for allocating hardware and software functions, a combination of hardware and software is selected that meets the requirements while minimizing the ECU price and development costs, and various specifications are then created. However, the specifications are often modified many times before mass production of the ECU starts. Any need for hardware changes or software structure changes lengthens the development period. Therefore, creating specifications capable of adapting to any likely requirement changes that can be anticipated at such time helps suppress the length of the development period.

At the hardware design and software design steps, the defined requirements are incorporated into design activities based on the technologies held by each ECU manufacturer.

At the hardware/software consolidated testing step, it is confirmed that the ECU satisfies all the defined requirements. Finally, the ECU is installed in a vehicle and system verification is performed, thus completing the ECU design process.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

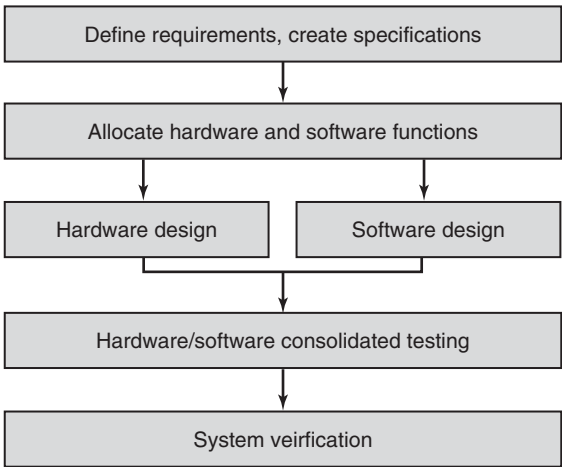

Figure 1. General design flow for ECU.

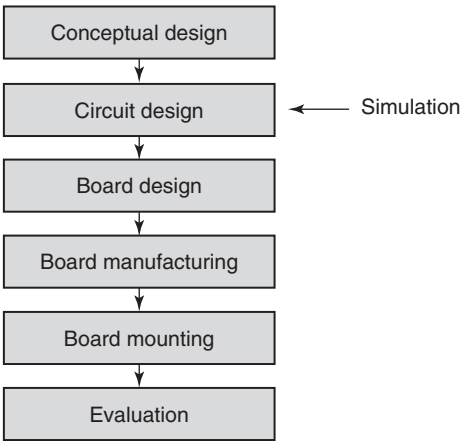

Figure 2. Design flow for printed circuit board.

2.2 ECU design support tools

As mentioned earlier, the ECU has grown in scale and become more complex. Designing and evaluating such an ECU by hand as in the past would require an enormous amount of man-hours and is not realistic. Therefore, the design support tools described below are gaining more widespread use.

2.2.1 ECU hardware development

Figure 2 shows the design flow for a printed circuit board. The process begins with conceptual design, and once the conceptual design is fixed, the process moves on to circuit design using circuit design tools. Next, operation verification is performed using an analysis tool (simulator). After circuit design, board design tools are used to set the layout and wiring for electronic components (board design), thus completing the printed circuit board design process (Kato, 2010).

2.2.2 Software development using virtual environments

Software used to be developed using actual chips. However, recent advances in simulation technology have enabled the co-validation of hardware (mainly microprocessors) and software by simulation (Keating and Bricaud, 2000). This virtual environment has the advantages of allowing software development to start before the trial production of actual chips with excellent observability. However, an amount of development time corresponding to roughly several hundred to several thousand times more than that needed when using actual chips is required (Keating and Bricaud, 2000). Accordingly, there is a trade-off relationship between the speed and precision of the simulation, which means that model development well suited to the simulation purpose and verification items is key.

2.2.3 Software verification using HILS

Instead of using actual automotive components, hardware-in-the-loop simulation (HILS) mimics (simulates) electric signals from such components (Figure 3). Software verification on the ECU is performed using signals originating from the HILS, without requiring the elaborate environment of the actual vehicle. Software-in-the-loop simulation (SILS) methods that build a simulation environment with only software on a computer and use no hardware such as an ECU or actuator have also been proposed (Kato, 2010).

2.3 Future of design support tools (CAE)

This section describes the prospects of high level design and model-based design as applications of design support tools for onboard electronics.

2.3.1 Onboard electronic system development using high level design technology

Owing to recent advances in onboard electronics, ECUs have increasingly sophisticated functions and the interaction between functions has grown more complex. In the future, this trend is expected to accelerate. As an example, the design and verification for an integrated control that requires cooperation among ECUs will become considerably more complicated. Therefore, a new ECU design environment that addresses broader concepts than individual optimization on a component level as in the past

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

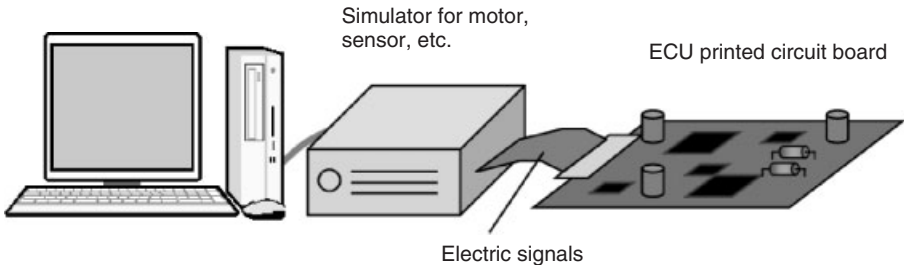

Figure 3. Example of HILS environment.

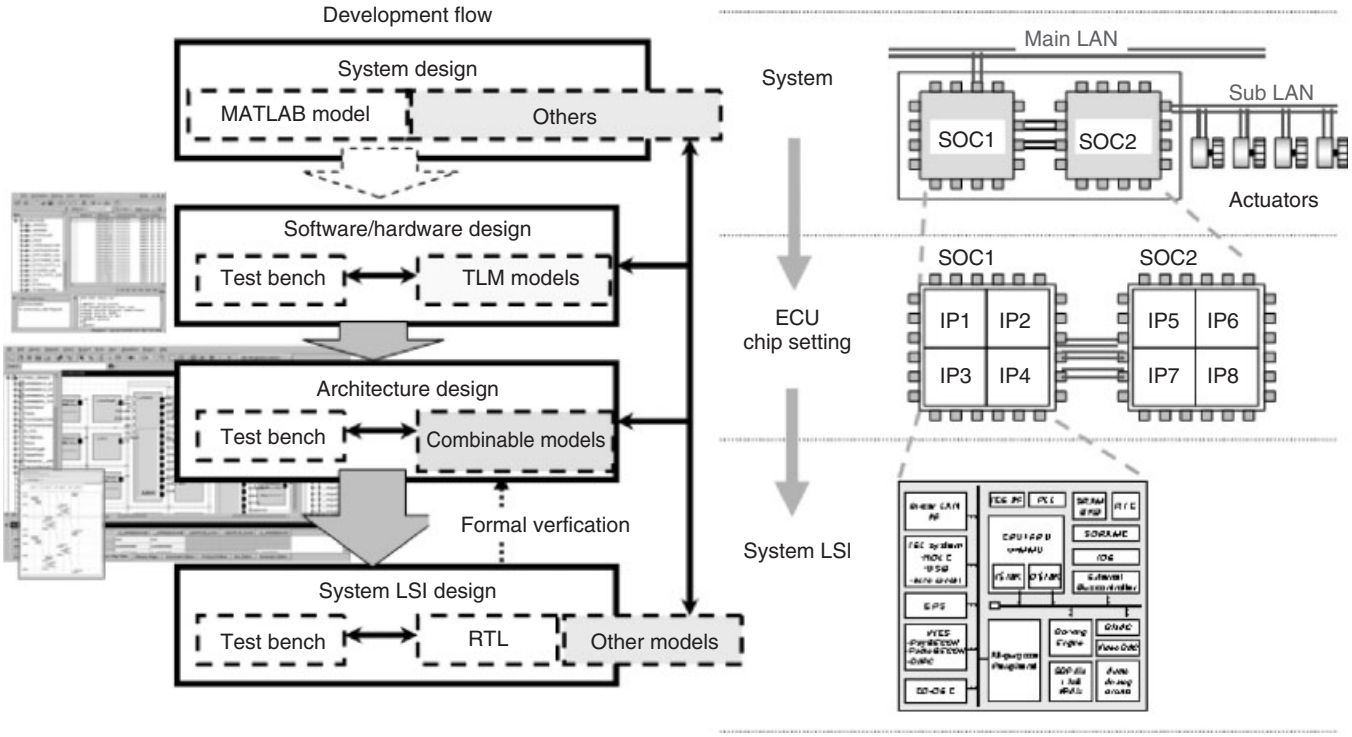

Figure 4. High level design and applicable layers.

is anticipated. One such environment gaining attention is electronic system level (ESL) design (high level design) for ECUs. In this field, the Open SystemC Initiative (OSCI) has standardized the design language SystemC and module interface TLM 2.0.

Figure 4 shows a design flow and applicable layers that apply high level design to an onboard electronic system. High level design has broad applicability ranging from onboard system operations to ICs. However, the pursuit of more precise verification lowers the abstraction level and reduces the simulation speed. Therefore, the verification items must be clarified and the abstraction level set for each applicable layer (Kato, 2010). Creating models of functional components and accelerating the speed of simulation including microprocessors are important elements in ESL design for ECUs.

The advantages of high level design in ECU design are listed below (Kato, 2010).

High level design can be considered as one type of SILS that does not require the actual device. However, high level design includes the concepts of hardware such as microprocessors and enables a system design that takes hardware into account.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

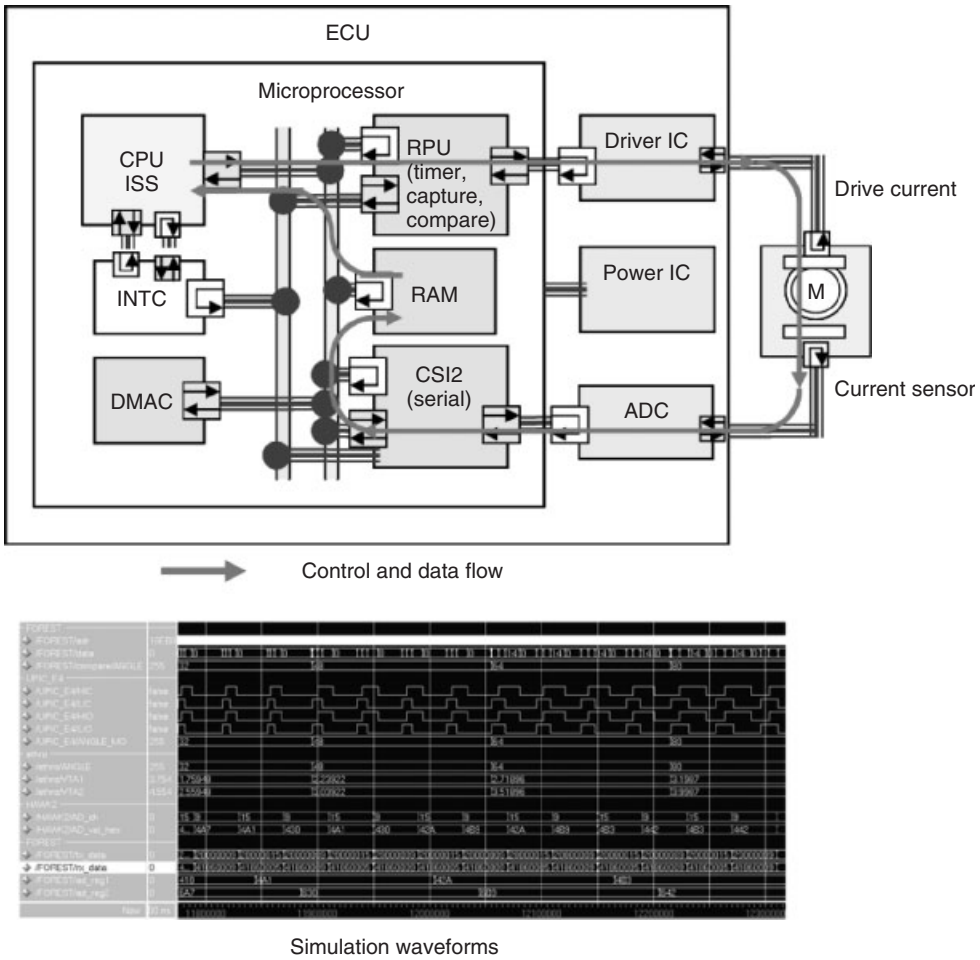

Figure 5. Example of high level design applied to ECU.

Instead of design that simply improves on the conventional ECU, various case studies of ECU architecture are possible in the virtual environment of high level design.

ECU design in the past involved mainly desk calculations, and it was necessary to incorporate a margin of error to achieve the required performance. Performance can be evaluated in a quantitative manner with high level design, which enables suitable design targets to be set and leads to cost reductions.

Problems can be discovered earlier by proceeding with verification in the virtual environment before making the actual device.

Advance software development is possible with the use of the microprocessor virtual environment.

Figure 5 shows an example of an ECU model. As the ECU, in addition to the microprocessor (CPU + peripheral circuits), models of the power IC and driver IC, as well as models of sensors and actuators connected to the ECU are required.

2.3.2 *Model-based design (linked to algorithm development)*

Physical states such as temperature and rotation angle are converted into sensor electric signals, and a feedback control is executed for actuators including the engine and motors based on these electric signals. This type of control development exists for many onboard systems.

The development process consists of developing algorithms first, and then designing the control hardware and building the system. MATLAB or the like is often used for algorithm development. An example of the flow of a model conversion that incorporates algorithms developed using MATLAB into a hardware model is described below.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

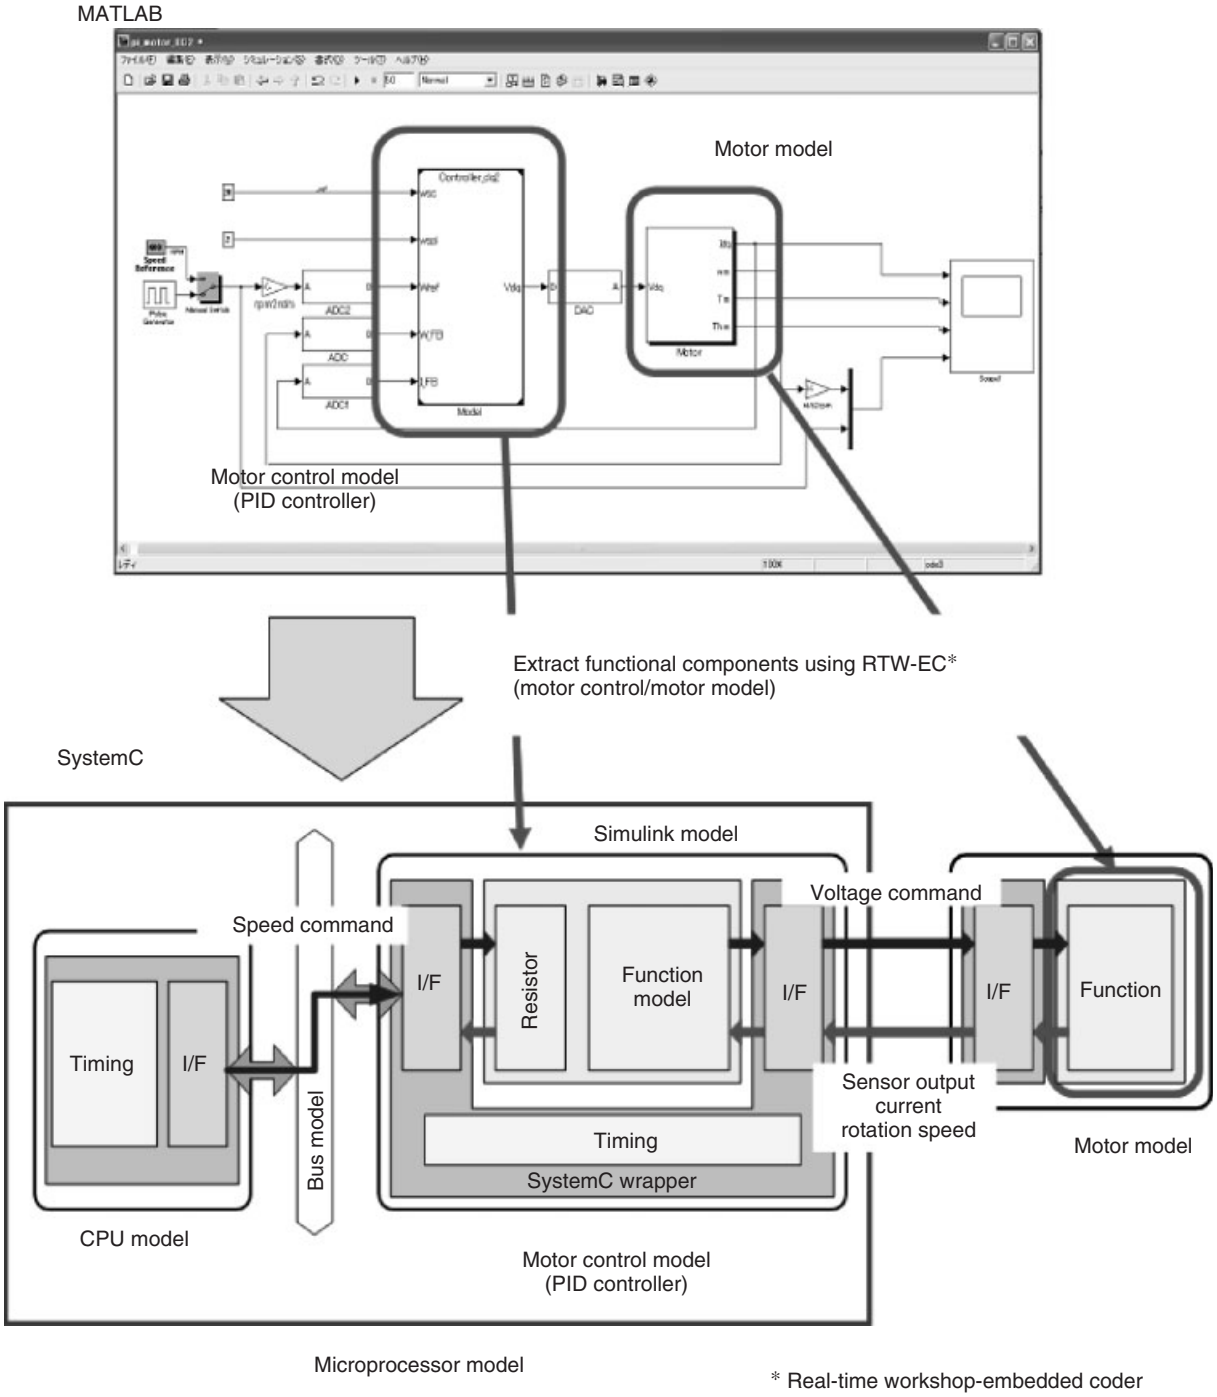

Figure 6. Example of conversion from MATLAB to SystemC model.

1. Algorithm development using MATLAB
2. Analog signal discretization
3. Function output in C code
4. Add interface and time control to C code and use as SystemC code
5. Use SystemC code circuit as high level design model

Although problems with simulation speed remain, tool vendors have recently developed simulation technology that combines MATLAB and high level design tools. Further advances in technology and application to onboard electronic systems are anticipated (Figure 6) (Kato, 2010).

3 ECU RELIABILITY

To ensure ECU reliability, first, the targeted quality and life are specified. Next, the environment in which the ECU will be used is studied. Finally, reliability testing that applies stresses corresponding to the use environment must be performed to confirm that the ECU satisfies the quality and life targets (Reliability Engineering Association of Japan, 1997).

A number of ECU failure patterns are represented by a bathtub curve in Figure 7. The failure rate tolerance and product service life shown in Figure 7 must satisfy the targeted quality and life.

The bathtub curve has an early failure period, a chance failure period, and a wear failure period based on shifts in the failure rate. The early failure period contains the highest probability of manufacturing and design defects, which means that there are many failures at the start of the period but the number gradually decreases. Screening by burn-in is effective for ensuring that defective products from this period do not enter the market (Renesas Electronics Corp, 2010). Burn-in is a method of applying stress to the ECU and ECU components over a set period to sort good and defective devices. This is explained in Figure 8 using an S-N curve.

Defective devices are normally distributed to a location away from good devices. Only defective devices fail after a fixed time (tB) following application of a stress (SB), so defective devices along with good devices can be stratified. Screening consists of focusing on the failure mode of the applicable device, and finding and eliminating design weaknesses and potential faults ahead of time through the

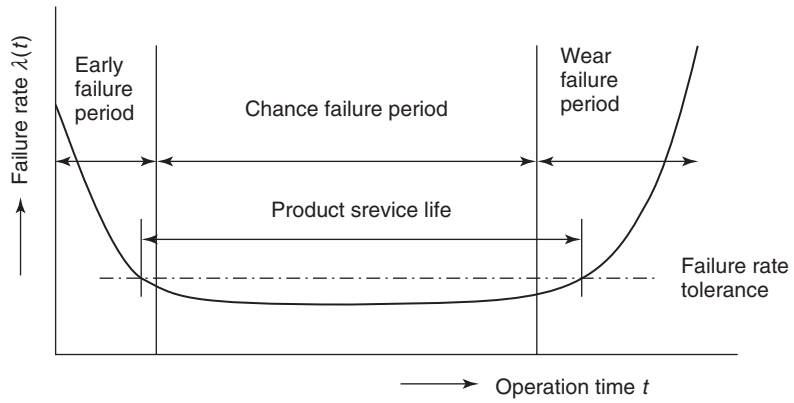

Figure 7. Bathtub curve.

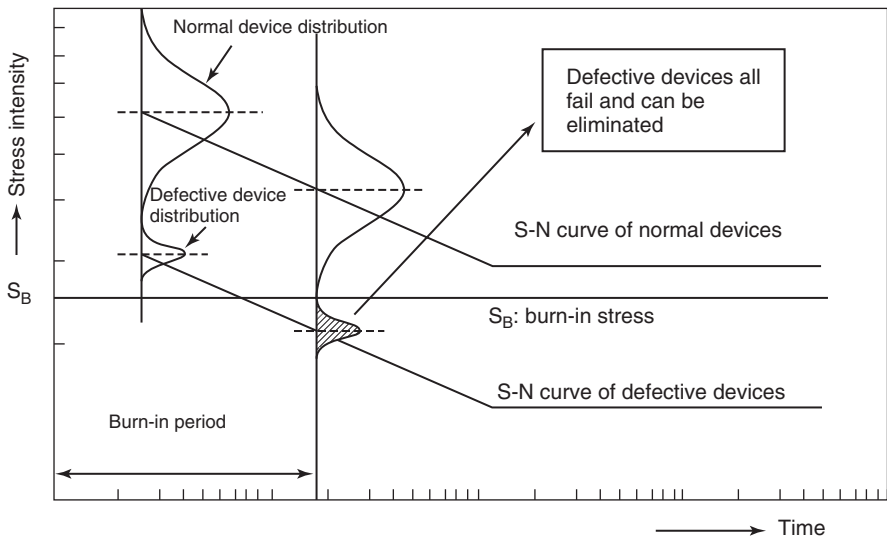

Figure 8. Burn-in.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

appropriate application of stress. For effective screening, a stress type and application time capable of exposing a failure in the defective device must be selected. However, applying excessive stress to shorten the screening time or applying stress over a long period to reliably eliminate defective devices may adversely affect the characteristics of good devices or cause failures. Therefore, it is important to select the appropriate conditions.

In the chance failure period, failures occur for any random reason and there is a fairly steady failure rate. The wear failure period is a period in which failures increase due to deterioration over time from product use. The only ways to reduce the failure rate in the chance failure period and the wear failure period are by understanding various types of failure mechanisms and continuing steady efforts to improve tolerance against failure. In particular, countermeasures for wear-related failures should ensure that a large number of defects do not occur within the warranty period.

3.1 ECU environment

Vehicles must be safe and comfortable under various environments and continue to operate normally until they are scrapped. The quality of onboard ECUs must also remain high over a long period under harsh conditions such as heat, humidity, vibration, noise, and static electricity. Table 1 shows examples of environment conditions for an onboard ECU (Kato, 2010). The values listed in the table are only examples, and the ECU mounting environment in the vehicle must be accurately understood in the course of ECU development. These values ensure the validity of the reliability assessment described later.

3.1.1 Temperature

While the engine is operating, the temperature in the engine compartment can increase until 100°C or more. The temperature is also influenced by weather conditions, and may increase until 90°C on the top of the dashboard and until 65°C in the trunk when parked under the hot sun. In addition, the temperature may alternate between high (during the day) and low (at night), and sharp temperature increases may occur due to self-heating during load driving.

Table 1. Examples of environment conditions for onboard ECU.

Temperature	−30 to 110°C: engine compartment
	−30 to 80°C: vehicle cabin
Humidity, water	95% RH or more, water immersion
Vibration	20G, 20–200 Hz: engine compartment
	4.4G, 20–200 Hz: vehicle cabin
Electricity	Power voltage fluctuation: 6–24 V
Vibration	Surge voltage from induction load
	Electromagnetic damage, static electricity
Electricity	Dust, salt, grease

3.1.2 Humidity and water

This environment refers not only to outdoor humidity but also to the condensation that occurs when devices cooled by the air conditioner are subjected to outside air with high humidity, which may leak inside the circuit board and cause electrical or other corrosion. Water immersion even in the vehicle cabin must also be considered due to the possibility of spilled drinks and water entering the cabin during car washing.

3.1.3 Vibration

Driving is always accompanied by vibration, and some regions may reach until 20 G depending on the road surface and running conditions. Therefore, trouble caused by vibration must be taken into account.

3.1.4 Electricity

Various loads are connected to the vehicle battery, and the power voltage varies depending on their on/off state. At cold starts in particular, there are considerable changes in power voltage, which may range from a nominal 12 V to approximately 6 V. Operation of induction loads such as motors, solenoids, and relays, as well as current interruptions, may be accompanied by induction noise in other devices or parallel wire harnesses due to electromagnetic or electrostatic coupling.

3.2 ECU failure examples

Understanding the failure modes that occur in the ECU environment is essential to securing ECU reliability. This is because the accelerated testing described later focuses on failure modes to calculate an acceleration coefficient, and proper testing cannot be performed if the failure modes cannot be anticipated. Figure 9 shows an example of failures that occur when humidity, heat, hot/cold stresses, and vibration are applied as typical stresses. Most of these failures are exposed after a number of years in a normal use environment, so countermeasures at the design stage and sufficient evaluations are critical.

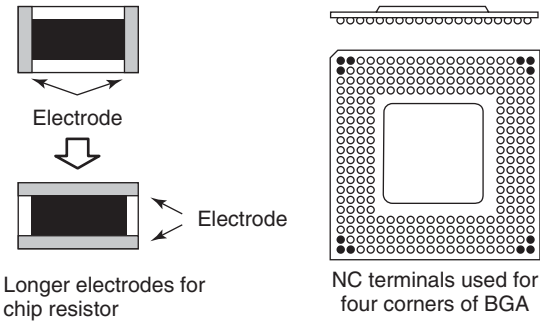

Figure 12. Solder crack countermeasures.

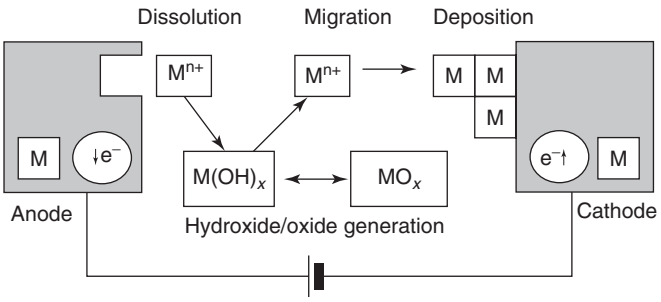

Figure 13. Ion migration mechanism.

3.2.1 *Solder crack*

The printed circuit board and its mounted electronic components have different coefficients of thermal expansion. Therefore, temperature fluctuations may produce stress on bonded sections (Figure 10). Such stress is absorbed by the solders, but with repeated heating and cooling, the solders may experience plastic deformation and exhibit minute cracks. The cracks may gradually grow as shown in Figure 11, and ultimately lead to an open defect.

For an ECU used in an environment with large temperature differences, to reduce hot/cold stresses, components with longer electrodes to shorten the interval between electrodes are adopted. For a BGA package IC, countermeasures such as using NC terminals without internal connections for the corner terminals subject to the maximum stress are adopted to ensure that functionality is not affected even if cracks occur (Figure 12) (Kato, 2010).

3.2.2 *Ion migration*

Ion migration is a phenomenon in which metal that includes electronic material ionized by the action of the electric field migrates between electrodes and is then reduced to metal again and deposited, as shown in Figure 13. The ion migration phenomenon is accompanied by visible tree-like branching called dendrites. An example is shown in Figure 14. The dendrites contain metal and are generated by the normal environment of the onboard ECU, such as temperature, humidity, electric field (voltage), and impurities (e.g., ions, contamination, and dust). These environment elements act in complex ways to form dendrites that cause insulation degradation in circuits and components.

For cases in which the ECU is used in an environment with high humidity and there are only narrow intervals of several millimeters between electrodes, countermeasures include avoiding the use of Ag, Pb, Sn, and Cu materials, blocking the ion migration path by covering the space between electrodes with a moisture-proof material or gel resistant to moisture absorption, and reducing the halogen concentration (Kato, 2010).

3.2.3 *Whiskers*

Whiskers are a phenomenon in which needle-like or nodule-like metal single crystals grow on a metal surface. Whiskers are known to occur from Sn plating and Zn plating. Whisker formation may lead to defects caused by short-circuiting between terminals of the circuit components. Figure 15 shows examples of whiskers found on an electrode of a chip capacitor and an IC lead in a temperature cycling test. Known causes of whiskers include formation by stress acting on the plating film, which occurs due to different coefficients of thermal expansion, intermetallics and their

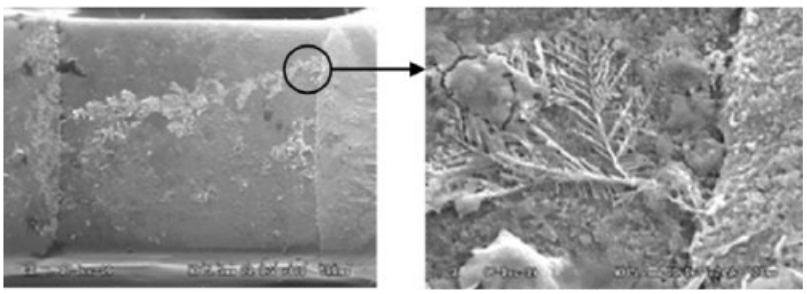

Figure 14. Dendrite formed between electrodes of ceramic capacitor.

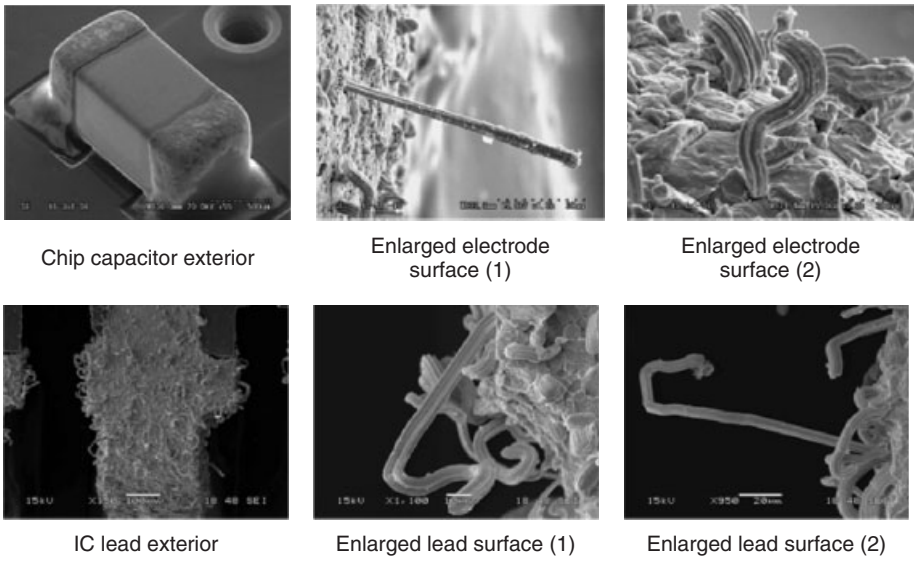

Figure 15. Whisker examples.

spread, galvanic corrosion, external stress, and the like. However, the mechanism is still not clear (Kato, 2010).

Countermeasures that have proved effective include applying a heat treatment (annealing treatment) after plating to reduce residual stress and adding a second metal to the Sn plating. Sn plating containing Pb was once often used in the industry. However, plating containing Pb can no longer be used because of the RoHS Directive, and reliability issues involving tin whiskers have arisen from the use of lead-free compliant components (Yoshino, Sanji, and Iguro, 2007). Therefore, whisker countermeasures for Sn plating are gaining attention again.

3.2.4 Kirkendall voids

Leaving the IC in a high temperature state or operating the IC in a continuous manner produces a solid phase reaction at the bonding portions of gold bonding wires and aluminum wiring. This may form a compound of gold and aluminum as a consequence and generate a disconnection defect as shown in Figure 16.

Interdiffusion at the Au–Al bond is accompanied by the formation of various types of metal compounds as shown in Figure 17. Voids known as Kirkendall voids may occur in intermetallics that are weaker than aluminum and gold, which could produce cracks after repeated cycles of heating and cooling and lead to fractures. Countermeasures include not using substances that accelerate the Kirkendall phenomenon such as bromine in the IC package resin and delaying the progress of the Kirkendall phenomenon by including palladium in the gold wires (Kato, 2010).

3.2.5 Aluminum wiring corrosion

Resin-sealed packages are widely used for semiconductor devices. However, external moisture may penetrate the package and corrode the aluminum wiring of the semiconductor chip, resulting in a failure (Figure 18).

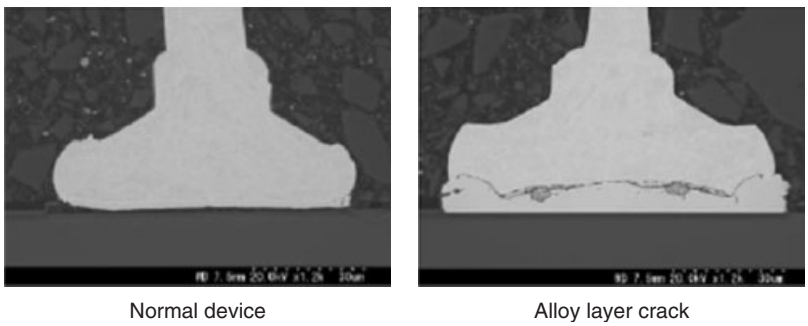

Figure 16. Kirkendall void.

DOI: 10.1002/9781118354179.auto215
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

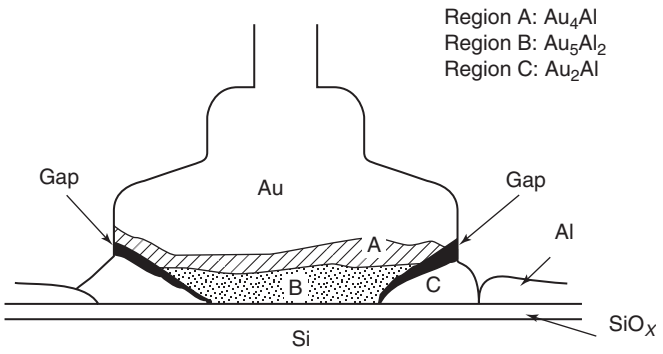

Figure 17. Alloy layers of bonding portion.

When left in dry air, aluminum develops a stable aluminum oxide (Al_2O_3) that acts as a protective film. However, an aluminum hydroxide ($Al(OH)_3$) soluble in acid and alkali is formed in the presence of moisture. If ions of impurities such as P^{3-}, Cl^-, F^-, and Na^+ are also present, corrosion occurs at exposed sections of aluminum wiring, bonding pads, pin holes in the chip protective film, cracks, and other locations. Countermeasures include adopting a highly moisture-resistant passivation film (chip protective film), lowering the moisture absorbency of the resin, and improving resin adhesion (Kato, 2010).

3.3 Reliability assessment

Before the ECU is mounted in a vehicle and shipped to market, it is evaluated by various tests and any design or manufacturing defects are corrected. To ensure effective reliability testing, it is important to accurately understand the vehicle environment and, using the accelerated testing approach described later, to select test conditions that correlate to stresses the ECU will likely receive once on the market, so that the extent of the margin with respect to the targeted life can be correctly grasped.

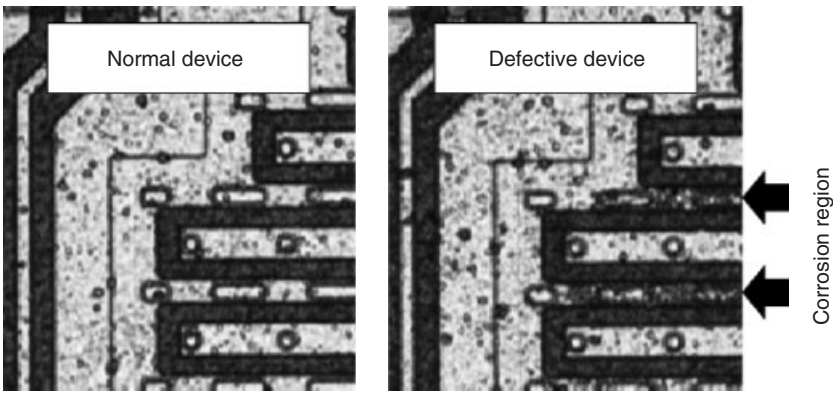

Figure 18. Aluminum wiring corrosion.

Table 2. Main reliability test items.

Test Item		Purpose
Life test	High temperature operation test	Evaluate ECU durability when subjected to electrical and thermal stress over a long period
	High temperature/high humidity operation test	Evaluate ECU durability when operating under a high temperature, high humidity atmosphere
	Humidity cycle test	Evaluate ECU durability in a temperature-varied environment that repeatedly cycles between high and low temperatures
	High humidity shelf test	Evaluate ECU durability when left in a high humidity environment
	High temperature/high humidity shelf test	Evaluate ECU durability when left in a high temperature, high humidity environment
Strength test	Load dump test	Evaluate ECU resistance to positive surge voltage applied with battery terminals removed
	Field decay test	Evaluate resistance to negative surge voltage from an alternator induction load
	RF immunity test	Evaluate ECU resistance when left under an intense electric field atmosphere
	Electrostatic test	Evaluate ECU resistance to static electricity during handling
	Vibration test	Evaluate ECU mechanical strength in a vibration environment
	Salt spray test	Evaluate ECU corrosion resistance when left in a saline environment

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.3.1 Reliability test items

Examples of general tests include ISO, IEC, SAE, and other standards. If the ECU will be used within the ranges assumed by these standards, the reliability of the ECU can be confirmed according to the test conditions set in the standards. However, car and parts manufacturers often set their own individual test items and evaluation conditions as internal standards to quickly respond to changes in onboard environments and achieve individual quality targets. Table 2 shows examples of test items (intended as only a partial list and not comprehensive). Many life tests overlap with test items performed for individual electronic components, and strength tests have many test items that concern the ECU used in an onboard environment such as the load dump test and the field decay test.

3.3.2 Accelerated testing

Utilizing the fact that applying a large amount of stress to a product shortens the life of the product, accelerated testing is used to perform a reliability assessment in a limited period of time by testing under stricter conditions than use conditions and environment conditions in the market. The acceleration coefficient A is expressed as a ratio of the test times at which a stress S_1 used as a reference and a stress S_2 used as an acceleration condition correspond to the same failure rate as shown in Figure 19.

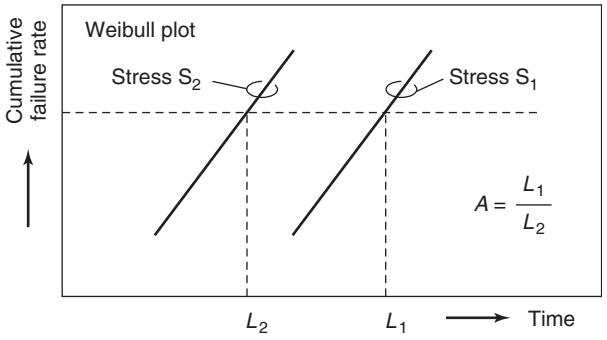

Figure 19. Calculation of acceleration coefficient.

Table 3. Representative acceleration models.

Acceleration Factor	Acceleration Model/Life Equation	Notes
Temperature	Arrhenius model $L = A \bullet \exp\left(\frac{E_a}{k \bullet T}\right)$	- Electromigration - Change in oxide film over time (TDDB) - Al electric field capacitor life L: life A: constant E_a: activation energy k: Boltzmann constant T: absolute temperature
Electric field	E model $L = A \bullet \exp(-\beta \bullet E)$ $1/E$ model $L = A \bullet \exp\left(\frac{\gamma}{E}\right)$	- Gate oxide film TDDB β, γ: acceleration factor E: electric field
Temperature difference	Modified Coffin–Manson model $L = A \bullet f^m \bullet \Delta T^{-n} \bullet \exp\left(\frac{E_a}{k \bullet T_{max}}\right)$ Temperature difference accelerated model $L = A \bullet \Delta T^{-n}$	- Solder thermal fatigue m, n: constant ΔT: temperature difference f: frequency T_{max}: maximum temperature - Al slide - Interlayer cracks
Humidity	Absolute water vapor pressure model $L = A \bullet V_P{}^{-n}$ Relative humidity model $L = A \bullet (\mathrm{RH})^{-n} \bullet \exp\left(\frac{E_a}{k \bullet T}\right)$	- Al corrosion Vp: absolute water vapor pressure RH: relative humidity
Current	Black model $L = A \bullet J^{-n} \bullet \exp\left(\frac{E_a}{k \bullet T}\right)$	- Electromigration J: current density

3.3.3 Acceleration model

Table 3 shows representative acceleration model examples (Kato, 2010), and Table 4 shows examples of activation energy used in acceleration equations (Japan Electronics and Information Technology Industries Association, 2011). Using an acceleration equation enables infinite acceleration in desk calculations, but the failure mode may change depending on the stress conditions. Therefore, consideration must be given to setting the acceleration conditions within a range where the failure mode does not change.

Manufacturing: An Introduction to Production Technology, Quality Assurance, and SCM

Naoki Ueda
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

The production of automotive electronic control units (ECUs) has many requirements. First, ECUs with various forms and structures must be produced for a wide range of purposes in addition to the engine ECU. Electronics have been applied to many automotive controls, which means that vehicles are now equipped with a number of ECUs (Kato, 2010a). As a result, it is necessary to create structures that can be mounted near desired locations based on ECU function, as well as to secure installation space and reduce vehicle weight. In addition to the need to reduce size and weight, there are demands for mountability at locations with harsh environments in terms of temperature, humidity, moisture, and the like. The ECU mounting position varies depending on function and purpose. The engine ECU is often mounted inside the engine compartment because many signals originate from the engine compartment and also because the role of this ECU is to control the engine. Body system ECUs often receive signals from inside and around the vehicle cabin and are usually mounted inside the occupant compartment as a consequence. As it is critical that the combination graphic display and car navigation system can be easily recognized and operated by the driver, the ECUs for these are placed near the instrument panel. A location near the transmission is desirable for the transmission ECU. The motor ECU is preferably mounted near the motor, and integration of the ECU and its control object is also being studied.

Thus, the form and structure of the ECU varies depending on differences in usage and the installation environment. An ECU in the occupant compartment often uses a low-cost, resin-printed board with high flexibility. An ECU with a resin-printed board is often used in the engine compartment as well, because the reliability of parts and the mounting technology of parts have been improved and structure of heat dissipation also have been improved. However, for severe environments such as direct mounting on the engine, a hybrid ECU that uses a ceramic substrate capable of withstanding this type of environment is adopted (Kato, 2010b).

As explained earlier, there are ECUs with various functions, specifications, forms, and structures, and the production technology for each ECU is appropriately selected in consideration of quality and cost.

Second, a stable and high-quality ECU must be provided as necessary to various users while adapting to the increased sophistication and diversification of specifications. Therefore, it is important to ensure stable supply performance and quality over the entire supply chain, starting with material and part suppliers and ending with the manufacturer and the user.

Third, environmentally friendly products and production methods are required. There have been demands for soldering using a solder that does not contain lead (lead-free soldering) as part of measures to reduce environmentally hazardous substances in recent years. This is a huge switch for electronic products that have been manufactured with lead soldering for many years (Japan Institute of Electronics Packaging, 2006). Going lead-free has also changed the solder melting point and wettability. Various countermeasures were required in addition to material improvement, such as improving component heat resistance, component plating, circuit board artwork (AW) design, production equipment, and process controls. In the home electronics industry, the switch to lead-free has rapidly progressed because of the Restriction of Hazardous Substances (RoHS) Directive effective from July 2006 (Official Journal of the European Union L 234/44, 2011). The automotive industry is similarly subject to the End-of-Life Vehicles (ELVs) Directive, in which the European Commission has set lead-free requirements for printed circuit boards in new vehicles to be sold from 2016 (Official Journal of the European Union L 85/3, 2011) and the automotive industry is starting to take action.

2 ECU PRODUCTION TECHNOLOGY AND QUALITY ASSURANCE

Using the example of an engine ECU among the various types of ECUs, this section summarizes an example of the manufacturing process for an ECU with a resin-printed board, and an example of the manufacturing process for a hybrid ECU with a ceramic substrate to be utilized in harsh environments such as direct mounting on the engine. Approaches to and methods for production technology and quality assurance from a production standpoint and examples of countermeasures against part variations are illustrated (Kato, 2010b; Japan Institute of Electronics Packaging, 2006).

2.1 Manufacturing process for printed board ECU

The manufacturing process for a printed board ECU is explained in the following text. The engine ECU shown as an example in Figure 1 is configured from approximately 500 parts, including a microprocessor, transistor, resistor, capacitor, connector, resin-printed board, case, and cover. The manufacturing process can be roughly divided into a mounting process and a subsequent assembling process. Figure 2 shows an outline of the processes.

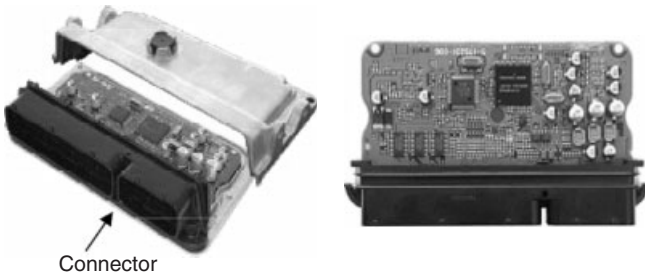

Figure 1. Example of a printed board engine ECU.

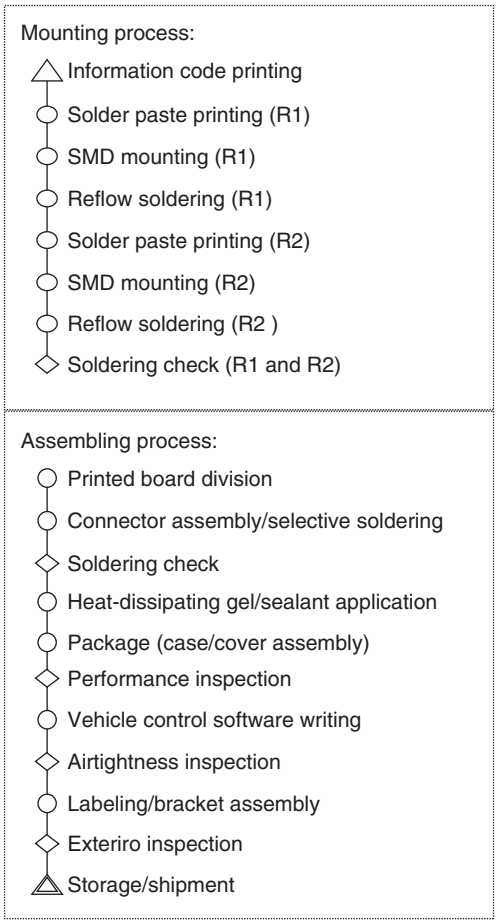

Figure 2. Example of the manufacturing process for a waterproof engine ECU.

Features of the automotive engine ECU manufacturing process include a selective soldering process because the engine ECU has a large connector that is a through hole device (THD), and include a high reliability inspection process. An ECU without a waterproof structure or with certain mounting specifications also requires an additional process for coating the entire printed board or required

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

sections with a drip-proof material to resist condensation and other humid environments. A detailed description of this process is omitted here as the main focus is on the manufacturing process for an ECU with a waterproof case structure.

2.1.1 Mounting process

Soldering is performed to mount electronic components on a printed board. To meet demands for reduced size and weight, surface mounting technology (SMT) is mainly used to mount the electronic components on both surfaces of the printed board (Japan Institute of Electronics Packaging, 2006).

2.1.1.1 Information code printing. An information code such as QR (quick response) code (ISO/IEC18004, 2006), which is a two-dimensional barcode, is used to print information such as the serial number and type number on the printed board with a laser. The information is utilized as automatic setup information for equipment and traceability, and within the assembly process for each product.

2.1.1.2 Solder paste printing. A pastelike solder material for bonding electronic components is printed on the printed board using a screen printer (Figure 3).

2.1.1.3 SMD mounting. Various types of surface mount devices (SMDs) are mounted on the printed solder paste material by a mounting machine. The code information is read to set the mounting program that corresponds to the product type and automatically perform mounting. Multiple suction nozzles are moved in succession to mount several tens of electronic components per second at high speed (Figure 3). Equipment that requires replenishing of electronic components is automatically displayed on a board, and a worker supplies the components. This operation takes advantage of the barcode information and prevents mistakes in the supply of electronic components.

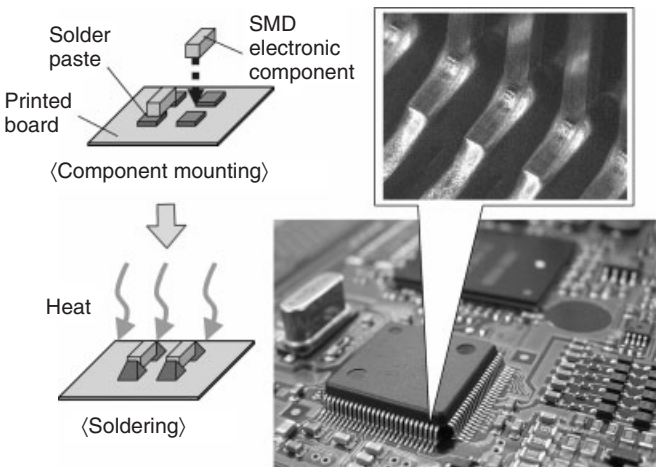

Figure 3. Solder printing, SMD mounting, reflow soldering.

2.1.1.4 Reflow soldering. Soldering is performed by melting the solder paste at approximately 230°C in a reflow (heating) oven (Figure 3). The temperature of the entire circuit board is controlled to maintain a uniform temperature and ensure a temperature that is below the upper temperature limit of the electronic components and that also melts the solder on all the components with different heat capacities. This temperature range has narrowed because of recent lead-free countermeasures, which has led to stricter temperature controls. This process completes the mounting of electronic components on one surface of the printed board. Once mounting on one surface is complete, electronic components are mounted on the other surface using the same process described earlier.

2.1.1.5 Soldering check. Next, the appearance of all soldered locations (roughly 1500 points) and the mounting condition of the components are automatically checked by an automatic viewing (optical inspection) device (Figure 4).

The principle behind the method of confirming the solder shape in a color image is explained here. The component and solder condition are judged based on the condition of this image. The component mounting process is subject to a meticulous process control to ensure that defects do not occur. However, as several hundred tiny electronic components are soldered all at once, there are rare cases of abnormal bonding as shown in Figure 4 (IPC-A-610E-2010, 2010). Therefore, all electronic components are checked so that defects are not passed on to downstream processes. The results, after the check, are fed back and used in the process control for the mounting process and to make further improvements. The checked printed board is then transferred to the subsequent assembling process.

There have been strong demands in recent years for higher functioning and smaller automotive ECUs, as well as smaller semiconductor packages with more pins. The commonly used quad flat package (QFP) form cannot satisfactorily meet these demands, and the ball grid alley (BGA) has been increasingly adopted. With this package, the solder-bonded sections are not visible after mounting on the circuit board, which means that inspection with the optical automatic viewing device used earlier is not possible. As a consequence, even tighter controls and even

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

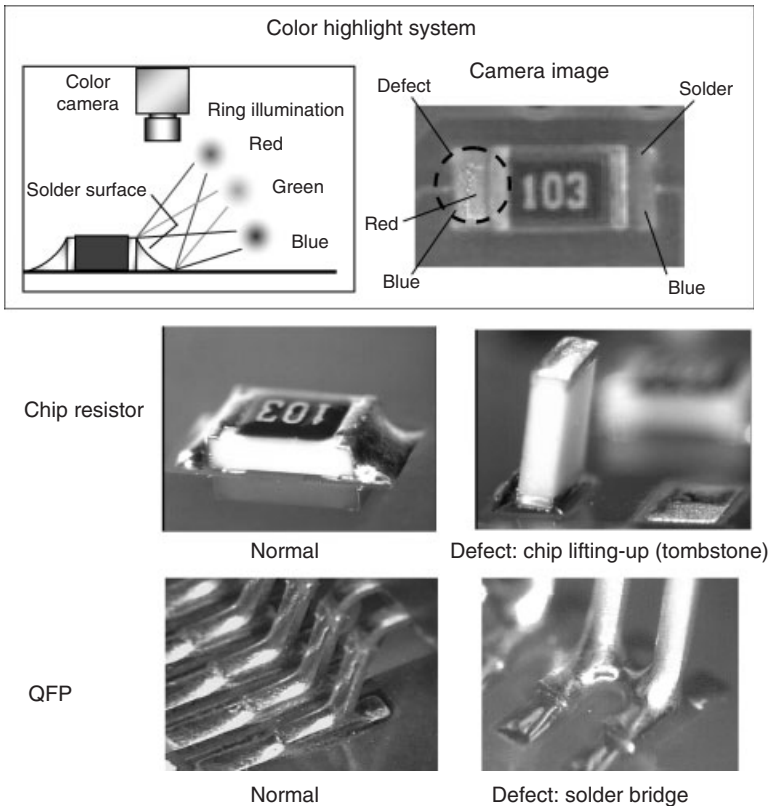

Figure 4. Soldering check by automatic viewing device.

better built-in quality from the component manufacturer up to the mounting process are required. After solder paste printing in the mounting process, an automatic viewing device is used to inspect that the solder paste has been normally printed. In addition, the solder-bonded sections may be checked by X-ray in the initial production as well as in the prototype stage (Figure 5).

2.1.2 Assembling process

2.1.2.1 Printed board division. In the mounting process, one sheet has multiple boards and the boards are cut and divided by a router or the like.

2.1.2.2 Connector assembly/selective soldering. The connector is inserted and assembled to the through hole of the printed board. For automotive ECUs such as the engine ECU, this connector alone is often a THD that is joined using a through hole. Also, as there are many pins, selective soldering is often used to enable soldering of all pins at once (Japan Institute of Electronics Packaging, 2006). First, the printed board is coated with flux to facilitate soldering. Next, it is preheated and then is on a soldering nozzle, after which melted solder is injected from below to perform selective soldering. The amount and range of the flux coating, the solder immersed state, and so forth greatly influence bonding, and process conditions are precisely set and tightly controlled for each type (Figure 6).

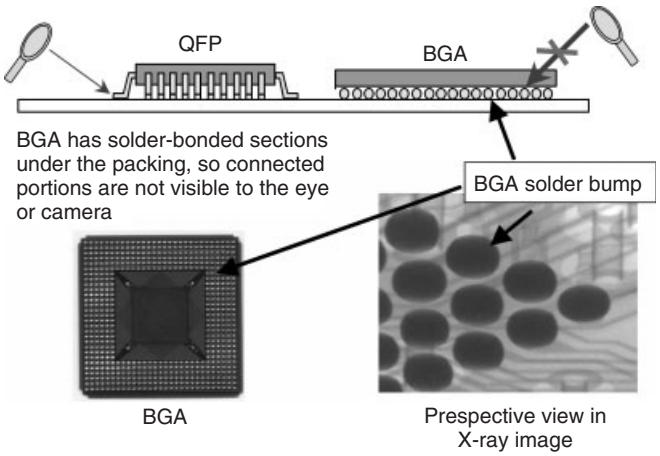

Figure 5. BGA and X-ray check.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

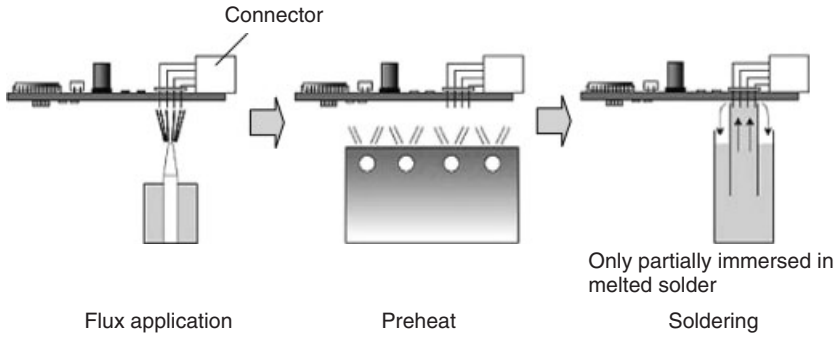

Figure 6. Selective soldering.

2.1.2.3 Soldering check. Similarly to the mounting process, the solder condition is checked by an automatic viewing device.

2.1.2.4 Heat-dissipating gel/sealant application. Heat from the electronic components must be dissipated to prevent excessive heating of the electronic components. Therefore, a heat-dissipating gel (silicone) is quantitatively applied to correspond with the layout of the electronic components on the case. To prevent water from entering the ECU interior, a sealant (silicone) is applied for hermetically sealing the outer periphery of the connector and case (Figure 7).

2.1.2.5 Package (case/cover assembly). A case and cover are attached to the printed board to package the printed board (Figure 8).

2.1.2.6 Performance inspection. To check the several hundred electronic components, as well as their assembling quality and operation as an ECU, a performance inspection is performed in which quasi-signals such as vehicle speed signals and engine speed signals are input to determine whether a set output signal can be acquired (Figure 9).

Inspections at high and low temperatures that estimate the temperature environment when mounted in a vehicle may be performed to detect any defects in the temperature characteristics of the components.

2.1.2.7 Vehicle control software writing. Programs for controlling the vehicle are automatically written based on ECU type. The programs are written in time to create an ECU capable of engine control.

2.1.2.8 Airtightness inspection. Hermetic performance is inspected to check whether the sealant applied for a

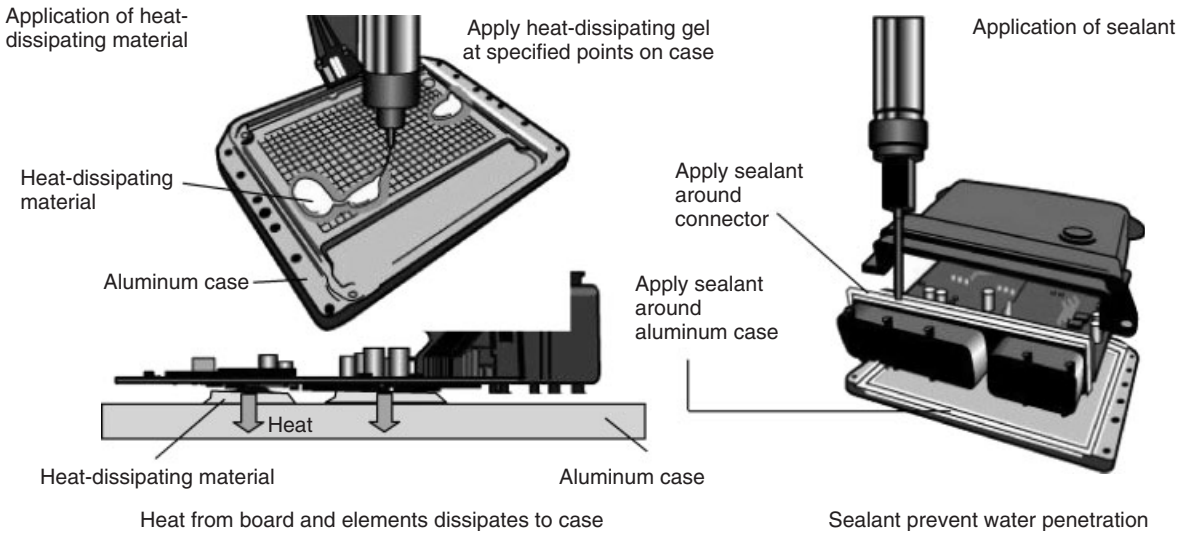

Figure 7. Heat-dissipating material, sealant application.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

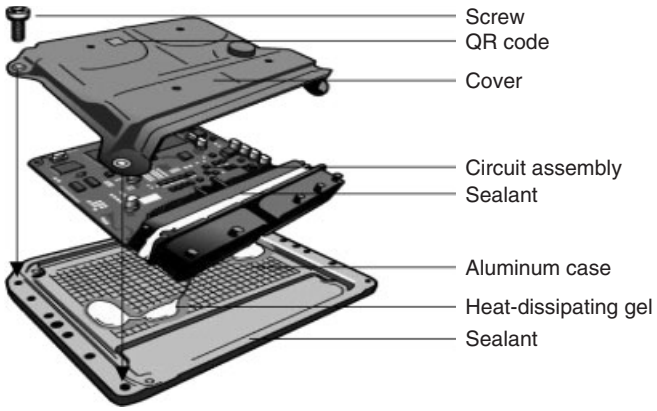

Figure 8. Package (case/cover assembly).

hermetic seal can withstand the installation environment in the vehicle.

2.1.2.9 Labeling/bracket assembly. Labels for each type are printed and attached. Brackets for attachment to the vehicle are assembled.

2.1.2.10 Exterior inspection. The exterior of the fully assembled product is inspected, including the name, labels, and the like. This completes production of the ECU.

2.1.2.11 Storage/shipment. Following completion of the inspection, the product is matched to an order and shipped in accordance with the order.

The preceding process and production technology examples are only brief summaries, and the processes may be differently ordered, omitted, or added to, depending on the product.

As mentioned earlier in one of the processes, each process uses the information code for the production progress management of each product, process controls, automation of in-process switching of product types, and the like. A traceability system is also employed so that history information can be traced to ensure thorough quality control. Although various inspections as mentioned earlier are implemented to prevent the outflow of any products with defects, quality is built into each process as a general rule.

For example, process capability is normally evaluated using the process capability index Cp (Cp = standard width/6σ, where σ is the standard deviation). However, the product data average may deviate from the standard median, and Cpk (Cpk = (data average − limit)/3σ) must be considered in this case. Cp and Cpk are used in combination to evaluate processes and implement necessary improvements. To ensure that excessive stress is not applied to electronic components or bonded portions during processing and assembling, the strain applied to the product in each process is evaluated and the positional relationships between components are reflected in the board design. Necessary improvements are also made to the processes themselves. Specific examples include the screw position and the locations of board divisions.

This section introduced some activities to ensure quality. As described earlier, stable manufacturing and supply is only possible after first building high-quality processes.

2.2 Manufacturing process for hybrid ECUs

Figure 10 shows an example of a hybrid ECU that uses a ceramic substrate. The ECU is directly mounted on the engine and used as an engine ECU. The ECU is configured from approximately 150 parts, including a microprocessor, transistor, resistor, capacitor, connector, ceramic substrate, case, and cover (Kato, 2010b).

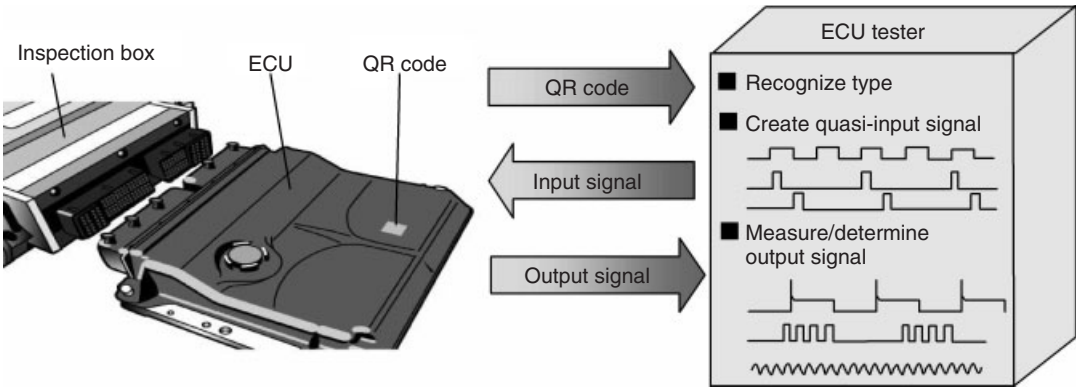

Figure 9. Performance inspection.

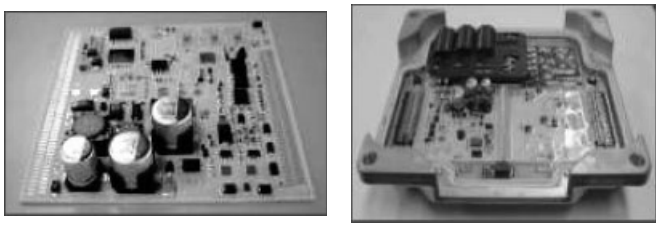
Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5



(a) (b)

Figure 10. Example of hybrid ECU directly mounted on engine. (a) Photo of exterior of components mounted on ceramic substrate. (b) Exterior of ECU product.

Directly mounting the ECU on the engine requires high heat resistance and a small size. To increase heat resistance, a ceramic substrate is used for the circuit board, and semiconductors are mounted on the circuit board by bare chip mounting.

The production technology for a hybrid ECU is outlined in the following text. Figures 11 and 12 illustrate examples of the process flow.

First, a solder material is applied to required locations on the ceramic substrate using a screen printing method. Parts such as semiconductor bare chips and chip capacitors are mounted on the solder material, and reflow soldering is performed at approximately 230°C. Flux contained in the solder material is subsequently cleaned. Fluorocarbon cleaning solvents have been used in the past as the cleaning solution, although water-based cleaning solutions are now employed in consideration of the global environment. Semiconductor bare chip components are mounted with an electrically conductive adhesive, after which gold (Au) wire bonding and aluminum (Al) wire bonding are performed to create electrical connections.

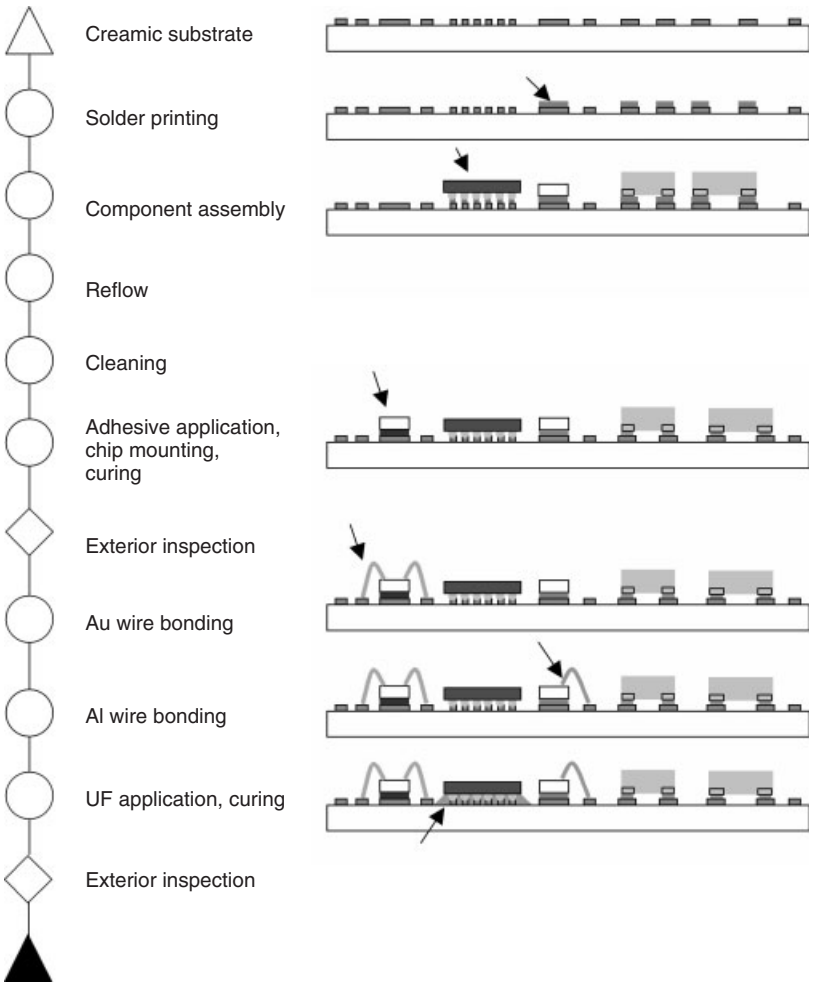


Figure 11. Example of manufacturing process flow for hybrid ECU (circuit board process).

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

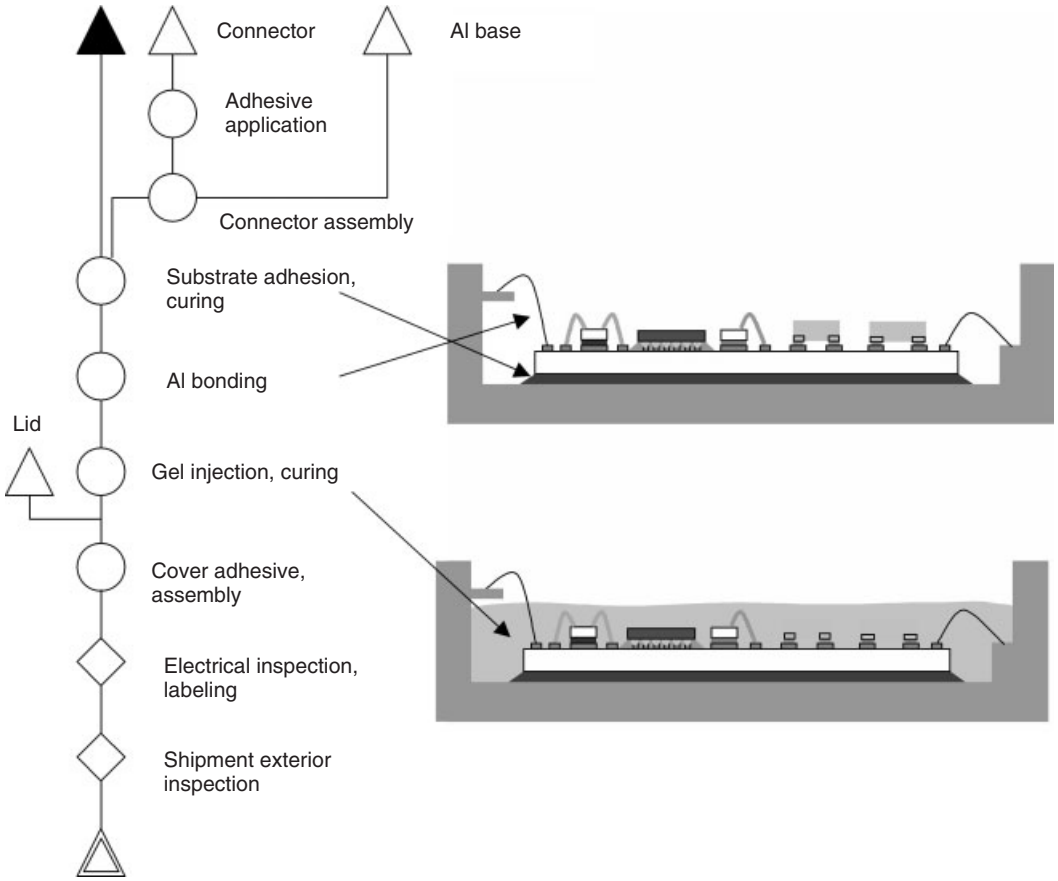

Figure 12. Example of manufacturing process flow for hybrid ECU (assembling process).

To improve the reliability of the solder-bonded portions of some components, an epoxy-based resin material [underfill (UF) material] is applied to reinforce the soldering. This completes the manufacture of one circuit board. An exterior inspection is performed at this stage, and the circuit board is then transported to the downstream process. Note that, although not described in detail here, the ECU shown in Figure 10 is configured from three boards.

The circuit board with assembled components is closely attached using adhesive to components to which a base made of metal (generally Al) and connector components are already adhered. Next, these are covered with a potting material (silicone-based gel) to protect the semiconductors and bonding wires, and a lid is then adhered. Following an electrical inspection, the product is shipped.

2.3 Comparison of hybrid ECU and printed board ECU

This section briefly compares the hybrid ECU that uses a ceramic substrate and the commonly used printed board ECU, while focusing on the merits of the hybrid ECU in particular. The hybrid ECU is advantageous in terms of having a small size, as well as good heat resistance and environment resistance (Table 1).

From the standpoint of downsizing, the hybrid ECU has an edge because of easy bare chip mounting. The printed board ECU uses molded ICs including QFPs, and the practical area required for mounting these components is, therefore, approximately five times larger than that needed for bare chip mounting. In addition, the hybrid ECU can adopt structures well suited for downsizing, for example, direct printing of resistors on the substrate and full-thickness via holes.

With regard to heat resistance, the hybrid ECU uses a ceramic substrate, that is, a sintered compact, and is extremely stable with respect to heat. Ceramic components mounted on the substrate have a matching coefficient of thermal expansion for reduced stress on connected regions and high reliability. The environment resistance of the hybrid ECU enables installation in high-temperature regions subject to large vibrations.

Table 1. Comparison of hybrid ECU and printed board ECU

			Hybrid ECU	Printed board ECU
Downsizing	IC		Bare chip	Molded IC
	Resistance		Direct printing resistor + chip resistor component	Chip resistor component
	Board design		Via hole	Through hole + via hole
Heat resistance	Board glass-transition point		Approximately 1600°C (firing temperature)	Approximately 140°C (FR4: glass epoxy board)
	Coefficient of thermal expansion	Board	7 ppm/°C	16 ppm/°C
		Components	6–9 ppm/°C	6–9 ppm/°C
Environment resistance	Use environment		Direct mounting on engine	Mounting in occupant compartment or engine compartment
	Vibration resistance		30G	5G

3 SUPPLY CHAIN MANAGEMENT

Automotive ECUs are configured from a number of materials and parts, including electronic components such as microprocessors, transistors, resistors, and capacitors, as well as printed boards, connectors, cases, covers, solders, sealants, screws, and brackets. In addition, those individual materials and parts are composed of raw materials and other parts and materials. Their quality and supply support ECU production, and the management, that is, supply chain management (SCM), of the material and part supply network is extremely critical to achieve high-quality and stable production.

In the automotive industry, consolidation of the supply of raw materials and parts has advanced thus far based on the pursuit of lower costs and higher quality. Partial modularization has similarly progressed. Furthermore, there are parts that demand lower costs and higher quality of both the ECU and components, which can only be achieved by surveying the supplier processes and the entire ECU production process, and considering all processes and inspections as a whole. Instead of a pyramid supply

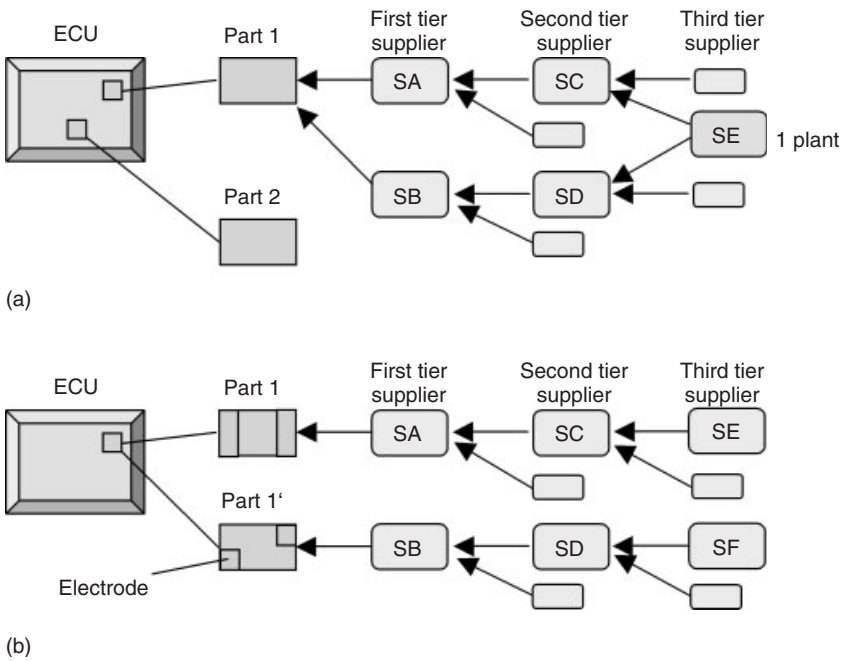

Figure 13. Supply chain. (a) Example of common raw material supplier. (b) Example of different suppliers and electrode geometry.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto216
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

configuration, it may be discovered that some materials or parts are restricted to a limited number of suppliers.

Supply risk management has become extremely important because of large-scale disasters, company risks, and other factors and is gaining more attention. As the ECU is configured from a large number of materials and parts as described earlier, it cannot be produced if the supply of even one part is interrupted. Although there are parts that can be easily substituted or are not directly linked to product competitiveness, materials and parts that sustain the competitiveness of the product in terms of quality, performance, and cost cannot be easily replaced. For this reason, restructuring and visualization of the supply chain, particularly in consideration of risk management, is necessary.

An in-depth and comprehensive examination of the supply chain must be performed. For example, as shown in Figure 13a, in the case of two first-tier suppliers, there should be no problem with the two first-tier suppliers purchasing materials and parts to manufacture their own parts from different second-tier suppliers. However, the fact that an underlying third-tier supplier supplies raw material to both second-tier suppliers and also has only one plant may be overlooked. If the third-tier supplier is affected by a disaster, the supply of raw material could be stopped. Moreover, this could happen again at any time in the future.

Parts with the same exterior shape and function cannot necessarily be easily interchanged. For example, as shown in Figure 13b, even parts with the same exterior shape and functions may have different electrodes. In this case, the geometry of the electrodes (lands) on a printed board may correspond to one part but not the other. If the other part is mounted to the noncorresponding printed board and soldered, a mounting defect such as part rotational displacement may occur. If possible, the geometry of the electrodes of printed board (lands) should be designed in advance so that either part can be mounted to printed board without any problems. This involves AW design technology, and in a wider sense, production technology.

Simply prioritizing risk avoidance by increasing inventory results in unnecessary costs and reduces product competitiveness. Instead of thinking strictly in terms of the quality, cost, and supply of materials and parts, the supply chain should be considered and strategically studied at the stages of design, part development/selection, and material development/selection.

4 CONCLUSION

There are ECUs with various functions, specifications, forms, and structures and appropriate production technology for each ECU is selected considering required quality and cost. This chapter takes the engine ECU as a representative example and gives an overview of production technology for printed board ECUs and hybrid ECUs made of ceramic substrate. It also summarizes approaches and methods for quality assurance taken during production of these.

It is important to ensure stable supply performance and quality over the entire supply chain, starting with material and part suppliers to the manufacturer itself and the users. Supplier chain management is outlined also in view of significant supply issues that have surfaced in recent years.

In the near future, integration of the ECU and its control object, that is, electro-mechanical integration, will increasingly progress. Further development of connection technology and size reduction technology will be required, together with improved production technology to achieve these goals.

Microcomputers and Related Technologies: Enlargement of Software Size, Algorithms, Architectures, Hierarchy Design, Functional Decomposition, and Standardization

Hideaki Ishihara
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Automotive electronics have been advancing rapidly in the successful pursuit of environmental friendliness, safety, comfort, and convenience. These advancements have been achieved through the adoption of microcomputers, which now total to approximately 100 in each luxury car. Since the late 1970s, microcomputer technologies have achieved enhanced performance, affinity with real-time processing, high fault-tolerance, and the like. However, the consequent enlargement of software size has resulted in the need not only for new software architectures such as hierarchical design by functional decomposition but also for international standardization [such as OSEK (open systems and the corresponding interfaces for automotive electronics) and AUTOSAR (automotive open system architecture)]. In the twenty-first century, there is public awareness of the need for the creation of more green and dependable automotive systems, driving the need for the reduction of CO_2 emissions. There is also a general interest in achieving high road safety levels. From these points of view, this chapter describes the histories and future directions in regard to both microcomputers and software in automotive electronics, while considering semiconductor technologies and their applications.

2 MICROCOMPUTERS

2.1 History of automotive microcomputer applications

The automobile and the microcomputer are two of the greatest developments of the twentieth century. The automobile enabled universal freedom of movement and the breakthrough of the microcomputer-enabled complex functions conceived by people and plays a main role in modern systems. Microcomputers have come to be used in almost every industry. This was triggered by the development of the integrated circuit (IC) after the invention of the transistor by John Bardeen, Walter H. Brattain, and William B. Shockley at Bell Laboratories, which had the effect of turning large computers into compact and portable

devices. Present microcomputers generally contain not only microprocessors but also input/output circuits and memory devices all within a single semiconductor chip. A microprocessor consists of an arithmetic unit and a control unit, which functions as a central part of microcomputer circuits. The terms *central processing unit* (*CPU*), *processor*, and *micro processing unit* (*MPU*) are also used as general synonyms for a microprocessor. In 1971, Intel Corporation created the 4004, which was the world's first commercially available microprocessor. It had a 4-bit processing capability and a clock speed between 500 and 741 kHz. A total of 2300 transistors were integrated on a chip with an area of 3 mm × 4 mm and it was manufactured using 10-μm semiconductor processes. The 4004 was developed as a joint venture between a Japanese electronics engineer called *Masatoshi Shima* and Intel Corporation based on a request from the Japanese company Busicom for use in an electronic calculator. Subsequently, microprocessor bit lengths evolved from 8 to 16 bits. From the beginning of the 1990s, 32-bit microprocessors also started to become available in certain embedded systems (Kato *et al*., 2010).

When implementing an electrical function, a key difference between the microcomputer and the hard logic is the length of the development period between the software and the hardware. Software functions can be changed in a period from several hours to several days. However, hard logic takes at least several months (i.e., at least 100 times as long) to change as different semiconductors have to be prototyped and evaluated. Furthermore, the number of software designers can be increased substantially at short notice as software education and training is not subjected to serious physical limitations. These are the main reasons why microcomputers have spread so rapidly in vehicles (Kato *et al*., 2010).

The operating voltage of microcomputers was generally 5 V, whereas the semiconductor manufacturing process was 0.5 μm or larger. Subsequently, since the beginning of the twenty-first century, the operating voltage has been decreasing, reaching 3.3 V at 0.35 μm, 2.5 V at 0.25 μm, and approximately 1 V at 90 nm. However, the operation voltage of most peripheral functions embedded in microcomputers remains 5 or 3.3 V for reasons related to sensor and actuator interfaces.

As automotive electronics have evolved, the number of microcomputers has increased to dozens in an ordinary passenger vehicle and more than a hundred in a luxury vehicle. Unlike personal computers, automotive microcomputers generally use a single chip in which the input and output circuits are integrated onto a semiconductor chip. This is to satisfy the various performance requirements of a vehicle, such as the built-in memory capacity, high real-time capabilities, strong electromagnetic compatibility (EMC), and wide operating temperature and voltage ranges. This has been enabled by the explosive evolution of semiconductor IC technology in the second half of the twentieth century. The aim of automotive microcomputers is not simply to achieve the basic moving, turning, and stopping performance aspect of the vehicle. Microcomputers are also installed in core portions of safety devices such as airbags, millimeter wave radar, and the like, antitheft, power window, and other body control devices, and intelligent transport systems (ITS) devices such as electronic toll collection (ETC), and navigation systems. These functions can now be cooperatively controlled through the local area network (LAN) (Ishihara, 2009; Tsuda, 2007).

The first use of a microcomputer in a vehicle was for engine control, prompted by the introduction of stricter emissions regulations. Microcomputers were adopted by General Motors (GM) in 1976 and by Ford in 1977 for engine controls, such as ignition timings. The automotive industry in Japan was also researching microcomputers in engine controls at virtually the same time. In 1980, Nippondenso Co., Ltd. (the current Denso Corporation) adopted a single-chip microcomputer-based engine control with a 12-bit microprocessor and an 8-input interrupt function. These microcomputers had superior processing capabilities, real-time performance, and operating temperature range than the 8-bit microcomputers provided by Intel at that time. For a long time after then, the bit length of automotive microprocessors became a logical target for developers. However, 8-bit microprocessors became the predominant microcomputer since the second half of the 1980s because of their sufficient performance for all aspects of engine control by establishing a 16-bit address range capable of pointing to locations in memory. Although mainstream modern microprocessors are 32-bit, some 8-bit devices are still used in low-cost systems (Kato *et al*., 2010).

Microcomputers entered widespread use over the second half of the 1980s. Figures 1 and 2 show two examples: the 1-bit microcomputer made by Denso for low-end electronic systems and the 8-bit microcomputer (ND8) made by Denso with a multithread structure to avoid runaway.

2.2 Requirements of automotive microprocessors

Non-multimedia automotive control systems require *hard real-time performance*. This refers to an absolute permissible maximum run time for individual software within the application. For microprocessors such as personal computers, the cache and other means are effective ways of

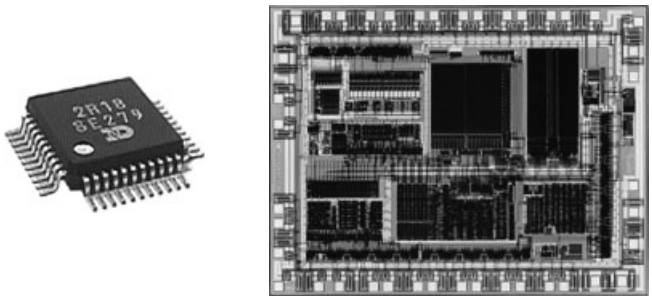

Figure 2. 8-Bit microcomputer (ND8) made by Denso. (Reproduced by permission of H. Ishihara/Denso. © Denso Corporation.)

improving performance. However, these do not satisfy the hard real-time requirements and therefore cannot be used in automotive microcomputers. Instead, memory devices are embedded in the chip to improve performance. As there is a limit to the capacity of memory that can be embedded in a chip, one key item for selecting a microcomputer is the efficiency of translating the software to machine code. This is also known as an *evaluation item* called *code size efficiency* (Figure 3) (Ishihara, 2007, 2009).

In 1995, Denso developed the Nippondenso reduced instruction set computer (NDR) machine, a 32-bit reduced instruction set computer (RISC) optimized for automotive controls. Using the RISC architecture of a general-purpose register machine (Figure 4), the development closely emphasized the relationship between the instruction set architecture and C compiler to enhance affinity with automotive control software. As a result, it was possible to greatly improve the code size efficiency in comparison with other microprocessors (Figure 5) (Ishihara, 2007; Kawamoto *et al.*, 2001).

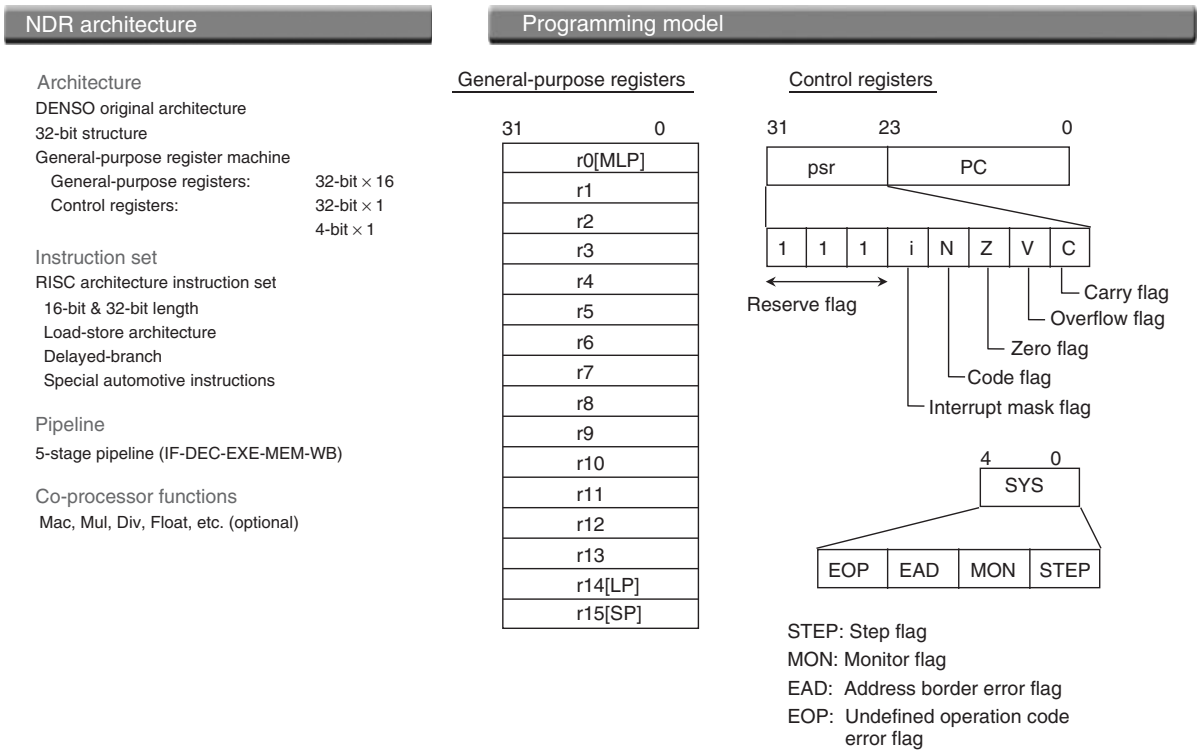

Figure 4. RISC architecture of general-purpose register machine.

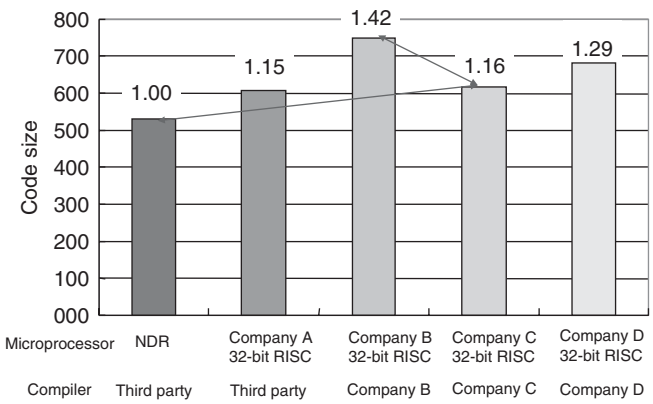

Figure 5. Affinity with automotive control software.

2.3 Internal structure of single-chip microcomputer

Figure 6 shows an example microcomputer structure.

In addition to the microprocessor, the integration of functions for special applications on single chips include embedded memory, interrupts (INT), timers, inputs [analog-to-digital converters (ADCs) and input capture], outputs [pulse width modulation (PWM)], communication functions [universal asynchronous receiver-transmitters (UARTs), serial peripheral interfaces (SPIs), and controller area networks (CANs)], and the like. Timers are used for the time management of tasks that are indispensable for real-time performance. Cooperative operations with INT are used to start periodic tasks and to measure the interval between events. ADCs are used to convert analog values from sensors to digital values that can be used by the microcomputer. PWM is capable of generating output waveforms with a modulation protocol that changes the duty ratio of the pulse wave and is used in motor control and for simple data transmission. SPI is characterized by clock-synchronized communication and is used for communication between the multiple peripheral ICs on the ECU (engine control unit) circuit board. CAN is used for communicating between ECUs. Input capture is used to measure the pulse width and interval. Other embedded functions may also include the voltage regulator required to operate the microcomputer, low voltage reset, and a watchdog timer. Recent years have also seen greater demands for extremely compact implementation as microcomputers are now being embedded within sensors and actuators. As an example of this trend, Figure 7 shows the microcomputer embedded in a power window motor (Ishihara, 2009; Ookura, 2005).

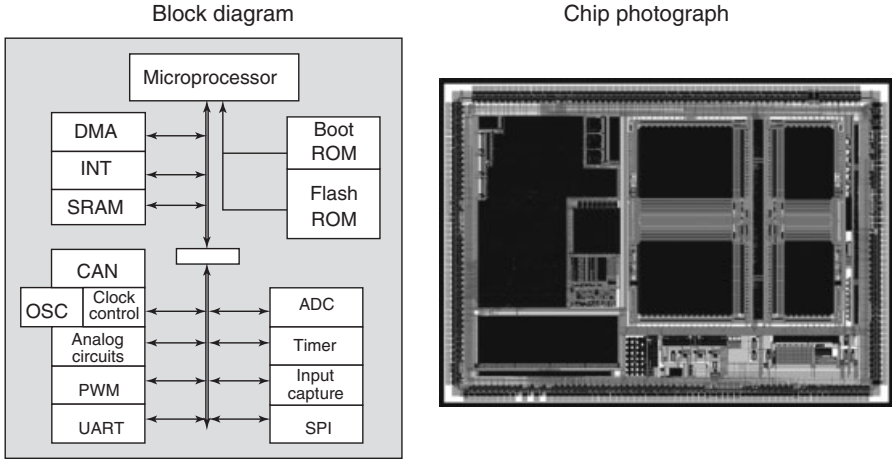

Figure 6. Example 32-bit microcomputer (body electronics).

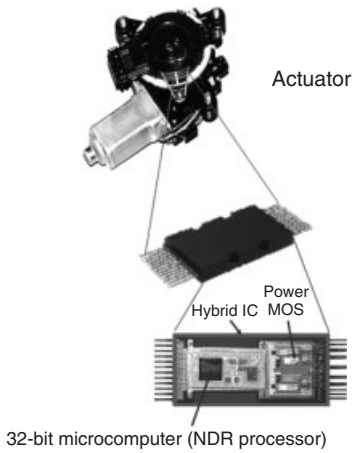

Figure 7. Example microcomputer (power window).

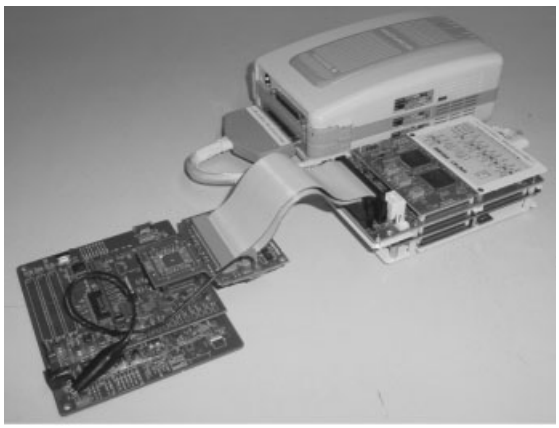

Figure 8. Example ICE.

2.4 Role of the software development environments

Use of the software development environment is an indispensable part of developing software to be embedded in microcomputers. When this software is developed in C language, the C programs are translated into assembly language by the C compiler and then further translated into machine language by an assembler and linker. The software is then written into the embedded memory of the microcomputer by a ROM (read-only memory) writer. The software is debugged by an in-circuit emulator (ICE) and/or RAM (random access memory) monitor, which confirms that the software operates according to expectations while monitoring the internal information of the microcomputer. Figure 8 shows an example ICE. As the integration density of semiconductors increases, the functions of the software development environments may be embedded into the microcomputer to confirm the software operation more efficiently.

2.5 Future prospects of automotive microcomputers

The amount of software is likely to increase dramatically in the future in response to requirements for greater environmental performance, safety, comfort, and convenience. Consequently, microprocessor performance will have to be enhanced to allow these processing requirements to be performed effectively. In the 30 years since 1980, microprocessor performance has improved by more than 1000 times. Moore's law is used by the world's semiconductor industries, computer industries, and research institutions

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto217
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as a guideline for making predictions regarding semiconductor and computer technologies. Gordon E. Moore, the cofounder and Chairman Emeritus of Intel Corporation, first proposed the law in 1965. Since then, Moore's law has been widely discussed among researchers, resulting in its use as a guideline for the prediction of future trends in both semiconductor and computer industries. This rule of thumb indicates that the numbers of transistors on an IC will double approximately every 18 or 24 months. This has been expected to be a driving force behind the progress of microprocessor performance. However, future trends remain unclear. As current developments are approaching their limits with respect to Moore's law in semiconductor technologies, the field of computer engineering is trending toward multi-core technologies that increase the number of microprocessors on silicon. However, multi-core technologies compatible with the hard real-time processing requirements of vehicles is still at a nascent stage around the world (Ishihara, 2007, 2009).

Hard real-time refers to systems in which the processing value switches to zero immediately after a preset time restriction (i.e., a deadline) is not satisfied. These are different from soft real-time systems in which processing values gradually fall over the course of time (such as personal computers and other information devices). In other words, automotive electronics resembles those used in the aviation field and are complex temporal protection systems. However, as the current focus of multi-core technology is on increasing average and optimum performance, these systems may even crash unless the minimum performance is guaranteed. In addition, as the number of microprocessors on a chip has increased, communication between microprocessors has also increased, which makes satisfying the fundamental temporal protection requirements unpredictable. Consequently, further technological innovation is strongly required. Figure 9 shows an example of a multi-core microcomputer with enhanced temporal protection performance (Ishihara, 2007, 2009).

Furthermore, many multi-core technologies are being researched that increase the number of processors on silicon from several tens to several hundreds. This is reputed to be generally suitable for applications that require high parallel performance, such as image processing. Multi-core technologies featuring more than 100 processors have already been applied for image recognition in automotive electronics.

In contrast, automotive microcomputers are trending strongly toward single-chip solutions. However, as technologies in ICs become increasingly advanced, it will be more difficult to integrate heterogeneous devices. Additionally, system in package (SiP) technologies that use through-hole vias are becoming more widely adopted. In the future, when the adoption of single-chip technologies is difficult or small amounts of a wide range of products are required, more fields are likely to request SiP solutions that combine standardized semiconductor chips.

3 SOFTWARE

Software is a key component of automotive systems. This section describes the fundamental details and characteristics of software for automotive electronics.

3.1 Role and positioning of software

The shape and form of software is invisible even under close examination of the ECU, which is the main component of automotive electronics. The software or programs are located within the internal ROM and RAM of the microcomputer. These are interpreted by the microprocessor and comprise rows of instructions to be operated and data

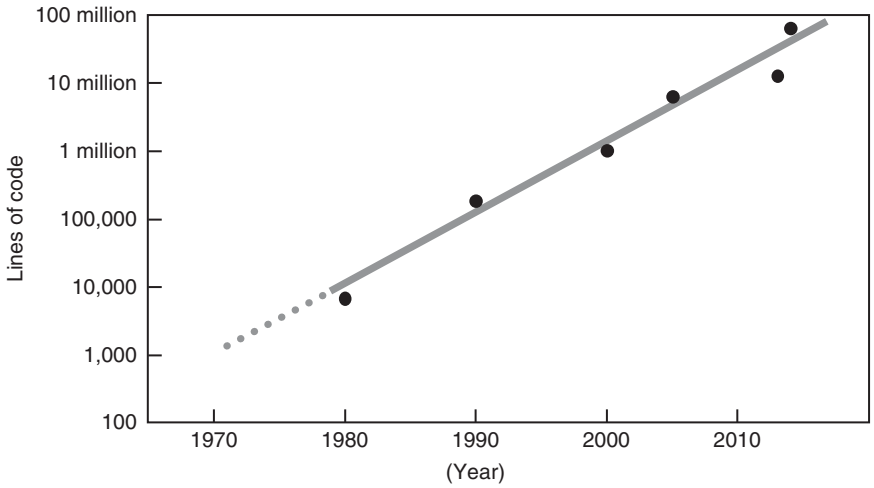

Figure 10. Trends for software installed per vehicle .(estimated from trends of Denso and other companies)

groups that represent the operation target. Software is the language used for comparison with the hardware and it defines how the hardware functions.

3.2 Increasing amount of software in automotive electronics

Initially, the adoption of microcomputers began in the 1970s with the development of engine controls. Subsequently, this trend began to spread to products used in body electronics, safety systems, and information systems.

In accordance with this growth, the number of microcomputers per vehicle increased to dozens in an ordinary passenger vehicle and more than a hundred in a luxury vehicle. From the standpoint of software, the lines of code increased from <10,000 in the 1980s to more than 10 million in 2010. This number is likely to continue growing (Figure 10) (Kato *et al*., 2010).

3.3 Algorithms

The functions of the microprocessor embedded in a microcomputer include inputting and processing external data, and outputting the results. The procedure and timing for performing this data input/process/output sequence is determined by the algorithm. As a computer operates in accordance with the instructed program, the algorithm must be written correctly to ensure that the computer operates as intended. Historically, although Euclid's algorithm is regarded as the first mathematical algorithm, other types of algorithms based on state transition rules, physical models, and hardware restrictions are also in use. In automotive electronics, the means and procedures for key

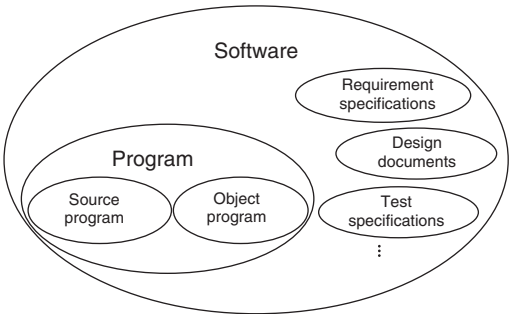

Figure 11. Software and program.

data processing are often regarded as the specifications. The software is implemented to realize the algorithm as concrete processing based on the specifications. Even if the same result is obtained, the algorithm used can result in substantial differences in the execution time required for microprocessor and the amount of data required for performing the work. The terms *software* and *program* are often used synonymously but actually represent slightly different nuances (Figure 11). A program is a set of instructions for computer processing, whereas *software* refers to all the documentation required to develop the programs in addition to the actual programs themselves (Kato *et al*., 2010).

3.4 Software architecture, functional decomposition, and hierarchical design

Software architecture refers to the basic component, framework elements of the software, and the relationship between these elements (i.e., the input/output characteristics and the

DOI: 10.1002/9781118354179.auto217
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

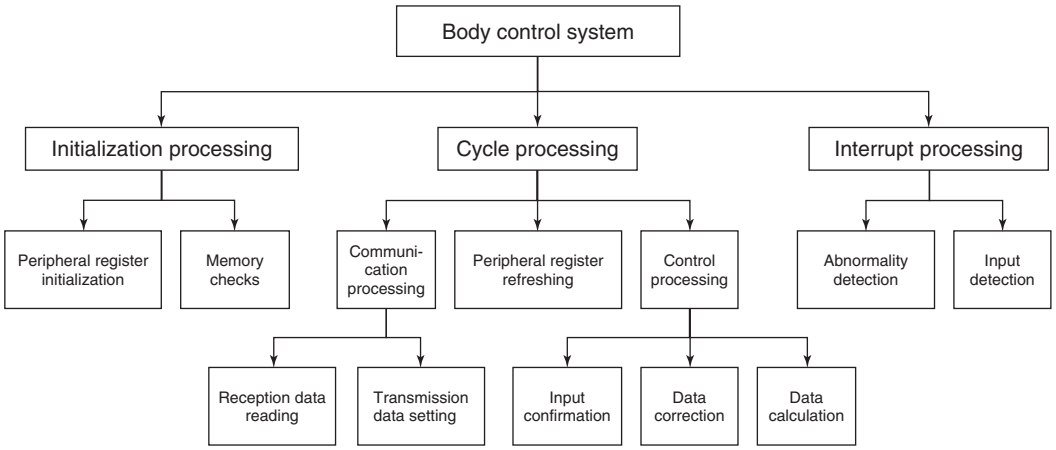

Figure 12. Example of hierarchical design in body electronics.

way one element uses another or is used). The software architecture can be used for mutual understanding and communication between software designers. In addition, the design policy is determined in the initial period of the development to ensure that the subsequent development steps proceed smoothly.

Hierarchical design by functional decomposition is used to clarify the component elements of software. In this design method, the software is divided into functional units that are assembled in a hierarchical manner (Figure 12). Hierarchical design enhances serviceability and quality by clarifying the design process.

3.5 Program categories

Programs can be categorized into system and application programs (applications). System programs can be further categorized into operating systems (OSs), device drivers, and middleware (Figure 13).

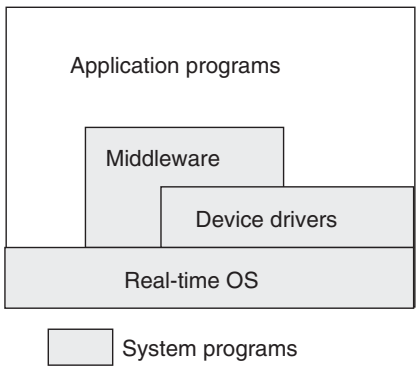

Figure 13. Categories of program.

Small-scale automotive systems are configured with interrupt processing programs, simple schedulers, and applications to reduce the processing time and memory overhead required by an OS. The OS is the fundamental program for ensuring that the computer resources are used efficiently. Automotive applications generally use a real-time operating system (RTOS). The basic functions of an RTOS include scheduling (task management), synchronization, and exclusive control. An RTOS with restricted functions may be referred to as a *kernel*. Under RTOS control, program units instructed by the microprocessor are called *tasks*. Task states are defined as run, ready, and wait. In addition, each task has a priority attribute. The RTOS transits to the run state of the task with the highest priority within the tasks that are in the ready state. This control is called the *scheduling function*. The wait state occurs when waiting for some kind of phenomenon to occur or when a resource cannot be used because it is being used by another task. The wait state continues until that phenomenon occurs or the object resource is released (Figure 14) (Kato *et al*., 2010).

The program portion that quickly carries out the minimum functions required of the interrupt processing is called the *interrupt handler*. This is regarded as a separate unit from the tasks. In the event that multiple tasks are operating the same resources, the exclusive control acquires those resources to secure the operation and excludes the operation of other tasks (Figure 15) (Kato *et al*., 2010).

The program that directly controls the hardware to allow the microcomputer to operate external data input and output is called the *device driver*. The device driver function is often achieved by a combination of the interrupt handlers and tasks. The aim of the device driver is to

isolate and conceal hardware differences and hardware control details from the applications. Isolating the hardware controls from the applications enables those applications to be reused with different hardware. Device drivers with the same hardware can also be used in common by different applications. In addition, the term *middleware* refers to *software* that is positioned between the RTOS and the applications.

3.6 Software development process

The series of activities involved in the development of software is referred to as the *software development process* or the *software process*. Each unit of these activities that occurs during the software process is called a *phase*. A *process model* is the general and abstract term for a software process. A

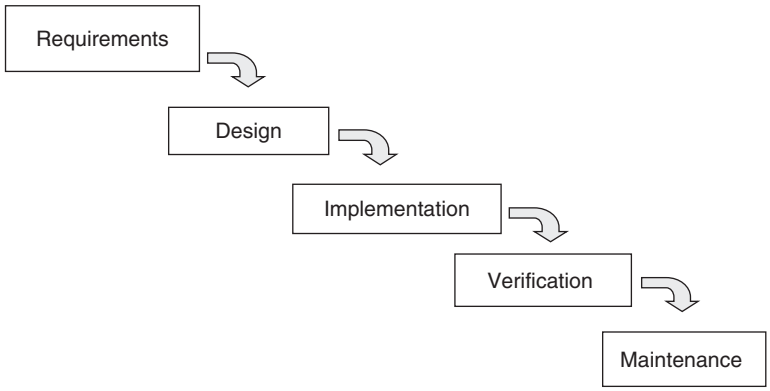

Figure 16. Waterfall model.

classic and well-known process is the waterfall model (Figure 16).

In the waterfall model, development is viewed as flowing downward through several phases throughout the software development process. In this model, the development moves on to the next phase only when the preceding phase is completed and perfected. The benefit of this process is the ease of quality control. If a problem is identified in the previous phase, it is fixable by reverting to the former phase. Therefore, it might be assumed that perfection within the given phase should ensure the perfection of the end product. However, this is often not the case. If the model itself has a problem that can only be revealed during development, perfecting each phase fails to produce the desired end result. Nevertheless, this development process is still widely used because of its ease of implementation.

The most popular process model employed in the automotive software development is the V-model, which is a modified version of the waterfall model. The V-model consists of the coding phase and the verification phase, in which the validation process is subdivided. As seen in Figure 17, the verification phase is divided into unit testing, integration testing, and system testing. Each of these serves the function of testing mounting, designing, and requirement analysis. The V-model shares weaknesses similar to the waterfall model but is superior because it emphasizes the verification phase. This ensures superior quality control of the software and is the most widely used model in the automotive industry.

3.7 Characteristics of automotive control software

The first characteristic of automotive control software is its hard real-time properties. Failure of an automotive control system to process a program within a certain deadline can have severe consequences for the vehicle.

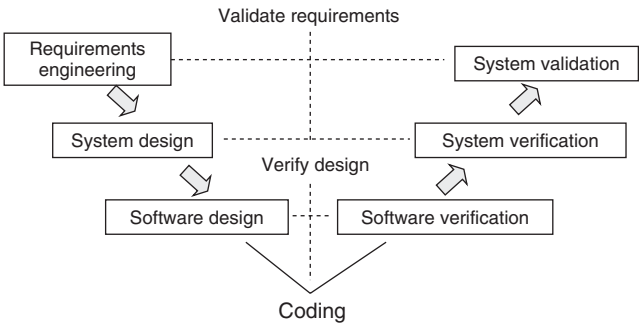

Figure 17. V-model.

The second characteristic is the importance of saving resources. As many automotive systems use single-chip microcomputers, it is crucial to implement the required functions as programs within the capacity of the chip. For this reason, there are strict requirements to save resources.

The third characteristic is the requirement for high quality. As software increases in scale and complexity, activities to ensure quality are becoming more difficult and are growing in importance.

4 ADOPTION OF ELECTRONIC SYSTEM PLATFORMS

4.1 Hierarchy of electronic systems

As automotive electronic systems have become more widespread, large numbers of ECUs, sensors, and actuators have been connected using automotive LAN. Consequently, compared with the early 1990s when the processes to be performed by the ECUs were determined for each function,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto217
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

there is now a greater need to determine the allocations of the role of each ECU from the standpoint of overall system optimization.

As the number of ECUs installed in a single vehicle increases, it is becoming clearly more difficult to secure adequate installation locations. Standard functions that do not rely on model variations (i.e., the intended region of sale, such as Asia, North America, Europe, and the like, and the vehicle grade) are being incorporated into integrated ECUs. In contrast, new nonstandard functions that are still in development as well as functions for certain regions and vehicle grades only are regarded as stand-alone functions.

As a result, function hierarchies have been created. This has generated an issue of function allocation, that is, which functions should be allotted to which hardware (i.e., ECUs, sensors, and actuators). A case of function allocation, in which multiple software and hardware items are defined in a hierarchy of related functions, is described later (Kato *et al*., 2010). For example, the electronic key is a function that facilitates the driver entering the vehicle. Even if the driver is carrying a heavy package, the electronic key detects weak radio waves emitted by the key when the driver approaches the vehicle, temporarily disengages the alarm mode, unlocks the doors, and illuminates the courtesy lights at the driver's feet. This system then drives the door opener when the driver touches the door handle. After the driver enters the vehicle and starts to shut the door, the system drives the door closer and adjusts the seat to the optimal preset position (Kato *et al*., 2010).

The air conditioning may also include functions that maintain the most comfortable environment in the vehicle for the driver by controlling the temperature and humidity in the occupant compartment, in addition to supporting the driver's field of vision through the windshield wipers, mirrors, and rear window defogger (Kato *et al*., 2010).

Future automotive electronic systems, especially in luxury vehicles, will probably become more hierarchical and structured. It is also likely that ECUs with sophisticated processing functions will become combined, while creating sensors and actuators integrated with standard input and output processing, regardless of the vehicle model. As a result, automotive network hierarchies have been created with backbone and subnetwork systems.

4.2 Standardization and reuse of electronic parts

There is a need for approaches that efficiently develop and design various automotive electronic systems in parallel and in a short period of time. This can be accomplished by standardizing and reusing as many parts as possible, and newly developing only the parts required for new systems. Such approaches must be capable of constructing various systems quickly and easily.

This approach of adopting standard and reused parts is also called an *electronic platform*. Although vehicle platforms tend to refer to the body and chassis and *computer platforms* generally refer to the hardware and OSs, the purpose of enabling the simple construction of multiple variations is the same (Kato *et al*., 2010).

Design is no longer focused on optimizing individual functions. Current trends are clearly highlighting the need to standardize and reuse many hardware parts, such as microcomputers, power supply ICs, communication circuits, connectors, passive devices, and the like.

4.3 Example of platform adoption

Modern vehicles use network systems to connect multiple ECUs to allow dynamic cooperative control to support the driver. For example, sensor data can be shared with corner prediction by the navigation system ECU to request the engine ECU to generate engine braking by automatically changing gear.

The longitudinal motion of the vehicle can be controlled by commands sent over the network. In addition to conventional accelerator and brake controls, engine and brake requests can be transmitted by adaptive cruise control (ACC) systems, which maintain a set vehicle-to-vehicle distance using millimeter wave sensors and/or cameras, vehicle stability control (VSC) that ensures stable vehicle behavior and maneuverability on poor road surfaces, parallel and reverse parking assist systems, precrash systems that detect the risk of a collision in advance, and so on. Such commands require arbitration systems that apply priorities to each signal (Kato *et al*., 2010). These systems are not limited to vehicles with four-cylinder gasoline engines and should be applicable in theory with six-cylinder, diesel, hybrid, and electric vehicles.

5 INTERNATIONAL STANDARDIZATION (OSEK AND AUTOSAR)

International standardization activities include those led by the International Organization for Standardization (ISO) and the International Electro Technical Commission (IEC). However, a growing number of consortiums have been set up under contract with the main organizations to respond to the speed of changes in technology and the market. However, although the consortiums are responsible for establishing new standards that require a speedy approach,

OSEK: open systems and the corresponding interfaces for automotive electronics

VDX: vehicle distributed executive

Figure 18. Software structure of OSEK/VDX.

items related to the maintenance, management, regulatory approval, and certification of these standards are still performed by the ISO, IEC, and the like.

The following sections describe some examples of international standardization for software. As development costs increase because of the multiplying types and scale of software, activities to standardize software and their use have been prompted by the European automotive industry, leading to the determination of an RTOS for automotive control called the *OSEK/VDX* (*vehicle distributed executive*) specifications. OSEK/VDX comprises of RTOS specifications (OSEK OS), communication specifications within and between ECUs (OSEK COM), and network management specifications (OSEK NM) (Figure 18). OSEK/VDX has been certified as ISO 17356 as an international standard for automotive OS.

The AUTOSAR consortium was established in 2003 for the purpose of international standardization. It is composed of more than 100 organizations including automotive manufacturers, suppliers, and tool vendors, divided into four types of membership consisting of core members, premium members, associate members, and development members. AUTOSAR specifications have been formulated based on the OSEK/VDX specifications and defined with extremely extended functions for realizing standardization, scalability, transferability, integration, maintainability, and software upgrades in the fields of automotive electrics and electronics (E/E) architectures. The AUTOSAR run time environment (RTE) provides a software application interface consisting of system services, memory services, communication services, I/O hardware abstraction, and complex drivers (Figures 19 and 20). These enable application programs to be used independently from the different hardware configurations (Kato *et al.*, 2010).

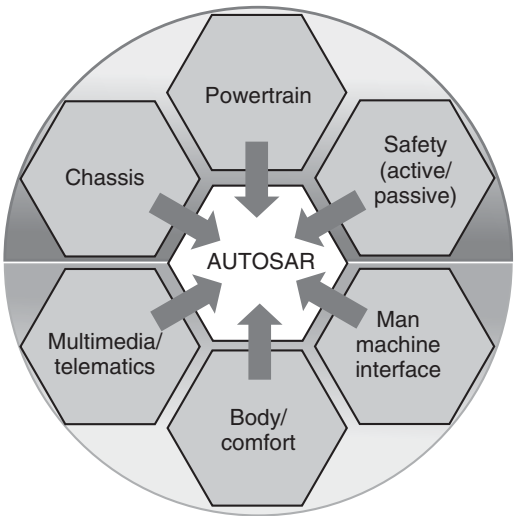

Figure 19. Field of applications in AUTOSAR.

This type of platform-based development may even form a key technological element with the potential to change the vertical integration business model into an open architecture business model.

6 SUMMARY AND CONCLUSION

This chapter has described the histories and future directions of automotive microcomputers, software, algorithms, architectures, hierarchy design, functional decomposition, and international standardization (OSEK and AUTOSAR), while considering semiconductor technologies and their applications in automotive electronics. These issues will continue to become increasingly important in the realization of further green and dependable automotive systems.

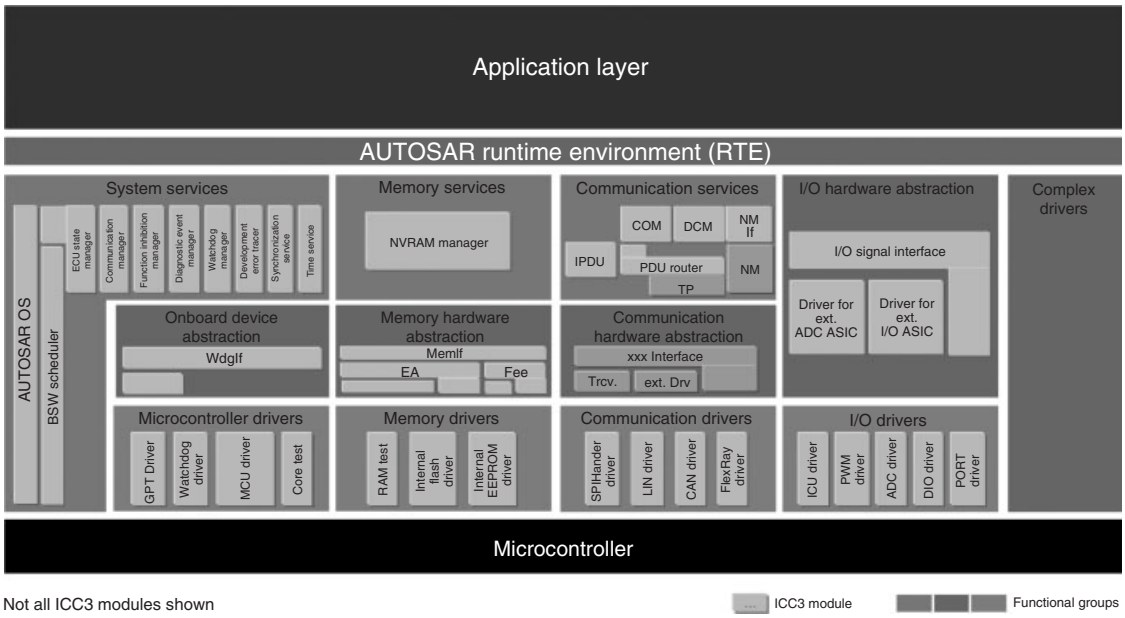

Figure 20. Software structure of AUTOSAR.

In the future, the progress of microcomputer performance and the evolution of software technologies are likely to result in advanced sensing technologies, super high speed data processing, higher integration, more efficient power electronics, and greater progress in high frequency applications such as millimeter wave and wireless functions. In addition to the need to advance these technologies, standardization across the industry will also be an important issue for pursuing development efficiency.

In-Vehicle Network

Susumu Akiyama
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Despite the origins of motor vehicles as a collection of mechanical parts, the introduction of electronic engine controls in the 1970s heralded the start of a trend that continues today. Now, electronic controls are utilized in a majority of automotive devices, including the brakes, steering, suspension, instrument cluster, climate control, airbags, door locks, power windows, navigation system, and so on.

Electronic control systems consist of sensors, actuators, and electronic control units (ECUs). To make a human analogy, sensors roughly correlate to the eyes and ears of a system, the actuators act as the hands and feet, and the ECU plays the role of the brain. In these systems, measurement signals are transmitted from the sensors to the ECUs. The measurement signals are used by each ECU to calculate control signals that are transmitted to the actuators. These signals are carried by wire harnesses and other related parts. ECUs consist of hardware such as microcomputers, peripheral integrated circuits (ICs), a power supply, and printed circuit boards, as well as software that define the algorithms used by the ECU.

A typical example is the electronic engine control system. As mentioned earlier, the role of the engine ECU is analogous to the brain as it is responsible for calculating fuel injection quantities and ignition timings. The engine ECU is connected to an in-vehicle network to enable information exchange with other ECUs. For example, engine coolant temperature data is sent from the engine ECU to the instrument cluster and displayed on the engine temperature gage. The in-vehicle network also carries signals from other ECUs to the engine ECU. For example, if the vehicle is equipped with adaptive cruise control (ACC), which functions to maintain a set distance with the vehicle ahead, the ACC ECU will send a signal to the engine ECU requesting acceleration if the distance to the preceding vehicle exceeds the set amount. Alternatively, if the vehicle is stopped in high temperatures during the middle of summer, the climate control ECU will send a signal to the engine ECU requesting an increase in the engine idling speed to supplement the cooling capability of the climate control.

Figure 1 shows the evolution of the vehicle system from an era of standalone controls (such as for the engine, brakes, and climate control) to a period of integrated control in which multiple controls cooperate to achieve a set of complex functions. It also shows current developments, in which electronic controls are starting to expand outside the vehicle and cooperate with external infrastructure. Conventionally, these types of complex and versatile functions were achieved by an automotive electronic system that grouped together individual ECUs performing individual controls. These ECUs are now connected to each other using the in-vehicle network. The number of ECUs connected to the in-vehicle network is increasing and hierarchical control structures, divided into a number of domains, are being developed.

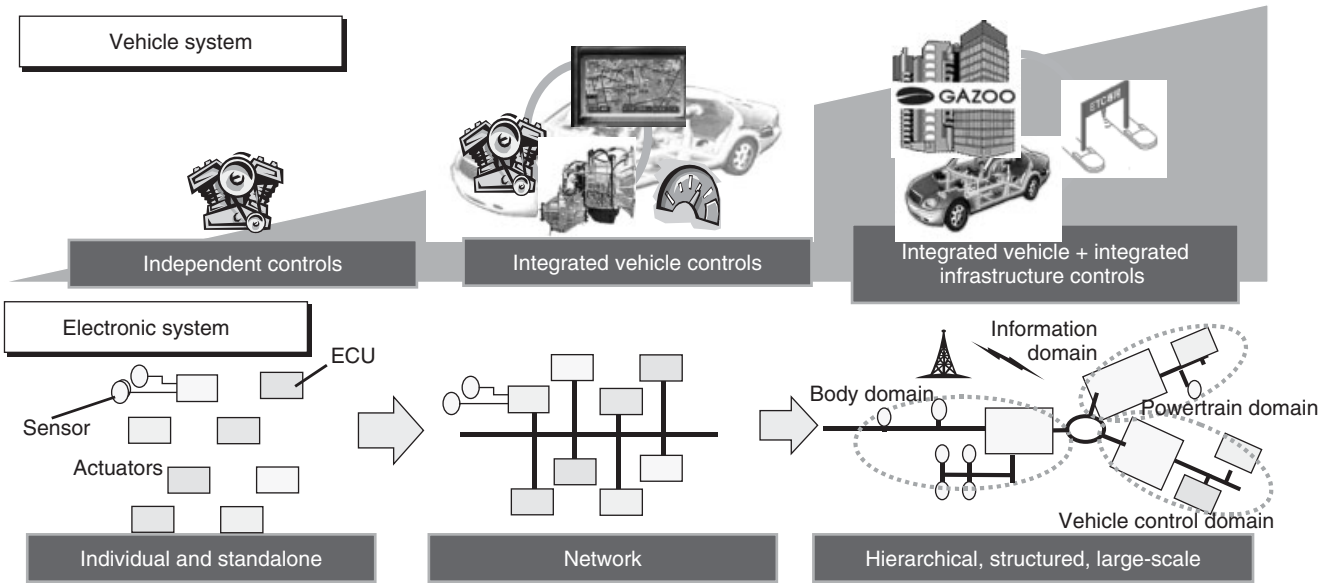

Figure 1. Evolution of automotive electronic system.

In a modern automotive electronic system, control functions for the powertrain, chassis, and body (i.e., the basic performance aspects of a vehicle responsible for driving, turning, and stopping) mutually interface with service functions that support the driver (i.e., information and communication) to achieve a high level of safety, comfort, usability, and environmental performance. The scale of systems responding to these social needs is likely to expand in the future, leading to more sophisticated and versatile functions. To achieve such large-scale systems, new control technology will be incorporated into vehicles alongside new information and communication technology. As a result, the optimum systems will have to be designed with hardware and software of the highest quality and reliability. Accordingly, the in-vehicle network will play an increasingly important role as a core component technology of the automotive electronic system.

2 IN-VEHICLE NETWORK

Typical familiar networks include data communication nets accessible through mobile devices, and the internet that can be used through computers at home or in the workplace. Vast quantities of information can be accessed by connecting to such networks at any time and in any location, enabling people to talk across huge distances. New network technology has been adopted to enable this type of communication environment. The main basic technologies behind these networks are communication devices, communication-related standards for procedures and the like, and software designed based on these standards.

As a result of the evolution of the automotive electronic system as described earlier, sensors and actuators are required to supply reliable information (data) to enable highly functional and accurate controls. Therefore, the construction of an in-vehicle network is necessary to enable information (data) exchange among sensors, actuators, and ECUs. From the standpoints of data communication efficiency and reliability, as well as cost, the in-vehicle network mainly uses multiplex communication technology with digital signals.

2.1 System structure

Figure 2 shows the typical structure of an in-vehicle network. The figure shows a total of 26 ECUs that exchange data in three mutually connected networks (the vehicle control system, body system, and information system). Exchanges among these systems are conducted through the gateway ECU. The gateway ECU switches the communication procedure, transmission speed, and frame format of the data as required by each network.

The major differences between the in-vehicle network and conventional computer-based networks used in university laboratories or design departments in corporations are as follows: the data flowing within the in-vehicle network is fixed in advance, and the connected devices are dedicated ECUs with set functions (such as engine control, door control, and current position estimation) instead of a

DOI: 10.1002/9781118354179.auto218
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

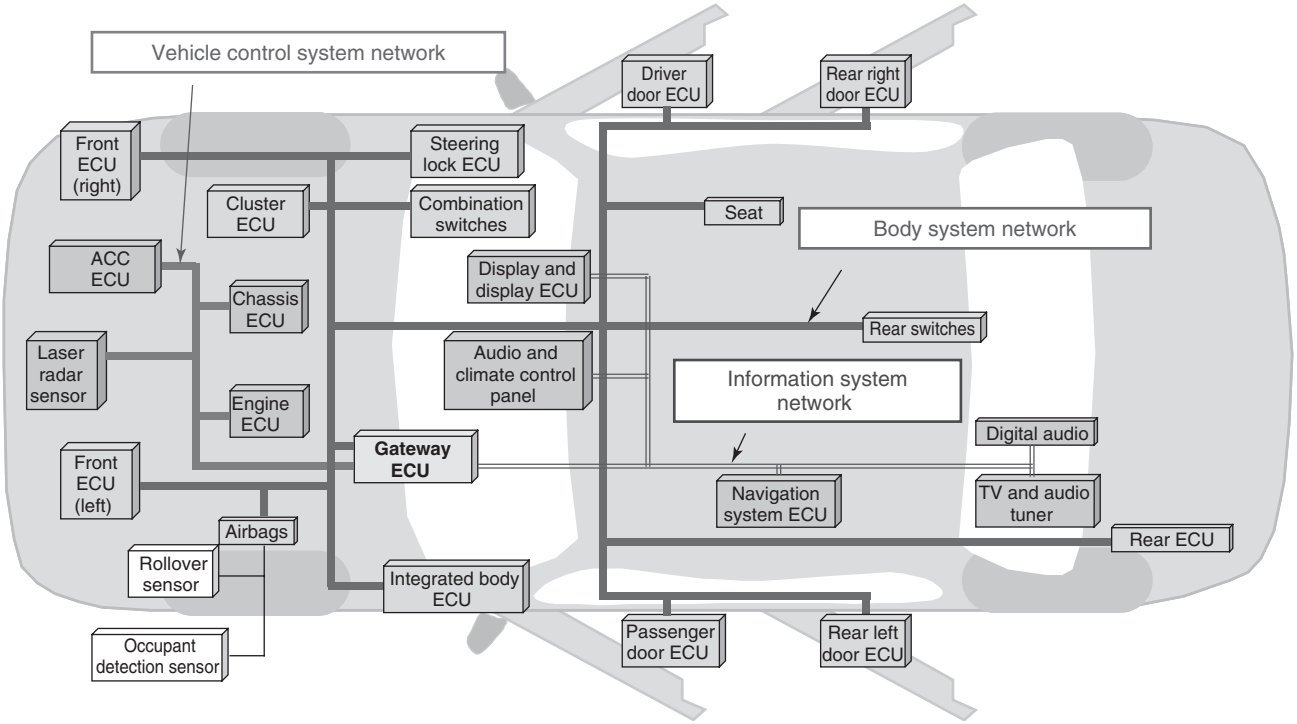

Figure 2. Example of in-vehicle network.

general-purpose computer or server with similar functions. Although the in-vehicle network is already prevalent even in mass-market vehicles, it has developed historically as a multiplex communication system to reduce wire harness complexity.

2.2 Multiplex communication systems

An automotive multiplex communication system is capable of carrying multiple types of signals through a single signal wire. This reduces the number of wire harnesses that have to be installed in a limited space and enables a larger number of functions to be performed with a smaller number of wires. Figure 3 shows the wire harnesses used throughout a vehicle and illustrates the effect of adopting multiplex communication systems for some of these harnesses. In this example, the multiplex communication system reduced the weight of the wire harnesses by 39.9% and the number of wires by 42.5%.

As an example of a body multiplex communication system introduced at the beginning of the 1980s, the control switches for the body-related control systems on the driver's side were collected and installed together. This system connected each ECU installed in the doors and body into a network to perform the following functions:

1. Door lock and unlock control
2. Vent window (i.e., triangular quarter glass) control
3. Power window control
4. Power seat control
5. Seat heater control
6. Ashtray and switch illumination control
7. Illuminated entry (i.e., the illuminated ignition lock and under-foot illumination lamps) control

2.3 Communication protocol

Early multiplex communication systems adopted optimum communication procedures that were newly developed for each model by the manufacturer. However, as the number of ECUs increased and the use of the in-vehicle network became established, several standard procedures began to be adopted around the world.

Figure 4 lists some typical network access methods. As a basic principle, an in-vehicle network transmits and receives data using one signal line. Therefore, if each ECU connected to the network starts to transmit information without coordination among the ECUs, transmitted data will collide and be lost. Consequently, rules are required to prevent data collision. These rules are called the *access method*. Access methods are broadly divided into master–slave types in which all communication is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto218
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

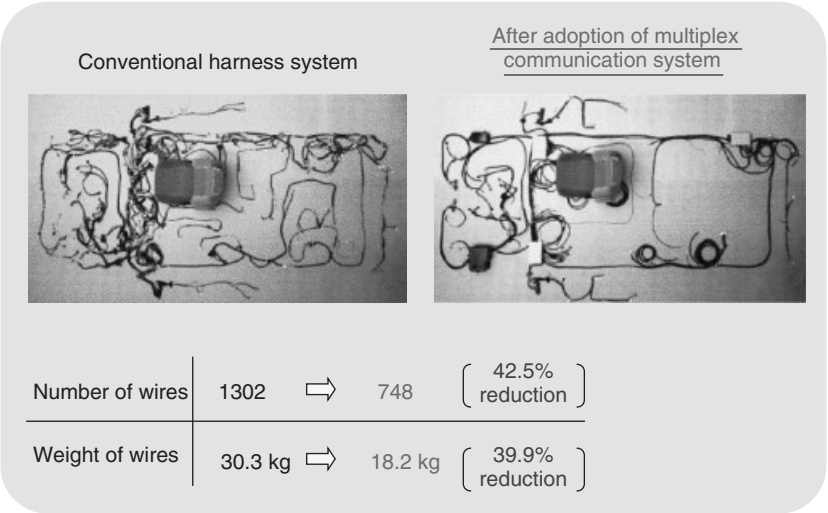

Figure 3. Effect of adopting multiplex communication system.

Access method		Characteristics	Example applications
Multi-master	CSMA/CA	Immediate transmission is possible when the bus is empty	CAN
	Token passing	Sequential transmission is possible	MOST
	Time triggered	Communication performed at set intervals	FlexRay
Master-slave		Communication performed following instructions from the master	LIN

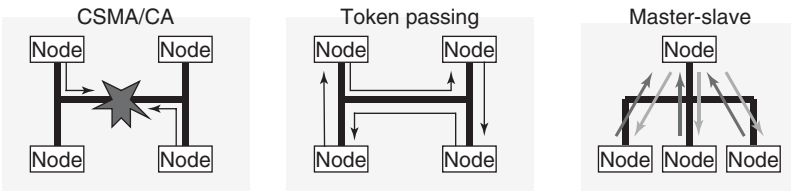

Figure 4. Access methods.

controlled by the master, and multi-master types (also referred to as *multiple access types*) in which each ECU has equal transmission rights as a master. Typical access methods used by the in-vehicle network include master–slave methods, and multi-master methods such as carrier sense multiple access with collision avoidance (CSMA/CA), time-triggered protocols, and token passing.

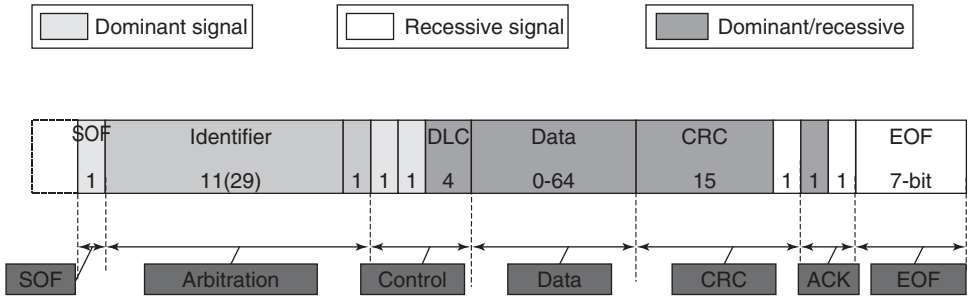
2.3.1 Controller area network (CAN)

Controller area network (CAN) is the most widely adopted type of in-vehicle network communication procedure. The CAN communication procedure uses CSMA/CA as the access method. Before transmission, the ECUs connected to the network check whether other signals are being sent through the communication line. Transmission starts once the communication line is empty. As a result, the ECU that accesses the communication line most quickly obtains the transmission right. As shown in Figure 5, ECUs attach an identifier (ID) to each message. If two ECUs start to transmit a message at the same time, the ECU with the smaller ID value obtains the transmission right. The ECU with the higher value ID immediately stops transmission and transits to reception mode.

This mechanism is a feature of CSMA/CA and is referred to as *arbitration*. Unlike the general carrier sense multiple access with collision detection (CSMA/CD) method, CSMA/CA has high data transmission efficiency as data is not lost in collisions, which means that lost data does

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto218
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5



Field	Content
Start of frame (SOF)	Expressed by one dominant bit.
Identifier (Arbitration)	Code field that expresses the details of the subsequent data and the priority of the message frame. The term arbitration also means prioritization and this field determines which message frame has priority if signal collision occurs.
Control	The DLC portion expresses the length of the data field (0 to 8 bytes).
Data	The data field contains the data (0 to 8 bytes).
CRC	Check code that detects if data in the message frame is garbled (transmission error).
ACK (Acknowledge)	A positive response. A node that has received a message normally uses the ACK field to transmit a dominant signal.
End of frame (EOF)	Comprises a 7-bit recessive signal.

Figure 5. CAN frame format.

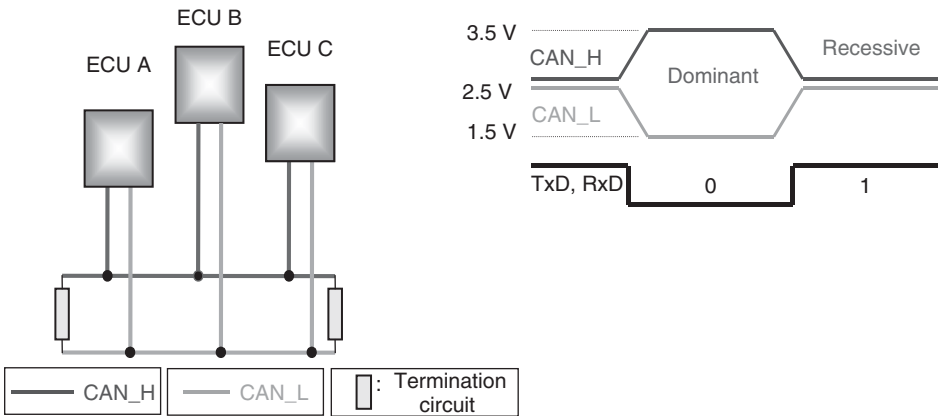


Figure 6. Communication waveform.

not have to be retransmitted. Consequently, this method is used in fields with comparatively short communication distances where the maximum delay time can be specified. In addition to the in-vehicle network, examples include networks among medical electronic devices, networks among control devices in factories, and so on.

Another feature of the CAN communication procedure is that it carefully defines the error detection, notification, and recovery process. In this way, the detection method when an error occurs and the operations after detection are clearly defined.

Figure 6 shows a waveform of a twisted pair communication cable for a high speed CAN with termination circuits at both ends. In a vehicle, communication among electronic devices is accomplished by this type of signal.

2.3.2 Local interconnect network (LIN)

Compared to CAN, which is mainly used in networks among ECUs, local interconnect network (LIN) is primarily used for low cost network systems from ECUs to sensors and actuators.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto218
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

LIN uses the master–slave access method in which the slave (usually a sensor or actuator) transmits information based on instructions from the master (usually an ECU).

LIN has a single communication cable and can use general-purpose serial communication ports normally built into microcomputers. The maximum transmission speed of LIN is 20 kbps and communication is possible without an expensive crystal oscillator using the synch field shown in Figure 8.

Figure 7 shows an example of a typical LIN system configuration. In many cases, LIN is used for subnetworks of network systems among ECUs, rather than as a standalone network. Many slave nodes are devices with single functions, such as motors and sensors.

The tasks written in each node can be described as follows. The master task is the function that manages the communication of all nodes in accordance with the LIN communication procedure. Here, it manages the

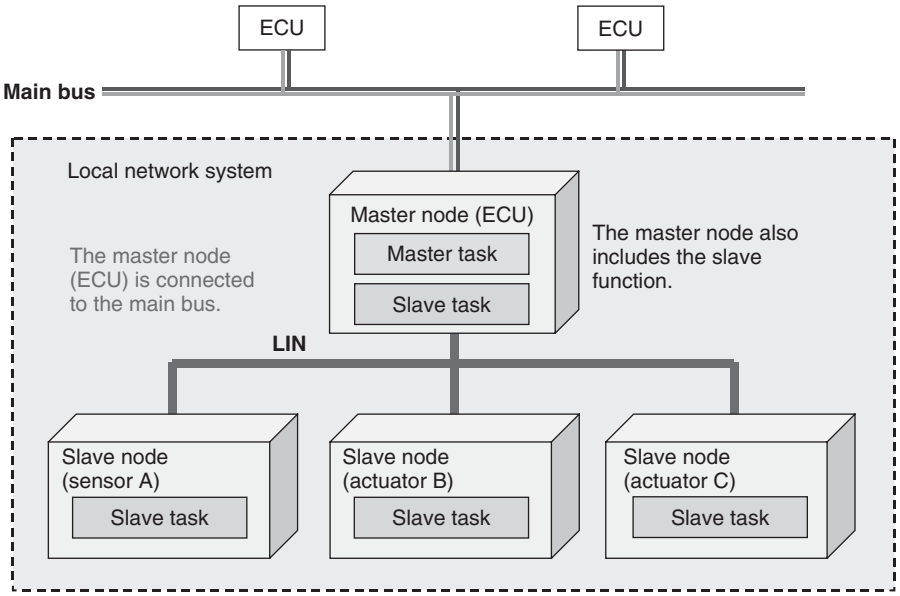

Figure 7. Example of LIN system configuration.

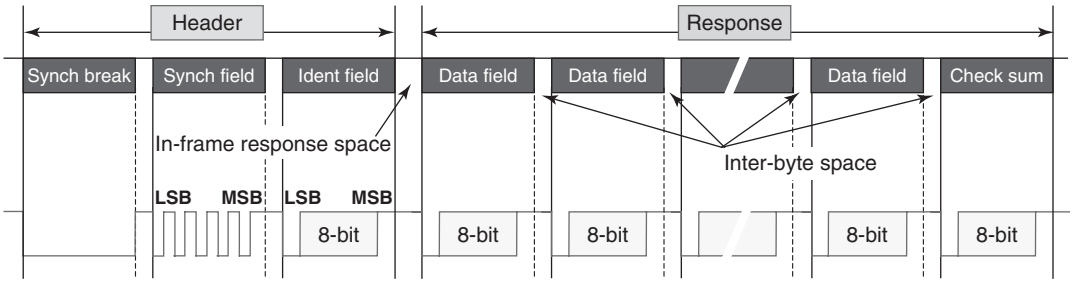

Field	Content
Header	Transmitted by the master task.
Response	Transmitted by the slave task.
Synch break	Field transmitted by the master task to notify the start of the LIN message frame.
Synch field	Field that enables the slave node to perform clock (transmission speed) correction.
Ident field	Field in which the master task specifies the slave task that should transmit the response.
Data fields	Fields that contain the data to be notified by the slave task in response to the master task.
Check sum	Field that enables the response of the slave task to be judged as normal or abnormal.

Figure 8. LIN frame format.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto218
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

transmission timing of all nodes. The slave task is the function that transmits data in accordance with the instructions from the master.

Every master task has a table that determines the transmission sequence of each node. This is called a *schedule table*. The master task transmits the header in sequence in accordance with this table. The data to be transmitted by the slave task in response to each ID is determined in advance (Figure 8).

As shown in Figure 8, LIN consists of one frame that comprises two blocks called the *header* and the *response*. The header is always transmitted by the master task and contains a code to express the start of the frame (the synch break), a code that teaches the slave the transmission speed (the synch field), and an ID that defines the node to transmit the data (the ident field).

The response is always transmitted by the slave task. The slave that holds the data specified by the ID (the ident field) included in the header transmits the data using the start–stop synchronization method.

2.3.3 *FlexRay*

FlexRay is a communication procedure developed for real-time controls such as X-by-wire that require high speed and reliability. It was used first in the suspension systems of luxury vehicles and is expected to be broadly adopted in the future.

The access method of FlexRay is the time-triggered protocol. All ECUs connected to the network share a clock and data is transmitted and received among the ECUs at set intervals. Therefore, this communication procedure can guarantee the arrival time of data in advance. This contrasts with CSMA, in which data arrival times depend on the busy status of the communication paths. FlexRay is also compatible with a duplex communication system, which is a far superior approach to other protocols from the standpoint of error detection, notification, and recovery.

Figure 9 shows a portion of the FlexRay communication procedure. One communication cycle consists of a static segment that always transmits data at the set time, and a dynamic segment that attempts to transmit data only when such data is present. The figure shows a duplex communication path comprising channels A and B. Frame A1 transmitted by ECU A and frame C1 transmitted by ECU C are used as the duplex communication path. In contrast, frames A2, D1, and E1 use channel A as the communication path and frames B1 and B2 use channel B. As each transmission node in the static segment is allocated, periodic transmission is secured and reliability is improved through a duplex communication system such as that illustrated by frames A1 and C1. In the dynamic segment, each frame is only transmitted when necessary and frames are not transmitted once the transmission start/stop line is exceeded. Therefore, in the example, frame C3 is not transmitted. These frames are transmitted from the next cycle.

Figure 10 shows the FlexRay frame format. Each frame consists of a header segment that includes synchronization and start frames, a payload segment with a maximum length of 254 bytes, and a trailer segment that functions as a 24-bit cyclic redundancy check (CRC) for detecting errors.

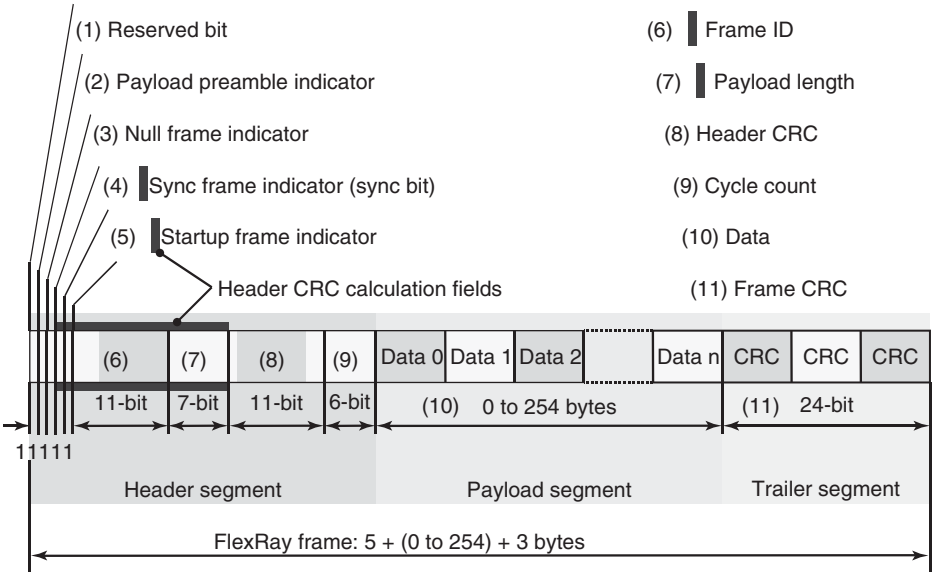

Figure 10. FlexRay frame format.

2.3.4 *Ethernet*

Unlike CAN, LIN, and FlexRay, which were primarily developed for automotive applications, Ethernet was originally a protocol for consumer applications developed for general-purpose LANs connecting computers, printers, servers, and the like. Owing to the demand for an in-vehicle network capable of transmitting greater volumes of data at higher speeds, the Ethernet protocol has recently begun to be applied in vehicles. Ethernet automotive applications include backbone networks that connect various domains, diagnostics, and reprogramming, as well as networks, control systems, body systems, entertainment systems, and so on for displaying moving images (see Figure 11 for some typical examples).

Figure 12 shows the Ethernet frame format for automotive applications. This protocol is capable of transmitting large volumes of data up to 1500 bytes in a single frame, which is not possible using other automotive communication protocols. Although standard communication lines for commercial applications contain two twisted pairs of cables, the development of single twisted pair cables for vehicles is also making progress.

3 CONCLUSIONS AND FUTURE OF IN-VEHICLE NETWORK

The number of onboard electronic devices has increased in accordance with the growth of electronic functions in vehicles. This trend is driving the development of the in-vehicle network. The introduction of new functions in the future is likely to increase the hierarchical levels, transmission speed, and transmission capacity of the in-vehicle network.

The current in-vehicle network is primarily used for communicating among ECUs. In the future, a similar network will also be established among ECUs and intelligent sensors, actuators, switches, relays, and motors, helping to reduce the number of wire harnesses, vehicle weight, and fuel consumption.

Furthermore, vehicles are also likely to evolve from independent units to more comfortable and safer means of transportation through two-way connections outside the vehicle. This will be accomplished through infrastructure-to-vehicle communication, vehicle-to-vehicle communication, battery charging communication, as well as the introduction of long-term evolution (LTE) wireless communication services, and so on. In these cases, the in-vehicle network will play a major role in distributing data received from external sources and collecting data from inside the vehicle.

From the standpoint of development efficiency, standardization of a larger scale automotive electronic system including the in-vehicle network is a key issue. Obviously, the in-vehicle network protocols described earlier are important key international standardization items. However, the necessary scope of standardization will expand in the future to include the types of data exchanged over a network, interfaces among controls, security guidelines for external data, and so on.

Application of Image Recognition Technology to Vehicles

Yukimasa Tamatsu and Naoki Nitanda
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Onboard cameras used in driver assistance systems can be broadly categorized into viewing cameras for displaying images from around the vehicle (e.g., rear view monitors) and sensing cameras that detect the driving environment using image recognition technology. Recent technological progress in image recognition, and the growing sophistication and lower cost of processors, has resulted in an influx of image recognition applications onto the market. This chapter outlines sensing camera systems that use image recognition technology.

2 CAMERA CATEGORIES

Sensing cameras can be categorized in accordance with the object recognition method into monocular systems that use one camera and stereo systems that use two cameras (Figure 1).

A monocular camera is generally used for recognition processing based on the density pattern of the images (the pattern or the texture). Example applications are the recognition of objects such as vehicles, pedestrians, lane markings, traffic signals, and the like. Monocular cameras may also be used for dynamic stereo processes using the disparity generated by camera movement (Yamaguchi, Kato, and Ninomiya, 2006). This is a method that identifies the distance to a stationary object from two images obtained at a time delay. Although issues remain to be resolved from the standpoints of distance estimation accuracy and calculation speed, single-camera systems have the merits of lower cost and installability.

In contrast, stereo cameras are capable of calculating the distance to an object by verifying the left and right images and applying the principles of triangulation (Kanade *et al*., 1996). Recently, the semi-global matching (SGM) method (Hirschmuller, 2005) has been used to enhance the accuracy of this verification process to improve the precision of distance estimation. However, systems that require two cameras are more expensive and require larger cases than monocular cameras.

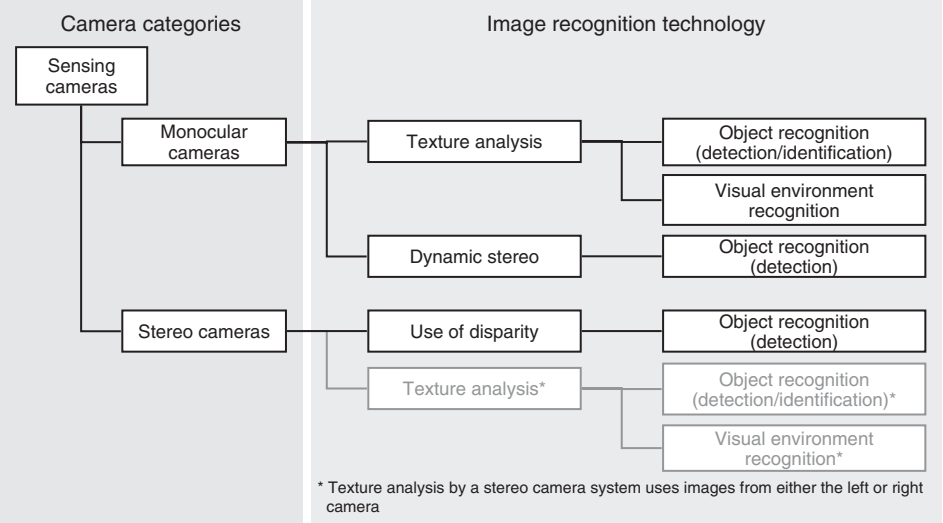

Figure 1. Sensing cameras and image recognition technology.

3 IMAGE RECOGNITION TECHNOLOGY BY ONBOARD CAMERAS

Image recognition technology that uses cameras installed in the vehicle generally employs a technology called *specific object recognition*. Specific object recognition consists of the following processes: the extraction of objects from an image that correspond to a certain target, such as vehicles, pedestrians, and the like; detection processing that determines whether the target object is present; and identification processing that judges what the detected object is. Approaches to detection processing include the detection of solid objects based on disparity using a stereo camera system, or object detection based on a certain shape or texture. Identification processing also generally uses the shape or texture of an object. In the following description, specific object recognition is simply referred to as *object recognition*.

In recent years, research into object recognition has also focused on visual environment recognition that identifies the appearance of objects. Visual environment recognition identifies objects and driving scenarios and may also be referred to as *visibility estimation*. The most common approach uses textures to estimate the appearance of an object to the driver. Although there are few cases of applications with onboard cameras, this is a key technology for realizing driving assistance systems adapted to the visual environment.

The following sections will describe the recognition of traffic signs, vehicles, and pedestrians as examples of detection objects, and visibility estimation of traffic signs and the driving environment as examples of visual environment recognition.

4 OBJECT RECOGNITION

Figure 2 shows the general process flow of object recognition. It consists of preprocessing, feature extraction, and identification and categorization. Preprocessing includes the normalization of pixel values and the like. Feature extraction refers to the effective recognition of aspects such as the brightness and color information of images, or geometrical characteristics such as corners and edges. Identification

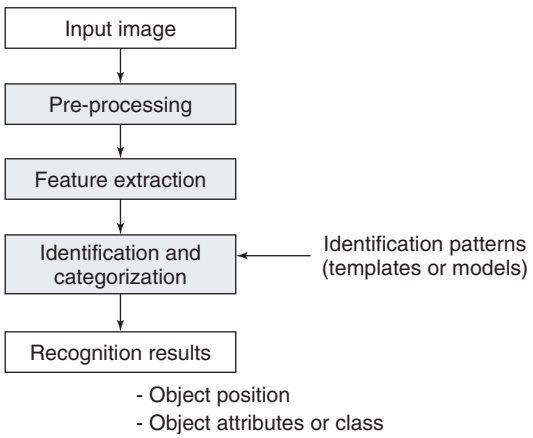

Figure 2. Process flow of object recognition.

involves the direct comparison of the extracted features with predetermined patterns (such as templates and models), or categorization using statistical pattern recognition methods or the like, and the output of recognition results such as the position or attributes of objects.

From the standpoint of onboard applications, the identification of traffic signs and other objects that completely match a pattern or shape is generally performed by a direct comparison using templates or models. In contrast, statistical pattern recognition is generally adopted for the recognition of objects that have different patterns or shapes due to physical differences or posture but are in the same category, such as vehicles or people.

This section describes the recognition of lane markings using classical features, the recognition of traffic signs as a typical onboard application that adopts direct comparison and identification, and the recognition of vehicles and pedestrians as a typical onboard application that adopts statistical pattern recognition.

Figure 3. TSR. (Reproduced with permission from Takaki et al., 2009. © Institute of Electrical Engineers of Japan.)

4.1 Recognition of lane markings

The recognition of painted lane markings on the road surface is used in systems that warn the driver when the vehicle is about to depart its lane (such as in lane departure warning systems) and systems that prevent lane departure by controlling the steering. The contrast edge distribution between the road and painted marking from images obtained by a forward monitoring camera are applied to a road model. The positional relationship between the paint on the road and the driver's vehicle, the curvature of the road, and the like are calculated, and the results are applied in the warning or control system.

4.2 Traffic sign recognition (TSR)

The recognition of traffic signs may help prevent the driver from driving too quickly or may help reduce instances in which the driver overlooks a stop sign (Figure 3). These systems judge the type of sign in an image from its texture.

Conventional detection and identification of traffic signs uses template matching. Template matching is a method that detects objects corresponding to images in a template prepared in advanced (called *template images*) and compares this template with the input images. However, the size and color of traffic sign images captured by an onboard camera change depending on the positional relationship between the camera and the traffic sign as well as due to fluctuations in light from the sun. Consequently, the detection and identification of traffic signs by template matching requires the preparation of template images considering the possibility of enlargement, reduction, and rotation of signs, as well as fluctuation in brightness levels. Accordingly, a huge amount of template images would be required to match every condition.

Takaki *et al*. proposed a TSR method to resolve these issues (Takaki *et al*., 2009). This method is called *scale invariant feature transform* (*SIFT*) (Lowe, 1999) and it does not use template images for matching. Instead, it calculates features that do not vary in accordance with changes in rotation and scale. It then detects and identifies traffic signs by matching between these features. SIFT features can be used to recognize signs at an angle or signs that are partially blocked. This is a robust TSR method that is also compatible with changes in brightness levels as the SIFT features do not require color information.

4.3 Recognition of vehicles and pedestrians

Applications that recognize vehicles in front of the driver's vehicle (referred to below as the preceding vehicle) and estimate the distance and relative speed between it and the driver's vehicle include forward collision warning (FCW), adaptive cruise control (ACC), and automatic emergency brake systems (AEBSs) (Figure 4). Systems have also been developed that recognize pedestrians and help avoid collision accidents by indicating their position to the driver (Figure 5).

As mentioned above, the pattern and shape of vehicles and pedestrians change in accordance with physical differences and posture. Therefore, as is the case with TSR, it

is difficult to apply matching methods that use specific template images. For this reason, vehicle and pedestrian detection tends to use statistical pattern recognition.

In statistical pattern recognition, large volumes of sampled data are analyzed, and the features and judgment criteria useful for recognition are extracted and learned from that data. The theory of this method has progressed from multiple standpoints as new learning algorithms have been proposed from the machine learning field since the 1990s. An algorithm that has gained attention recently uses a process called *boosting* and has been adopted in various fields inside and outside onboard applications, such as household electrical appliances.

Boosting uses weak classifiers that have a low recognition rate but are simple and have a low calculation load. Weak classifier points are used to compensate each other to construct single strong classifiers. The Viola-Jones method is a typical example that uses boosting (Viola and Jones, 2001). This method constructs a strong classifier by forming a cascade of weak classifiers arranged in sequence. It stops the recognition process as soon as an object is judged not to be the target object, thereby enabling a rapid process with a high recognition rate.

In addition, high recognition performance requires optimization of the image features used by boosting, in accordance with the recognition objects. Although the Viola-Jones method uses Haar-like features, recent proposals include the use of histograms of oriented gradients (HOGs) (Dalal and Triggs, 2005), an improved version of HOG called *co-occurrence histograms of oriented gradient*s (*CoHOG*s) (Watanabe, Ito, and Yokoi, 2009), and shapelet features (Sabzmeydani and Mori, 2007). In actual fact, the features used in boosting, the method of constructing strong classifiers, and the like are optimized in accordance with the application. Boosting is used in several examples of vehicle and pedestrian recognition, as well as in facial recognition using digital cameras.

5 RECOGNITION OF VISUAL ENVIRONMENT (VISIBILITY RECOGNITION)

Recently, sensing camera technology has begun to be developed that is capable of recognizing various objects in the driving environment, such as vehicles, pedestrians, traffic signs, traffic signals, and the like. However, if the driver is informed of all detected objects, the processing capability of the driver will be overwhelmed and the recognition technology itself will become a cause of driver distraction (Pettitt, Burnett, and Stevens, 2005). For this reason, the system must judge whether to inform the driver in accordance with the state or appearance (visibility) of the object. Research is currently in progress to evaluate the visibility of objects and the environment based on this approach. This section describes the application of visibility to traffic signs and the driving environment as typical examples of visual environment recognition technology.

5.1 Visibility of traffic signs

Figure 6 shows an example of traffic sign visibility. Some signs are located in complex backgrounds and are difficult to identify at a single glance. The type of sign may also be difficult to visualize due to the light levels or fading. Types and positions of signs that can be identified instantly are referred to as having high visibility. In these cases, the driver is notified only of traffic signs with low visibility to prevent driver distraction and provide the minimum necessary information.

More specifically, the visibility of an object is an integrated property that describes how easy it is to see and how easy it is to understand. Object visibility estimation technology based on this property is being researched on following two approaches: focusing on background and contrast (Kimura, 2010) and focusing on the appearance of the object itself (Simon, Tarel, and Bremond, 2009)–(Maerz and Niu, 2003). The former uses the idea that the complexity of the background has a large impact on

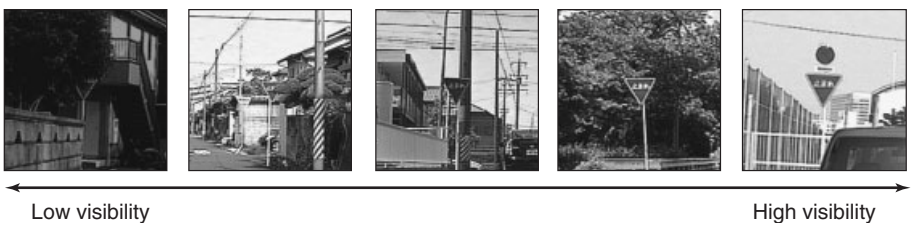

Figure 6. Visibility of traffic signs.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto224
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

object visibility. This method evaluates visibility based on contrasting complexity. The latter uses the idea that the visibility of an object is affected by the brightness and its color distribution, and evaluates visibility based on the brightness of the image, the red–green–blue (RGB) components, color histograms, and the like. An onboard camera must factor in both of these two approaches when estimating the visibility of objects. This is because the positional relationship of the driver, object, and background changes as the driver's vehicle moves, because the complexity of the background is constantly changing, and because the brightness of the environment also changes as the vehicle turns and so on. In addition, as the apparent size of the object (i.e., its size in the image) also changes as the vehicle moves, the effect of time variations must also be considered.

On the basis of these characteristics of onboard cameras, Doman *et al*. have proposed a method of estimating the visibility of traffic signs using multiple temporally connected image groups (Doman *et al*., 2011). This method first extracts the traffic signs from the images captured by the onboard camera and then evaluates the visibility at that time (i.e., an instantaneous visibility value). This instantaneous value is expressed by a linear combination of five types of features: the color of the sign and background, the edges, the texture contrasts (each average color, average edge intensity, and color histogram difference), the image quality (difference with template image), and the size in the image. This instantaneous value is calculated for every captured image containing a traffic sign and the final traffic sign visibility is obtained by determining an average within a predetermined time.

5.2 Visibility of driving environment

The previous section covered object visibility. Research is being carried out that expands on these ideas to evaluate the visibility of the driving environment (Nitanda *et al*., 2011). This technology has potential application in driving assistance systems and systems that adapt to timing and intensity in accordance with visibility.

This section only covers a method that estimates the visual burden of the driver using a forward monitoring monocular camera (Nitanda *et al*., 2011). This method first calculates a saliency map (proposed by Itti *et al*.) for the images from the forward monitoring camera (Itti, Koch, and Niebur, 1998). This saliency map is a calculation model that uses physiological information to extract visual features that are different from the surrounding area as salient regions to predict the target of the driver's gaze. The use of this model in onboard camera images is equivalent to predicting the direction of gaze of someone sitting in the front passenger seat, who is looking forward without any particular purpose. This gaze movement process depends on features such as color and brightness when the observer glances at the surroundings. It is referred to as a *bottom-up process*.

In contrast, in actual driving, the driver focuses on the front of the vehicle and alters the gaze direction to obtain the necessary information when objects such as other vehicles, pedestrians, traffic signals, traffic signs, and the like appear, whose position or status has to be confirmed before a driving action is carried out. In this process, gaze movement is determined based on the purpose of the observer or the existence of problems. It is referred to as a *top-down process*.

These bottom-up and top-down processes can be used to roughly predict the driver's gaze movement and to estimate the visual burden. Figure 7 shows the system model. In this model, the gaze position of the driver is predicted by the sum of the bottom-up and top-down processes. Here, the bottom-up process expresses the physiological gaze movement of the driver, whereas the top-down process expresses the intentional gaze movement. The theory behind this system states that the gaze position should exist within one of these processes. In addition, as safe driving requires the driver to pay attention to the front of the vehicle, the physiological gaze movement must be reduced. On the basis of the idea that the suppression of physiological reactions is a way of defining driver burden, the visual burden can be estimated from the difference between the bottom-up and top-down processes.

Figure 8 shows examples of the bottom-up and top-down processes, and a calculated image that shows the differential between the bottom-up and top-down processes. This differential image is shown in Figure 8d, which shows the calculated results for visual burden as the total brightness value. Figure 8d demonstrates that the system reacts strongly to objects such as electronic shop signs that naturally attract the driver's gaze, although the driver does not need to look at them for driving. A high correlation coefficient of 0.90 has also been reported between the visual burden calculated from five types of images at night and subjective evaluations by test subjects (Nitanda *et al*., 2011).

6 CONCLUSION

This chapter has outlined typical examples of technology that senses and recognizes the circumstances around the vehicle using a sensing camera from the standpoints of object recognition and visual environment recognition. The future is likely to see the development of cooperative processes with other sensors and demands to share recognition results and create recognition databases by integrating, accumulating, and communicating sensing and recognition information. As a result, it will be necessary to develop even more sophisticated technology for sensing and recognizing the circumstances around the vehicle as vehicles grow even more dependent on information.

Engine ECU Systems

Yukihide Niimi
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

In modern vehicles, the engine is controlled by the engine control unit (ECU) system. This system has developed in conjunction with tightening of exhaust emissions and fuel economy regulations. In the future, these trends will likely continue. The performance requirements of the engine ECU itself will also continue to increase from the standpoints of promoting greater safety, comfort, and protecting the environment. These are the three major requirements of vehicles in recent years.

The engine control parameters include the quantity of intake air, the amount of fuel injection, the ignition timing, and the opening and closing timing of the intake and exhaust valves. All of these parameters are controlled by the engine ECU. This chapter describes the hardware and software of the engine ECU system. It also explains the fuel injection control system, ignition control system, and electronic throttle control system as representative examples of the engine controls performed by the engine ECU system.

2 ENGINE ECU

2.1 Overview of engine control

The engine system (Kato, 2010a) provides optimal control of combustion-related parameters in accordance with the operating conditions of the engine to improve engine output and fuel economy, and to achieve cleaner exhaust emissions. There are two types of engine control: gasoline engine control and diesel engine control. This chapter uses gasoline engine control in the explanations of the engine ECU system.

The gasoline engine control parameters include the amount of intake air, the amount of fuel injection, the ignition timing, and the opening and closing timing of the air intake and release valve. All of these parameters are controlled by the engine ECU.

Figure 1 shows a diagram of a gasoline engine control system. The system is composed of sensors and actuators, whereas the ECU is the nucleus of the engine control. The sensors detect information such as the engine speed and the depression angle of the accelerator pedal. The ECU then takes in this information, makes calculations, and controls each of the actuators, starting with the throttle valve, so that the engine is in the optimal state.

The following are the main controls of the ECU: electronic throttle control that controls the amount of intake air, idle speed control, fuel injection control that controls the amount of fuel injection, ignition timing control and knock control, variable valve timing control for the air intake and exhaust valve, and the variable cylinder management system that disables certain cylinders. Additional controls of the ECU include the evaporator control that inhibits the escape of evaporated gasoline from the fuel tank, exhaust gas recirculation (EGR) control that recirculates exhaust emissions and reduces nitrogen oxides (NO*x*),

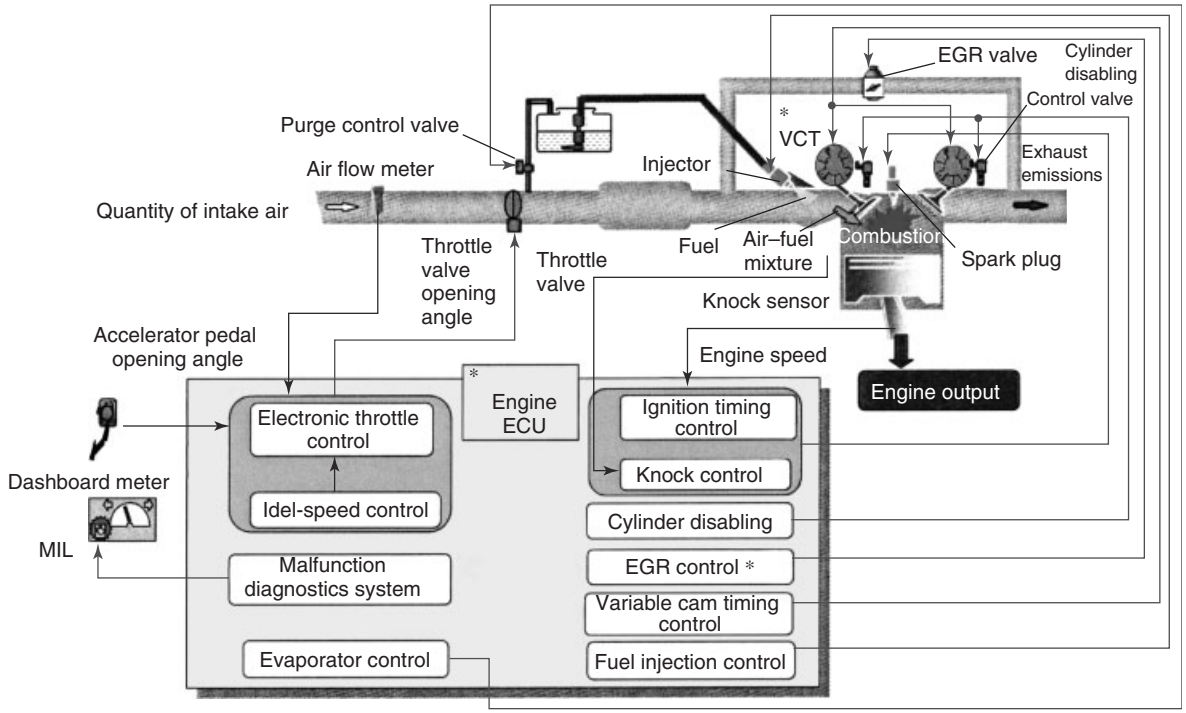

Figure 1. Electronic control system of gasoline engine.

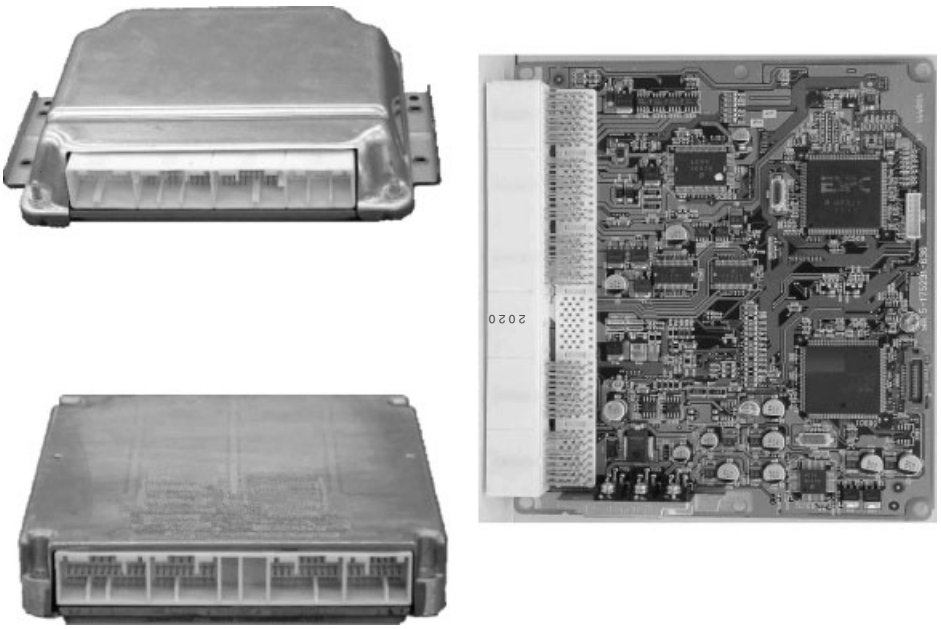

Figure 2. Interior and exterior of engine ECU.

the malfunction diagnostics system, and the like. The ECU is normally covered by a case made from aluminum alloy, with the microcomputers and various electronic parts located inside, as shown in Figure 2.

2.2 Evolution of engine ECU

This section describes the evolution of the engine ECU. Exhaust emissions regulations started to be implemented

ULEV: ultra-low emission vehicle
SULEV: super ultra-low emission vehicle
ZEV: zero emission vehicle

in the 1970s. At that time, the main types of engines still used carburetors, so engine performance was sacrificed to comply with these new laws and regulations (Table 1).

Electronically controlled fuel injection became widespread in the 1980s in response to tighter emissions regulations in the United States. These regulations were satisfied using microcomputers to control fuel injection and ignition, as well as to improve engine output. By the first half of the 1990s, most vehicles were equipped with electronic fuel injection control and the ECU performed integrated control of both the engine and the transmission. In the latter half of the 1990s, the low exhaust emissions regulations concerning ultra-low emission vehicle (ULEV), super ultra-low emission vehicle (SULEV), and zero emission vehicle (ZEV) were strengthened even further. Alternative fuels and electric vehicles (EVs) were developed and direct injection gasoline engines also appeared. Integrated control by the ECU is steadily becoming more complicated. It was a common practice to install the engine ECU within the occupant compartment, such as behind the instrument panel, to protect the electronic parts from the high temperatures of the engine and the electric noise from ignition (Figure 3). However, the limitations on installation space in the occupant compartment became more severe over time, as more interior space was required to ensure passenger comfort. As a result, in recent years, the engine ECU is increasingly installed in the engine compartment (Kato, 2010b).

The conditions within the engine compartment are very severe for the electronic parts that make up the ECU. If the ECU is near the engine, it is exposed to high temperature heat sources during operation and directly receives vibrations from the engine. There is also a lot of electric noise, mainly produced by the ignition within the engine, and the presence of water spray. There are examples of the ECU being placed inside a plastic box to protect it when it is installed in the engine compartment. Some engine ECUs may be installed directly on the engine and the development of special electronic parts that can adequately withstand this severe environment is now under way.

As described in Section 2.1, the engine control ECU installation environment is becoming increasingly severe. Figure 4 compares this environment with that of other electronic parts. The vertical axis shows the required level of reliability and safety, whereas the horizontal axis shows the temperature.

Focusing on the temperature environment, it is common for household appliances, such as personal computers and televisions, to be used indoors where the temperature range is limited. However, vehicles are characterized by a much broader range of operating temperature, and it is assumed that they will be driven in outdoor environments all over the world. On the other hand, if the required level

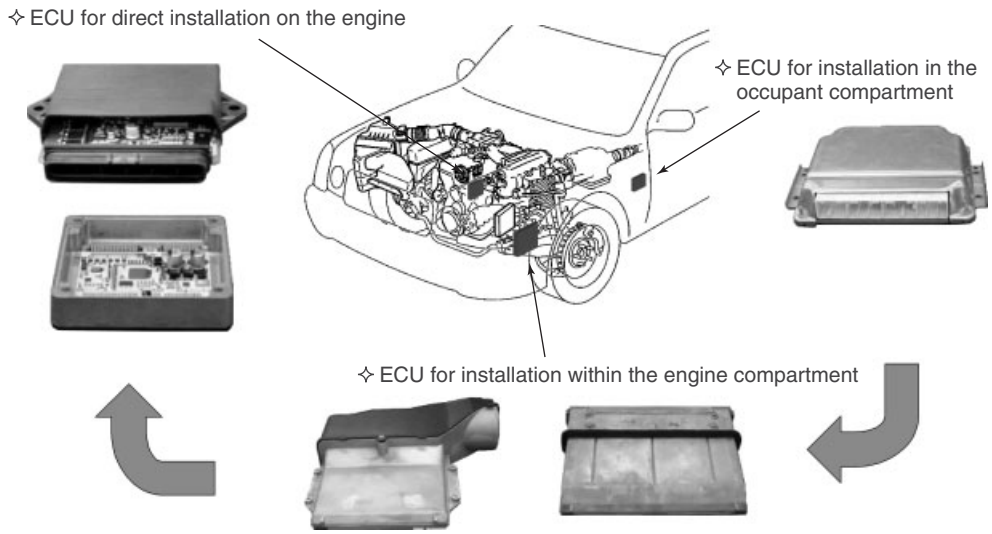

Figure 3. Changes in installation environment of engine control ECU.

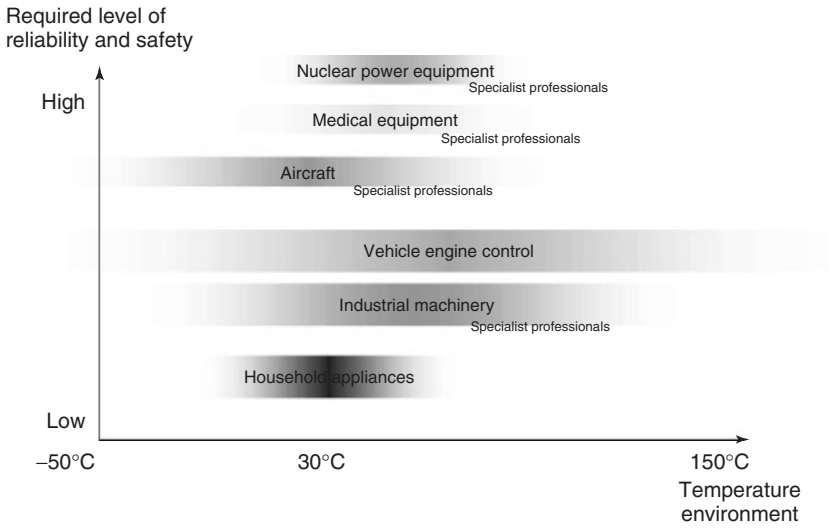

Figure 4. Required level of quality.

of reliability and safety is considered, vehicles have the potential to immediately threaten human life by not moving (not starting), going out of control, or catching fire. For these reasons, the required level of safety is quite high. Vehicles are also often used for many years, so reliability over a long operating life is another requirement. Vehicle users often do not possess any specialized knowledge or specialized skills (i.e., they are not specialist professionals). Therefore, it is crucial to consider how best to ensure the safety of users, even if they operate the vehicle in a manner that is unexpected.

2.3 Circuit configuration of engine ECU

Figure 5 shows the function blocks (Kato, 2010b) of the engine ECU. The engine ECU uses the calculations of a microcomputer to realize optimum control in response to the vehicle state. It possesses a means to receive inputs that detect the external conditions as an external interface, and a means to supply outputs that actually drive the controls. In recent years, many ECUs have also been equipped with a means of communicating with each other to promote closely coordinated control.

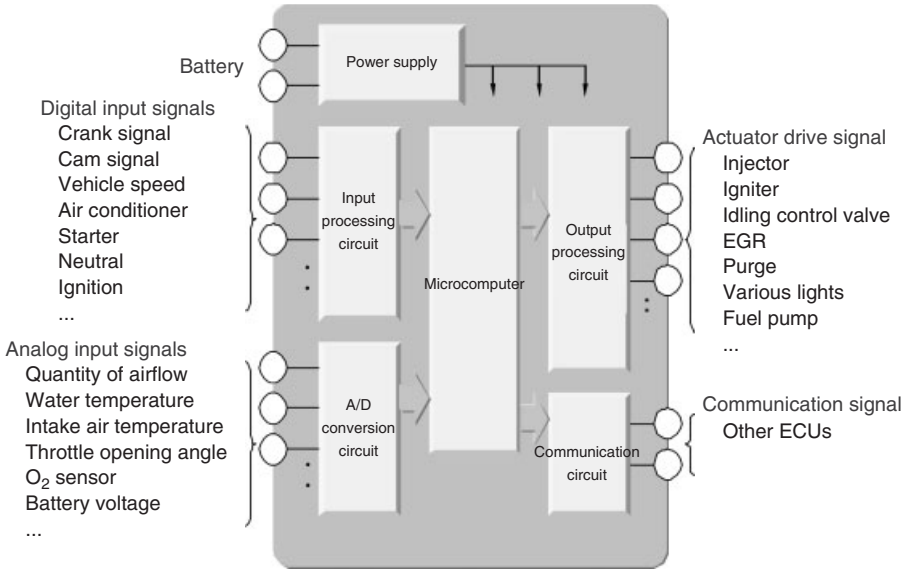

Figure 5. Function block diagram.

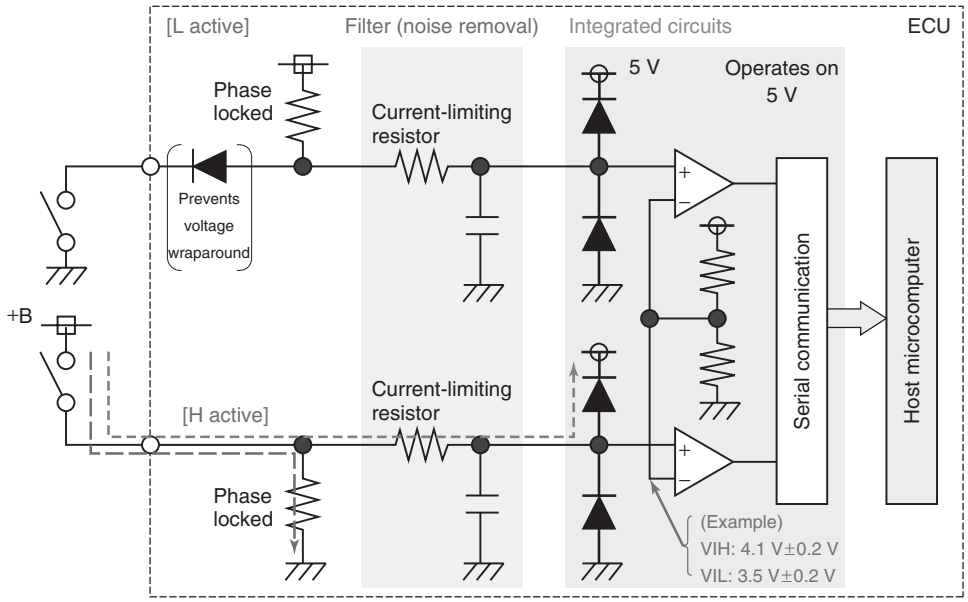

Figure 6. On and off inputs.

The following sections describe representative examples of the input processing circuit, output processing circuit, and communication circuit interface.

2.3.1 Input processing circuit

Figure 6 shows an example of a circuit used to input the "on–off" condition to the microcomputer in accordance with the switch operations of the driver.

The resistance for phase locking ensures the input voltage when the switch is open. In the case of an ECU in a poor usage environment where there is a lot of electric noise, the ECU must be equipped with a proper filter circuit and other mechanisms that prevent noise penetration. The software in the microcomputer is also protected to prevent improper operation because of noise by implementing noise removing functions and other means.

In the environment created by various devices installed on a vehicle, different input voltages exist side by side

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

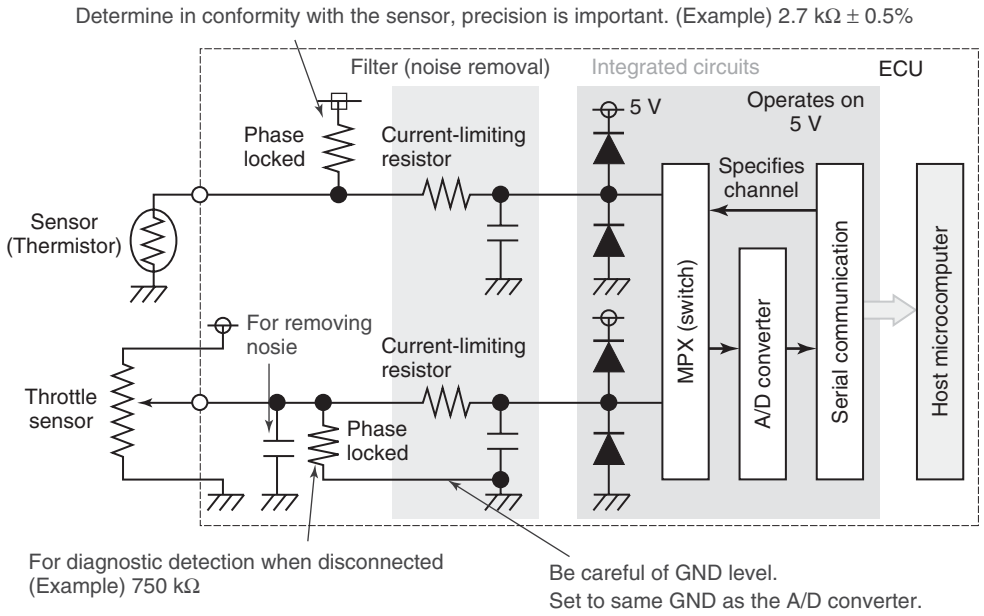

Figure 7. Analog inputs.

(such as the battery voltage and ECU internal power supply voltage). These different voltages have to be separated. Multiple inputs are collected together and then input into the microcomputer using serial communication for the purpose of handling the numerous on–off inputs. The adoption of integrated circuits (ICs) is being promoted in an effort to reduce the size of the ECU.

Figure 7 shows an example of a circuit used to input the "level" condition to the microcomputer of items such as the temperature of the engine coolant and the throttle operations of the driver.

The resistance for phase locking ensures the input voltage from the sensor. It also ensures the input voltage when the sensor is disconnected, so that abnormalities can be detected. Detecting a vehicle abnormality and then warning the driver is an extremely important function of the ECU.

Analog inputs are converted into digital signals that can be used by the microcomputer through analog/digital (A/D) conversion. In recent years, demand has grown for A/D converters with very high conversion performance (conversion speed and conversion accuracy) because of the increasing precision of control.

2.3.2 *Output processing circuit*

Figure 8 shows an example of the circuit that communicates with and drives the fuel injector based on the fuel injection pulse sent to the engine. The pulse is determined from the control calculations of the microcomputer.

2.3.3 *Communication interface*

The communication signal of the communication bus is input into the microcomputer, so that data can be exchanged with another ECU. Figure 9 shows an example of the circuit for controller area network (CAN) communication that is output from the microcomputer.

2.4 Microcomputer

The microcomputer for engine control is required to operate for a long time and must also operate under some of the harshest conditions in the world, from the high temperature regions in the Near and Middle East to low temperature regions such as Alaska. As a result, it must have an operating temperature range −40 to 125°C and a service life of 20 years or more (Figure 10).

The microcomputer is equipped with an A/D converter for sensor input processing, a highly precise timing function for injector output processing, and a serial function for use with the malfunction diagnostics tools in the marketplace. It is also equipped with a debug function to develop and check these other functions.

The large-capacity memory in the microcomputer for increased performance must be rewritable flash memory to satisfy laws and regulations. Finally, the microcomputer is required to realize this high quality and high performance at a low cost. The read-only memory (ROM) capacity of the microcomputer for engine control was

approximately 4 kB in the 1980s, but in response to the introduction and strengthening of the laws and regulations previously described in this chapter, in 2010, the capacity had increased to exceed 2 MB. This trend is fully expected to continue in the future, so microcomputers will be required to become even smaller in size and run at even faster speeds.

2.5 Software

2.5.1 Trends in engine control software

The use of microcomputers to control the engine began in the 1970s–1980s, but this trend really started to accelerate due to the introduction of regulations for exhaust emissions and fuel economy. The size of the software (Kato, 2010b)

- High reliability
  - Mounting conditions: –40°C to 125°C
  - Service life: 20 years or more
- Highly functional
  - A/D conversion performance: Sensor input processing
  - Highly precise timing function: For injector output, etc.
  - Serial communication function: Malfunction diagnostics tool communication
  - Debug function
- High performance
  - Large-capacity memory: Flash memory
- Low cost

Figure 10. Requirements of microcomputer for engine control.

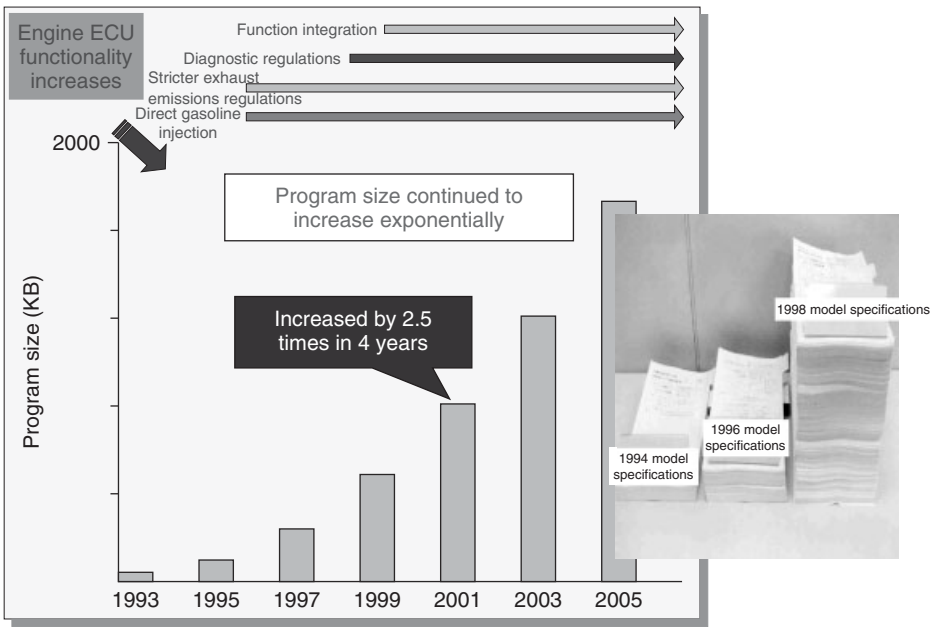

Figure 11. Increasingly sophisticated and larger scale software.

for engine controlling microcomputers has continued to grow, as described in this chapter, and the engine controls have also continued to increase steadily. Taking a representative piece of engine controlling software as an example, the program size in 2005 was 2.5 times larger than it was in 2001 and this trend is also expected to continue in the future (Figure 11).

2.5.2 *Engine control software operations*

The structure of engine control software is often divided into the application layer, which is the software that realizes the control, and the platform layer, which drives the sensors and actuators. This gives the software the flexibility to be adapted to the different regulations in each country and to optional vehicle parts. Figure 12 shows fuel injection control as an example to outline and explain the operations of the engine control ECU software.

(a) The required amount of fuel injection is calculated from the engine speed and engine load in the application layer. This amount is then transmitted to the sensor and actuator layer.
(b) The program in the platform layer that determines injector operation adjusts the required amount of fuel injection according to the injector characteristics

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto225
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

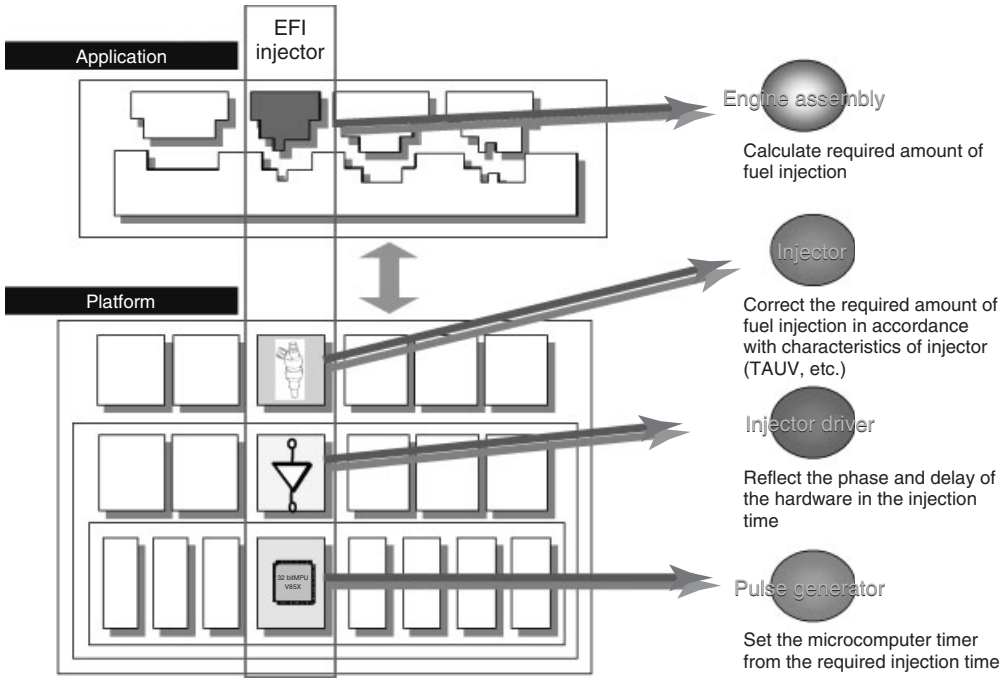

Figure 12. Outline of fuel injection software operations.

(invalid injection time and so on) and corrects the fuel injection time. It then transmits this information to the injector driver in the ECU layer.

(c) The injector driver reflects the phase and delay of the hardware in the corrected fuel injection time. This is then transmitted to the pulse generator in the CPU layer.

(d) The pulse generator sets the initial value of the microcomputer timer as the required fuel injection time. Structuring the software parts in this manner means that it is only necessary to change the pulse generator if the microcomputer is changed and the other parts can continue to be used as is. This improves the reusability of the software.

2.5.3 *Software development process*

A special characteristic of the engine control ECU software development process in comparison to that of general software development (IPA of Japan, 2008) is the use of a calibration process (Figure 13). In this calibration process, the parameters within the program are set to the optimum values and confirmation carried out to verify that the control logic was realized by the ECU. The optimum values are determined by examining a variety of different factors, such as the cleanliness of the exhaust emissions, fuel economy, engine output, and the like.

2.5.4 *Model-based development*

There are many actuators and sensors in the engine control system. If software development did not begin until all of those were completed, it would take a long time to develop the whole system. Therefore, in recent years, a method called *model-based development* (Otsuka and Oi, 2006) has been used. Stated simply, model-based development is software development based on simulation technology. Figure 14 shows the main simulation technology. The control logic can be examined using simulations before the sensors, actuators, and ECU hardware are completed. This drastically shortens the development period.

Creating a model of the problem region is a necessary prerequisite of model-based development. Block diagrams are often used in software development for controls and the MATLAB and Simulink tools of MathWorks, Inc. in the United States are the de facto standards for computer-aided software engineering (CASE) tools (Figure 15).

3 ENGINE CONTROL

This section outlines fuel injection control, ignition control, and electronic throttle control systems as three representative examples of engine control. This is preceded by an explanation of basic engine operations. In a gasoline engine, an air–fuel (A/F)mixture is created and supplied inside the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto225
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

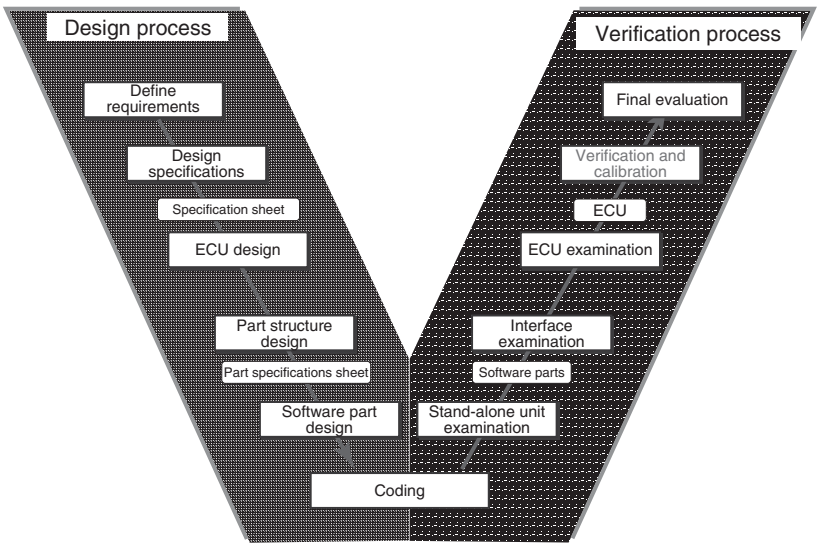

Figure 13. Engine ECU software development process.

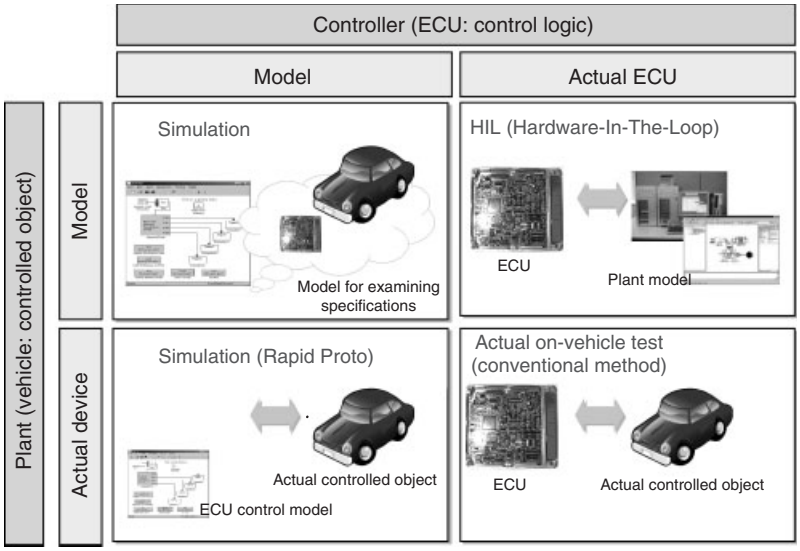

Figure 14. Main simulation technology used in model-based development.

cylinders. Heat energy is produced by causing this A/F mixture to combust. The heat energy pushes on pistons and the movement of the pistons is turned into torque, also called *rotating force*.

Figure 16 shows a diagram of a normal four-stroke engine. These four strokes are air intake, compression, expansion, and exhaust. In the air intake stroke, the piston starts at the top dead center (TDC) and then drops, causing the air intake to start. Once the piston reaches the bottom dead center (BDC) and begins to rise again, the air intake valve closes and the compression stroke begins. The A/F mixture in the cylinder is compressed until just before the piston reaches TDC again. The spark plug fires at that moment and ignites the A/F mixture. The combustion energy that is produced pushes the piston back down and this is the expansion stroke. The exhaust valve opens when the piston drops to the BDC and the exhaust stroke begins.

This means that combustion occurs once in a given cylinder for every 720° that the crank rotates in a four-stroke engine. In the case of the four-cylinder engines that are often used in compact cars, the combustion process occurs four separate times, once in each cylinder, so combustion occurs each time the crank rotates 180°.

3.1 Outline of fuel injection control

3.1.1 Controlling amount of fuel injected and injection time

This section discusses the control of the amount of fuel that is injected and the injection time in a port-injection-type gasoline engine. Figure 17 shows a general gasoline fuel injection system.

The engine ECU calculates the amount of fuel to inject as the injection time (T_i) and then sends this information to the injector. Three elements are used to determine this injection time (T_i): the basic injection time (T_p), the amount of feedback correction, and the transient correction. First, the necessary amount of fuel for a single combustion is calculated from the quantity of intake air (G_a) and the engine speed (N_e) as the basic injection time (T_p). After this,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto225
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

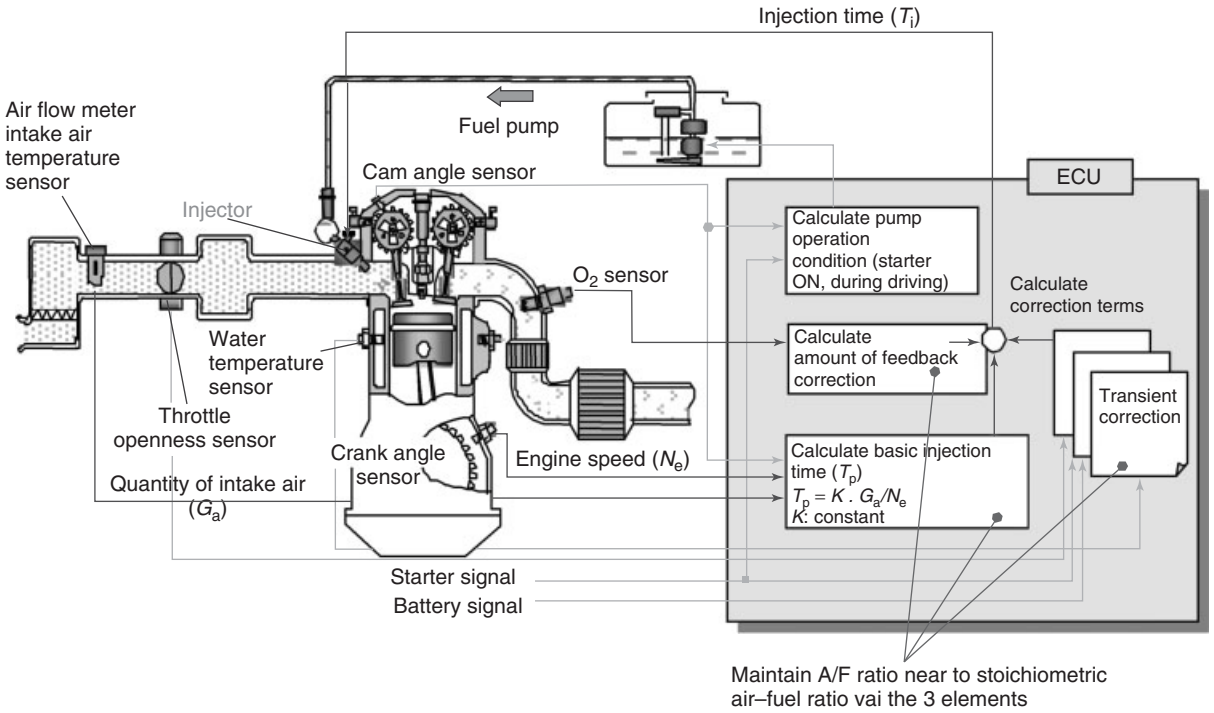

Figure 17. Fuel injection control of port-injection type gasoline engine.

the amount of feedback correction from the O_2 sensor or any difference from the target A/F ratio during the transition is added to bring the A/F ratio into line with the target stoichiometric A/F ratio.

There are also cases where the amount of fuel that is injected is increased, such as when the engine is started and when high engine output is necessary. Table 2 summarizes the concepts behind control that is performed in accordance with the operating conditions, such as before and after engine start.

3.1.2 Air–fuel ratio feedback control

The exhaust emissions from the engine contain toxic substances such as hydrocarbons (HCs), carbon monoxide (CO), and NO*x*. A catalyst is used as part of an aftertreatment process for the exhaust emissions to reduce the amounts of these toxic substances. Currently, a three-way catalyst is the most common catalyst that is used. A three-way catalyst simultaneously causes an oxidation reaction with CO and HC and a reduction reaction with NO*x*, so that they are converted into nontoxic carbon dioxide (CO_2), water (H_2O), and nitrogen (N_2), respectively. This catalyst possesses excellent conversion efficiency characteristics when the A/F ratio of the exhaust emissions (λ) is controlled and kept within a narrow range near to the stoichiometric A/F ratio (Figure 18).

Always maintaining the A/F ratio near to the stoichiometric A/F ratio ($\lambda = 1$) is necessary to keep the catalyst operating efficiently, even when the driving conditions change. The O_2 sensor installed on the exhaust manifold is used for this purpose. The O_2 sensor detects the concentration of oxygen in the exhaust emissions and the output voltage of the sensor changes greatly depending on this concentration with the stoichiometric A/F ratio as the dividing line. A judgment is made about whether the A/F mixture is rich or lean based on the output voltage that is detected and this is used as A/F ratio feedback to correct the amount of fuel injection. However, the voltage of the O_2 sensor changes abruptly with the stoichiometric A/F ratio as the dividing line. Therefore, a linear A/F ratio sensor (Figure 19) is used to realize even more highly precise feedback control. In a linear A/F sensor, the saturation current of the sensor changes linearly in response to the changes in the A/F ratio.

3.1.3 Fuel injection timing control

The fuel injection timing control switches the fuel injection start timing depending on the engine speed and the load. The fuel injection is controlled, so that it finishes before the intake air valve opens. The purpose of this timing control is to prevent the injected fuel from blowing into the exhaust manifold because of the overlap of the air

Table 2. Control in accordance with operating conditions.

Various corrections		Outlines
At start	Start injection time	Determines the basic injection time from amount of engine exhaust, water temperature, and engine speed.
After start	Increased amount for warm up correction	Increases amount when coolant temperature is low and gasoline evaporation is poor.
	Increased amount after start correction	The rate of increase is at maximum immediately after start but then gradually decreases to stabilize the engine speed.
	Transition time air–fuel ratio correction	Acceleration or deceleration is determined from the changes in the quantity of intake air and the amount is increased or decreased in accordance with the conditions to improve driving performance.
	Increased amount for high load correction	Amount is increased when the exhaust temperature exceeds the predetermined value.
	Increased amount for output correction	Corrections are made so that air–fuel ratio for maximum output is attained during high load driving.
	Air–fuel ratio feedback correction	Amount of fuel injection is increased or decreased based on the signal from the O_2 sensor. The air–fuel ratio is controlled within a narrow range near to the stoichiometric air–fuel ratio where the three-way catalyst has superior conversion performance.
	Voltage correction	Prevents fluctuations in the amount of fuel injected by the injector because of battery voltage fluctuations.
Other	Fuel cut	Fuel supply is cut off when decelerating, as torque is unnecessary, and also when throttle is fully closed.

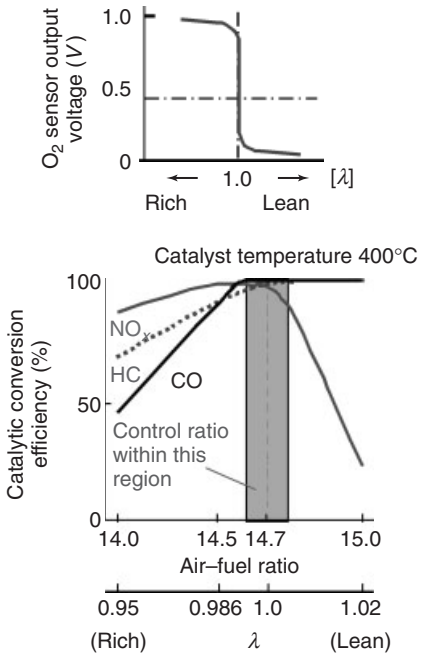

Figure 18. Output voltage of O2 sensor and catalytic conversion efficiency compared to air–fuel ratio.

intake and exhaust valves (both valves being open at the same time). This also increases the amount of time for fuel evaporation and prevents an increase in the amount of HC from unburned fuel that is produced when the fuel is ignited before it evaporates.

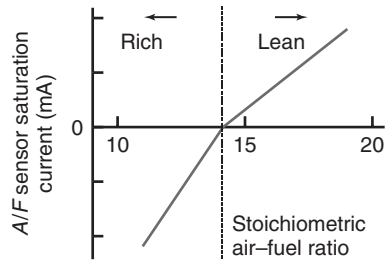

Figure 19. Linear A/F sensor output characteristics.

3.2 Outline of ignition control

3.2.1 Ignition control system

The ignition system calculates the ignition timing and power application time for the spark plugs attached to the cylinder head. It also outputs the ignition signal in accordance with the crank angle of the engine. Figure 20 shows the composition of this system. The crank angle of each cylinder is detected from the signals of the crank angle sensor and the cam angle sensor, which differentiates between the different engine cylinders. The ECU calculates the optimum ignition timing for each driving condition. It then outputs the ignition signal to the ignition device (ignition coil and igniter). The ignition device generates a high voltage based on these ignition signals and applies this voltage to the electrodes of the spark plugs. This causes

DOI: 10.1002/9781118354179.auto225
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

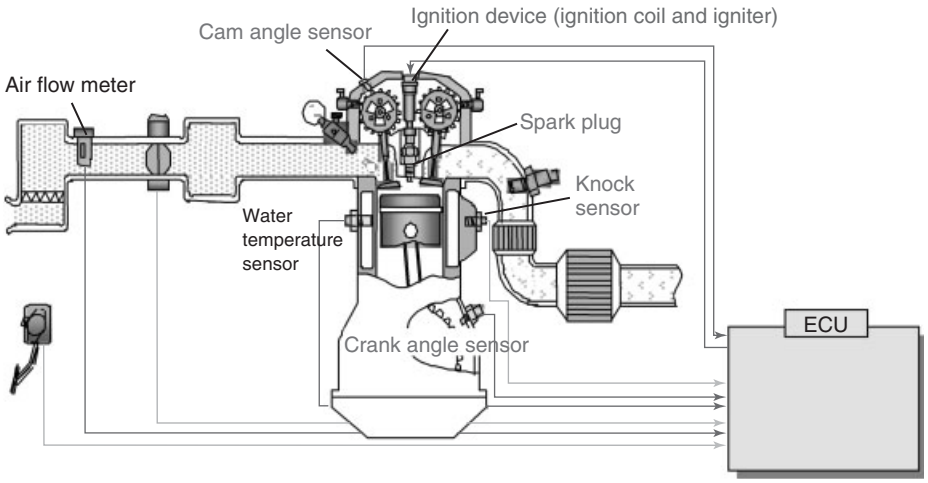

Figure 20. Ignition control system.

a spark to be formed that ignites and combusts the A/F mixture within the cylinder.

The maximum effective work due to the combustion energy is obtained when the maximum voltage is generated when the piston is slightly past-TDC. This ignition timing is called *maximum spark advance for best torque* (MBT) and the ignition timing is usually controlled, so that this condition is achieved. In the majority of engines, the piston position that attains maximum firing pressure and MBT is approximately 10°CA after top dead center (ATDC).

3.2.2 *Ignition timing control*

The ECU calculates the ignition signal, consisting of the ignition timing and power application time, based on the information from each sensor and then transmits this signal to the ignition device. The cylinders are differentiated by the output of the cam angle sensor, and the engine speed is calculated from the output of the crank angle sensor. Corrections are added based on the engine load and water temperature and then the ignition timing is determined. The power application time is determined by adding the correction for battery voltage to the engine speed (Figure 21).

3.2.3 *Knock control*

The ignition timing is advanced when the engine is in the high load region to get closer to the MBT. This increases the maximum firing pressure and causes the A/F mixture to ignite early, which produces abnormal combustion called *knocking*. The knock control system limits the degree

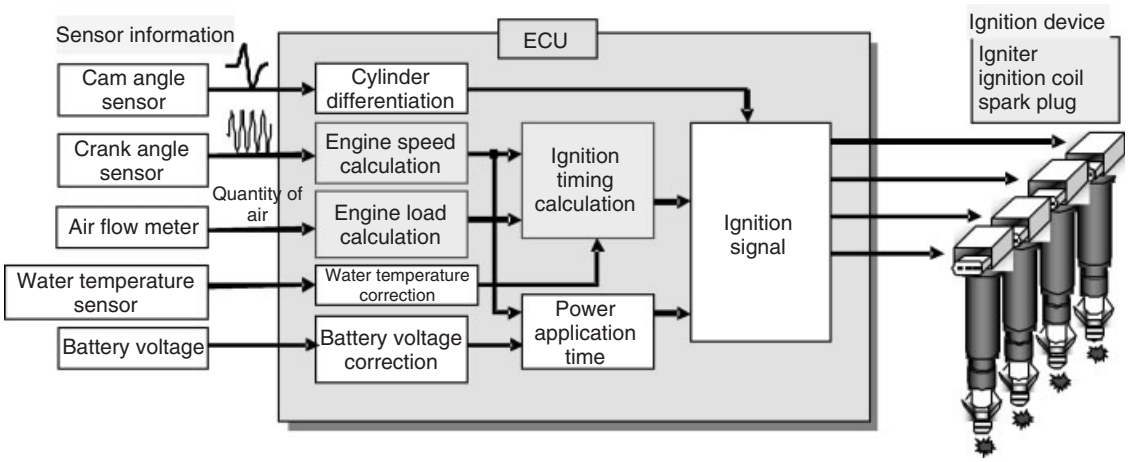

Figure 21. Content of ECU control.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto225
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of knocking to an allowable level that does not damage the engine. Allowing for some leeway and flexibility in the ignition timing is necessary in consideration of the mechanical tolerance and other factors. Ignition will occur well in advance of the MBT if knock control is not implemented and this will lead to a corresponding reduction in torque. The power and fuel economy of the engine can both be improved by incorporating knock control.

3.3 Outline of electronic throttle control

3.3.1 Electronic throttle system

Owing to ever-increasing demands for better fuel economy and lower exhaust emissions, improving the flexibility of control over the quantity of airflow is becoming more important. Each year, a growing number of vehicles are adopting an electronic throttle, which can control the throttle valve independently of the accelerator pedal operations of the driver. As this feature also is being adopted on the majority of engines currently in development, use of an electronic throttle system is becoming more and more common. Figure 22 shows a diagram of an electronic throttle system that is composed of a throttle body, accelerator pedal module, and an ECU.

The throttle body consists of a throttle valve, a motor that opens and closes that valve, and a sensor that detects the valve opening angle. A sensor that detects the depression angle of the accelerator pedal and the speed of depression is built into the accelerator pedal module.

3.3.2 Throttle opening angle control

The throttle opening angle control determines how far the throttle is opened in consideration of the acceleration, based on how far the accelerator pedal is depressed by the driver. The target opening angle is calculated from the accelerator pedal sensor. That is then compared to the actual opening angle of the throttle sensor to find the deviation in the opening angle. The necessary amount of control for the motor is also calculated (Figure 23). The motor that drives the throttle valve provides the drive by changing the duty ratio, so the amount of control is converted into the duty ratio and a current pulse is transmitted to the motor. In the case of a throttle valve that uses a DC motor, switches A and D are turned ON and the current flows in the direction of A when the valve is opened. Conversely, switches B and C are turned ON and the current flows in the direction of B when the valve is closed.

4 THE FUTURE OF ENGINE ECU

The engine control parameters include the quantity of intake air, the amount of fuel injection, the ignition timing, and the opening and closing timing of the intake and exhaust valves. All of these parameters are controlled by the engine

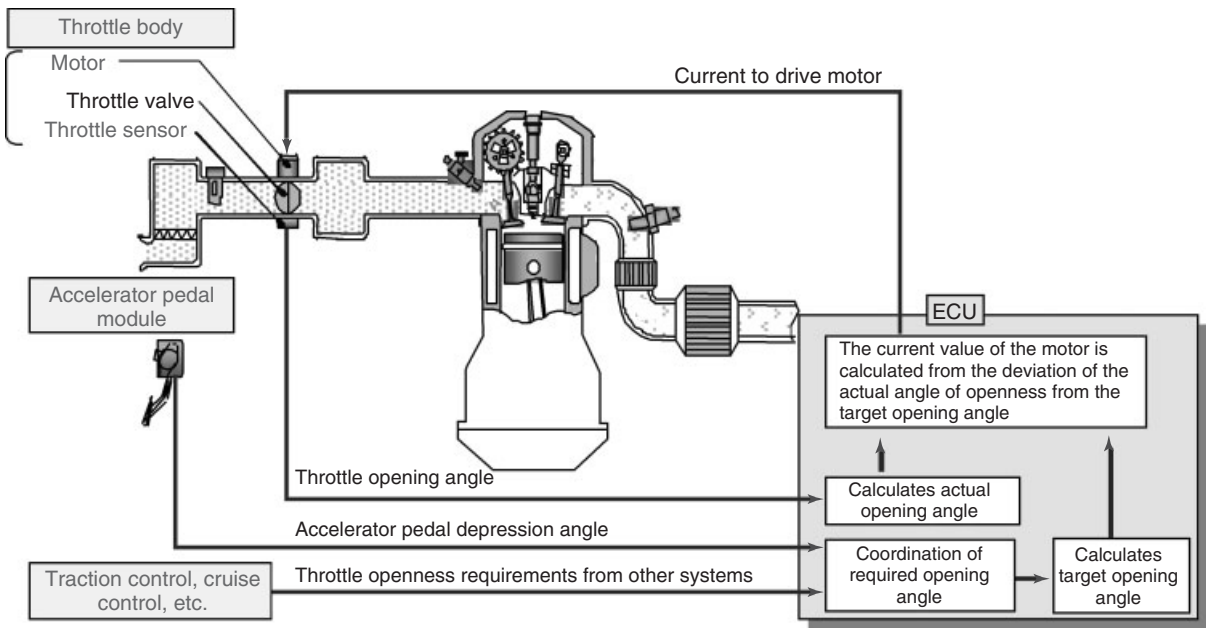

Figure 22. Configuration of electronic throttle.

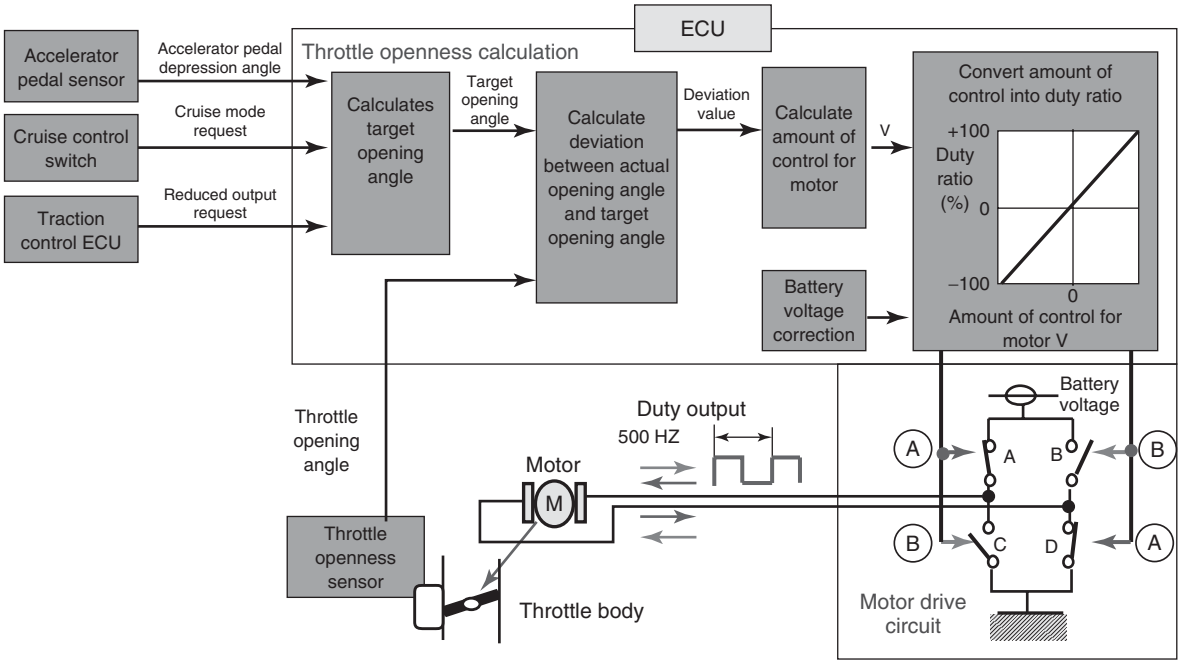

Figure 23. Throttle valve control.

ECU. This chapter described the hardware and software of the engine ECU system, as well as the fuel injection control, ignition control, and electronic throttle control as representative examples of engine controls.

In modern vehicles, the engine is controlled by the engine ECU system. This system has developed in conjunction with tightening of exhaust emissions and fuel economy regulations. In the future these trends will likely continue. The performance requirements of the engine ECU itself will also continue to increase from the standpoints of promoting greater safety, comfort, and protecting the environment. These are the three major requirements of vehicles in recent years.

The ECU system must be designed so that a fatal accident will not occur, even if the ECU system malfunctions. There has also been a great deal of attention and focus on ISO 26262, functional safety for road vehicles, in recent years.

The use of materials in the ECU system that include substances that are harmful to the environment, such as lead (Pb) and cadmium (Cd), are being abolished and demands to use materials that are renewable and recyclable are increasing to make vehicles more environmentally friendly.

There are also demands to reduce the size of the engine ECU system and install it somewhere other than in the occupant compartment in an effort to ensure more interior room and to improve passenger comfort. The recent trend is to install this ECU system closer to the engine, such as in the engine compartment or even directly on the engine. As a result, materials are needed that can withstand the more severe heat and vibration conditions of that installation environment, while also satisfying the demands for environmental friendliness.

Hybrid Systems and High Voltage Components

Masami Morikawa
DENSO Corporation, Kariya, Japan

1 HISTORY

The history of hybrid vehicles (HVs) is part of the long history of electric vehicles (EVs). EVs first appeared in the Japanese market in extremely small numbers around 1950 as alternative energy vehicles. However, these EVs were only produced for about a year because the level of performance did not match that of internal combustion engine (ICE) vehicles. Development of EVs restarted some 20 years later around 1970, this time as environmentally friendly vehicles. The Agency of Industrial Science and Technology in the Ministry of International Trade and Industry (MITI) drew up a plan for a major EV project that was then undertaken with the cooperation of many vehicle manufacturers and components manufacturers. Unfortunately, this project also came to an end after several years due to the oil shocks and other circumstances in the 1970s. Another 20 years passed and once again EV development started up in the 1990s in response to the exhaust emissions regulations implemented in the state of California in the United States. The regulations were to take effect in 1998 and would have required every vehicle manufacturer to sell a predetermined percentage of EVs. Vehicle manufacturers worked feverishly to develop EVs to meet the new requirements. However, the regulations were not implemented as planned and once again the curtain fell on EVs after several years of limited production. In the end, their cruising range, recharging time, and cost made it difficult to seriously consider EVs as a viable substitute for conventional vehicles. They did find a niche in some limited markets (such as forklifts), however.

The vehicles that finally overcame these issues with EVs and became known for their fuel efficiency and environmental-friendliness were the HVs that went on sale in the later half of the 1990s. HVs were positioned as the vehicles of the twenty-first century and were ultimately equipped with much of the new technology developed for the EVs that were intended to comply with the Californian emissions regulations. Nickel-metal hydride (Ni-MH) batteries in particular achieved levels of performance that far surpassed that of conventional lead acid (Pb) batteries. It is not an overstatement to say that HVs would not have become a reality if not for these batteries. In addition to the batteries, the new hybrid drive systems that were proposed were also groundbreaking technology for HVs. The development and mass production of HV components made a major contribution to the improvement of EV performance and the reduction of overall costs.

2 OUTLINE

This chapter uses the hybrid systems adopted in the Toyota Prius and Honda Insight as typical examples. These systems utilize an electric motor to greatly reduce the energy consumed and exhaust emissions generated during start up, acceleration, and deceleration, which are the weak points of conventional ICE vehicles. These systems also resolve the cruising range and recharging time issues of EVs. Electric motor systems were originally adopted on EVs, and the HV system is a skillful integration of this EV technology with conventional gasoline engine technology. This chapter describes the types and special characteristics of HV systems based on an EV system and also explains the configuration and roles of the main HV components.

3 EV SYSTEM

3.1 EV system

Figure 1 shows the configuration of the EV system in a Toyota RAV4 EV. The EV engine control unit (ECU) controls the inverter and drives the motor in accordance with the signals from the accelerator pedal. A permanent magnet (PM) motor is used for the electric motor, whereas a Ni-MH battery is used for the main battery. The voltage is 288 V and the state of charge and discharge of the battery is monitored by the ECU, which can also calculate the remaining battery capacity as needed during driving. The main battery is recharged using a commercial power supply via the charger installed in the vehicle. The auxiliary battery is charged by converting the voltage from the main battery using a direct current (DC)–DC converter.

3.2 Driving control of EV

Figure 2 shows the driving control of an EV. The vehicle drive torque is determined by the angle of depression of the accelerator pedal, the brake signal, the shift position, and the vehicle's speed based on a drive torque map that was recorded in advance. Commands are then sent to the motor control portion to achieve this torque. For example, it is controlled as a motor during acceleration and as a generator during deceleration.

4 HV SYSTEMS

There are two ways of classifying HV systems, in accordance with their functions or their drive system. First, Figure 3 shows the different HV systems categorized according to function. A system that only has the idling stop function is referred to as an *ISS* or *micro HV*. The addition of other functions, such as acceleration assist, energy regeneration, and high efficiency engine operation, turns the system into a mild HV. The system is called a *strong HV system* if it includes an EV drive mode. CO_2 and exhaust emissions both decrease the further that the system progresses toward a strong HV. Once the vehicle becomes

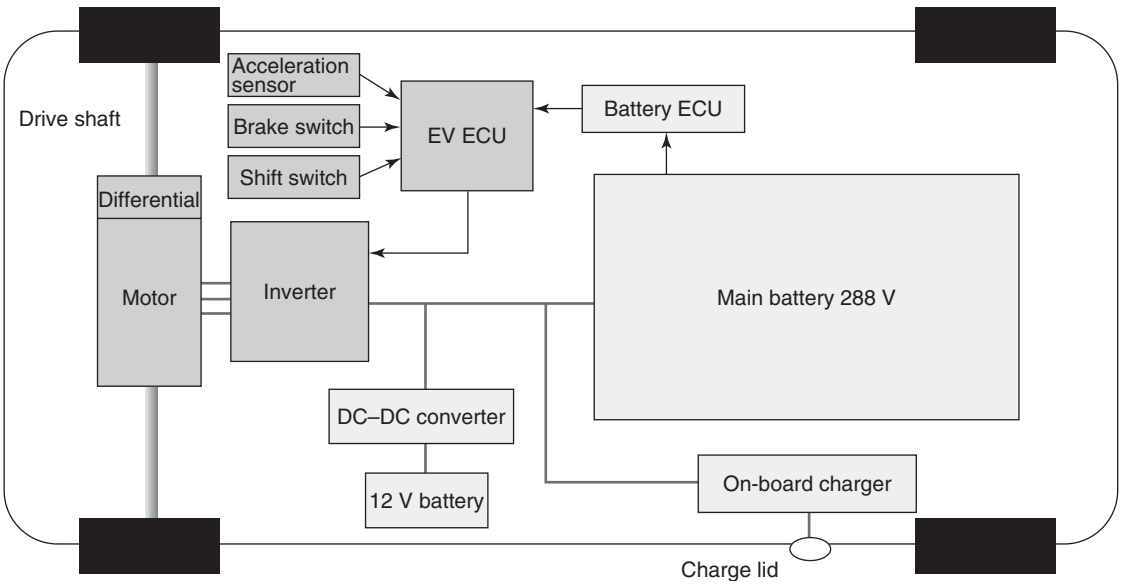

Figure 1. Configuration of RAV4 EV system.

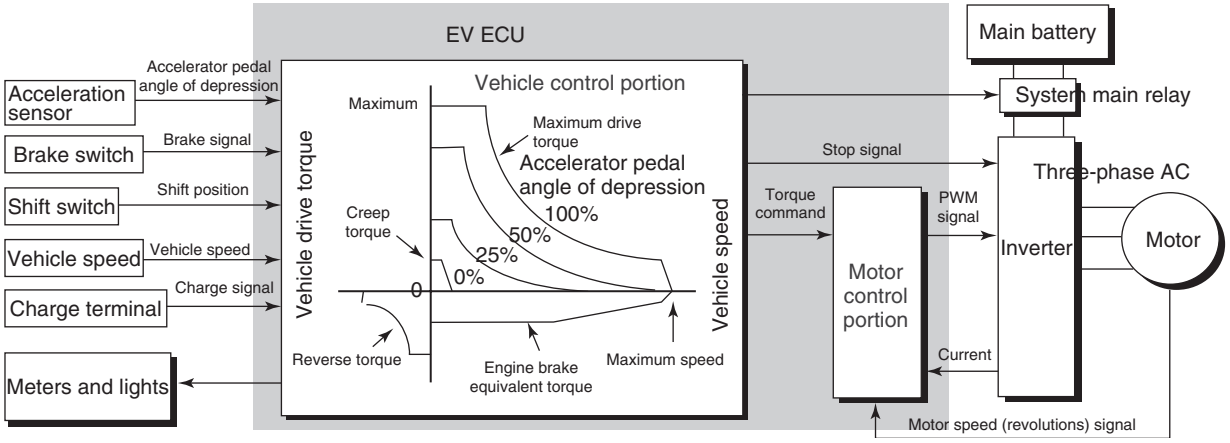

Figure 2. Driving control of EV.

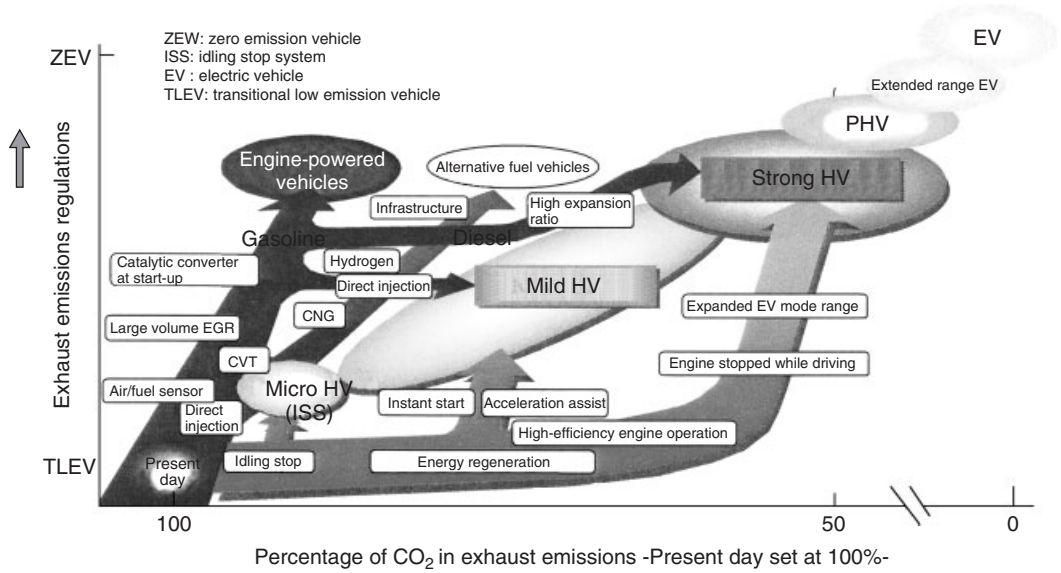

Figure 3. Reduction in CO_2 emissions by HVs and EVs.

an EV, there are zero exhaust emissions. Plug-in hybrid vehicles (PHVs) and extended range EVs are positioned somewhere in between a strong HV and an EV.

HV systems can also be classified according to their drive system. There are three main HV drive systems: series, parallel, and series parallel. The configuration and special characteristics of each of these drive system are explained in the following sections.

4.1 Series HV

Figure 4 shows the configuration of a series HV system. An engine is installed in the vehicle to drive the generator that charges the main battery. The vehicle is propelled by an electric motor and the main battery is constantly being charged.

4.1.1 Special characteristics

– The vehicle is propelled only by the electric motor so the power and size of the motor and generator are larger than in the other drive systems (based on an EV with an engine and generator added).
– All of the motive power from the engine is converted into electrical power, so the conversion efficiency (transmission efficiency) is slightly poor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

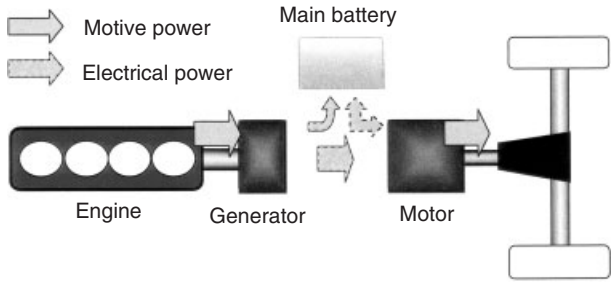

Figure 4. Configuration of series HV system.

– It is easy to control the drive power and output.
– It is comparatively easy to control the exhaust emissions because the engine speed is steady.

4.2 Parallel HV (Honda insight)

Figure 5 shows the configuration of a parallel HV system. The engine and electric motor are arranged parallel to each other and the motive power to propel the vehicle can be supplied from both of these sources. However, in the case of this example, the engine and motor form a directly connected structure, which must move simultaneously.

4.2.1 Special characteristics

– The configuration of the system is simple as an electric motor is added between the engine and the transmission of a conventional vehicle.
– The engine is used a large portion of the time, so the electric motor plays a mostly auxiliary role. The motor system itself is small as there is no EV mode and there is comparatively little change from a conventional vehicle.
– Electrical power can only be used to propel the vehicle after the battery is charged.

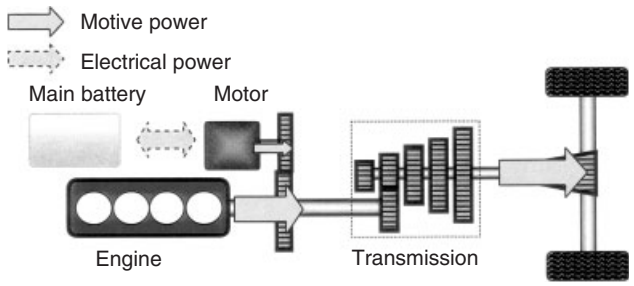

Figure 5. Configuration of parallel HV system (Honda insight).

– EV mode becomes possible if the engine and motor are separated and designed to provide drive independently. In this case, the motor system would become larger.

4.3 Series parallel HV (Toyota Prius)

Figure 6 shows the configuration of a series parallel HV system. Three power sources, the engine, MG1, and MG2 are connected by a planetary gear train. These provide drive to the vehicle in combination with each other in accordance with the driving conditions. Here, MG is an abbreviation for motor generator. Usually, these devices are referred to separately, but each is frequently used for their electrical operation function and electrical generation function, respectively, so they are referred to collectively as MG to reflect their actual usage. The role of the engine is to provide drive to the vehicle and MG1. The role of MG1 is to charge the main battery and also to provide assistance during engine start and auxiliary drive to the vehicle as an electric motor. The role of MG2 is to provide drive to the vehicle (EV mode) and any necessary assistance, as well as energy regeneration as a generator.

4.3.1 Special characteristics

– This system achieves both good fuel economy and driving performance, because it possesses the advantages of both the series HV system and parallel HV system.
– There is great potential to improve fuel economy, because the system is very efficient.
– The system and its various controls are complicated.

4.3.1.1 Configuration of HV system. Figure 7 shows how a HV is equipped with both an engine system and

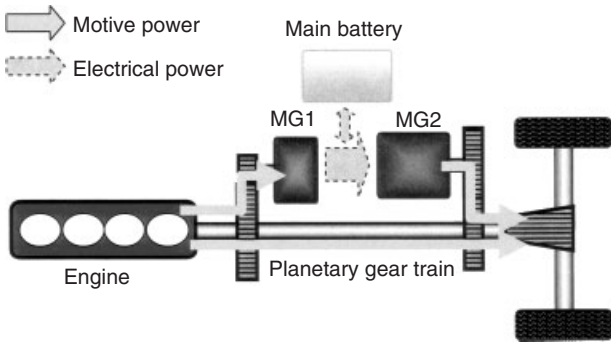

Figure 6. Configuration of series parallel HV system (Toyota Prius).

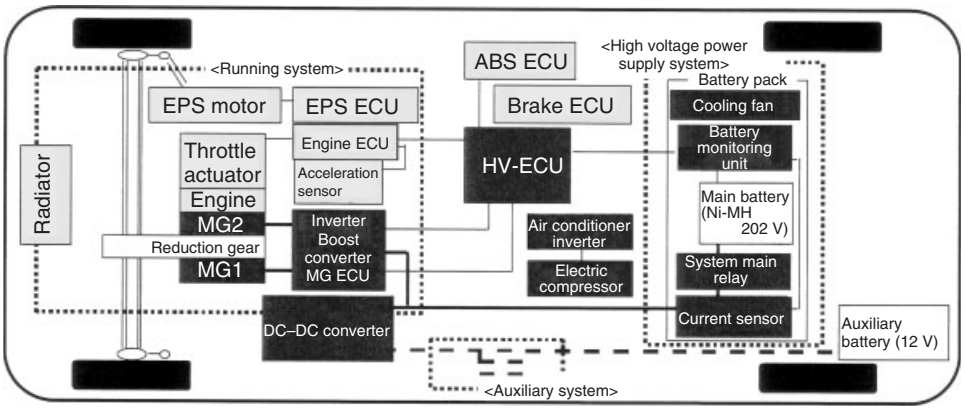

Figure 7. Configuration of HV system (Toyota Prius).

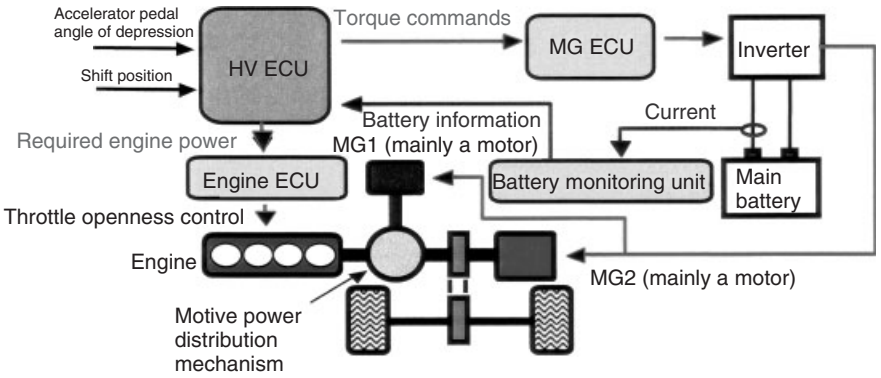

Figure 8. Configuration of HV control system.

two MG (motor) systems. The HV ECU is provided for integrated control to ensure optimum operation of the two drive systems. A Ni-MH battery is used for the main battery, and the components that compose the electric power supply system, such as the battery ECU and current sensors, are the same as those used on an EV. A DC–DC converter is used to charge the auxiliary battery and an electric compressor is used for the air conditioner, exactly the same as on an EV. One difference from an EV is that there is no battery charger.

4.3.1.2 System control. Figure 8 shows the configuration of the control system in a HV.

– The HV ECU issues commands to the engine ECU to produce the required engine power based on the requests from the driver, the state of the vehicle, and the state of charge (SOC) of the main battery. It also calculates the MG1 torque and MG2 torque and then issues the torque commands to the MG ECU. After this, the engine ECU controls the degree of openness of the electronically controlled throttle in accordance with the engine power requirements from the HV ECU.
– The MG ECU controls MG1 and MG2 via the inverter in accordance with the torque commands from the HV ECU. It also controls the drive power, so that operation is in line with these torque commands.
– The battery monitoring unit monitors the SOC of the main battery and other items. It then transmits the SOC and other battery information to the HV ECU.
– The HV ECU controls the SOC of the main battery so that the system is in the optimum state.

4.3.1.3 Regenerative braking control. Figure 9 shows the brake configuration. The motor generates power during deceleration by converting kinetic energy into electricity. This electricity is then stored in the battery. The distribution of braking force between the mechanical brake and the regenerative brake is controlled so that even the slightest increase in kinetic energy can be recovered.

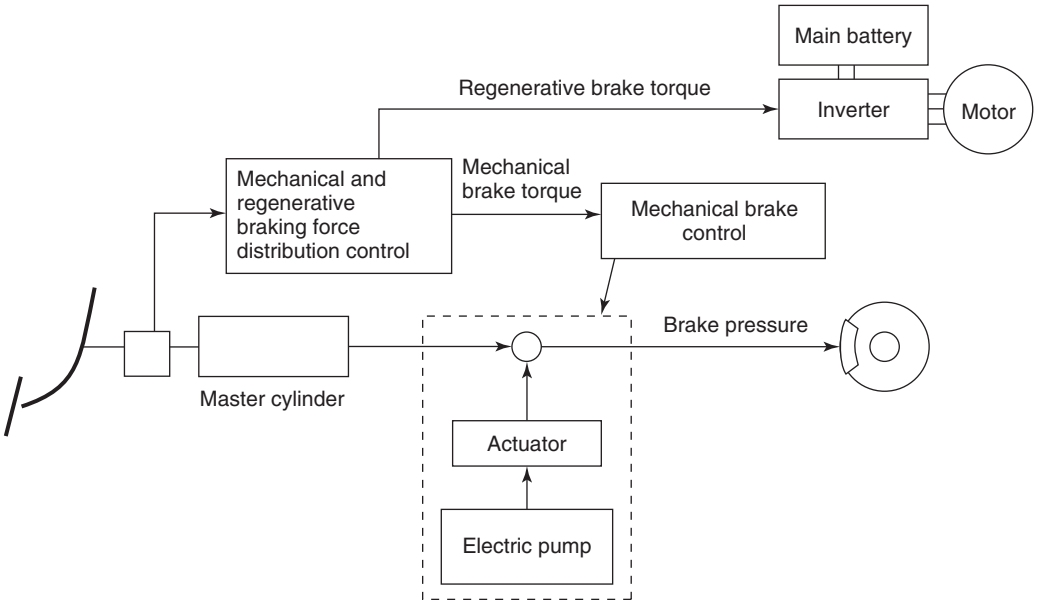

Figure 9. Configuration of HV brakes (example).

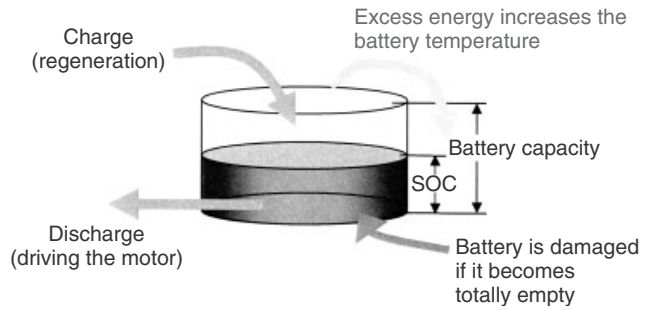

Figure 10. Concept of electrical power control.

4.3.1.4 Electrical power control: management of main battery capacity. Figure 10 shows the concept behind electrical power control. In a HV, the main battery is discharged when the MG is used as a motor, such as during EV mode. The main battery is charged when the MG is used as a generator, such as during regenerative braking. A longer EV mode is possible when the remaining main battery SOC is high, but less energy regeneration occurs. The opposite is true when the remaining SOC of the main battery is low.

Figure 11 shows how an actual battery is used. The main battery is repeatedly charged and discharged in accordance with the driving conditions of the vehicle. Properly maintaining the remaining SOC in the main battery is necessary to optimize its use. Therefore, regeneration and discharge are monitored at all times to constantly calculate the SOC.

4.4 EV and HV application systems

4.4.1 Extended range EV

With this type of vehicle, an engine and generator are added to an EV to extend the cruising range. Figure 12 shows the configuration of this system and the flow of energy.

- EV mode is the basis of this system.
- The cruising range can be extended in an emergency as a series HV.
- The vehicle is equipped with the smallest engine possible.

4.4.2 Plug-in hybrid vehicle

The EV mode distance is extended by keeping the main battery of a strong HV at full charge. Figure 13 shows the configuration of this system and the flow of energy.

- A strong HV is the basis of this system and a charger is added.
- The capacity of the main battery is augmented.

5 ELECTRIC MOTORS

5.1 Types and uses of electric motors

Figure 14 shows the different types of electric motors and their applications. DC motors (wound DC motors), induction motors (squirrel-cage type), and permanent magnet motors are the types of electric motors that are most often adopted as traction motors to propel the vehicle.

5.2 Summary of HV motor requirements

The following items are the required characteristics and capabilities of a HV motor. The motor must have high power, high revolutions, and high voltage to reduce its size. The motor must be highly efficient to improve the fuel economy of the vehicle. The motor must also be reliable and largely maintenance free to be used in the system that provides drive for the vehicle. Figure 15 compares the main types of electric motors. Currently, alternating current (AC) motors have the advantage in terms of their ability to handle high voltages and to require little maintenance. In particular, the PM motor is often used due to its small size and high efficiency. Rare-earth magnets are often used in these types of motors to realize significant reductions in size and increases in power.

5.3 PM motor

PM motors can be divided into two different types depending on where the magnet is located: surface permanent magnet (SPM) and internal permanent magnet (IPM). Figure 16 shows the structure of the rotor in both these types of motors.

Currently, IPM motors are often used in HVs, because it is easy to increase their speed and to utilize reluctance torque (Figure 17). SPM motors are used in systems (such as the power steering) where vibration noise is expected to be a problem. However, there are cost and supply issues that arise when using large amounts of rare-earth magnets. Figure 18 shows a photograph of an actual motor for a HV.

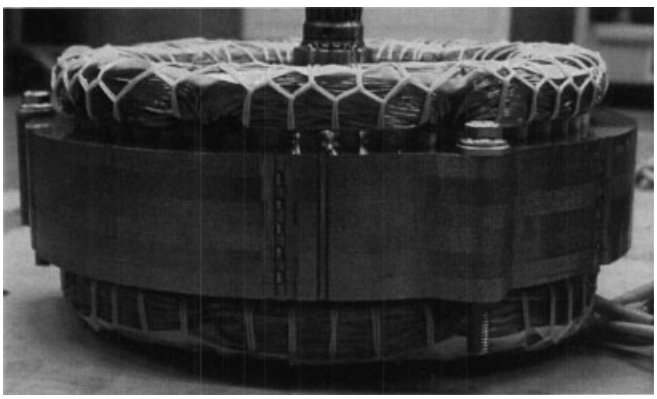

Figure 18. Electric motor for HV.

6 INVERTER

6.1 Overall configuration and functions

Figure 19 shows the configuration of an inverter. The inverter is a device that takes the DC from the main battery installed in the vehicle and converts it into three-phase AC via six bridge-linked power devices to supply it to the motor. The application of pulse width modulation (PWM) control to the power devices enables output of voltage-controlled sine wave AC and controls the torque of the motor. (PWM control is explained below.)

The necessary torque is calculated by the HV ECU from the acceleration commands indicated by the amount of accelerator pedal operation by the driver. This is then sent to the inverter as drive signals of the power devices. The torque that can be obtained changes depending on the relationship between the voltage phase and the rotor position. Therefore, the electric power is supplied at the time that will obtain the maximum torque by detecting the position of the rotor.

6.2 Principle of three-phase AC generation

This section explains the principle behind the method of creating the voltage-controlled sine wave three-phase AC (Figure 20). The sine wave voltage commands that are phase shifted by 120° are compared to triangular wave and ON and OFF signals created for the two power devices in the upper arm and lower arm in each of the three phases, U, V, and W. This allows pulse voltages to be obtained for each of the phase voltages (V_U, V_V, and V_W) in the form of sine waves that are phase shifted 120° (the average voltage of each pulse is changed into the form of a sine wave). The pulses can be changed ON and OFF by changing the amplitude of the voltage command and this in turn changes the voltage value. The current will only flow through the motor when ON in this state, but the current will also flow through the motor during the OFF period due to the flywheel diode (FWD) that is connected in parallel. This allows for uninterrupted sine wave current to be applied to the motor. The higher the frequency of the triangular wave, the more that the motor magnetic noise and current ripples can be suppressed. However, this will increase the loss of the power devices, so usually the frequency of the triangular wave is set between 5 and 10 KHz.

6.3 Power devices

The power devices are the most important components of the inverter from the standpoints of functionality and cost. One of the key points for lowering the cost is reducing the size of the elements that make up the inverter as much as possible. Reducing the loss that is generated by the elements is vital to reducing their size. Figure 21 shows that in an ideal switch, no loss is generated no matter how much current flows through it, but that the switch ON voltage in a semiconductor that is generated when current flows through it becomes ON loss.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

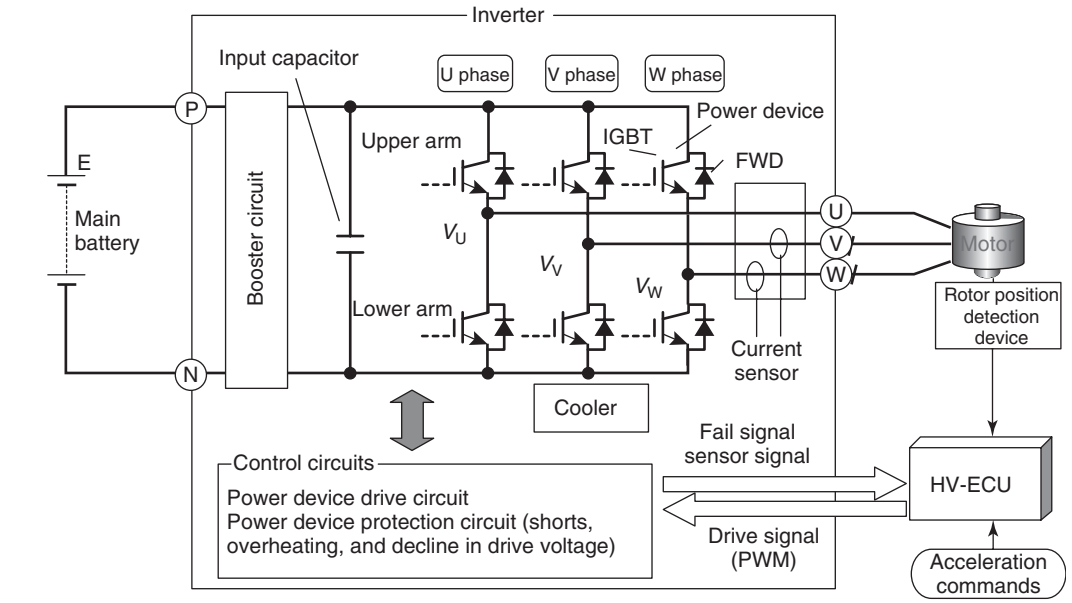

Figure 19. Configuration of inverter.

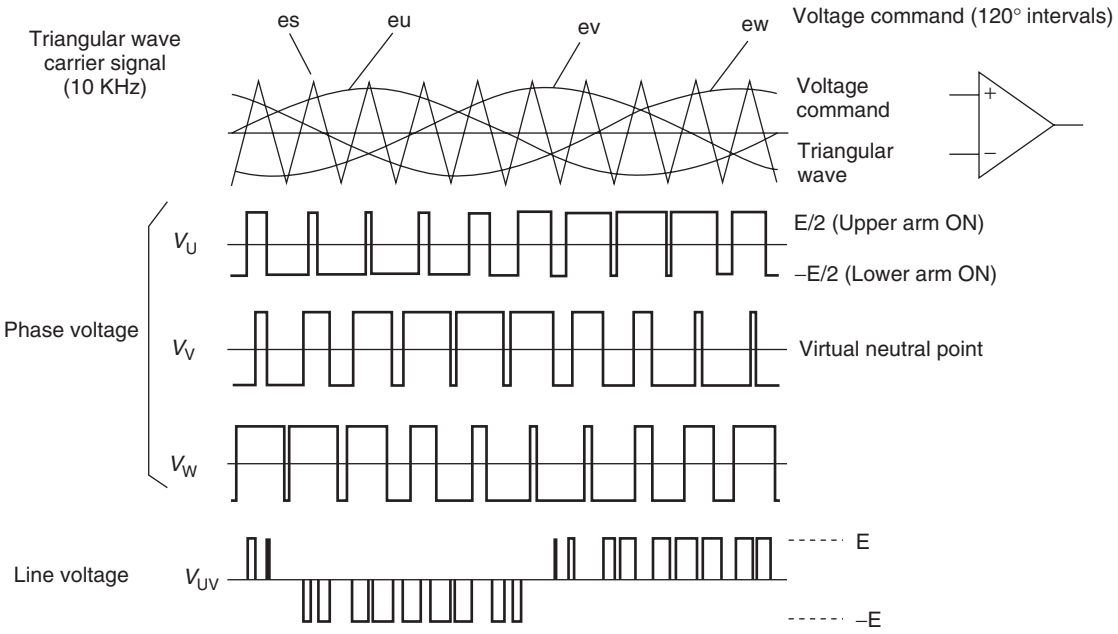

Figure 20. Principle of three-phase AC generation.

In addition, although a switch is turned ON and OFF, it does not switch to the other state instantly. This extra time (switching time) results in switching loss. There are three methods of reducing loss, as shown in Figure 21: (i) decrease the current, (ii) decrease the ON voltage, or (iii) shorten the switching time. The following sections provide explanations of these methods.

6.3.1 Decreasing current

Figure 22 shows the configuration of a booster circuit. A booster circuit is provided between the inverter and the main battery. It boosts the voltage to 650 V and supplies it to the inverter. The current flowing through the power devices can be reduced because the current in the motor

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

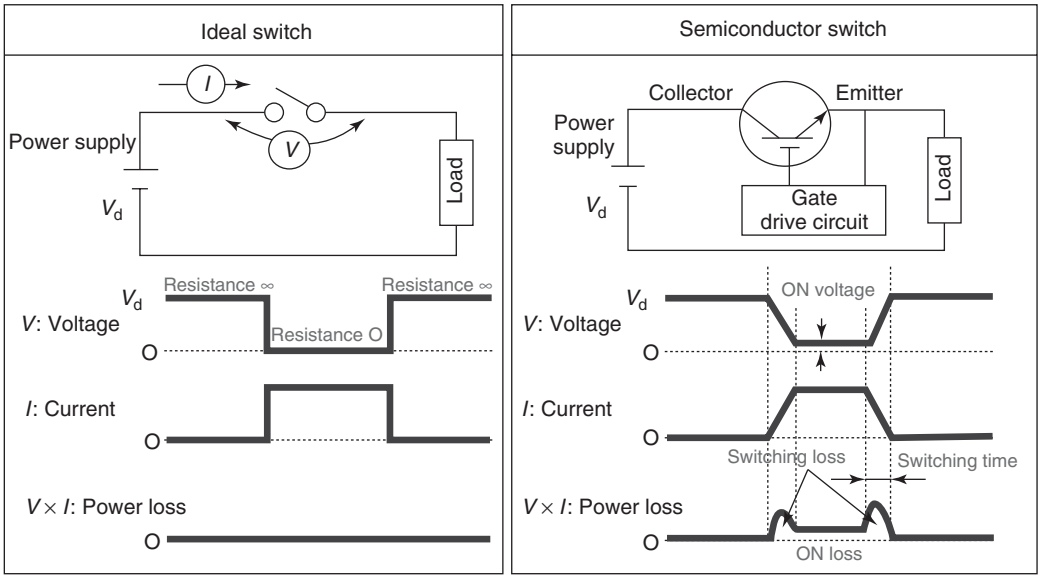

Figure 21. Ideal switch and semiconductor switch.

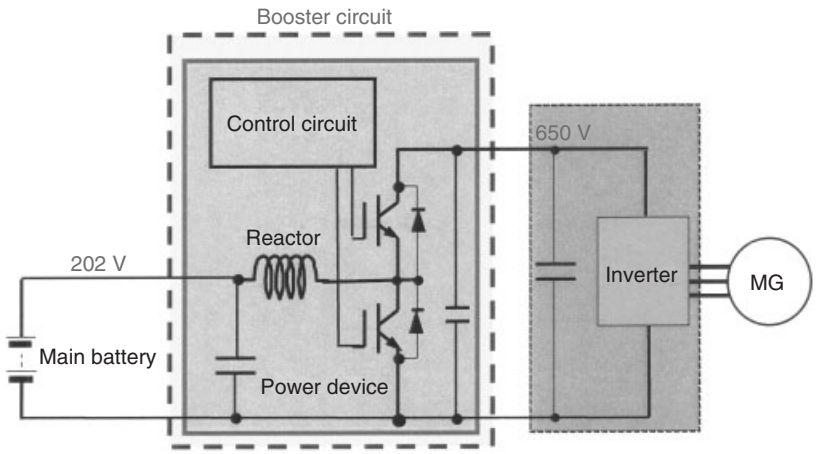

Figure 22. Configuration of booster circuit.

will decrease in proportion to the voltage. The more that the boost voltage is increased the more that the current will decrease. However, the use of very high voltage will cause devices such as the inverter and motor to increase in size due to insulation problems. Therefore, this level of voltage (650 V) is optimum for onboard devices.

The reduction in cost attained by reducing the current is sufficiently large to offset the cost of including the booster circuit, so this method of decreasing the current is often adopted. The booster circuit operates as follows. The power device on the lower side is turned ON and energy builds up in the reactor. The voltage then rises when this power device is turned OFF. This voltage is then stored in the capacitor after passing through the diode on the upper side, thereby boosting the voltage. When regeneration occurs, the power device on the upper side and the diode on the lower side are operated causing current to flow to the main battery.

6.3.2 *Decreasing ON voltage*

The most suitable power devices are selected because their characteristics determine the ON voltage. As a result, the power devices that can be used in an onboard inverter are insulated-gate bipolar transistors (IGBTs) or power metal oxide semiconductor field effect transistors (MOSFETs). Figure 23 shows that an IGBT has a low ON voltage

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

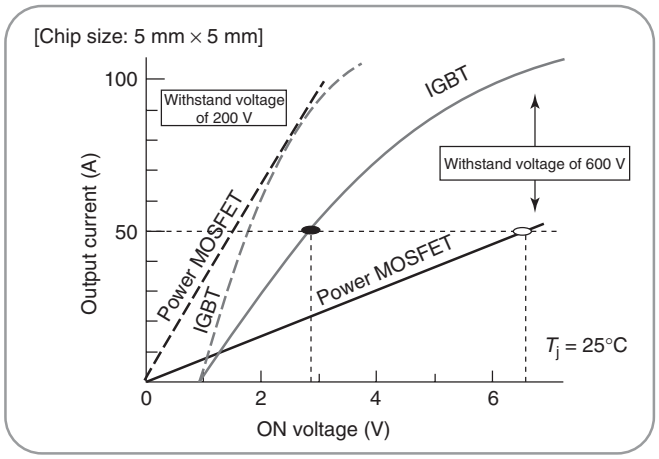

Figure 23. Comparison of IGBT and power MOSFET characteristics.

compared to other power devices with a withstand voltage of 200 V or more. Since the actual operating voltage is boosted to 650 V, the withstand voltage of the power devices must be around 1000 V, which makes IGBTs even more advantageous. IGBTs have been adopted due to the reasons explained above. However, it goes without saying that the higher the withstand voltage rises, the higher the ON voltage will also become, so the power devices and inverter must be formed from low withstand voltage components as much as possible.

6.3.3 *Shortening switching time*

It is easy to understand that shortening the switching time will result in a decrease in the switching loss. This can be accomplished by changing the gate resistance, as the time will decrease the smaller that the resistance becomes. However, increasing the withstand voltage of the power devices is necessary because the change in the current (d*i*/d*t*) increases and the surge voltage, ΔV, also increases. In this case, the ON loss will increase, although the switching loss has been reduced. Figure 24 shows that keeping the wiring inductance as small as possible is a key point of the design because the surge voltage is generated by wiring inductance.

In concrete terms, the capacitor should be placed as close as possible to the IGBT and the wiring should be kept short, but extensive. The + and − poles should be placed between thin insulating material and arranged as close to each other as possible as the mutual inductance effect will reduce *L*. Methods such as these can be employed to reduce the surge voltage.

There is also one other method of reducing the size of the power devices, besides reducing the loss. This is to lower the temperature of the power devices by improving the heat dissipation performance. Figure 25 shows the mounting structure and heat dissipation channels of a power device. The most common cooling method is to use water cooling and there are also cases where air cooling is used for power devices with comparatively small capacities.

The rise in the temperature of the power device, ΔT, is the product of the element loss, *P*, and the heat resistance, *R* (inverse of the heat dissipation performance). The loss can be permitted at the rate that *R* is reduced, so a small-sized element can be used.

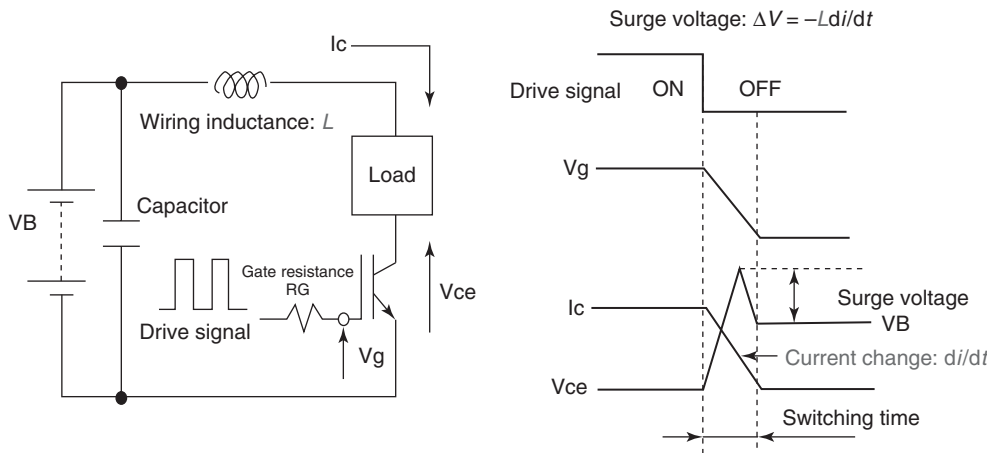

Figure 24. Principle of surge voltage generation.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

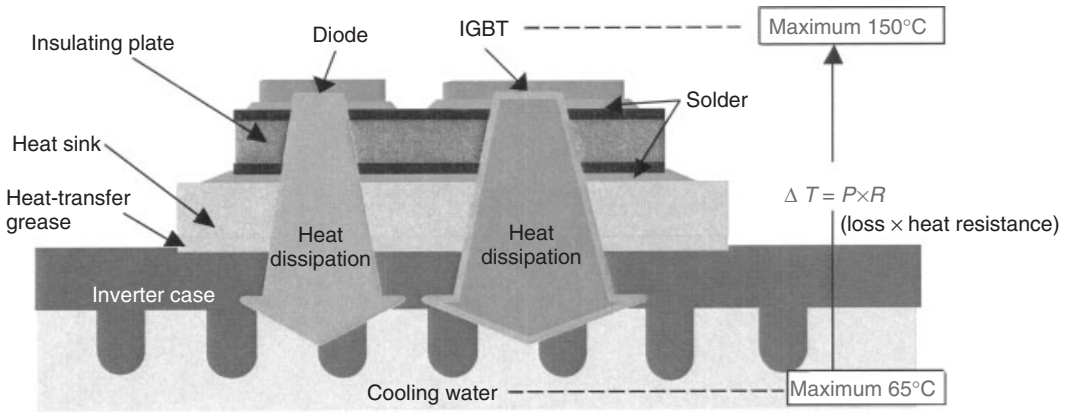

Figure 25. Power device mounting structure and heat dissipation channels.

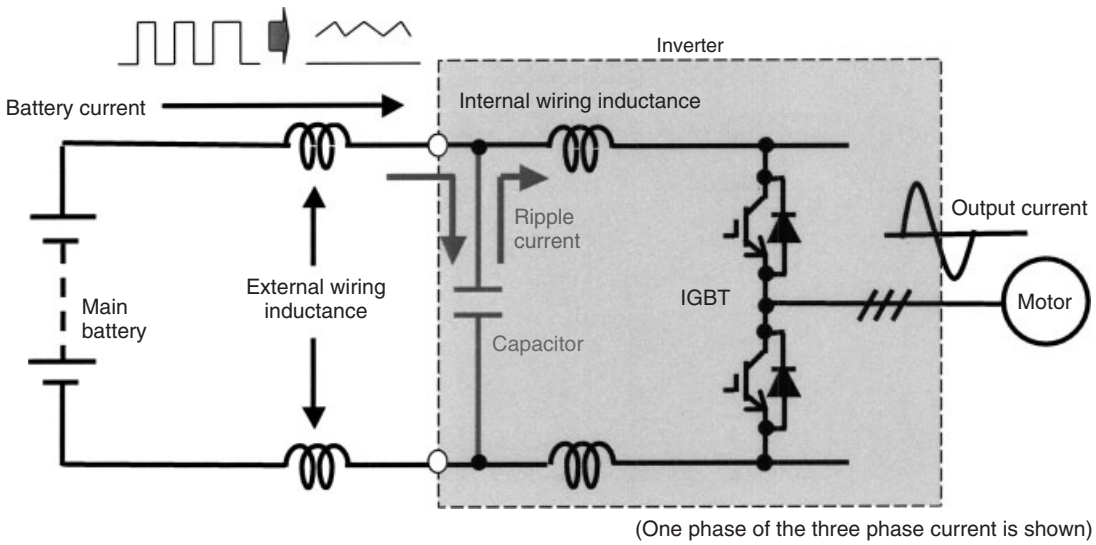

Figure 26. Capacitor role.

6.4 Capacitors

Figure 26 shows that the role of the capacitor is to smooth out the current from the main battery. As explained previously, if there is no capacitor, the current will change into the form of a pulse because of the ON and OFF operations of the IGBT. In this case, an excessively large surge voltage will be produced when the current is OFF due to the external wiring inductance and the IGBT will be destroyed instantly.

This surge voltage is suppressed through the use of a capacitor to gently decrease the current. Another issue is that when the current flows in the form of a pulse, it radiates noise with a wide frequency component from the wiring in between the main battery and the inverter. This noise can cause interference with the vehicle's radio and other devices. This noise is also suppressed by smoothing the current with a capacitor.

6.5 Control circuit

Figure 27 shows the configuration of the control circuit. The control circuit is composed of the drive circuit that drives the IGBT and the protection circuit that protects the IGBT. The low voltage system and the high voltage system are electrically insulated from each other by photo couplers and a transformer.

The drive signals are produced by vector control of the MG ECU. The protection circuit detects any overcurrents, short circuits, overheating, or drive voltage decrease in the

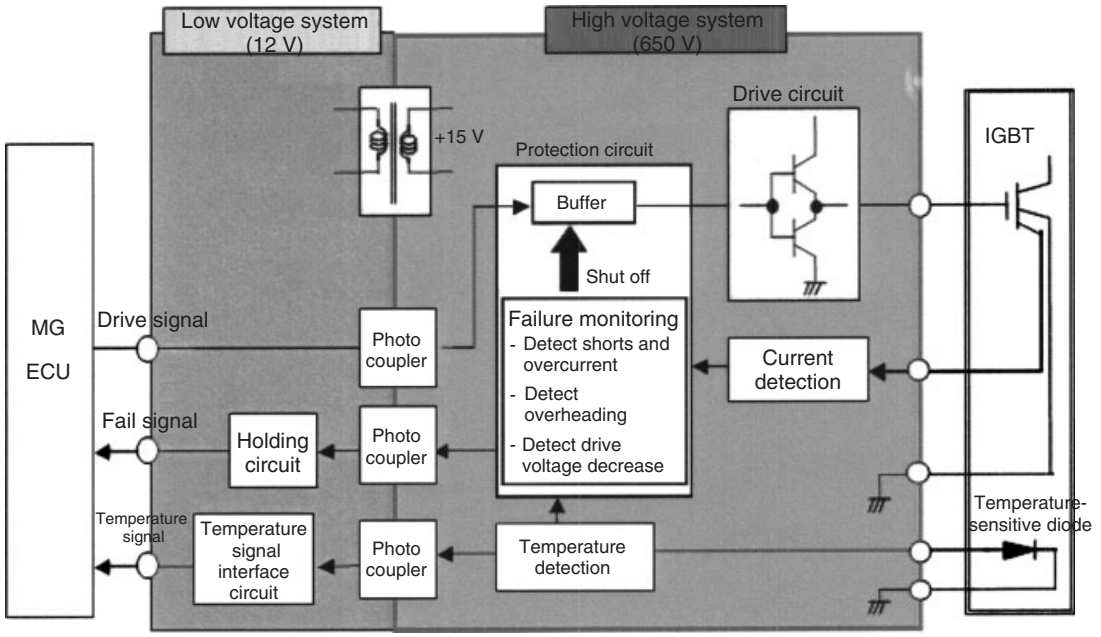

Figure 27. Configuration of control circuit.

IGBT and will shut off the IGBT when it detects any of these problems.

7 ELECTRIC POWER SUPPLY SYSTEM

7.1 Configuration

Figure 28 shows the configuration of the electric power supply in a HV. The electric power supply of a HV is composed of the following items: the main battery and the battery cooler, the battery ECU (monitoring unit) that monitors the battery, the system main relay (SMR) that mechanically supplies or shuts off the high voltage, the precharge relay and resistor for preventing inrush current, and the current sensor that senses the current being input into and output from the battery, and the like. All of these items are contained within a single case, which is also called a *battery pack*. A DC–DC converter is also used in a HV as a substitute for a conventional alternator to charge the auxiliary battery.

7.2 Main battery

There are four major points that define the main battery installed in a HV. The first point is the cycle life. The main battery in a HV is frequently and repeatedly charged and discharged. The cycle life of Pb batteries is short, so Ni-MH and lithium-ion (Li-ion) batteries that have longer cycle lives have become the mainstream batteries for use in HVs.

The second point is the energy density. A compact battery that can deliver large amounts of energy is necessary from the standpoints of fuel economy and cruising range. Li-ion batteries are superior from the standpoint of energy density (Figure 29).

The third point is power density. A battery that can produce large power is necessary to obtain faster acceleration performance. Li-ion batteries also have superior power performance, but efforts are being made to significantly improve the performance of Ni-MH batteries as well.

The fourth point is safety. In the event of an accident or unintentional overcharge or over-discharge of the battery, the battery must not catch fire. Although Li-ion batteries have superior performance, their use of combustible metallic lithium is a fire risk. Consequently, the incorporation of a protection system via the battery package and controls on the vehicle side are necessary. This makes the system more complicated, which is a weak point of Li-ion batteries.

7.3 Concept behind insulation of high voltage system

The main batteries in HVs use voltages that can exceed 200 V. At this level of voltage, a person who comes into contact with it would be electrocuted to death. Consequently, thoroughly developed insulation concepts and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

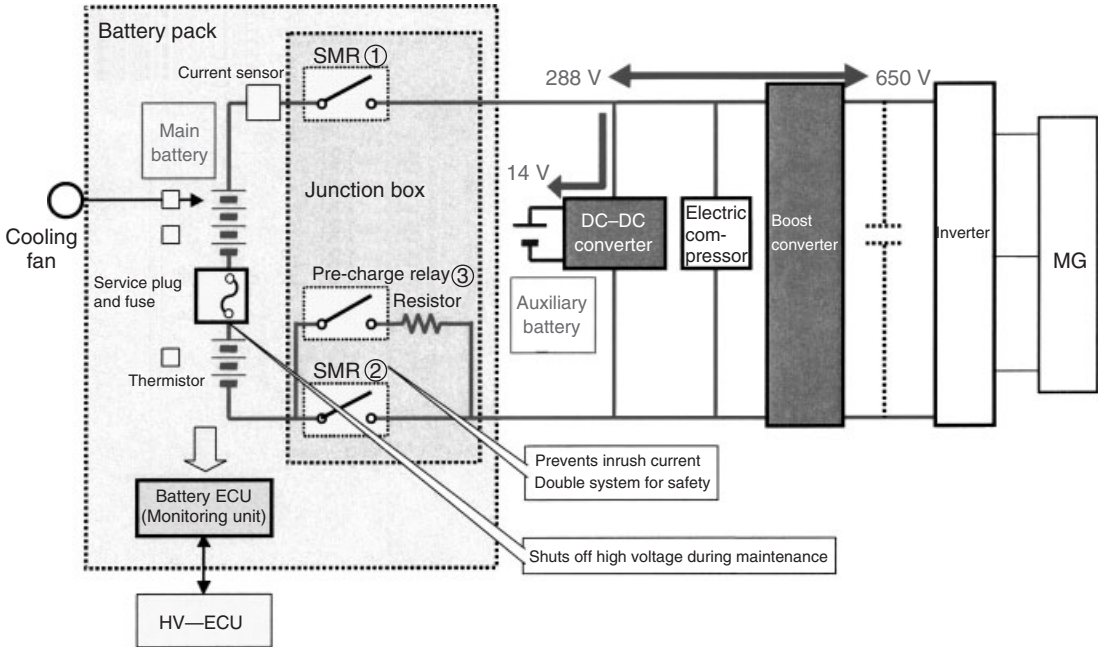

Figure 28. Configuration of HV electric power supply.

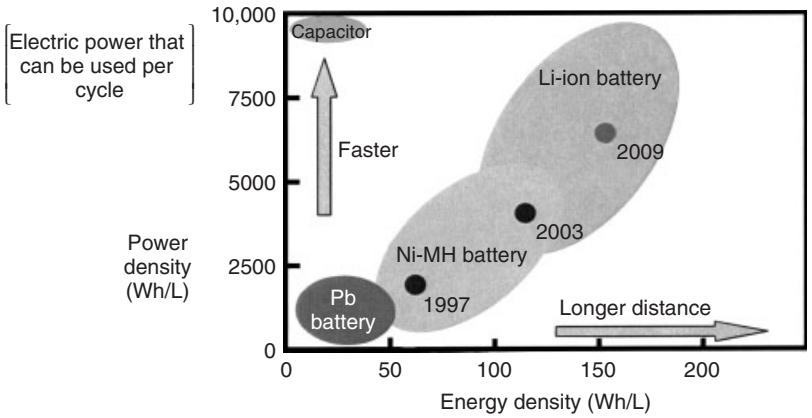

Figure 29. Energy and power densities of various batteries.

measures are a necessity. The voltages in a conventional vehicle only range from 12 to 24 V, so even if a person was shocked, it would not be a major problem. The body of the vehicle is used as the earth in this case to simplify the wiring. However, if this same way of thinking was applied to a high voltage system, then a person may be electrocuted if they accidentally touched a high voltage component. There is also the risk that an insulation failure of a high voltage device may lead to a fire. Therefore, the high voltage circuits in a HV do not use the vehicle body as the earth. Instead, the minus line is directly wired, the same as the plus line, and utilizes a floating earth. The use of a floating earth means that even if a person directly touched a high voltage component and the vehicle body, they would not receive a shock. In a further effort to improve the safety of HV, there are also some vehicles that are equipped with a warning system that will detect an insulation failure of a high voltage device or wiring and then warn the driver.

7.4 DC–DC converter

In a conventional ICE vehicle, the alternator charges the auxiliary battery. In a HV, however, the engine is stopped frequently, so using an alternator for charging would result

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto226
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

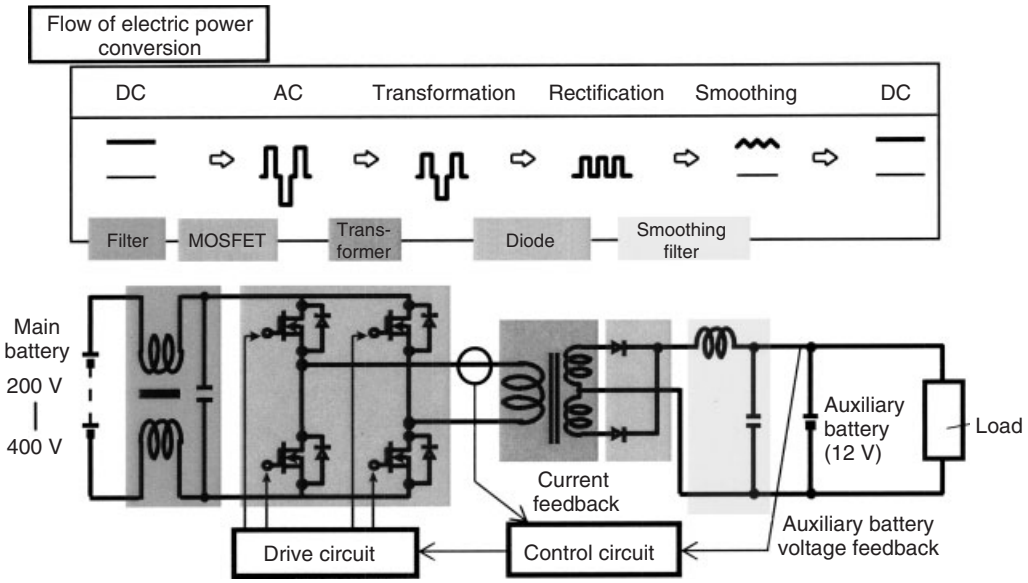

Figure 30. Principle of electric power conversion.

in voltage fluctuations. This in turn would lead to flickering lights and fluctuations in the volume of air coming from the blower. Therefore, the method used for battery charging in a HV is completely different. The voltage from the main battery is converted and this is used for charging. The device that converts the voltage from the main battery is the DC–DC converter. Figure 30 shows the principle of electric power conversion.

The high voltage DC from the main battery is subjected to high frequency switching in the power devices (MOSFETs) and then the voltage is transformed (lowered) by the transformer. This voltage is then rectified by the diode, smoothed by the smoothing filter, and converted into low voltage DC for charging the auxiliary battery. The transformer is used as a part of the safety design of the DC–DC converter to prevent the fires and shocks that would occur if high voltage was accidentally applied to the low voltage side due to some kind of malfunction. The high frequency switching allows for the size of the transformer to be reduced significantly. Figure 31 shows a photograph of an actual DC–DC converter for use in HVs.

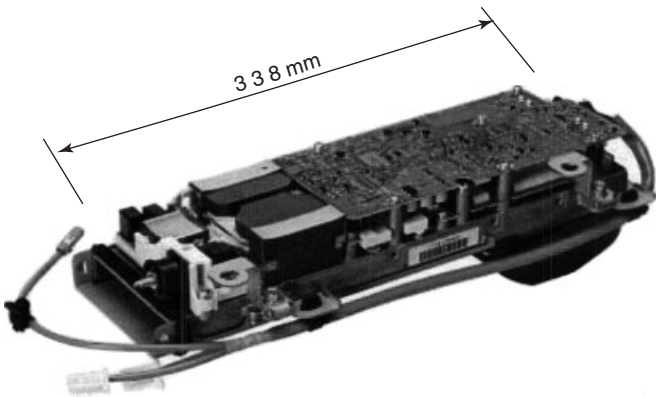

Figure 31. DC–DC converter for HV.

8 HIGH VOLTAGE AUXILIARY SYSTEM

The engine is frequently stopped in a HV, so it is necessary to examine the feasibility of converting all of the loads that are driven by the engine to electric power. A HV is equipped with a main battery so it is possible to reduce the size of systems with large load capacities by designing them to have high voltage specifications. This section describes systems in current commercial HVs that utilize these concepts.

8.1 Electric compressor system

In an ICE vehicle, the compressor is driven by the engine. In a HV, however, the electric motor drives the compressor so that the air conditioner does not turn off each time that the vehicle comes to a stop. The air conditioner places a large load on the vehicle, so this system is designed to have high voltage specifications. The system is installed in the HV in the same location as on an ICE vehicle. Therefore, efforts are being made to combine the compressor, motor,

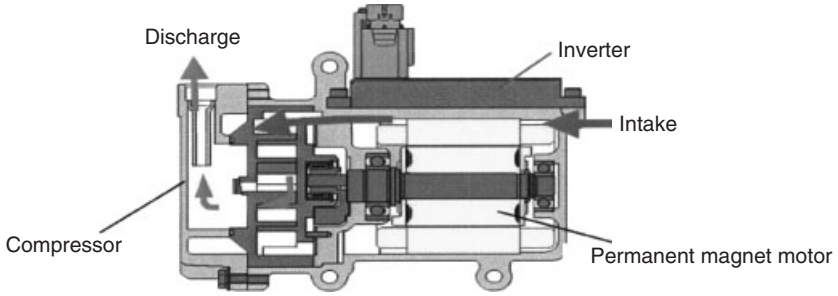

Figure 32. Structure of electric compressor.

inverter, and control ECU into a single unified structure and reduce its size. Figure 32 shows this structure.

The electric motor is a permanent magnet motor (IPM). The motor coil and inverter utilize the refrigerant of the compressor for their own cooling. Special consideration was given to how the components are mounted and radiate heat and to the water-resistant structure to satisfy all of the environmental requirements, such as vibrations, temperature, and water exposure.

9 FUTURE TRENDS

HVs have become popular and accepted by the market in the 10 years since their launch in 1997. These are groundbreaking vehicles that are environmentally friendly and have realized excellent levels of fuel economy without placing a larger burden on their users. It can be said that these vehicles changed the consciousness of their users and indicated the direction that all future vehicle design should move in. However, current HVs merely mount an electric motor system onto an existing engine system, so they suffer from fundamental problems of mounting all the necessary components and controlling the total cost. The key to further improving the popularity and widespread use of HVs is reducing the size and cost of the components that make up the electric motor system.

The major issue for HVs is the main battery. HVs were only realized once Ni-MH batteries that can endure frequent and repeated charging and discharging were developed. Currently, Li-ion batteries that possess even higher performance are being developed. It is expected that this will lead to significant reductions in size and increases in power. However, the development of batteries with even greater performance is expected and needed for use in EVs, PHVs, and extended range EVs. Electric motors and inverters are critical components of HVs. Electric motors have a long history, but there is still plenty of research that remains to be done into issues such as winding methods and magnet placement to further reduce their size. The development of new power devices for inverters is also widely expected and efforts to reduce their size through improved cooling technologies are continuing to advance.

Research into vehicle controls, such as motor and battery control, is essential to using energy as efficiently as possible. There are many other HV components. Research into the best ways of reducing their size and cost is also being pursued aggressively. The number of people now working on HVs and EVs has increased dramatically compared to 10 years ago. This of course includes those working at vehicle and component manufacturers, but it has now expanded to include active efforts by those at electronics manufacturers and various research institutes. This trend is not limited just to Japan but has become a worldwide movement. This large shift in focus and resources toward HVs and EVs will not stop and will likely only continue to grow larger in the future.

Body ECU (Airbag)

Takashi Noguchi
DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Airbags are a technology that protects the occupants of a vehicle in an accident. When a vehicle collides with an object, this is referred to as the *primary collision*. The vehicle will decelerate rapidly if the object that it collides with has a heavy mass and high rigidity. However, the occupants will continue to move forward because of the existing inertia before the collision and will hit their heads and chests on items in the vehicle interior. This is referred to as the *secondary collision* and it accounts for the great majority of injuries in a vehicle accident. The same occurs in the case of a collision between a vehicle and a pedestrian or a bicyclist. The secondary collision between the person and the vehicle pillar, hood, the base of the windshield wipers, or if they hit their head on the road surface, results in much more serious injuries than the primary collision.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto227
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

Collision safety devices, such as putting a cushion (i.e., an airbag) between the person and the collision object, or restraining the occupants in their seats to prevent movement due to inertia (i.e., with seat belts), reduce the injuries caused by the secondary collision. In the event of a side impact collision, the primary collision also becomes a problem depending on how far the object penetrates into the vehicle interior. However, the basic safety principles behind the devices used to protect the vehicle occupants do not change in this case. Airbags are still deployed as a cushion and seat belts help prevent the occupants from being thrown out of the vehicle. Collision safety devices have a long history. The first safety devices were the two-point seat belts installed by the Ford Motor Company on their vehicles in 1955. The airbag was invented by Yasusaburo Kobori, a Japanese, in 1963, but it was not until 1973 that it was actually installed in vehicles for the first time by General Motors (GM). In both cases the initial safety devices were mechanical in nature, but advances in electronics technologies have led to the addition of numerous new functions and improvements in performance. Airbag technology in particular has advanced and adopted electronic acceleration sensors (G sensors), pressure sensors, roll rate sensors, and the like. These sensors enable the airbags to handle a variety of different kinds of accidents, including side impact collisions and rollovers, in addition to frontal collisions.

In recent years, other safety technologies have been placed on the market, such as crash compatibility technology (which protects the occupants of the other vehicle in the event of a collision with a compact car) and airbags and active hoods (which protect pedestrians). These kinds of technologies, which protect the other party in the collision, have been advancing and evolving.

There are also other safety technologies such as fuel shut-offs, electric power shut-offs, and mayday systems in

addition to those that protect vehicle occupants directly. In the case of a collision that is strong enough to cause the airbags to deploy, the fuel shut-off closes the valve on the fuel tank after the collision to prevent any secondary accident due to a fire. The electric power shut-off performs the same role in vehicles that possess a high voltage power supply, such as hybrid vehicles and electric vehicles. The electric power is shut off in the event of an accident to prevent electric shocks when the occupants are rescued. Some vehicles are even equipped with a data communication module (DCM) that uses the band frequency of mobile phones to contact a call center with an SOS message after a collision has occurred.

2 COLLISION MECHANICS

This section provides an explanation of the mechanics of a collision using a frontal collision between two vehicles as an example. Figure 1 shows a frontal collision between vehicle A, with a mass of m_1 and a velocity of v_1, and vehicle B, with a mass of m_2 and a velocity of v_2. The hatched portions on the front of both vehicles are referred to as the *crushable zones*. These zones absorb the kinetic energy of the collision by deforming adequately and control the acceleration at the time of the collision. On the other hand, the occupant compartment is referred to as a *noncrushable zone* and the rigidity of this compartment is increased to ensure the survival space of the occupants. This *vehicle structure* is referred to by different names depending on the vehicle manufacturer, but in general it is referred to as a *collision-safe body* and it helps ensure the integrity of the vehicle.

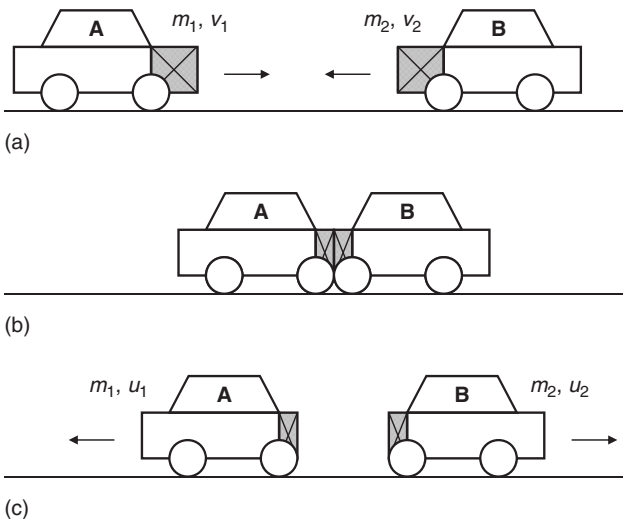

Figure 1. Frontal collision between two vehicles. (a) Before the collision. (b) Collision is complete. (c) After the collision. (Reproduced by permission of Denso Corporation.)

At time in Figure 1b, the collision is ongoing, but the velocity of the center of gravity is zero and the crash stroke (amount of crumpling) of both vehicles has reached the maximum. After this, as shown in Figure 1c, both vehicles advance in opposite directions because of rebound. Finally, the vehicles will stop moving because of the force of friction. This type of collision is referred to as an *inelastic collision* and results from the absorption of the kinetic energy by the crushable zones. The rebound coefficient (e) is approximately 0.2 in this frontal collision. The amount of change in velocity before and after the collision is divided proportionally between each of the masses involved because the momentum is conserved. Consequently, the vehicle in this collision that has a smaller mass will have a larger amount of change in velocity before and after the collision. This amount of change in velocity largely conforms to the velocity of the secondary collision and so the injuries suffered by the occupants in the vehicle with the smaller mass will be more severe.

Collision phenomena differ depending on the type of collision, but the crash stroke generally reaches its maximum from 50 to 150 ms after initial impact. If it is assumed that the rebound coefficient is approximately 0.2 and the amount of change in velocity is 60 km/h in a collision between two vehicles traveling at 50 km/h, then an average acceleration of 350 to 110 m/s^2 is applied with a peak acceleration of 700 to 220 m/s^2. Therefore, this is an extremely intense phenomenon in which a force of 10 times to 70 times a person's body weight is applied in a time of about 0.1 s.

The injuries suffered by occupants due to the secondary collision are also determined by the rigidity of the objects that the occupants collide with. The strength design of items such as the steering wheel, dashboard, and interior materials are important factors in ensuring the safety of the basic vehicle itself.

3 AIRBAGS

3.1 Introduction to airbags

Initially, airbags were installed within the steering wheel to protect the person in the driver's seat in the event of a frontal collision. This was followed by airbags in the instrument panel to protect the person sitting in the front passenger's seat. Now airbags are also installed within the seats (side airbags) and within the headlining (curtain airbags) to protect passengers in the event of a side impact

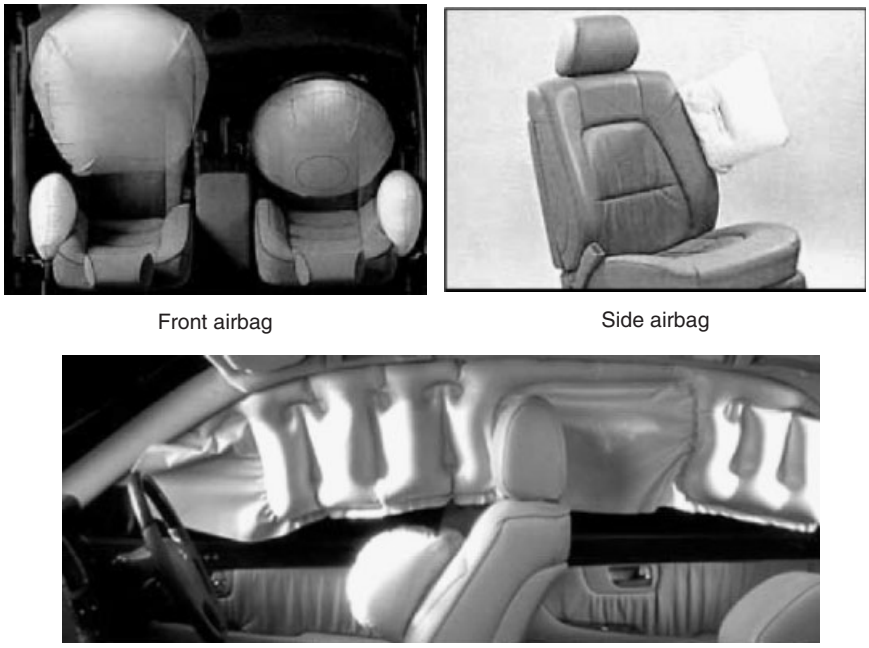

Figure 2. Examples of airbags. (Reproduced by permission of Denso Corporation.)

collision. There are also some curtain airbags that have a larger width and cover more area to prevent passengers from being thrown out of the vehicle in a rollover crash. In addition, there are also knee airbags installed in the lower portion of the instrument panel to protect the lower legs of passengers and active hoods to help protect pedestrians struck by a vehicle. Airbags to protect pedestrians are also being developed. Figure 2 shows images of typical airbags. Figure 3 shows the structure of the airbag modules for the driver's seat and the front passenger's seat airbags. The airbag for the driver's seat is installed within the steering column and the airbag for the front passenger's seat is installed within the instrument panel. The main parts of an airbag are the inflator that produces the gas and the bag itself. The airbag is folded up and the gas is injected into it causing the bag to expand and burst through the surface material when it is deployed.

Airbags are currently installed in most vehicles. However, airbags did not become widely used after they were invented. This was because an explosive powder was used during airbag inflation and the extremely intense force that the occupants were subjected to when the airbags operated unnecessarily caused serious adverse effects. GM installed airbags as optional equipment on mass produced vehicles starting in 1973, but accidents due to malfunctioning airbags occurred and production was discontinued in 1977. The current popularity and

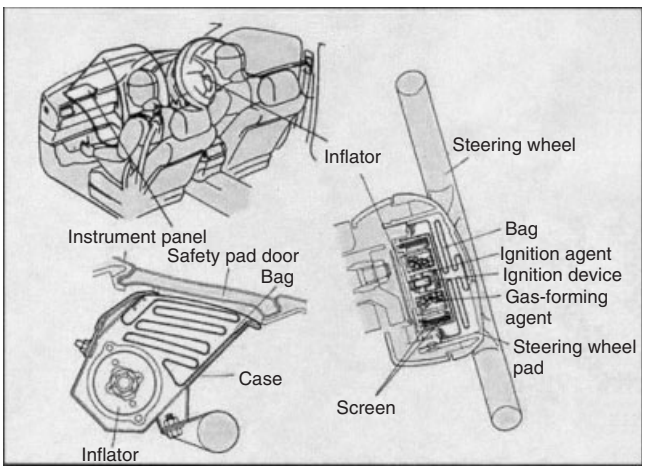

Figure 3. Structure of airbag modules. (Reproduced by permission of Denso Corporation.)

widespread use of airbags in vehicles started in 1987 when the installation of airbags in vehicles became required by law in the US. At that time, the US government was under pressure from an active consumer movement and a law known as *FMVSS208* was implemented. Vehicles in Japan and Europe were required to be equipped with seat belts but they were not required by law to be equipped with airbags at that time. The legal requirement for vehicles

to be equipped with airbags in the US greatly increased awareness of vehicle occupant safety issues and prompted vehicle manufacturers to compete with each other on the basis of safety features. This in turn led to a major increase in development and the advancement of widespread airbag use.

Another factor that accelerated the use of airbags in vehicles was the new car assessment program (NCAP). This program evaluates the safety performance of new vehicles, gives the tested vehicles grades, and then announces them to the public. A typical evaluation is the 64 km/h offset deformable barrier (ODB) test. In this test, the vehicle is forced to collide with a fixed barrier that has an aluminum honeycomb block attached to the front of it that simulates a collision with another vehicle. This is a very strict test that evaluates the occupant protection performance in a frontal crash between two vehicles at a relative velocity of 128 km/h. Figure 4 shows an example of this test. This test has practically become an international standard through the adoption of the JNCAP (Japan new car assessment program) in Japan, the Euro NCAP in Europe, and the ANCAP (Australia new car assessment program) in Australia. The existence of these assessment programs has spurred on the safety competition between the world's vehicle manufacturers.

Table 1 shows the evaluation results from Euro NCAP. The evaluations of the NCAP are called *star ratings* and the level of performance is expressed by the number of stars. The table clearly shows that new models of vehicles have improved safety performance in comparison to older models, even for the same vehicle by the same manufacturer, because the number of stars they received increased. This demonstrates how the benefits to vehicle

users have increased thanks to this fair safety competition. In the twenty or so years since airbags have become readily available in the market on a large scale, the safety of vehicles has increased dramatically.

3.2 Operating principle of airbags

Figure 5 shows the operating principle of an airbag. After a collision, the front satellite sensor that is equipped on the front of the vehicle, and the G sensors that are located

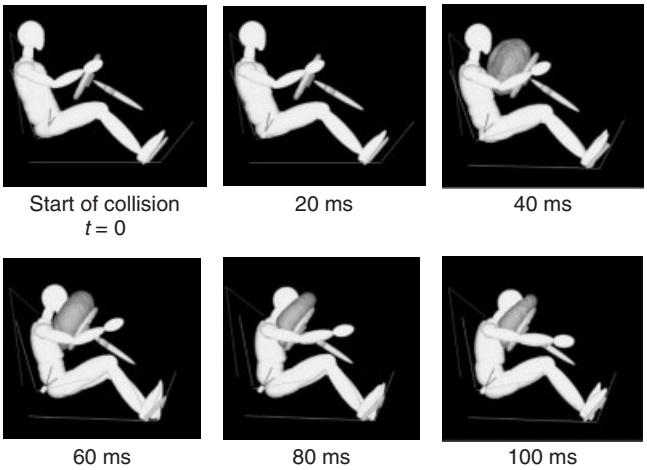

Figure 6. Deployment of airbag and occupant behavior. (Reproduced by permission of Denso Corporation.)

within the engine control unit (ECU) detect the collision. If the ECU determines that deploying the airbag is necessary, power is applied to the squib, which then ignites. The ignition agent then transfers this heat to the gas-forming agent, which produces a large amount of gas. This gas then fills the airbag, the pressure increases, and the airbag bursts out of the surface material and deploys. Holes in the airbag called *vent holes* allow the gas in the air bag to escape when the vehicle occupant collides with the bag and the pressure inside the bag rises. These vent holes prevent the pressure inside the airbag from rising too high. Figure 6 shows the behavior of an occupant at the time of a collision and the appearance of the airbag when it deploys. The scene shown in this figure is of a collision with a fixed barrier at 50 km/h. This is an extremely severe collision that is equivalent to a frontal collision between two vehicles each traveling at 50 km/h.

It takes approximately 10 ms after the start of the collision for the ECU to determine if the collision requires the airbag to deploy and ignites the squib. First the airbag vigorously bursts through the surface material and shoots out to the maximum stroke (primary expansion). Then the airbag inflates out to the sides (secondary expansion). Approximately 30 ms elapse between these two expansions. At 40 ms after the collision the secondary expansion is finished and all preparations to catch the occupant are complete. At 60 ms after the collision the occupant's head begins to drive into the airbag. The occupant is restrained as the gas is gradually expelled from the vent holes and the restraining process finishes at approximately 100 ms. The required sensing operations finish in 10 ms while the airbag's job is completed and all operations are finished in just 100 ms. Precise operation over this extremely short time to protect the life of the occupant is fully expected and this can be said to be the fundamental purpose of airbag technology.

The fact that it takes 30 ms until the secondary expansion is complete indicates how difficult it is for the airbag sensing to predict the acceleration after this 30 ms has elapsed. Of course it is best for the sensing to be completed as quickly as possible, but predicting the acceleration 100 ms later based on the acceleration after just 10 ms is necessary. The acceleration that is produced by the collision will naturally be different depending on the structure of the vehicle body and the type of collision that occurs. Therefore, the airbag sensor tuning is performed based on data obtained from crash tests of actual vehicles at a variety of different speeds and involved in various different types of collisions.

3.3 Crash tests

Figure 7 shows a crash testing facility. There is a motor behind the massive concrete wall that acts as the fixed barrier and this motor tows actual vehicles toward the barrier using a wire rope. Once the vehicle approaches near to the barrier, the wire rope releases from the latch on the vehicle and then it collides with the barrier under its own inertia. Crash test dummies that simulate occupants in the vehicle are placed on board and these dummies are fitted with various sensors so that the injuries sustained during the collision can be evaluated. Several G sensors are also attached to the vehicle and a total of over 100 channels of measurements are taken.

Figure 8 shows examples of the different types of collisions used in crash testing. There are three basic kinds of crash testing: testing at the lower limit velocity at which the airbags must operate, testing at the upper limit velocity at which the airbags must not operate, and testing at the upper limit velocity to confirm the occupant protection performance. The crash testing is carried out at a great variety of different velocities for each of the various types of collisions. There are also other non-crash tests that are performed as intentional defect tests when working on the airbag tuning, such as a rough road running test, extreme rough road test, and an abuse test. There are also non-operational mode tests. All of this testing is carried out to ensure the performance of the airbag system in the market.

There are many different kinds of crash test dummies with different body types used in the crash tests. The dummy called *AM95* is the largest and it represents American males in the 95 percentile, in other words the largest 5% of body types. The AM50 dummy is the standard

body type for an American male and it is used in the laws and regulations, as well as for the safety ratings. The AF05 dummy simulates the body type of a smaller American woman and there are also dummies that simulate the body types of a 6-year-old child and a 3-year-old child. Figure 9 shows an image of a family of these crash test dummies.

4 AIRBAG SYSTEM

Figure 10 shows the configuration of a typical airbag system. The main parts are the satellite sensors for both frontal collisions and side impact collisions, the ECU, the airbag modules, and the seat belt pre-tensioners. The satellite sensors are located in the crushable zones to speed up the response of the system when a collision occurs. These sensors transmit the acceleration data to the ECU in a collision. The ECU is located on the floor of the center console. The ECU has two internal G sensors that have different detection axes for frontal collisions and side impact collisions. The ECU combines the data from these G sensors with the acceleration detected by the satellite sensors to make the calculations and then the determination about whether a collision is occurring. At the same time, if it determines that deployment of the airbags is necessary, the ECU will also provide current for ignition to the airbag modules and the seat belt pre-tensioners. The ECU possesses this ignition function and a malfunction diagnostic function to check the system for any malfunctions. The ECU also possesses an energy reserving function using a capacitor to ensure that the ignition current is supplied, even in the event that the battery becomes disconnected during the collision. Figure 11 shows an

image of an ECU. Figure 12 shows a block diagram of the ignition system

The malfunction modes are broadly classified into two kinds of malfunctions: ignition and airbag deployment when it is not necessary and failure to deploy airbags when they are necessary because the ignition could not be performed. The overall design concepts of the system described below demonstrate the consideration given to preventing inadvertent airbag deployment.

- Improve the reliability of parts.
- Adopt a series redundant structure so that a single malfunction will not lead to inadvertent airbag deployment.
- The system shall be able to detect any malfunctions that may lead to inadvertent airbag deployment.
- A warning light or other means shall be used to alert the vehicle user when a malfunction is discovered and encourage them to have it repaired.
- Simultaneous processing so that the next malfunction does not lead to inadvertent airbag deployment.

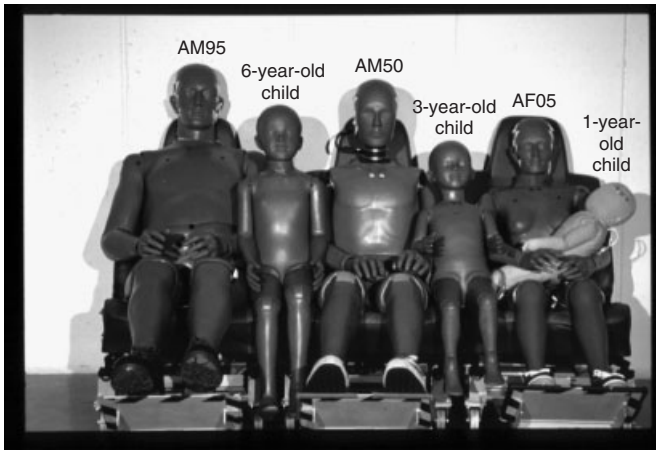

Figure 9. Family of crash test dummies. (Reproduced by permission of Denso Corporation.)

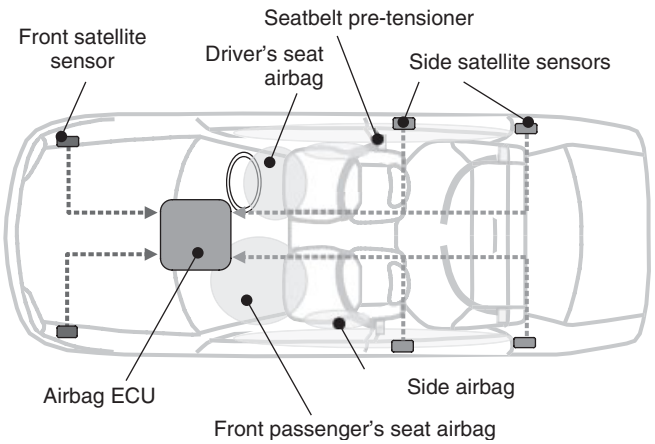

Figure 10. Configuration of airbag system. (Reproduced by permission of Denso Corporation.)

The following design considerations also aim to prevent airbag deployment failure.

- Improve the reliability of the parts.
- The system shall be able to detect any malfunctions that may lead to airbag deployment failure.
- A warning light or other means shall be used to alert the vehicle user when a malfunction is discovered and encourage them to have it repaired.
- Adopt a parallel redundant structure to handle malfunction modes that cannot be detected.

The reliability of the airbag system is ensured through the design concepts listed above. In recent years, some airbags for frontal collisions are being equipped with two squibs. These squibs may ignite simultaneously or one may ignite

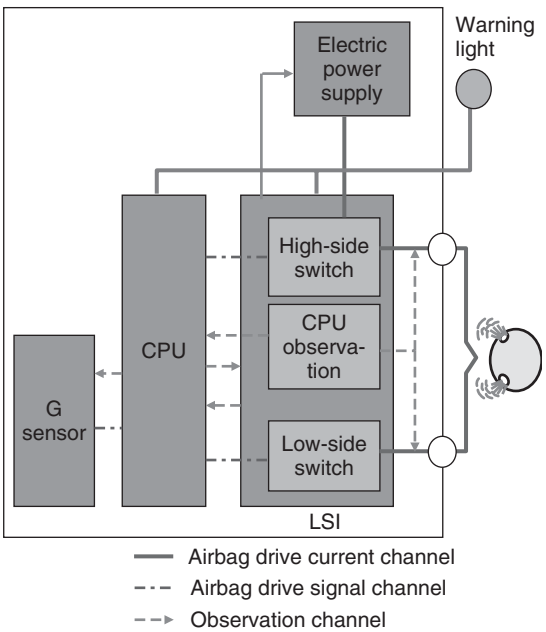

Figure 12. Configuration of ignition system. (Reproduced by permission of Denso Corporation.)

after a delay depending on the severity of the collision to control the increase of pressure within the airbag. In the case of side impact collisions, it is not uncommon for there to be 14 channels or more of squibs operating in conjunction with the curtain airbags and the seat belt pre-tensioners.

Consequently, all of these circuits are integrated and are mounted in the vehicle as part of a large-scale application specific integrated circuit (ASIC). This is a key part of the airbag system for realizing low cost.

The airbag system is extremely complicated and a malfunction may have a direct impact on human life. Therefore, the ECU is equipped with malfunction memory, which keeps a record of all malfunctions that occur so that they can be read out later. The NHTSA (National Highway Traffic Safety Administration) is promoting the standardization of this memory function through the event data recorder (EDR). The acceleration waveforms and the amount of change in velocity at the time of a collision are also recorded so that the kind of collision that occurred can be re-created during the investigation into a vehicle accident.

5 AIRBAG SENSING SYSTEM

The principle behind the airbag sensing system is extremely simple. If the type of collision is the same, then the higher the collision velocity, the greater the acceleration that is produced. Therefore, it should only be necessary to

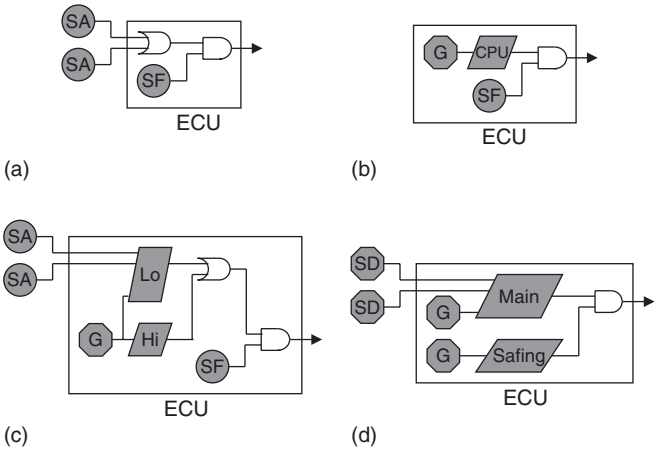

Figure 13. Sensing system evolution. (a) Electromechanical multi-point; (b) electronic single-point; (c) electronic electromechanical multi-point; (d) electronic multi-point. (Reproduced by permission of Denso Corporation.)

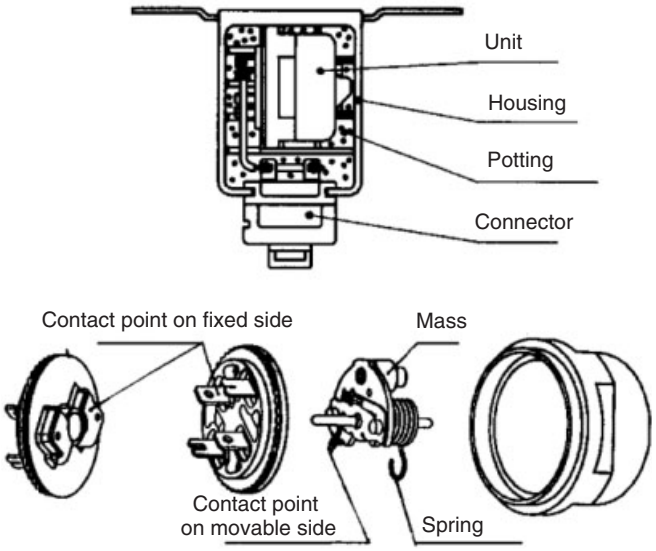

Figure 14. Electromechanical satellite sensor. (Reproduced by permission of Denso Corporation.)

compare the magnitudes of the accelerations. However, this is complicated by the fact that the vehicle deformation characteristics change when the type of collision is different. The rigidity of the vehicle crushable zones is different in a 100% full-lap frontal collision and a 40% offset frontal collision. There are cases where a higher acceleration is produced from a low velocity full-lap frontal collision than from a high velocity offset frontal collision, so sensing becomes difficult. Figure 13 shows the changes in airbag systems over the years. More details about the sensing performed by the airbag system will be presented in the following sections. This evolution in the sensing system demonstrate the history of efforts to solve this acceleration sensing issue.

5.1 Initial sensing system

Figure 13a shows the initial airbag system. The main sensors are the two electromechanical sensors at the front of the vehicle and the electromechanical safing sensor located within the ECU. An electromechanical sensor utilizes a spring-mass system mechanism. The acceleration at the time of a collision is applied to a spring-biased mass and this mass moves, closing the electrical contact. Figure 14 shows a structural diagram of this sensor. This system is designed so that ignition will not occur if the main sensors at the front of the vehicle and the safing sensor in the ECU are not all turned ON simultaneously. This forms a series redundant system. Multiple electrical contacts are provided within the sensors where the ignition current flows directly. This forms a parallel redundant system to prevent the airbag from failing to deploy.

The characteristics of an electromechanical sensor are determined by the equation of motion of the spring-mass system. The sensor has low degree of freedom for tuning, diagnostics cannot be performed on the sensor to prevent an airbag deployment failure, and it has a high cost. Therefore, this type of sensor was gradually replaced by electronic sensors and it is no longer used. Following this, sensing systems appeared in which an electronic G sensor was added within the ECU. This system was equipped with an analog arithmetic integrated circuit (IC), but the degree of freedom for tuning was low, and this system is also no longer used.

5.2 Single-point sensing

Figure 13b shows a sensing system referred to as a *single-point system*. It is equipped with one electronic G sensor and one electromechanical safing sensor. Both of these sensors are located within the ECU. The purpose of this design was to reduce the cost of the sensing system. However, the ECU was located on the floor of the occupant compartment, which is a noncrushable zone, so it transmitted the acceleration information at a slow speed. This made it difficult for this sensing system to conform to the gradually increasing performance requirements of the NCAP, and so it currently occupies only a minor position among the other types of sensors. After this, an attempt was made to use a microcomputer to calculate the output from the G sensor within the ECU and make the system capable of performing the collision determination. This was achieved through improving

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto227
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

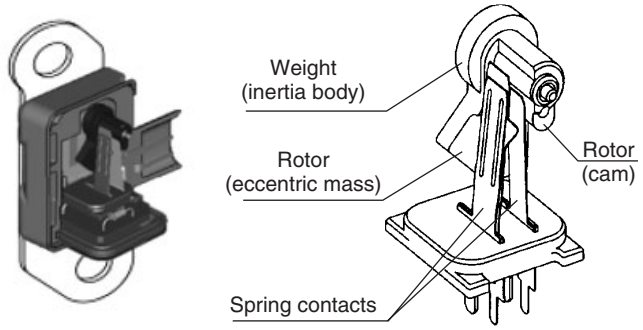

Figure 15. Electromechanical auxiliary sensor. (Reproduced by permission of Denso Corporation.)

the performance of the microcomputer and lowering the cost. It also increased the degree of freedom for tuning and made it possible to perform even more meticulous settings.

5.3 Electromechanical satellite sensing

Figure 13c shows a sensing system equipped with an electromechanical satellite sensor. The electromechanical sensor was revived, but in comparison to the one in the initial sensing system, the sensor itself is low performance and low cost. The ignition current does not flow directly through the sensor. Instead, it outputs the contact point ON/OFF signals to the CPU (central processing unit), so it is referred to as an *auxiliary sensor*. In comparison to the initial sensing system, the performance of this system was focused on the detection of large impacts coming from the front of the vehicle. This system was introduced to meet the demands for improved sensing system performance. However, it is continuing to disappear under the wave of electronic sensors that have high degrees of tuning freedom as the cost of those sensors continues to decline. Figure 15 shows a structural diagram of an electromechanical auxiliary sensor.

5.4 Electronic satellite sensing

Figure 13d shows the newest sensing system. The satellite sensors in Figure 13c have been replaced with electronic ones. The figure shows that the acceleration waveforms from the satellite sensors and the signals from the two G sensors within the ECU are sent to the CPU where calculation is made freely and the collision determination is made. The degree of freedom for tuning has also increased dramatically. Originally the electronic satellite sensors communicated with the ECU via serial communication, but currently a bus communication system called a

The G sensor and communication IC are packaged together. The detected acceleration is sent to the ECU via digital communication

Figure 16. Electronic satellite sensor. (Reproduced by permission of Denso Corporation.)

sensing bus is the mainstream method being used. This bus has special reliability requirements that are different from a general vehicle-mounted bus. For example, the communication will not be interrupted even if it contacts the earth during a collision. A bus that is exclusively for airbags is used. Figure 16 shows an image of an electronic satellite sensor.

As described in the previous sections, the airbag sensing system is now based on electronic G sensors that possess a high degree of tuning freedom to realize a higher level of sensing performance. It has evolved into an electronic multipoint system that makes a comprehensive judgment of the sensing results coming from multiple locations.

6 AIRBAG ECU

6.1 Configuration of ECU

Figure 17 shows the configuration of an airbag ECU. The ECU consists of the ignition circuit area, the collision determination area, the auxiliary power supply area, and the malfunction determination area.

6.2 Ignition circuit area

The circuits that drive the squibs that deploy the airbags receive commands from the collision determination area through the signals from each sensor. The configuration of these circuits is different depending on the number of loads (driver's seat airbag, front passenger's seat airbag, seat belt pre-tensioners, driver's seat side impact airbag, and the like), the type of ECU, and other factors. The ignition circuit is designed to have serial redundancy by installing two or more independent drive circuits to prevent the inadvertent deployment of airbags due to a single malfunction (squib earth short, drive circuit malfunction, and the like) or when a malfunction is diagnosed. The reliability of the ignition circuit is further ensured through the performance of malfunction diagnostics. Malfunction

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto227
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

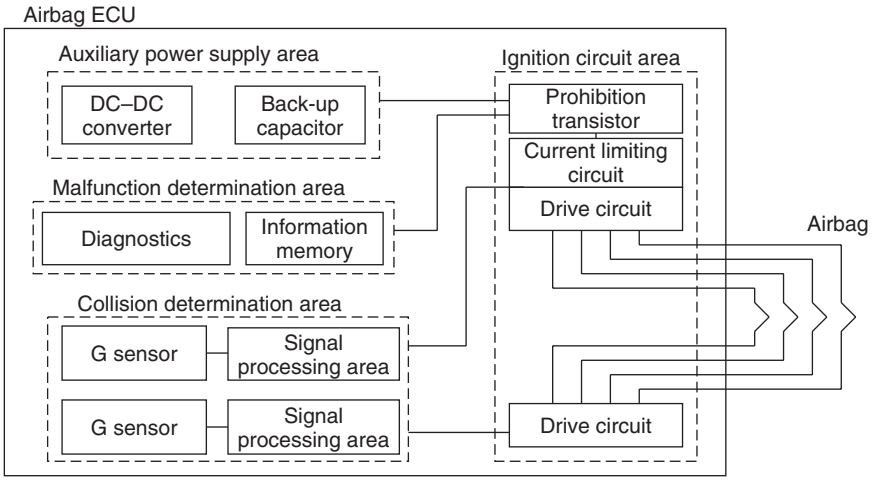

Figure 17. Schematic diagram of ECU. (Reproduced by permission of Denso Corporation.)

diagnostics help prevent airbag deployment failure and the vehicle user is encouraged to obtain a replacement part when a malfunction occurs. In the case of parts that cannot be checked through malfunction diagnostics, the reliability of the parts themselves must be ensured or they must be designed to have a parallel redundant configuration.

6.2.1 Drive circuits

These are the circuits that apply current to the squibs based on the signals from the collision determination area within the ECU. These circuits are located both upstream and downstream from the squibs and are designed to have a series redundant configuration.

6.2.2 Current limiting circuit

In the case where there are multiple squibs, as the impedance of each squib and wire is different, a squib may be short circuited by the electric power supply or earth due to a malfunction or ignition. Current will concentrate at that squib and the specified current will not be able to flow to the other squibs. The current is limited by constant current circuits and resistance shunt circuits to prevent this from happening and to ensure that the specified current flows to each squib.

6.2.3 Prohibition transistor

This is one element of a series redundant circuit. This circuit breaks the ignition circuit in the case where a malfunction occurs that may lead to inadvertent deployment of the airbags. In the past, a mechanical switch was often used for this purpose, but now this function is realized through the use of a semiconducting element. There are cases where the drive circuits also make use of this element.

6.3 Collision determination area

This determines whether it is necessary to activate the occupant protection devices (airbags and the like) by detecting the physical quantities (deceleration, amount of deformation, etc.) generated at the time of a collision. These physical quantities are detected by electromechanical and electronic sensors the collision determination is performed using those output signals in the processing circuit. The system is always composed of two or more determination pathways, which include the sensors and the signal processing circuit, to ensure the redundancy of the system.

6.3.1 Sensors

The sensors detect the physical quantities at the time of the collision and then generate the corresponding electric signals. In an electromechanical sensor, the collision determination is made in the mechanical portion and then this result (ON or OFF) is output as an electric signal. An electronic sensor also outputs an electric signal that corresponds to the physical quantities at the time of the collision. However, any components that are unnecessary for the collision determination (including noise and others) are removed and the sensor is equipped with a built-in low-pass filter for the purpose of waveform shaping. This low-pass filter also possesses an antialiasing function for digital signal processing.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto227
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6.3.2 *Signal processing area*

This processes the electric signals from the sensors and then determines whether the collision is strong enough to require the activation of the occupant protection devices. The collision determination has a serial configuration, comprising the main determination area and the safing area. The main determination area mostly determines the degree and severity of the collision, whereas the safing area is set so that it will not respond to normal driving or normal operations and that it will also not inhibit the main determination to ensure redundancy. In the case of a collision determination that uses electronic sensors, the determination is performed by an IC and general purpose CPU with an integrated collision determination algorithm, and by using the specific determination threshold value that is set for each vehicle.

6.4 Auxiliary power supply area

There are cases where the electric power supply to the airbag ECU declines or is cut off because of damage to the vehicle battery or because of the power line getting caught up in the vehicle body during a collision. There are also cases where it is necessary to operate the airbags even though the battery voltage has dropped due to an abnormality in the vehicle power supply system. Therefore, the ECU possesses an auxiliary power supply function to handle these kinds of situations. The auxiliary power supply area possesses enough energy to operate the airbags in approximately 100 ms in the event of a frontal collision and to operate them for 1 s in the event of a rollover crash after the ECU power supply has been cut off.

6.4.1 *DC–DC converter*

This circuit increases the voltage when the vehicle power supply voltage is low to ensure that there is enough electric energy to activate the squibs. The CPU and sensors of the ECU, as well as the satellite sensors possess enough voltage and capacity to be able to operate when the power supply voltage of the ECU is 6–8 V or more. The output voltage is 25–35 V to ensure that the energy reserve capacitor can efficiently store up energy.

6.4.2 *Energy reserve capacitor*

This is an energy storage device that enables airbag operation even if the battery or power supply cable is damaged during a collision. It is necessary to store up energy so that the collision determination area can operate, the squibs can be activated, and information can be written into the memory, or the like. This capacitor is composed of either one aluminum electrolytic capacitor or several of them. In general, the capacity is from 3000–15,000 μF. This capacitor is required to have a low equivalent series resistance because discharging large currents in a short time is necessary and it is also required to have good performance at low temperatures and after a durability test.

6.5 Malfunction determination area

This performs diagnostics to check for any abnormalities in the ECU and the system, including outside the ECU. A warning light is illuminated and the driver is notified when an abnormality is detected. Information related to the malfunction diagnostics result is recorded in the nonvolatile memory and other locations. There are cases where this information is later utilized for malfunction analysis and investigation into a vehicle accident.

6.5.1 *Malfunction diagnostics*

This area observes the internal workings of the ECU and the entire system as a whole. The driver is notified via a warning light when an abnormality occurs. In many cases it possesses a function that generates a code (diagnostic code) to identify the malfunctioning component via operation of the diagnostic terminal (set on the vehicle). The basic concepts behind the malfunction determination are as follows.

6.5.1.1 Inadvertent airbag deployment. In the case where the airbags deploy unnecessarily due to a malfunction (primary malfunction) and then the occurrence of another malfunction (secondary malfunction), the initial primary malfunction is detected and the driver is notified.

6.5.1.2 Airbag deployment failure. In the case where the airbags fail to deploy due to a malfunction, that malfunction is detected and the driver is notified. There are also cases where malfunction diagnostics to detect potential inadvertent deployment or failure to deploy cannot be performed. In those cases, redundant design is employed to cover those undetected items or the reliability of the parts is sufficiently ensured. The detection of a malfunction will illuminate a light for a fixed time when electric power is initially supplied to the ECU as an indicator and a means of informing the driver that the system is prepared, ready, and waiting. This also notifies the driver that the light is operating properly.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6.5.2 *Information memory*

This memory stores the results that were detected by the malfunction diagnostics function as well as other information so that the state of the system when an accident occurred can be understood to a certain extent. Usually, nonvolatile memory is used so that information can still be recorded in the memory, even if the power supply is shut off. EEPROM (electrically erasable programmable read only memory) is often used as the nonvolatile memory, but flash memory that is built into the CPU has begun to be employed recently.

6.5.3 *Procedures after malfunction detection*

Measures are often taken to prohibit the airbag ignition from operating due to a malfunction, in addition to notifying the driver by illuminating the warning light. For example, when a G sensor malfunction is detected, the output of ignition signals to the collision determination area is stopped to prevent the inadvertent deployment of the airbags.

6.6 G sensors

Figure 18 shows a conventional capacitive G sensor. The sensor head and processing circuit are contained within a package with a size of 6.2 mm by 5 mm. The sensor head measures approximately 2 mm square and is composed of a fixed electrode and a movable electrode. The position of the movable electrode changes, altering the gap between the two electrodes when the sensor head is subjected to acceleration. This acceleration is then detected as a change in the capacitance and this is converted into voltage by the sensor. The opposite is also true. The electrode can be moved by applying a voltage to the sensor, which means that the sensor can perform self-diagnostics.

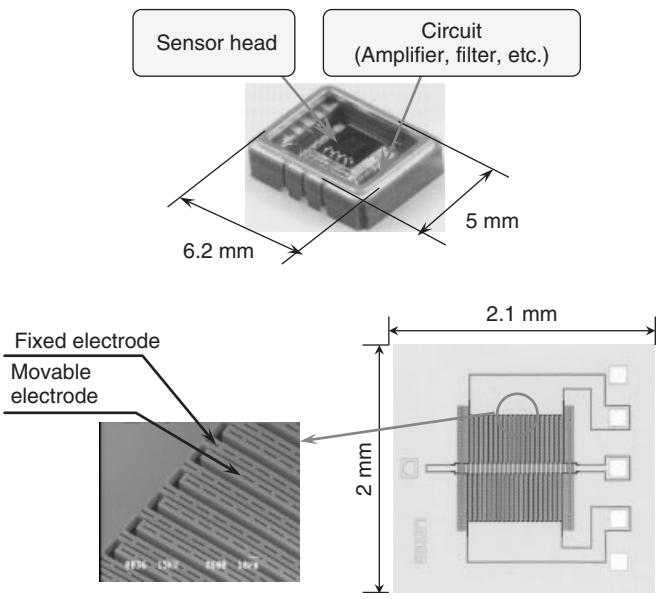

Figure 18. Capacitive G sensor. (Reproduced by permission of Denso Corporation.)

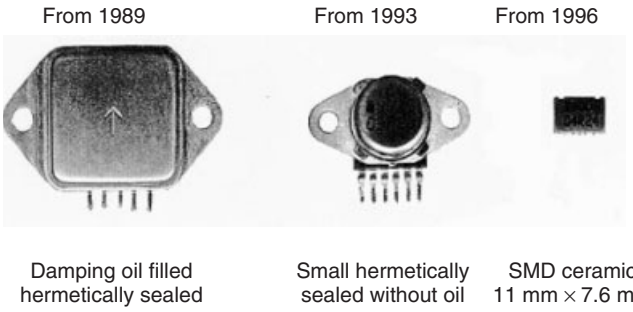

Figure 19. Evolution of piezoresistive G sensors. (Reproduced by permission of Denso Corporation.)

Figure 19 shows the evolution of G sensors. Piezoresistive sensors were used before capacitive-type sensors. The principle behind piezoresistive sensors is that a cantilever bends when it is subjected to acceleration and then this deformation is detected by a bridge circuit. The initial sensors did not have good sensitivity, so the sensor head was large and the sensors were encased in a large hermetically sealed package filled with damping oil. Following this, advances in both micro electromechanical systems (MEMSs) technology and circuit technology led to major miniaturization of the sensors down to 1/25 (projected area) of their previous size in just 7 years. The current day sensors are even smaller and are also highly precise.

6.7 Roll angle sensors

Current roll rate sensors are vibrating gyroscope-type sensors. The Coriolis force is generated in the tuning-fork-shaped oscillator when the vehicle rolls is converted into voltage and then output. AC voltage is constantly being applied to the oscillator that vibrates at a frequency of 2 kHz. When an angular velocity is applied due to the roll of the vehicle body, the apparent force that is generated is the Coriolis force and the oscillator becomes strained. The sensor then converts this strain into voltage. At the time that the actual determination of vehicle roll is made, the vehicle behavior is predicted in conjunction with the acceleration produced in the lateral direction. This means that these sensors are able to handle a variety of different roll modes.

6.8 Collision determination algorithm

6.8.1 *Collision determination algorithm and tuning*

The comprehensive judgment of whether to deploy the front impact airbags is based on the output from the satellite sensors in the crushable zone and the output from the G sensors in the ECU located in the noncrushable zone. The acceleration that is produced depending on the collision velocity and the type of collision is calculated and a judgment is made about whether it is necessary to deploy the airbags. The role of the collision determination algorithm is to send the ignition signals to the airbag modules if deploying the airbags is necessary. The collision determination algorithm possesses parameters that allow it to adapt to the characteristics of each vehicle. Simulations based on acceleration signals from actual crash tests are used to tune the algorithm. The calibration parameters are set after first establishing a margin in consideration of sensor error and variation in the collision. This thoroughly ensures the operation and non-operation of the airbags under real-world conditions. The necessity of air bag deployment is determined based on the specifications obtained from the vehicle manufacturers. The algorithm is tuned using the crash test data, the must fire/no fire requirements for airbag operation or non-operation, and the required response time [time to fire (TTF)] in the case of a must fire requirement. The collision determination must be completed within that amount of time.

6.8.2 *Concepts behind collision determination algorithm*

There are an infinite number of different types of collisions that occur in the real world, and it is impossible to test for all of these different collisions at a crash testing facility. Therefore, crash tests are conducted using limited test modes as typical examples, and the airbag sensors are brought into conformity with this data during the tuning process. Table 2 shows the typical test modes and the required TTF. These crash tests are conducted once the vehicle has reached the prototype stage. The number of crash tests that are conducted increases in the case of an important type of collision. Therefore, the airbag sensor tuning for just one model of vehicle normally requires that 50 or more crash tests be conducted using expensive prototype vehicles.

The collision determination algorithm is required to be robust enough to handle the different collision modes and velocities when it is being constructed. For example, an offset collision is normally referred to as a *40% offset* and the crash test is conducted so that the vehicle only has 40% overlap with the fixed barrier. Therefore, no crash test data exists between this 40% offset collision and the 100% full-lap frontal collision. The structural members of the vehicle have a strain rate dependency, so the acceleration that is produced depending on the velocity of the collision becomes nonlinear, even in the same type of collision. This means that an algorithm that correctly understands the collision phenomena must be constructed to ensure that the airbags will operate as intended, even in a collision mode that was not part of the crash tests. The vehicle collision waveform is composed of the waveforms of the accelerations produced by the deformation of the individual structural members and parts of the vehicle. A larger acceleration is produced at the time of a high velocity collision because of the strain rate dependency. No change in acceleration is produced in the extreme rough road mode. The algorithm must be based on the principles behind these kinds of physical collision phenomena. Stated in concrete terms, the collision waveform is based on the digital signal processing theory. The deformations of the individual structural members and parts of the vehicle comprise this collision waveform. These deformations produce pulse components. The algorithm then makes the collision determination by extracting these pulse components and combining their sizes and characteristic parameters. Consequently, the robustness of the algorithm is ensured by detecting the characteristic part deformation pulses, even if the collision lap rate is different. Figure 20 shows an actual collision waveform. The figure clearly shows how the overall waveform is composed of the combination of pulses produced by the deformations of various structures and parts.

The following section first describes the collision determination made by a floor-mounted ECU in a basic frontal collision. After this, the collision determination made in conjunction with the front satellite sensors is explained.

Table 2. Typical crash test modes.

Type of Collision	Velocity	TTF
Full-lap frontal collision	50 km/h	15 ms
	25 km/h	50 ms
	18 km/h	No fire
40% lap offset frontal collision	50 km/h	25 ms
	18 km/h	No fire
Oblique collision	50 km/h	30 ms
	35 km/h	50 ms
Pole	50 km/h	25 ms
ODB	64 km/h	25 ms
Extreme rough road	Pothole	No fire
	Driver over a bump	No fire
	Driver over a card	No fire

Figure 21 shows a block diagram of the collision determination algorithm.

6.8.3 *Preprocessing*

The signals from both the satellite sensors and the G sensor within the ECU are first subjected to preprocessing. Abnormality determination processing using a guard value is performed to carry out the malfunction determination for the G sensor. A high-pass filter that possesses time constants of several seconds to tens of seconds is used to correct any drift from the zero point due to the temperature and changes due to aging of the G sensor. A low-pass filter with a specified time constant is then applied for preprocessing of the signals before they move on to the subsequent stages. These filters are composed of digital filters and all of the processing is done by software.

6.8.4 *Signal analysis*

In the signal analysis area, the collision waveform is broken into pulses using a method called *wavelet conversion*. This method is used because it can detect pulses of various time constants to grasp the characteristics of various structural members and parts. In the case of a large vehicle that suffers a large amount of deformation to absorb a large amount of collision energy, the time constants of the pulses from the structural members will also become larger. However, a smaller vehicle may not be able to obtain a sufficient amount of deformation, and so the pulse time constants will become smaller. A sharp pulse is produced if the deformation reaches the engine or other large auxiliary equipment, so this can also be used as a characteristic parameter for that vehicle. The set of collision waveforms for tuning is first passed through this analyzer and the characteristic pulses of the time constants for that vehicle are investigated. The key pulses are determined based on these results and the calibration parameters for the subsequent-stage determination area are also determined.

6.8.5 *Collision determination*

The collision determination is performed in this block based on the sizes of the pulses, which are a characteristic parameter of that vehicle, and when the pulses appear. In general terms, the combination logic is assembled in accordance with each of the different types of collision: a frontal collision that strikes both side members, which are the main load-bearing structural members of the vehicle, an offset collision that strikes only one structural member, a diagonal collision that strikes structural members diagonally, a collision with a pole that strikes no structural members, and the like. Tuning can then be

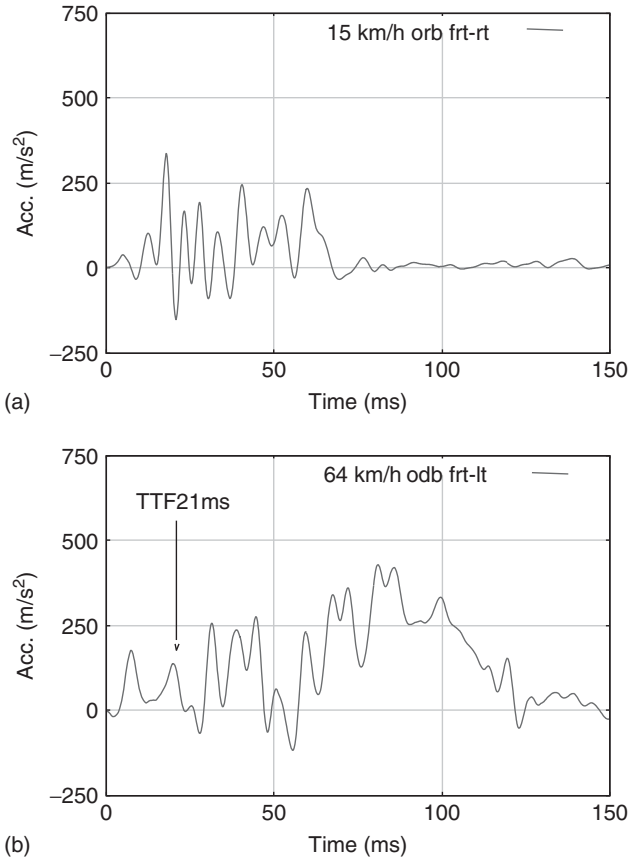

Figure 23. (a,b) Difficulty of determining collision with front sensors only. (Reproduced by permission of Denso Corporation.)

performed by simply setting the calibration parameters appropriately.

6.8.6 *Determination in conjunction with satellite sensors*

Figure 22 shows acceleration waveforms from the front satellite sensor and the floor ECU in the same frontal collision at 25 km/h. The graph shows that there is an extremely large acceleration produced in the crushable zone where the front satellite sensor is located because of the large deformation during the initial stage of the collision. In comparison, the increase in the acceleration is delayed in the floor ECU, which is located in the noncrushable zone. This collision has a must fire requirement, so it is necessary for the airbags to deploy.

Figure 23a shows the acceleration waveform from an offset frontal collision at 15 km/h using the same vehicle model as in Figure 22. Only one half of the vehicle receives the impact, so the acceleration in the area where the front satellite sensor is located is very intense. This collision has a no fire requirement, so it is not necessary for the airbags to deploy. Figure 23b shows the collision waveform of a 64 km/h ODB crash where the required TTF is 21 ms. The rise of the acceleration up to the required TTF is slow, even though the collision velocity is over 4 times faster. Consequently, the collision determination is performed by combining the waveform from the upper graph with the acceleration of the floor ECU.

The principle of an integrated collision determination is the same as for the individual determinations. The acceleration pulse produced at the time of the collision is detected. The size of the pulse and the time difference between the front and floor sensors are grasped as the characteristic parameters of the vehicle. These are then set as the calibration parameters. Figure 24 shows the acceleration waveform of an ODB collision at 64 km/h. The pulse produced at the front sensor is indicated by A, and this same pulse is then transmitted to the floor sensor, as indicated by B. Collision determination is then performed using this information.

7 THE FUTURE OF AIRBAG

A collision phenomenon, sensing technologies, the sensors for airbags, ECU, and the collision determination algorithm were described as passive safety technologies of a vehicle collision. In recent years, other safety technologies have been placed on the market, such as crash compatibility technology (which protects the occupants of the other vehicle in the event of a collision with a compact car) and airbags and active hoods (which protect pedestrians). These kinds of technologies, which protect the other party in the collision, have been advancing and evolving. There are also other safety technologies such as fuel shut-offs, electric power shut-offs, and mayday systems in addition to those that protect vehicle occupants directly. Moreover passive safety technologies will be combined with driving assist technologies, active safety technologies, and precrash safety technologies. A safety system with few traffic accidents will be developed.

Chassis ECU (ACC and Sensor)

Takayuki Nagai[1] and Masayuki Furuhashi[2]

[1]*DENSO Corporation, Kariya, Japan*
[2]*DENSO Corporation, Inabe, Japan*

1 INTRODUCTION

1.1 Adaptive cruise control (ACC)

Adaptive cruise control (ACC) (Figure 1) is an enhanced cruise control (CC) system with drastically improved functions. CC basically enables the vehicle to drive at a constant speed. It has become widespread, for example, in the United States where long-time driving on roads with a low traffic volume is the norm, as it saves the driver the trouble of constantly keeping the accelerator depressed. However, the adoption of CC is limited, in countries such as Japan where even highways often have heavy traffic, because of frequent resetting of CC after braking. Compared with CC, ACC is easier to use for the driver. It recognizes objects ahead of the vehicle and, if it judges that the vehicle is a relevant ACC target, the system controls the vehicle speed in accordance with the speed of the preceding vehicle. In addition, a new type of ACC system called *full speed range adaptive cruise control* (*FSRA*) has also been developed (Figure 2). It is capable of following the preceding vehicle in the entire speed range from start to stop.

2 ACC OPERATION

2.1 ACC in driving assistance systems

Figure 3 shows a block diagram that illustrates the relationship among the driver, vehicle, and driving assistance systems. Figure 3a indicates a vehicle without assistance control. The driver operates the vehicle according to the surrounding conditions. Figure 3b shows a vehicle with chassis control. The control detects locking of the tires on a frozen road through the ABS (antilock brake system) ECU (electric control unit). In this case, it lowers the oil pressure of the brakes and helps the vehicle recover enough grip to enable the driver to perform avoidance operation through steering. The role of the chassis control is to maintain the vehicle state in accordance with the driver's intentions. Figure 3c adds driving assistance systems. Unlike the chassis control ECU, which is positioned in parallel with the vehicle, driving assistance systems are positioned in parallel with the driver. These systems provide the driver with information by processing the surrounding conditions. Specific examples of these systems include the navigation system, night vision, adaptive front-lighting system (AFS), and the like. Figure 3d incorporates vehicle speed and in-lane driving controls. ACC is included in this final type of systems.

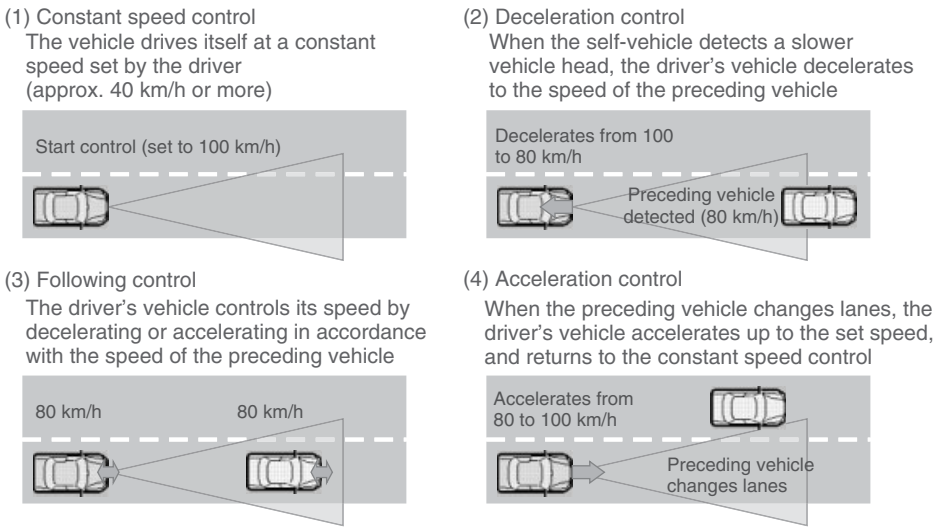

Figure 1. ACC control. (Reproduced with permission from Denso.)

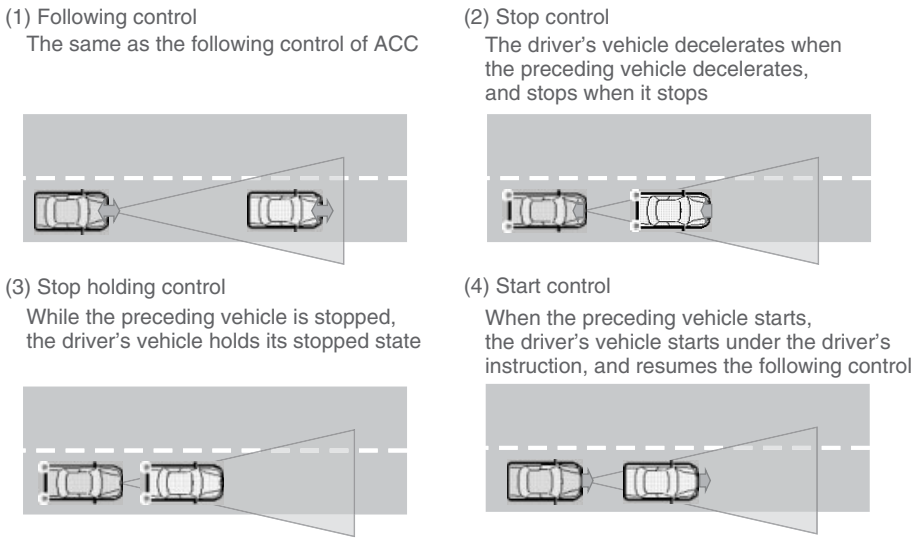

Figure 2. FSRA control. (Reproduced with permission from Denso.)

2.2 Distance control

Conventional CC achieves constant speed driving by controlling only the engine to hold the speed set by the driver. ACC has radar that functions as the eyes of the system. When the preceding vehicle is driving slower than the set speed, it can control the brake to decelerate the self-vehicle and follow the preceding vehicle at a certain following distance. When there is no longer a preceding vehicle, the system accelerates again and resumes driving at the set speed.

Furthermore, FSRA covers the entire speed range from start to stop. Even when the self-vehicle stops because the preceding vehicle has also slowed down and stopped, it resumes following the preceding vehicle when the driver turns on a switch or depresses the accelerator.

2.3 Drive override

The essential concept is that driver operation always takes precedence over ACC. When the driver depresses the brake pedal, ACC is cancelled, and deceleration is carried

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto228
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

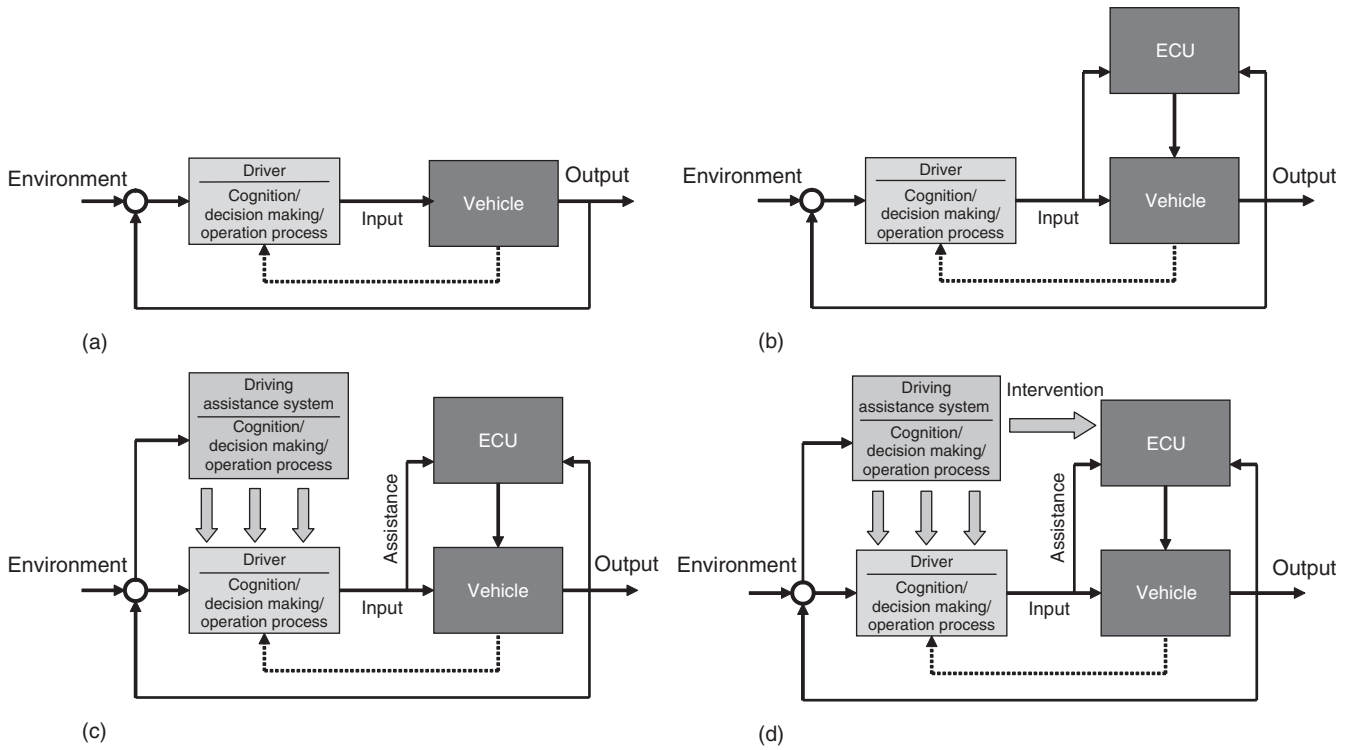

Figure 3. (a–d) Relationship among driver, vehicle, and driving assistance systems. (Reproduced with permission from Denso.)

out by normal braking based on the driver's intention. Furthermore, when the driver depresses the accelerator to increase the speed, the vehicle accelerates accordingly. When the driver releases the accelerator, the system returns to ACC mode.

3 SYSTEM CONFIGURATION

3.1 Overall configuration

The example in Figure 4 shows a configuration that incorporates AEBS (advanced emergency braking system) and LKAS (lane keeping assist system) in addition to ACC. ACC uses a millimeter-wave radar for detecting vehicles ahead. AEBS also uses the millimeter-wave radar for detecting potential collision objects. LKAS employs a video sensor for recognizing lane markings. The information collected by these sensors (such as the distance and the relative speed to the preceding vehicle, and the azimuth) are processed by driving assistance system ECU together with vehicle information from other ECUs to identify the target operative amount necessary for safe driving. ACC gives instructions to the engine and brake control ECUs to operate the engine and electronic stability control (ESC) actuator. The ACC operation state and alerts are shown to the driver in the display.

3.2 Range sensor (millimeter-wave radar)

Range sensors to perform ACC include radar, LIDAR (light detection and ranging), and stereo cameras. Figure 5 shows an example of a millimeter-wave radar. Automotive millimeter-wave radars employ various detection methods. The radar shown employs the frequency modulation-continuous wave (FM-CW) method to detect distance and relative speed and digital beam forming (DBF) to detect the azimuth. Figures 6 and 7 show the principle of each method (2004).

In Figure 6, the horizontal axes show the time, and the vertical axes show the frequency. The radar launches pulses modulated to form a triangle shape as shown in the figure. The time lag until it receives the reflective pulse is proportionate to the distance. Here, as it is difficult to measure the time lag accurately, the distance is obtained by calculating the frequency difference of fs − fr instead. The bottom graph in Figure 6 shows a case when a relative speed is present between the self-vehicle and the preceding vehicle. In this case, the entire reflective pulse shifts because of the Doppler effect. Thus, the fs − fr difference

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto228
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

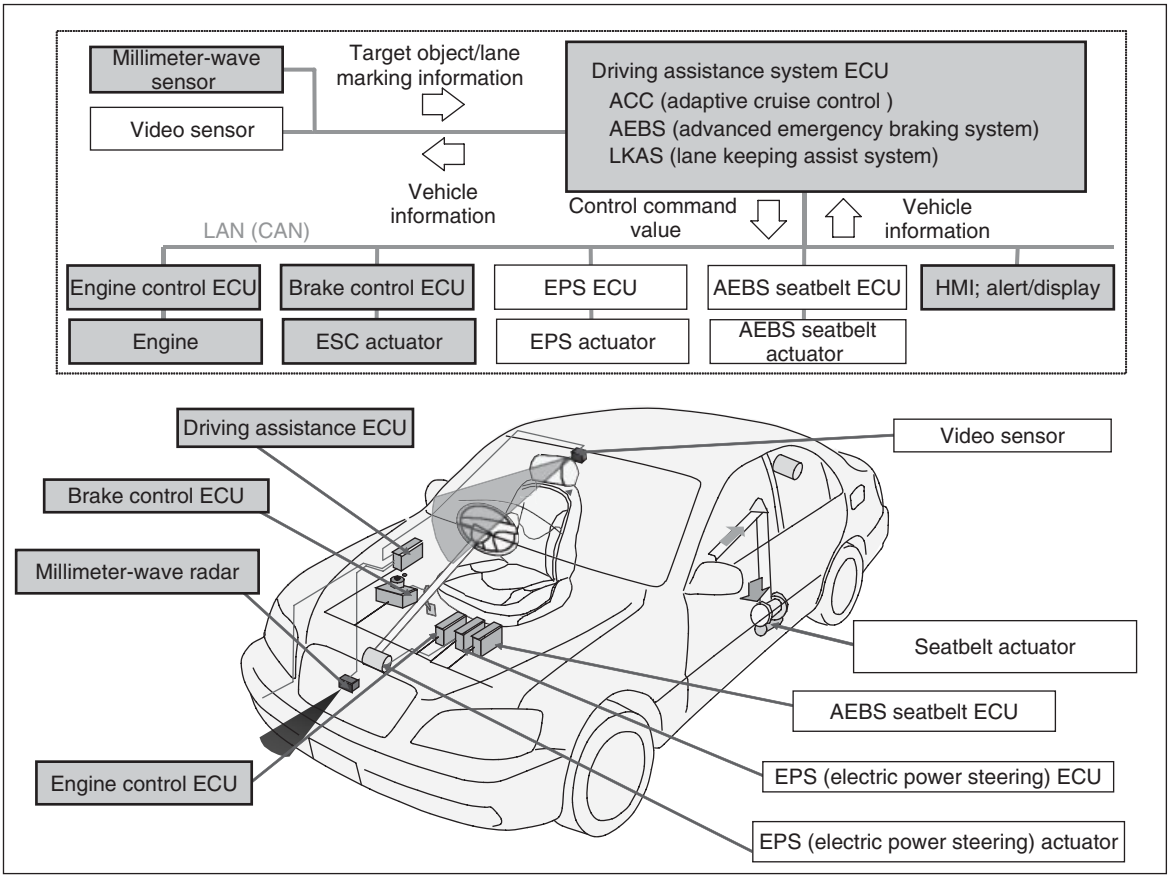

Figure 4. Example of driving assistance/safety system configuration. (Reproduced with permission from Denso.)

Figure 5. Millimeter-wave radar. (Reproduced with permission from Denso.)

becomes smaller by the amount of the Doppler effect at the rising portion, and the difference becomes larger at the descending portion. The relative speed can be obtained by subtracting the differences in the rising and the descending frequencies, and the distance by adding up the differences.

Figure 7 shows the azimuth detection principle. An outgoing pulse is transmitted from one channel antenna, and the reflective pulse is received by multiple antennas (five channels in this example). As the path length of the reflective waves that reach the channels varies depending on the azimuth it comes from, the azimuth is obtained by detecting the phase difference between the channels.

3.3 Controller (driving assistance system ECU)

ECUs used for driving assistance systems including ACC obtain information from sensors via the network and send requests to other ECUs to control the brakes, engine, and steering. Furthermore, they judge diagnosis information from sensors and actuators comprehensively and shift the system operation to the fail-safe mode as needed. The control system has a hybrid configuration that consists of a state transition model and a continuity model, manages ACC operation, and achieves safe and smooth transition between the normal driving and

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

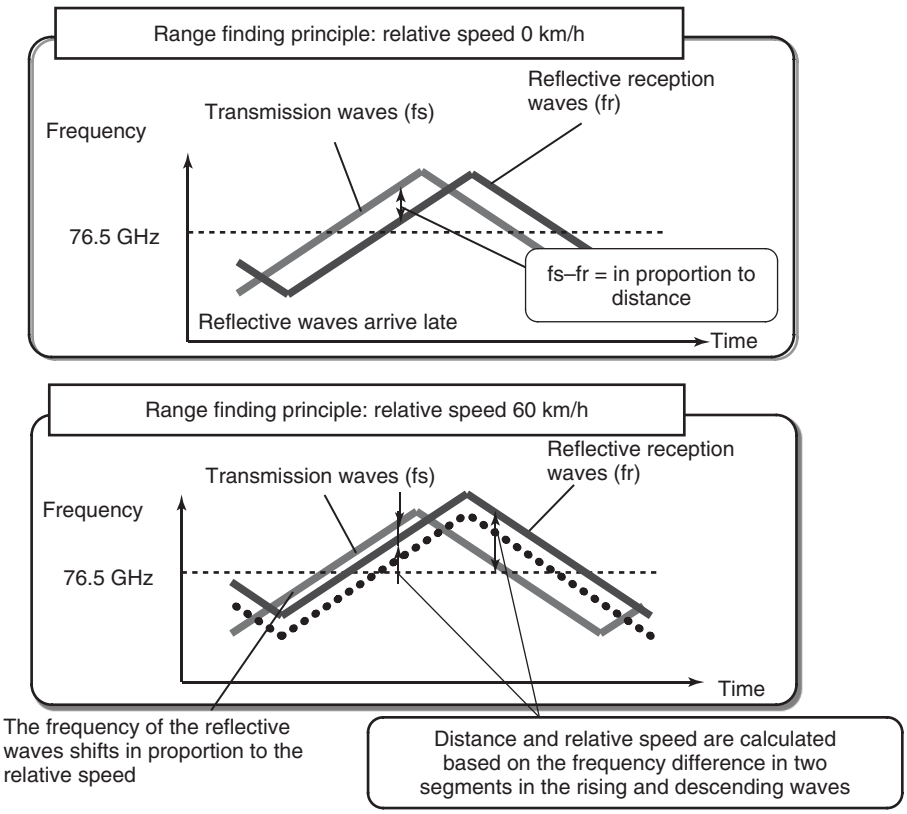

Figure 6. Range finding principle based on FM-CW. (Reproduced with permission from Denso.)

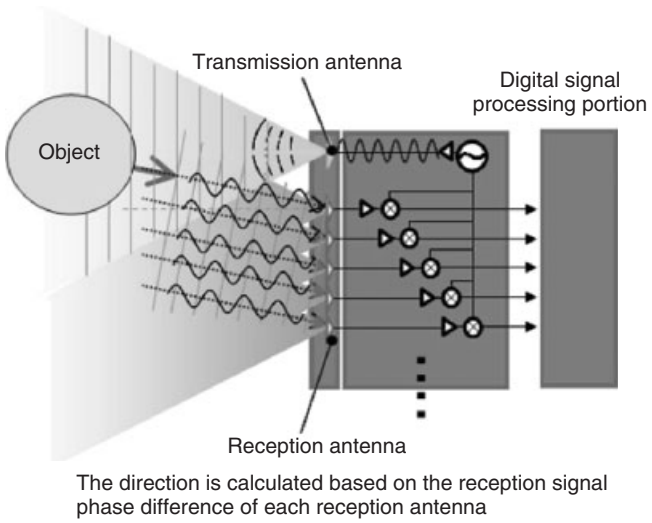

Figure 7. Direction measurement based on DBF. (Reproduced with permission from Denso.)

the ACC operation states in accordance with the driver operation (brake pedal, accelerator pedal, and input to ACC system). In addition, the driving assistance system ECU often includes applications such as AEBS and LKAS. When the value to execute each control is parallel and the control command value issued to the vehicle system from various applications differs, it arbitrates the control command value based on the priority among applications and outputs the command values to the engine/brake ECUs. It includes the operation to shift ACC mode to the AEBS mode if the frontal collision is inevitable because of the sudden deceleration of the preceding vehicle. System configuration is shown in Figure 8.

The CAN (controller area network) communication is a main communication approach employed nowadays. Adoption of high speed and large-volume communication technology such as FlexRay achieves a high level and high speed recognition and control.

Control logic development is based on models, which are fitted directly into the rapid prototyping ECU of the actual vehicle. The control constants directly impact the driver's comfort, and these are important calibration elements in addition to the calibration of the sensors and actuators. Automatic code generation method from the model is also utilized (Figure 9).

4 FUTURE DEVELOPMENT

Although ACC presently achieves driving assistance through longitudinal speed and distance controls, it is likely to be fused with lateral vehicle control in the future. Integrated longitudinal and lateral vehicle control will require more sophisticated recognition and decision-making process in the system by utilizing obstacle and maneuverable space identification, road profile detection, digital mapping, and vehicle-to-infrastructure and/or vehicle-to-vehicle communications as a maximum set of sensing elements. As the recognition confidence level increases, autonomously drivable scenario will expand, including autonomous lane change as one of the challenging maneuvers. The technology also would be usable to realize fuel-efficient driving assistance, route guidance assist, and convoy driving.

The technical evolution as described earlier will require the driving assistance system ECU to deal with much larger inputs and outputs. Calculation amount inside ECU will also increase to handle comprehensive surrounding recognition, increasing applications, and busier communication with other ECUs.

Body and Lighting ECU (Key-less Entry, Sonar, HID, LED Usage for Lamps)

Masafumi Yamaura
DENSO Corporation, Kariya, Japan

1 OUTLINE OF BODY CONTROLS

The purpose of body controls is to improve aspects of vehicle performance, such as comfort, usability, safety, theft prevention, serviceability, and the like. This is accomplished by controlling the output of motors, lamps, and the like, based on inputs mainly from switches and sensors. Table 1 lists some examples of products and functions that aim to improve these aspects of performance. Many of these body control products are designed to enhance the perceived value of the vehicle and to create an appealing impression to the user. For this reason, these controls were conventionally installed mainly in luxury vehicles. In recent years, however, technological innovations have reduced costs to the level where more and more have become available in mass-market vehicles.

2 BODY CONTROL ECUS

Each vehicle contains multiple body control engine control units (ECUs). This section describes the integrated body ECU, clearance sonar, and headlamp control (functions such as the air conditioning, cluster, remote door locking, and the like are covered elsewhere).

2.1 Integrated body ECU

This refers to an ECU that incorporates multiple body system ECUs for functions that originally existed independently. The in-built functions of this integrated ECU differ depending on the vehicle, based on the installed functions and electronic systems in the vehicle as a whole. One factor in the emergence of integrated ECUs is the dramatic increase in wire harnesses for electronically connecting ECUs with inputs (switches and sensors), outputs (motors and lamps), and other ECUs as the scope of body control functions has spread. The integration of ECUs is one method of minimizing the space required for installation and costs. The feasibility of integration is generally determined based on the commonality of inputs and outputs (i.e., whether the same inputs and outputs are connected), the similarity of control (body functions often operate with the ignition turned off), the functions adopted on the vehicle (i.e., what functions are standard or optional), and the division of responsibilities with other ECUs. Since the 1980s, the number of wire harnesses has been reduced even further by the adoption of multiplex communication, which is capable of transmitting data over a single wire harness in a time-sharing format. This has also led to the development of new functions using data obtained through multiplex communication. Figure 1 illustrates the merits of integrating body system ECUs.

2.2 Clearance sonar

This is a system that detects objects close to the vehicle and notifies the driver of their location and distance via a buzzer or display. It operates when the vehicle is being driven at low speeds such as during parking maneuvers, using ultrasound sensors with an integrated reception/transmission function built into the front and rear bumpers.

2.2.1 Example system configuration

Figure 2 shows the configuration and detection range of a typical system with eight sensors. In the system shown in the figure, the vehicle information required to control the sonar (i.e., the vehicle speed and whether it is moving forward or backward) is obtained through the controller area network (CAN) or another type of vehicle local area network (LAN). This information is used to control the sensors. Detected objects are notified to the driver by a buzzer and displayed on the cluster in front of the driver by the LAN. The detection range of the system is 50 to 60 cm from the sensors at the vehicle corners and 100 to 150 cm in front and behind the vehicle. The buzzer tone changes from an intermittent to a continuous sound as the vehicle approaches the object to help the driver identify the distance aurally.

2.2.2 Principle of object detection

Figure 3 shows the principle of object detection. Ultrasonic waves are transmitted from the sensors, which are reflected back by objects. The return time t of the ultrasonic waves is measured to calculate the distance to the object D. Furthermore, the control of each ultrasonic sensor changes the transmission timing and interval of the sensors dynamically (i.e., randomly) to prevent false detection due to ultrasonic waves from the same system or from other sources.

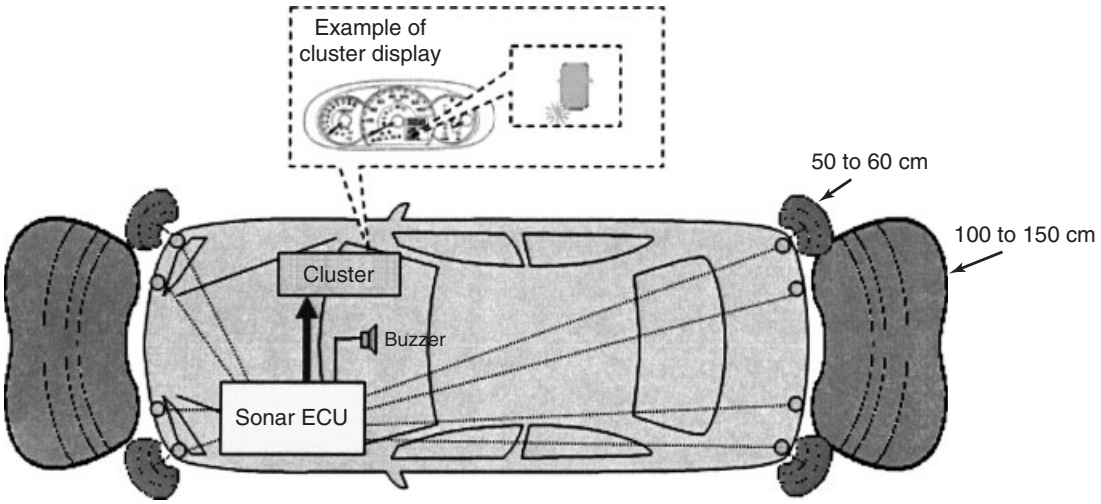

Figure 2. Example configuration and detection range of sonar system.

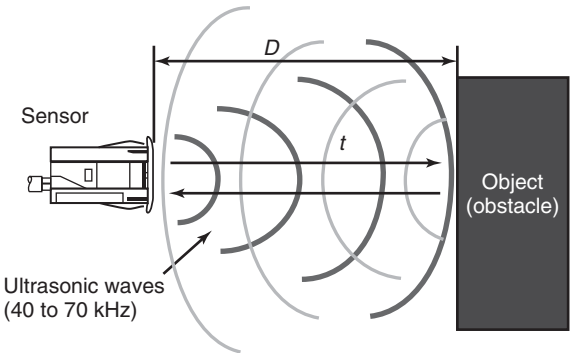

Method of calculating distance D between sensor and object:
- Transmission rate of ultrasonic waves $v \approx 331.5 + 0.6\,T$
(T : temperature)
- t = Time for ultrasonic waves to return from object
- Distance to object $D = v\,t / 2$

Figure 3. Principle of object detection.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto229
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

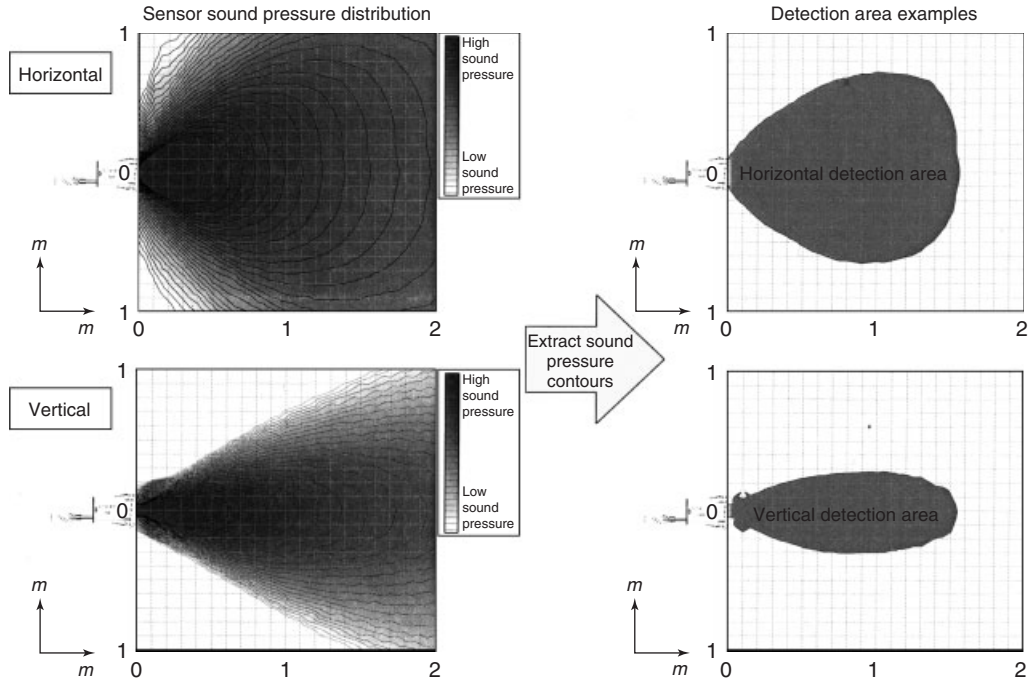

Figure 4. Detection area control.

2.2.3 *Detection area control*

As Figure 4 shows, the detection area can be divided by sound pressure contours for the ultrasonic waves. These are formed by applying voltage transformation to the sound pressure reflected from the object within the sensor. Actual sensor control is performed so that certain items are not detected. These include small objects and tire-stops on the floor, which should not be considered as collision risks, as well as side walls when reversing into a garage.

2.2.4 *Ultrasonic sensors*

Figure 5 shows the structure and appearance of an ultrasonic sensor. It consists of an ultrasonic microphone portion that transmits and receives ultrasonic waves, which is composed of a piezoelectric device (lead zirconate titanate (PZT)) and an aluminum case, a voltage boosting circuit that drives the piezoelectric device, and an ultrasonic wave reception circuit. The circuit inside the circuit uses a dedicated IC to reduce size. As the sensor is installed inside the bumpers, it has a waterproof structure that integrates the circuit with the connector using a filler material. The surface of the microphone is painted the same color as the bumper to improve its appearance. The materials used are selected to prevent damage from stone chipping during driving and the structure is designed to quickly damp fluctuations in the ultrasonic waves.

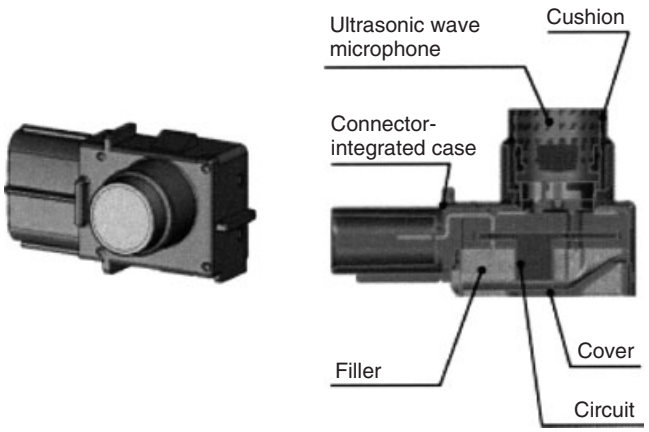

Figure 5. Ultrasonic sensor.

3 HEADLAMP CONTROL

3.1 Evolution of headlamps

Since the 1960s, automotive headlamps have used halogen lamps as a light source. In the 1990s, brighter high intensity discharge (HID) lamps were introduced and entered widespread use. Sophisticated adaptive front-lighting systems (AFSs) were developed in the 2000s to enhance forward visibility at intersections and on curves at nighttime by optimizing the distribution of light in

accordance with the driving conditions of the vehicle (such as the vehicle speed, steering angle, and the like). Furthermore, LED headlamps, which were introduced in 2007, have the merits of increasing bulb life, saving energy, and achieving stable brightness levels immediately after being switched on. LED headlamps are also more compact, which increases the design freedom of the headlamps and surrounding areas. As improving safety and usability are constant priorities, it is likely that further improvements will be made in the future to light sources (in terms of brightness and energy saving) and visibility enhancement control. This section describes the controls for HID and AFS (Table 2).

3.2 HID headlamps

3.2.1 Outline of HID headlamps

According to statistics, the rate of fatal traffic accidents is roughly three times higher at night. Poor visibility is recognized as one factor contributing to this issue. This led to the introduction of discharge bulbs as light sources. Discharge headlamps emit white light similar to the sun and are three times brighter than conventional halogen headlamps, while consuming 30% less power.

3.2.2 Configuration and control of HID headlamps

An extremely high voltage of approximately 20,000 V is required for discharge bulbs to operate. The power must also be controlled to maintain brightness at a constant level. These controls are performed by an electronic circuit called the *ballast*, which is located outside the headlamp housing. The ballast consists of a DC–DC converter that boosts the battery voltage, full bridge inverters that generate square waves for stable illumination of the bulbs, and a control circuit that controls these items. It also includes a fail-safe circuit, which shuts off operation of the headlamps when an abnormality occurs, and a starter circuit that generates

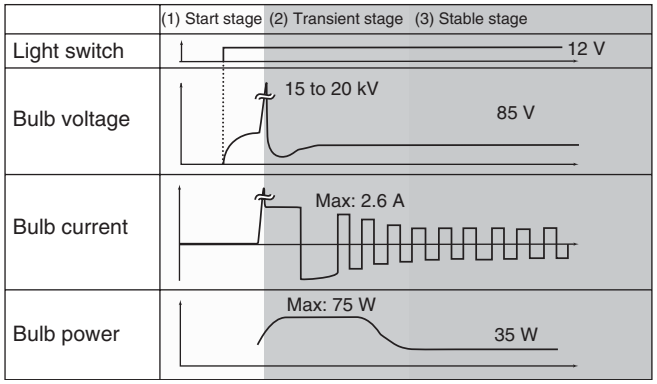

Figure 7. Ballast control operation.

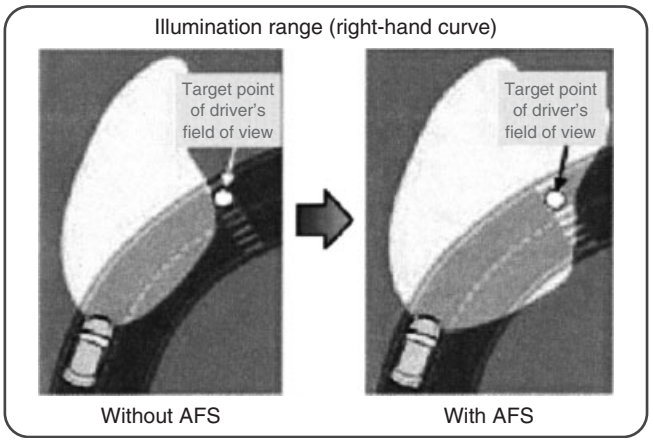

Figure 8. Effect of AFS.

a high voltage pulse to break down the insulation between the bulb electrodes when the headlamps are switched on (Figure 6).

Ballast control operation can be categorized into the following three stages when the discharge bulb is switched on (Figure 7).

3.2.2.1 Start stage. The control applied a high voltage pulse between the electrodes of the discharge bulb to break down the insulation. Although the required voltage changes depending on the bulb state, it is generally in the range of 15,000 to 20,000 V.

3.2.2.2 Transient stage. This is the stage between insulation breakdown and stable illumination of the bulb. This stage requires an extremely large amount of power to increase the brightness in a short period of time. However, as applying unrestricted power to the bulb will dramatically reduce the lifetime of the bulb, the power must be controlled within a maximum bulb output power and current. Subsequently, the control reduces the power in accordance with the bulb impedance.

3.2.2.3 Stable stage. In this stage, the voltage and power of the bulb are controlled to stable values of 85 V and 35 W, respectively.

Consequently, ballast design requires control technology capable of handling large voltages and power levels.

3.3 Adaptive front-lighting system

3.3.1 Outline of AFS

AFS is a headlamp system that automatically changes the light distribution pattern in accordance with the conditions after detecting the driving environment (i.e., whether the vehicle is being driven around a curve, through city streets, at high speed, or while it is raining) using sensors installed in the vehicle. In a curve, headlamps with conventional fixed optical axes will illuminate a different location to the intended vehicle travel direction (i.e., the outside of the curve). In contrast, AFS allows the headlamps to illuminate the intended vehicle travel direction (i.e., the inside of the curve). In addition, AFS reduces the glare of the headlamps visible by oncoming vehicles and pedestrians. Therefore, AFS plays an important role in danger avoidance by making approaching vehicles clearer (Figure 8).

3.3.2 AFS configuration and control

AFS is based on a conventional auto-leveling system, which consists of height control and vehicle speed sensors. Additional components in AFS include a steering sensor to detect the angle of the steering wheel and headlamp

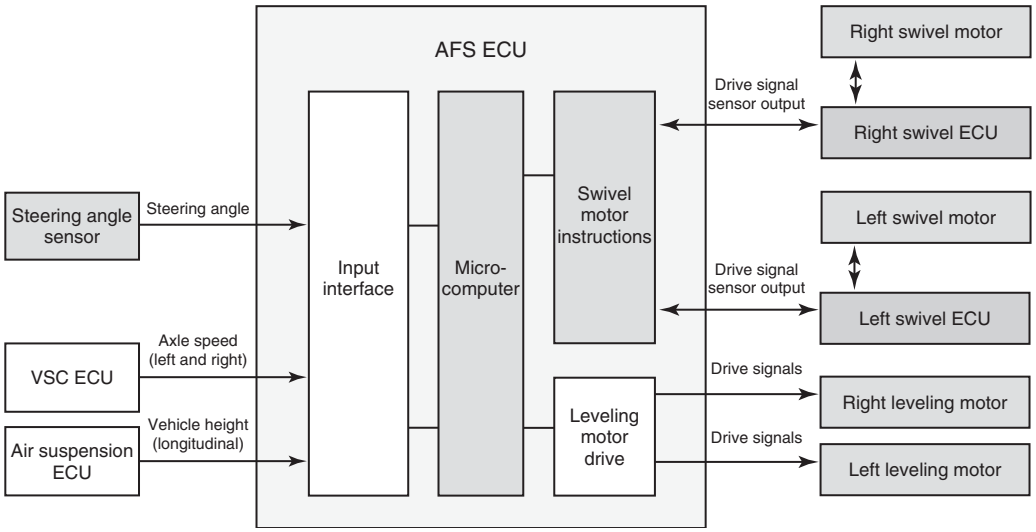

Figure 10. AFS configuration.

swivel actuators that rotate the headlamps in the horizontal direction. The AFS ECU determines the control (swivel) angle of the low beam headlamps based on the information from each sensor (i.e., the vehicle speed and steering angle) and operates the swivel motors in the headlamps. In addition to the swivel motor control, the AFS ECU has an auto-leveling control function that moves the headlamps up and down in accordance with the longitudinal angle of the vehicle. These two controls are combined to optimize the headlamp light distribution for all driving conditions. Figure 9 shows the AFS lamp structure and Figure 10 shows the AFS configuration.

1 OUTLINE OF COMMUNICATION

In addition to the fundamental driving, turning, and stopping functions, modern vehicles are also capable of utilizing various services through wireless-based communication with objects outside the vehicle. Although this is used to simply refer to radio reception, it now encompasses radio waves from the Global Positioning System (GPS), analog and digital television broadcasts, and external wireless communication with electronic toll collection (ETC) systems, mobile telephone networks, and the like. It has even come to include hands-free use of telephones inside the vehicle through Bluetooth.

There are three categories of wireless communication used in vehicles. The first category is used inside the vehicle (near field). A typical example of this technology is Bluetooth. The second category is short-range wireless communication, which is used for ETC and other functions that are operated from fixed locations. The third is broadband wireless communication, which is used for mobile telephone networks. This chapter describes the characteristics of each category of wireless communication technology, as well as examples of the available services (Figure 1).

2 BLUETOOTH

2.1 What is Bluetooth?

Bluetooth is a wireless communication technology for mobile devices. The main companies behind this technology include Ericsson from Sweden, IBM from the United States, and Toshiba from Japan. As Bluetooth is a form of short-range communication that uses radio waves in the 2.4 GHz band, it does not require licensing or registration to use. Bluetooth is used for relatively low speed communication, such as for personal computers and mobile telephones. Its characteristics are as follows.

1. It divides the 2.4 GHz band (ISM band) into 79 frequency channels and hops between use frequencies at random.
2. Low power consumption (during reception: 10 mA, during standby: several μA).
3. Compact size (active chip area: max. 1 cm^2).
4. Low cost (chip price: max. 5 US dollars).
5. Joint transmission of audio and data (calls can be made with up to three different people).
6. Security assured by authentication on connection and data encryption.
7. Profiles can be established for each usage scenario (Table 1).

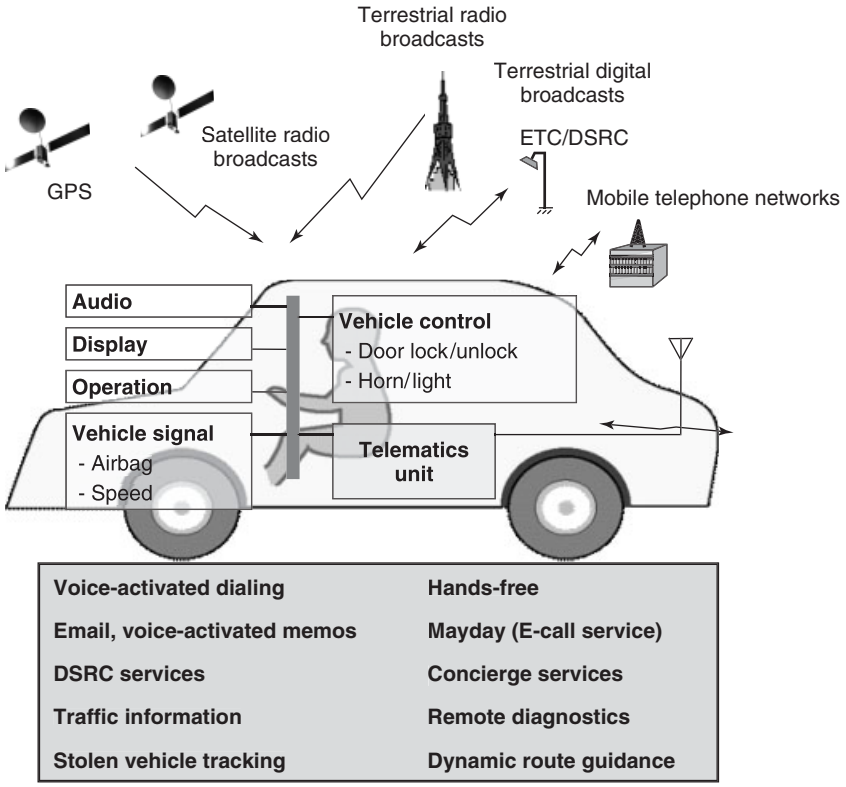

Figure 1. External communication functions.

Table 1. Bluetooth specifications.

Item		Specifications	
Wireless	Wireless band used	Industrial, scientific, and medical (ISM) bands (2.400 GHz to 2.4835 GHz)	
	Transmission distance	Class 1: Approx. 100 m (100 mW) Class 2: Approx. 25 m (2.5 mW) Class 3: Approx. 10 m (1 mW)	
	Bit rates	1, 2, 3 Mbps[a]	
	Primary modulation protocols	Gaussian frequency shift keying (GFSK) (frequency modulation protocol), differential quadrature phase shift keying (π/4DQPSK), differential phase shift keying (8DPSK)[a]	
	Secondary modulation (expansion) protocol	Frequency hopping spectrum expansion protocol 79ch ($f_{(k)} = 2402 + k$ [MHz], $k = 0, 1, 2, \cdots 78$)	
	Frequency hopping rate	1600 hops/s (625 μs)	
Transmission speed	Synchronous mode (synchronous connection-oriented (SCO) link)	Voice: 64 kbps	
	Asynchronous mode (asynchronous connectionless link (ACL))	Symmetrical	433.9 kbps
		Asymmetrical	Maximum download: 723.2 kbps, upload 57.6 kbps

[a]Protocol with Bluetooth 2.0 + enhanced data rate (EDR).

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.2 Services achieved using Bluetooth

Figure 2 shows an outline of the services accomplished using Bluetooth. In addition to the typical example of hands-free communication, Bluetooth can be used to forward and play music data from iPods or other mobile music players on the vehicle's audio system, to perform wireless communication between mobile telephones for data communication, to forward an address book from a mobile telephone to the vehicle's navigation system, and to forward e-mails from a mobile telephone to an on-board device.

Protocols are determined for each service a communication device can use. These protocols are called *profiles*. If two devices are compatible with the same profile, then that service can be used. Examples of profiles include the hands-free profile (HPF), dial-up network (DUN) for data communication, the object push profile (OPP) for data exchange, the basic imaging profile (BIP) for forwarding still images, and so on. Figure 3 shows an example of a device configuration for hands-free telephone calls. This consists of a mobile telephone and vehicle navigation system with Bluetooth compatibility, and switches on the steering wheel.

First, initialization and profile confirmation (profile check) is performed between the mobile telephone and the vehicle navigation system. Once pairing is complete, the driver presses a button on the steering wheel to speak into the telephone. The telephone call is carried out through the microphone and speakers in the vehicle. The driver can also use the system to respond to calls from outside the vehicle.

3 DEDICATED SHORT-RANGE COMMUNICATION

3.1 What is DSRC?

Dedicated short-range communication (DSRC) is a short-range wireless technology that uses 5.8 GHz band radio waves. It is used in ETC systems, which are nonstop automatic toll collection systems for highways recommended by the Japanese Ministry of Land, Infrastructure, Transport and Tourism (MLIT). DSRC is also used for the vehicle information and communication system (VICS), which collects and sends out real-time traffic information on highways, and various on-board intelligent transport system (ITS) devices that expand the functions of ETC.

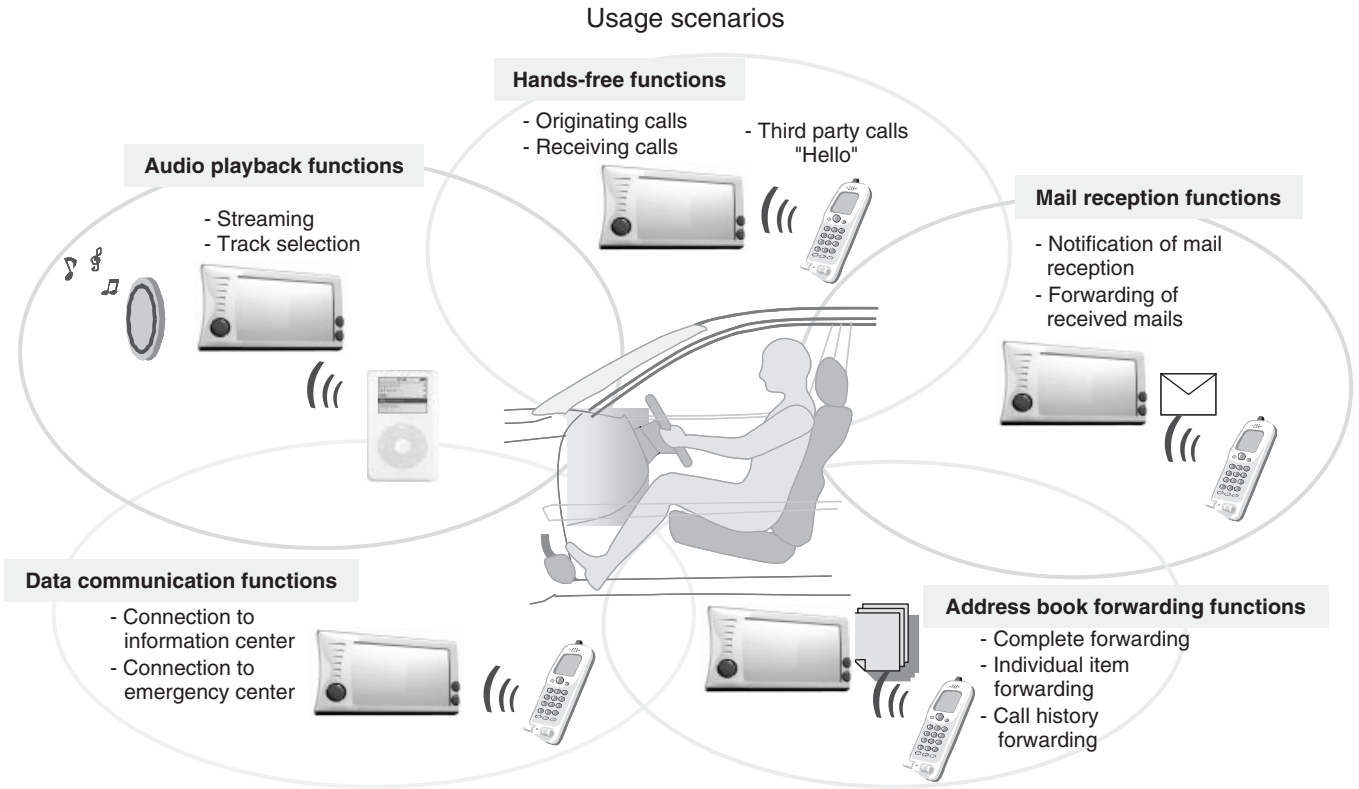

Figure 2. Bluetooth services.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

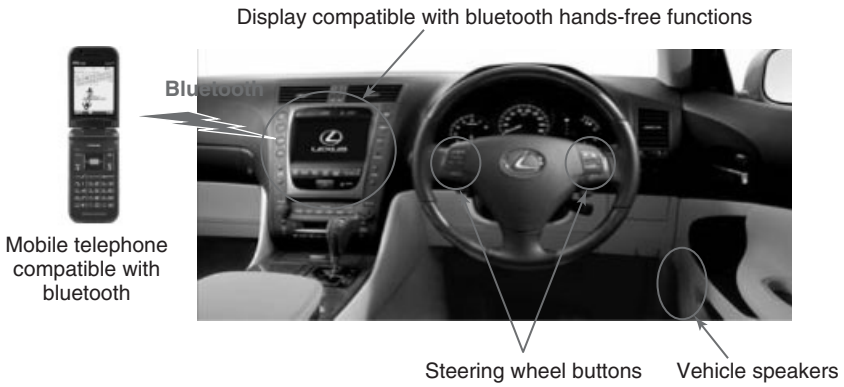

Figure 3. Device configuration for hands-free telephone calls.

3.2 Outline of ETC

ETC uses antennas located at highway toll booths in combination with an on-board device and wireless communication to enable the automatic payment of tolls without the driver having to stop the vehicle (Figure 4).

One of the merits of ETC is the alleviation of congestion. In Japan, most vehicles are now equipped with ETC devices. In the past, 35% of congestion occurred at toll booths, but as a result of ETC, major congestion no longer occurs at the on/off ramps of highways (Figure 5). The vehicle capacity of tool booths has increased dramatically as the drivers do not have to stop to use ETC. Capacity has jumped from 230 vehicles/hour to 800 vehicles/hour.

Another merit is the fact that vehicles no longer have to stop or accelerate away from toll booths after paying. As a result, the noise and emissions levels around toll booths have decreased, and fuel efficiency has been improved. Cashless payment is more convenient and it has enabled the introduction of various discount systems for commuters and travelers at night. ETC systems have spread to other countries outside Japan. It was introduced in Italy and the United States in 1990, and Singapore in around 2000. Many other countries are also thinking about introducing the system (Figure 6).

3.3 ETC technology

3.3.1 Active protocol

ETC in Japan has adopted an active protocol that uses 5.8 GHz band radio waves. With this protocol, the on-board

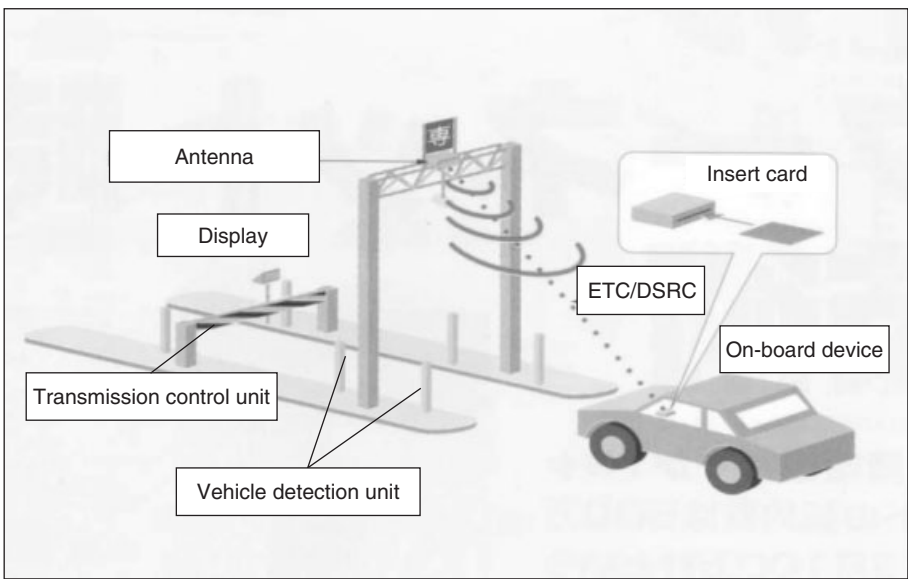

Figure 4. ETC system configuration.

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

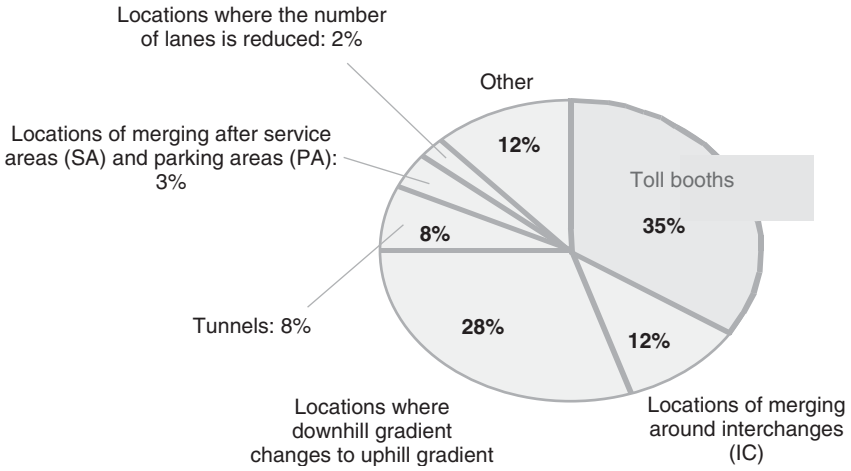

Figure 5. Congestion locations before ETC introduction.

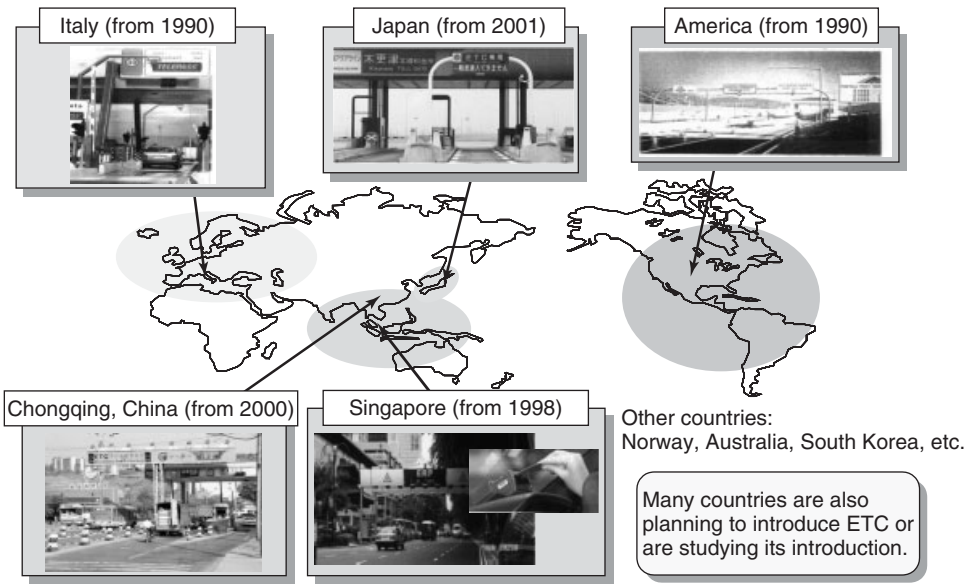

Figure 6. Examples of countries that have introduced ETC.

device has a power supply and is capable of transmitting its own radio waves. This has the following merits (Figure 7).

1. Strong reception and high noise resistance
2. High speed and large-capacity communication (1024 kbps)
3. Wide communication area (max. 30 m)
4. Capable of simultaneous communication with multiple vehicles (max. eight vehicles)
5. Future expandability (i.e., the potential of use with applications other than ETC)

In contrast, some ETC systems outside Japan use a passive protocol. This protocol reflects transmitted radio waves and performs data communication by changing the rate of reflection.

3.3.2 Security

ETC in Japan uses card authorization similar to that of a credit card. Improper use of the card is prevented by providing an integrated circuit (IC) chip in the card. The roles of the on-board device and IC card are separated. The on-board device memorizes only its device ID and

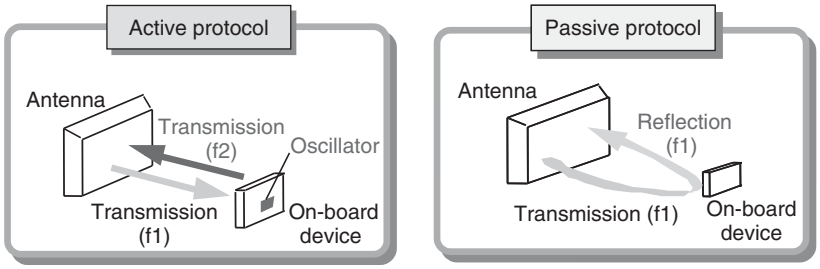

Figure 7. ETC communication protocols.

the vehicle information. The IC card stores the personal information and use history of the user. Communication between the on-board device and roadside antenna is also encrypted to help secure a high level of security (Figure 8).

3.4 Systems compatible with ITS spot service

ITS Spot Service is used by systems that carry out two-way communication between roadside and on-board devices over short distances and small zones. The application of ETC in vehicles is not only capable of paying tolls but it can also be expanded to the reception of VICS information, the payment of parking fees in car parks or the like, the utilization of services that provide information about tourist attractions, and so on (Figure 9). Some ITS on-board devices compatible with ITS Spot Service that have a selection of these functions are already on the market.

3.5 ITS spot service technology

Table 2 shows the specifications of an ITS Spot Service-compatible system. Unlike the ETC system, it carries out modulation by quadrature phase shift keying (QPSK). This achieves a fast communication speed of 4 Mbps. The characteristics of an ITS Spot Service-compatible system are as follows.

1. Use of 5.8 GHz-wave radio waves
2. Signal speed: 1 Mbps and 4 Mbps
3. Modulation protocol: amplitude shift keying (ASK) or QPSK
4. Communication over short distances
5. Large capacity and two-way mobile communication within a small zone mobile communication in small zones

4 VEHICLE-INFRASTRUCTURE COOPERATIVE SYSTEMS

These are new types of systems that aim to enhance safety through infrastructure-to-vehicle or vehicle-to-vehicle communication using 700 MHz or 5.9 GHz band radio waves. These systems use the IEEE 802.11p communication protocol, which is a standard for wireless LAN communication, to allow communication between multiple vehicles.

The requirements of this technology are described below. Vehicle-to-vehicle and infrastructure-to-vehicle communications have been defined, and various services are currently being examined. The services being considered for use with vehicle-to-infrastructure cooperative systems are shown in Figure 10.

2. Systems to help prevent drivers failing to see a traffic signal or stop sign
3. Systems to help prevent rear-end collisions
4. Systems to help prevent collisions when turning right (particularly in countries such as Japan that drive on the left of the road)
5. Systems that provide information about objects in front of the vehicle

As the radio wave environment changes depending on the country, there are differences in frequencies, wavebands, and so on (Table 3).

5 MOBILE TELEPHONE NETWORKS

5.1 Evolution of broadband wireless

With broadband wireless, the mobile telephone wireless communication network can also be used for data communication. Therefore, the vehicle is installed with a communication module compatible with mobile telephone networks also for communicating with objects outside the vehicle. This communication module can be used to obtain real-time traffic information for the vehicle navigation system, tourist information around a destination, hands-free telephone calls, and so on.

First-generation mobile telephones were bulky and used analog communication. These telephones were developed exclusively as audio-based car phones. Digitalization was achieved in the second generation, and advances in semiconductor technology led to successive reductions in size and weight. Second-generation mobile telephones were also capable of low speed data communication. Third-generation devices can be used for applications requiring high speed data communication, such as music downloading and online gaming (Figure 11). The growing popularity of smart phones and increasing network speeds (currently in generation 3.9) are encouraging the construction of high speed infrastructure systems.

However, the rapidly increasing number of smart phones is consuming large amounts of wireless resources, giving rise to concerns about communication problems. Owing to the depletion of radio wave resources, the next trend in broadband wireless systems may be toward micro cells.

5.2 Communication protocols for mobile telephones

Although vehicles are used throughout the world, telematics services that use mobile telephone networks depend on the wireless environment in each region. Therefore, wireless devices for each region have to be prepared before a service can be established.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 3. Comparison of radio wave media for vehicle-infrastructure cooperative systems.

Characteristics \ Communication system		700 MHz	5.9 GHz	5.8 GHz
		WAVE (RC006)	WAVE (802.11p)	DSRC (T-75)
		Japan	Europe and the U.S.	Japan
Communication control		Autonomous distribution (asynchronous access, base station not required) Many-to-many communication (connection authentication not required)		Base station control (synchronous access, base station required) One-to-one communication (connection authentication required)
	Number of terminals allowed	Approx. 100 vehicles		7 vehicles
	Possibility of infrastructure-road or vehicle-vehicle communication	- Infrastructure-road: Possible - Vehicle-vehicle: Possible		- Infrastructure-road: Possible depending on the application - Vehicle-vehicle: Not possible
Radio wave wraparound performance		Good wraparound performance	Poor wraparound performance	Poor wraparound performance
Communication distance		Several hundred meters (100 mW): Medium band	Several hundred meters (100 mW): Medium band	30 m (10 mW): Short range
Modulation protocol		Orthogonal frequency division multiplexing (OFDM)		ASK/QPSK
	Usage environment	- Compatible for use on streets containing many reflective surfaces - Compatible with vehicles travelling at high speed		-Poor compatibility for use on urban streets - Not compatible with vehicles travelling at high speed

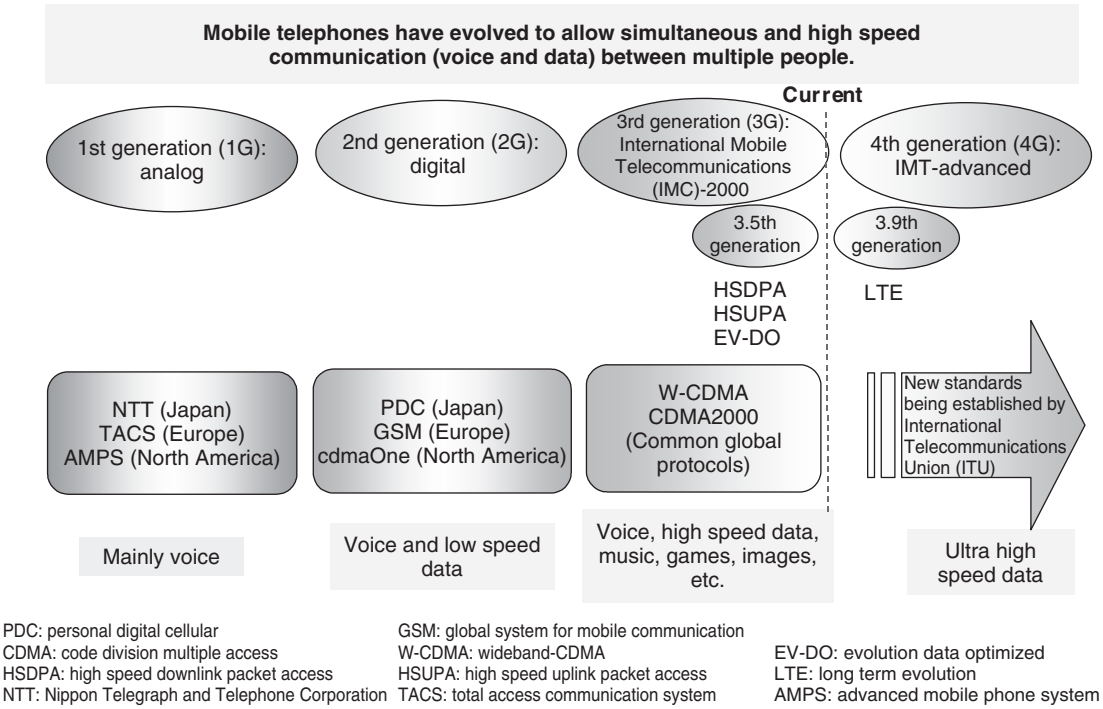

Figure 11. Evolution of mobile telephones.

As shown in Figure 12, the mainstream communication protocol around the world is the second-generation Global System for Mobile Communications (GSMs). The third-generation CDMA 2000 protocol is also prevalent in Japan and the United States. Japan uses the W-CDMA (high speed packet access, HSPA) and CDMA 2000 protocols.

Telematics services in Japan frequently use mobile telephones in place of modems. Dial-up connections using Bluetooth are also common. Some dedicated on-board devices have been developed. These include Toyota's G-Book service, which uses a CDMA 2000 communication module, and Honda's Internavi Premium Club, which uses

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

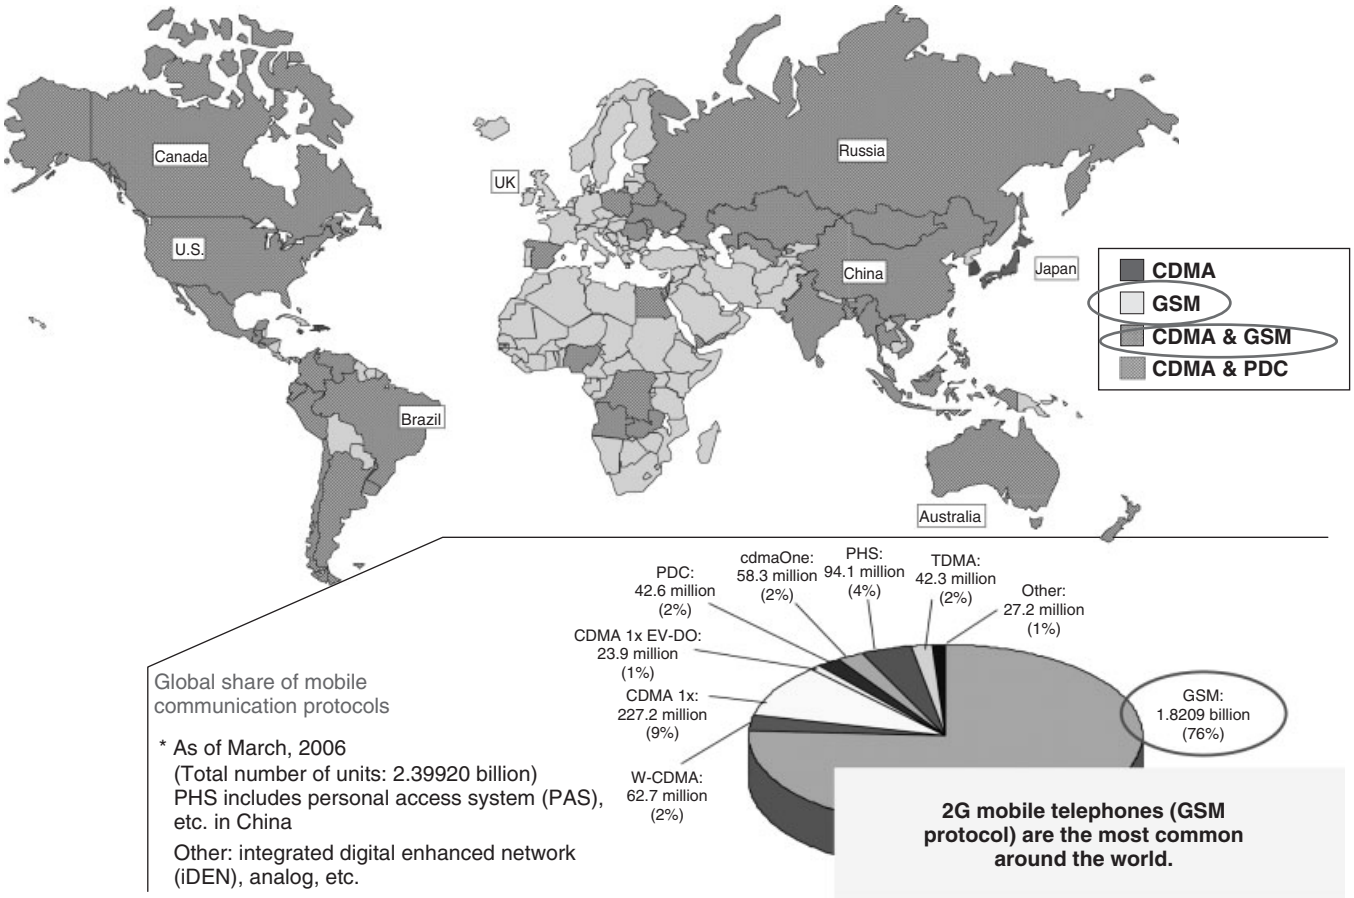

Figure 12. Mobile telephone communication protocols.

a PHS communication module. In North America, General Motors (GM) has developed the OnSTAR service, which also uses a CDMA 2000 communication module.

In China, the government has ordered the reorganization of the communication industry and the introduction of third-generation mobile telephones is progressing. China Mobile Ltd. uses TD-SCDMA, which was developed independently in China. The state-owned telecommunications operators China Telecom and Unicom are making progress in rolling out the HSPA and CDMA 2000 protocols.

In contrast, GSM (GPRS) remains the mainstream protocol in Europe. The 2.5th-generation GSM protocol with an upward compatible EDGE (384 kbps) was partially adopted, but HSPA third-generation systems are now being introduced.

5.3 Wireless frequencies

The frequency bands used by mobile telephones are determined by law. Devices used inside the vehicle must also conform to the Radio Law. Similar laws are in place in each country.

Different communication formats are used in each country, such as GSM, CDMA 2000, W-CDMA, HSPA, and LTE (see subsequent text for a definition of these terms). Communication must also conform to the technical standard determined by each communication company.

5.4 Evolution of communication protocols

5.4.1 Frequency division multiple access

First-generation mobile telephones used frequency division multiple access (FDMA). This protocol divides and allots the wireless channel frequency bands between multiple participants. A guard band was set between the channels to prevent interference between users (Figure 13).

5.4.2 Time division multiple access

Time division multiple access (TDMA) divides and allots the frequency bands on the same wireless channel

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

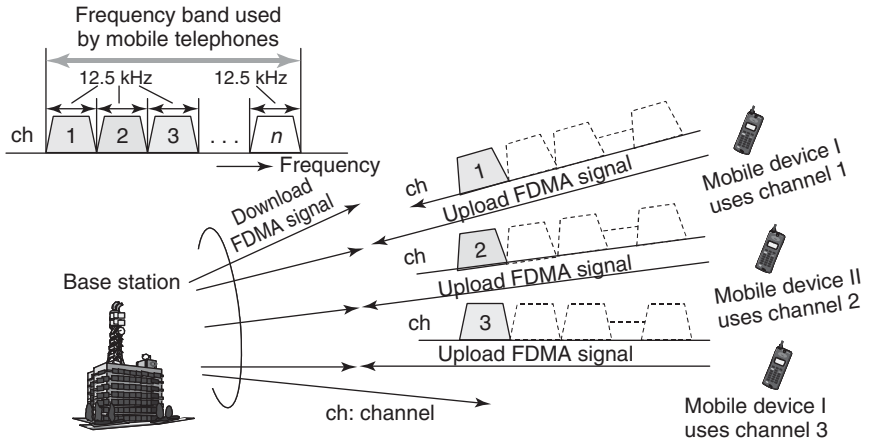

Figure 13. FDMA protocol.

between multiple participants on a time-basis. A guard time is provided to prevent signals from users overlapping (Figure 14).

5.4.3 Code division multiple access

Code division multiple access (CDMA) divides and allots the frequency bands on the same wireless channel between multiple participants using a spread code. Transmission data is modulated by the transmitting system. Transmission occurs after the data expanded by the spread code to the broadband region. The received broadband signal is then returned to the short-range region and demodulated by a reverse spread code (Figure 15).

The CDMA protocol is superior for the following reasons.

1. Large capacity: Data capacity can be increased by utilizing the same frequency in the neighboring channel.
2. Broadband: The high speed spread code enables broadband transmission for high speed multimedia services.
3. High quality: CDMA is resistant against interference or obstruction from existing systems. It is also less likely to interfere with or obstruct these systems itself. CDMA can also be used with rake receivers to prevent transmission quality deterioration due to multi-path propagation.
4. Mobile communication processing function: CDMA is capable of soft handovers with little line disconnection.

5.4.4 3.5th-generation technology

When communication technology is updated from the third to the 3.5th generation, audio data that does not require high

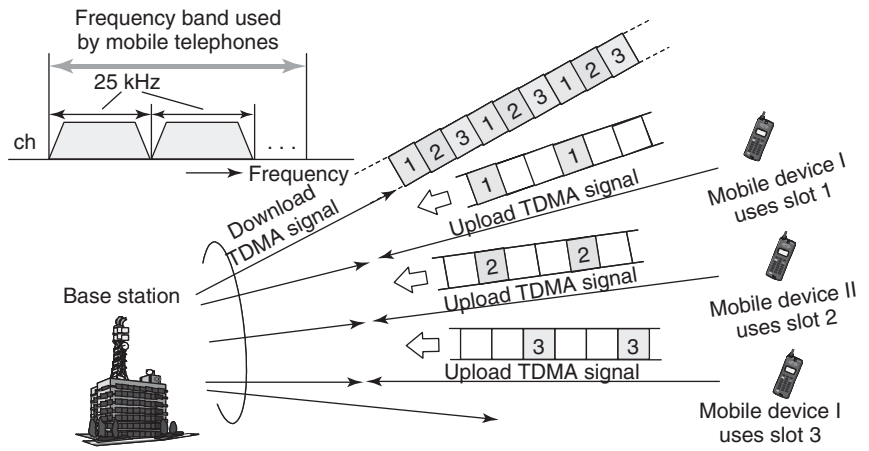

Figure 14. TDMA protocol.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

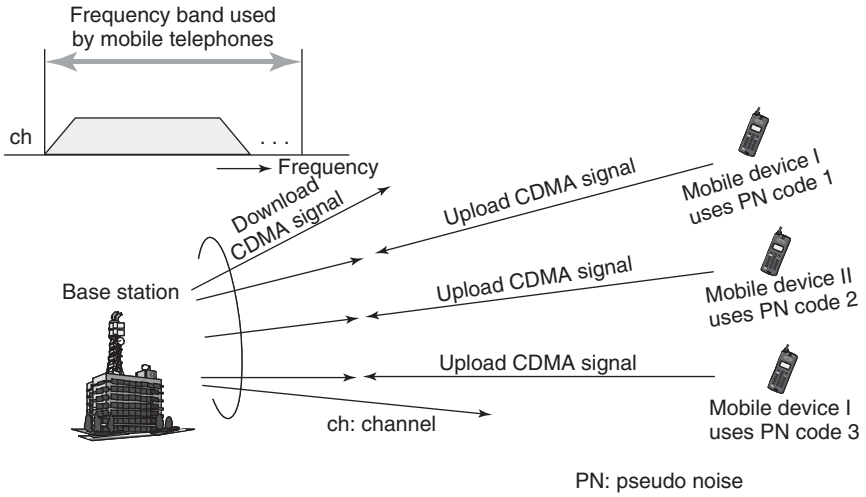

Figure 15. CDMA protocol.

speed communication will be transmitted at approximately 8 kbps. A high speed data communication function will be prepared separately from the audio channel to boost speed by changing the modulation protocol when required by the wireless communication state (Figure 16).

5.4.5 3.9th-generation communication

This technology is referred to as *long-term evolution* (*LTE*), and is capable of achieving communication speeds of 100 Mbps or higher. Multiple-input and multiple-output (MIMO) technology has been introduced to increase antenna speed, and orthogonal frequency-division multiple access (OFDMA) is used as the modulation protocol. OFDMA combines an orthogonally modulated subcarrier and technology such as 64-quadrature amplitude modulation (QAM) to achieve high throughput (Figures 17 and 18).

5.5 Services using mobile telephone networks

Various automakers are providing telematics services in vehicle navigation systems that use mobile telephone

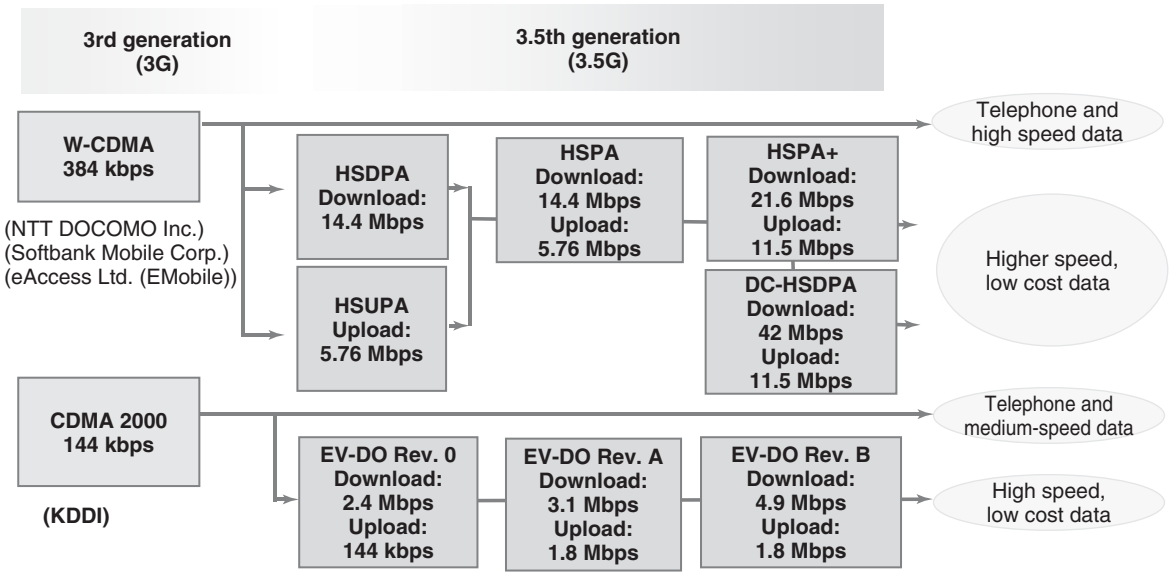

Figure 16. 3.5th-generation protocol.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

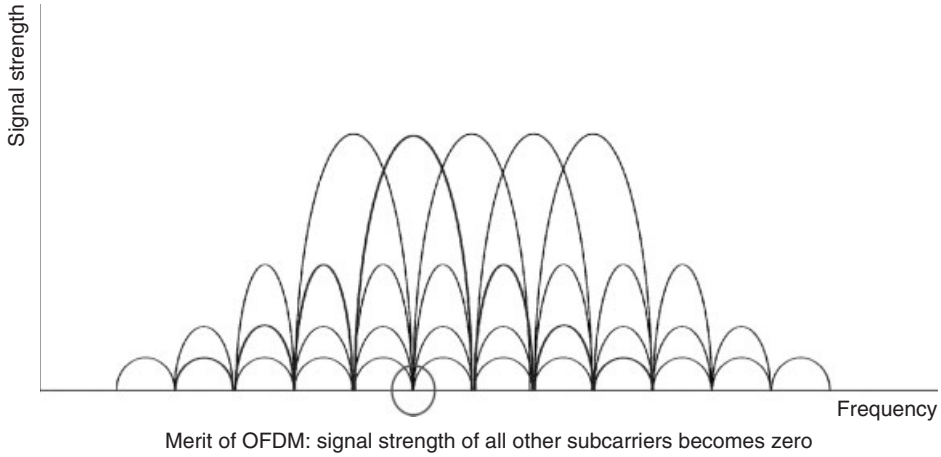

Figure 17. 3.9th-generation protocol.

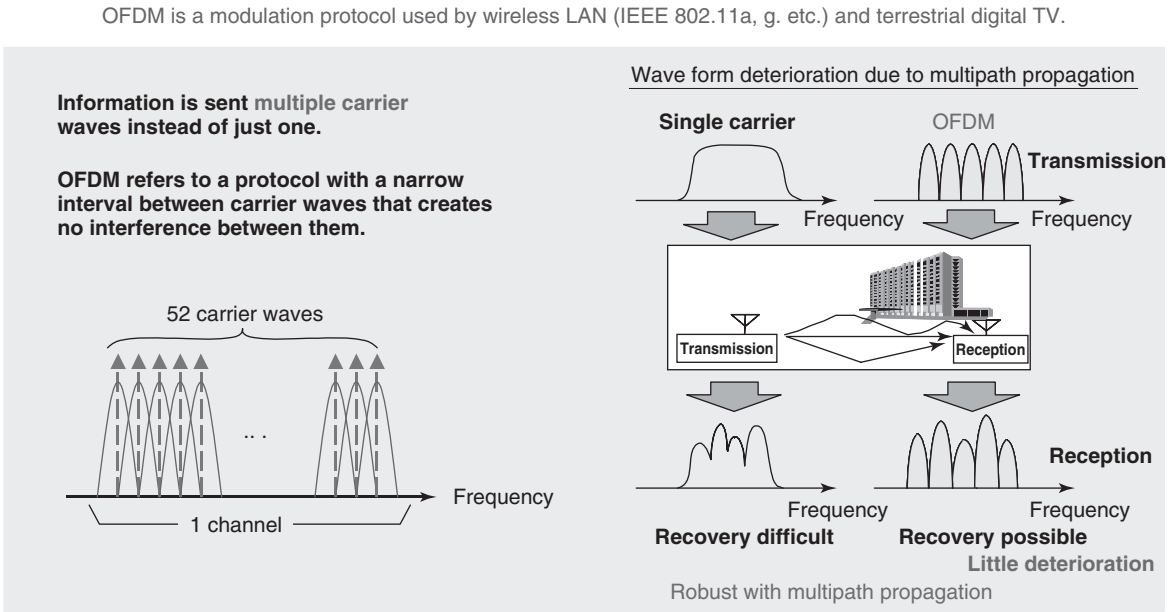

Figure 18. OFDM.

networks in combination with communication modules (Figure 19).

Automakers have introduced two broad categories of services, dedicated vehicle services and general-purpose services. Dedicated vehicle services include those related to (i) the vehicle navigation system and traffic information, (ii) safety and emergency services, (iii) vehicle services, and (iv) intelligent systems. In contrast, general-purpose services include (i) the provision of information such as news and weather forecasts, (ii) mobile commerce, (iii) multimedia entertainment, and (iv) mobile communication functions that display e-mails and the like through on-board devices. The following section gives a brief description of some of the general services offered by each automaker.

5.5.1 Emergency notification

System configuration: The system connects airbag deployment signals to an on-board wireless device. This device is connected to a microphone and speakers, and optionally to a backup battery. The backup battery ensures functionality even if the vehicle battery is damaged in a collision or the battery lines have been cut. Because the controller

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto231
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

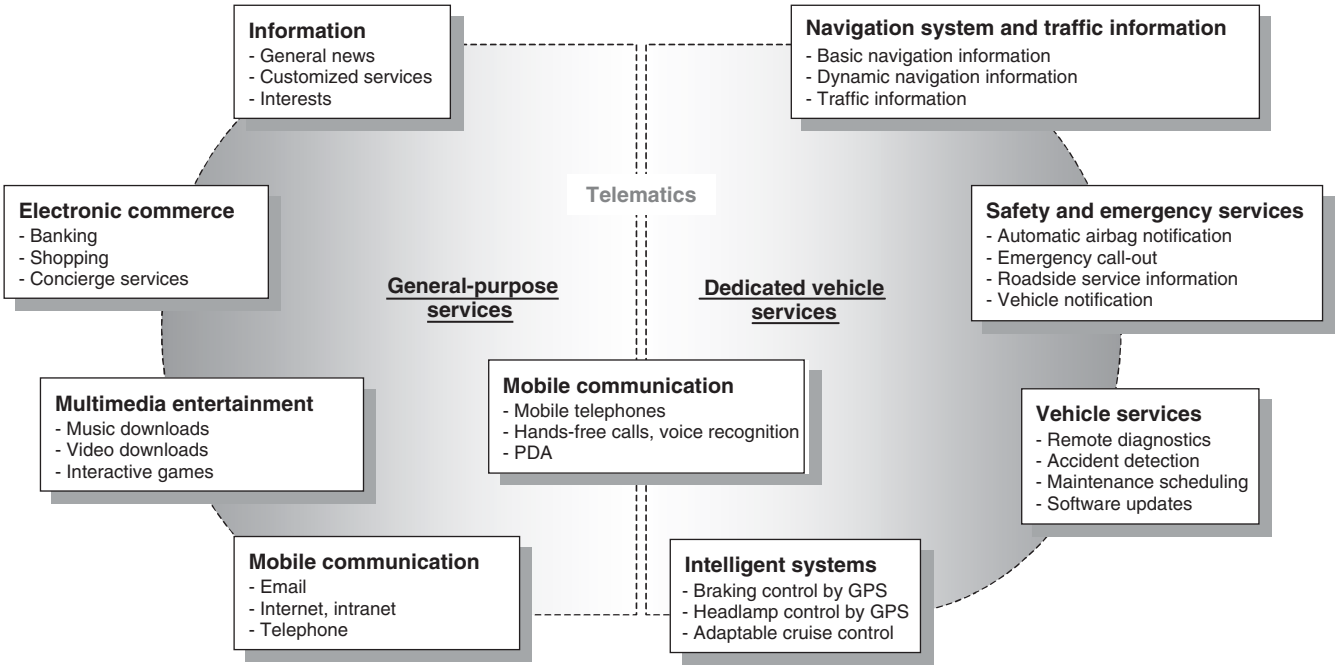

Figure 19. Example of telematics services.

area network (CAN) bus is also connected with each electronic control unit (ECU) in the engine compartment, it may suffer a short circuit or communication interruption after a collision. For this reason, a direct line is also used for communication.

1. If an accident occurs, the airbag deployment signal is communicated to the data communications module (DCM).
2. The DCM automatically notifies the support center of the accident location and other information.
3. The support center that received the emergency notification calls the driver, confirms the urgency of the accident, and summons emergency vehicles to the scene as required.
4. If the accident results in a situation in which the user of the system cannot respond to the operator, the operator calls emergency vehicles to the scene.

5.5.2 *Manual notification*

The on-board wireless device includes a switch that is pressed by the user to activate this service. Pressing the switch connects the user to an operator at a service center, who then provides the necessary road service by speaking to the user.

5.5.3 *Theft notification and tracking*

The on-board device is connected to an intrusion center and the smart key system. An alarm is then communicated by an on-board wireless device if abnormal vehicle entry is detected. Triggered by this alarm, the on-board wireless device communicates the vehicle abnormality to the emergency center, which sends a mail explaining the situation to the user's registered e-mail account. In addition, the user may request the center to track the vehicle. The center is capable of identifying the vehicle's current position by sending inquiry signals to the vehicle. Depending on the vehicle, the center can also send commands to lock the doors and shut the thief inside, or to reduce the vehicle speed.

5.5.4 *Operator services*

Users of vehicles with a wireless device-compatible navigation system can audibly notify the operator of their destination. The operator can then make complex navigation system settings by remote center command. Other operator services include remote door unlocking, access to medical networks, and so on.

5.5.5 *Remote services*

As the on-board wireless device is connected to the CAN bus, it can store various types of information at the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

center. That information can be viewed through the center homepage using a smart phone to check if the doors have been locked, or the like. The doors can then be locked or unlocked remotely. Other functions that can be activated remotely include the engine, automatic air-conditioning, and so on.

6 CONCLUSION

For vehicle users, the mobile phone is a necessary item. Telematics devices are becoming available in all vehicles as an accessory equipment.

The adoption of the LTE communication protocol provides a rough indication of the future of telecommunications. One example currently evolving is 4G communications. As it is a broadband protocol with a delay of less than 50 ms, LTE has the potential to enable various applications that have been difficult to achieve in the past. As an example, LTE may allow real-time remote operation of certain devices installed in the vehicle or of the whole vehicle itself. It might facilitate prevention of accident through active diagnostics that measure more detailed vehicle information in real time. Furthermore, LTE may also accelerate the introduction of autonomous driving technology through background communication.

DENSO Corporation, Kariya, Japan

1 ACTIVE SAFETY SYSTEMS

1.1 Relationship among the driver, vehicle, and driver assistance systems

Figure 1 shows block diagrams that illustrate the relationship among the driver, vehicle, and driver assistance systems. Figure 1a shows a vehicle without any controls, which is driven in accordance with the surrounding environment. Figure 1b shows a vehicle with a chassis control system. For example, the driver of this vehicle can perform avoidance maneuvers by steering as the anti-lock brake system (ABS) electronic control unit (ECU) detects tire lockup on frozen roads and reduces the brake pressure to recover grip. The role of chassis control systems is to enable the vehicle to be driven in accordance with the driver's intentions.

Figure 1c adds driver assistance control. As a result, the driver is located in parallel to the driver assistance system. This system processes the information from the surrounding environment and provides information to the driver. Specific examples include car navigation systems, night vision, adaptive front-lighting systems (AFS), and so on. Figure 1d includes systems such as precrash safety systems (PCS), adaptive cruise control (ACC), and lane keeping assistance systems (LKAS) that also function to control vehicle speed or the driving lane (Kato, 2010a,b).

Figure 2 summarizes the driver assistance and safety systems based on the relationship with a human model. This figure categorizes driver assistance systems into three categories based on Rasmussen's reflex skill, rule, and knowledge (SRK) model of decision-making. Chassis control is an example of skill-based assistance because it functions to supplement an insufficient action by the driver. ACC is rule based and it replaces the driver's function to maintain a set distance to the preceding vehicle based on vehicle speed. Car navigation systems are knowledge based and function to support the driving plan (Kato, 2010a,b).

This way of describing driver assistance systems suggests that supporting the driver and the vehicle through control that simulates the driver's brain is the future of the automobile, within the feasible range of autonomous driving. The sections below describe these driver assistance systems in more detail. These systems include those that simply provide information to the driver, and those that control the vehicle and assist driver operations (Masegi *et al*., 2007).

1.2 Driver assistance systems that only provide information

1.2.1 Night vision

Night vision is a device that enhances the field of view of the driver at night by displaying infrared images on

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto232

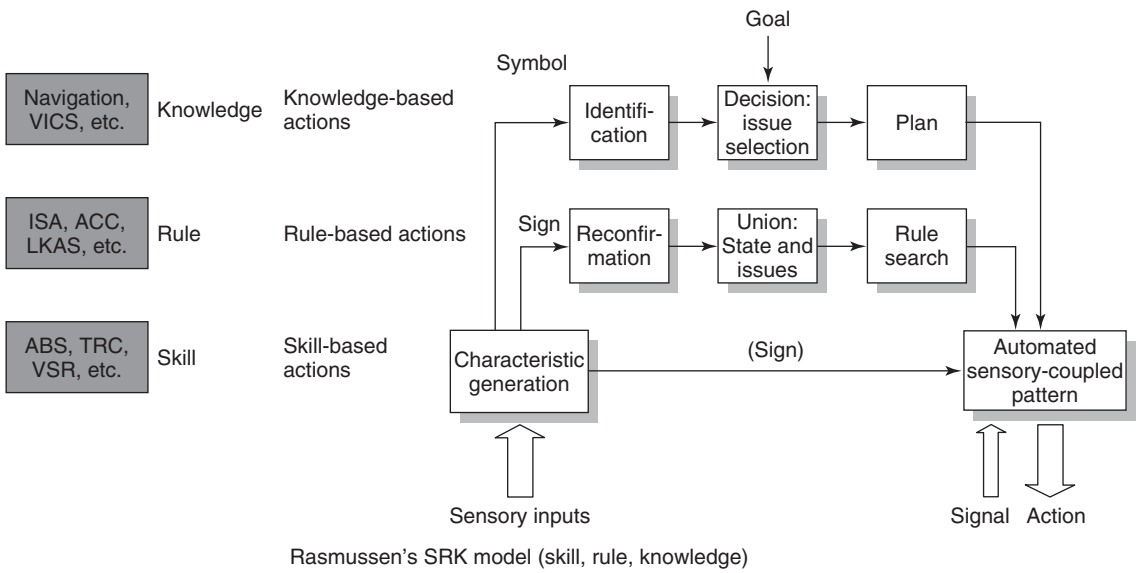

Figure 2. Human model and driver assistance systems.

a screen. There are two types of system, far-infrared and near-infrared. Far-infrared systems display images obtained from heat sources. The camera and lenses of this type of system are costly and the image quality is poor because of the long wavelengths of far-infrared rays. These include two-camera stereo systems that use heat sources to detect and emphasize the location of pedestrians at night.

Near-infrared systems illuminate the front of the vehicle with near-infrared light to obtain and display images using a camera sensitive to near-infrared rays. Some systems use a dedicated lamp or pass the light through a visible light cut filter placed in front of the high beam lights. Near-infrared rays can be used to obtain images that are close to those obtained using normal visible light. As a result, these systems are used for pattern matching recognition of pedestrians at night, the results of which are then emphasized and notified to the driver (Figure 3). The quality of these images is close to that of images obtained with visible light because near-infrared rays have short wavelengths.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

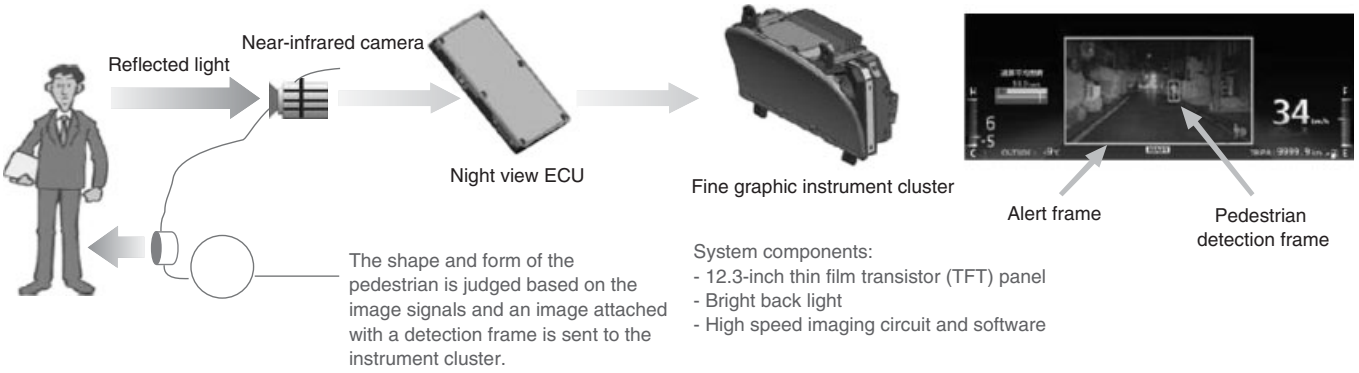

Figure 3. Night vision.

1.2.2 Adaptive front-lighting systems

AFS controls the optical axis of the vehicle headlamps to illuminate curves (Figure 4). For example, when the driver turns the steering wheel to the right to negotiate a right-hand curve, the steering angle and yaw rate sensors detect that the vehicle has entered a curve and move the optical axis of the headlamps to the right using motors. This helps the driver see the driving lane more clearly.

1.2.3 Other systems

Other examples of driver assistance systems that only provide information are proximity sensors such as rear-view cameras and sonar (Kato, 2010a,b).

1.3 Vehicle control systems

1.3.1 Adaptive cruise control

A conventional cruise control system maintains a set constant vehicle speed by controlling the engine only. In contrast, ACC uses radar as eyes to decelerate the vehicle using the brakes if the preceding vehicle is driving slower than the set speed. In this case, ACC maintains a constant vehicle-to-vehicle distance and then accelerates the vehicle to the set speed once the preceding vehicle has disappeared. Full speed range adaptive cruise control (FSRA) is capable of performing the functions of ACC at all vehicle speeds. Although a conventional ACC system will not function below around 40 km/h, FSRA can be used in all speed

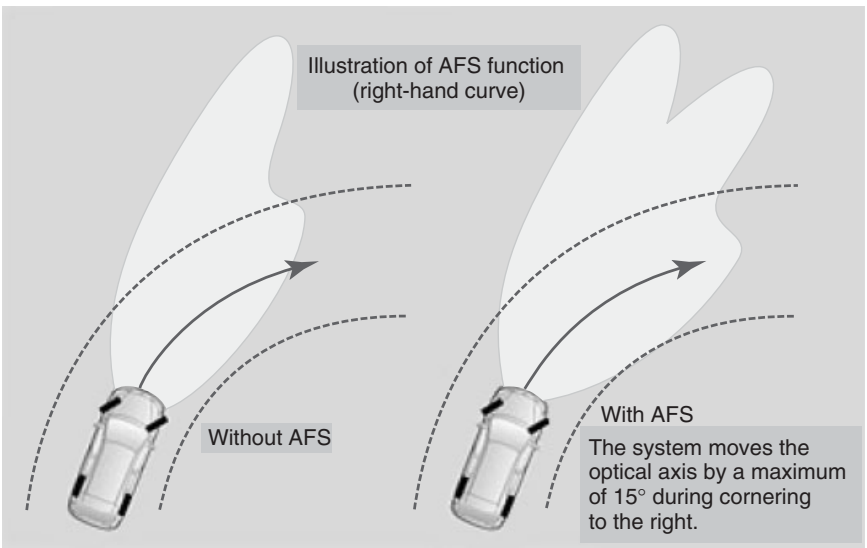

Figure 4. Adaptive front-lighting systems.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ranges from starts to stops. After the preceding vehicle has decelerated to a stop, the driver can perform a simple operation to follow that vehicle once it moves off (Kato, 2010a,b).

1.3.2 LKAS and lane departure warning (LDW)

LKAS recognizes the driving lane using a camera to detect lane markings. If the vehicle is about to leave the lane, LKAS applies assistance torque to the steering wheel to bring the vehicle back to the center of the lane. LKAS is designed to stop operating if the driver is not holding the steering wheel. Lane departure warning (LDW) warns the driver when the vehicle has left its lane. This alarm may use sounds or vibrations. Both of these systems monitor the operation of the turn signal switch and do not perform control or issue a warning if the driver intentionally turns the steering wheel by a large amount (Kato, 2010a,b).

1.3.3 Precrash safety systems

PCS systems may also be called *automatic emergency braking systems* (*AEBSs*) in Europe. Such systems use radar to measure parameters such as the distance to forward objects and relative speeds. If there is a risk of a collision, PCS systems warn the driver, tighten the electrically powered seatbelts, and increase the pressure of the brake fluid. If the driver depresses the brake pedal, PCS systems assist the braking operation. If the driver does not depress the brake pedal, the system brakes automatically. In Japan, the functions of PCS systems are regulated by technical guidelines. In passenger vehicles, the brakes are applied at an acceleration of 5 m/s^2 or more, which is more than twice the speed of ACC systems (maximum 2.45 m/s^2).

Although the most common type of radar is the 76 GHz band millimeter-wave radar, laser radars are also used. Systems have also been adopted that combine radar with cameras to increase the accuracy of collision judgment. Other systems monitor the state of the driver using a camera inside the vehicle and image processing to detect the orientation of the driver's face or the motion of the driver's eyelids. These systems then apply warning braking or early warning notification if the attention level of the driver is judged to be low.

Currently, PCS systems for head-on collisions are most common. However, PCS systems for collisions from the rear have also been developed and it is likely that the scope of these systems will be expanded to include side-on collisions, rollovers, and the like in the future.

Europe is leading the way to legislate the installation of PCS systems in trucks, which have the potential to cause major damage in a collision. In the United States, it has been proposed to expand the New Car Assessment Program (NCAP) to include a forward collision warning (FCW) system, which notifies drivers when a collision cannot be avoided, along with LDW. In the future, it is possible that these advanced safety systems will become standard equipment on all vehicles in the same way as airbags and ABS. The main issue is the cost of these systems, but this may come down with mass production after the introduction of regulations and standards (Kato, 2010a,b).

1.3.4 Closing vehicle warning (CVW) and blind spot monitor (BSM)

Systems such as closing vehicle warning (CVW) and blind spot monitor (BSM) monitor the blind spots behind the driver and issue warnings as required when changing lanes. The aim of CVW systems is to encourage safe lane changing by warning the driver when a vehicle is approaching from behind at high speed in an adjacent lane. BSM systems have the same aim and warn the driver of vehicles in the blind spots at the side. The range covered by CVW and BSM sensors is different. The range of CVW is approximately 30–50 m, whereas BSM covers only a few meters close to the driver's vehicle. Although these systems mainly use 24 GHz millimeter-wave radar, some also use cameras.

1.4 The eyes of driver assistance systems

This section describes the sensors used by driver assistance sensors. These include conventional acceleration (*G*) sensors, gyroscopes, global positioning system (GPS) information, and the like. However, the characteristic feature of these systems is the capability to identify target objects by a process of recognition from measured physical quantities. Millimeter-wave radar and cameras are the most typical examples of such sensors.

1.4.1 Millimeter-wave radar

Figure 5 shows a millimeter-wave radar manufactured by Denso Corporation, which is used in ACC and PCS systems. Figure 6 shows the antenna and circuit boards used in the radar. Automotive millimeter-wave radars employ various detection methods. The radar shown below employs the frequency modulation-continuous wave (FM-CW) method to detect distance and relative speed, and digital beam forming (DBF) to detect the direction. Figure 7 illustrates the principles of each method.

In Figure 7, the horizontal axes show the time, and the vertical axes show the frequency. The radar launches

Figure 5. Millimeter-wave radar.

pulses modulated to form a mound shape as shown in the figure. The time lag until it receives the reflective pulse is proportionate to the distance. Here, as it is difficult to measure the time lag accurately, the distance is obtained by calculating the frequency difference of fs−fr instead. The bottom graph in Figure 7 shows a case when a relative speed is present between the driver's vehicle and the preceding vehicle. In this case, the entire reflective pulse shifts because of the Doppler effect. Thus, the fs−fr difference becomes smaller by the amount of the Doppler effect at the rising portion, and the difference becomes larger at the descending portion. The relative speed can be obtained by subtracting the differences in the rising and descending frequencies, and the distance by adding up the differences.

Figure 8 shows the direction detection principle. An outgoing pulse is transmitted from a one-channel antenna, and the reflective pulse is received by a five-channel antenna. As the path length of the reflective waves that reach the channels varies depending on the direction from which it comes, the direction is obtained by detecting the phase difference between the channels. The latest sensors add a new signal processing technology called *multiple signal classification* (*MUSIC*) to improve the separation performance of targets positioned closely (Miyake Y *et al*., 2007).

When driven on actual roads, radio wave interference due to the reflection of various objects at the side of the road generates ghost images and objects that are irrelevant to the detection targets, such as manhole covers that are almost the same height as the road surface. The post-processing technology that recognizes, categorizes, and discards these objects is extremely important. One typical issue is merging, in which two adjacent objects are detected as one. If the preceding vehicle merges with a stationary object at the side of the road, the system may judge that the vehicle has instantly braked. In response, tracking with

Kalman filters, processing with target selection algorithms, and methods to improve resolution are employed to enable appropriate recognition.

FM-CW and DBF are means of analyzing and processing reflective waves using calculations based on fast Fourier transform (FFT). The growing sophistication of automotive microcomputers and advances in digital signal processing technology are supporting the adoption of systems that use millimeter-wave radar.

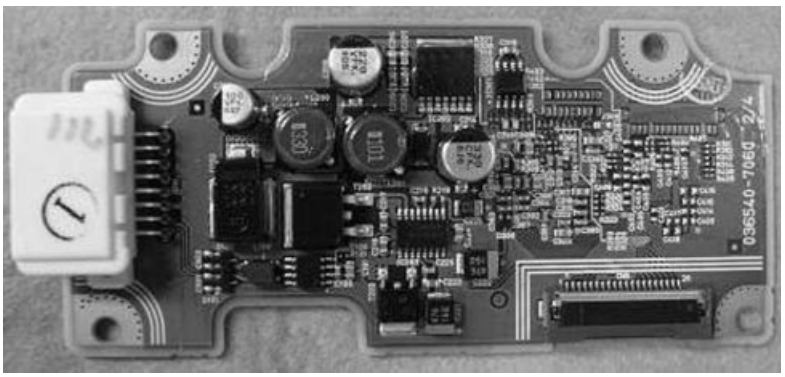

Figure 11. Camera circuit board.

detect straight lines using an algorithm called the *Hough transform*. Finally, tracking is performed using a Kalman filter to improve the precision frame by frame. As roads are not always straight, a method called *model matching* is used to handle curves.

Cameras are more susceptible to disturbances than millimeter-wave radar. The key for a camera-based system is achieving stable recognition with respect to disturbances such as day/night differences, the entrance and exits of tunnels, sunlight and shade, the afternoon sun, rain, wet road surfaces, faded or interrupted lane markings, glare, and halation. As a result, optical technology such as the image sensor, exposure control, and optical design of the lens assembly is extremely important.

Recently, software that recognizes vehicle bodies has been integrated with millimeter-wave radar for use in precrash brake systems. This so-called sensor fusion technology that incorporates millimeter-wave radar systems is capable of accurately calculating the potential of collisions, leading to more appropriate brake application (Masegi *et al*., 2007).

Recognition targets have also begun to expand from lane markings to include systems that recognize traffic signs such as speed limits, and warn the driver if the set speed is exceeded, systems that warn the driver of pedestrians, and so on. Pedestrian recognition uses an image processing technology based on pattern matching. The recognition targets are extremely complex and use dedicated high-performance processors such as the EyeQ from MobilEye and IMAPCAR from Renesas Electronics. EyeQ is hardware that contains a recognition image processor (IP) and uses an innovative means of accessing an image memory bus. IMAPCAR is a unique high speed architecture that enables parallel processing by 128 processors, and the like.

1.5 Future driver assistance systems

Sensors have already been developed that monitor the front, sides, and rear of the vehicle, as well as the driver. Infrastructure-coordinated systems can be combined with these autonomous type vehicle sensors to recognize the traffic flow situation. In addition to safer driving, such systems can be used to help reduce fuel consumption and provide route information. Furthermore, it may also be possible to use vehicle-to-vehicle communication to achieve platoon driving and various other services (Gallagher B *et al*., 2007).

Junction Blocks Simplify and Decrease Networks When Matched to ECU and Wire Harness

Takezo Sugimura, Kaoru Sugimoto, and Mamichi Tsuyuki

The Furukawa Electric Co., Ltd, Hiratsuka, Japan

1 INTRODUCTION

In this chapter, there is a description of the growth in the number of electronic control units (ECUs) and wire harnesses with the change in vehicle systems over time and the introduction of vehicle installation local area network (LAN). The number of ECUs on a vehicle has increased with new introductions and extension of vehicle systems year by year. Integration has been applied to control this ECU increase.

Along with this, the number of wire harnesses and their weight have increased, too. In addition, with the introduction of multiplex communication control, the computerization of the system and in-vehicle LAN has been introduced. Reduction of the amount of wire harnesses has been achieved by the introduction of this in-vehicle LAN.

2 CAR ELECTRONICS

2.1 Transition of car electronics

In the 1950s, motorized body electric equipment has progressed, with the introduction of, for example, starters, wipers, power windows, and air-conditioning.

In the 1960s, automotive electronics still had single-control-function devices, such as voltage/current regulators and igniters. Later, in the 1970s, it became possible to control complex functions such as anti-lock brakes (ABS), air-conditioning, and fuel supply control by the advent of the microcomputer.

Since the 1980s, with the improved performance of the semiconductor, the reduction of cost and size in automotive electronics has progressed rapidly. After that, the installation of versatile electronic control for various individual systems made the wide expansion of applications possible (Figure 1).

In the late 1990s, engine, brakes, and power-integrated control systems were mounted on to HEVs (hybrid electric vehicles), which support an energy regeneration function.

Moreover, in recent luxury cars, vehicle lane-keeping functions, with integrated engine, brakes, steering control, and cooperative driver assistance systems that utilize infrastructure and information technology, have appeared with the aim of improved safety and comfort.

In addition, electric vehicles (EVs) and fuel cell vehicles that have no internal combustion engines have been developed with full-by-wire systems that have no mechanical backups at all. The aim is to introduce a system of full-by-wire (The Institute of Electrical Engineers of Japan, 2006, pp. 8–9).

Currently, by-wire systems such as throttle-by-wire, brake-by-wire, and shift-by-wire have been put to practical use. However, the complete control only using the by-wire technologies has not been achieved. For example, brake-by-wire keeps a safety mechanism in combination with a mechanical transmission. Steering-by-wire has still not been put to practical use, but progress of motorizing the steering is moving forward with electric power steering (EPS) and active-steering. The installation of the steering-by-wire system has started on many vehicles. For complete steering-by-wire, the most important developmental challenges are the establishment of reliability, development of legislation, and a dedicated communication protocol for practical use. These are progressing, and it is expected that market introduction will occur in the near future. By the introduction of by-wire systems, the mechanical transmission mechanism can be eliminated from the operation of the vehicle, and thus the flexibility of automotive design will be significantly increased. Many benefits such as space, power consumption, lighter weight, fuel consumption, and cost reduction can be expected. For this reason, the next generation of cars will be built with a system only using full-by-wire.

3 INCREASE OF ECUs

3.1 History

3.1.1 Outline

Undergoing this transition of car electronics, the number of ECUs and circuit wire harnesses has undergone rapid changes. An example of the growth of the number of ECUs mounted on a luxury car is shown in Figure 2.

By increasing the systems installed in a given model of car, at every full model cycle, the number of vehicle ECUs tends to increase. The number of ECUs is increasing in luxury vehicles more than smaller cars. In the example of the luxury car shown in Figure 2, the number of ECUs exceeded 70 in 2005, whereas in 2010, 100 or more ECUs are installed. The reason for the ECU increase is due to the addition of comfort and safety features at an acceptable price and environmental protection functions since 2000 (Figure 2).

In classifying ECUs by their functions, such as "HEV/EV system," "safety system," "information systems," "body electronics system," and "power train system," every function tends to increase in the number of ECUs.

3.1.2 Power train

Power train systems have one or two ECUs for the transmission and the engine. The number of ECUs depends on whether the function is integrated or independent. In recent years, for the realization of high engine efficiency, various systems have become electric-electronic. Processing by the engine ECU only is possible if the electronic control is simple, such as adjusting value timing, but if the aim is to control a complex motion, such as electric controlled variable valve timing and lift, to avoid strain on the engine ECU, a dedicated valve train ECU has begun to be installed.

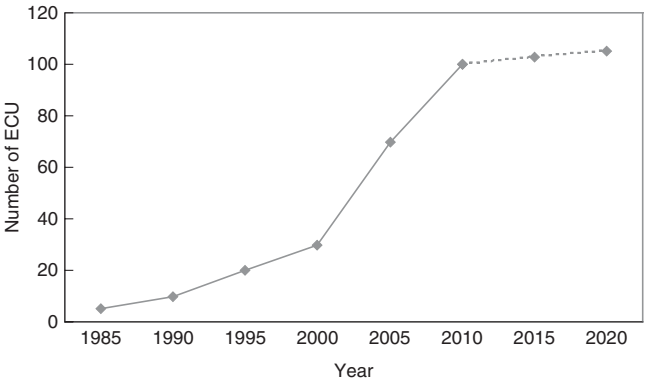

Figure 2. Transition of the number of ECUs (luxury car).

An automatic stop and start control system, which is basically controlled by the engine ECU, may be performed by an increasing number of dedicated ECUs to accommodate factors such as supply voltage fluctuation.

3.1.3 Body system

Body system ECUs include air-conditioning, meters, smart key, latches, body control module (BCM), and so on. Basically, each ECU is installed individually. In some cases such as BCM, some control functions are integrated, for example, lighting system such as head lamps, door locks, wipers, and interior lamps. On the other hand, by functional integration to the BCM, there are increased problems in the number of circuit wire harnesses and need for increased installation space because of the larger ECU. For this reason, the case for mounting a dedicated ECU depends on how many functions for control are needed. For example, ECUs mounted on the doors, the engine, or around the steering. It is considered that there will be an increase in separated BCM functions controlled by ECUs in distributed areas.

3.1.4 Information system

ECUs of information systems, such as navigation, audio, telematics, and digital TV, have dedicated ECUs for each system, because there are many system configuration options. In the future, the addition of various information

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto233
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and services, such as communication between car and car and car and road transport infrastructure, will increase the number of ECUs further.

3.1.5 Safety system

The ECUs for safety systems, such as airbag, electronic stability control (ESC), vehicle camera systems, radar systems, and peripheral monitoring, have, because there are many system configuration options, dedicated ECUs mounted for each system. In the future, the addition of advanced safety functions will require an increase of ECUs.

3.1.6 Hybrid electric vehicle/electric vehicle

In the ECU systems of HEVs/EVs, the number of ECUs differs from that of an EV to a mild-HEV or a strong-HEV. Typically, dedicated ECUs are mounted for motor control, HEV/EV management, inverter control, and battery management.

3.2 Problems of increased ECUs

While increased ECUs can deliver benefits, a significant problem is that the space where the ECU can be mounted in the vehicle is limited. Usually, the place is in the vehicle cabin, such as the foot space under the driver's seat or passenger's seat, as a good temperature and/or vibration condition is required. On the other hand, expanding the cabin living space in the quest to comfort leaves less space for the ECU. Thus, it is difficult to keep the space for the ECU and this has become a serious problem.

In order to solve these problems, reducing the number of ECUs by integration is underway. For example, in the case of BCM, some ECUs belonging to the body electronics function are integrated into one ECU. In the case of safety systems such as the driving support ECU, the system is integrated with the face-direction-detecting ECU, the millimeter-wave radar ECU, and the stereo-camera ECU. In the case of the information system, an ECU is mounted in the center display module that is integrated with the audio and navigation ECU.

This ECU integration trend is expected to expand more and more in future generations of vehicle. In the future, the integration of ECUs will proceed beyond the function field, such as information systems and safety systems with the system detecting the field around the car.

3.3 Predictions for the future

Beyond the integration of ECUs, integrating power lines and signal lines that were necessary for the individual ECU is becoming possible; the effect is a reduction in overlapping circuits on wire harnesses.

Thus, as was indicated in Figure 2, the number of ECUs on a vehicle will tend to decrease as existing systems integration proceeds. However, this reduction effect is offset by the increase of ECUs with new systems. Therefore, the trend in the number of ECUs may remain flat until around 2020, or it may only increase slightly (Tanokura, Shindou, and Okubo, 2006, p. 115).

4 HISTORY OF WIRE HARNESSES

4.1 Historical trends in number and weight

An example of the trend in the number of circuits mounted on a luxury car is shown in Figure 3. The trend in wire harness mass for the same luxury car is shown in Figure 4.

For environmental control, safety, and comfort, electrical systems in cars have been increasing in functionality and circuits per vehicle wire harness every year.

Moreover, the number of wire harnesses will also increase as new electrical systems are added, and ECUs and multiple types of electrical equipment such as switches, sensors, valves, and motors are connected in a one-to-one connection.

In the past, when new electrical systems have been added, the number of circuits increased to a dozen at most, but the electrical systems advanced in recent years, which mean that 30–60 extra circuits have been added in one system.

4.2 Problems of increased wire harness

Although the space for mounting the vehicle wire harness is limited, owing to an increase in the number of these circuits, the problem of finding a suitable location for the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

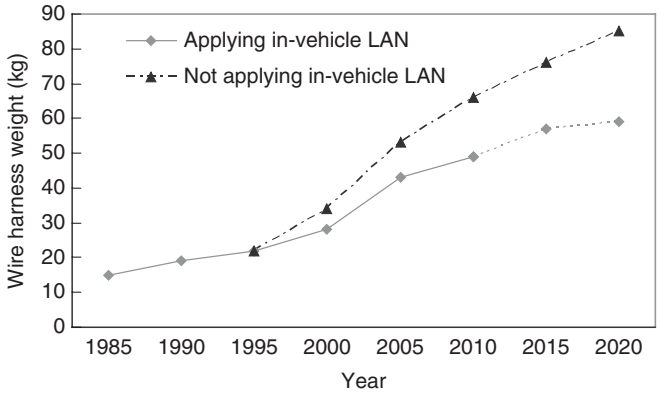

Figure 4. Transition of the wire harness weight (luxury car).

wire harness has arisen. In addition, the increase in the number of circuit wire harnesses has led to an increase in the vehicle weight and a deterioration in the ease of assembly work of the vehicle. As is required to improve the fuel efficiency of automobiles because of the rise of environmental concerns in recent years, the reduction in the weight of the entire car is being promoted and therefore lighter wire harnesses are also required.

4.3 Introduction of in-vehicle LAN

In order to solve these problems, the technology of in-vehicle LAN had begun to be introduced from the 1980s. Figure 3 shows the number of circuit wire harness introduced with the presence or absence of in-vehicle LAN. Comparing the 1990s to the present, the circuits increased from 1000 to 2600 circuits (applying in-vehicle LAN), but the increase of the number of circuits is estimated to be up to about 3500, without the introduction of in-vehicle LAN.

Figure 4 shows the mass growth of the wire harnesses in the presence or absence of in-vehicle LAN. Comparing the 1990s to the present, wire harnesses have increased from 15 to 49 kg (applying in-vehicle LAN), and the increase in weight of wire harnesses is estimated to up to about 66 kg if there is no application of in-vehicle LAN.

In this way, even though new electrical systems have been added each year, by introducing the vehicle LAN mode, it is possible to suppress the increase in the number of circuits and wire harness mass.

4.4 Rearranging of power supply distribution and the wiring

Generally, there are two roles for the junction block. The first is the storing/fixing/protecting the safety equipment such as a fuse, the relay, or the control of the power supply ON/OFF by the relay or rearranging the power supply distribution according to load and the joint circuit of the power supply. Secondly, there is a role for an organizing BOX wire harness to split the wire harness, to make for easier assembly in the vehicle. Duplication of circuit power lines and signal lines can be reduced by the aggregation of components for safe distribution and function, including power in the junction block, thus realizing a reduction of wire harnesses.

4.5 Decentralization of the power supply

In recent years, with the increase in the number of electrical systems for environmental, safety, and comfort purposes, there has been a rise in the number of circuit wire harnesses. Architecture has been considered to be a solution to this problem, by the distribution of the power source to the junction block for each area (i.e., a decentralization of the power supply). Specifically, a junction block placed on the engine, where the electrical equipment is concentrated, in the driver's seat and passenger's seat sections, the instrument panel section, or the center cluster section. Such decentralization of power reduces the wire harness power delivery (e.g., circuit lighting or a ground circuit). In addition, further lightweight wire harnesses can be used by minimizing the total wire length of power lines and electrical equipment cable leading to further weight reduction. Moreover, the power distribution architecture with in-vehicle LAN connections between the junction blocks for each area makes it possible to share power control information. The purpose of this power distribution method has the effect of reducing power by efficient distribution and management of ordered power, avoiding enlargement or concentration of the wire harness. In addition, ordered power distribution architecture contributes to the standardization of power supply arrangements: the standardization of power distribution (The Institute of Electrical Engineers of Japan, 2006, p. 18). It follows that junction blocks will have the role of power management and distribution control functions.

5 NETWORKS BETWEEN ECUs

5.1 Histories

Figure 5 shows an example of network deployment and the time of application LAN technology started to be introduced into cars from the 1980s. Many automobile manufacturers adopted in-vehicle LAN interfaces using their own original

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto233
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

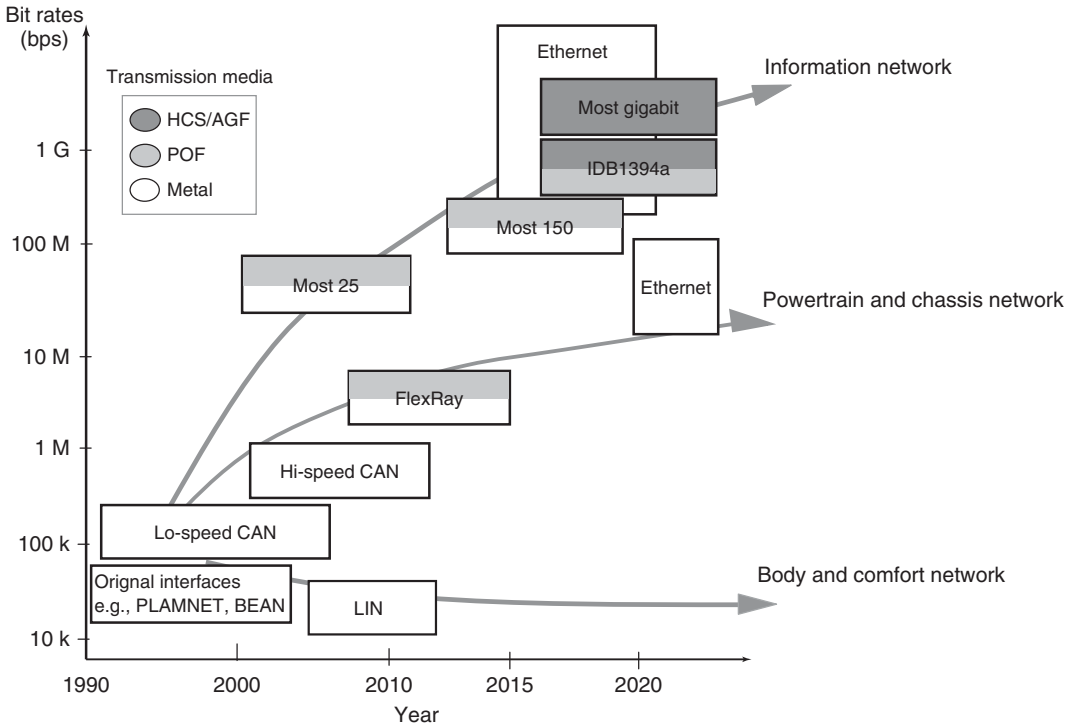

Figure 5. Network deployment and transition period.

standards developed independently of each other. Introduction of the automotive in-vehicle LAN began with the body control system. Examples are Chrysler "C2D", GM "J1850VPW," in the year 1990, Daimler "CAN," BMW "I-BUS" and "K-BUS," Toyota "BEAN," Mazda "PLAMNET," Honda "MPCS," and Nissan "IVMS." In many of these original interfaces, the data transmission speed was about 10 kbps.

5.2 Standardization of in-vehicle LAN

Not only does the wire harness continue to increase in number of systems installed in vehicles, but also there is a problem with the lack of data transmission speed in the standard interfaces previously adopted. From around 2000, world automobile manufacturers started to adopt the controller area network (CAN), which is a single interface for standard in-vehicle LAN.

In this way, CAN has become the mainstream in-vehicle LAN, although other LAN interface standards have also appeared since 2000. Those are not developed for each automobile manufacturer, as was the case in the 1980s, but standardized organizations such as Tier1 suppliers, automobile manufacturers, and semiconductor manufacturers participate and formulate optimal in-vehicle LAN standards for each vehicle system.

5.3 LAN structure

As shown in Figure 5, several kinds of standard LAN interface are used according to the difference of data transmission speed, purpose, or reliability.

Classification according to the in-vehicle LAN domain can be divided into three systems: control systems, body systems, and information systems. CAN and FlexRay are control systems, CAN and LIN are for body electronics systems, and MOST is for the information system; all are used widely as the typical in-vehicle LAN.

In this way, communication goes ahead through multichannel LAN in the car, which is made up of plural subnetworks and used properly according to the domain. Currently, a typical luxury car may have multichannel networks composed of a LIN local network of multiple channels, MOST subnetworks, and nine channels of CAN subnetworks. Transmission of information between these subnetworks has been realized by a dedicated gateway ECU; its gateway function is set up to connect with the ECU's multiple plural subnetworks.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto233
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.4 Problems of high functionality of electronic control

So far, with the high function of cars, LAN has been applied to cooperation or integrated controlling functions, by sharing actuator and sensor information between ECUs. In future, equipment related to the precrash safety advanced safety features developed in order to prevent a car accident, which will have wide applicability in the next generation of cars, and if cooperative control of vehicle infrastructure and road traffic by intelligent transport systems (ITSs) becomes widely used, the importance of in-vehicle LAN systems connecting each ECU is expected to progress further.

On the other hand, MOST and CAN have limits with this transmission speed; the maximum transmission speed of CAN is 1 Mbps and MOST25 is 25 Mbps. It follows that there can become a difficult situation transmitting by MOST25 or CAN, with an increased number of ECUs or growth in complexity of control, when the amount of data increases dramatically.

For example, control systems for the basic function of vehicle running required the improvement in motor control, to enhance vehicle safety, for which LAN interfaces need higher reliability and a faster real-time response. In addition, in information systems, LAN interface standards require emphasis on communication speed and a large amount of data transmission, with increased application of environmental monitoring cameras and simultaneous streaming of audio and video that this will mandate (Tanokura, 2011, p. 11).

5.5 Next-generation standard LAN interface

To compensate for these weaknesses and new requirements, various next-generation standard LAN car interfaces are being developed. In control systems, the standard interface equivalent to the next generation of "CAN" is "FlexRay," which has better speed and reliability, and guarantees a response at a given time, with a maximum transmission speed of up to 10 Mbps, and has begun to be adopted in some luxury cars. Other standardizations, such as the "automotive Ethernet" as a long-term measure, are being developed.

In information systems, the equivalent to next-generation "MOST" are "MOST150" with up to 150 Mbps transmission speed, "IDB1394" with a maximum transmission speed of 800 Mbps, and the "Ethernet" with a maximum transmission speed of 1 Gbps, as the standards for transmitting voice or video data.

The "Ethernet" has been developed as the standard to encompass both control and information systems in the long term.

In this way, the transmission speed of the next-generation standard LAN interface is moving in the direction of large capacity/high speed communications. In addition, using a standard LAN interface of the next generation, it will be possible to interact faster with much more information. This will be needed unless the number of ECUs does not decrease dramatically, using multichannels with multiple subnetworks (Noumi *et al*., 2007, p. 20). However, it is thought that the future LAN constitution in the car will be multichannel and layered according to domain, with CAN, LIN, MOST, and Ethernet.

6 CONCLUSION

The introduction to the function of the junction box, the in-vehicle LAN, and integration of multiple ECUs discussed in this chapter has become indispensable in the solution of issues such as the increase in the number and weight of the wire harness circuits to transmit power and signals with the increase in number and ECUs as new electrical systems that are mounted on a vehicle. To build the overall architecture of the automobile electrical system by combining these solutions, to be developed further are the methods that deliver lightweight wire harnesses and reduced numbers of ECUs and the number of electrical systems for an increasingly complex future vehicles.

The Wire Harness

Takafumi Kawauchi, Masaharu Onda, Kenji Matsuo, Yukihiro Kawamura, Yoshihiro Shiotani, and Nobuaki Sakai

Furukawa Automotive Systems, Shiga-ken, Japan

1 INTRODUCTION

A power supply system in a vehicle electrical system has three basic functions: power generation represented by an alternator, power supply-storage function represented by a battery, and power distribution represented by a wire harness. In this chapter, we discuss the power distribution function of the wire harness.

2 THE WIRE HARNESS

The "wire harness" is a collective term for the composition of a set of wires used for supplying power and transmitting signals linked to electrical equipment by means of connectors, clamps to install these wires in the units, and protectors to protect the wires from damage. Functional parts such as the junction block (J/B) and the relay block (R/B) are also included in some cases. The wire harness that is used for modern automobiles with an internal combustion engine has drastically changed in the latter half of the twentieth century with the introduction of advanced electronics in vehicles.

An electronic engine-management system, with which controlled ignition and injection timing was introduced by Bosch in 1979, achieved fuel efficiency improvement and exhaust emission reduction. Today, this system is widely used because of tight regulations on exhaust-gas emissions, as part of global environmental consciousness. The introduction of the engine-management system has largely influenced the wire harness structure. For instance, the R/B has been added to the wire harness because this system composed of many relays. Owing to the addition of R/Bs, the wire harness divided into parts, as the wire installation was unable to pass through the hole between the engine room and the indoor area with the normal through the hole. For a switch system utilizing the R/B in the indoor area, direct switch types replaced relay types, so this replacement was an important factor in altering wiring routes.

Wire harnesses have increased their presence in terms of role and volume in the introduction of advanced electronics. The total length of wire per vehicle has extended from 35 m (16 connectors) in 1949 to 150 m (200 connectors) in 1965 and then surged to 2000 m (1500 connectors) in 1990 (Eckermann, 2001, p. 204). For vehicle reliability, weight reduction, and space saving, the introduction of local area network (LAN: multiplex telecommunication technology) systems started in the 1980s, and controller area network (CAN) systems were announced by Bosch in 1986 and practically used in 1992 in order to reduce wire volumes (see Increase of ECU and Wire Harness,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

JB Simplify and Decrease Networks). Nevertheless, the introduction of sophisticated electronic systems such as the by-wire system, already introduced in the aviation industry, has induced much higher dependence on electronics. The cost of electronics was about 15% of a vehicle in 1992; this rose to reach 25% in the early 2000s and is now expected to surge to up to 50% after 2010 (Eckermann, 2001, p. 205; Gomes and Fernandes, 2010, p. 378). As a result, wire length now extends to 1000 m even for small cars, and is no less than 4000 m for luxury models.

Owing to the wire volume increase in recent years, the wire harness was required to be much smaller and lighter, so conductor downsizing and insulation thickness thinning have been developed. As for conductors, core size was reduced from 0.5 mm^2 of annealed twisted copper wire to 0.3 mm^2, and 0.3 mm^2 of annealed core wire was replaced by 0.13 mm^2 of alloy copper after 2000. Meanwhile, the insulation thickness was reduced to 0.2 mm. As a result, about 10–40% core size reduction and about 30–60% weight saving was achieved (in comparison, 0.5 mm^2 of annealed twisted copper wire with 0.3 mm^2 of alloy copper and 0.3 mm^2 of annealed core wire with 0.13 mm^2 of alloy copper). Further, wire harness weight reduction (about 30% reduction compared to conventional wire harness) was achieved by the introduction of a flexible, flat cable with rectangular-shaped conductors. There has also been the movement to introduce aluminum for the conductor instead of the now dominant copper, to reduce the risk in fluctuations of material prices.

Moreover, investigation of environmental technology was activated during late 1990s. After the introduction of lead-free and high recyclability insulation material, halogen-free polyethylene (PE) was developed around 2000 as a replacement for polyvinyl chloride (PVC) and has since been applied to the automobile wire harness. For PVC-insulated wires, much thinner insulation reduced its usage.

The wire harness in electric vehicles (EVs) such as hybrid electric vehicles (HEVs), EVs, and fuel cell vehicles (FCEVs), introduced with the objectives of fuel efficiency improvement and carbon dioxide reduction of exhaust gases that should withstand over 200 V and be required to resist vibration and electromagnetic noise (IRC, 2010, p. 795).

The wire harness volume tends to enlarge in high demands for comfort, convenience, and safety such as intelligent transport systems (ITSs) (see Intelligent Transport Systems: Overview and Structure (History, Applications, and Architectures), and precrush safety systems. In addition, the wire harness has begun to play an important role in the requirements of communications with social infrastructure, households, and other automobiles, thus meaning that continuous improvements of weight reduction, downsizing, and cost reduction of wire harness are indispensable.

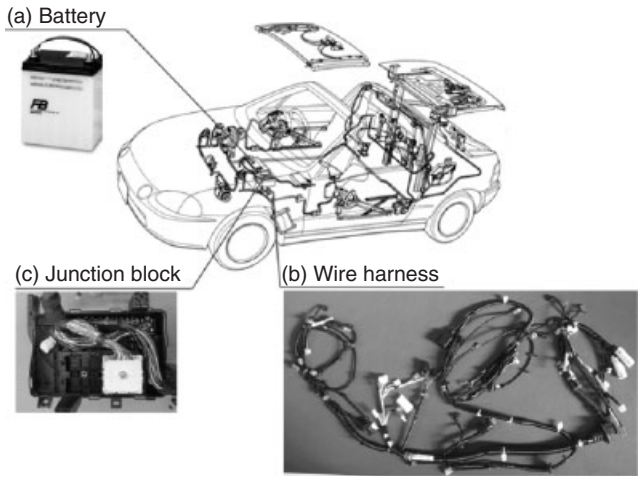

Figure 1. (a–c) Example of wire harness and related parts in a vehicle.

2.1 Role of the wire harness

The battery (Figure 1a) supplies electric power and the engine is started by activating the starter motor. After the engine starts, the power-generating alternator supplies electric power to the power supply block. The power supply block is equipped with power-related parts such as wire-protecting fuses and switching relays. Once the power supply block is activated, power is supplied to each unit.

The wire harness (Figure 1b) connects these units and supplies power and transmitting signals. The total wire length depends on the vehicle and has a range of approximately 1000 m for a small vehicle to 4000 m or more for a higher grade vehicle. Although the wire harness is installed out of sight, it serves an important function in the vehicle.

Power supply blocks such as the R/B with relays, fuse block with fuses, and J/B (Figure 1c) with relays and fuses and circuit connections are used in a vehicle. These power blocks are located in the engine room (under the bonnet/hood) or the instrument panel. The location of the power supply block depends on the individual car maker or model.

2.2 Wire harness types and examples of grouping

Wire harness grouping depends on the installation condition, power supply distribution, and operating environment.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The following are the wire harness types and features in a typical sedan-type vehicle.

2.2.1 *Battery harness*

The battery harness supplies power from the battery to the starter, power block, and other systems. Owing to the high current, large-size wires are used.

2.2.2 *Engine harness*

The engine harness is assembled on the engine itself. Wires are routed along the engine, which generates high heat and therefore heat-resistant wires and tubes are used on this wire harness. Also, designing an engine harness requires engine vibration to be considered.

2.2.3 *Engine room harness*

This type of harness is assembled on the body panel in the engine room. Waterproofing is important as well as the engine harness. Wire protection is also required when it is assembled around metal brackets, brake pipes, and so on.

2.2.4 *Instrument harness*

Instrument harnesses are installed inside the instrument panel. This harness is mainly connected to various instruments and audio switches. Since this harness is located inside the vehicle, chattering noise suppression is needed.

2.2.5 *Floor harness*

The floor harnesses are installed on the indoor floor of the vehicle, and located widely from the front to the rear of the vehicle. These harnesses tend to be longer as they cover the floor area.

2.2.6 *Other small harnesses*

Small harnesses are divided in the process of installation process and operating environment. Examples of small harness types are found in the door, trunk room, and so on. Door harnesses require a high durability design that will withstand door opening/closing.

Other than the examples listed above, there also are hybrid harnesses combining the engine room harness, instrument harness, and floor harness or combining engine harness and engine room harness.

2.3 Functions of wire harness components

This section introduces the main components of wire harnesses and their functions. Examples of the wire harness components are shown in Figure 2 and their functions are listed in Table 1.

(a) Wire
(b) Connector
(c) Clamp
(d) Grommet
(e) Tape
(f) Protection part

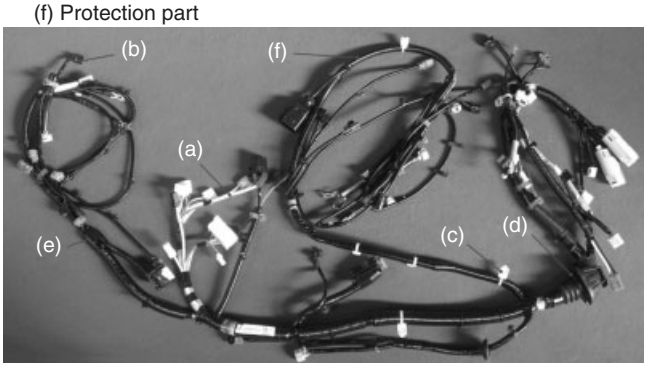

Figure 2. Wire harness components.

Table 1. Wire harness components, a summary.

Item	Component	Summary
a	Wire	The wire transmits the power and signal and it consists of a metal conductor, such as copper, and insulation materials made of plastics such as PVC.
b	Connector	The connector connects the wire harness to equipment or wire harness to wire harness. It consists of the copper terminal attached to the wire end and resin housing.
c	Clamps	Clamps are used to fix the wire harness on to the vehicle body.
d	Grommets	Grommets are used when wire harness passes from the inside to the outside of the vehicle body and it protects the wire from physical damage and prevents water penetration.
e	Tapes	Tapes are used to bundle wires and fix components.
f	Protection parts	The protection parts protect electric wires from physical interference from neighboring parts. Corrugated tubes or protectors are used.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

A detailed description of the components is given in the following.

3 WIRE

3.1 Standard for automotive wire

Automotive wires are used in a variety of harsh conditions and are exposed to vibration, heat, cold, machine oil, and the elements. For this reason, wire specification standards have been established in each country for standard performance, for example, the SAE standards of America, DIN standards of Germany, and the JASO standards of Japan. Automotive manufacturers are obliged to use these wires for wire harnesses or lead wires. These standards for automotive wires define the temperature rating for the environment, conductor size for the allowable current, insulating materials for each wire type, and wire performances for each wire type that must be met through the test methods for wires.

In part because of globalization, the establishment of a unified standard (ISO standard) has been promoted more recently. However, the situation is still a time-consuming process, because each of the automotive manufacturers and markets are still using different standards and specifications of wire suitable to them.

3.2 Conductor material

For automotive wire conductors, annealed copper, bunched with a few or hundreds of drawing wires, is commonly used. Flexible conductors with much finer drawing wires are used the areas such as those experiencing engine vibration or the opening and closing of the doors. Tin-plated conductors are also commonly used in order to obtain high reliability of the connection with terminals or to withstand high temperatures in the engine bay. In this way, various automotive wires corresponding to different requirements have been developed.

3.3 Insulation material

PVC has been commonly used as an insulation material. For wires used in high temperature environments such as the engine bay, heat-resistant insulation materials such as cross-linked PVC and cross-linked PE have been used. In a time of high global environmental consciousness, lead-free insulating material has been promoted by the End-of-Life Vehicles Directive in Europe. Although more advanced halogen-free insulation material has been introduced, PVC is still the major insulation material for automobile wires today.

3.4 Twisted pair wire, shielded wire

Wires emit weak electromagnetic waves during electric current flow. Conversely, noise due to electromagnetic interference is generated by equipment. For this reason, twisted pair wires or shielded wires are used in some cases. Twisted pair wires are twisted at a constant pitch, so the current flows in opposite directions in each wire. As a result, the electromagnetic waves emitted from the wire are canceled. Shielded wires include a shielding layer that shields the electromagnetic wave. Copper wire braid or/and metal foil (for high density shields) are used as shielding layers.

3.5 High voltage cable

Conventionally, the electrical voltage in passenger cars is about 12 V, while it is 24 V for heavy-duty vehicles such as buses and trucks. In recent years, voltage and current in vehicles has tended to rise with the introduction of electric vehicles powered by motor only and hybrid vehicles powered by a combination of engine and electric motor. As a result, special automotive wire is needed for high voltage and high current circuits. The insulation material for such cables is required to withstand high voltage and high heat resistance due to heat generated by the current. In addition, a shielding layer such as braid shield is required for shielding the electromagnetic waves emitted by high current energizing. From a safety standpoint, the insulation color of this cable is orange for easy recognition from other wires in case of an urgent check-up or maintenance.

3.6 Future vision for wires

With high global environmental consciousness, a need for lighter vehicles has emerged in the market. With this trend, smaller and lighter automobile wires are required. For this purpose, ultrathin wall wires with compressed conductors and thinly coated insulation have been introduced. In addition, the development of much smaller size wires than those available at present is in progress. In addition, aluminum wire whose conductor is aluminum alloy, which is lighter than copper wire, has been developed.

4 CONNECTOR

The connector, composed of a terminal and housing, is a component for transmitting electrical current between

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

devices or wire harnesses. The "terminal" is electrically connected to the wires and equipment. The "housing" has the mechanical connectivity features of insulation between terminals, terminal retention, and locking ability.

The male terminal structure is shown in Figure 3 and female terminal structure in Figures 4 and 5. A terminal is composed of a contact section (male: tab, female: box) for mating, a wire barrel section for connection with wires, and an insulation barrel section for holding wire insulation.

A spring blade is placed in the female terminal and contact pressure is created between the male tabs and the spring blade. This type of connection is widely used. Another type of connection, the Faston type, is composed of a male terminal with a hole and female terminal with a dimple corresponding to the hole in the male terminal. For high current applications, multicontact terminals have been also used.

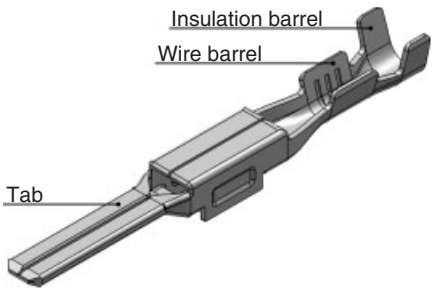

Figure 3. Structure of the male terminal.

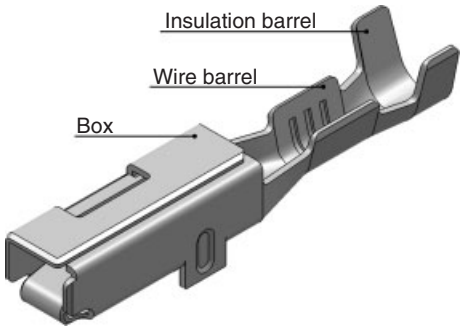

Figure 4. Structure of the female terminal.

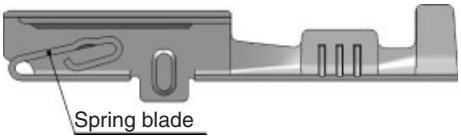

Figure 5. Internal structure of the female terminal.

Terminal material is copper alloy such as brass, with Sn, Ag, and Au plating for stable electrical contact. Crimped connections with the wire have been widely used, while other connections such as insulation displacement or ultrasonic welding have also been used.

The housing is composed of a cavity to accommodate the terminals, a lance to hold the terminals, and a retainer to strengthen the hold of the terminals and to prevent half mating. The structure of the cavity is shown in Figure 6 and the structure of the retainer is shown in Figure 7. When the terminals are inserted, the retainer is in its released position. After all the terminals are inserted, the retainer is fitted in the locked position. In a defective insertion state, the retainer doe not get fitted in the locked position. Owing

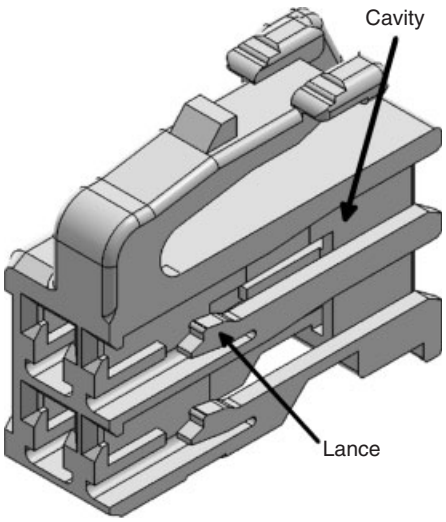

Figure 6. Structure of the cavity.

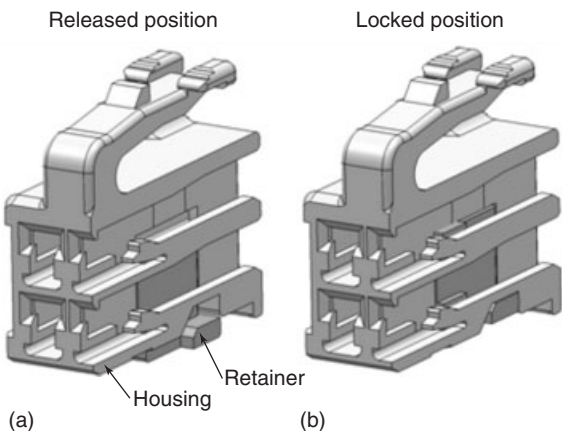

Figure 7. Structure of the retainer. (a) Released position. (b) Locked position.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

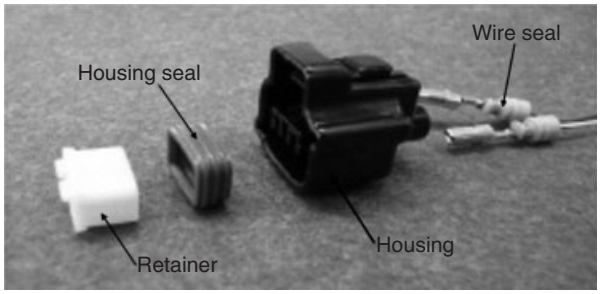

Figure 8. Structure of a waterproof connector.

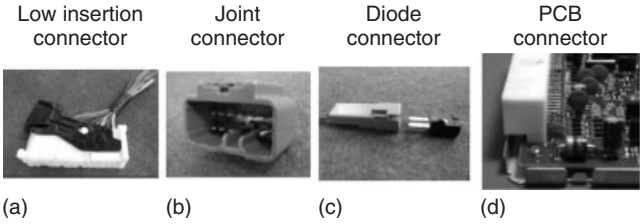

Figure 9. (a–d) Types of automotive connectors.

to the retainer holding the terminals in the locked position, the retention force is stronger than when a lance alone is used. The structure of a waterproof connector is shown in Figure 8. The waterproof connector is composed of a housing seal for waterproofing between housings and a wire seal for waterproofing of the wires.

Polybutylene terephthalate (PBT) has been commonly used as housing material, while PBT filled with fiber glass or polyamide (PA) has been used for heat-resistant applications. Silicon rubber has been commonly used as a seal material, while nitrile rubber or acrylic rubber has been used for oil-resistant applications.

Automotive connectors must be able to maintain stable connections under harsh automotive environments, so they need to have heat resistance, vibration resistance, and water resistance. Owing to enlarged wire harnesses corresponding to the recent introduction of advanced electronics into vehicles, the multipolarization and miniaturization of connectors are required. In addition to the conventional low voltage connectors for HEV and EV, connectors that withstand high current and high voltage are required. For this application, connectors with high dielectric strength insulation and shield for noise reduction are needed.

The following are features of automotive connectors:

1. ease of connection and disconnection in a single operation of the locking mechanism;
2. waterproof type for harsh environment applications;
3. various types of terminals for high or low current circuit, including the hybrid type (using two or more terminal types);
4. having a retainer for strengthening terminal retention and preventing half mating (particularly for small terminals).

Four types of automotive connectors are shown in Figure 9, including the nonwaterproof and the waterproof types mentioned above. For mating, connectors are categorized into the following types: the wire-to-wire connecting type (male and female type), the direct connecting to the equipment type (females only), and the type mounted on a printed circuit board (PCB connectors). Other features of these types are the following: (i) the type that has a lever and slide for reduction of high insertion forces induced by multiple terminals, (ii) the joint connector (J/C) type for connecting multiple circuits with the bus bar type male terminal, and (iii) the type with built-in diodes for preventing circuit bypassing. In addition to the examples shown in Figure 9, round terminals, fastened with nuts and bolts, are used for starter motor, alternator, and ground.

5 POWER SUPPLY BLOCK

The J/B connected with electronic equipment through the wire harness, is an electric box that makes intensive connections of circuits, and has incorporated circuit components such as fuses and relays. J/Bs are mainly installed in the engine bay or in interior near the instrument panel. In many applications, a J/B is incorporated with an ECU, especially large-scale ECUs corresponding to the introduction of advanced electronics.

Among electric connection boxes, a box with built-in relays is called a *R/B* and the box with built-in fuses is called the *fuse block* (*F/B*). In principle, these boxes usually do not have the intensive connection functions of circuits. Parts with no power supply function and with only connecting functions are called *J/C*. The J/B has functions such as joint integration and circuit reduction, power distribution, and circuit component integration. The J/B has been effective in downsizing, weight saving, cost reduction, and installation improvement of large wire harnesses induced by the adoption of advanced electronics.

Examples of internal wiring of J/Bs for various applications are shown in Figure 10 and the suitable type is selected for any particular application.

5.1 Wire connection type

In this type, wires are inserted with the terminals into a case, and, owing to easy drainage, the case is usually installed

DOI: 10.1002/9781118354179.auto234
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

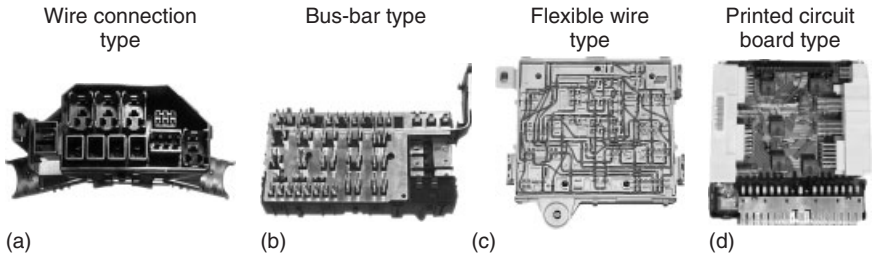

Figure 10. (a–d) Types of internal wiring system of junction blocks.

in the engine bay. Although production equipment costs are low and part costs are also low, the installation costs of wire harnesses are high. Moreover, it is unsuitable for connection with ECUs.

5.2 Bus bar type

For internal circuits of this type, copper strips are pressed and bent into the required form. This has been one of the main types since the introduction of J/B. Among this type of circuits, one consists of laminating the bus bar with plastic plates for complex circuit patterns. The plastic molded bus bars may be used for vibration resistance or waterproofing applications and bus bar integration with a divided bus bar may be used for improvement of bus bar flexibility and reduced tool charges. Although this is a simple structure with low machining costs and ease of high current handling, the costs of the die and press equipment for bus bars are high and their flexibility for circuit changes is low. So, this type is most suitable for mass production.

5.3 Flexible wire type

This type uses electric wires for internal circuit connectors instead of bus bars. In many applications, a hybrid type with wires for low current and bus bars for high current are used. There is also a case where a flexible flat cable is used in addition to an electric wire. This type has higher flexibility for circuit changes than the conventional bus bar type and weight saving is possible. However, it is best suited to small-lot production owing to high wiring equipment costs and machining costs.

5.4 Printed circuit board (PCB) type

The PCB type is one of the main circuit systems. Patterns are printed on the circuit board using an etching process instead of using a bus bar or wires. Compared to the two types mentioned in the preceding sections, the smaller size and weight of the PCB make savings possible and allow the flexibility of circuit change, so design change is comparatively easy.

Owing to the high temperatures induced by high circuit component integration, heat dissipation may pose a problem in many cases. Therefore, countermeasures such as circuit pattern layout design in consideration of heat rejection and cooling may be needed. In the case of the metal-core PCB, which has a thin copper plate embedded in an inner layer, heat generated from circuit parts can be distributed, so this type is suitable for highly integrated circuits and high temperature applications.

6 WIRE HARNESS EXTERIOR PARTS

In order to avoid damage caused by obstacles (such as the edges of the body panel) and harsh environments (such as high temperature or vibration) for wire harnesses, the wire-protecting parts described below are used (Figure 11). For exterior parts, the material is required to be flame retardant, flexible, heat resistant, and abrasion resistant. In some cases, oil resistance and chemical resistance are also required.

6.1 Tapes

Tapes are used to bind wires and fix components. Vinyl tapes are commonly used. In some cases, heat-resistant and flame-retardant vinyl tape or butyl tape with water-proofing and cloth for noise suppression is used. Environmentally friendly halogen-free tapes are also used in other cases.

6.2 Tubes

Tubes are used to protect the wires. Although they offer inferior protection compared to corrugated tubes, plane tubes incur a lower cost than corrugated tubes (the corrugated tube is described in the following.) Vinyl is generally

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

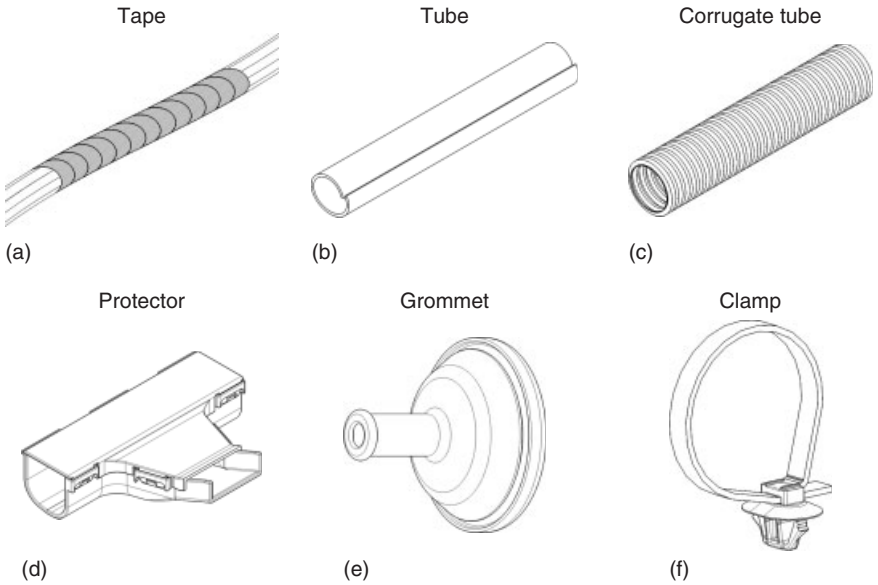

Figure 11. Types of wire harness exterior parts.

used as tube material. In addition, heat-resistant vinyl tubes, slit tubes for easy handling, spiral tubes for high flexibility, aramid cloth for heat-resistance, and twisted tubes for noise reduction are used.

6.3 Corrugated tubes

Corrugated tubes are used to protect the wire harnesses in areas with severe mechanical interference. In addition to polypropylene (PP) corrugated tubes, flame-retardant and heat-resistant corrugated tubes are also used. Slit corrugated tubes are generally used.

6.4 Protectors

Protectors are used to protect the wires and to regulate the routing of the wires. Different shapes are needed for each vehicle and the cost is higher than that of a corrugated tube. PP protectors and heat-resistant protectors are also used.

6.5 Grommets

Grommets are used at pass-through holes to protect wires and to prevent water penetration into the interior.

Ethylene-propylene-diene monomer (EPDM) is commonly used as grommet material. Chloroprene rubber and silicon rubber are used for oil-resistant and heat-resistant applications, respectively. In some cases, a resin inner type grommet is used for easy harness assembly.

6.6 Clamps

Clamps are used to bind and fix wires to the body panel or structure parts for instrument panel reinforcement. Generally, wires are bound with bands and tapes; corrugated tubes are also used. For fixing clamps onto the vehicle body, usually, an anchor-shaped portion is inserted into a hole drilled in the body. In some cases, a stud-shaped portion or plugs are inserted into the supporting bracket.

7 THE FUTURE OF WIRE HARNESS

The wire harness, as part of the infrastructure of automobiles, has achieved comfort, safety, and convenience required in automobiles, with reliable power supply and signal transmission. It has also contributed to the development of the automotive industry An automotive power train shifts electricity (such as on EV and HEV) from an internal-combustion engine; and automotive electrical systems are now evolving at an accelerated rate. The wire harness is necessary for the corresponding high current, large-voltage, and high speed communications. Furthermore, the wire harness is expected the communication and the electric power relation with not only inside of the automobile but outside of it, such as other automobiles, a social infrastructure, and households. The continuous improvements in weight reduction, downsizing, and cost reduction of the wire harness will make it indispensable for continuous evolution of the automotive industry.

The Fascination of Car Body Manufacture: Requirements for Car Body Manufacture from Viewpoint of Production

Andreas Kropf

Volkswagen AG, Wolfsburg, Germany

1 INTRODUCTION

Being a globally operating car manufacturer, today Volkswagen Group has over 94 production sites across the world with more than 30 bodywork plants for the Volkswagen brand. In 2011, these bodywork plants produced around 62% (5 million vehicles) of all group vehicles (around 2 million Volkswagens in Europe). Over 800,000 vehicles were built in Wolfsburg alone. Our production turntables and a multibrand strategy at individual sites allow us to react to regional market developments. This requires a high level of flexibility in the body designs and also far-reaching standardization of the production systems and the production processes across the world.

2 A CHALLENGE FOR THE AUTOMOBILE INDUSTRY

The following chapter deals with four aspects from the viewpoint of a globally operating car manufacturer.

Market: A differentiated perception of mobility on the automobile markets sets new challenges for all volume manufacturers not only in the development of their products but also in the design of their production processes and their production systems. Today our customers can choose from over 200 different group models. Modular transverse construction (MTC) and the modular production kit (MPK) help to handle the increasing variant diversity in car production in the economic sense. Building high quality cars and, at the same time, saving resources requires an ideal green factory. For bodywork assembly, this means systematically and consistently using all options to save energy in joining processes and with production equipment.

ISBN: 978-0-470-97402-5

CO_2/E-mobility: Reducing the weight of bodies with new lightweight concepts improves the carbon footprint and allows greater ranges for electric vehicle concepts. New material combinations are leading to further development of today's joining processes and joining methods.

Demography: The demographic developments in Europe will change the way we organize our production processes in car factories to a great extent. For example, an integrated ergonomic strategy and supplementary training concepts are also required in body assembly in view of the aging workforce. Our being a learning organization ensures that the expertise of our staff is further developed to the same extent as our products and manufacturing technology.

3 CROSS-BRAND STANDARDIZATION IN BODY ASSEMBLY

The answer to the increased complexity is cross-brand standardization of products, processes, and production equipment. MTC for products, the Volkswagen production system (VPS) for manufacturing processes, and the MPK for production equipment provide the framework for this standardization (Figure 1).

4 MODULAR TRANSVERSE CONSTRUCTION (MTC)

Combining fixed and variable dimensions in the vehicle architecture reduces the complexity considerably. In addition to conventional combustion engines, MTC allows all common alternative drives from natural gas and hybrid versions to purely electrical drives to be installed in identical positions (Figure 2).

5 MTC MODULAR STRATEGY

MTC is the logical development of our platform strategy and is complemented further by modular systems, for example, modular longitudinal construction (MLC). MTC consists of seven modular kits: front axles, front ends, front seats, front floors, rear seats, rear ends, and rear axles.

6 INTERACTION OF MTC AND MPK IN BODY ASSEMBLY

The interaction between MTC and MPK is illustrated by the example of side panel manufacture and the group framer. Standardized components such as the two-shell side panel will allow standardized joining sequences and joining processes. In turn, these product or production standards enable use of standardized production equipment such as the group framer. The implementation of the modular strategy therefore not only leads to considerable unit cost reduction and to a reduction of the run-up times for model changes but also ensures the same quality standards across the world.

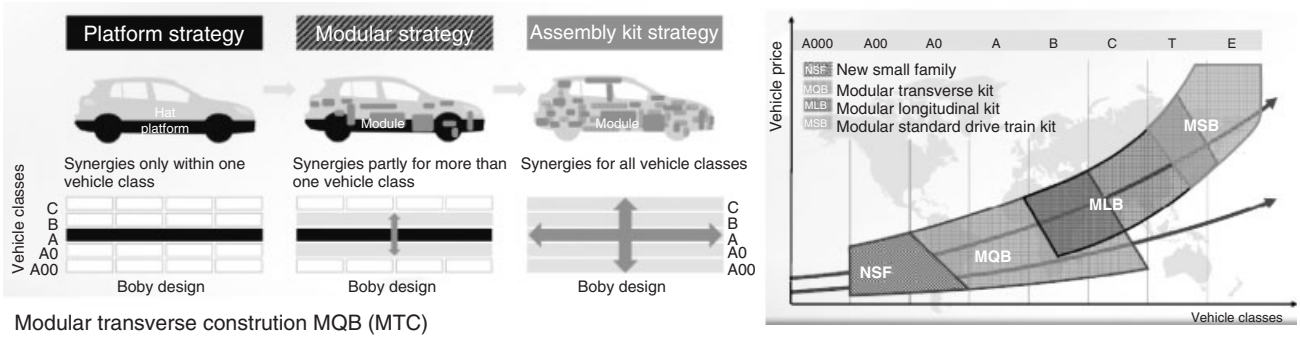

Figure 2. Modular transverse construction MQB (MTC). (Reproduced by permission of Volkswagen AG.)

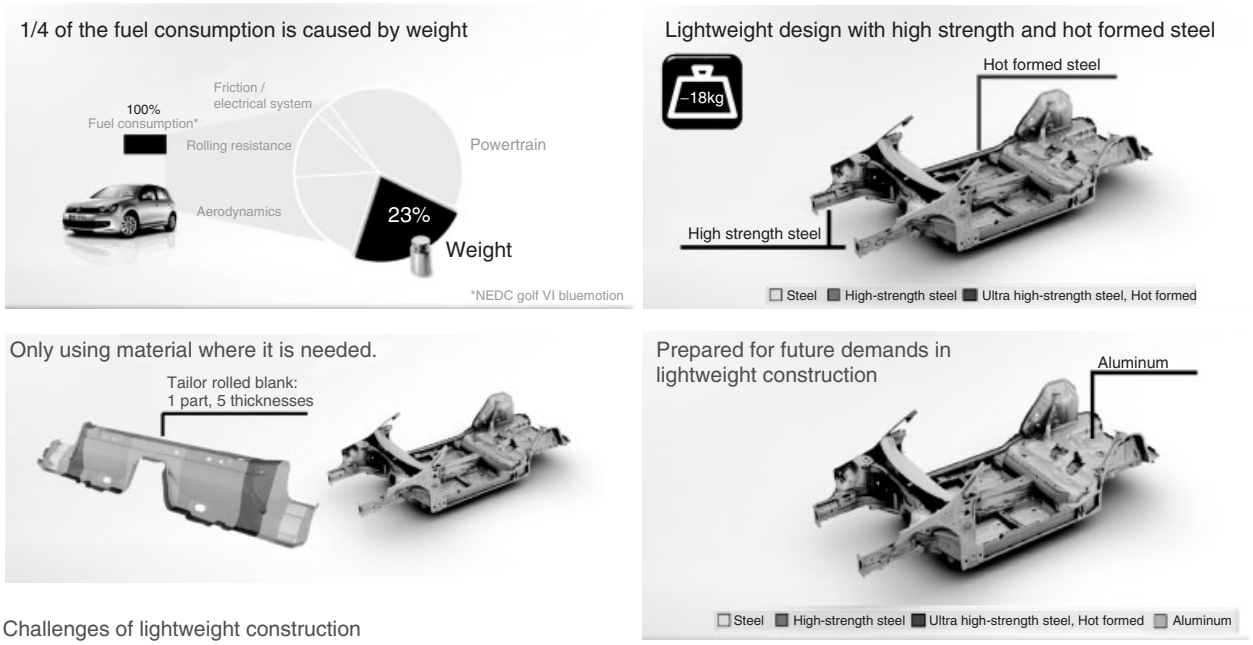

Figure 3. Challenges of lightweight construction. (Reproduced by permission of Volkswagen AG.)

7 CHALLENGE OF LIGHTWEIGHT DESIGN

By combining different materials, lightweight concepts in body assembly make a considerable contribution to reducing the weight of our vehicles. These lightweight concepts lead among other things to further reductions in sheet metal thickness, to an increasing proportion of high strength and ultra-high strength thermoformed steels, or to completely new material combinations, for example, steel and aluminum (Figure 3).

8 THINK BLUE. FACTORY.

The "Think Blue. Factory." scheme sees Volkswagen take on ecological responsibility not just with its particularly low consumption vehicles featuring BlueMotion technology, but also in the production of vehicles. Our factory in Chattanooga represents a milestone on the road to the green factory. It has received LEED® certification in platinum for sustained and environmentally friendly construction. With the Energy Way in Wolfsburg, we are using best-practice examples to show what savings potential is already

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto237
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

possible today in different areas of traditional factories. Our aim: Volkswagen production should become 25% greener by 2018. "Think Blue. Factory." in Body Assembly means putting all processes to the test also in terms of a complete energy approach in order to secure further savings potential. Furthermore, a complete approach concerning the question of energy generation has begun in Wolfsburg. Our production halls are equipped with a photovoltaic system covering 40,000 m^2 of roof area including the roof of the Touran body assembly plant in hall 10. The latest generation of robots with energy-optimized drives are used with the new vehicles. There is also potential for optimization in conveyor technology, joining technology, and joining processes. The use of the latest diode laser technology can, for example, improve the energy balance of laser welding by a factor of 10. Remote laser technology allows greater joining speeds. This reduces the required number of joining stations.

9 USE OF LASER TECHNOLOGY IN BODY ASSEMBLY

The laser-welding clamp allows laser welding without a laser cabin. As a result, investments and energy costs resulting from operation of the laser cabin extraction system are eliminated and space requirement is reduced considerably. The laser-welding clamp can be integrated at a later stage into existing spot-welding lines and thus increase flexibility in body assembly. In the future, the use of laser technology will be concentrated even more on the areas with direct benefits for customers. This is why, for example, the laser-soldered roof seam is a characteristic design element of our vehicles. The laser-welded joins in the area of the door entries increase ease of entry for our customers as a result of narrower flanges and improve the crash behavior.

10 DEMOGRAPHICS IN PRODUCTION—VOLKSWAGEN INTEGRATED ERGONOMIC STRATEGY

Demographic developments in Europe will change the way we organize our production processes in automobile factories for at least as long as the aforementioned technical and ecological changes are in place. The workforce that will build the Golf in 2018 will be in the work process almost 10 years longer than the team for the Golf IV. For body assembly, as for all other areas of production, this calls for a further reduction in the burden of industrial work by means of an integrated ergonomic strategy. This integrated ergonomic strategy sees Volkswagen tackle three points: people, technology, and organization. In body assembly, this means ergonomic design of all workstations starting with provision of materials and insertion windows to the use of assembly aids for fitting doors and lids and the use of man movers in the finish areas. A further point is the decoupling of man and machine by using insertion concepts that are independent of cycles. This relieves staff, enables the integration of indirect activities into the work procedure, and generally increases productivity.

11 THE VOLKSWAGEN WAY TO A LEARNING ORGANIZATION

As a result of demographic developments, new training strategies are also necessary in body assembly. As a learning organization we ensure that the expertise of our staff is further developed to the same extent as our products and the manufacturing technology. For staff in body assembly this is done, for example, on-site in our learning workshops. In addition to imparting basic skills in real work situations, professional training courses are held. The learning workshop concept is part of the Volkswagen Way. The Volkswagen Way is an extensive organization development process and a permanent feature of company strategy. In addition to the VPS, it covers the basic elements of demographics, learning organization, communication, and management and thus contributes to the success cycle of the 2018 strategy. Only an attractive employer can take good players on board and turn them into a top team. Only a top team can give an excellent performance.

12 SUMMARY: REQUIREMENTS FOR BODY ASSEMBLY

Volume manufacturers such as Volkswagen face the challenge of simultaneously building different body structures with the greatest possible flexibility in existing and future body designs, thus creating additional growth potential across the world and even in niche markets. Volkswagen is responding to this challenge with a cross-brand modular strategy—MTC for products and the MPK for production equipment (Figure 4). New innovative joining methods are the key to future lightweight design concepts in body assembly. A second key is the consistent implementation of sustained, that is, resource-saving production in all areas of vehicle production. "Think Blue. Factory." combines economic and ecological goals in the factory. Despite all

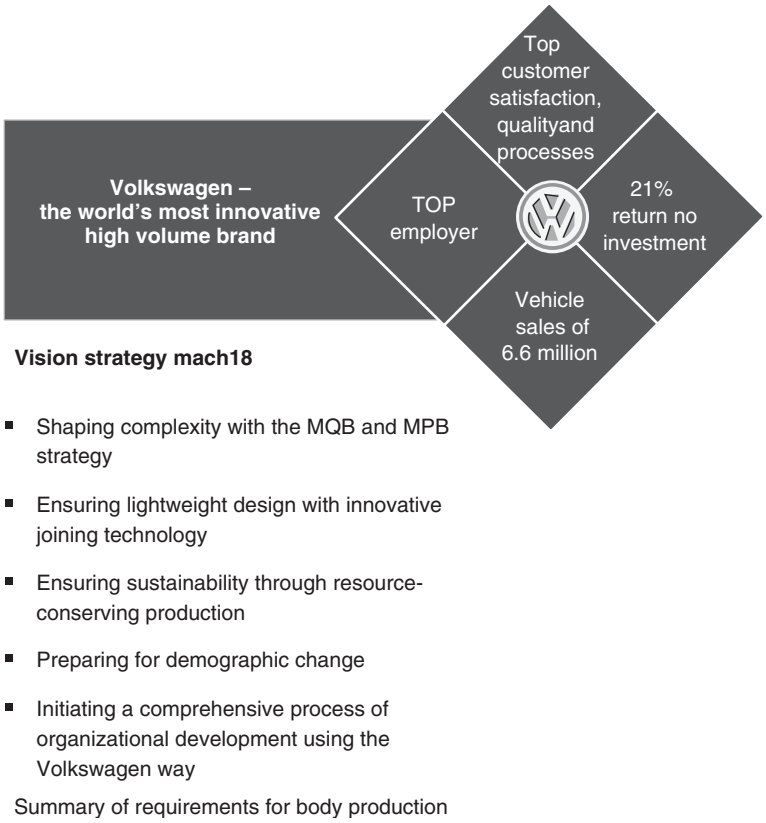

Figure 4. Summary of requirements for body production. (Reproduced by permission of Volkswagen AG.)

this, the complexity of future production procedures in body assembly will also remain manageable for staff as regards demographic aspects. For Volkswagen as a volume producer, the Volkswagen Way will provide the necessary method, building blocks, and elements for this extensive change process. Together with the aims of the 2018 strategy, the areas of action for body assembly on the way to its becoming the most innovative volume manufacturer are clearly described.

Styling of Cars, from Sketch to Realization, Main Trends and Milestones

David R. Brisbourne and Brian A. Clough

Coventry University, Coventry, UK

1 INTRODUCTION

Today, all motor cars perform reliably and efficiently so that the economy and performance metrics across a particular class of vehicle are now very similar from one manufacturer to another. Large global car manufacturers who control a number of brands even use a platform-sharing strategy to reduce development costs. The VW Group remains one of the greatest exponents of platform sharing and its stable includes brands that are considered conservative, sporty, mainstream, and premium. It has several platforms for different sizes of vehicle. Versions of the VW "Group A" platform (PQ34/PQ35) for compact and midsize cars have underpinned 15 very distinctive products based on the same C-segment platform (Škoda Octavia, Skoda Yeti, Skoda Superb, SEAT León, SEAT Toledo, SEAT Altea, VW New Beetle, VW Golf, VW Jetta, VW Eos, VW Tiguan, VW Touran, VW Scirocco, Audi A3, and the Audi TT). In this situation, it is even more important that the models are different from each other in the minds of the consumer, particularly if there is considerable price differentiation between badges.

Brand image and visual design have become critical product differentiators. Buyers may be fully aware that the current Skoda Fabia is underpinned by the same platform as the VW Polo and Audi A1 but the cars will be seen in a very distinct brand pecking order. Some badges can command a higher price and it is vital that the design reflects this. To sell in high enough numbers to recover the investment and return a profit, the car must be desirable and meet the needs and expectations of its intended buyers (who are also free to shop elsewhere) and so the role of the automotive designer in the success of a new car should not be underestimated. Advertisers are able tap into the passions and desires of car buyers with greater emotional effect than for any other product.

Image alone is not enough without substance, and as inferred above, all of the various parties involved in developing a new car must work closely to ensure that all the important criteria are met in each specialist discipline. Visual surfaces and functional requirements are inextricably linked and the styled surfaces of car exterior and interior have structural or operational tasks to perform. Although design is constrained by many ergonomic and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto238
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

engineering "hard points," the top 20–25 mm of the visible surfaces belong to the automotive designer during the design creation stage up until design freeze. Thereafter, styling-generated surface data drives many of the body engineering and trim design functions working inward from the surfaces. During the design delivery stage, after design freeze, further changes in the styled surfaces can only be initiated by engineering requirements.

However, designers stay involved in the development of a new car from the first sketches to the first car produced, and may even be involved in marketing activities extending to point of sale and merchandise design. This is to ensure consistency of brand image and to ensure that the design intent is maintained through to final production.

Different manufacturers operate on shorter or longer timescales and have their own terminology for the deliverables and gateways. This chapter investigates the detailed process and key milestones in designing a car from first styling sketches through to realization in the context of the process employed by many mainstream manufacturers (Appendix 1).

2 DESIGN PROCESS OVERVIEW

The process of bringing a new vehicle to market is complex and extremely costly and involves many stakeholders, including separate design and engineering departments within a company as well as external suppliers (described as original equipment manufacturers or "OEMs") not to mention the very buyers whose needs will have led to the product being earmarked for production in the first place. For a car company to remain competitive, the process must not only be efficient and timely but also the product itself must be desirable and targeted carefully at the intended buyers.

Typically 36 to 40 months in duration, a new vehicle programme has become more synchronised due to technological developments in Computer Aided Design and Computer Aided Manufacture and in the visualisation of 3D virtual styling and engineering models. Data from packaging, drivetrain, and chassis engineers can be used by styling to create extremely precise armatures to support physical (clay) and digital (CAD) models. In turn, surface data captured from styling models can then be quickly utilized by body, trim, and drivetrain engineers in a carefully choreographed sequence of concurrent activity.

Different companies have their own particular approaches to vehicle development programs but common to all is the use of "gateways." These gateways are effectively checkpoints at the end of key stages of activity where specific "deliverables" must be completed before progression to the next stage of development.

Design/styling departments may have involvement throughout the development of a new vehicle from the earliest exploration of new ideas and concepts carried out in the, usually separate, advanced design studio through every stage of design for production even up to point of sale. At all stages, there is pressure to maintain the original design intent. Typically, the production styling studio will operate from program start through to final production approval when it becomes the main responsibility of the engineering and manufacturing departments to deliver the car to market. In reality, designers remain engaged with the program right up to launch to deal with design-related issues and they often also take part in presenting the vehicle to dealer principals, press, and customers via dealer networks or launch events.

The remainder of this chapter explains the stages of the design process in detail and indicates the gateways that must be passed at the end of each stage.

3 DESIGN DEFINITION STAGE

3.1 Advanced design and concept definition

The advanced design and concept definition stage allows a company to explore new potential product concepts, emerging trends, and potential applications of new technology outside its main business activity and without the pressure of clearly defined timescales. This stage includes inputs from other parts of the business, including transformation and strategic projects (which looks beyond just the product to strategic issues such as the company's integrated environmental policies or manufacturing strategy, new processes, and perhaps new manufacturing or market locations), business plan (to determine if the long-term aim is to build on an existing strategy or to lead with a new riskier product), and cycle plan (which takes an overview of the current availability of research and development, design, engineering, and manufacturing resources—not all programs can be accommodated at once and to the same scale, so the overall plan of products needs to be considered), and turns it into content for programme teams.

Few designs originate directly from the design studio. Within a company, there are many factors that influence the decision to proceed with a given project. These can include the state of the market or economy generally, a company's resources, or even emerging technologies and trends. Sometimes, a company may wish to explore

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto238
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

design concepts that are unrelated to its current products or business strategy. A group of executives who support a particular strategic direction may call upon the services of design to create the most convincing artwork, scale models, and prototypes to sell a concept to the main board of directors or even to the buying public. Concept cars may be produced which, although costing millions, are a low cost way to test the market response to new ideas before risking the huge investment of a production programme.

Usually, however, the advanced design team will be engaged in a planned program of strategic design activity, working with a multidisciplinary team that may include product planning, marketing (evaluating customer requirements), engineering, purchasing, and external suppliers. For the program to be approved for production design, a business case will have to be formed that predicts a high level of success. Sometimes, a project may not get approval because it is "ahead of its time," or the company may simply not have the production capacity, or it may not be considered viable owing to predictions of low demand or high build costs. Very few, if any, companies are now willing to take risks on a product that cannot pay for itself and in order to proceed further, a concept must meet the criteria of all the stakeholders. Some products may take a number of years for the conditions to be right, while others may never see the light of day; and there are many concepts that spend time in the press spotlight at motor shows but go on to be stillborn.

Concept exploration is a carefully managed process that involves all the various disciplines up until a gateway known as *final check* (*FC*). This is where approval to proceed with a new concept is sought at a management review. If approval is denied, the team may be sent away at this point to go around the concept exploration process loop again. Between final check and program start, a number of management reviews will take place to review the program parameters and to assess its viability. Once all parameters are met and management reviews are completed, the scope of the program and its scalability (a measure of the complexity and resource demands of a programme) will be agreed ready to progress to programme start. The two key gateways at the end of concept definition stage are

FC—final check
- Project teams working on concept development prepare concept presentations.
- This may take the form of 2D artwork and 3D models (may even include driveable concept vehicle).
- Approval to proceed is sought at management review.
- Program parameters are assessed for viability.
- The scope of the programme and "scalability" are agreed on.

PS—programme start
- If all areas agree the business case is viable, approval will be granted for programme start.

4 DESIGN CREATION STAGE

4.1 Program approval/programme start

For an advanced concept to gain approval for a production, programme start, the business case criteria must met for all the stakeholders of marketing (from customer research), product planning, design, purchase, engineering, manufacturing, and external OEM suppliers. If all areas agree the business case is viable, the project starts.

A brief is generated, which defines the new vehicle architecture and the place of the new product within the business strategy and future plans. The type of vehicle, target customer group, manufacturing materials and processes, drivetrain, platform, production volumes, and pricing are established. The new product's function is planned and confirmed and the scopes of themes and concepts that will be explored are put into place. Approval to proceed is then granted and the design process begins

4.2 Theme development—interior and exterior design

Design is not simply a question of sketching ideas randomly. The design team will initially gather information about competitors in a process known as *benchmarking*. There are many ways to present this information beginning with "product positioning" diagrams which, in graphical form, place vehicles broadly against two or more axes representing specific design criteria (Figure 1). The advantage of this method is the ability to quickly identify "white space" indicating there may be a market niche for a new product. The features and specifications of vehicles closest to the design target can then be compared in more detailed tables (Figure 2).

Mood boards and scenario boards may also be generated to inspire and guide concept development by identifying a theme or topic relevant to future customers (Figure 3).

Visual mood boards may include words and images that evoke the identity a brand wishes to project or provide the guiding theme of a new product (e.g., "sporting luxury" or "comfort and connectivity"). Future scenario boards may include content relating to considerations such as green issues, economy, recycling, premium quality, technology, communication, information technology, luxury, comfort, youth culture, targeted generation groups (x and y, baby boomers, silver surfers), and so on.

Figure 2. Detailed benchmarking comparison table. (Reproduced with permission from Daniel Chindris. © Daniel Chindris.)

Increasingly, design teams will create detailed "personas" to represent the target users of a new vehicle. On the basis of user research gathered from visits, interviews, and surveys with real potential users, these personas amalgamate various physical and cognitive traits and tastes of the collected behavioral groups into archetypes. Personas boards (Figure 4) then show the persona in pictures and words along with evidence of their lifestyle, places where they live and work, their leisure activities, personal image, preferred brands, and so on. Personas effectively become "real" consumers and allow designers to understand with some clarity who they are designing for. Well-defined personas become a reference tool during the design work.

Two-dimensional sketching, which, of course, starts straight away, is a quick and efficient way to generate a number of ideas. The process is also motivated by competition because selected themes have the potential to go forward to future stages led by the designers who create them. This encourages creativity and productivity. As designers start to explore potential themes and endeavor

to communicate those thoughts to the team and senior management, their 2D sketches are loosely drawn and not too tightly constrained by the package. Their purpose is to capture the emotion and excitement of the new concept. Hence the early sketches and renderings will not have the evidence supporting them to direct or influence the vehicle "hard point" negotiations that take place at this time. At this stage, the research carried out by the designers, marketing teams, and chief program engineers is concerned with appropriateness of the design, its potential for innovation, and general feasibility rather than detailed engineering.

Increasingly 3D modeling software (Autodesk ALIAS) is being used as a design visualization tool during these early stages (most design graduates now have experience of ALIAS model making). Designers who are familiar with ALIAS can "sketch-models" their proposals (Figure 5). Images of the model can then be imported into 2D graphics software (e.g., Adobe Photoshop, Illustrator, or Autodesk Sketchbook Pro) and rendered over. Particularly when used for interiors, this technique provides a strong, and dimensionally accurate, composite sketch capable of describing their thoughts without ambiguity and including ideas about color, materials, and textures.

Initial engineering package hard points may well be in place at this point, especially if the project is a "facelift" of an existing vehicle or so-called "new top hat." The former is a midlife refresh of an existing design that may include new front- and rear-end treatments affecting bumpers and lights. The latter is a program where the chassis and drivetrain are carried over from a previous program/production vehicle but with a completely new body and interior. For a completely new "ground-up" design involving new chassis and drivetrain, an initial concept package will exist from the advanced design and product definition phases. Sometimes, an existing product may be used as the starting point with the designers challenging what they wish to change.

4.3 Multiple theme selection (design shortlist)

Two-dimensional theme sketches are the quickest way to generate ideas and direction for a new design program and often a single "key sketch" is identified, which provides an identity. However, sketches have their limitations as automotive design eventually leads to a three-dimensional outcome. To truly gain confidence in the evolving design directions, 3D physical and digital models are created to properly realize the designer's thoughts. Physical exterior clay models may be produced at scales of 25%, 30%, or 40%. Virtual alias models can be produced for both exterior and interior and viewed at close to full size for evaluation.

Typically, in the large studios of major car companies (e.g., Ford or General Motors), around eight initial exterior themes are developed as scale models (Figure 6), some hand-modeled in clay and some machined from digital data. At the end of this phase, the models are presented painted or "dressed" for selection. The models are developed with skilled physical or digital modelers over 10–12 weeks, the work being done in close conjunction with the studio feasibility engineers and senior design managers.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

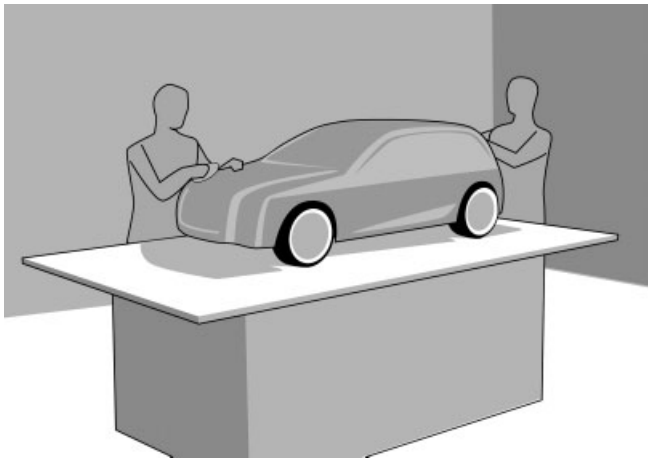

Figure 6. Three-dimensional development using a scale clay model. (Reproduced with permission from Brian Clough. © Brian Clough.)

The eight exterior themes may well be split across four actual "half models" (Figure 7) where each side of the same model will explore a different theme. A designer may develop more than one theme in the program and each will have a modeler to translate the design into 3D.

All hand-worked models will at some point be digitally scanned to capture the surface form, allowing data to be compared with the other themes and help support feasibility engineers in their parallel work streams. Computer visualization software such as "Autodesk Showcase" and "Bunkspeed SHOT" can be used to show material changes and lighting effects on photorealistic digital models in convincingly real environments quickly and with considerable sophistication (Figure 8).

Some digital models can even be animated or "driven" in real time to see how they may look on the road long before a physical prototype exists.

Interior design and model making may begin some weeks after the exterior is underway. Interior models are developed virtually in Alias and reviewed on large screens so that they can be seen close to full size. The data can be exported to ergonomics simulation software such as RAMSIS and evaluated even before a physical seating buck is created. Comfort, ergonomics, and packaging are usually then explored through engineered full-size seating bucks and rigs (Figure 9).

Interior design is more complex because of the number of surfaces and parts that need to be generated in different materials and interior designers must work closely with ergonomists and color and trim designers. Interiors are modeled precisely over the engineering hard point data to give a high level of feasibility so that they will be readily deliverable if selected. A couple of important gateways occur at the end of the design shortlist stage:

PSC—programme strategy confirmed
- Project strategic targets and guidance are put in place.
- The business case is confirmed across marketing, finance, quality, functional targets, hardware selection and programme timing.

FDC—first development competition for design
- Themes are evaluated in line with programme brief—sketches, physical scale models, and virtual models are presented to management.
- A decision is then made to go forward on a reduced number of themes.
- Management decides on the direction for continued development

Figure 9. Interior seating buck clay model shown with seats partly dressed. (Image used with the kind permission of Jaguar Land Rover 2013.)

4.4 Theme reduction

Following a senior design and programme management review that is supported by color and materials proposals, marketing information, and engineering assumptions, the number of themes is reduced down to four exterior and two or three interior proposals. The four exterior proposals are developed using two more split clay models (different themes on each side), but this time modeled at full size (Figure 10).

Interior design moves forward with full-size clay interior bucks, which over time will be dressed to be a full facsimile of the design intent (Figure 11).

Exterior clay models can be dressed using painted film called *Dynoc* and rolled outside to be viewed in natural light. The theme reduction phase concludes with another important gateway:

PTCC—programme target compatibility checkpoint
Target attributes for the design are agreed and approved.
Systems selection (electrical, powertrain, chassis) is completed and confirmed.

4.5 Design selection (final design selection)

To enter the final phase of creative design development, a single exterior and interior theme is selected at the most important gateway of the design creation stage:

Final design selection "Go for One"
The final exterior and interior design themes are selected to go forward into production, hence "Go for One."

4.6 Single theme

All the concept and design development now comes down to a single full-size clay model of the exterior and interior, which represents all the design development up to this point and confirms that there is now one clear direction approved by the business.

This phase of development focuses on fine-tuning the design details of the full-size models in conjunction with suppliers and engineers, so it is a fully balanced interpretation of what the design team imagined. The end of the single-theme phase also concludes the design creation stage with design freeze or "pencils down." From now on, any detail interior or exterior design changes can only be initiated by "engineering change" documents released in a rigorously controlled manner by the program team. This

gateway signals the end of any design changes being initiated by the design (styling) team:

Design freeze (design creation stage "Pencils Down")
Acknowledges the hand over from design creation to design delivery.
The point at which further design changes can only be initiated by engineering

5 DESIGN DELIVERY STAGE

5.1 Microfeasibility

A new car contains thousands of component parts that require detailed design and engineering solutions during the design delivery phase. Component engineers work with design and with external suppliers to confirm specification, quality, material selection, fit and finish, functionality, and durability. During this tightly managed intense period, production dates are on the horizon and decisions critical to success.

"Design Digital Data" which is the digital representation of 3D design surfaces sourced from clay, physical, or virtual models is confirmed and handed over to engineering in preparation for production surfacing. By this phase, the surfaces and features will have design engineering feasibility due to close, ongoing collaboration with both a company's own engineering teams and those of its suppliers. At this stage, the design (clay and digital model) may still be subject to some levels of engineering initiated change before going into full production.

Designers are responsible for continuing the relationship with engineers to ensure the design is developed

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto238
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as intended and to avoid the focus of the theme being diluted. They will add value with every opportunity that presents itself during perceived quality and "optical quality" discussions. Three gateways conclude the microfeasibility phase:

PTC—program target compatibility
  Ongoing program targets are set.
  The business case is updated in line with latest program assumptions.
M1DJ—first drivable prototype (M1) data judgment
  Data readiness for M1 (the first drivable prototype) tooling, test, and build verification
  All underbody components are now produced to the first production build (Job #1) specification intent
DDJ—design data judgment
  Clay model freeze

5.2 Surfacing

The surfacing process is where the creative design surfaces meet engineering feasibility and tolerance of associated component parts. Surfacing as a department takes design digital data and engineering data from a company's own engineering departments and those of external OEM suppliers and develops working surfaces for tooling, including all the relevant requirements from material selection like grain, draught angles, and fit and function.

The forum for this phase is described in many companies as "optical quality" and provides the opportunity for making judgments optically using the digital surface data (typically, ICEM Surf), where parts are "stacked" in a virtual form in a highly precise format. Owing to the accuracy of the data, minute irregularities that may be invisible to the naked eye on the clay can be smoothed out in the software. Joint conditions, material differences, grain finishes, and molding split lines are all areas that are explored in conjunction with their individual tolerances, so designers can see what a customer may experience when the vehicle is built. The aim of this phase is to confirm the design intent virtually so the data is ready to release for initial tooling.

5.3 Feasibility cube

The feasibility cube takes the "surface transfer data" to build a functioning representation of the design data. Surface transfer data come from the styling models developed by design, supported by studio engineering who ensure feasibility, and also with some supplier input. Data are sourced directly from digital styling models or by scanning exterior and interior physical clay models to capture the design intent before obtaining final approval to pass to engineering who will go on to create production surfaces. Detail can change beyond this point but usually for technical reasons. Feasibility cubes are precise physical representations of the exterior and interior styling surfaces milled in sections in hard resins and foam such as "Ureol®," and assembled on aluminum jigs. They are accurate to fractions of a millimeter enabling all interfaces and gaps to be critiqued to ensure they match the styling intent. Assembled feasibility cubes look like real cars with opening doors but there are no telltale welds or clinched joints around door edges (Figure 13). Seats, dashboards, door cards, and other trim items are not padded but machined from hard materials that represent their surfaces as the designers modeled them.

Feasibility cube data are also the basis for the complete exterior/interior see-through models known as *design realization models*, *styling reference models*, or "*prove out*" *models* (Figure 12). Some manufacturers call them "*design experience cars*." To all intents and purposes, these are real cars built very accurately in a variety of appropriate materials and processes (fabricated metal and composites, rapid prototyping using "additive" 3D printing or "subtractive" machining from solid) all fully painted and trimmed in representative finishes. They may sometimes, but not always, be fully drivable. The design realization model is a design property and is used to confirm design intent and to help start to sell a design throughout the business, including the sales councils and dealer networks. They are so convincing that they may even be used in early press release photographs many months before a real production car is available. The feasibility cube phase ends with the first of three appearance approval gateways:

AA1—appearance approval 1 (of 3)
  First of three appearance approvals complete
  Feasibility of interior and exterior themes approved
  Production intent surfaces released
  Upper body mechanical package and software activity started

5.4 Modify surface and engineering

This is the final phase of design "fine-tuning" intended to catch all the snagging issues identified and tracked by the engineering change documents. All surfacing and engineering issues should be resolved and released for

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto238
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

final approval at this point. This stage ends with two more gateways including the second appearance approval.

PA—programme approval
- Business case, quality targets, and market equation confirmed
- Ongoing programme objectives approved
- Mass production upfront activities launched
- Upper body mechanical package and software activity completed

AA2—appearance approval 2 (of 3)
- Final exterior and interior design approval
- Design data released

5.5 Design and engineering freeze (design delivery "pencils down")

Design and design engineering now stop.

5.6 Function cube (environmental cube)

The function cube (or tooling reference model) is a master physical representation of a vehicle body machined in aluminum with fixing points to allow body trim and hardware to be fitted (Figure 13). This reference model will be maintained throughout the life cycle of a complete vehicle (to incorporate future design updates/ facelifts etc.). Built to show every aesthetic design surface as it will be released for tooling, the function cube is usually machined from solid aluminum billets, thinly painted and assembled to look like a real if extraordinarily heavy version of the vehicle. Doors open and every component interface will be as described by the "data tree." Since a function cube represents the surfaces exactly as they will look when the real car is assembled from the pressed parts, even the shape of welds and clinched joints will be milled into the surfaces.

Since new cars contain thousands of separate parts that may be changed during the design development, it is essential that a record is maintained of changes to ensure that only the latest version of a component is in use. The data tree records and holds all program components in a virtual 3D state. The complete work history of each individual component is contained here so that all components are the most current.

The data tree also allows virtual 3D models to be built by the various module teams to illustrate how their areas come together and function in isolation or in conjunction with the rest of the vehicle. Virtual reality systems can even employ component data to assess tasks such as serviceability and access to engine components.

The only components that are not created to machining precision tolerances are the glazed areas, typically because on an all-new vehicle they will initially be made from Perspex not glass. The "glass" will include the "blackout"

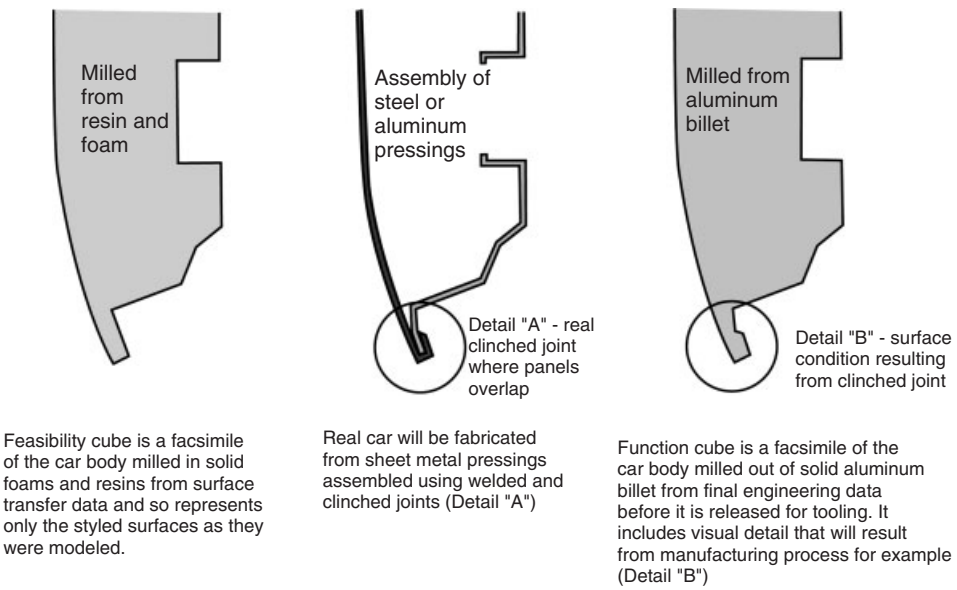

Figure 13. The difference between feasibility cube and function cube explained using the example of a car door bottom edge. (Reproduced with permission from Brian Clough. © Brian Clough.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto238
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

obscuration areas where paint or decals hide pillars, adhesive joints, and items mounted to the glass such as interior mirrors. Even the areas that are left unswept by the windscreen wipers will be "frosted" for visibility evaluation purposes.

The purpose of the function cube is for every component area to evaluate critically all the surfaces and how they relate to each other across the whole vehicle. If something is deemed unsatisfactory in a particular area, the module teams responsible often initiate change themselves before tooling. Some items such as bumpers and any metal pressings for the "body in white" are time critical at this point as they are the longest lead items, so any change that is initiated has to proceed through the change and correction process swiftly and efficiently to prevent delay to the programme.

Completion of the function cube signifies the end of the design delivery stage with three final gateways remaining:

M1DC—(M1 = first drivable prototype) development completion
  Verification of upper body systems and subsystems
  Engineering change notices issued
  M1 development completion authorized by engineering management
FAA—final appearance approval (3 of 3)
  Appearance approval completed
  Interior and exterior surface final refinements/highlights approved
  Design data updated
FDJ—final data judgment
  Engineering designs and associated confirmation complete
  Confirmation across all business functions that designs satisfy business requirements
  Outstanding issues have solutions in place meeting measured company standards, and are judged deliverable for future phases

6 DELIVERY TO MARKET (MANUFACTURING ENGINEERING)

6.1 Beyond final data judgment

In theory, designers could let a program go at this point as it now becomes the core responsibility of the engineering and manufacturing departments to deliver the car to market. However, it is rare that the designers cease to be involved through the manufacturing engineering stage.

As an intrinsic part of the program team, the designers, especially color and material designers, are still engaged in making sure that design intent is delivered, supporting program activity until launch where they will often also take part in presenting the vehicle to dealer principals, press, and customers via the dealer network or launch events. Their ongoing responsibilities can include

Generating and illustrating the various trim levels
Working with marketing agencies on artwork and images for communications and launch material
Preparing properties (models, displays, and actual vehicles)
Preparing artwork for press releases detailing the design story
Interviews
Filming for development stories, attending motor shows, vehicle launch events, customer events, to support launch
Being part of snagging teams, problem-solving last minute issues

In effect, designers will be involved from the earliest concept sketches until the first customers take delivery of their new car.

7 SUMMARY

A designer's role is vast and varied and many may only ever work in a specific area during a program; early sketching, or detailed delivery, but those experienced and rounded enough to work from start to finish hold a unique insight into the project they are inextricably linked to. It becomes part of their life and it is like bringing a living thing into the world, complex but wondrous. Designers require a strong empathy with the wider team around them and they are required to lead the design language debate but they also have to reach acceptable compromises in order to deliver a desirable design solution in a very tight time frame and to cost targets.

For a designer there is no greater pride than viewing a piece of design they have played a large or small part in being used by the customer they have designed it for. The lucky ones may even get to own and drive the car that they have helped to design.

Fundamentals, Basic Principles in Road Vehicle Aerodynamics and Design

Simone Sebben, Tim Walker, and Christoffer Landström

Volvo Car Corporation, Gothenburg, Sweden

1 INTRODUCTION

Road vehicle aerodynamics considers the interaction between the vehicle, the road, and the surrounding airflow, and the resulting effect on fuel consumption, handling, and cooling performance. Drag and lift are the best-known aspects of aerodynamics. Drag for its contribution to fuel consumption and lift for its influence on vehicle handling. However, aerodynamics influences a large number of other vehicle attributes that contribute to customer satisfaction.

Aerodynamics is an important aspect of today's automotive product development process, and most car manufacturers utilize both wind tunnels and computational fluid dynamics (CFD) for optimizing the aerodynamic properties of their products. This chapter gives an introduction to basic principles of road vehicle aerodynamics including some basic fluid mechanics, the importance of aerodynamics in automotive engineering, and an overview of the aerodynamic design process with focus on passenger cars.

2 SOME FUNDAMENTALS OF FLUID MECHANICS APPLIED TO VEHICLES

The aim of this section is to briefly describe some basic fluid dynamic principles and their importance to road vehicle aerodynamics. A more thorough explanation of all the basic definitions can be found in several fundamental books in fluid mechanics, for example, White, 1986; White, 2006; and Panton, 2005; and applied to road vehicle aerodynamics books such as Allen, 1982; Hucho, 1998; Hummel, 1998; and Barnard, 2001.

2.1 Air properties

2.1.1 Density

The density of any material is defined as its mass per unit volume and it is commonly denoted by the symbol ρ. For liquids and gases, this physical property is a function of both pressure, p, and temperature, T. Air, as most other gases, follows the ideal-gas law, stated in Equation 1.

$$\rho = \frac{p}{RT} \tag{1}$$

where R is the gas constant.

Air density decreases with increasing altitude, as air pressure does, and it is inversely proportional to temperature. At sea level ($p = 1$ atm and $T = 288$ K), air has a density of

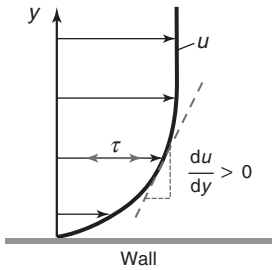

Figure 1. Velocity profile near a wall and the shear stress proportional to the gradient of velocity.

1.225 kg/m^3. Aerodynamic forces acting on ground vehicles are directly proportional to air density. At speeds for which passenger cars operate, variations of air density can be considered negligible and the air can be considered as incompressible.

2.1.2 *Viscosity*

Viscosity is the mechanical property of a fluid that represents a measure of its resistance to deformation by shear. When a fluid is sheared, it starts to move at a strain that is inversely proportional to its dynamic viscosity μ. The applied shear is also proportional to the velocity gradient. According to Newton, for a shear layer near a wall (Figure 1), the shear force acting on a surface is defined as Equation 2.

$$\tau = \mu \frac{du}{dy} \tag{2}$$

For air at sea level, the value for dynamic viscosity is 1.789×10^{-5} N·s/m^2. As we discuss later, viscosity is the reason for the existence of drag.

2.2 The Bernoulli equation

A fundamental principle to the study of fluid flow past bluff bodies was derived by Daniel Bernoulli based on Newton's second law, and it relates pressure and air speed. Bernoulli's principle states that for an inviscid flow (a flow that has no resistance to shear stress), an increase in the speed of the fluid occurs simultaneously with a decrease in pressure or the fluid's potential energy.

A common form of the Bernoulli equation used by aerodynamicists is seen in Equation 3.

$$p + \frac{1}{2}\rho V^2 = \text{constant} \tag{3}$$

where p is the static pressure and $\frac{1}{2}\rho V^2$ is called the *dynamic pressure*.

The sum of the static pressure and the dynamic pressure is the total pressure, $p_{tot} = p + \frac{1}{2}\rho V^2$. Equation 3 states that for inviscid flow, the total pressure is constant along a streamline. A streamline is a curve that shows the path that a fluid element will travel in any point in time. Streamlines are always tangent to the velocity vector of the flow, as shown in Figure 2.

For external flow around a vehicle, p and V are taken as the free-stream pressure and the free-stream velocity, respectively. On the road, this means that p is the atmospheric pressure and V is the vehicle speed.

2.3 Stagnation pressure and pressure coefficient

According to the Bernoulli equation, if the flow comes to a rest, the static pressure assumes its highest possible value. Because this maximum value of the pressure is associated with zero-flow velocity, it is called *stagnation pressure* and the position where it occurs is known as the *stagnation region*.

A stagnation region is always present on the nose of the vehicle, where the flow is split over the top and under the bottom of the car. A typical pressure distribution at the center line of a passenger car is seen in Figure 3.

It is convenient in aerodynamics to work with values of pressure, which are nondimensionalized. The advantage

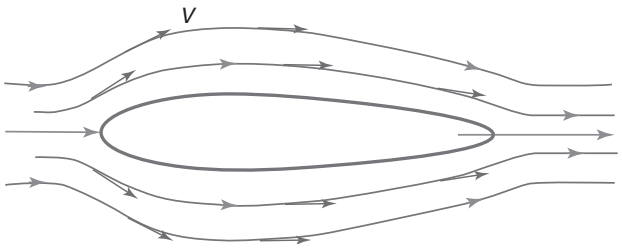

Figure 2. Streamline pattern around an arbitrary body shape immersed on an inviscid flow stream.

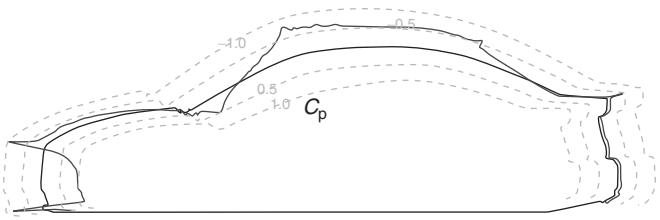

Figure 3. Typical pressure distribution at the symmetry line of a passenger car.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of working with the nondimensional pressure coefficient rather than with actual pressure values is the fact that the pressure coefficient will not vary with the vehicle speed. A dimensionless pressure coefficient, denoted as Cp, is defined in Equation 4 as the ratio

$$C\mathrm{p} = \frac{p - p_\infty}{\frac{1}{2}\rho V_\infty^2} \tag{4}$$

or

$$\frac{\text{local static pressure} - \text{free stream static pressure}}{\text{free stream dynamic pressure}}$$

where p is the local static pressure and V_∞ and p_∞ the free-stream velocity and free-stream static pressure.

If the Bernoulli equation is applied into Equation 4, we obtain

$$p + \frac{1}{2}\rho u^2 = p_\infty + \frac{1}{2}\rho V_\infty^2$$

or

$$C\mathrm{p} = \frac{p - p_\infty}{\frac{1}{2}\rho V_\infty^2} = 1 - \left(\frac{u}{V_\infty}\right)^2 \tag{5}$$

Equation 5 states that in stagnation regions where the flow field comes to a rest, that is $u = 0$, Cp reaches its maximum value of 1. Equation 5 also yields $C\mathrm{p} = 0$ at the free stream where $u = V_\infty$. Negative values of Cp are also possible and are encountered, for example, in regions where the velocity is higher than the free-stream velocity. On the example given in Figure 3, regions of negative Cp are seen at the leading edge of the bonnet, roof, and base.

2.4 The boundary layer

The boundary layer is defined as the layer of fluid in the immediate vicinity of a bounding surface where the effects of viscosity are significant. The aerodynamic boundary layer was first defined by Ludwig Prandtl. It simplifies the equations of fluid flow by dividing the flow field into two areas: one inside the boundary layer, dominated by viscosity and creating the majority of drag experienced by the body, and the other outside, where viscosity can be neglected without significant effects on the solution. The thickness of the velocity boundary layer, $\delta(x)$, is usually defined as the distance from the body at which the flow velocity is 99% of the free-stream velocity. With increasing distance from the leading edge, the boundary layer gets thicker and less stable and eventually becomes turbulent. Velocity fluctuations are superimposed to the mean velocity leading to more mixing between fast- and slow-moving airs. The result is an increase in the thickness of the boundary layer and a velocity profile that is more flat with higher velocity values close to the walls. This is schematically shown in Figure 4.

Similarly to the representation of the flow on a flat plate, as the air passes a vehicle, the creation of a boundary layer close to the surface of the car also takes place. Within this boundary layer, which is a few centimeters thick at the most, the velocity of the air decreases from its value at the free stream (at the outer edge of the boundary layer) to zero at the surface of the vehicle owing to nonslip conditions. This tiny region close to the vehicle walls has an important influence on the development of the flow around it. At the front part of the vehicle, the airflow is practically steady and with no major perturbations. Downstream the vehicle front end, the flow develops to a turbulent type. In the turbulent region, the flow is unsteady and can contain a few areas with small recirculation zones; nevertheless the flow is mostly attached and streamlined with the shape of the body. At the rear, the flow separates, the boundary layer gets dispersed, and the flow is entirely governed by viscous effects. A representation of the flow around a vehicle can be seen in Figure 5.

2.5 Flow separation and reattachment

As explained previously, all solid objects traveling through a fluid (or alternatively a stationary object exposed to a moving fluid) acquire a boundary layer of fluid around

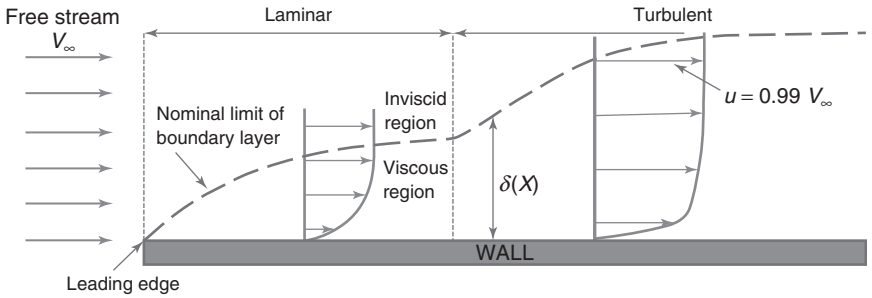

Figure 4. Representation of the boundary layer over a flat plate.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

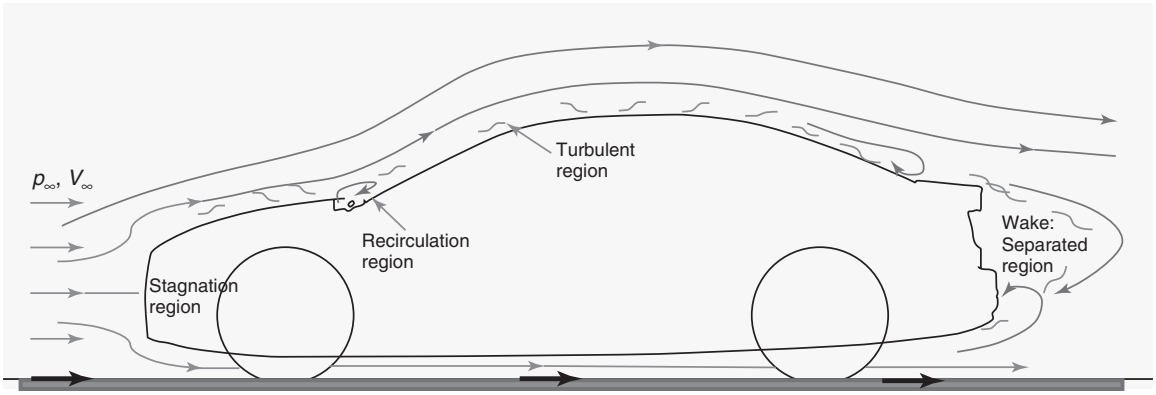

Figure 5. Schematic representation of the flow around a vehicle.

them where the effect of viscous forces is significant. When the boundary layer travels far enough against an adverse pressure gradient (when the static pressure increases in the direction of the flow, $\frac{dp}{dx} > 0$), flow separation occurs. The fluid flow becomes detached from the surface of the object, and takes the form of eddies and vortices. The separation point S is defined as the point between the forward and the backward flows, where the shear stress is zero, $\left(\frac{du}{dn}\right) = 0$ where n is the vector normal to the surface at each point. The overall boundary layer thickens at the separation point and is forced off the surface by the reversed flow. This can be visualized in Figure 6.

Compared to laminar boundary layers, turbulent boundary layers can tolerate much stronger flow deceleration, or adverse pressure gradient, before the flow separates. For a given adverse distribution, the separation resistance of a turbulent boundary layer increases slightly with increasing Reynolds number. This is because turbulent mixing increases momentum transport from the outer flow toward the wall.

In aerodynamics, flow separation often results in increased drag, particularly pressure drag (see definition on Section 3.2.3). Depending on the flow conditions, the separated flow can terminate and may again become reattached to the body. Between the point of separation and reattachment, a separation bubble is formed. A variety

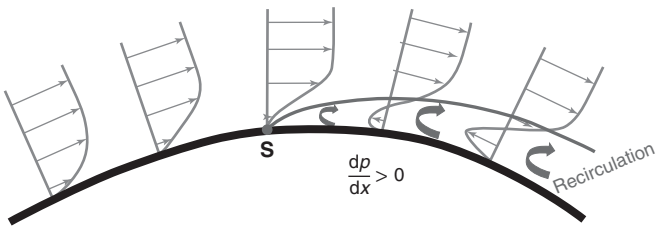

Figure 6. Flow separation over a curved surface.

of factors can influence reattachment, such as: the pressure gradient may become favorable owing to body geometry; the flow initially laminar may undergo transition within the bubble and may become turbulent. In aerodynamics, a short bubble may not be of much consequence.

2.6 The Reynolds number

The Reynolds number, Re, is a dimensionless number that gives a measure of the ratio of inertial forces to viscous forces and quantifies the relative importance of these two types of forces for given flow conditions. It is defined as in Equation 6

$$\mathrm{Re} = \frac{\rho V_\infty L}{\mu} \tag{6}$$

where L is a characteristic length of the vehicle.

Different flow patterns around a same vehicle occur for different Reynolds numbers. The Reynolds number can be used to determine dynamic similitude between different experimental cases. It is also used to characterize different flow regimes, such as laminar or turbulent flow: laminar flow occurs at low Reynolds numbers, where viscous forces are dominant and is characterized by smooth, constant fluid motion; turbulent flow occurs at high Reynolds numbers and is dominated by inertial forces, which tend to produce chaotic eddies, vortices, and other flow instabilities.

For passenger cars, typical values of the Reynolds number are of the order of 10^7.

3 FORCES AND MOMENTS

3.1 Forces and moments of immersed bodies

Any body of any shape will experience forces and moments when immersed in a fluid stream. For a vehicle or any

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

arbitrarily shaped body, the flow will exert forces and moments about all three coordinate axes. Figure 7 represents the forces and moments acting on a vehicle submitted to a cross-wind load.

The force on the body along the *X*-axis is called *drag*, F_D, and the moment around this axis is called the *rolling moment*, *R*. It is essentially the force that needs to be overcome in order for a body to move against the stream. The force on the body acting normal to the ground plane is called *lift*, F_L, and the moment around its axis is the yaw moment, *N*. The third component is called the *side force*, F_S, and the moment around its axis is the pitching moment, *M*. For a symmetric body about its drag–lift axis traveling directly into a stream (V_∞ parallel to *X*-axis), the side force, yaw, and rolling moments disappear and only the drag, lift, and pitch moments are left.

3.1.1 Bluff bodies and streamline bodies

A body is said to be a bluff body when the source of air resistance is dominated by pressure forces. When the drag is dominated by viscous forces, the body is called a *streamlined body*. Whether the flow is viscous drag dominated or pressure drag dominated depends solely on the shape of the body. A streamlined body looks like a fish or an airfoil at small angles of attack (Figure 8a). A bluff body looks like a cylinder or a block (Figure 8b). Road vehicles are bluff bodies. For a given frontal area and velocity, a streamlined body will likely have a lower resistance than a bluff body. See references White, 1986; Hummel, 1998; and Barnard, 2001 for drag values of different shaped objects.

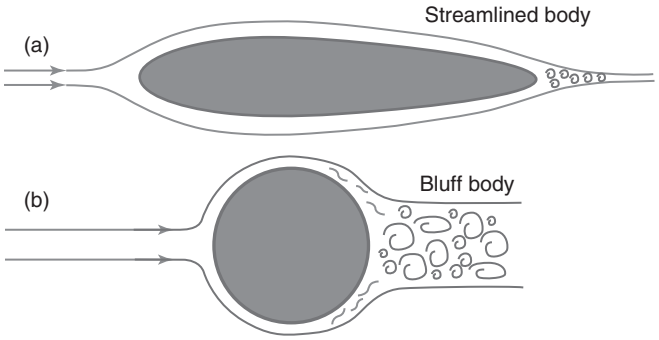

Figure 8. Airflow around a streamlined body and a bluff body.

3.2 Aerodynamic drag

Drag is the force that opposes motion. In aerodynamics, aerodynamic drag is the fluid drag force that acts on any moving solid body in the direction of the fluid free-stream flow. In vehicle aerodynamics, drag is conventionally taken as the resulting force acting along the *X*-coordinate (Figure 7). Drag comes from forces due to pressure distribution over the body surface and forces due to skin friction, which is a result of the fluid viscosity. These sources of drag are denoted as pressure drag and frictional drag, respectively. For passenger cars, drag is the most important aerodynamic force. It is the dominant source of resistance to motion at speeds above 50–70 kmph. There is a lot to gain from drag reduction as it directly influences fuel consumption, top speed and acceleration as we shall see in Section 4.

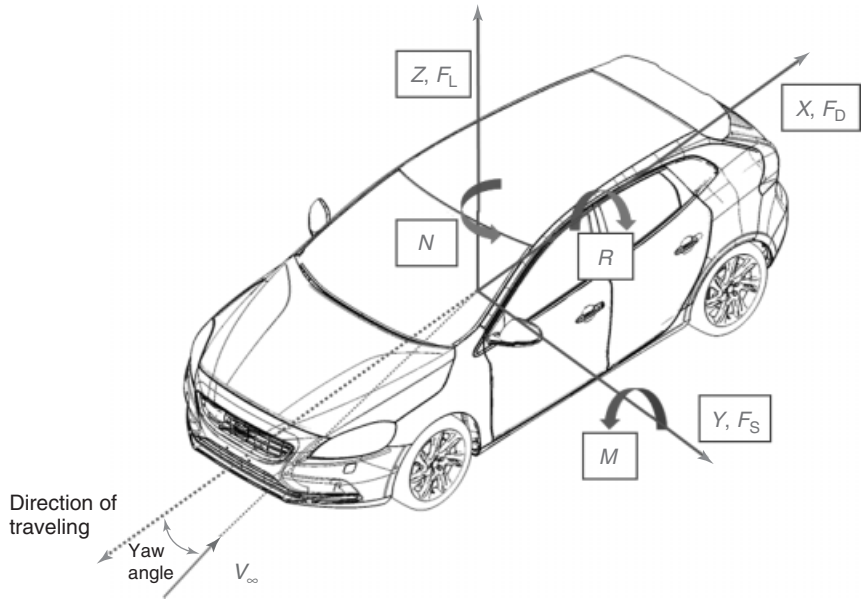

Figure 7. Forces and moments acting on a vehicle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.2.1 Drag coefficient

Drag coefficient is a dimensionless quantity used to express the resistance of an object in a fluid stream. It is a common variable in automotive design. Drag depends on the properties of the fluid and on the size, shape, and speed of the object in motion. This relationship is expressed in Equation 7.

$$C_D = \frac{F_D}{\frac{1}{2}\rho V_\infty^2 A} \tag{7}$$

where C_D is the drag coefficient, F_D the drag force, $\frac{1}{2}\rho V_\infty^2$ the free-stream dynamic pressure, and A the cross-sectional area as shown in Figure 9.

The drag coefficient can also be denoted as C_X or C_W. Equation 7 implies that for vehicles with approximately the same frontal area and traveling at the same speed, the vehicle with the lowest drag coefficient value will produce less drag.

3.2.2 Friction drag or viscous drag

Friction drag comes from friction between the fluid and the body surface. Frictional forces act tangentially to the body surface. It is this friction which is associated with the development of boundary layers. For passenger cars, which as described are bluff bodies, the contribution of viscous drag to the total drag is relative small, of the order of 7% to 10%.

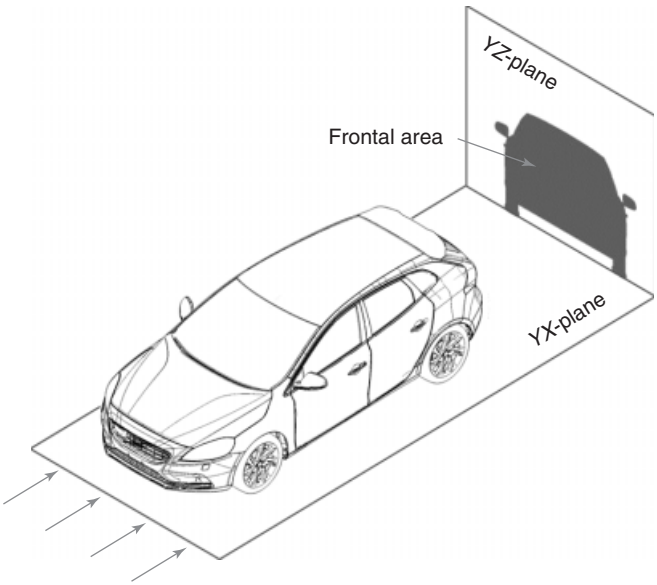

Figure 9. Definition of frontal area of a vehicle.

3.2.3 Pressure drag or form drag

Pressure drag or form drag arises because of the shape or form of the body. The size and shape of the body are the most important factors in form drag. Generally, bodies with large cross-sectional area have higher drag than slick or streamlined bodies. Form drag is associated with flow separation and the formation of a wake, as shown in Figure 8. Formally, both viscous drag and pressure drag appear because of the effects of viscosity that is responsible for the creation of a boundary layer. If the body was moving through an inviscid fluid, the viscous drag and the pressure drag would be zero. It is, however, useful to make a distinction between these two types of drag because they are due to different flow phenomena. Frictional drag is important for attached flows (flows with no separation), and it is related to the surface area exposed to the flow. Pressure drag is important for separated flows, and it is related to the cross-sectional or frontal area of the body.

3.2.4 Local drag

It is common in vehicle aerodynamics to analyze the areas of the flow field where drag is generated using a variable called the *local drag* (sometimes also called the *micro drag*). The local drag is derived from the integral form of the momentum equation and uses simplified approaches to exclude terms that are less relevant to the formation of drag. The resulting expression, Equation 8, relates the aerodynamic drag to the pressure and velocities at a given plane. Its derivation can be found in the works of Onorato, Costelli, and Garonne (1984); Cogotti (1989); and Ivanic and Guillieron (2005).

$$C_{D_{local}}.A = \int_S (1 - C\,p_{tot})dS - \int_S \left(1 - \frac{V_X}{V_\infty}\right)^2 dS + \int_S \left(\frac{V_Y}{V_\infty}\right)^2 dS + \int_S \left(\frac{V_Z}{V_\infty}\right)^2 dS \tag{8}$$

where S is the wake section at the plane of interest.

The local drag can be subdivided into wake drag, which includes the total pressure energy loss term and the streamwise velocity energy loss term. The two last terms in Equation 8 are known as the *vortex drag* or *induced drag*. That is,

$$\text{wake drag} = (1 - C\,p_{tot}) - \left(1 - \frac{V_X}{V_\infty}\right)^2$$

$$\text{vortex drag} = \left(\frac{V_Y}{V_\infty}\right)^2 + \left(\frac{V_Z}{V_\infty}\right)^2$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For bluff bodies, wake drag is always larger than vortex drag, as it is related to form drag. Wake drag can be reduced by body streamlining. At the free stream, $C_{D_{local}} = 0$, because $V_X = V_\infty$ and $Cp_{tot}, V_Y, V_Z = 0$.

Figure 10 shows a typical example of the wake behind the rear end of a vehicle plotted with the local drag variable.

3.3 Aerodynamic lift

As defined in Section 3.1, for a body immersed on a fluid stream, lift is the component of the force that is perpendicular to the oncoming flow. Lift might be desired to be upward, in the case of an aircraft, or downward, in the case of road vehicles, especially racing cars. In racing car aerodynamics, the term *down force* is usually used to describe negative lift.

3.3.1 Lift coefficient

The lift coefficient is a dimensionless quantity that relates the lift generated by a body, the free-stream dynamic pressure of the fluid flow around the body, and a reference area associated with the body. Similarly to the drag coefficient, the lift coefficient is defined as in Equation 9

$$C_L = \frac{F_L}{\frac{1}{2}\rho V_\infty^2 A} \tag{9}$$

where C_L is the lift coefficient and F_L the lift force. A and $\frac{1}{2}\rho V_\infty^2$ have already been defined.

In case of lift, the use of A as the frontal area is more a matter of convenience, because lift is actually more related to the area parallel to the flow direction. The lift coefficient can also be denoted as C_Z or C_A. Modern passenger cars have values of C_L that are considerably low, whereas racing cars are designed to have negative values of lift (down force). In vehicle aerodynamics, both the magnitude and the balance between the front and the rear axle lifts are of importance. The front and the rear axle lifts are denoted by C_{LF} and C_{LR}, respectively.

3.4 Moments

As described schematically in Section 3.1, in addition to drag and lift forces, there are other forces and moments acting on a vehicle. As for drag and lift, it is also convenient to use dimensionless coefficients to refer to the side force and the three torques, Equations 10–13, respectively. Thus,

$$C_S = \frac{F_S}{\frac{1}{2}\rho V_\infty^2 A} \quad \text{Side force} \tag{10}$$

$$C_M = \frac{M}{\frac{1}{2}\rho V_\infty^2 A l} \quad \text{Pitching moment} \tag{11}$$

$$C_N = \frac{N}{\frac{1}{2}\rho V_\infty^2 A l} \quad \text{Yawing moment} \tag{12}$$

$$C_R = \frac{R}{\frac{1}{2}\rho V_\infty^2 A l} \quad \text{Rolling moment} \tag{13}$$

Note that as the moments have dimensions force × length, an additional characteristic dimension, l, is introduced in the definitions. This characteristic length is usually taken as the wheelbase, which is the distance between the front and the rear axles.

4 IMPORTANCE OF AERODYNAMICS ON ROAD VEHICLES

The airflow around a vehicle has a significant effect on several different attributes of a road vehicle. Table 1 presents a summary of such key areas, and as can be seen, there are several critical aspects related to aerodynamics that needs to be considered when developing a vehicle. The first section of Table 1 is labeled performance and includes aspects such as fuel consumption, acceleration, top speed, and emissions. As all of these are related to engine power, reducing the aerodynamic drag will reduce the power requirement for a given driving condition and may thus reduce fuel consumption and emissions. For a given engine, reducing aerodynamic drag will allow both improved acceleration and in particular higher top speed.

Handling is an important area not only for racecars but also for passenger cars. The handling properties of a passenger car are of course affected by several factors, aerodynamic lift forces being only one of them. At high speeds, the front-axle and, especially, the rear-axle lift forces have a significant influence on handling. Achieving a stable vehicle during strong winds gusts and high speed braking are two examples where aerodynamics is important. On high performance vehicles, it is not uncommon to introduce variant specific add-on devises such as a custom spoiler to reduce rear lift to be able to meet high speed requirements, often at the cost of slightly increased aerodynamic drag.

Contamination, number three in Table 1, focuses on keeping critical areas of the car clean from water, snow, and dirt. This can, for example, be to avoid significant water flow over the a-pillar onto the side window, which may obscure driver visibility, prevent water sprays from the wheels from entering the engine bay, or making sure the vehicle operates without issues in very snowy conditions.

Table 1. Overview of areas of importance for road vehicle aerodynamics (Hucho, 1998).

1. Performance • Fuel consumption • Acceleration • Top speed • Emissions	2. Handling • High speed stability • Braking stability • Cross-wind stability
3. Contamination • Visibility • Dirt/snow packaging • Splash and spray	4. Thermodynamics • Engine cooling • Transmission cooling • Brake cooling • Exhaust system cooling
5. Comfort • Climate control • Heating • Wind noise	

The fourth key area is summarized in the thermodynamics section of Table 1. In this case, cooling performance is the main consideration as the airflow around and through a vehicle will dictate the cooling performance of critical components such as the engine components, transmission, and brakes. Ensuring that sufficient amounts of air passes through the engine bays is an important requirement as the engine bays are getting increasingly occupied. Together with increased need for closing off the engine bay area for reasons such as NVH (noise, vibration, and harshness), contamination, and aerodynamic drag, getting sufficient cooling air through the engine bay poses a challenge to the engineer. Consequently, there is a need to optimize these kind of interacting attributes together.

Of course, the demand for cooling is not constant but depends on the specific driving condition. On modern cars, it is therefore becoming common with different kinds of mechanical systems to close off the cooling inlets when cooling is not required. Such systems are sometimes referred to as shutters. By closing off the cooling inlets in the front of the vehicle, drag reductions in the range of 5% can easily be achieved.

The last focus area in Table 1 reflects comfort aspects, which largely relates to aero acoustics but also internal climate control. Ensuring a comfortable climate in the driver compartment of the vehicle depends on several aerodynamics-related issues. Fresh air needs to be extracted from the airflow around the car and then conditioned to the desired settings. Another example is defrosting of the front screen, which is subject to legal requirements.

Aerodynamically generated noise relates to both external and internal noise levels. There are several design features on a passenger car that generate noise; a lot of work is, for example, often spent on optimizing the a-pillar and external rear view mirrors.

Of course, it is relatively easy to optimize each and every one of these attributes one by one, but as already indicated, in every vehicle project, there will always be a need for compromises between not only the areas in Table 1 but also with other aspects such as cost, weight, legal requirements, and manufacturing. The great challenge in developing a vehicle with good aerodynamic properties therefore not only lies in the purely aerodynamic field but also to be able to find solutions that do not only meet the aerodynamic targets but can also be managed by all other project members. Sections 4.1 and 4.2 will give more detailed presentations of the influence of aerodynamics on the performance and handling attributes separately.

4.1 Aerodynamic influence on performance

As described in Section 3.1, the aerodynamic forces and moments acting on a road vehicle are usually divided into components, three forces and three moments. Aerodynamic drag, lift, and side force together with pitch, yaw, and roll moments are the common ones that are usually measured or calculated for a given passenger car configuration. Lift and side force are divided into front and rear components at the front and the rear wheel centers.

All parts of the exterior, wheel housings and wheels, as well as the engine bay and underbody contribute to the aerodynamic drag. Figure 11 shows typical numbers for how the drag generation is distributed on a modern passenger car. Approximately half of the aerodynamic drag is generated from the exterior. The wheels and wheel housings generate somewhere between 25% and 30% of the aerodynamic drag (Landström, 2011), and the remaining 20–25% is generated by the underbody and engine bay region. These numbers are estimates and should be treated as such; of course, there will always be specific models where these numbers do not apply. It is also important to understand that the net aerodynamic force on a specific region of a car is not only an effect of the design of one specific part, but may often be a result of the design of several surrounding parts influencing the flow simultaneously. This is referred to as interference effects and is a very common phenomenon in aerodynamics because of the complex geometries and strong nonlinear physics of fluid flow.

To be able to understand such interactions between different parts of the flow around a road vehicle, it is often necessary to investigate the local flow field, in addition to the net forces. Flow field investigations can be done both experimentally in wind tunnels and numerically using CFD.

Equation 14 gives the total propulsion force necessary to operate a vehicle at any driving condition. The first term on the right represents inertia effects from accelerating the vehicle. For simplicity, this has been summarized as the product of vehicle mass and acceleration, but should also include terms for rotating parts. The second term is called *climbing resistance* and represents the gravitational effect if driving up or down a slope. The third term is the rolling resistance and the fourth term is the aerodynamic drag. As three of the four contributors to the necessary propulsion force are dependent on mass and aerodynamic drag depends on the size and shape of the vehicle and the velocity, it is reasonable to assume that their relative contributions to the necessary propulsion force will depend on driving conditions.

$$F = m\frac{\mathrm{d}V}{\mathrm{d}t} + mg\sin\alpha + mgf_{\mathrm{R}}\cos\alpha + \frac{1}{2}\rho V^2 C_{\mathrm{D}}A \quad (14)$$

Figure 12 shows the required power necessary to operate an average passenger car as a function of different steady state velocities on flat ground, hence eliminating the first two terms in Equation 14. The remaining force has been split into aerodynamic drag and rolling resistance. For a

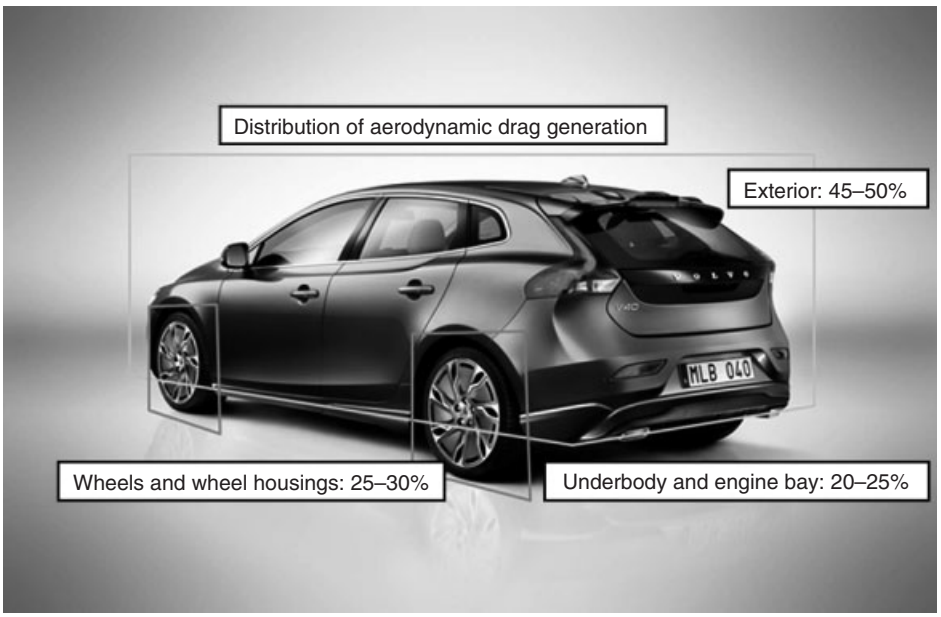

Figure 11. Aerodynamic drag distribution on a modern passenger car. Approximately half of the drag originates from the exterior, 25–30% from the wheels and wheel housings, and the remainder from the underbody and engine bay area.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

passenger car, the curves typically intersect in the range 50–70 kmph, and above these velocities, the contribution from aerodynamic drag grows significantly larger than rolling resistance.

From Figure 12, it is obvious that the contribution to fuel consumption from aerodynamic drag is strongly dependent on velocity. As shown by Woll (2005), reducing mass by 10% gives approximately twice the reduction in fuel consumption as a 10% reduction in aerodynamic drag when considering the New European Driving Cycle (NEDC), keeping all other factors constant. If instead considering driving at a constant speed of 150 kmph, a 10% reduction in aerodynamic gives four times larger reduction in fuel consumption than the corresponding reduction in weight. The reason for this difference lies in the shape of the NEDC with a relatively low average velocity of 33 kmph, and several sections of acceleration and braking that increase the relative importance of inertia in Equation 14.

Figure 13 shows an example of how the total amount of energy used by a car during NEDC is divided among different areas. In this case, the aerodynamic drag represents approximately a quarter of the overall energy loss during the NEDC. Rolling resistance and inertia losses makes up approximately half of the energy consumption, both depending on vehicle mass. If considering driving at a constant velocity of 90 kmph (Figure 14), distribution changes significantly. The aerodynamic drag now generates slightly more than half of the total energy loss. At even higher velocities, this part should increase even more according to Figure 12. This is of course an effect of inertia losses not being present in the constant velocity case.

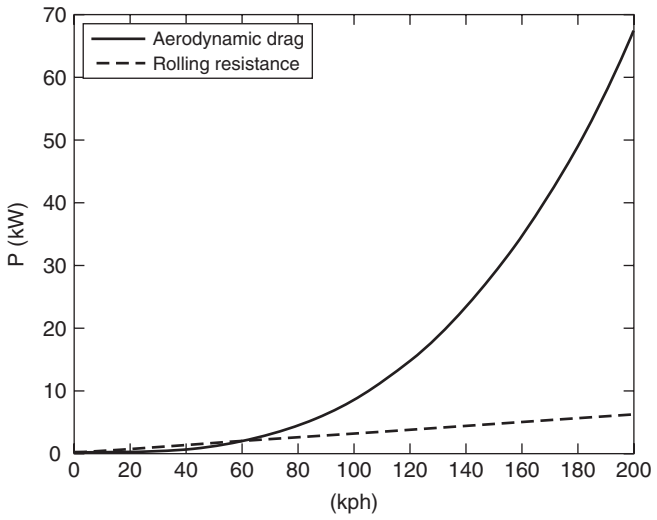

Figure 12. Power requirement for an average passenger car divided into aerodynamic drag and rolling resistance at different steady state velocities.

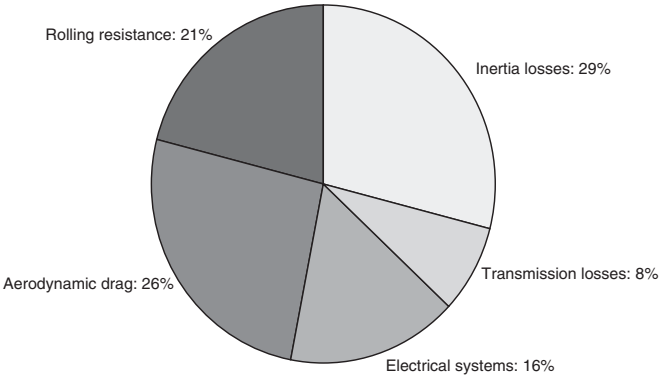

Figure 13. Energy losses for a passenger car during NEDC.

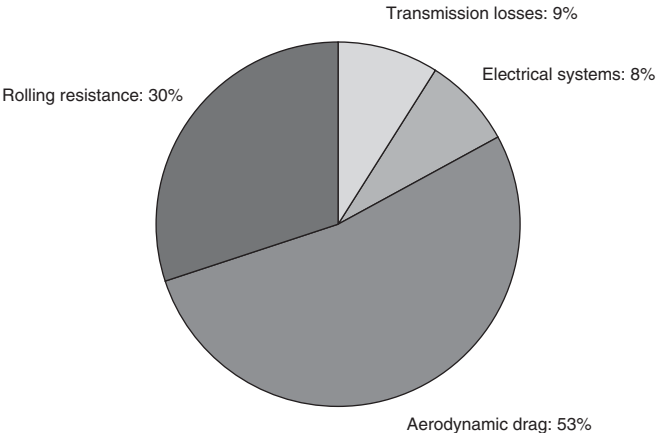

Figure 14. Energy losses for a passenger car during 90 kmph constant velocity.

Even though reducing weight is more efficient in reducing fuel consumption in the NEDC, achieving a weight reduction may be significantly more challenging—and expensive—compared with a reduction in aerodynamic drag.

The aerodynamic drag, however, may be significantly easier to reduce at a low cost. If the general shape of the exterior design of the vehicle can be improved during the design phase, the aerodynamic drag can be reduced at practically no additional cost. Improving the flatness of the underbody is common on many modern cars in order to reduce aerodynamic drag even further. This will most likely require underbody panels, but still at a relatively low cost. Other small features such as spoilers and deflectors can achieve significant reduction in aerodynamic drag and lift. Consequently, if the basic principles of aerodynamic design such as well-defined separation regions and a smooth underbody can be introduced and accepted early in the vehicle development process, the potential for low aerodynamic drag is good.

4.2 Aerodynamics influence on handling

Apart from fuel economy and top speed, which for road vehicles is fundamentally decided by the aerodynamic drag of the vehicle, the other major influence of aerodynamics is the handling of the car. This is normally a result of the aerodynamic lift acting on the car, or transient or unsteady changes to the lift or side forces acting on the car during nonsteady conditions.

The high speed stability of a car is dependent on many factors, primarily weight distribution, suspension design, tires, and aerodynamics. Normally road cars have positive lift forces acting on both the front and the rear axles. Depending on the type of car and how the manufacturer wants the car to behave, the magnitude and difference between the front and the rear lift forces will need to be analyzed and controlled. Too much lift on the front axle will create a car with less steering response, too little lift may result in the steering becoming too responsive and nervous for some drivers. Too much lift on the rear axle will reduce the vertical loading on the rear tires leading to less lateral grip and consequently greater yaw sensitivity. This behavior will be more noticeable when braking at high speed.

Reducing the rear lift will often improve stability although if the rear lift is too low or even negative, that is, down force, the front lift will increase, perhaps leading to a lack of steering sensitivity. In general, a modification to the front of a car that results in a reduction to the front lift will almost certainly result in an increase in rear lift. Similarly, changes that increase the front lift will reduce the rear lift. Typically, the magnitude of the changes on the front lift will be reflected by an opposite change of between 50% and 75% on the rear lift. Although modifications at the rear of the car that effect the rear lift can also affect the front lift, the degree of influence is only 0%–30% of the change of the rear axle lift change.

Because of these interactions and also the influence that modifying the car will have on drag, it is important to consider the complete aerodynamic package that would be suitable for a particular type of car.

It is also important to consider the change to both drag and lift on the car as the angle of the wind relative to the cars direction changes as a result of natural side winds or the passing of other vehicles or buildings will be significant.

Figure 15 is a diagram for an SUV-type vehicle for drag, front lift and rear lift as a function of the relative, or yaw, angle of the wind.

It is important to identify if there are any sudden changes to drag and or lift at a particular yaw angle. This typically arises when the airflow around the rear of the car, near areas of flow separation, changes from a separated flow to an attached flow, or vice versa. If this occurs the rapid change of forces acting on the car may be felt by the driver as an unwanted nervousness in the behavior of the car. To avoid this, small changes to surfaces or radii in the problem area can create a better airflow and avoid rapid flow pattern changes.

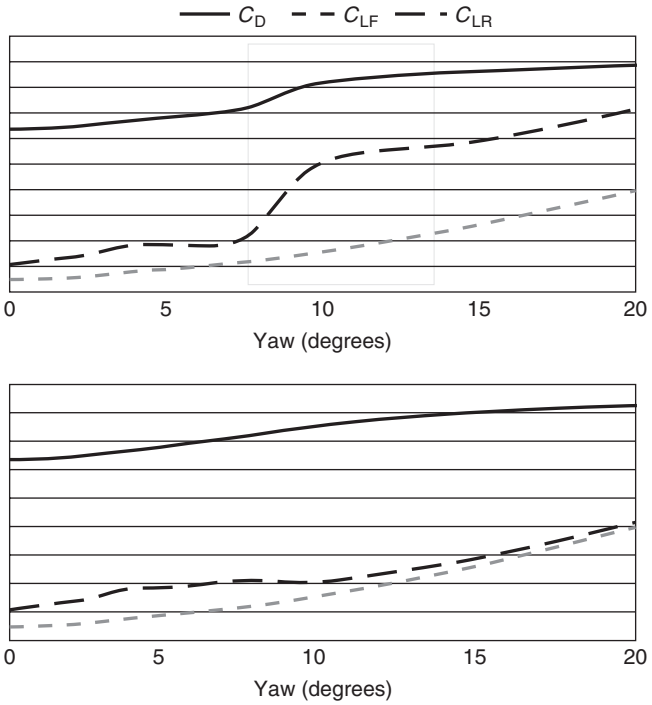

Figure 15. C_D, C_{LF}, and C_{LR} versus yaw angle for two roof wing configurations.

The upper graph in Figure 15 shows such a case where between 8° and 10° yaw, there is a significant change to the drag and rear lift forces. By means of a small modification to the upper rear corner of the roof wing, the sudden step is eradicated as shown in the lower graph.

As the airflow over the car is intrinsically time dependent, this change of force on the surface of the car can even be apparent when there is no particular change of yaw angle. Normally this is not noticeable but in some designs, it can create repetitive nervousness with a frequency of between 1 and 2 Hz.

5 DEVELOPMENT PROCESS

The typical aerodynamic development process for high volume production cars is, in general, largely generic. This process has evolved in parallel with the development process for the entire car with increasing complexity

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and demands leading to an increased need for aerodynamic research and development. Although including aerodynamic features and concepts into the car's design was present already since the early 1900s, this chapter relates mostly to the vehicles developed since the mid-1960s. A more detailed chapter relating to the historical development of automotive aerodynamics can be found in the work by Le Good *et al*. (2011). This time period reflects the beginning of the era when manufacturers started to be aware of the benefits of aerodynamics even for normal production cars. Figure 16 shows the evolution of Cd for a large number of different vehicles from the 1950s until the present day.

A central part in the development process of production cars is that the design of the vehicle has to be attractive in order to appeal to potential customers. The degree to which the external design of the vehicle can or may be influenced by aerodynamics will vary enormously among different model types, manufacturers, and market demands. There is never, therefore, a single solution to how the design process of a particular automotive project will be. Obviously, if the project in question has particular aims of offering significantly lower fuel consumption through low aerodynamic drag, more emphasis of the aerodynamic characteristics will have to be considered. Conversely, if a project is focused on offering a stunning looking form with little consideration for fuel consumption, design will be prioritized before low drag. Even in this case, however, the aerodynamicist will still need to ensure that other areas that are influenced by the airflow around the vehicle are satisfactory.

5.1 Design process—from multiple models to single model

A typical vehicle project will normally start with several different designers making sketches or models of a vehicle. These may sometimes be completely free of engineering restrictions, conceptual designs, but will normally have a number of design limitations already set. This would typically include major dimensions (width, height, length, etc.), but will probably include some basic aerodynamic guidelines. These guidelines, or aerodynamic hard-points, will be a result of previous experience with similar vehicle concepts and development, as well as preparatory research and development made in advance of the project start. The project targets will also have been investigated with regard to the fuel consumption levels, handling and stability needs, cooling air requirements, and other areas where aerodynamic performance is of significance.

Already from the dimension criteria in a project, one vital characteristic of the aerodynamic drag has been decided, that of the frontal area of the car. Since the late 1950s, the frontal area of passenger cars has steadily increased as a result of design trends, safety aspects, and customer demands and needs for bigger interior space. Subsequently, the frontal area has, market segment for market segment, increased by approximately 10% with each generation change. As the aerodynamic drag is a product of the C_D and the frontal area, the increase to area obviously has a negative effect. Restricting or controlling the size of the frontal area is therefore an important factor when defining the layout and dimensions of a new project.

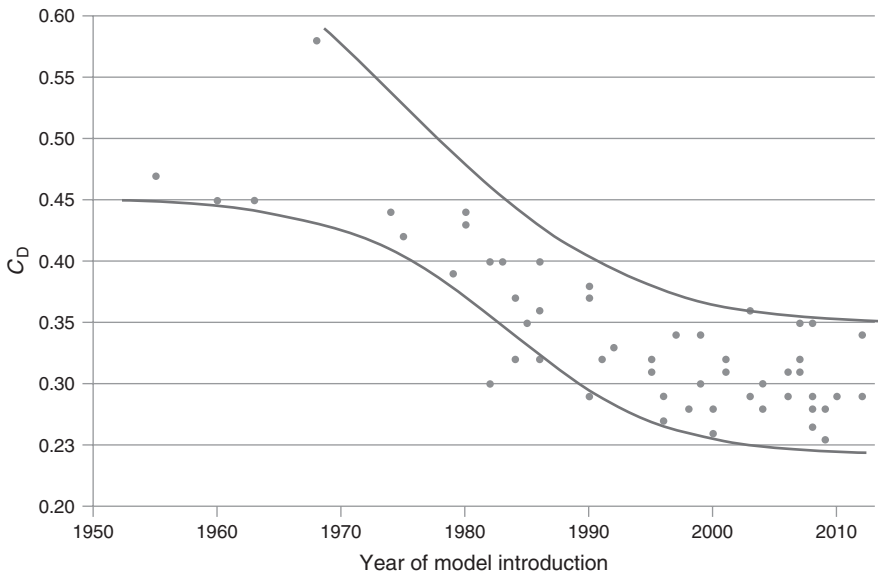

Figure 16. Evolution of C_D versus year of model introduction.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto241
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

An overview of the frontal area of C and D/E segment cars from 1993 to 2013 is shown in Figure 17.

The range of typical frontal areas, expressed in square meters, for different vehicle segments is given in Table 2.

During this period of many design models being studied, the aerodynamics group will try and analyze as many as practicable, in order to give feedback to each designer. This analysis will often be based again on previous experience, simple geometrical analysis of some or all the models, or even the results of testing the design. This may be done with physical testing of scale- or full-scale models and, since the mid-1990s, the increasing use of CFD. The degree to which method is used varies considerably between manufacturers, depending on the facilities and techniques available.

The purpose of aerodynamic analysis at this stage of the project is not to develop each model to its full potential but rather to identify the possibility of that model being able to reach the aerodynamic targets of the project. Fundamental analysis of the shape and design features can easily highlight areas where the design needs to be aerodynamically improved, and indeed areas where the aerodynamics works well. Typically, this analysis follows the basic guidelines for good aerodynamic design as outlined in Chapter 7.c.ii. This analysis, together with suggestions for improvement, is then given back to the designer and further changes to improve the situation may be implemented in the next iteration of the model. In some circumstances, however, this may be in conflict with the design theme that the designer is aiming for and may not be accepted.

It is not unusual at this stage of the design processes that the geometrical differences between different design proposals can be large. Similarly, the magnitude of suggested changes to the design of the car in order to improve the aerodynamic performance will also be large. In practice, this could be in the order of moving surfaces several centimeters. Even at this stage of the project, it is important to consider other attributes. For example, certain

design proposals can be identified as having difficulties of supplying sufficient cooling air without making significant changes to the design language or packaging. It is important that these conflicts are identified during the concept phase. Failure to do so will lead to difficulty of meeting the project targets during the production phase of the project, resulting in increased costs or reduced performance. Figure 18 summarizes the number of models and magnitude of possible design change during the course of the project.

As the project continues, the number of design proposals normally becomes less, perhaps being reduced from 10 or more to 6 or less within half a year. The reasoning behind this reduction is often styling based although other attribute conflicts, including aerodynamics, could be an influencing factor.

The reduction in the total number of models in the project may offer possibilities of the aerodynamics team working and analyzing all the models more thoroughly. Depending on the company development facilities and resources, more full-scale models may be built and tested in the wind tunnel. Alternatively, more CFD analysis, probably using more detailed models will also be made. By this stage of the project, the possibility to modify the design of the car in order to influence the aerodynamic performance of the car becomes more and more restricted. In practice, the surfaces of the car will not be modified during the development loops more than a few centimeters.

At this stage in the development process, it is also important to consider the interaction between the upper body design and the underside of the car. As described in Section 4, the mass flow of air over and below the car will sometimes determine how the optimum shape of the rear of the car will be. Furthermore, the degree to which the underside of the car is aerodynamically shaped will also influence the upper body shape optimization. Therefore, it is necessary to coordinate the development of both the upper and the lower surfaces.

Eventually, typically between 2 and 3 years before the start of production, a single model will be selected by the project from the models that have been developed. The choice of model will often be based on the design esthetics, together with an analysis of many different attributes that the project will need to consider.

Once the project has moved into this stage, the emphasis of aerodynamic development is more focused on the detail development and optimization. The development focus is normally shifted toward full-scale physical wind tunnel testing, although detailed CFD models may still be used for particular analysis. By this stage in the project program, the full-scale model should have a fully detailed underbody, representative cooling airflow and sufficient exterior detailing to give a correct aerodynamic behavior. This will be necessary in order to make correct suggestions for modifications to the design of the car if more work is required to meet the project targets. Typically, sheet metal changes of more than 5 mm will not be common at this stage as the risk of influencing other characteristics of the car, and thereby delaying the project, become greater the nearer the final "frozen" design of the car is made. It may still be possible to make design changes to the areas of the car where the lead-time for the part tooling is shorter. This could include the design of the rear lamps, or other exterior parts where small changes may be needed in order to obtain a clean flow separation, for example. It could also include small modifications to the underbody of the car, spoiler lips, and deflectors or under body panel design, which can still make a significant change to the drag and lift behavior of the complete vehicle. It is the aerodynamicist's responsibility to ensure that all the aerodynamic fine tuning is complete before the design is finalized.

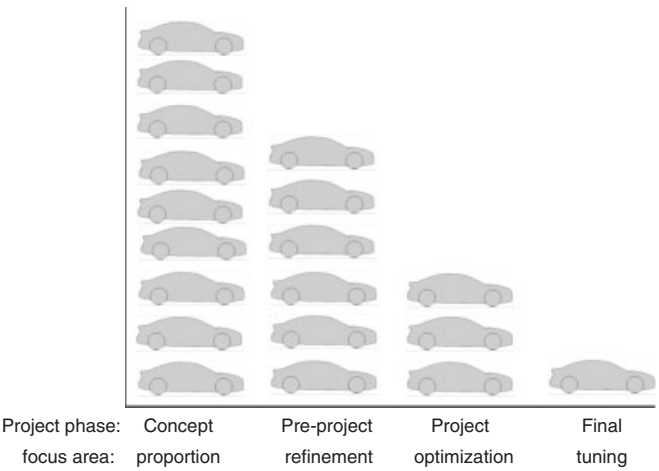

Figure 18. Design model and aerodynamic development process.

5.2 Attribute balancing

The drag targets will also consider those project prerequisites that will affect the aerodynamic performance of the car. This will include the basic underbody layout of the car, the packaging needs of the occupants, powertrain installation, visibility and safety requirements, manufacturing possibilities and limitations, and of course the cost limitations.

As a road-going vehicle fundamentally behaves as a wing creating both drag and lift forces, an acceptable balance between these two has to be found. This will depend on the project in question. If the vehicle has a relatively low top

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

speed (perhaps <190 kmph) perhaps it is sensible to prioritize lower drag than ensuring low lift. On the other hand, if the high speed handling properties of the car are considered more important, the lift levels on the front and the rear axles may be prioritized before drag. In practice, this balance will almost always be an engineering compromise.

In general, it is easier to modify details on the body of the car to adjust the lift forces and distribution front and rear than modify the drag levels. Often this is managed by modifying the height and shape of the car in the area where the airflow separates from the body. For sedans, this is typically on the upper surface of the boot/trunk lid and side surfaces of the rear fender.

5.3 Interaction effects

A fundamental part of the aerodynamic development process that has to be considered is the interaction effects of different areas of the body. Furthermore, these effects may well change the degree to which a design modification will work on the car. Therefore, for example, it is very important to analyze how the upper body design of a car can be optimized for a given under body design and vice versa. An example of this is shown in Figure 19. This summarizes a number of different aerodynamic changes when tested in isolation, compared to their respective effect on drag when tested as the complete optimized aerodynamic package.

As can be seen the effect adding the individual floor panels of the car is $\Delta C_D = -0.005$, whereas the combined effects is -0.008. Even more striking is the individual effect of the rear diffusor panel and the roof wing. The individual effects are only -0.004 but the combined effect, with the smoother underbody in position, is three times greater.

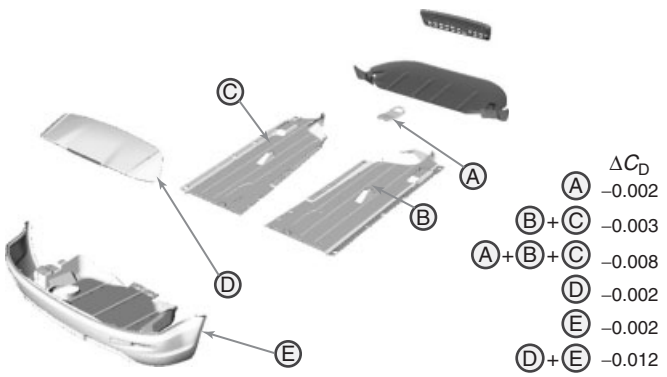

Figure 19. Interaction effects on drag for under and upper body parts.

5.4 Future trends

From the early 1980s, some volume production cars have offered designs with C_D of 0.30 or less. Since then, cars with C_D's of 0.30 have not been unusual, and from 2000 to 2010, there have been vehicles marketed with C_D as low as 0.25. Unfortunately, the reduction to C_D has in many cases been neutralized by an increase in frontal area, although a combination of low C_D and a small frontal area has been shown to be possible without creating a design that might only appeal to a limited customer base.

The need to reduce the fuel consumption in order to meet current and future legislation has forced manufacturers to include a low aerodynamic drag on more and more variants. Apart from keeping the frontal area to a minimum, for a given size of car, more effort will be required to achieve C_D values of 0.20 or less. As mentioned in Section 4.1, more than half the total drag on a typical car is from the underside, cooling, and wheels. Subsequently, more effort is being made to improve the flow underneath the car, generally achieved by designing the underside of the floor to be flatter or to have larger and flatter paneling. Initially, this concept was used by premium manufacturers but is becoming more normal even in high volume production cars.

A consequence of the improved under floor airflow is that the drag contribution from the cooling air and the tires has become more significant. By reducing the cooling air through the radiator and engine bay when not needed, this penalty is reduced. Furthermore, restricting the cooling air can also contribute to reduced fuel consumption by helping the engine reach its operating temperature quicker. Currently, systems that restrict ambient air reaching or passing through the cooling package are the most common. By 2020, there will probably be more variants that can control when and which cooling system should receive cooling air. The increased use of hybrids will create a need to cool different temperature cooling circuits in different manners, and will be suitable for new methods of flow control.

Optimized cooling air drag, a smoother under body, combined with a good basic aerodynamic design and attention to details has already shown that C_D values of under 0.24 are possible with a conventional design. The challenge to reach C_D values of 0.20 or less with road legal cars has been shown to be possible with the Saturn EV1 and the Volkswagen XL1 (Figure 20).

Both these cars (two seater, coupé-like) however have design features and packaging that would not be acceptable for high volume production cars. The challenge facing the automotive aerodynamicist and the design department is to create a five-seater vehicle with a C_D of under 0.20 that

Figure 20. 2013 Volkswagen XL1. (Reproduced by permission of Volvo Car Corporation.)

is not considered radical or unattractive. Covered wheel arch openings, for example, offer lower drag but may not be acceptable by the customer. The task is therefore to find aerodynamic solutions that offer a similar influence on the airflow around the car without the visual impact of fully covered wheel arches. New wheel concepts may be one solution, more sophisticated under body aerodynamic control may be another. One other possibility that may be introduced is the use of devices that actively influence the local airflow over certain critical areas of the car. These devices could be either moveable panels or even systems that attempt to influence the local boundary layer or flow separation behavior. These devices will undoubtedly add cost to the car but if the benefits are considered to outweigh the investments and product cost they may become a standard feature on higher priced vehicles by 2020.

Exterior Vehicle Noise Development: Assessment and Control

Ismael Fernández, Juan J. García-Bonito, and Javier Iturbe

Applus + IDIADA, Tarragona, Spain

1 INTRODUCTION

All vibrating bodies surrounded by a fluid, gas, or liquid compress the layers of fluid adjacent to their surface. This compression is transmitted to the mass of surrounding fluid and is conveyed beyond the body. In these circumstances, the vibrating surface acts as a source of noise. Independently of whether the source of noise radiates in an open space (free field) or in an enclosed space (reverberate field), the acoustic field at a particular point is determined by the fluctuating pressure due to the wave propagation. The measurement of this acoustic pressure is of vital importance in any test to quantify the level of noise produced by a component or vehicle. Furthermore, the analysis of the variation in this pressure in the time and frequency domain gives us fundamental information about the origin of the noise studied.

2 SOUND AND NOISE

Sound is a disturbance in the balanced state of the air molecules that vibrate due to the propagation of a compression wave created by a vibrating object. This disturbance is associated with an alternative displacement of the layers of air and a fluctuation of pressure (acoustic pressure) that, on reaching our ears, produces the auditory sensation. Sound may generate pleasant or unpleasant sensations depending on the spectral and temporal characteristics of the fluctuating pressure affecting our eardrums.

A clearly unpleasant or annoying sound is called *noise*. Nevertheless, the level of nuisance does not only depend on the type of sound but also on our attitude toward it; for example, a type of music that some people may like may annoy others, especially if it is very loud. Another example of the subjectivity of the possible nuisance of a sound is the sensation that the exhaust system of a sports car produces: it is pleasant for fans of this type of vehicles, but extremely annoying for others.

3 THE NATURE OF SOUND

Sound is defined as a pressure variation that the ears can detect, ranging from very low variations to levels that could

cause damage. The study of sound is called *Acoustics* and covers all fields of generation, propagation, and reception of sound. Noise is an unavoidable part of daily life and technological development, which has produced a notable increase in the noise level coming from machines, factories, traffic, and the like.

Figure 1 shows a piston mounted at the end of a cylindrical tube producing an alternative forward and backward movement. When the piston moves forward, the particles near to its surface accumulate creating a compression zone; when it moves backward, the particles separate creating a rarefaction zone or dilation. In compression, the air pressure will be a little higher than its value of balance and in dilation it will be a little lower. Therefore, a series of compressions and dilations will be created along the tube. Thus, a sound wave will be generated in the tube, which can be heard at the other end. The speed of sound propagation along the tube is a function of the elasticity and air density, which depend on the static pressure and temperature. At atmospheric pressure and at 20°C, the speed of sound in air is 344 m/s.

Figure 2 shows the variation in pressure around the static value P_o (atmospheric pressure) as a function of time for a generic point inside the tube. The maximum fluctuation is called *sound amplitude* and the number of oscillations per second that coincides with the rhythm of vibration of the piston is called the *sound frequency*. We will call this sound a *pure tone* because it has been created by a sound source that oscillates at a single frequency.

Very few man-made noises or natural sounds are pure tones. Even the sounds of a musical instrument, which seem to be made up of a clear single note, contain more than one frequency. Normally, the sensation of frequency that we perceive (tonality) corresponds to the dominant frequency of the sound heard.

The range of audible frequencies, for a young and healthy person, goes from approximately 20 Hz until 20,000 Hz. Frequencies below 20 Hz give rise to infrasound and frequencies higher than 20 kHz to ultrasound. On the other hand, as we will see later on, not all audible frequencies are perceived equally by the human ear.

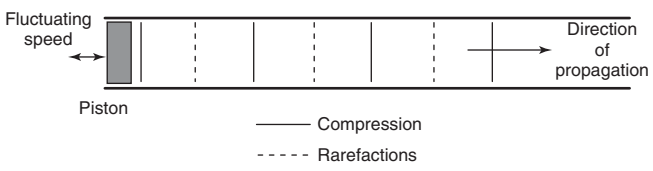

Figure 1. Vibrating piston at the end of the tube generates a compression wave that propagates along the tube, producing a compression and rarefaction (wave), which propagates at the speed of sound (345 m/s). (Reproduced by permission of IDIADA.)

4 SOUND PRESSURE: THE DECIBEL

As described above, sound is made up of a series of oscillations of pressure in relation to atmospheric pressure. Therefore, it is logical to think that this pressure is the most obvious parameter to express the magnitude of the sound field. Strictly speaking, the amount to measure is the difference between the fluctuating value of pressure and its value of balance P_o (atmospheric pressure). However, as the frequency of the wave increases, it is more difficult to measure these fluctuations as they become faster. It is obvious that, even for the lowest vibration able to produce audible sound, it is necessary to make a time average that serves as an indicator of the amplitude of the signal. The way this average is calculated is as follows:

- Square all the values of pressure difference during any cycle. Hence, negative values become positive.
- Average
- Calculate the square root.

The final result is known as the *root mean square* (r.m.s.) *value* represented as $p_{\text{r.m.s}}$. From now on, we will refer to the value of acoustic pressure that characterizes an acoustic field at the measuring point as the r.m.s. value of the pressure difference.

Mathematically, this is expressed by

$$p_{\text{r.m.s.}} = \sqrt{\frac{1}{T}\int_0^T p^2(t)\mathrm{d}t} \tag{1}$$

The measurement unit of pressure is the Newton/m^2, called *Pascal* (Pa). Typical acoustic pressures have values of fractions of a Pascal, whereas atmospheric pressure is approximately 100,000 Pa (=1 atmosphere). Therefore, sound waves are associated with tiny variations in air pressure.

Unfortunately, the measurement of sound pressure directly in Pascal gives rise to a series of difficulties, whose origin comes from the characteristics of the human ear, and which are explained below:

- The pressure range that the human ear can perceive is wide. The weakest sound pressure that can be perceived by a normal, healthy person is 2×10^{-5} Pa at a frequency of 1000 Hz (auditory threshold), while the sound pressure that begins to be painful is 100 Pa (pain threshold). That is, the scale of audible pressures covers a dynamic range of 1 to 5,000,000, which leads to the use of unmanageable numbers.
- Our auditory system does not respond lineally to the stimuli that we receive but rather has a logarithmic form.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

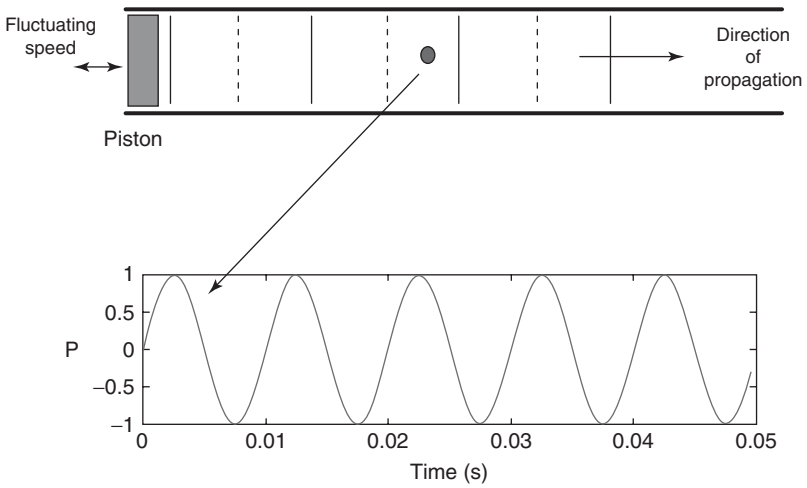

Figure 2. Variation in acoustic pressure with time at a particular point in the tube, which is induced by the vibration of the piston. If that vibration is sinusoidal, pressure will follow the same trend. (Reproduced by permission of IDIADA.)

For example, if the pressure of a pure tone of 1 kHz is doubled, the sensation produced by it will not be double. This is a clear demonstration of the nonlinearity of hearing.

For these two reasons, it seems reasonable to use a logarithmic scale in order to quantify the sound pressure. However, as the logarithm of a number lower than 1 is negative, this would mean that any sound pressure whose value were a fraction of 1 Pa would be expressed by a negative number. In order to avoid this problem, a reference amount for which it will always be necessary to divide the corresponding pressure before taking logarithms is introduced. This amount is in fact the threshold of perception, that is, 2×10^{-5} Pa. On the basis of this, the level of sound pressure is defined by:

$$\mathrm{SPL} = 10 \cdot \log \frac{p^2}{p_{\mathrm{ref}}^2} = 20 \cdot \log \frac{p}{p_{\mathrm{ref}}} \tag{2}$$

This expression is called the *sound pressure level* and is measured in decibels relative to 2×10^{-5} Pa. The word *level* is added to indicate that the amount has a certain level above a preset reference value. The acronym *SPL* or the symbol L_{p}. is used.

5 ACOUSTIC INTENSITY

Another parameter of interest in the definition of an acoustic field is the intensity. The *intensity* of a sound wave is the amount of acoustic energy crossing the unit of area normal to the direction of propagation of the wave per unit of time. Therefore, it is expressed in units of power (energy per unit of time) per surface unit, that is, in watt/m^2. In the case of a flat wave, as seen in the tube in Figure 1, the acoustic intensity is given by:

$$I = \frac{p^2}{\rho c} \tag{3}$$

where p is the acoustic pressure (r.m.s), ρ is air density (kg/m^2), and c denotes the sound speed (m/s). Figure 3 illustrates the concepts associated with the measurement of intensity. The vector crossing the plane that denotes the unit of area indicates acoustic power and has information about its associated direction.

As with the sound pressure, one can talk about the sound intensity level defined as

$$\mathrm{SIL} = 10 \cdot \log \frac{I}{I_{\mathrm{ref}}} \tag{4}$$

where *SIL* is the sound intensity level, I is the intensity in W/m^2, and I_{ref} is the intensity of reference that, in this case, is taken as 10^{-12} Watt/m^2. The measurement of sound intensity offers the opportunity to detect *in situ* the area of a vibrating surface that emits more noise. In this context, the expression *emits more noise* suggests that the surface injects acoustic energy into the environment and acts like a loudspeaker. Intensimetry may also reveal those parts of a surface acting as energy drains and subsequently absorbing noise.

It is of vital importance to keep in mind the vectorial nature of the measurement of intensity, that is, all measurements of intensity have amplitude and direction. Therefore,

(Reproduced by permission of IDIADA.)

it is very useful for the location of sources in acoustically complex spaces to be known.

6 ADDITION AND SUBTRACTION OF DECIBELS

6.1 Addition of decibels

When two sound sources radiate sound, they both contribute to the existing sound pressure level at a point far from both sources. Let us assume that dB_1 and dB_2 are the sound pressure levels due to two sources that are radiating simultaneously. The acoustic pressure at a point in the space associated with each source is given by

$$dB_1 = 10 \cdot \log \frac{p_1^2}{p_{ref}^2} \Rightarrow p_1^2 = p_{ref}^2 \cdot 10^{\frac{dB_1}{10}}$$
$$dB_2 = 10 \cdot \log \frac{p_2^2}{p_{ref}^2} \Rightarrow p_2^2 = p_{ref}^2 \cdot 10^{\frac{dB_2}{10}} \quad (5)$$

In order to know what is the total sound pressure produced by the acoustic surfaces, we will refer to the concept of intensity established previously: intensity is the energy per unit of surface and per unit of time. Therefore, it seems logical to think that the intensity due to both sources will be the sum of the intensities of each source. We have also seen that intensity is proportional to the r.m.s. pressure squared (Equation 3), and so, we can deduce that the r.m.s. pressure squared due to the two sources will be the sum of the r.m.s. pressures squared for each of the sources; therefore, it will be

$$p^2 = p_1^2 + p_2^2 = p_{ref}^2 10^{\frac{dB_1}{10}} + p_{ref}^2 10^{\frac{dB_2}{10}} \quad (6)$$

And the total sound pressure level will be

$$dB_{1+2} = 10 \cdot \log \frac{p^2}{p_{ref}^2} = 10 \cdot \log \frac{p_{ref}^2 \left(10^{\frac{dB_1}{10}} + 10^{\frac{dB_2}{10}}\right)}{p_{ref}^2}$$
$$= 10 \cdot \log \left(10^{\frac{dB_1}{10}} + 10^{\frac{dB_2}{10}}\right) \quad (7)$$

This result could be extended to n sources, that is,

$$dB_n = 10 \cdot \log \left(\sum_{i=1}^{n} 10^{\frac{dB_i}{10}}\right) \quad (8)$$

According to Equation 8, the sum of two equal levels of SPL produces an increase of 3 dB. Therefore, two sources producing individually a sound level of 80 dB at a certain point will generate a total pressure of 83 dB when acting simultaneously.

6.2 Subtraction of decibels

In some cases, it is necessary to subtract levels of noise. By means of a mathematical development similar to that explained in the previous section, it is deduced that the difference in two levels of noise given by dB_1 and dB_2 is

$$dB_{1-2} = 10 \cdot \log \frac{p^2}{p_{ref}^2} = 10 \cdot \log \left(10^{\frac{dB_1}{10}} - 10^{\frac{dB_2}{10}}\right) \quad (9)$$

The most usual case of the subtraction of decibels arises when we need to measure the noise of a component in the presence of background noise. In these cases, it is important to know whether the measured noise is dominated by the noise of the machine, the background noise, or by a combination of both. The procedure is as follows:

(a) The total existing noise with the component in L_{s+n} operation is measured.
(b) The component is stopped or encapsulated and the background noise measured L_n.
(c) The ΔL difference is calculated as $L_{s+n} - L_n$.

If ΔL is <3 dB, the background noise is too high for an accurate measurement and, therefore, the level of noise produced by the component cannot be measured accurately as long as the background noise does not decrease. On the other hand, if the difference is above 10 dB, the background noise can be ignored. If the difference is between 3 dB

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and 10 dB, the correct level of noise can be found using Equation 9.

7 FREQUENCY WEIGHTING SCALES

The human ear is not consistent in its sensitivity to different frequencies. Therefore, the ear will perceive a sound at 1000 Hz with greater intensity than one of the same intensity at 200 Hz. In order to take into account this phenomenon, weighting scales of different frequencies have been standardized. These are shown as A, B, C, and D in Figure 4. Initially, these weighting scales were developed for different levels of noise: scale A was for low noise level (40 dB), scale B for medium sounds (70 dB), and scale C for loud sounds (100 dB). However, in the end, scale A has been applied universally to all levels. Scale D is used exclusively for aircraft noise.

It is important to observe that scale A noticeably attenuates frequencies below 300 Hz. This aspect should be borne in mind in the analysis of vehicle interior noise at low speeds as this is dominated by the structural excitation that the engine introduces into the passenger compartment, predominately at low frequencies (<200 Hz).

8 NOISE CONTROL

The term *noise control* refers to all those techniques that reduce the level of acoustic pressure at a point in free space or inside a given enclosed space. The method used to get this noise reduction (or control) basically depends on the level of understanding of the noise source and of the difficulty and cost associated with implementing this method. The techniques of noise control most commonly used at present are based on the following principles:

- Acoustic isolation
- Acoustic absorption
- Reduction of the excitation force that acts on the radiant surface
- Reduction of the level of vibration on the surface of the source
- Reduction of the transmissibility of the medium of propagation (air/structure)
- Cancellation of noise through destructive interference (active noise control)

Of the above techniques, the first two stand out for the simplicity of their application in a great number of situations. Acoustic isolation and absorption use the idea of inserting an acoustic barrier combined with noise-absorbing materials. The combination of both principles could be used in those cases in which the noise problem is found at high frequencies (>1 kHz). However, these methods are ineffective in reducing noise at low frequencies (<400 Hz) as; in this case, the wavelength of the sound to be controlled is much greater than the thickness of the materials and the absorbents used in the construction of the barriers (or encapsulation).

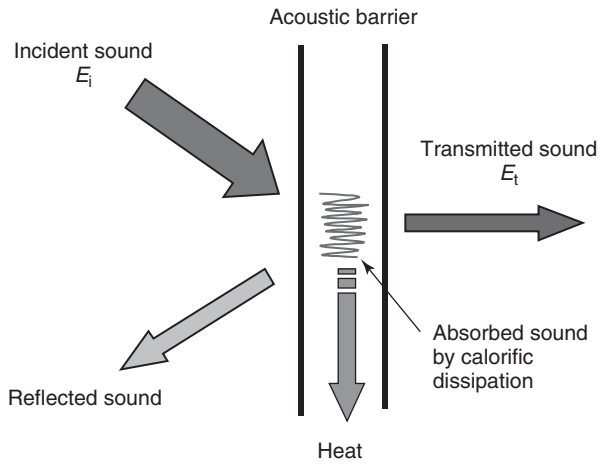

Figure 5. Sound reflected, absorbed, and transmitted. The energy of the incident wave is not destroyed; it is only reflected and transformed into heat. The rest of the energy generates a transmitted acoustic wave of lower amplitude than the incident wave. (Reproduced by permission of IDIADA.)

Noise does not always spread freely in space (propagation in free field). On many occasions, the sound reaches obstacles such as roofs, walls, and structural panels which cause reflections. Vehicle engine noise, for example, finds an obstacle in the wall that separates the engine compartment from that of the passengers (the firewall). A car with the bonnet open is noisier (external noise) than with bonnet closed as the bonnet obstructs the noise escaping to the exterior. When an acoustic wave reaches a solid surface, such as the firewall of a vehicle, part of the acoustic energy is transmitted to the other side of the barrier, another part is reflected, and the barrier absorbs the rest. Figure 5 shows the distribution of the acoustic energy of a wave that hits a barrier of this type.

Isolation and absorption are the two characteristics that make a material interesting from an acoustic point of view. They are two different characteristics, but the combination of both is very desirable from the point of view of noise control.

9 EXTERIOR NOISE MEASUREMENT

The main exterior noise measurement for homologation purposes is performed nowadays in wide open throttle acceleration condition, but in a short time, a new testing procedure will enter into force. This procedure is the result of wide studies of driver behavior in the urban traffic and it intends to simulate the real urban driving conditions. On the contrary to the current method, it takes into account the vehicle noise at full throttle acceleration and constant speed conditions.

The current method is explained in standards and regulations (Regulation No 51–02 – Rev.1/Add.50/Rev.2/Amend.1, 2012), (EU Directive 92/97/EEC amending Directive 70/157/EEC, 1992); (ISO 362, 1998) and it will be explained here. In order to explain the procedure, we need to introduce the concept of vehicle category.

9.1 Vehicle category

Vehicles can be classified into the following categories:

- Category M_1. Vehicles used for the carriage of passengers and comprising not more than eight seats in addition to the driver's seat.
- Category M_2. Vehicles used for the carriage of passengers, comprising more than eight seats in addition to the driver's seat, and having a maximum mass not exceeding 5 tons.
- Category M_3. Vehicles used for the carriage of passengers, comprising more than eight seats in addition to the driver's seat, and having a maximum mass exceeding 5 tons.
- Category N_1. Vehicles used for the carriage of goods and having a maximum mass not exceeding 3.5 tons.
- Category N_2. Vehicles used for the carriage of goods and having a maximum mass exceeding 3.5 t but not exceeding 12 tons.
- Category N_3. Vehicles used for the carriage of goods and having a maximum mass exceeding 12 tons.

9.2 Test track

The exterior noise tests are performed in a track that consists of two areas (Figure 6):

- A drive line with a length l_a and a width of 3 m minimum. The minimum value of l_a is 20 m for long vehicles and 10 m for the other ones.
- A propagation area that extends at least 10 m from the center of the drive line CC′ and at least 10 m at both sides of the line PP′.

The microphones must be located at a distance of 7.5 ± 0.2 m from the reference line CC′ (Figure 6) of the track and 1.2 ± 0.1 m above the ground. Their axes of maximum sensitivity must be horizontal and perpendicular to line CC′.

Two lines AA′ and BB′, parallel to line PP′, situated, respectively, 10 m forward and 10 m rearward of PP′ are marked out on the test runaway.

9.3 Test procedure

9.3.1 Test with vehicle in motion (pass-by test)

The vehicle is driven at constant speed as specified below on the drive line until it reaches the line AA′. Its longitudinal median plane will be as close as possible to the line CC′. Just when the vehicle front end reaches line AA′, the driver has to depress the pedal as rapidly as practicable and will keep in this position (wide open throttle) until the vehicle rear end reaches line BB′, when the pedal also will be released as rapidly as practicable (Figure 7).

The maximum sound level, expressed in A-weighted decibels, shall be measured, at both vehicle sides, as the vehicle is driven between lines AA′and BB′. Such values shall constitute the results of the measurement (Figure 8). The time weighting has to be "fast".

9.3.1.1 Choice of gear ratios

9.3.1.1.1 Vehicles with manual transmission

9.3.1.1.1.1. Vehicles of categories M_1 and N_1. When these vehicles are fitted with a gearbox with four forward gears or less, they shall be tested in second gear.

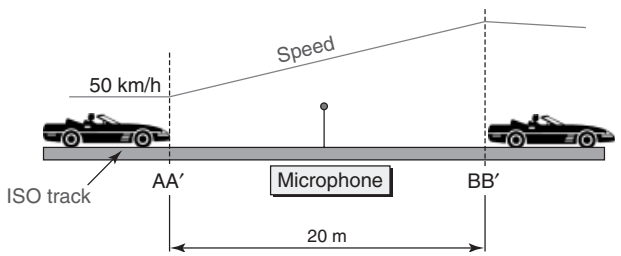

Figure 7. Layout of the exterior noise test. (Reproduced by permission of IDIADA.)

When they are fitted with a gearbox with five forward gears or more, they shall be tested in second and third gear.

9.3.1.1.1.2. Vehicles of categories other than M_1 and N_1. These vehicles shall be tested sequentially at different gear ratios. Initial testing will be carried out using the gear ratio which gear is (x/n) or the next higher gear ratio if (x/n) is not an integer.

where
x is the number of forward gears
$n = 2$ when the engine power is not >225 kW
$n = 3$ when the engine power is >225 kW

The testing shall continue from the gear (x/n) to the next higher gear. Shifting up ratios from (x/n) shall be terminated when in the gear x in which the rated rotating engine speed S is reached just before the rear of the vehicle has passed the line BB′.

9.3.1.1.2 Vehicles with automatic transmission. The test will be conducted with the selector in the position recommended by the manufacturer for normal driving.

9.3.1.2 Approach speed

9.3.1.2.1 Vehicles with manual transmission

9.3.1.2.1.1. Vehicles of categories M_1 and categories other than M_1 whose engine power is not $>$ 225 kW The approach speed is the lowest of the following: $V_A = 50$ km/h or V_A corresponding to $N_A = \frac{3}{4}S$

where
V_A: Uniform vehicle speed at the approach of line AA′

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

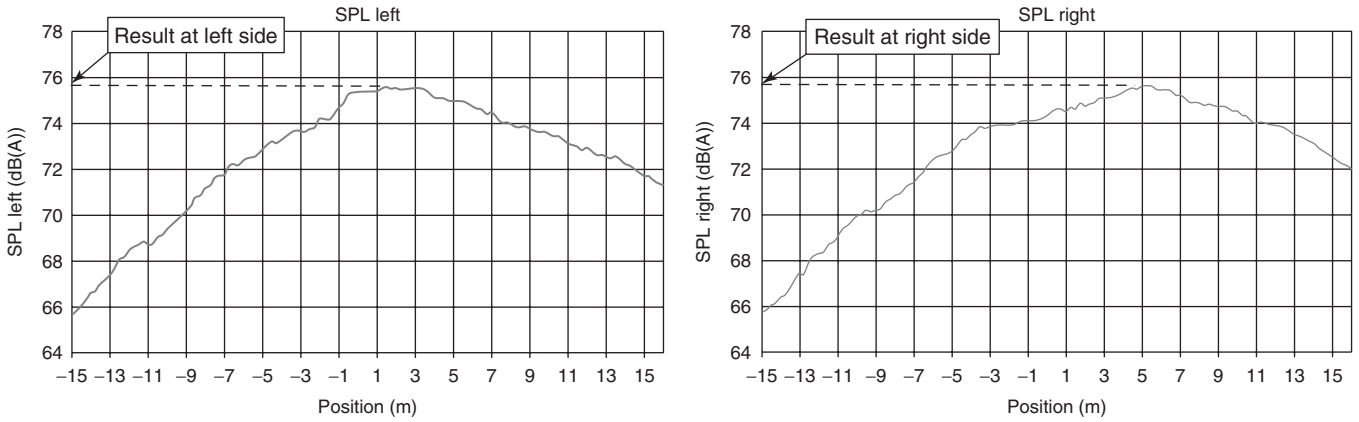

Figure 8. Results of the exterior noise test. (Reproduced by permission of IDIADA.)

S: Rated engine speed—engine rotation speed at which the engine develops its maximum power, according to Regulation 85 (2013).

9.3.1.2.1.2. Vehicles of categories other than M_1 whose engine power is >225 kW The approach speed is the lowest of the following: $V_A = 50$ km/h or V_A corresponding to $N_A = \frac{1}{2}S$

where
V_A: Uniform vehicle speed at the approach of line AA′
S: Rated engine speed—engine rotation speed at which the engine develops its maximum power, according to Regulation 85 (2013)

9.3.1.2.1.3. Vehicles powered by an electric motor The approach speed is the lowest of the following: $V_A = 50$ km/h or $V_A = \frac{3}{4}V_{max}$

where
V_A: Uniform vehicle speed at the approach of line AA′
V_{max}: Maximum vehicle speed declared by the vehicle manufacturer

9.3.1.3 Interpretation of results.

9.3.1.3.1 Vehicles of categories M_1 and N_1. Two runs are performed at each one of the tested gears. When the vehicle has more than four forward gears, we have to test in second and third gear. Then, we will have four results for the second gear and four results for the third gear, according to Figure 8 (two runs and two sides per run). We have to take the maximum of the four results in the second gear and the maximum of the four results in the third gear, and we calculate the average value between them.

$$dB_{avg} = \frac{dB_{max\,2} + dB_{max\,3}}{2} \quad (10)$$

where,
$dB_{max\,2}$ is the maximum of the four results in second gear
$dB_{max\,3}$ is the maximum of the four results in third geard
B_{avg} is the average

When the vehicle is tested in one gear only, we have to take the maximum of the four results. Finally, we round the value and reduce by 1 dB and the obtained value is the final result of the vehicle in motion.

9.3.1.3.2 Vehicles of categories other than M_1 and N_1. Vehicles other than categories M_1 and N_1 are tested at different gears (Section 9.3.1.1.1.2). The final result of the vehicle in motion test is the maximum of all results corresponding to all the tested gears, rounded and reduced by 1 dB.

9.3.2 *Test with stationary vehicle*

In order to facilitate the checks of the vehicles in-use, the sound level must be measured close to the exhaust outlet.

9.3.2.1 Target engine speed. The target engine speed is defined as follows:

- When $S \leq 5000$ rpm, target speed $N_T = \frac{3}{4}S$
- When $5000 < S < 7500$ rpm, target speed $N_T = 3750$ rpm
- When $S \geq 7500$ rpm, target speed $N_T = \frac{1}{2}S$

where
N_T: target engine speed. Engine rotation speed at which we perform the test

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

S: Rated engine speed—engine rotation speed at which the engine develops its maximum power, according to Regulation 85 (2013).

9.3.2.2 Test procedure. The vehicle will be located in the center of the test area with the gear lever in neutral position and the clutch engaged.

The microphone will be located at a distance of 0.5 ± 0.01 m from the reference point of the exhaust pipe as defined in Figure 9.

The engine speed will be gradually increased from idle to the target engine and held constant when we reach it. Then, the pedal will be rapidly released and the engine returned to idle. The sound pressure will be measured during a time period consisting of a constant engine speed of at least one second and throughout the entire deceleration period. The maximum sound level will be taken as the test value. The result has to be given in A-weighted decibels (dB(A)) and the time weighting will be "fast".

9.3.3 Compressed air noise test

Vehicles having a maximum permissible mass exceeding 2800 kg are subjected to an additional measurement of the compressed air noise with the vehicle stationary, if the corresponding brake equipment is part of the vehicle. This test is described in Regulation 51 (2012).

9.4 Evolution of the exterior noise measurement procedure

The first noise limits for motor vehicles having at least four wheels, adopted by the European Economic Community, entered into force in 1970. The test procedure used at that time was almost similar to the one described above,

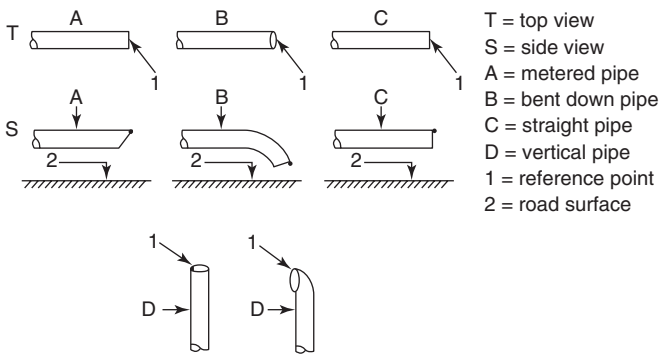

Figure 9. Reference point of the exhaust pipe. (Reproduced from Regulation No 51-02-Rev.1/Add.50/Rev.2/Amend.1.)

Table 1. Exterior noise limits from 1970 to 1992 (in dB(A)).

	Year of Entry into Force			
	1970	1981	1984	1992
Cars	82	80	77	74
Buses	91	85	83	80
Trucks	91	88	84	80

and it was intended to evaluate the noise emitted by the powertrain.

Since 1970, engines and the rest of the powertrain have become much quieter as a result of the big development work done during the last 40 years. This is reflected by the noise limit reduction from 1970 to 1992 shown in Table 1.

These reductions range between 8 dB(A) for the cars and 11 dB(A) for trucks and buses. It is interesting to remark that a reduction of 3 dB means that the acoustic power emission is reduced by 50%. This means that the acoustic power emission of a car is now 16% of the one of 1970 and the acoustic power emission of a truck or bus is now 8% of the one of 1970.

Nowadays, the vehicle noise emission is not any more dominated by the powertrain. The noise generated by the rolling of tires on the road surface (rolling noise) is also significant for the overall noise. This noise is not well evaluated in the actual procedure that measures vehicles in wide open throttle condition only.

Consequently, a new procedure that takes into account the actual level of noise due to vehicle emission in urban traffic has been developed recently although it has not entered into force yet. This procedure is described in references (Regulation No 51–02 – Rev.1/Add.50/Rev.2/Amend.1, 2012) and (ISO 362–1, 2007). This new procedure is described in the following paragraphs.

9.4.1 Vehicles of categories M_1, N_1, and M_2 with test mass not >3500 kg

The test of vehicles of categories M_1, N_1, and M_2 with test mass not >3500 kg according to the new procedure shows the following characteristics.

We perform acceleration and constant speed (steady) tests instead of only acceleration tests. (Figure 10b)

In the acceleration tests, the vehicle reaches the speed of 50 km/h at the center of the track instead of at the beginning (Figure 10a and b).

In the new method, the concepts of reference acceleration and urban acceleration are defined.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

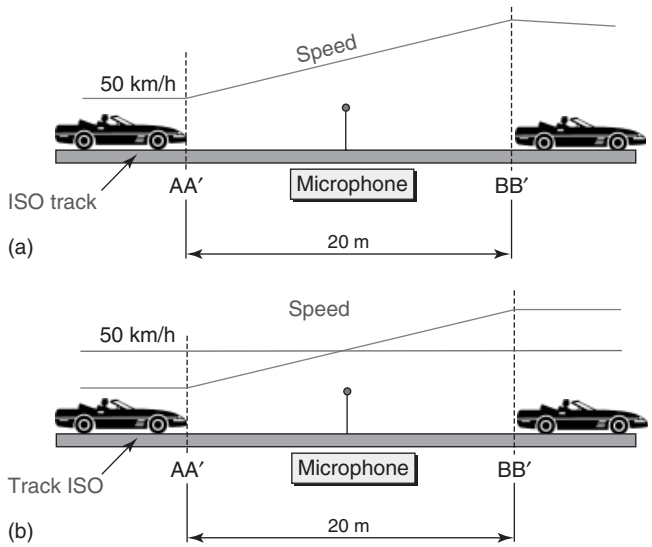

Figure 10. Exterior noise test. (a) Current method with wide open throttle acceleration test only. (b) New method with wide open throttle acceleration and constant speed tests. (Reproduced by permission of IDIADA.)

9.4.1.1 Reference acceleration. Reference acceleration is defined according to the following expression:

$$a_{\text{wot ref}} = 1.59 \cdot \log(\text{PMR}) - 1.41 \tag{11}$$

where

$a_{\text{wot ref}}$ is numerical value of the reference acceleration in m/s^2

PMR is the power to mass ratio, a dimensionless quantity according to the equation

$$\text{PMR} = \frac{P_{\text{n}}}{m_{\text{t}}} \cdot 1000 \tag{12}$$

where

P_{n} is the numerical value of the engine power measured according to Regulation 85 (4), expressed in kW

m_{t} is the numerical value of the vehicle mass, expressed in kg

9.4.1.2 Urban acceleration. Urban acceleration is defined according to the following expression:

$$a_{\text{urban}} = 0.63 \cdot \log(\text{PMR}) - 0.09 \tag{13}$$

where

a_{urban} is the numerical value of the urban acceleration in m/s^2

PMR is the power to mass ratio, as defined in 12

Both accelerations are characteristic parameters of the vehicle.

In the new method, reference acceleration is the required acceleration in the test track. We can find two scenarios.

First scenario: the vehicle has a gear position i whose corresponding wide open throttle acceleration is in a tolerance band of $\pm 5\%$ of the reference acceleration.

$$\frac{|a_{\text{wot } i} - a_{\text{wot ref}}|}{a_{\text{wot ref}}} \leq 0.05 \tag{14}$$

where

$a_{\text{wot ref}}$ is the reference acceleration as defined in Equation 12

$a_{\text{wot } i}$ is the wide open throttle acceleration corresponding to the gear position i

In this case, we perform the acceleration measurements in this gear.

Second scenario: none of the gear ratio positions gives a wide open throttle acceleration that fulfills the condition in Equation 14. In this case, we choose a gear ratio i whose wide open throttle acceleration $a_{\text{wot } i}$ is higher than the reference acceleration $a_{\text{wot ref}}$ and another gear ratio $i+1$ whose wide open throttle acceleration $a_{\text{wot } (i+1)}$ is lower than the reference acceleration $a_{\text{wot ref}}$.

Then, we test both gears and the final acceleration noise level $L_{\text{wot rep}}$ is the weighted average of sound levels of both gears, and the weighting factor depends on the differences between the achieved accelerations in the different gears.

In the constant speed tests, the vehicle passes the test track at 50 km/h in the same gear or gears as used in the acceleration tests. When we perform the test in two gears, the final constant speed noise level $L_{\text{crs rep}}$ is the weighted average of sound levels of both gears, and the weighting factors are the same as the ones used in the acceleration tests.

The urban acceleration is defined in Equation 13. This expression is the result of statistical studies of the behavior of different vehicles, driven in different driving conditions (economical, normal, and aggressive) in different cities.

The urban noise level is a weighted summation of sound levels from acceleration and constant speed tests, where the weighting factor depends on the ratio between the urban acceleration a_{urban} and the reference acceleration $a_{\text{wot ref}}$. This weighting factor is called *part power factor* for urban driving k_{p} and it is defined as:

$$k_{\text{p}} = 1 - \frac{a_{\text{urban}}}{a_{\text{wot ref}}} \tag{15}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where
k_p is the part power factor
a_{urban} is the urban acceleration as defined in 13
$a_{wot\ ref}$ is the reference acceleration as defined in 11

The part power factor ranges between 0 and 1. When a car has a part power factor close to 1, this means that the reference acceleration is much higher than the urban acceleration ($a_{urban} \ll a_{wor\ ref}$). This vehicle uses a small part of its power in urban acceleration condition. This is the situation of high powered cars.

When a car has a part power factor close to 0, it has the reference acceleration close to the urban acceleration ($a_{urban} \approx a_{wor\ ref}$). This vehicle uses almost full power in urban acceleration condition. This is the situation of low powered cars.

The final test result is calculated by combining the levels from acceleration and constant speed tests using the following equation:

$$L_{urban} = k_p \cdot L_{crs\ rep} + (1 - k_p) \cdot L_{wot\ rep} \qquad (16)$$

where
L_{urban} is the urban noise
k_p is the part power factor as defined in 15
$L_{crs\ rep}$ is the noise level in constant speed
$L_{wot\ rep}$ is the noise level in acceleration

High powered vehicles have a part power factor close to 1; consequently, according to expression 16, its urban noise is dominated by the noise level measured in constant speed condition. On the contrary, low powered cars have a part power factor close to 0 and, according to Equation 16, its urban noise is dominated by the noise level measured in acceleration condition.

9.4.2 *Vehicles of categories M_2 with test mass >3500 kg, N_2, M_3, and N_3*

For other categories of vehicles, the test procedure is less complex. The wide open acceleration test has to be performed within a target speed range and a target vehicle speed range instead of a target acceleration. Testing can be done in one gear if target ranges are reached in this gear. If no gear fulfills the target conditions for the vehicle speed, we have to test two gears, one above and one below the prescribed speed range. The constant speed test is not included for these vehicle categories.

10 AUTOMOTIVE APPLICATIONS

10.1 Evaluation of ambient urban noise

Most of the investigations on acoustic pollution are based on the measurement of the levels of ambient noise produced by different sound sources and especially by transport vehicles. It has been demonstrated that traffic is the most important and widespread source of noise in industrial countries.

In order to express the existing relationship between exposure to noise and the subjective responses of people affected by this environmental factor, all the studies have used various noise indicators. However, in fact, it has been shown that all these indicators are closely related to each other. One of these is the equivalent continuous sound level measured during a 24-h period, (L_{eq} (24 h)). It can be used, with certain limitations, to predict the general response of a community (subjective nuisance for the residents) in the face of the impact produced by a wide variety of different sound sources. The L_{eq} (24 h) evaluates the average value of the noise level to which a predetermined zone is exposed during a period of time. In general, the L_{eq} measured in an interval of T time is calculated by means of the expression:

$$L_{eq}(T) = 10 \cdot \log\left(\frac{1}{T}\int_0^T \frac{p^2(t)}{p_0^2}\mathrm{d}t\right) \qquad (17)$$

That is to say, its value is the average constant amplitude of noise with the same acoustic energy as that of the noise measured. Figure 11 illustrates the time variation of an arbitrary acoustic signal during an interval of time T, its energy, and the value of L_{eq} associated with this interval, that is, L_{eq} (T). In general, urban noise measurements show a frequency range between 125 and 2 kHz, which is typical of the noise generated by traffic. Above these frequencies, the spectral level decays progressively. These bands of relative low frequency tend to be easily transmitted through building structures (walls, windows, foundations, etc.), making the impact on the population still greater than expected.

More recent investigations have shown that the characterization of ambient noise in a given urban location with the L_{eq} parameter alone could be incomplete. This is particularly true for those environments that experience big variations in noise level during the time interval studied. In these circumstances, we also need to describe the statistic and time variability of the noise level as a random variable.

10.2 Analysis of contribution of external noise sources

The above-described procedures (current and new) do not give information about the structure or the main components of the total noise emitted by a vehicle. In order to understand this structure, we should bear in mind that the noise produced by vehicles is composed of the contribution of the following sources:

- Engine
- Intake system
- Exhaust system
- Rolling
- Aerodynamic

The contribution of each one of these acoustic sources to the overall noise level changes, both in level and spectral content, depending on the vehicle speed and/or the engine speed. The reduction in vehicle noise emissions achieved in the last years is linked to the increasing knowledge of the contribution associated with each noise source present in a vehicle. This section describes a method for analyzing the contribution that each acoustic source in a vehicle makes to the total noise. The results obtained in IDIADA for a group of vehicles show that rolling noise has acquired a notable importance as a source that contributes to the external measured noise both in the pass-by test and in normal driving conditions. In the case of the pass-by test described, we can consider that the contributing acoustic noise sources are:

- Engine
- Intake system
- Exhaust system
- Rolling

Depending on the type of vehicle and the problem, we can consider others such as gearbox, transmission system, radiation from the walls of the exhaust and intake mufflers, radiation of the catalytic converter, and the like.

Figure 12. Vehicle with minimum or residual noise by means of the use of intake and exhaust jumbo mufflers and engine encapsulation. (Reproduced by permission of IDIADA.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto245
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Obtaining a vehicle that complies with the levels marked in the Directive (EU Directive 92/97/EEC amending Directive 70/157/EEC, 1992) and the Regulation (Regulation No 51–02 – Rev.1/Add.50/Rev.2/Amend.1, 2012) obviously happens by achieving partial reductions in the levels of noise radiated by some or all of the sources that contribute to the level of exterior noise of the vehicle. In order to get these partial reductions, we need to know which sources radiate and their contribution to the global levels of emitted noise. To do this, *source decomposition studies* are carried out. These studies allow us to quantify the contribution of each source to the global level of exterior noise and also to study it as a function of the position of the vehicle on the track, the vehicle side, and the vehicle speed and/or engine speed. The contribution could be expressed as a percentage of the total or as a contribution in dB(A). The source decomposition method consists of reducing as much as possible the different noise sources until a vehicle with minimum or residual noise has been obtained. The vehicle is equipped with additional intake and exhaust super-silencers and the engine is encapsulated as shown in the example in Figure 12.

Next, the source under study is uncovered and the levels of noise measured during the pass-by test in both states are compared. The difference between the level of this last test and that of minimum or residual noise is the contribution of that source. The contribution of each source F_i in dB(A) along the position of the vehicle on the track is given by:

$$F_i = 10 \cdot \log\left(10^{\mathrm{NF}_i/10} - 10^{\mathrm{NR}/10}\right) \tag{18}$$

where
F_i: contribution of the i-th source.
NF_i: level of noise with the i-th source unshielded.
NR: level of minimum or residual noise.

The percentage contribution of an acoustic source to the level of global noise is calculated using the following equation:

$$F_i(\%) = 100 \cdot \left(10^{\mathrm{NF}_i/10}/10^{\mathrm{NT}/10}\right) \tag{19}$$

where

F_i: contribution of the i-th source.
NF_i: level of noise with the i-th source unshielded.
NT: level of total noise.

Figure 13 shows the result obtained for the contribution of the exhaust system of the vehicle (Figure 12) to the total noise of the vehicle (second gear).

If this process is repeated for each source of interest, the contribution of each one of these sources to the overall noise level is obtained. Figures 14–17 show the noise contributions of the exhaust system, the intake system, the engine, and the tire rolling in second and third gear, all as a function of the position of the vehicle shown in Figure 12. Values are expressed as a percentage of the total level in Figures 14 and 15 (see Formula 19) and in dB(A) in Figures 16 and 17 (see Formula 18).

We can see that the most important noise contributions come from the engine and the tires both in second and in third gear. This result is general for current passenger cars, which is illustrated by the comparative graphs (Figures 18 and 19) obtained in IDIADA between six vehicles, four diesel (vehicles A, B, D, E), and two petrol (vehicles C and F), of the same category and currently on the market. Figures 18 and 19 show the measured contribution of the different noise sources of the above vehicles for the position in which the maximum noise level is obtained during the pass-by test.

[3]*University of Graz, Graz, Austria*

1 INTRODUCTION: WHAT IT MEANS—DEFINITION AND SCOPE OF HMI

The human machine interface (HMI) in a vehicle is subject to constant change. The growth in number and complexity of technical systems in the vehicle cockpit confronts the driver with new displays, components, and interaction logic. It is estimated that the majority of all automotive innovations is in the area of electronics. The majority of these electronic innovations communicate with the driver and/or need to be monitored and/or controlled by the driver. Therefore, an appropriate HMI is of fundamental relevance for the easy, safe, and pleasant control of a vehicle. Nowadays, the human machine interface can be seen as the "Face" of the electronic system. Customer research has demonstrated that positive and negative experiences with these systems can massively influence the overall acceptance of a vehicle (Ford internal investigations).

On the background of the fundamental relevance for business success, this chapter aims to provide an overview to the HMI:

– *Definition and scope*: What HMI is and has to cover (Section 1)
– *User*: What we know about the user and his or her needs (Section 2)
– *History*: How HMI concepts, displays, and controls are developed over time (Section 3)
– *Process*: What the HMI development process is (Section 4)
– *Interfaces*: How displays and controls can be classified (Section 5)
– *Interaction*: What the fundamentals of interaction design are (Section 6)
– *Trends*: What future innovations in HMI can be envisaged (Section 7).

1.1 From human machine interface to human machine interaction

In the beginning, automotive HMI focused on the interface. Regions of interest have been displays and controls located in the cluster or the center stack of a vehicle as well as in the steering wheel. In addition to mechanical components, HMI was also interested in nonmechanical interfaces such as voice control. The fact that system functionality becomes more complex leads to a stronger dialog orientation. So the "I" in HMI has changed its meaning from interface to interaction, which meant thats nowadays HMI stands for human machine interaction, which also includes states and transitions and not only displays and controls (Figure 1).

The term *interaction* describes the circumstances that "(. . .) we no longer simply use machines, we interact with them" (Suchman, 1990, p. 25), which also includes that "each action by the user affects an immediate machine response" (Suchman, 1990, p. 25). Interfaces can be seen as one important part of the interaction between humans and machines.

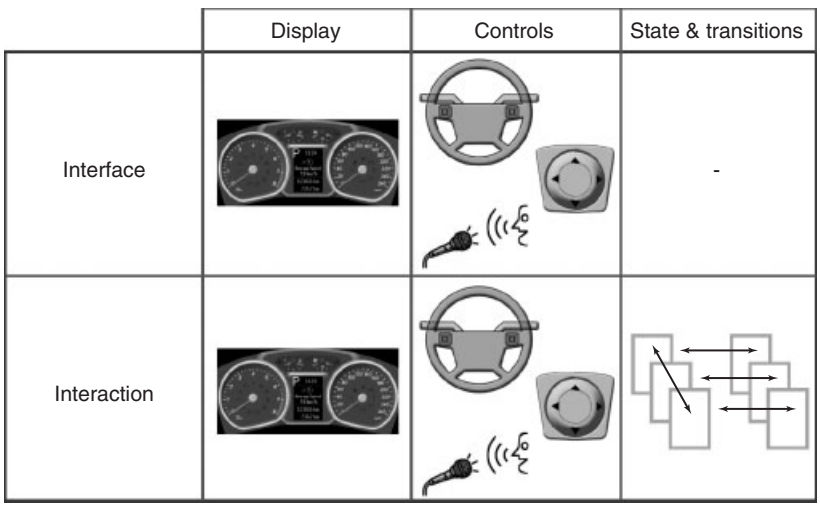
1.2 Scope: infotainment, comfort features, and assistance

Automotive HMI deals with three different scopes: infotainment, comfort features, and driver assistance features (see Table 1 for more details).

For these three scopes, both generic and special issues result. Issues that will be addressed in the automotive HMI development process include the following:

- General issues
  - o How should the system be switched "on" or "off"?
  - o How should all relevant information be configured and presented?
  - o How is the status of the system displayed?
  - o Does the system fulfill user needs?
  - o What is/are the basic function(s) of the system?
  - o Are the functions and the dialogs easily comprehended by the user?
- Special issues
  - o Can the system be controlled easily?
  - o What are the appropriate controls to accomplish an accurate, safe, and comfortable interaction with the system?
  - o Is the system distracting while driving?
  - o Do the dialogs and graphics of the system create a positive "experience/user experience"?

The primary components is of an appropriate automotive HMI is the consistent logic of operation throughout the entire cockpit, which includes the operation of the cluster display as well as the display(s) of the center stack unit. Complimentary use of well-known operation paradigms enables the easy, intuitive, fast, and safe operation of the system and leads to minimum driver distraction. The HMI of a vehicle can also be seen as an important contributor to strengthen brand identity and customer restraints.



Note. □ … *states,* <-> … *transitions*

Table 1. Scopes of automotive HMI.

Scope	Examples
Infotainment	• Trip computer • Radio and media • Navigation
Convenience	• Power sliding door; power tailgate • Keyless vehicle • Assisted parking • Vehicle personalization and seat adjust
Assistance	• Longitudinal control (cruise control; speed limiting, distance control; Stop&Go) • Lateral support and control (blind spot monitoring; lane departure warning and intervention) • Traffic sign recognition; night vision

2 WHO WILL USE IT: PSYCHOLOGY AND PHYSIOLOGY OF THE USER

For the definition of system requirements, the understanding of the user from a psychological (see, e.g., Gerrig, 2012) and physiological perspective (see, e.g., Bear, Paradiso, and Connors, 2007) is fundamental for a safe system operation (see, e.g., Salvendy, 2012) and product acceptance (Becker, 2004).

2.1 Perception

In terms of driving a car and operating any kind of on-board HMI, visual perception is the prime source of information. Visual perception reflects the activity of the peripheral sensor ("eye") and its signal analysis on the so-called visual cortex. Beyond readability (see Section 2.5), four typical characteristics of that system have to be considered: contrast perception, color blindness, movement perception, and geometrical feature extraction.

Contrast perception is fundamental for vision and any identification of meaningful objects. This "job" is performed by specific neurons in the retina as well as visual cortex. The better the contrast is, the faster the objects can be detected and identified. Therefore, a good contrast ratio can be seen as the first requirement based on human factors (Figure 2).

Figure 2. Contrast requirements.

Color blindness is the next perceptual item to be considered. It occurs in about 8% of the population, making the people unable to see one or more specific colors or even no color at all. Here, good graphic design should compensate for that in using a strategy of "multicoding" (redundant use of color as well as other graphical attributes). This could, for example, mean coding a street on a navigation map by color and thickness of line.

Movement perception strongly directs attention. This effect can be used for guiding the user's eyes to the position of interest on a screen. The realization could, for example, be made by any kind of screen transition animation.

Geometrical feature extraction means a process of detecting the "key" information in complex visual stimuli. This means detection of simple geometrical elements such as lines, angles, and quadrangular structures. The more the screen design reflects in a "minimalistic design" approach such simple structures, the faster the signal detection and the appropriate the reaction could be.

2.2 Cognition

This topic deals with attention, information reduction, and semantic interpretation.

Attention is essential for correct information selection, processing, and reaction. In the automotive environment in particular, the so-called divided attention needs special consideration. This means that any operation of an HMI has to be regulated against the primary task of driving a car. Knowing that a real "timesharing" is not possible for the human brain HMI systems should be designed to keep the driver always in the loop and in control. An intelligent definition of controls in the steering wheel, intelligent dialogs, and use of voice control is of substantial help.

Information reduction and semantic interpretation means that every (overwhelming) sensory input has to be extracted down to the essential information and its fundamental

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto248
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

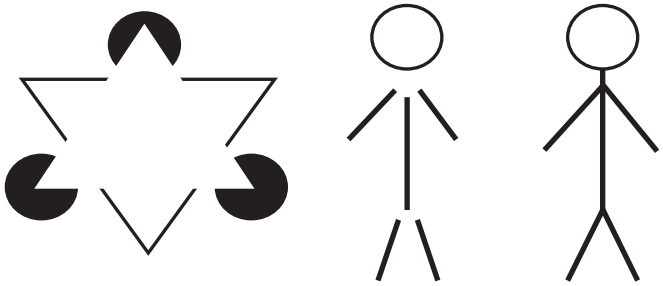

Figure 3. Information reduction by form recognition ("Gestalt").

semantic. The so-called Laws of Good Gestalt (Figure 3) are demonstrating that effect. Therefore, good graphics design should use simple geometrical structures supporting any semantic categorization and building of classes of identical elements (e.g., clustering frequency bands and radio stations graphically).

This information reduction and extraction process is in addition accelerated by graphical elements creating "*mental models*" of a function. Such mental models describe user's assumptions on how a function works. A good HMI design ensures that these assumptions are in line with the *functional models* describing how the system really works.

2.3 Learning and memory

Comprehensibility is not sufficient for an effective HMI operation. Particularly with elderly users, it is well known that memory plays a fundamental role for easy and correct operation. In particular, functions that are used seldom may require a well-working long-term memory. It is obvious that memory load can be reduced by consistency in a dialog, always using identical logical rules, terminology, and symbols. Beyond that, the use of widely accepted informal standards of operation is very helpful. Such so-called stereotypes are telling the story of operation by its *affordance* (Figure 4), guiding the user in operation. This is very often the basis of what is called an *intuitive system*.

In addition, such a process of recognition of essentials can be supported by a picture language using the opportunity of human cognition to think on the basis of the picture. Operational logic is could therefore be translated into the so-called metaphors, describing graphically the way of operation (e.g., the "jukebox" metaphor for operating music folders).

2.4 Emotion and motivation

We study human behavior with the intend of delivering rewarding and pleasant experiences to our consumers in

Figure 4. Examples of stereotypes with high affordance showing the "five-way toggle" stereotype of TV/Sat remote controls (Samsung, Technisat; Comaq). (Reproduced with permission of Stefan Becker. © S. Becker.)

life. "*User experience*" (*UX*) is meanwhile one of the key terms within the HMI-expert language. A pleasant HMI experience can be triggered by comprehensible dialogs and emotionally appealing visualizations. Fulfilling such requirements is a key to success and product acceptance (Hanna, 2012). On the other hand, incomprehensible menus can lead to *disappointments and frustrations*. On a long-term perspective and based on several "bad" experiences, feelings of "learned helplessness" might raise. Such customers might not be willing to invest in the future in "innovative" products but would look back more to "good old days" when everything was pretended easy. This first requires a dialog structure that supports exploring without losing the orientation (see, e.g., the "undo" button on the upper left corner in Microsoft products). Beyond that, special strategies reflecting the needs of more "conservative" versus "innovative" users have to be defined. This could, for example, lead to "beginners" versus "expert" modes in an interaction system.

2.5 Psychomotor performance and age influence

It is a well-known effect that at least in Western hemisphere, the structure of the society is changing toward elderly people. The average buyer of a car in Germany

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto248
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is currently around 50 years old with a constant trend to increase. And people within their 80s are still driving a car. HMI designers need to pay special attention to the *presbyopia effect*. This means that the distance for clear vision is moving from 40 cm for 25-year-old to 4 m for 70-year-old people (Goldstein, 2010). Even this impairment can be (partially) compensated by spectacles, it is accompanied by a slower refocusing from near to distance view (slower "*accommodation*"). This effect requires the legibility of "big-fonts views" and may be as well a reason to think about head-up displays having the projected virtual display in front of the car.

2.6 Intercultural differences

Intercultural differences play an important role in the design process of an automotive HMI for a global marketed brand (Becker *et al*., 2011). Different understandings of the meaning of the representations of icons and/or colors can give rise to usability problems of products (Bourges-Waldegg and Scrivener, 1998). Therefore, some issues such as the acceptance and understanding of icons, color preferences of different markets, and preferences of commonly used logic of operation of different culture groups has to be kept in mind during the automotive HMI development process. For example, icons designed to mark points of interest such as graveyards, zoos, and restaurants in the navigation settings of a navigation system have to be designed in a way that users of different cultural areas are able to easily understand them. Sometimes, these cultural differences do not allow the use of unitary/global icons and market-specific icons and symbols have to be implemented. The same is valid for color coding: in Western countries such as Europe or North America, the color "red" is connected to "alarm" and/or a warning. In Eastern countries such as China or Taiwan, the color red has a contrary meaning and stands for "luck" (Zißler-Gürtler, 2002). Also, the way of writing (from left to right or from right to left) can have an impact on the logic of operation of a system, especially when a hierarchical logic of operation is used. On the basis of these examples, it can be advised to investigate cultural characteristics as one important step to better understand customers' needs (Choong and Salvendy, 1998).

3 HOW IT HAS DEVELOPED OVER TIME: A BRIEF HISTORY OF AUTOMOTIVE HMI

In the automotive context, a brief description of the history of the human machine interaction can be illustrated as "from a *classic* radio to head-up display and gesture control."

Figure 5 describes the history of HMI innovations in the consumer electronics (CE) as well as in the automotive environment.

Key milestones in CE were defined by the introduction of the mouse concept (1981), followed by first touch-screen applications (1983), functional integration on one touch screen (in 1990), and smart phones with new interaction paradigms up to high performance voice systems and gesture control (Figure 5). It is obvious that the automotive innovations always followed these CE developments with a certain time gap.

4 HOW TO MAKE A GOOD HMI: DEVELOPMENT PROCESS

To ensure that an automotive HMI is accepted and preferred by costumers, a development process has to be followed that is informed by user needs that are then translated into technical recommendations (for a deeper understanding of the process see: Norman, 1988; Nielsen, 1993; Cooper, Reimann, and Cronin, 2007; Moggridge, 2007; Rogers, Sharp, and Preece, 2011; Nielsen and Budiu, 2012).

The so-called HMI development process (see also Figure 6) usually starts with research that concentrates on different segmentations and a global marketing perspective. On the basis of the research results, goals for the new HMI will be identified and finally defined. These goals help derive recommendations for action. The next step is to describe relevant use cases, which lead to a description of functions that have to be implemented into the new system. Then, the HMI framework definition has to be crafted—which includes the interface framework that defines the controls and displays of the system, the interaction framework (logic of operation), and also the visual framework (graphics). To succeed, the different parts of the development process as well as iterative validation need to occur. This iterative process happens throughout the whole HMI development process. Here, it is described in detail.

4.1 Research: from market segmentation to personas

The first step of the automotive HMI development process can be described as the development of customer and marketing studies that help understand the segmentation and global user needs for the new product. Questions that should be answered with the help of these studies include the following:

- Who are the customers that will use the new system?

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto248
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

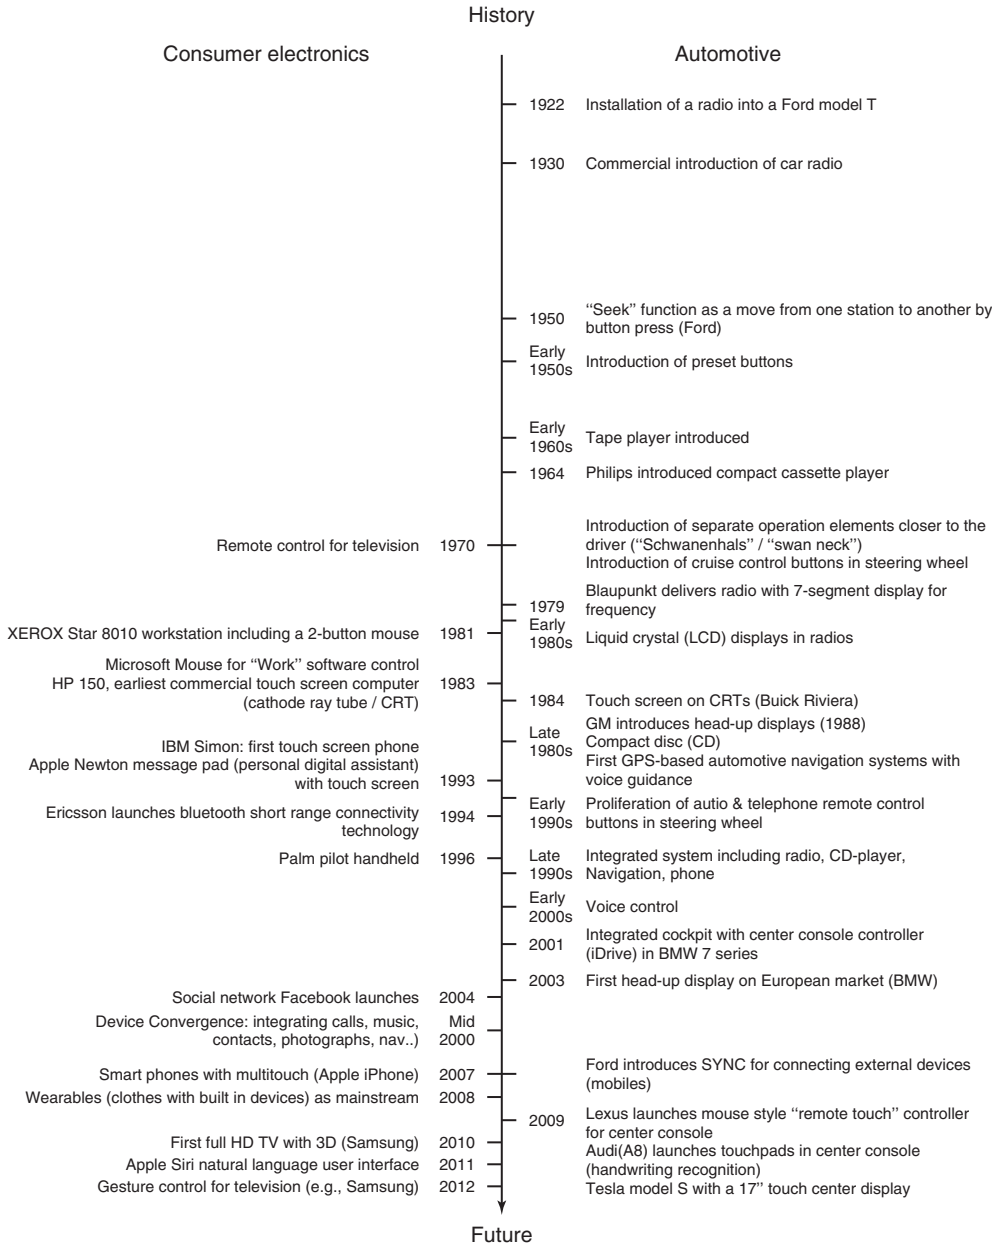

Figure 5. Historical milestones in development of automotive (and consumer) HMI (see also: Bhise, 2012; Wikipedia.org/vehicle audio; Wikipedia.org/Autoradio; Wikipedia.org/Steering wheel; Wikipedia.org/Touchscreen).

- How can they be described both demographically and psychographically?
- Is the product normally used by males or females? One or many?
- What is their cultural background?
- What are their mindsets and motivations for using the system?
- How are they anticipated to use the system?
- Concerning the use of technology, are they innovators or laggards? What are the needs, habits, and expectations of the future users of this product?

The questions that should be answered at this stage explore the dimensions in which possible users or user groups are hypothesized to be different.

A commonly used strategy to define different user groups is called *personas*. Personas can be defined as models that

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

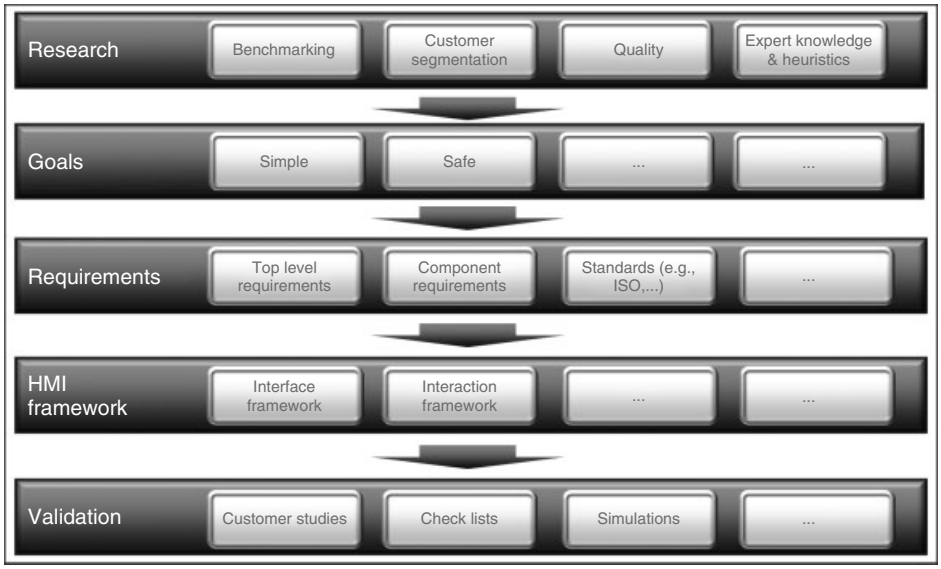

Figure 6. HMI development process: from research to validation.

describe a prototype of the user of the system and his or her needs (Cooper, Reimann, and Cronin, 2007). The representation of personas as "real" people shall help the designers and engineers to develop a product that focuses on real customer needs, habits, and expectations. Normally, personas are represented within 1–2 pages. One important part in the creation of personas is to decide whether a global HMI strategy should be informed by one specific user or if different users are needed to define the personas of a global HMI perspective. In other words, should the strategy of the HMI development process follow market-specific HMI needs or should the goal be to develop one global HMI that has the strength to inspire users all over the world?

4.2 Goals, use cases, and functions

On the basis of the research results described in Section 4.1, goals for the new HMI had to be derived, identified, and finally defined. Some top-level goals can be described as follows:

- comprehensibility,
- controllability, and
- user experience.

Goals can be seen as a first step that describes at a high level what the newly designed system shall provide in order to satisfy user requirements. The next step is "(...) breaking these goals down into the more specific physical or cognitive actions necessary to obtain the goal" (Wickens and Hollands, 1999, p. 6). This can be done with the help of use-case definitions and task analysis. The description of use cases of a new system can be seen as the basis of the requirements definition (see Section 4.3 for more details). In the product development process, use cases describe all tasks that a user can perform with the system (Wickens and Hollands, 1999). The integration of use cases in the automotive HMI development process helps design an appropriate system and avoid errors. One significant benefit of the integration of use case analyses in the early phase of the automotive HMI development process is that potential error sources of the system can be eliminated before the first prototype of the system is built. As an example, one use case of a radio in a vehicle can be that the user not only wants to hear his or her favorite radio station but also prefers to store it as a preset to enable quick access when he wants to listen to the same radio station during his or her next trip. This use case example for a radio task can also lead to the requirement that there has to be a function included in the radio system where radio presets can be stored (e.g., a physical button and a dedicated space on a touch-screen display).

4.3 Requirements

On the basis of the goals, recommendations for action are derived. These result in requirements that the newly developed system has to fulfill. Besides requirements that each organization individually defines for a product, there are ISO standards that a system has to fulfill. Part 10 of the ISO standard 9241–110 (2006) deals with general ergonomic principles that apply to the design of dialogs

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto248
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

between humans and information systems. The different principles are as follows:

- suitability for the task (which stands for an appropriate functionality and minimization of unnecessary interactions),
- suitability for learning (guiding the users to minimize the time for learning),
- suitability for individualization (adaptability of system to user and his or her context),
- conformity with user expectations (consistency to user's model of operation),
- self-descriptiveness (comprehensibility by feedback and help functions),
- controllability (controllability of dialog by the user), and
- error tolerance, which means that the systems keep functioning even in case of failure.

Besides the requirements of the ISO standards, Nielsen (1994) introduces 10 usability heuristics for user interface design. These heuristics can be seen in Table 2.

A comparable heuristic system was developed by Shneiderman and Plaisant (2009).

4.4 HMI framework definition

When questions of segmentation and the global perspective are answered, goals of the new system are defined and use cases and functions are described. The next step in the automotive HMI development process is to define the HMI framework of the system. The HMI framework definition includes the interface framework (see Section 5 for more details) that defines the displays (technology, size, orientation, and resolution) and controls (location, type, and functional and logical behaviors) of the system. It also includes the interaction framework (see also Section 6), which specifies the implemented logic of operation including the use of metaphors and stereotypes, the specification of the underlying menu structure as well as the distribution of information on a screen (screen layout), and the information flow between screens. Finally, it also includes the visual framework that defines the graphics that the user will see while interacting with the system (style guide).

4.5 Validation

The validation process of a human machine interface can be described as an iterative one (Wickens and Hollands, 1999). On the basis of the results of customer studies, a refinement of the design of the interface will be done. Further, the refined system will be evaluated by customers and the results can lead to new refinements and so on. Also, the results of the validation process give the developer of a system an answer as to whether the defined system requirements are implemented in an appropriate way. Furthermore, validation results demonstrate whether the purpose is accomplished or not (e.g., the system is reaching the top-level goals and defined tasks can be executed accurately and in a user-friendly way). Therefore, the so-called RESPONSE check list (Becker, 2005), which is shown in Figure 7, can be used especially for driver assistance features.

Concerning validation, the choice of research method is a very important step. The researcher has the choice between a plentitude of different research methods—such as reports of accidents/incidents, press feedback, surveys, field studies, laboratory experiments, task simulations (mock-up or static cockpit simulator, moving-based simulator, and vehicle-based simulator—investigations under real road conditions), or models based on human simulations. They differ in terms of cost, their appropriateness concerning the circumstances in which the system will be used, and the ease of product change because of their results. They also differ in their ease of control and inference and regarding their design relevance of conclusions (Wickens and Hollands, 1999). Figure 8 shows examples for simulators that are normally used to validate automotive HMIs.

It is particularly important to involve users in the evaluation process of an interface! So, during the HMI development process, customers usually assess the actual system that is already in the market against a new reference model. During these evaluations, the customers have to accomplish the most important and typical tasks that are defined during the use case analyses (see Section 4.2). Following Wickens and Hollands (1999), different measures of performance and behavior can be used to measure the performance of a user with a system:

- measures of speed or time,
- measures of accuracy or error,
- measures of workload or capacity demands, and
- measures of preference.

The choice of the measures is just as important as choosing the appropriate research method.

Designing an automotive HMI has to be seen as a challenge that deals with the circumstances that driving effectively requires the safe control of the vehicle to always be the first task. Therefore, the HMI of an in-vehicle system has to be designed by keeping in mind that using the system should "only" be the secondary task, besides driving, which can be demanding by itself. It is also important that the human–machine interface is designed in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto248
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 2. Ten usability heuristics for user interface design.

Heuristic	Description
1. Visibility of system status	The system should always keep users informed about what is going on, through appropriate feedback within reasonable time
2. Match between the system and the real world	The system should speak the users' language, with words, phrases, and concepts familiar to the user, rather than system-oriented terms. Follow real-world conventions, making information appear in a natural and logical order
3. User control and freedom	Users often choose system functions by mistake and will need a clearly marked "emergency exit" to leave the unwanted state without having to go through an extended dialog. Support undo and redo
4. Consistency and standards	Users should not have to wonder whether different words, situations, or actions mean the same thing. Follow platform conventions
5. Error prevention	Even better than good error messages is a careful design that prevents a problem from occurring in the first place. Either eliminate error-prone conditions or check for them and present users with a confirmation option before they commit to the action
6. Recognition rather than recall	Minimize the user's memory load by making objects, actions, and options visible. The user need not remember information from one part of the dialog to another. Instructions for use of the system should be visible or easily retrievable whenever appropriate
7. Flexibility and efficiency of use	Accelerators—unseen by the novice user—may often speed up the interaction for the expert user such that the system can cater to both inexperienced and experienced users. Allow users to tailor frequent actions
8. Aesthetic and minimalist design	Dialogs should not contain information that is irrelevant or rarely needed. Every extra unit of information in a dialog competes with the relevant units of information and diminishes their relative visibility
9. Help users recognize, diagnose, and recover from errors	Error messages should be expressed in plain language (no codes), precisely indicate the problem, and constructively suggest a solution
10. Help and documentation	Even though it is better if the system can be used without documentation, it may be necessary to provide help and documentation. Any such information should be easy to search, focused on the user's task, list concrete steps to be carried out, and not be too large

Reproduced from Nielsen (1994). © John Wiley & Sons, Inc. See also http://www.nngroup.com/articles/ten-usability-heuristics/

a way so that the driver always has available to him or her the necessary resources to respond to unexpected events. As a consequence of this, the level of workload can be seen as important safety-related factor in the HMI development (Lumsden, 2011). So, the designer of a system has to know how busy the driver will be using the system during driving. Will the driver be able to respond to unexpected events, how many resources will be required from the driver to fulfill a task with the system, and how does the driver feel using the system? These questions can be summed up in the concept of mental workload and help the developer to design an efficient and easily usable system. Wickens and Hollands (1999) propose three different workload assessment techniques for the analyses of mental workload:

- secondary-task technique,
- psychophysiological measures, and
- subjective measures.

With the help of the secondary task technique, resources that will be demanded for the primary task can be made visible. Recording psychophysiological measures such as cardiovascular measures (heart-rate variability and heart rate), electromyogram from facial muscles, pupil diameter, eye movements (saccades and fixations), electrodermal measures (e.g., amplitude, frequency of nonspecific electrodermal responses, and skin conductance level), blood pressure, pulse volume amplitude, and changes in the electroencephalogram (EEG) can show the autonomic or central nervous system activity while operating the system (Boucsein, 2006; Boucsein and Backs, 2009; Wickens and Hollands, 1999). The third workload assessment technique is subjective measures. Two commonly used subjective assessments are the NASA Task Load Index (TLX) scale (Hart and Staveland, 1988) and the subjective workload assessment technique (SWAT) (Reid and Nygren, 1988).

Question	Yes / No / not suitable
Are system reactions understood by other road users? If not can they still control the situation (e.g., system based deceleration without activation of brake lights)?	
Is the driver's attention necessary to keep him in the **physical control loop** while the system is running?	
Is the vehicle **controllable** in the case of a system **malfunction by overruling or switching off** the system?	
Can **system parameters be changed while driving** without causing unexpected behaviour?	
Is the system function **self - explanatory** (i.e., without user manual)?	
Can the operation or observation of the system (e.g., possible driver distraction by displays) be achieved **without a major change in attention distribution** relating to the driving task so that potentially hazardous situations may not occur?

5 WHAT IT IS: INTERFACE DESIGN

Interface design is concerned with the classification of displays, controls, and other input possibilities such as voice control or other modalities (e.g., gestures). The *classification of displays* for an automotive system can be seen as the decision which display technologies should be applied. For example, the development engineer has the choice between segmented and full graphics capabilities, nontouch versus touch-screen displays. And if he or she decides to implement a touch-screen display, then it should be between monotouch and resistive touch displays or multitouch and capacity touch displays (see also Table 3).

In the automotive environment, there is a clear trend toward high value displays realized by LCDs with active light emission, color, and high resolution dot matrix. They are designed as the so-called thin film transistor (TFT) displays.

In terms of the *classification of controls* (Table 4), the development engineer needs to choose, for example, between discrete (e.g., on/off) versus analog (e.g., volume control) control modalities, touch versus controller-based operation of the system or a combination of both (touch screen with supplementary list controller mostly implemented as additional rotary), the usage of a keypad versus a touch pad for handwriting input, and more.

5.1 Voice control

Voice control is meanwhile a well-known and accepted technology of interaction. It is used for all menu operations as well as selection of specific content such as addresses for navigation or artists within an audio database. If the system is to be controlled via voice or other modalities such as gestures, then the interface design has to ensure that the commands are embedded into the overall dialog structure. Also, there should be implemented some support from the system for situations in which the system is not able to understand the input of the driver in an appropriate way. This support can, for example, be a list displayed on the multifunctional display where the driver has the choice to select between different possibilities. The main advantage is the reduction of driver distraction by avoiding manual control (e.g., on a navigation entry keyboard) and reading of a display. While, at the beginning, the voice dialog was very much driven by keywords that the user had to learn, voice

Table 3. Classification of displays from a HMI point of view perspective (see also Wikipedia.org/wiki/Electronic visual display; www.pcmag.com/encyclopedia)

Light Emission Effect	Active Displays	Passive Displays
	Liquid crystal display (LCD) + backlight (e.g., LCD TV screen) *Electroluminescence* Organic light emitting diode (OLED) *Photoluminescence* Plasma display panel (PDP)	*LCD* *Electrophoresis* Electronic paper (e.g., e-book reader)
Display mode of observation	Direct view displays Picture directly seen on display Example: navigation screen	Projection displays Picture projected Examples: head-up display, laser projection displays
Layout of picture elements	Segmented displays Fixed shape of characters, numbers, and symbols Examples:  7-segment display 14-segment display (source: Ford)	Dot-matrix displays (graphic displays) Any graphical element (including characters) created by a pixel matrix  (source: Ford)
Coloring	Monochrome displays	Color displays
Special view effects	Dual view displays	3-Dimensional (3D)
Control capability	Nontouch Pure display	Touch screen Resistive technology (gaps of two layers are electrically connected by mechanical force of finger on surface layer) Capacitive touch (change in electrostatic field by electrical conductivity of human body)

dialogs (such as Ford SYNC System; Figure 9) are meanwhile flexible in understanding. Dialogs between system and user can be carried out nearly "naturally" based on the opportunity of "natural language understanding (NLU)."

Concerning *gesture communication*, a distinction must be drawn between display-based gestures and camera-based gestures. Display-based gestures are already known from use of touch screens of a smart phone or tablet PC. Nowadays, these well-known gestures can help the user to easily operate with a touch system in a vehicle. There are currently only limited applications on the market such as proximity sensing. Here, more or less hidden buttons are enlarged when the finger of the user is moving toward the screen (e.g., Volkswagen Golf Infotainment system). In the future, another typical and intuitive application might be a wiping gesture for horizontal moving of content.

Camera-based gestures, on the other hand, allow the user to control functions with the help of hand gestures in the space. These operation concepts are well known from video game consoles. However, before a successful introduction into the automotive environment, several open issues have to be solved:

- *Dialog initiation*: How to start a dialog (comparable to Push to Talk button).
- *Semantic bandwidth*: Compared to speech (unlimited bandwidth) gesture, dialogs can only transmit a limited number of dedicated information. Full information bandwidth would require learning of a complex gesture language such as gestures for hearing impaired people.
- *Ambiguity handling*: If the system cannot clearly identify the message, a modality change to written speech on screen would be required (in the case of voice control, such a modality change is not required).
- *Intercultural comprehensibility*: Sometimes specific gestures signalizing cultural-specific messages.

Table 4. Classification of controls from a HMI point of view.

Type of Control	Generic Function	Typical Application
Push	1-way logic	On/off function
Push/pull	2-way logic, up and down	Opening/closing power windows
Rocker	2-way logic	Volume control
Toggle	4-way	Control of outside mirrors
Toggle	5-way	Dialog control List up/down Menu deeper/higher Ok for select 
Rotary	Analog	Set temperature
Rotary/push	Analog + 1-way logic	Volume + on/off 
Rotary/shift	Analog + 4-way	Multimedia control in center stack (e.g., BMW) Also providing haptic feedback 
Touch pad	Analog (2D)	Handwriting input in center console
Rotary/touch pad	Analog (1D and 2D)	Multimedia controller in center stack with integrated touch pad (e.g., Audi A3, 2013) 
Touch screen	Direct addressing	Multimedia system
"Hybrid" touch screen	Direct addressing on screen + rotary controller	Touch screen system (e.g., Golf 2013)

6 WHAT IT IS: INTERACTION DESIGN

In a first step, decisions that have to be made on the overall screen layout include the choice of which information is presented where on the display(s). An important design goal for the overall screen layout is that a consistent grid of information enables a fast orientation of the user and results in a faster finding of content. As an example, a variant of a multifunctional display of Ford is shown in Figure 10. The overall screen layout of this Ford's multifunctional display is divided into three sections: a bottom line that includes information such as the actual time, settings of the air conditioning system, and the charge condition of the bonded mobile phone. On the left side of the display, different information of the above-mentioned classes are shown (e.g., different wave spectrums of radio signals as shown in Figure 10). On the middle-right side of the screen, more detailed information of the selected device (in Figure 10: radio) is presented.

The second step of interaction design is the implemented logic of operations and menus. This means that the organization of screen flows has to be designed. For example, the presented content of the cluster can be organized based on a hierarchal logic. Using a hierarchal logic allows the user to operate with well-known stereotypes like those from other devices such as a mobile phone. A system that uses a hierarchal logic of operation supports the user to easily understand the geometric logic in which the menus and menu entries are arranged within the system. The use of a hierarchal logic for the cluster display can, therefore, be seen as geometrical representation of the system.

And in the third step, interaction design deals with the visualization, which metaphors and stereotypes should be used to facilitate the users' operation, and the logic of operations and menus.

Interface metaphors are the central component of the conceptual model of a system. The metaphors used should help the user to easily understand the functionality without additional help. One example of a well-designed HMI using metaphors is the translation of hardware calculators into software. These software calculators look and work like the hardware the users are used to since years, which makes them easy to use (Rogers, Sharp, and Preece, 2011). Examples for automotive HMI metaphors can be seen in visual displays of driver assistance features. As an example (Figure 11), the radar beam used in the adaptive cruise control driver assistance feature shows the driver the distance to the vehicle in front of their own vehicle. The radar beam is used as a metaphor, which can be intuitively understood by the driver. Another metaphor also used in the automotive HMI is the so-called jukebox metaphor. This metaphor enables the user not only to choose by list browsing (text based search) between different albums but also to search between different album covers that are shown in a graphical way. The user can scroll between the different album covers by vertically moving the covers, like the jukebox had worked in formerly.

7 WHAT IT WILL BE: FUTURE TRENDS

7.1 Goals: combination of safety and experience

A trend can be seen toward a combination of the safe usage of a system and user experience. So, it becomes more and more important to develop in-vehicle infotainment systems that do not distract the driver during driving. Also, because of the increasing number of driver assistance systems implemented in vehicles, the controllability of them can be seen as another important part in future vehicles. It will be important that the driver is able to understand the system behavior in every traffic situation and in every use case in which the driver assistance features may use or intervene automatically. Also, considerations will be important so as to ensure that the driver always has the ability to intervene and override or switch off these systems without a safety-related risk. The objective is a user experience that delivers on the so-called fascination of simplicity and is designed in such a way that results in extreme ease of operation and use (Hanna, 2005, 2012).

7.2 Interfaces

7.2.1 Universal interfaces and connectivity

The tracking of trends in the industry of consumer products shows a trend toward a universal usage of smart phones and/or tablet PCs. At this stage, smart phones are used to control machines, home environments, offices, and, maybe

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

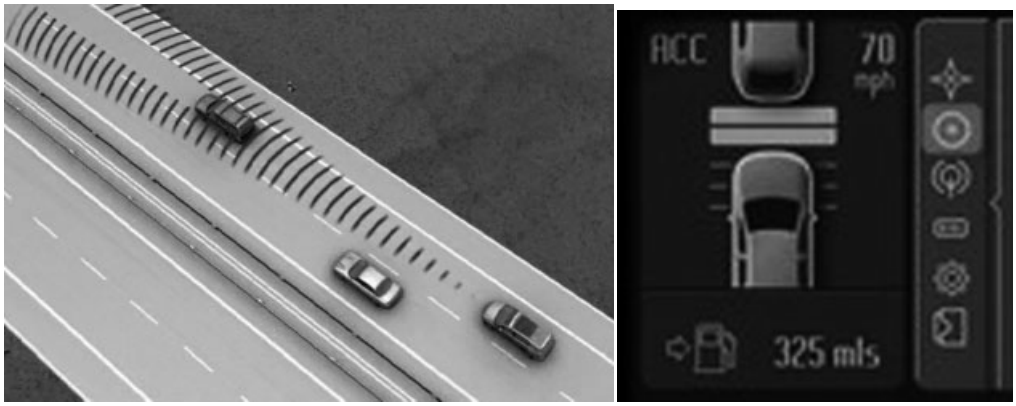

Figure 11. Example for automotive HMI metaphor: the radar beam used in the adaptive cruise control driver assistance feature as part of the driver information (cluster). (Reproduced with permission from Ford. © Ford.)

in the nearer future, vehicles. Also, the usage of smart phones allows a fast reaction on changing use cases, because every new use case that comes up can be covered by offering a new app for mobile devices. The integration of mobile devices can deliver new interfaces in a vehicle, which enable new ways of interaction in the automotive context. In this context, issues regarding driver distraction become important as well.

7.2.2 Augmented reality

Augmented reality describes a technology that adds virtually generated objects and elements into the real-world scene. To create a virtual overlay, which is added to the real-world scene, users normally have to wear special goggles, but in the future context of the automobile, these accessories may not be required. Numerous concepts and technologies are evolving that deliver augmented reality elements via an existing technology: the head-up display. Also, some automotive manufacturers have presented their ideas to implement augmented reality into vehicles at motor shows of the past years [see, e.g., the "DICE"-concept (dynamic and intuitive control experience) of Mercedes-Benz—2012 presented at the CE Show in Las Vegas]. Other conceptual demos include the enhanced vision system of GM, an augmented reality layer placed on the rear seat windows such as Toyota presented with its Window to the World interactive vehicle concept, and finally the "Window of Opportunity" presented by GM.

7.3 Graphic-based interaction

Nowadays, interaction between a driver and a vehicle happens through text. This causes two different issues for the application of a new HMI of a vehicle: First, because of a global selling of vehicles of one brand, the wording used has to be translated into a lot of different languages. Second, complex functions are often very hard to understand when they are "only" described by words (without pictures). One example which demonstrates that shortfalls of a text-only system are user manuals and specifically the descriptions of how driver assistance features will work and intervene. One in-vehicle system that solves this problem is the onboard user manual "your BMW in brief" offered by BMW. This system allows the driver to get more information on selected functions of the vehicle without knowing the correct wording of the topic. The functions are represented as pictures and the user can select the different pictures to get more information on the underlying system.

Whatever the future will be, designing HMI solutions is one of the most challenging activities in the automotive environment. HMI is meanwhile at all OEMs in the focus of cross-functional teams incorporating people from

- electric (function and technology),
- design (seamless User Experience of HMI and Interior),
- marketing and planning (Global user requirements and product definition), and
- quality department (short- and long-term learning from market).

It needs the collective intelligence of engineers and computer scientists, interaction and visual designers, as well as psychologists and physiologists. At least one thing is clear: the working life of HMI people will not be boring.

1 INTRODUCTION

The investigation of real world crashes in the 1950s spawned research and improvements in vehicle crashworthiness, occupant restraints, and friendly interiors (Schwimmer and Wolf, 1961). By the early 1980s, the concept of HARM was used to develop priorities for safety improvements (Malliaris, Hitchcock, Hedlund, 1982; Malliaris, Hitchcock, Hansen, 1985). HARM combined the incidence and severity of crash injuries into priority rankings of crash types and injury sources. Today, field accident data is available online to study the most significant sources of injury. It is also possible to investigate electronic files with individual crashes for in-depth understanding (http://www.nhtsa.gov/NASS).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto252

A vehicle in motion has kinetic energy. In a crash, energy is absorbed by deformation of vehicle structures, causing rapid decelerations that slow the vehicle. Primary measures of crash severity are the change in velocity (ΔV) and amount of intrusion of the occupant compartment. These measures describe the physics of a car crash and risks for occupant injury.

2 FIELD ACCIDENT DATA

Priorities for automotive safety are based on an understanding of field accident injuries. In-depth analysis of real-world crashes provides information on the sources for injury by crash type and occupant position in the vehicle. The field data describe the type of crash and deformation to vehicle structures that involve acceleration of the vehicle's cg (center of gravity) and intrusion of the occupant compartment. Field data also address the use of occupant restraints in the crash. This gives information on the effectiveness of seat belts, airbags, and other safety features.

Some of the most comprehensively investigated field accidents are collected by the NHTSA (National Highway Traffic Safety Administration). The National Automotive Sampling System (NASS) was designed to help NHTSA identify the most common safety problems in motor vehicle crashes, prioritize methods to reduce injury rates, and help enable regulations. NASS is made of NASS-GES and NASS-CDS. NASS-GES is based on police reports and NASS-CDS data provides comprehensive information on police reports, NASS investigator reports, and medical records.

NASS-CDS is a nationally representative sample that is publicly available. It contains detailed crash information

representative of a random sample of thousands of minor, serious, and fatal crashes. The data are collected by trained investigators. The crashes investigated in NASS-CDS are based on a probability sample of all US police-reported crashes. A NASS-CDS crash must be police reported and involve at least one towed vehicle.

Field research teams study about 5000 crashes a year, involving light vehicles (passenger cars, light trucks, vans, and utility vehicles). Approximately 400 variables are collected. Trained crash investigators obtain data from crash sites. They study evidence such as skid marks and broken glass. They locate the vehicles involved, photograph them, measure the crash damage, and identify occupant contact marks on the vehicle interior. The researchers then follow up with on-site investigations. They interview crash victims and review medical records to determine the nature and severity of injuries.

Because of its quality and nationally representative attributes, NASS-CDS data has been used by industry, universities, and other research organizations to assess the significance of various crash scenarios, identify ways to improve vehicle crashworthiness, to improve restraint system performance, and to identify needs and assess the safety benefit of various countermeasures. It provides important means of understanding injury mechanisms and is the basis for cost–benefit analyses used to support rule-making and report to Congress on the traffic accidents in the United States.

Figure 1 shows the risk for severe injury by crash severity (ΔV), crash type, and belt use based on 1994–2009 NASS-CDS. The risk for severe injury increases with crash severity and is different for unbelted compared to belted occupants. Risks are higher for unbelted occupants. For belted occupants, the highest risks are in side impacts followed by frontal crashes and then rear impacts at any particular crash delta V. There is an increase in risk for side impacts above 15–20 mph, for frontal crashes above 25–30 mph, and for rear impacts above 40–45 mph. For

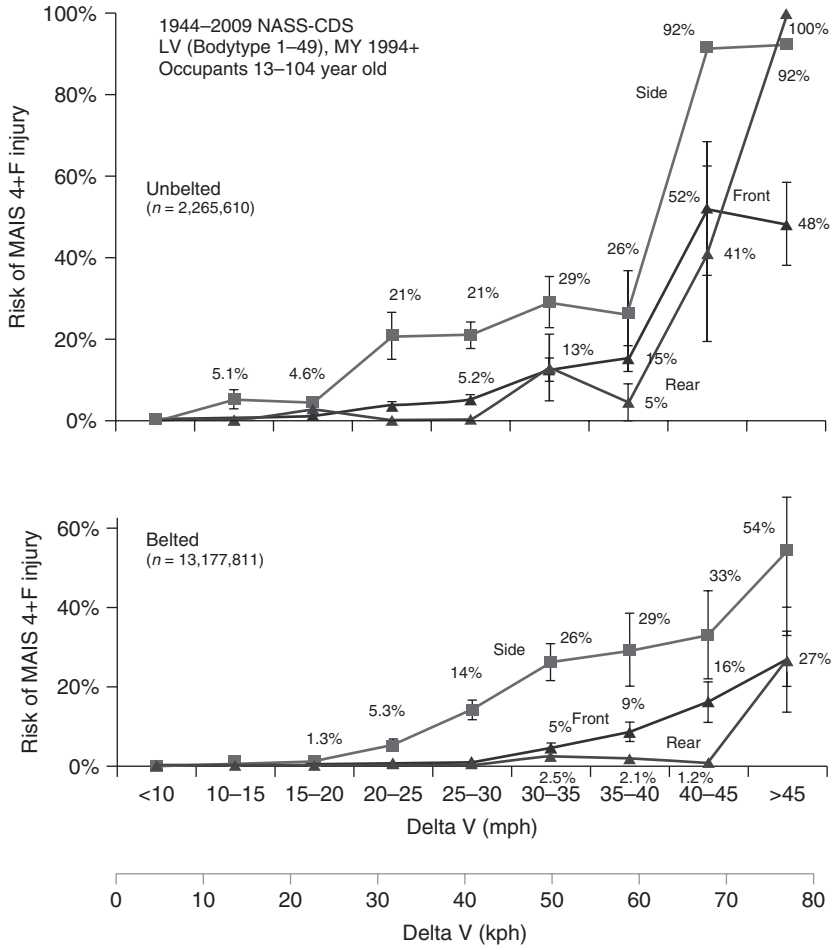

Figure 1. Risk for severe injury by delta V, crash type, and seat belt use.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto252
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

unbelted occupants, the increase in risk starts at lower severity crashes.

The trend in risk with delta V can be fit by a power function. For unbelted occupants in frontal crashes, the risk (R) in percent is $R = 0.000659\Delta V^{2.829}$ indicating risk increases by more than the square of crash ΔV, which is in miles per hour. For belted occupants in frontal crashes, $R = 0.00000874\Delta V^{3.728}$, indicating a stronger influence of crash severity at higher delta V but with lower risks than for unbelted occupants. For this sample of crashes, essentially all frontal crashes involve airbag deployment, so the risk is for the combination of belt use and airbags for crashes above 15 mph. For unbelted occupants in frontal crashes, the airbag is also part of the restraint.

For unbelted occupants in side impacts, the trend in risk with delta V shown in Figure 1 is given by $R = 0.000932\Delta V^{3.012}$. For belted occupants in side impacts, $R = 0.0000339\Delta V^{3.779}$. For unbelted occupants in rear impacts, $R = 0.0000636\Delta V^{3.288}$ and for belted occupants, $R = 0.000000165\Delta V^{4.744}$. The data show a strong correlation between injury risk and crash severity.

Table 1 shows the occupancy of vehicles of different types and the risk for severe injury (MAIS 4+F). Occupants of cars constitute 59.6% of occupants exposed to towaway crashes. In 71.4% of the crashes the driver is the only occupant. In 18.8% of the crashes, there is a driver and right-front passenger. Only 9.8% of the crashes involve three or more occupants in the vehicle. For vans, 18.1% of crashes involve three or more occupants. The lowest occupancy is in trucks with only 5.9% of crashes involving three or more occupants.

When severe injury is considered, the importance shifts to vehicles with multiple occupants. For vans, 46.3% of severely injured occupants are in vehicles with three or more occupants. The fraction drops to 12.1% in trucks. The highest risks are in sport utility vehicles (SUVs) and trucks with six or more occupants.

Table 2 shows the occupancy by crash type and the risk for severe injury (MAIS 4+F). In terms of exposure, 36.4% of occupants are in frontal impacts, 16.3% in side crashes, and only 5.8% in rollovers. In contrast, the largest fraction of severely injured occupants are in rollovers

Table 1. Occupancy, severe injury, and injury risk by vehicle type.

(30.1%, followed by side impacts (28.6%) and frontal crashes (25.7%). The highest risk for severe injury is in rollovers at 3.47%, followed by side impacts at 1.37%. The lowest risk is in rear impacts at 0.27%.

Table 3 shows exposure and risk for injury by ejection status. For nonejected occupants, the risk for injury AIS 3–6 is greatest in rollovers at 9.38% followed by side impacts at 6.59%. The risk is shown for each body region by crash type. The most common AIS 3–6 injuries are to the head (2.82%) and chest (2.52%) for nonejected occupants. With complete ejection, the risks increase to 63.3% for the head and 40.1% for the chest in rollovers. When nonejected occupants are compared to completely ejected occupants, the highest relative risk is 479 times for AIS 3–6 neck injuries in frontal impacts (Viano and Parenteau, 2010).

Table 4 summarizes the effectiveness of seat belts in preventing injury to the head, chest, spine, and lower extremities (LX) by crash type. The data show high effectiveness in preventing AIS 4+ injuries to the head and torso and AIS 3+ injuries to the LX.

3 CRASH DYNAMICS

For frontal impact, the vehicle has a traveling speed when it collides with another vehicle or roadside object. The collision deforms vehicle structures and decelerates the occupant compartment. The deceleration of the occupant compartment depends on the amount of crush and is often approximated by a Haversine function. Integration of the acceleration pulse gives the delta V of the impact and double integration gives the stopping distance of the vehicle's cg.

Figure 2 shows the peak acceleration and distance traveled for a Haversine of 80, 120, and 160 ms duration crashes of different severity in terms of delta V. For example, a 35 mph frontal NCAP crash test of 120 ms duration involves 30.4*g* peak acceleration and 1.07 m (42.2″) stopping distance for a 40 mph delta V. The overall severity of the crash is greater than the impact speed because of restitution that involves rebound of the vehicle away from the barrier. The vehicle acceleration increases as the duration of the collision decreases and the stopping distance decreases.

4 INTRUSION

As the severity of a crash increases in offset impacts, the risk for deformation of the occupant compartment increases. Intrusion or deformation of the occupant compartment increases the risk for injury, particularly to the occupant adjacent to the intrusion. This occurs because of the velocity of the intrusion.

Evans (1991) showed that deformation of the occupant compartment or intrusion adjacent to the seated position of an occupant increased fatality risks by up to four times that of occupants seated at a distance from the intrusion. Viano and Parenteau (2008) found the same effects on the risks for severe injury. When the occupant compartment was deformed in front, side, or rear impacts, the severity of the collision increased and there were higher risks of injury.

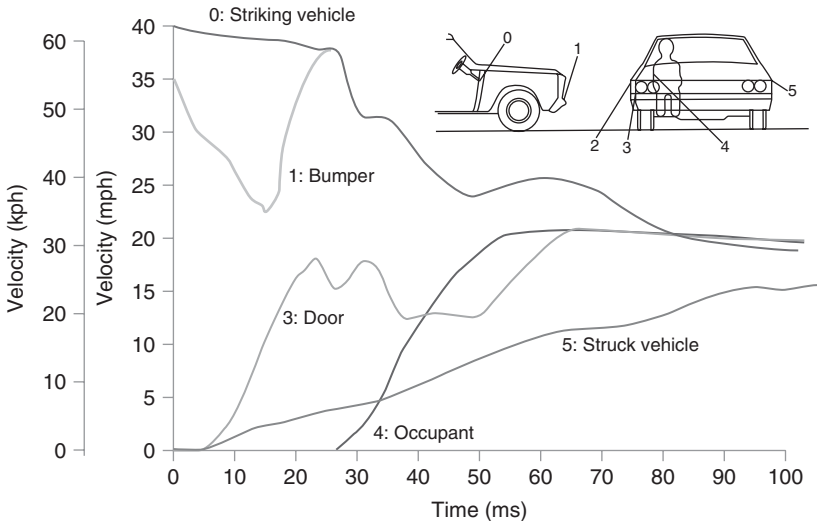

Figure 3. Side impact showing the velocity of the striking vehicle, struck vehicle, door intrusion, and occupant. (Based on Strother *et al*. 1984. Reprinted with permission from the Association for the Advancement of Automotive Medicine.)

The relationship between injury and intrusion has been studied in side impact crashes. Strother *et al*. (1984) described the injury mechanism for a near-side occupant in a side impact. Figure 3 shows the velocity in a car-to-car side impact. The striking vehicle is traveling at 40 mph when its bumper impacts the side of another vehicle. Since the bumper is in the crush zone of the striking vehicle, its velocity drops as it deforms the door of the struck vehicle. At the same time, the door of the struck vehicle rapidly accelerates up to more than 15 mph in 20 ms in this example. The occupant is adjacent to the door and is struck at high velocity. The occupant is accelerated in the direction of the door intrusion. Later, the struck vehicle accelerates through the delta V of the crash.

The higher injury risks in side impacts shown in Figure 1 are related to intrusion of the side interior and high velocity loading on the occupant in the struck vehicle. There have been a number of improvements in side impact protection since this example was presented. Vehicle side structures have been reinforced to reduce the intrusion velocity and amount. Padding and inflatable restraints have been added to door and windows providing protection for the head, neck, and torso (Lau, Capp, Obermeyer, 1991).

5 INJURY CRITERIA AND TOLERANCES

Injury criteria are mechanical parameters such as force, acceleration, or deflection that are related to injury of a body region (Eiband, 1959; and Melvin, 1992). For example, the acceleration of the head has been used to describe the risk for skull fracture and brain injury (Mertz, Prasad, Nusholtz, 1996). Head injury is related to the duration of the impact and acceleration raised to the power 2.5. This led to HIC (Head injury Criterion), which is specified in government and consumer testing with dummies. Today, a family of dummies is used in crash testing. They represent adults, children, and infants, and instrumentation is used in the dummies to measure mechanical responses of the head, neck, chest, abdomen, pelvis, and extremities in the collision. The responses are related to injury risks based on biomechanical analysis and consensed injury criteria and tolerance levels.

Table 5 summarizes some information from a comprehensive collection of human tolerances developed by Mertz, Irwin, and Prasad (2003). It covers injury criteria for various body regions and tolerances for the family of dummies. There are three adult hybrid III dummies, three hybrid III child dummies, and three infant dummies. The tolerances include the HIC_{15} and peak head acceleration, upper neck force and bending tolerances, as well as the *Nij* intercepts, chest injury tolerances for acceleration, compression, and viscous response, and the femur compression tolerance. Other tolerance criteria and values included in Mertz, Irwin, and Prasad (2003) are not summarized here. In addition, there is a new family of dummies for testing in side and rear impacts with specific response measurements and injury criteria (www.humaneticsatd.com, www.carhs.com). For completeness, Table 5 also includes some basic anthropometry information on the nine crash test dummies. This includes standing and seated height, weight, head mass, and other dimensions of the dummy.

6 COMPATIBILITY

Compatibility between two vehicles generally refers to the response of vehicles and its occupants in two-vehicle collisions. Although the subject has been of interest since the beginning of crashworthiness studies, no consensus has been reached as to the definition of compatibility. Some studies have tried to define compatibility in terms of an aggressivity metric, which essentially had a good correlation with vehicle mass (Gabler and Hollowell, 1998, 2000), and others have used experimental data (Digges and Eigen, 2001; Barbat, Li, Prasad, 2001a, 2001b). However, it is commonly agreed that in two-vehicle collisions, the vehicle responses in terms of delta V, crush, and intrusion are strongly affected by the mass ratio, relative stiffness, and the relative geometry of the two vehicles. The above three factors also affect the injury responses of occupants in collisions.

For example, in a head-on collision between two vehicles of unequal masses, all else being the same, the likelihood of fatality of occupants in the lighter vehicle will be higher than that in the heavier vehicle. Similarly, even if the two vehicles are equal in mass, the likelihood of fatality in the softer vehicle will be higher than that in the stiffer vehicle. The geometrical alignment of the crash interface between the two vehicles can result in under-ride/override between the two vehicles. In general, the injury outcome of occupants in the vehicle being overridden is greater than that of occupants in the vehicle that is under-riding, except for large truck under-ride. The vehicle and occupant responses are a direct consequence of the physics of the collision.

If we assume that the masses of the two vehicles are m_1 and m_2 and they are in a head-on collision while moving at velocities v_1 and v_2 (closing velocity $= V_c = v_1 + v_2$), conservation of momentum dictates that $m_1{*}v_1 - m_2{*}v_2 = (m_1 + m_2){*}v_c$, where $v_c =$ common velocity and $m_1 > m_2$.

As a result of conservation of momentum, the delta V of the two masses will be inversely proportional to their masses, that is, (delta v_1 of m_1)/(delta v_2 of m_2) $= m_2/m_1$.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto252
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For example, if m_1 is twice m_2, the mass m_1 will undergo a velocity change one-half that of the mass m_2. Since the velocity changes of the two masses take place in the same time duration of impact, the average acceleration of the lighter mass will be two times that experienced by the heavier mass. The occupants in the lighter vehicle will have to contend with two times the vehicle accelerations than the occupants in the heavier vehicles. The injury responses of the occupants will be proportional to the vehicle accelerations, but not in a linear manner. Eiband's (1959) curves indicate that it should be in the order of $(m_2/m_1)^{2.5}$. Accident data also indicate that this relationship is nonlinear and is represented by a power function of delta V as indicated in the section on accident data. In other words, if R_{21} is the ratio of severe-to-fatal injury risk of occupants in vehicle 2 versus that in vehicle 1, and the occupants are restrained, $R_{21} = (m_1/m_2)^{3.728}$, where, the exponent 3.728 is derived by a power fit of field-observed severe-to-fatal injury risk as a function of delta V for belted occupants in frontal crashes as mentioned in an earlier section of the chapter.

If the mass ratio is 2, an occupant in the lighter vehicle is nearly 13.25 times more likely to be severely injured than an occupant in the heavier vehicle. On the basis of acceleration effects only, it should have been $2^{2.5} = 5.7$ approximately. The difference in observed and predicted risk of occupants in the lighter car arises from other factors like relative stiffness and geometry of the front ends of the colliding vehicles. Evans (2004) analyzed FARS data for two vehicle head-on crashes in which at least one occupant was killed and derived the relative risk R_{21} as a function of mass ratio (m_1/m_2) as $R_{21} = (m_1/m_2)^{3.58}$ where R_{21} is the ratio of fatal risk in vehicle 2 colliding against vehicle 1. The absolute risk of fatality as a function of delta V could not be determined from the available data because delta V is not available in FARS. Once again, if the mass ratio is 2, the likelihood of an occupant being killed in the lighter vehicle is nearly 12 times that of an occupant in the heavier vehicle. This predicted risk is not too different from 13.25, and perhaps within the errors of estimation, derived for risk of severe-to-fatal injuries based on momentum principles applied to field data discussed earlier in this chapter.

In two-vehicle collisions, energy principles dictate that the kinetic energy absorbed in the collision $= (1/2)*((m_1*m_2)/(m_1 + m_2))*V_c^2$. The energy is absorbed by deformation of structures of the two vehicles. The amount of crush experienced by the individual vehicles depends on the relative stiffness of the interacting structures and determines the stopping distance of the collision. For example, if we assume that the two vehicles are equal in mass and front-end stiffness, both vehicles will absorb half the energy and will have equal amount of crush. However, if one vehicle is substantially stiffer than the other, the softer vehicle will have to absorb the major portion of the energy and will crush substantially more than the stiffer vehicle. An extreme manifestation of this phenomenon is in front-to-side collisions in which the side structure is substantially softer than the front end of a vehicle, resulting in substantially higher intrusions of the side structure of the struck vehicle than in the front end of the striking vehicle.

When vehicles of substantially different masses are involved in frontal collisions, there is disparity in mass as well as stiffness. This results in generally greater crush and structural intrusions in the lighter vehicle. This phenomenon is generally observed in crashes between LTVs (light truck and van) and cars. The LTV fleet in the United States is heavier than the car fleet and the LTV is generally stiffer than cars because of their functionalities. Figure 4 shows the acceleration of a midsize car and an SUV of nearly the same mass. In a collision between the two vehicles, the car will have more crush than the SUV. For a more "compatible" crash, changing the front-end stiffness of the car or the SUV may be in order so that both vehicles participate in energy absorption and reduce the crush of the car front end. This could be accomplished by increasing the front-end length of the SUV. However, it may not be practical as the increased length of the SUV will affect some of its functions such as off-road capability. Also, changing the front-end stiffness of the SUV or the car would not be effective if the structural interactions between the SUV and the car front ends were not adequate, for example, if the bumpers and the energy-absorbing structures in the two vehicles did not match in height, resulting in the car being overridden by the SUV. Car bumper heights above the ground are standardized as they have to be in the Part 581 zone specified in a Federal Motor Vehicle Safety Standard. However, the bumper heights of LTVs are not regulated. These observations have led to the development of two principles for "compatible" crashes: "stiffness matching and geometry matching." Obviously, stiffness matching cannot be accomplished if the geometries are not matched.

Geometry matching between the LTV and the car fleet was the subject of research by a working group composed of vehicle manufacturers in the United States. In December 2003, the WG recommended that to improve "compatibility" between LTVs and cars, the light trucks primary frontal energy absorbing structure shall overlap at least 50% of the Part 581 Zone. If the above geometrical requirement could not be met, there must be a secondary energy-absorbing structure (SEAS), connected to the primary energy-absorbing structure, whose lower edge shall be no higher than bottom edge of the Part 581 zone. This

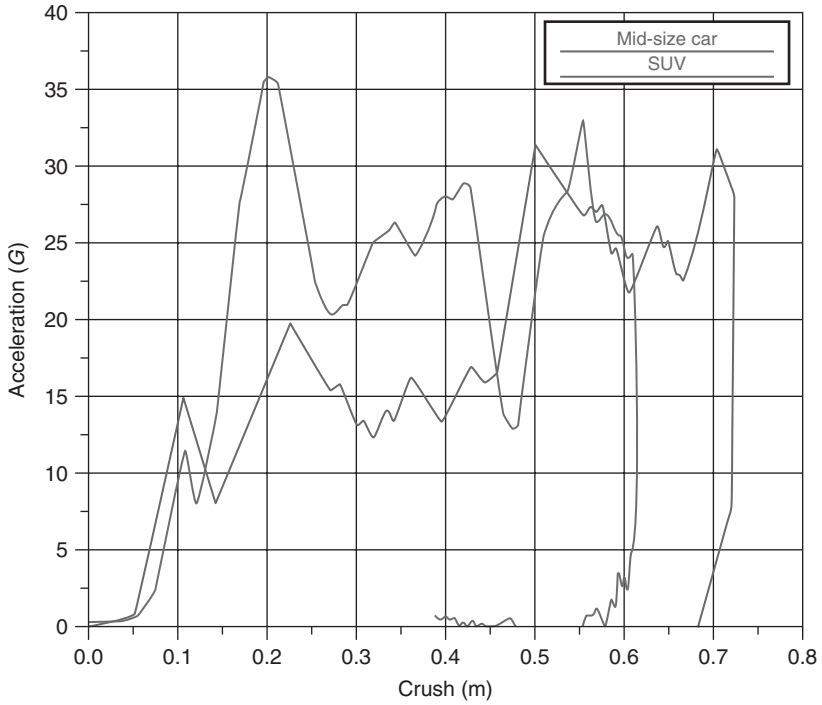

Figure 4. Crash pulses of two vehicles at 56 kph against a rigid barrier (NCAP).

secondary structure shall be designed to reduce the structural override of a passenger car during a frontal crash. The SEAS is commonly known as the *BlockerBeam*™ was introduced by the Ford Motor Company between 1999 and 2001 in heavy SUV and super duty pickup trucks. The details of the research performed by the WG were reported by Barbat (2005).

The recommendation of the WG was accepted by the domestic and foreign automotive manufacturers in the United States for all vehicles (<10,000 lb GVWR) manufactured and sold in the United States by MY 2009. The industry also agreed to fit all vehicles <10,000 lb GVWR with side airbags capable of providing head protection when impacted by an LTV, noting that practical structural changes in LTVs to improve compatibility in front-to-side crashes were not possible (see Insurance Institute of Highway Safety (IIHS) side impact test procedure, www.iihs.org).

7 RESTRAINT SYSTEMS

This section discusses some of the basic principles of restraint systems currently used in vehicles to provide occupant protection in front, side, and rear impacts and rollovers (Table 4). In case of a collision, two impacts occur. The first impact is when the vehicle collides against a fixed object or a moving object. Just before impact, the occupant and the vehicle are traveling at the same velocity. Subsequent to the initiation of impact of the vehicle with an external object, the vehicle structures deform causing the vehicle to slow down. This creates a differential velocity between the occupant and the vehicle, causing the occupant to move toward the point of impact. Without any restraint system, for example, seat belts, the occupant will contact the interior of the vehicle at a velocity dictated by the initial velocity of the occupant and the velocity of the contacted part of the vehicle. The occupant decelerates until they come to rest relative to the vehicle. The occupant–vehicle contact phase is generally referred to as the "*second collision*". In order to minimize injurious loadings on the occupant, energy-absorbing foams or energy-absorbing deforming structures are designed into the vehicle. The goal of the traditionally recognized restraint systems, for example, seat belts and airbags, is to minimize or avoid, if practicable, injurious contacts with the vehicle interior by minimizing occupant excursion within the occupant compartment during impact and retaining the occupant within the vehicle.

Since the early 1970s, three-point seat belts have become common in all vehicles as the primary restraint system. Since the mid-1980s, inflatable restraints have been introduced in various phases in all vehicles in the United States and more recently in vehicles around the world. The first application of inflatable restraints was for providing

incremental protection to belted front outboard occupants in frontal crashes, hence the term *supplemental restraint system* (SRS) for airbags. The early development of airbags can be found in Viano (1987), which is a compendium of published safety research through 1986 and more recently in Kent (2003). Initially, the frontal airbags were introduced in the United States, by law, with the goal of providing protection to unbelted occupants in frontal impacts. The test procedure to demonstrate such a level of protection was specified in the FMVSS 208. The test procedure involved a crash of the vehicle against a rigid barrier at 30 mph with unbelted driver and passenger dummies. The levels of injury criteria required by the law could be met. However, field data indicated that airbags designed to meet the required injury criteria could seriously injure occupants who were in the path of the deploying airbag, typically in low-speed crashes and with small occupants. FMVSS208 crash test velocity was reduced to 25 mph for the unbelted dummy tests to reduce the severity of airbag-induced injuries. This law became fully effective as of MY 2006. In an interim period 1998–2006, the unbelted crash could be substituted with a sled test driven by a generic half-sine pulse. Some background information of the development and changes of the FMVSS 208 are described by O'Neill (2009). The effectiveness of the sled test-certified airbags has been reported by Kahane (2006).

Inflatable restraints have undergone major developments since their first introduction for frontal protection. Even knee airbags have been introduced in fairly high volumes. More recently, airbags deploying from the shoulder belt have been introduced in the rear seats of several vehicles manufactured by Ford Motor Co. (Sundararajan *et al*., 2011). Inflatable restraints to provide head protection in side impacts were introduced in the mid-1990s. This was in the shape of a tube originally stowed in the side rails of the vehicle. Approximately, in the same time frame, inflatable restraints to provide chest protection in side impacts were also introduced. These side airbags were mounted on the door. The head airbag was integrated with the chest airbag as one system and is commonly referred to as the "*combo side airbag*". This combo bag was mounted on the outboard side of the front seats. The "combo bag" has evolved further to provide chest and pelvis protection, and the head protection is now provided by an inflatable curtain. The initial application of the inflatable curtain was for providing head protection in side impacts, an event lasting milliseconds. The curtain technology has further evolved to provide protection in rollovers, an event lasting for seconds, by the use of coated bags that retain pressure for 5–6 s. Future curtains will have to comply with the requirements of FMVSS 226, which specifies a series of tests and acceptance criteria, including containment in the vehicle to avoid ejection.

Over the years, substantial improvements in the belt system has taken place, some would not be possible without standard frontal airbags. Today's belts have pretensioners that apply forces on the occupant early in the crash to create an early coupling of the occupant with the vehicle, increasing ride-down of structural crush. Most shoulder belts in the front outboard seating positions have load limiting. The level of load limiting varies from vehicle to vehicle, but has proven to be effective in reducing chest injuries (Foret-Bruno *et al*., 2001; Mertz and Dalmotas, 2007). The level of shoulder belt load limiting used in today's vehicles could not be used without the airbag as lower belt loads lead to greater occupant excursion within the vehicle and partial and full ejection in some circumstances. Since the seat belt is the earliest form of restraint system, its installation in vehicles in United States is also regulated. For example, the anchor locations are controlled by the FMVSS 210, and comfort and convenience specifications have been developed by NHTSA. The seat belt retractors have to meet the requirements of the FMVSS 209, which specifies the deceleration levels ($0.7g$) at which the retractor will lock and the maximum amount of belt payout from the retractor (most retractors use a "no lock" at $<0.3g$ and "must lock" at $>0.45g$ within 25 mm of webbing payout). Most retractors also include webbing sensitive locking at $2g$ acceleration within 50 mm.

Early designs of the seat belt were influenced substantially by studying accident data, identifying injuries that could have been caused by the belt system, and injuries caused in spite of the belt system. During the early development of the seat belt, lack of biofidelic crash test dummies, led to kinematic design criteria to judge the quality of the restraint system. On the basis of analysis of accidents in Germany, Adomeit and Heger (1975) proposed seat belt anchor locations and seat cushion designs that would reduce the likelihood of submarining under the belt and reduce the likelihood of unfavorable kinematics of the occupant. Although the guidelines developed by Adomeit and Heger (1975) are still valid and generally followed by designers, the quality of restraint systems is now judged in crash tests with sophisticated dummies.

Crash tests to evaluate restraint systems: Regulatory and new car assessment programs (NCAPs) are in place in the United States, Europe, Japan, Australia, Korea, China, and Latin America, and more are expected in future. A common thread in all the NCAPs is a frontal crash against a crushable barrier, engaging 40% of the front end of the vehicle at 56 to 64 mph initial velocity. In Europe, this test is also a regulatory test; however, the velocity is 56 kph as opposed to 64 kph in the NCAP. In the United States, FMVSS 208

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

has required a test against a rigid barrier engaging the full front end of the vehicle. The impact velocity used to be 30 mph, but has been raised to 35 mph since MY 2006. The United States also has an NCAP frontal test at 35 mph against a full-width rigid barrier and the rating is based on dummy occupant responses. However, the vehicles sold in the United States are also designed for a test similar to that conducted in European NCAP.

These tests are conducted by the IIHS and are generally referred to as the *offset deformable barrier* (ODB) test. The rating system utilizes dummy occupant measures and structural responses of the vehicle. The structural responses considered in the rating system include post-crash intrusions of the toeboard and the dash. As a result, the overall stiffness of the front end is generally dictated by this test and has become a *de facto* standard for structural strength of the front end of vehicles. Since an ODB is used in the test, in general, the occupant compartment accelerations are lower and the crash pulse is of longer duration than those observed in the rigid barrier tests. The common understanding among safety engineers is that the ODB test is a test of the vehicle structure and the rigid barrier test, generating higher vehicle accelerations, is a test of the restraint system. We now discuss the physics of vehicle and occupant responses in rigid barrier impacts with a simple spring mass model.

Figure 5 shows a vehicle occupant represented by a point mass M_D. The mass is connected to the vehicle by a linear spring representing the stiffness of a restraint system that develops a force when a certain amount of prescribed slack is taken out when the occupant moves to the left. The vehicle and the occupant are initially traveling at the same velocity. When the vehicle impacts an external object it begins to slow down depending on the stiffness of the vehicle, causing the occupant to move to the left. After the slack is taken out, restraining forces are developed on the occupant. The restraint force in this case is the highest when the occupant stops moving relative to the vehicle. The maximum force can be easily estimated by solving the equation of motion of the mass M_D. For simplicity, we will assume that the mass is 1 kg, the spring stiffness is 2.5 kN/m and the initial velocity of the vehicle and the occupant is 56 kph. Note that the natural frequency of the spring–mass system is approximately 8 Hz and the time period of one oscillation is approximately 125 ms. In addition, the time period of one-half oscillation is 62.5 ms. The natural frequency selected in this example is an approximation of modern airbags plus belt restraint systems. The solution of the differential equation governing the motion of the occupant can be obtained in closed form, for illustrative purposes. We show the results of several different conditions of vehicle structural characteristics in terms of peak deceleration of the occupant mass, M_D, expressed as multiples of the acceleration due to gravity (g).

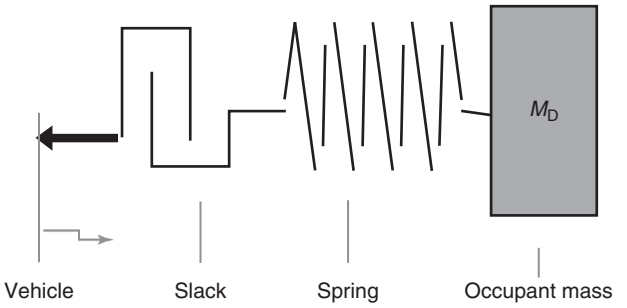

Figure 5. Spring–mass model of occupant in vehicle crash with slack.

Several scenarios are studied with and without the slack in the restraint system (Table 6). In the first scenario, we assume that the vehicle stops suddenly, in which case the occupant will move to the left, load up the restraint system and stop. In this case, the peak deceleration of the occupant will be at the instant when the energy absorbed by the restraint system is exactly equal to the initial kinetic energy of the occupant. Simple calculations show that the peak deceleration of the occupant is 79.3g. In the other scenarios, we will stop the vehicle with a prescribed deceleration–time history that is Haversine in shape. The peak acceleration of the pulse and the duration were adjusted to yield approximately 17.8 m/s delta V of the vehicle. The 17.8 m/s corresponds to an initial velocity of 15.56 m/s plus a rebound velocity of 2.2 m/s (commonly observed rebound velocity of vehicles tested against rigid barriers at 15.56 m/s). As the vehicle deceleration decreases, the stopping distance increases for the assumed impact. The results show the importance of increasing stopping distance in reducing the forces on the occupant. It is also shown that even with 30 mm of slack in the restraint system, forces on the occupant increase when compared to those without slack. Hence the deployment of pretensioners in modern vehicles that minimize slack in the belt system.

The preceding analysis is a simplified analysis of the dynamics of an occupant involved in frontal crash and how the front-end design and restraint parameters can affect the forces on and decelerations of the occupant. Since the start of crash tests against rigid barriers, the topic of the optimum shape of the vehicle deceleration time history (the "crash pulse") has been studied. The earliest study was reported by Egli (1967) and a more recent one has been reported by Kral (2006). Kral's (2006) study followed those by Takahashi *et al.* (1993) and two studies by Motozawa and Kamei (2000), Motozawa *et al.* (2003). All studies

Table 6. Effect of belt slack and stopping distance on occupant acceleration.

Stopping||distance (mm)	Haversine||acceleration (g)	*Duration* (*ms*)	Occupant acceleration (*g*) Slack in belt (mm)	
			0	30
0	Infinite	0	79.3	79.3
430	60.0	60	77.6	82.0
517	45.3	80	69.4	75.3
713	36.3	100	60.0	66.8
855	30.2	120	51.4	58.5

indicate that the optimum pulse should have an early rise followed by a dwell period that is followed by a square wave pulse. This is generally known as a *front-loaded pulse*. Kral (2006) goes on to mention that a front-end structure capable of delivering such a front-loaded crash pulse may not be ideal in lower velocity collisions. Designing a front-end structure to deliver the optimum pulse has proven to be elusive as most vehicles in the field do not exhibit the desired characteristics of the theoretically optimum pulse. One aspect not considered in the above studies is the aspect of compatibility with other vehicles. A fast rising, front-loaded pulse would be aggressive to other vehicles, especially in front-to-side crashes.

Reparability and Insurance Ratings in the Development of Cars

Frank Leimbach and Helge Kiebach

KTI GmbH & Co. KG, Lohfelden, Germany

1 INTRODUCTION

Decades ago, the analysis of real world accidents determined that most accidents happen at low speeds. German statistics (Anselm 1997) revealed that 85% of all frontal impacts occur at velocities below 9 mph (15 km/h), resulting in the primary crash safety requirement for the front structure of cars to fully absorb the energy of an offset impact at 9 mph (15 km/h).

From an insurance cost view, the requirements are to limit the deformation or damage to structural parts and cost-intensive components.

The crash safety performance could be implemented relatively easily, that is, in the design of rigid bumpers and beams. However, the design of car front structures is a very complex process, including marketing and visual design criteria, as well as pedestrian safety. Along with the insurance cost aspects, other regulatory and consumerism low speed crash tests are often employed to reduce damage and improve the repairability of vehicles.

In addition to frontal testing, low speed tests for the rear and side areas of the vehicle have also been introduced for similar purposes.

This chapter addresses the history of low speed repair crash tests and the relevance of crash repair tests in the calculation of insurance premiums for fully comprehensive cover. Various standards and crash tests for consumer information and insurance tests have been introduced in many markets. RCAR (Research Council for Automobile Repairs) provides an overview of the variety of low speed test procedures.

2 HISTORICAL BACKGROUND

In the United States, the Insurance Institute for Highway Safety (IIHS) started to conduct low speed crash tests at 5 mph into a flat barrier in 1969. These tests led to the first federal bumper test rules for cars, requiring the bumpers to resist damage at impacts up to 5 mph (8 km/h). In April 1971, the National Highway Traffic Safety Administration (NHTSA) issued its first regulation on passenger car bumpers.

Federal Motor Vehicle Safety Standard (FMVSS) 215 was initially enacted in September 1972, imposing requirements to prohibit damage to specified safety-related components such as headlamps and fuel systems in a series of perpendicular barrier impacts at 5 mph (8 km/h) for front bumpers and 2.5 mph (4 km/h) for rear bumper systems.

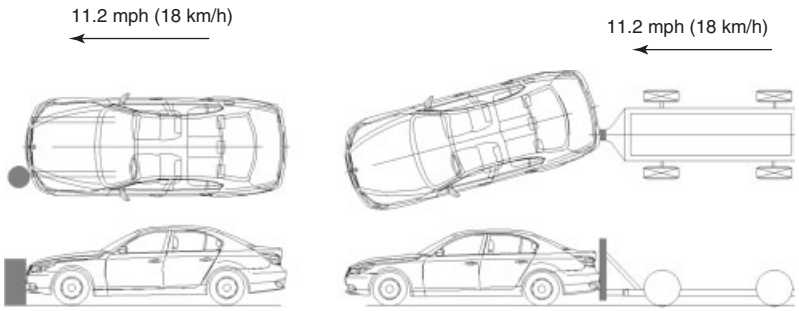

Figure 1. Test setup of the first crash repair tests in Germany.

These standards were further enhanced for MY 1974 passenger cars, specifying standardized height front and rear bumpers that could resist angled impacts at 5 mph (8 km/h) with no damage to the car's lights, safety equipment, or the engine.

Performance requirements have been improved several times. For MY 1979 cars, the standard required no damage to safety-related parts and exterior surfaces not involving the bumper system. This was known as *Phase 1* and required an impact test speed of 5 mph. More stringent tests were introduced for MY 1980–1982, applying 5 mph longitudinal front and rear impacts and 3 mph pendulum (corner) impacts resulting in no damage to the bumper itself beyond a 3/8 inch "dent" and 3/4 inch "set," or displacement from original position. These requirements, limiting damage to the bumper itself, are referred to as *Phase II*.

The last change in the bumper standard took place on 14 May 1982 when the tests were modified, reducing the test impact speeds from 5 to 2.5 mph for longitudinal impacts and from 3 to 1.5 mph for pendulum impacts. The Phase II bumper damage requirement was dropped and replaced with the previous Phase I requirements. After considering the available data and public comments, the NHTSA completed a Final Regulatory Impact Analysis (FRIA) in support of the latest rule amending the bumper standard to the 2.5 mph impact with Phase I damage requirements. These standards became effective on 6 July 1982, affecting 1983 and subsequent model year cars as American standard (SAE J980a) and have been adopted by the European Community, enacted as part of ECE Regulation No. 42 in June 1980 (UN, 1980). This regulation applies to the behavior of certain parts of the front and rear structures of passenger cars when involved in a collision at low speed and says: "Exterior protection is assured by protective devices, which are essentially elements located at the front and rear ends of vehicles and designed in such a way as to allow contacts and small shocks to occur without causing any serious damage" (United Nations, 1980).

During the late 1970s, Germany introduced a car insurance classification system (Gustafsson, 2001). These frontal-impact tests required the left chassis leg/side member to crash centrally against a pole of 40 cm in diameter (Figure 1). For the rear test, a 20 cm wide, 500 kg ram was driven into the left rear corner of the car at an angle of 15°. The impact speed applied in both tests was 11 mph (18 km/h). The damage caused by these tests was calculated and the repair procedure was documented.

In 1982, the frontal and rear test procedures were revised, along with the addition of side crash tests and the average repair cost per vehicle type was determined.

These procedures involved front and rear offset crash tests with a 40% width overlap (excluding the exterior mirrors) against a rigid barrier (0° angle) at a collision speed of 9.3 mph (15 km/h [+1/−0 km/h]). The rigid, mobile barrier weighed 1000 kg and was 70 cm high with a ground clearance of 20 cm. The mobile barrier moved parallel to the test car's longitudinal axis. For the side crash test, a rigid barrier weighing 1000 kg was rammed into the left side front door of the test car at a collision speed of 6.2 mph (10 km/h) at 45°.

When determining the result, in order to determine the final average cost per vehicle, each test was weighted based on the actual incidences of each type of impact (frontal 54%, rear 30%, and side crash test 16%).

The German system and its application to insurance rating had a great influence on the car manufacturers' interest in lowering crash repair costs. They realized that they were partly responsible for setting the insurance premium level of the cars they were producing and selling, affecting sales, so focusing on the reduction of crash repair costs would help in their aims.

This test method has been further developed in cooperation with other RCAR members and is documented in an RCAR document. The method was later incorporated in an RCAR Standard (low speed 9.3 mph offset insurance crash test). The test was included in the type class calculation of the German Insurance Association in 1991.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In 2006, the low speed offset crash test was revised. The angle of front and rear impacts was changed from 0° to 10°, and the rear impact moving barrier weight was increased from 1000 to 1400 kg. This test is referred to as the *RCAR Structural Test*. Speed and overlap have been not modified.

Car manufacturers design their vehicles to perform well in the RCAR structural test, but some vehicles do not exhibit a good crash behavior in "real world" crashes. In some cases, manufacturers have eliminated the bumper beam (a strong part) as a backstop and replaced it with localized measures such as crush cans in order to perform well in the tests. Such sub-optimized designs are in most cases not robust or are damaged too easily, often leading to expensive damage in car-to-car crashes.

Insurance claims data also indicates that rear bumpers are often underridden in low speed impacts by a striking vehicle because of bumper system movement or vertical "dive" of vehicles during braking, resulting in misalignment of the "strong" areas and excessive damage. In these cases, it is desirable to have bumper systems that have sufficient vertical overlap to ensure proper engagement. To this end, bumpers should ideally be mounted at slightly different heights at front and rear, but should also have sufficient height to maintain engagement over a wide range of circumstances. Insurance data also shows that rear bumpers are often overridden when struck by high ride-height vehicles (SUVs, pickup trucks, and so on). Vehicle damage would be reduced in both these situations with taller front and rear bumper beams.

With this in mind, an international RCAR working group has developed test procedures to assess how well a vehicle's bumper system protects the vehicle from damage in low speed impacts. The damage in these tests closely replicates the damage patterns observed in real world low speed crashes.

This test represents a typical city accident, with interaction of the bumpers of the involved vehicles. The test vehicle crashes with a collision speed of 6.2 mph (10.0 ± 0.5 km/h) against a deformable, energy-absorbing element with a solid rear backing, which replicates real world damage where an underride situation occurs. The test encourages designs that absorb crash energy while limiting intrusion into the vehicle structure. Vehicles with qualifying bumper beam heights of 100 mm or more shall be subject to the dynamic test even if the front-to-rear bumper engagement is less than 75 mm if a reasonable test result can be anticipated. The vehicle's bumper system must sufficiently engage with the bumper barrier to be deemed acceptable. Systems that use the vehicle main structure as a backstop for energy management will be regarded as unacceptable.

3 INSURANCE SCHEME

In countries where it is legally permitted, insurance rating systems have been introduced. The cost of repairs as a result of low speed crash test criteria (mostly, the RCAR standard) plays a major role in deciding the insurance group rating and, therefore, the whole life insurance costs of the vehicle.

In Germany, motor vehicle insurance premiums (motor liability, semi-comprehensive cover, and fully comprehensive covers) are calculated by separating the individual car types into categories. Until 1996, the main criterion for the classification was the engine power. As of 1996, the classification depends on two criteria; the frequency of claims as a percentage of total number of claims and the average loss across the total vehicle stock. Fully comprehensive cover consists of 25 categories.

While the frequency of claims depends primarily on driver behavior, the average loss can be affected by the vehicle's construction. This system regulates itself because the frequency of claims and the average loss of any car type must be a substandard of all cars in the market. At the first classification of a new car type, the frequency of claims is as far as possible assumed from the comparable predecessor model. The claim amount is derived directly from the RCAR test, which is then projected on the total of average losses. Since 2010, the RCAR bumper test has served as test procedure by the German Insurance Association in addition to the RCAR low speed test.

The car insurance scheme in the United Kingdom is like the German model. Since 1992, cars have been condensed to car groups and then classified by car type. Testing is based on the RCAR test. After a crash, the damage is determined and the car is repaired. The original price of the car, the engine power, the availability of body in white as a spare part, and the protection against theft (as standard equipment) are further influences on the classification. The frequency of claims is not considered. France, Spain, Italy, Sweden, Norway, and Finland also use tests that are in line with the RCAR test.

In the United States, there is no uniform insurance scheme. In the majority of the States, motor liability insurance is obligatory. In some States, simply proof that there is enough capital available for adjustment of a loss is a sufficient precondition to get the vehicle registered. The calculation of the insurance premium depends on driver experience, car type, place of residence, family status, age, sex, and capital assets of the owners.

In the United States, the repair costs are determined in tests that are carried out by the IIHS. The Institute's series of four tests (front and rear full-width impacts at 6 mph and front and rear corner impacts at 3 mph) produce the types and amounts of damage that commonly occur in low speed

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

collisions. The results of this test are made public, allowing the consumer to choose a car with low repair costs.

The Insurance Australia Group (IAG) is the operator of the Technical Research Centre in Australia and a member of RCAR. The IAG performs research into repair costs and gives recommendations regarding classification of cars. Furthermore, the repair costs determined from tests are published on the Internet. As in the United States, the Australian consumer can use this information in choosing a car with low repair costs.

4 TERMINOLOGY

The terms *damageability* and *repairability*, as used in the following sections, are according to the guidelines of RCAR (2008), which says:

"Damageability is the capacity of a vehicle to withstand the force of a collision and embraces the ability of the vehicle to absorb crash energy and in so doing limit the physical displacement, deformation and damage to structures and high cost components."

"Repairability means the possibility and ease of repair, firstly in the physical sense and secondly in terms of cost. Good repairability will mean that the vehicle can be restored to its pre-accident condition either by repair or by economic component replacement."

5 IMPORTANT TEST PROCEDURE

5.1 RCAR tests

5.1.1 RCAR low speed offset crash test (until 2006)

The RCAR low speed offset crash test was established in 1983 in Germany and was developed at the suggestion of the insurance industry. The RCAR test specification describes a front crash and a rear crash. The damage, as a consequence of a side crash, which is needed in the German first classification of cars, is considered as a theoretical damage within the RCAR procedure. For this, a partial replacement of the sill and a replacement of driver's door will be calculated.

In the front and rear impact tests, the vehicle overlaps the face of the barrier by 40% ±25 mm (Figure 2) at 0° (parallel) to the front/rear of the vehicle. The 1000 kg mobile barrier is propelled into the test vehicle with an impact speed of 9.3 mph (15 km/h [+1/−0 km/h]).

An alternative rear impact test method is acceptable, whereby the test vehicle is propelled rearward into a fixed barrier that is dimensionally compliant with the fixed dimensions of the mobile barrier. The speed of the vehicle on impact must be adjusted according to the mass of the test vehicle and is determined by Equation 1.

$$v = 15\,\text{km/h}\sqrt{\frac{1000\,\text{kg}}{1000\,\text{kg} + \text{m}}} + 1\,\text{km/h} \qquad (1)$$

where v = test speed in kilometer per hour and m = mass of test vehicle.

5.1.2 New RCAR low speed offset crash test (since 2006)

In 2006 (RCAR, 2006), the low speed offset crash test was revised. The impact angle was changed from 0° to 10° and the rear impact moving barrier weight was increased from 1000 to 1400 kg (Figure 3). This test is referred to as the *RCAR Structural Test*. Speed and overlap were not modified.

5.1.3 RCAR bumper test

The RCAR bumper test uses a standardized bumper beam that is 100 mm tall with a flexible, energy-absorbing cover that replicates a real bumper on a car. A 200 mm tall backplate is fitted to the top surface of the bumper barrier, 25 mm behind the front face, which represents the upper

structure of the impacting vehicle (see Figure 4, RCAR, 2010). The tests are run at 6 mph (10 km/h) with the bumper barrier height set to 455 mm from the ground to the lower edge of the barrier for the front test and 405 mm for the rear test. These dimensions recreate the underride phenomenon seen in real world crashes and encourage the car manufacturers to produce tall bumper beams that are at least 100 mm tall, and that overlap between front and rear. The RCAR test only recommends testing beams that are within the 75 mm overlap test zone.

5.2 IIHS tests

The IIHS's low speed crash test protocol was revised in 1997, 2001, and 2002 (IIHS, 1996, 1997, 2001a, b, 2002, 2012).

5.2.1 IIHS low speed test 1996 until 2007

This older crash test protocol (Version 1) described four different low speed crash tests (IIHS, 1996) at a nominal 5 mph (8 km/h) impact speed. The following tests were performed on each vehicle model:

- front into full-width flat barrier;
- rear into full-width flat barrier;
- right front into 30° angle barrier;
- rear center into pole.

The first two tests followed the patterns of the perpendicular barrier impacts required by federal regulations for passenger cars (49 CFR, Part 581). The latter two tests were added to simulate a broader range of impacts occurring in actual on-the-road crashes.

For the front- and rear-into-flat-barrier tests, the impact barrier is an unyielding (rigid) block of reinforced concrete weighing 145,150 kg positioned perpendicular to both the crash hall floor and the longitudinal centerline of the test vehicles (Figure 5). The barrier is augmented with a solid steel face plate measuring 366 cm wide, 184 cm high, and 8 cm thick. The impact area of the face plate is covered with 2 cm-thick plywood.

For the front-into-angle-barrier test, a rigid steel fixture is bolted to the impact barrier face plate (Figure 6). The fixture includes a solid steel face plate measuring 214 cm wide, 92 cm high, and 4.5 cm thick. The entire face plate is covered with 2 cm-thick plywood. The angle barrier face plate is perpendicular to the floor, and the angle between the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

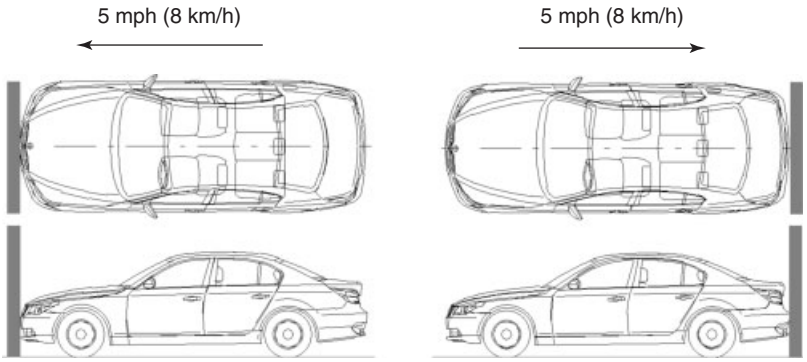

Figure 5. Test setup of IIHS low speed test front and rear into full-width flat barrier (1996 until 2007).

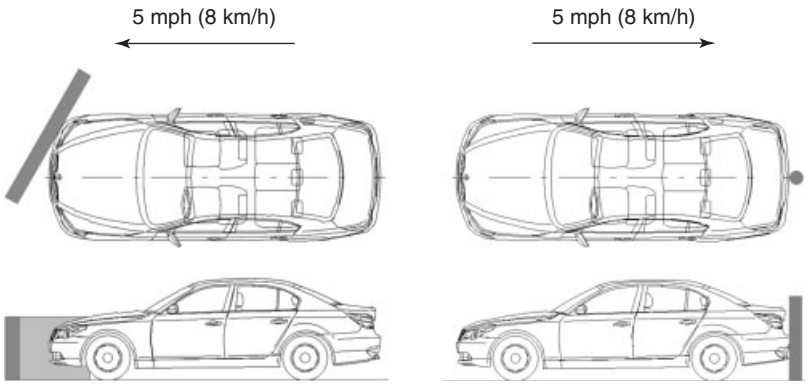

Figure 6. Test setup of IIHS low speed test front into inclined barrier and rear into pole (1996 until 2007).

longitudinal centerline of the test vehicles and the plane of the face plate is 60° (90° minus 30°). If any vehicles have hoods or front fenders whose top leading edges are more than 92 cm above the floor, the entire angle barrier fixture is raised, so that the bottom edge of the angle barrier face plate is 18 cm above the floor. Otherwise, the fixture is not raised.

For the rear-into-pole test, the test pole is 152 cm long and 18 cm in diameter (Figure 6). The pole extends 92 cm above the floor surface and 60 cm below.

For the flat barrier impacts, this target point is located midway between the vertical edges of the impact barrier face plate. For the angle barrier impacts, the target point is offset 53 cm to the left of the vertical centerline of the angle barrier face plate. For pole impacts, the target point is the pole surface located in the tangent plane perpendicular to the track centerline. The crash test speed range is 4.95 ± 0.15 mph (7.96 ± 0.24 km/h).

Following the completion of the tests, the damage will be estimated. The appraisers indicate "no damage" if there is damage only to the external bumper surfaces and no other damage to the vehicle body or bumper or localized dents are no more than 0.95 cm deep, and overall bumper distortion or displacement is no more than 1.9 cm from the original contour and there is no breakage of fasteners. These criteria were part of the federal requirements in effect from 1 September 1979 to 6July 1982 for passenger car bumpers, under which minor cosmetic damage to exterior bumper surfaces was permitted after specified 5 mph (8 km/h) barrier and pendulum impacts and 3 mph (5 km/h) corner pendulum impacts (49 CFR, Part 581). For part replacement indicated in the estimates, new original equipment replacement parts at full list prices are specified. If vehicles have clear coat (two-stage clear over color) paint, all estimates requiring refinishing include the appropriate additional labor time.

5.2.2 IIHS low speed test (since 2007)

The baseline for these tests is the crash test procedure according to RCAR. Four different bumper crash tests into a contoured, bumper-like barrier are conducted on each vehicle model. Front and rear full-overlap tests are

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

conducted at 6 mph (10 km/h, see Figure 4), and front and rear corner tests (Figure 6) are conducted at 3 mph (5 km/h). The four tests were developed to promote compatible, stable, and energy-absorbing interfaces among vehicles in the fleet. Each vehicle is run into a steel barrier designed to mimic the design of a car bumper, with the barrier's plastic absorber and flexible cover simulating typical cars' energy absorbers and plastic bumper covers. The barrier heights for full-overlap and corner tests differ to simulate a broader range of impacts occurring in actual on-the-road crashes.

For front and rear corner tests, the impact barrier is mounted with the forward-most portion of the bottom edge of the barrier that is 406 mm from the floor. At impact, the vehicle overlaps the lateral edge of the barrier by 15% of the vehicle's width, as measured at the wheel wells (including moldings and sheet metal protrusions) at the corresponding axle—front axle for front corner tests and rear axle for rear corner tests (Figure 7).

The damage-estimating process is conducted as it would be done in a repair shop; each bumper assembly is generally removed and dismantled to check for possible hidden damage. Damage repair estimates are conducted using industry standard appraisal techniques and documented in a computerized system developed by Audatex, a Solera company.

For hourly labor rates indicated in the estimates, Audatex supplies an average of labor rates for body repair and refinishing used in actual estimates by its clients across the country as of the most recent calendar year quarter. This average rate is rounded to the nearest dollar and used in calculating labor costs. Similarly, the cost for paint and related materials are based on the average rate used by Audatex clients during the most recent quarter (rounded to the nearest dollar) and is directly proportional to the total refinishing time for each estimate.

For part replacement indicated in the estimates, new original equipment replacement parts at full list prices are specified (based primarily on the most recent Audatex information, but secondarily on data from the appropriate Mitchell Collision Estimating Guide, Motor Crash Estimating Guide, or vehicle manufacturers or dealers). No discounts, betterments, appearance allowances, insurance deductibles, taxes, or vehicle storage fees are applied. If a vehicle has clear coat (two-stage clear over color) paint, all estimates requiring refinishing include the appropriate additional labor time (in most cases, automatically computed by the Audatex system, otherwise manually calculated by the appraisers).

The front and rear full test damages are multiplied by two—because in the real world, full-width impacts occur approximately twice as often as corner impacts; that total is added to the front and rear corner test damages. The sum is then divided by 6 to get the weighted average. This number determines the overall rating. The good/acceptable boundary is $500, the acceptable/marginal boundary is $1000, and the marginal/poor boundary is $1500. However, no vehicle can earn a rating of good or acceptable if it is deemed undrivable or unsafe after a test because of headlamp or taillamp damage, hood buckling, coolant loss, or the like. The IIHS's bumper test protocol was revised in 2009 (IIHS, 2007, 2009, 2010, 2012).

5.3 Pedestrian protection tests

There is always a conflict between the requirements of the front of a car for the pedestrian protection test and the requirements for the car front repair crash tests. The original EC Directive on pedestrian protection, 2003/102/EC (published on 6 December 2003), introduced pedestrian protection requirements in two stages. Both stages utilized the same test procedures, but the injury limits for Stage 2

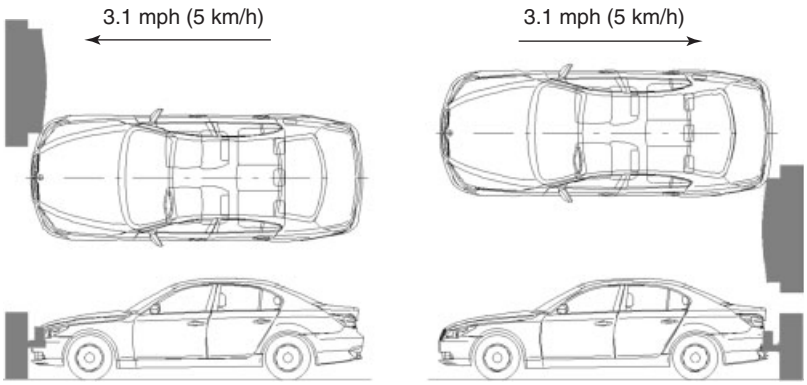

Figure 7. Test setup of IIHS low speed corner test (since 2007; according to the test of RCAR).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

were more stringent than those applied in Stage 1 (valid from 1 October 2005).

Additional energy-absorbing material is often used to enhance crash protection and insurance ratings. The thickness, width, height, and stiffness of the energy-absorbing material must now be optimized to meet the pedestrian legform impactor acceleration criteria. Therefore, the distance between the bumper face and the cross member will be limited. A method of managing the energy resulting from an impact to the bumper, as used by some manufacturers, involves a combination of deforming energy-absorbing element and the crush cans attached to the side member. This arrangement forms a two-stage energy management system.

The pedestrian safety tests are performed at 25 mph (40 km/h) of the 13.4 kg legform impactor in "free flight." In the process, the energy-absorbing element (e.g., a foam pad) behind the bumper has to absorb an energy of 830 J. This is the result of Equations 2 and 3, respectively

$$E = \frac{m}{2}v^2 \tag{2}$$

$$E = \frac{13.4\,\text{kg}}{2}\ (11.1\,\text{m/s})^2 = 830\,\text{J} \tag{3}$$

where v = test speed in meter per second and m = mass of test device.

At an impact of the vehicle against a rigid barrier, such as the RCAR test at 9.3 mph (15 km/h), initially, the barrier penetrates deep into the vehicle's front structure. Assuming a car test weight (m) of 1500 kg and an impact speed of 9.3 mph (15 km/h), the bumper structure must absorb a maximum energy of around 13,000 J (Figure 8).

Owing to the required space necessary for the fulfillment of the pedestrian protection tests using the lower legform, there is a little space for an effective energy absorption in a vehicle impact against an obstacle.

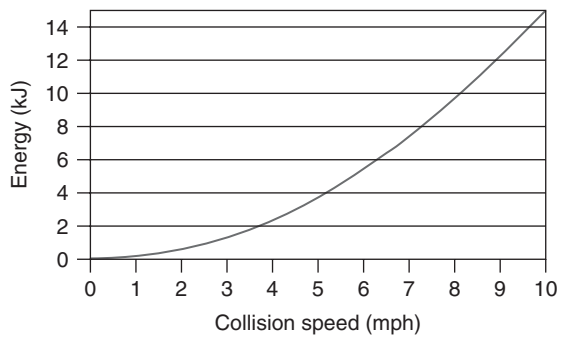

Figure 8. Increase of the collision energy with rising speed.

This means that impact forces are transmitted to the main vehicle structure more quickly over shorter distances in low speed crashes. This conflicts with the requirement to damage as few parts as possible during the crash repair test. Headlights, fenders, and engine cover cannot always be set back for design reasons, which also increase the risk of damage. Therefore, the requirements on the bumper systems increase to afford pedestrian protection (soft deformation at the front) as well as to absorb the energy of a low speed crash in shorter distances, without large amounts of total deformation.

6 MEASURES FOR THE CONFORMANCE TO LOW SPEED CRASH TESTS

The "RCAR Design Guide—A manufacturers' guide to ensure good design practice for repairability and limitation of damage" can serve as a tool to assist for the automobile manufacturer in optimizing damageability and repairability. Implementation of the guidance in this document can ensure a competitive vehicle with strong economic and practical selling points; the insurer and the policy holder pay less, and the vehicle repair industry is able to carry out the repairs needed easily.

It is important to ensure, however, that both damageability and repairability enhancements must be achieved without compromising the safety of vehicle occupants or other road users.

The most important test procedures are tests at speeds up to 9.3 mph (15 km/h), as performed by the insurance industry (e.g., testing of RCAR and the American Institute IIHS). In addition, the bumper systems must also conform to performance testing in relation to the overall vehicle concept. The primary standards are UN/ECE-R42, CMVSS 215, and FMVSS 215, which provide the ability to drive the car after a crash at low speed, that is, between 2.5 and 5 mph (4 and 8 km/h). Other mandatory and legally prescribed test standards include those on pedestrian safety (2003/102/EC) and occupant protection in crashes at speeds of up to 40 mph (64 km/h; e.g., UN/ECE-R94, FMVSS 208, and CMVSS 208).

An optimization of the bumper systems to meet these requirements is sometimes so different that the systems used can vary depending on the market (e.g., USA, Europe, and Japan). The design in terms of crash behavior is often complicated by the test specifications being subjected to changes in procedures, as new influences come into play.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6.1 General crash behavior

Figure 9 shows the stages of damage to the vehicle structure at different collision speeds. To minimize the repair costs, the components should, as far as possible, be consecutively involved from the outside inward, as the energy is absorbed.

In a frontal crash up to 2.5 mph (4 km/h), no damage to the main structure should be evident. The energy should be absorbed only by the external bumper skin and absorbent components inside the bumper, that is, foam elements. In accordance with regulation ECE-R42, little damage should occur; for example, marking on the outer bumper skin and punctures are acceptable.

At speeds between 2.5 mph (4 km/h) and 9.3 mph (15 km/h), the repair costs should be at an acceptable level, that is, cross members and elements such as impact absorbers or crushable crash boxes (Figure 10). Only the extreme front sections of side member should be damaged.

At speeds above 9.3 mph (15 km/h), the longitudinal beams will probably be damaged, in addition to the deformation of the wheel arches and other load-bearing parts in the front structure. In frontal impacts with even higher speeds, the deformation often extends to the bulkhead, regularly leading to an economic total loss.

To ensure appropriate crash impact absorption in front of the passenger compartment, the structure should be designed from the outset to accommodate high crash loads. This design should consider the increasing requirements of the crash test procedures, such as the EuroNCAP, 40% overlap at 40 mph (64 km/h). This means that, in accordance with differing crash repair tests, parts will already be appropriately stiff by design, combining to absorb energy in the early phase of a high speed crash as well as individually in low speed impacts.

During the RCAR test, it is most important that no airbag or belt tensioner is triggered; otherwise, the repair costs will rise sharply. The threshold for triggering the front airbags must, therefore, be above the delay profile caused by the RCAR test. Neither should the threshold be too high because in a crash test against a soft, deformable barrier the airbag should not trigger too late; for example, crash test with 40% coverage at 25 mph (40 km/h) in accordance with FMVSS 208 (Rüter *et al*., 2007).

Figure 9. Stages of damage.

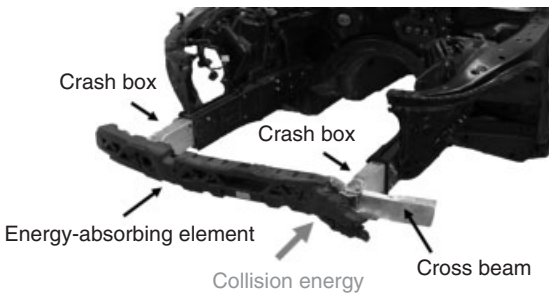

Figure 10. Bumper system after crash (BMW 5 series, type F10, European model).

6.2 Bumper skin

Bumper skins are design elements and often form supporting element for other components; for example, license plate, parking sensors, nozzles of the headlight washers, and distance sensors.

In addition, the skins are contributing more and more to conform to regulatory requirements such as in pedestrian protection tests. For this to be achieved, some of the kinetic energy of the impactor is converted to rotational energy. In addition, soft foams are integrated behind the bumper skin and in front of the cross member. Therefore, even more space is required to allow for the cross members as well as energy-absorbing elements. These requirements may lead the manufacturers to make the energy-absorption elements stiffer in order to ensure effective energy reduction over shorter distances. As the thickness of the skins is only approximately 2 mm, they are very flexible, and in an impact like that tested in the RCAR crash repair test, they absorb very little energy.

The outer panels are bolted to the front module. In the region of the fender, there are very often connectors, so that a slight collision can flex the outer skin of the body, and no lasting damage to the body occurs. At the 9.3 mph (15 km/h) impact speed tests according to RCAR procedure, the most likely damaged part is the bumper skin, so that a replacement is normally necessary. In the low speed crash tests by the IIHS of approximately 5 mph (8 km/h) impact speed, replacing the bumper skin after the crash test is not always required.

As with the crash-absorbing elements (impact damper and crash boxes), the bumper skins of the European version of a particular vehicle may be different to versions of the same model sold in the United States in order to comply with the different requirements (USA: FMVSS 215 "bumper standard" and Europe and worldwide: RCAR).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

6.3 Cross member

In a frontal crash, the cross member has to absorb as much energy as possible. This requires a force versus deflection curve, which remains as consistent as possible. Furthermore, the beams must have a defined bending rigidity, so that, for example, in a central pole rear impact (IIHS Test Specification), the transverse beam buckles immediately and forces are introduced into the longitudinal beams. In a crash with an overlap of 40%, in which only one side member is exposed directly to the load, the load should be guided to the opposite side longitudinal beam as well.

If the outer contact surface area of a cross member should fall below a minimum level, its resistance during crash tests with a deformable barrier will be reduced; for example, EuroNCAP with 40 mph (64 km/h) impact speed and 40% overlap. It may be necessary to design quite a large surface in order to prevent the barrier (representing the structure of another car) penetrating too deeply.

In relation to the "packaging," meaning the integration of the beam system into the overall concept of the front or rear module, there are very limited margins to the requirements the vehicle manufacturer has to fulfill (Figure 11).

Outer design specifications of the vehicle often determine the shape of the cross member. A highly curved bumper skin requires the inner parts to be adapted to the shape of the bumper. Especially, when designing compact cars, usually the case for the European and Japanese markets, very little deformation space is available and the deformation distance must be very short. The choice of locations for the connection points between the cross member and the side members may also be limited.

The material used for steel and aluminum cross beams is critical and the requirements for the systems has led to a noticeable tendency toward high strength materials. Hot-formed steel cross beams can achieve a tensile strength of about 1300 MPa, and the weight of the systems will be reduced.

Figure 11. Energy-absorbing element front, cross beam bolted to the side member (BMW 5 series, type E60, European model).

6.4 Crash-absorbing elements

Owing to the demand for in-expensive repair costs, especially in view of the RCAR test, energy-absorbing elements, for example, impact absorbers and crash boxes, have proven to be very effective. In the event of a crash at speeds up to 9.3 mph (15 km/h) by these measures should ensure that damage to the side member structure and other expensive parts is avoided in most cases.

Almost every car manufacturer uses energy-absorbing elements at the front and rear of the car. These specific elements absorb the energy resulting from crash loads at low impact velocities [collisions to about 9.3 mph (15 km/h) and pedestrian accidents]. Various energy-absorption elements can be used, including

- foam plastic elements;
- structured plastic elements;
- crush boxes;
- dampers.

Plastic elements, usually hollow body with reinforcing ribs are used as alternative solution for foam elements in order to prevent minor damage and for pedestrian protection. These elements are either integrated in the bumper skin or separately attached to the vehicle structure, for example, cross member.

For higher energy absorption designed to prevent structural damage, for example, in the RCAR test, about 5 mph (8 km/h) impact speed, foam elements and structured plastic parts are not alone sufficient because of their low strength and stiffness. Elements placed between the cross beam (bumper support) and the ends of side members should have a higher energy absorption capacity. For this purpose, there are various systems for the purpose of absorbing the energy, most of which use the common principle of the deformation of metals (usually, aluminum or steel).

Within the actual side member structure, an energy-absorption element can be formed by including regular folds in the member. While effective, this method still requires the replacement or repair of the actual side member. By incorporating a separate "crash box" of folded metal, which is bolted to the end of the side member, in case of damage, the cross beam and energy-absorbed elements are simply unbolted from the longitudinal member and replaced. The type and strength of the materials used for the crash boxes, side members and the cross beam (usually, aluminum and steel), and the design of the folds can be combined to produce the required amount of controlled deformation when an impact occurs, reducing the risk of damage to the main side members at the tested speeds.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Crash energy into the main structure can also be reduced by the compression of a round tube inside a tightly fitting or tapered outer sleeve. The inner tube is pushed into the outer sleeve in a crash, either expanding or seizing, as it does so. Other types absorb the energy by shearing, and in all these cases, nearly constant force-displacement characteristics can be generated. The advantages of these types of crash box are low weight and costs. All of these "crash box" solutions enable energy absorption by means of irreversible deformation.

Reversible crash absorbers, however, can absorb the energy from a crash load up to a certain limit and without plastic deformation get the original shape back. These elements can be installed as crash boxes between the crossbeam and the side rails as well.

In these systems, silicone, gases, and/or liquids act as shock absorbers and are usually reusable up to 9.3 mph (15 km/h), suiting the requirements of RCAR tests. It should be noted that the impact damper is designed for a particular stress direction. In the later RCAR low speed offset crash test (Section 5.1.2), the systems have to be adapted to the new test conditions; therefore, for example, the damper can be installed at an angle of 10° to the vehicle's longitudinal axis. Disadvantages of these reversible systems are the relatively high mass and the expensive production.

For simplified replacement, the advantage of bolting the components together is that the crash boxes, cross members, and longitudinal members may be made of different materials in order to perform correctly. Compared to the often-welded cross members in the past, there are advantages in production; for example, preassembly of the front module, inserting the engine from the front. In order to save more costs, a combination of common crossbeams and crash boxes can be used for various models.

6.5 Side member

The longitudinal members should be constructed with an increasing modulus of resistance from front to rear. This could be achieved by ensuring that the cross-sectional area or material thickness is larger toward the rear of the side member, for example. Buckle initiators can be used in order to restrict unavoidable partial repairs to the front section of the side beam. This can be achieved by means of varying stiffness or "weak" areas toward the front of the side members.

If a towing eyelet is permanently connected, for example, welded, to the longitudinal beams, an impact on the towing eye in various directions, for example, "snatching" when towing, can initiate torsional moments to the longitudinal beam, leading to failure of the member. In order not to adversely affect the deformation behavior of the longitudinal beams in case of collisions, the towing eyelet is provided with a thread so it can be easily fitted, but only when required.

7 SUMMARY

Good deformation behavior, ease of repair, and low cost of spare parts have a favorable impact on the running costs of a car. Often, these properties are subject to crash repair tests and are included in the calculation of insurance premiums. Relevant tests for evaluating the ease of repair of a car are the crash repair test by RCAR and the low speed crash tests by the US IIHS. In the RCAR test procedures, one front crash test and one rear crash test are described, in which the vehicle crashes at 9.3 mph (15 km/h [+1/−0 km/h]) with a 40% overlap against a rigid barrier, which is inclined by 10°. In the rear test, the vehicle is crashed at 9.3 mph (15 km/h [+1/−0 km/h]) with an overlap of 40% against a mobile barrier at an angle of 10°. The IIHS test procedure describes four tests for front and rear of the car.

Tests by the insurance industry have shown that the cross member systems have been optimized to such an extent, due in part to this test method, that in case of slight modification of the test procedure, the energy-absorption elements can fail and may result in considerably higher repair costs. This was taken as an opportunity to test and modify the RCAR and IIHS low speed tests.

Partly owing to the differing requirements of RCAR tests and the IIHS tests and partly owing to different markets, different systems are used. Energy-absorbing elements for vehicles that are intended for the American market may be different to those fitted to the same model offered on the European market.

In addition to the requirements in terms of ease of repair, there are many factors that influence the design of the crossbeam systems. Thus, only in terms of crash behavior in the initial impact phase can a variety of test procedures be considered. These include low speed repair crash tests conducted worldwide. Regarding the fulfillment of statutory safety standards, crash tests in the lower speed range (from 2 mph) are only considered in order to demonstrate the drivability of the car.

The cross beam systems also contribute to the occupant protection in high speed crash tests [up to 40 mph (64 km/h)]. Within the European Directive on pedestrian protection (2003/102/EC), which has been mandatory since 2005 for all new models, under the bumper skin and in front of the cross beam, soft, energy-absorbing elements are housed that are thick enough to satisfy the test type with the leg impactor. The majority of the energy absorption

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto254
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is done behind the soft cross beam system. Therefore, the crossbeam system must absorb energy within a very short distance; otherwise, the impact forces are transmitted to the main structure, increasing the average deceleration of the entire vehicle as well as causing the total deformation to be too large and more expensive to repair.

Therefore, manufacturers are increasingly using absorption elements such as the impact-absorbing crash box placed between cross beams and side beams. These elements can absorb energy at minor crash loads [i.e., between 5 and 9.3 mph (8 and 15 km/h)] and prevent damage to the longitudinal beam to a large extent. Bolting the crash-absorbing elements on the longitudinal beams allows for a quick and cost-effective repair.

1 INTRODUCTION

Vehicle crash sensors record the accelerations of car components and pressure increases in door cavities. If defined thresholds are exceeded, several restraint systems are triggered in stages to protect the vehicle occupants. The airbags and seat belts deploy their protective functions like clockwork and react adaptively to variable occupant characteristics and accident severities.

Inertial sensors measure translational and rotational vehicle accelerations during vehicle motion. These kinematic data are continually compared to the control input given by the driver. If dynamical thresholds are exceeded and critical driving situations are predicted, for example, stability control systems work to stabilize the vehicle and thus support controllability.

The increasing variety of available driver assistance systems has led to stronger utilization of forward-looking sensors. These sensors monitor the car's surroundings. They also monitor the driver's current state and attention level. In traffic situations requiring higher attention, driver assistance systems support situational awareness by targeted information and/or warnings. In addition, suspension control and brakes are preconditioned in order to provide maximum response at the first sign of a driver reaction. If the driver fails to react independently in time to avoid an impending collision with a pedestrian or a leading vehicle, the car can trigger an automatic braking sequence. By reducing the collision speed, the accident consequences for all involved persons would be reduced in a considerable percentage of conflicts.

Information concerning the vehicle and driver states and the traffic environment enable targeted preparation of the vehicle and the occupants for an impending collision. To this end, all available data from forward-looking, inertial, and crash sensors can be fused to predict crash criticality. In accident scenarios compatible with measurement of the so-called precrash data, reversible actuators can be deployed to precondition the occupants and the vehicle by moving them into optimal positions and orientations. Irreversible restraint systems can also be pretensioned to deploy adaptively,

ISBN: 978-0-470-97402-5

according to the situation, and provide protection at the earliest possible moment following the collision. In addition, protective strategies are deployed in a controlled manner and adapted to the constitution of the occupants, the accident scenario, and the collision speed. This integrated safety approach links active and passive safety systems and aims to reduce the risk of injury even beyond what can be provided by passive safety systems alone.

This summary has described the potential and the limits of adaptive safety systems for preconditioning the vehicle and the occupants before an accident. In the following, the achievable protective performance will be illustrated using several examples; methods for reliable and comprehensive assessments of the protective sequence of integral safety systems under laboratory conditions will be elucidated.

2 POTENTIAL OF ADAPTIVE RESTRAINT SYSTEMS

Vehicle safety has already achieved a very high level of performance. The risk of serious injury or mortality in traffic accidents has been steadily decreasing in recent years despite increasing exposure (mileage driven), primarily because of the development of passive safety systems.

On the other hand, it is evident that further development of passive safety is reaching a point of diminishing returns, although some weak points still can be identified based on our comprehensive knowledge of passive safety development. However, classical methods may not suffice to further improve passive safety.

For one thing, collision scenarios in tests can never precisely match the spectrum of accidents under realistic traffic conditions. Moreover, the true positions of occupants within the vehicle can deviate markedly from an optimal configuration—not to mention unbelted occupants. Presumably for an increased sense of comfort, seat backs are often quite reclined, seatbelts are fastened with too much slack, or tightening of the seatbelt is hindered by thick winter clothing.

In addition, the variance among occupants is quite large: systems must protect people who are short, tall, thin, corpulent, and all combinations thereof. Demographic trends result in increasing proportions of older drivers and passengers. They have stricter requirements on maximum stresses because of their more fragile physiology, including vulnerability to skeletal, muscular, and internal injuries. Indeed, it is certainly beneficial even for average occupants to minimize the forces acting on the body in an accident.

The key mechanisms that can be addressed by adaptive restraint systems are matching of the occupant's forward displacement in a crash to the accident severity, reduction of seat belt tension acting on the occupants, and/or adaptation of this tension to the forces acting in the crash.

In recent years, research on occupant restraint systems has focused on the development of adaptive restraint systems. Adaptive restraint systems are able to adapt their behavior to individual occupant characteristics and crash conditions using information from sensors that gather information during the precrash and crash phases. They can provide the best compromise between occupant load and forward displacement in given situations. Nowadays, adaptive load limiters and airbags are already available in cars. However, they currently only distinguish two classes: occupants smaller than a "5th percentile woman" versus all larger occupants. Scientific research is currently focusing on more advanced adaptive safety measures, for example, the so-called continuous restraint control systems, which can continuously optimize their configuration during impact considering individual occupant characteristics and crash severity.

The potential of adaptive restraint systems has been shown in a parameter study in the PRISM project of the European Union, where simulations were performed with MAthematical DYnamic MOdels (MADYMO) based on late-model vehicle models and various dummy sizes. In the frontal Euro NCAP crash test, the ISS1 value of the occupants could be significantly reduced (up to 60%) by adapting various restraint system parameters to the specific occupant (Lemmen *et al*., 2005). Extreme cases included a small driver close to the airbag, a very large driver, or a driver missing the airbag entirely. The restraint system was optimized for each case by, for example, varying the load limiting level of the seat belt between 2000 and 7000 N and varying the firing time of the driver airbag between 10 and 40 ms.

Hesseling (2004) has investigated the possibility of controlling airbag and seat belt behaviors to mitigate the consequences of a crash for the occupants. By controlling the airbag mass flow and vent size and the belt force, a significant reduction in chest and head accelerations could be achieved. A MADYMO simulation model of a mid-size passenger car was used with a dummy, representing a 50-percentile (median) male. Simulation of a US NCAP frontal crash test2 with this simulation model and the controlled restraint system showed a reduction of chest and head injuries by 60% and 50%, respectively, compared to the same test with a conventional restraint system. Similar results were found in simulations with a 5-percentile female dummy. However, conclusions drawn from this research are subject to several limitations because of idealized assumptions: it was assumed that the crash pulse (the deceleration profile of the vehicle during the crash) was known *a priori*;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

that ideal restraint actuators were present; and that all required measurement data, such as biomechanical occupant responses, were available in real time.

The aforementioned research approaches show that adaptive restraint systems may offer considerable potential in terms of injury reduction in frontal vehicle crashes. The challenge in the implementation of these systems in production vehicles is to ensure that the adaptive system will always perform as well or better than the corresponding nonadaptive system in terms of injury reduction. When an adaptive restraint system receives incorrect information on, for example, occupant size or impact conditions, the occupant's injuries could theoretically be more severe than in the case of nonadaptive systems. Therefore, a study will be performed on the malfunctioning of adaptive restraint systems and the consequences thereof. To be able to make a comparison between the two systems, a system definition is needed, for both a current car with nonadaptive restraint systems and a future car with adaptive restraint systems.

3 STATE-OF-THE-ART AND FUTURE RESTRAINT SYSTEMS

3.1 Modern restraint systems

The protective performance of modern restraint systems begins a few milliseconds after collision detection. The data required to trigger the appropriate "choreography" of an adaptive restraint system are measured by vehicle sensors.

Occupants are classified at the beginning of the trip, for example, by pressure-sensitive seat cushion mats and by detection of the longitudinal seat position. In most cases, two occupant classes are currently distinguished: occupants smaller than a "5th percentile woman" (height less than 152 cm and weight less than 54 kg) and all others.

Numerous sensors measure accelerations occurring at different points of the chassis and pressure increases in the door cavities. In a collision, the severity and impulse direction are derived from sensor signal data, particularly the rise in signal amplitude. Front, side, and rear collisions can be clearly distinguished. The crash severities are divided into different stages. Once the signals exceed defined thresholds and have been verified for self-consistency, in the majority of cases, pyrotechnic propellant charges are ignited to activate belt pretensioners and airbags.

The use of adaptive restraint systems enables the selection of trigger times for multistage airbags and force characteristics for adjustable safety belts. Thus, the protective effect of the restraint system can be optimally adapted to different accident scenarios, their resulting crash severities, and classes of occupants. These adaptive capabilities are implemented by several different techniques. Airbags can be fitted with two pyrotechnic propellant charges, whereby the stages can be triggered simultaneously, separately, or with a time offset. Additional airbag volume can be released or ventilation holes can be opened according to time or pressure actuation by means of controllable air bag tethers. The diverse range of possibilities extends to self-adaptive solutions, in which ventilation openings are closed or remain open after physical contact with the occupant depending on his or her size. Belt forces are adapted by the so-called "force limiters" using linear, digressive, or switched controllers. The required belt forces are generated and modulated using friction, straining, or torsion effects.

By coordinated action of all these adaptive components in an accident, the system aims to provide a restraint capability with the lowest possible burden and optimized to the accident severity and the occupant classification.

3.2 Controlled restraint systems

Until now, progress in implementation of restraint systems has included self-adaptive and multistage devices. A further stage of development could involve protection systems with feedback controllers that can adapt their restraining action within milliseconds during the entire course of the crash. This development would of course require rapid and reliable sensing of all relevant feedback parameters, real-time processing of these data in the controllers, and a mechatronic actuator concept for adaption of the restraining system components. The sensor, restraint system, and controller requirements would need to be improved by substantial factors compared to the state of the art. While some progress has been made, there remain fundamental technical challenges.

One possible solution could utilize a precrash model: for example, just before an impending accident involving two cars, all data from both cars relevant for prediction of accident severity and estimation of occupant injury risks would be measured by forward-looking sensors. Here, it is also conceivable to send the relevant data shortly before the crash via car-to-car communication systems. On the basis of this sensor data, the optimal triggering strategy for the controllable restraint system could then be determined either by real-time prediction of the collision dynamics or by a knowledge-based approach.

3.3 Preconditioning before T_0

Using current technologies, it is possible to precondition the vehicle and its occupants for an impending collision. Once the predictive sensors have detected an unavoidable

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

collision, the occupants and vehicle components could be moved to optimal positions using reversible actuators. In this way, the full potential of both the vehicle structure for energy absorption and restraint systems for the reduction of injury risk can be optimally utilized. If the driver manages to avoid the accident or if a collision does not occur, all actuators would be restored to their original positions. Reversible electromotive belt pretensioners could play a particularly important role in accident scenarios with automatic brake intervention. Before emergency braking, they link the occupant to the seat structure at an early stage and reduce the slack in the belt, which may be present because of an effect similar to slack in a film reel. The deceleration caused by forward displacement of the upper torso is reduced, and the occupants remain in a favorable position for the seat airbag. Occupants sitting with highly reclined seat backs just before the collision are rapidly shifted to an optimal, upright seating position. In addition, by seat angle adjustment, a seat ramp is formed, which helps prevent "submarining," the tendency to slide out under a seatbelt in an accident. An adaptive shock absorber control on the front axle counteracts brake pitch by setting a more rigid damping characteristic just before automatic braking. Thus, the crash-absorbing structures of the front end maintain the best possible overlap with the structures of the collision partner. If a sensor system becomes available that can detect an unavoidable accident situation with a very high reliability, it would be feasible to design an irreversible precrash system.

Various factors play a role in the design of a restraint system. Use cases demanded by lawmakers and by several consumer groups must be fulfilled by one single restraint system on crash test dummies differing in construction and size percentiles. Car manufacturers are succeeding in achieving these rather high occupant protection goals increasingly often, as evident from a glance at EuroNCAP evaluation results of current vehicles. On the other hand, more and more effort is required for small safety gains. This raises the question of how occupant safety can be enhanced by intelligent concepts in an efficient and customer-oriented way.

The fact that vehicles have been designed for human occupants rather than dummies suggests an approach. A look at customer-driven vehicles reveals that occupants do take a large variety of seating positions. In the case of the driver, seating positions in the real world closely correspond to those in crash tests, because these positions are geometrically constrained within narrow limits by the requirement that the driver must reach the pedals and the steering wheel as well as maintain a good view of the instruments and the vehicle exterior. Hence, for a given driver size percentile, seating positions remain within narrow limits. In the case of the passenger seat, these limitations do not apply, so that predominantly comfort aspects have an influence on the seat position chosen. Another factor regarding passengers is that they often simply keep whatever position was previously set, only to avoid the effort of positioning the seat for only a "few minutes." In either case, the result is a higher probability that the passenger side occupant sits in a less favorable position for a crash.

While satisfying the comfort needs of some passengers, highly reclined seat back settings are not recommended for safety reasons. The belt then does not make proper contact around the chest and pelvis and can slip into the rib cage area (Figure 1). In a crash, submarining can occur, where the occupant slides out under a seatbelt and, in the worst case, can suffer severe internal injuries. A suitable approach toward reconciling the conflicting demands of safety and comfort could be to use the power seat motors automatically to bring the seat back into an upright position before an impending crash.

The seatbelt itself offers further potential for improvement. Despite the installation of pyrotechnic belt

pretensioners as standard equipment, loose fitting belts cannot always be entirely avoided. Customers rarely tighten the seat belt to remove slack after buckling the belt. Here, a reversible electromotive belt retractor (REMA) can realize its safety potential by gently tightening the belt after it is buckled and more strongly pretensioning the belt in critical driving situations. REMA has a high relevance in practice, whereas crash tests assume that the vehicle is not braking; in reality, braking often occurs just before the crash. In these cases, REMA provides the additional advantage that timely pretensioning counteracts the forward displacement of the occupants resulting from their forward momentum in the braking vehicle. If the crash does occur, more distance remains available to spread out and thus further reduce the forces on the occupants.

Nowadays, in some cars, the already high safety level with standard equipment is extended by the features presented here. If the vehicle detects a precrash situation, it corrects an excessive seat back reclining (in certain seat configurations) to the extent possible. Electromotive belt pretensioners are activated on the driver and the passenger sides, resulting in a reduction of possible belt slack and prevention of excessive forward displacement of the occupants in case of strong braking. In accordance with the situation, open windows and the sunroof are closed. These strategies serve to reduce the risk that extremities—which flail about because of violent motions of the vehicle—might hang out of the vehicle, or that external objects might penetrate the vehicle through the openings.

Basically, two classes of precrash situations can currently be detected: critical driving states and unavoidable rear-end collisions. Critical driving states, for example, skidding or driver-initiated emergency braking, can be detected by sensors relatively easily. In these cases, the occurrence of a crash cannot be predicted with certainty, and in case of a crash, whether it will occur within seconds or even milliseconds. However, if the system is triggered in such a critical situation without a subsequent crash, customers still do not perceive the triggering as a false alarm. On the contrary, the driver is sensitized to the ability of the system to correctly trigger in critical situations and tends to see this triggering as a positive confirmation of the decision to purchase the system. The second class of situations consists of unavoidable rear-end collisions detected using environmental sensors installed for driver assistance systems, for example, cameras or radar sensors. The distinction between truly critical precrash situations from "sporty" but uncritical driving maneuvers is not that simple, so that a reliable crash prediction is possible only a few hundred milliseconds before the crash. Unjustified triggering is more intrusive for the customer in these cases, which implies that the classification as an unavoidable crash must be made late enough to avoid false alarms/triggers.

Future improvements will optimize these features. Faster seat motors are required to improve the chances of achieving the optimal seat position within the precrash in situations detected by environmental sensors. In addition, the range of reliably detectible precrash events will be extended to collisions with a vehicle located to the rear as well as side crash constellations, which are even more difficult to detect in a timely manner.

The currently available and future functions described here illustrate how adaptive capability mentioned earlier can be achieved in practice. Even if the customer ignores the recommended settings for seats and seatbelts for whatever reason, these functions aim to realize the full occupant protection potential of the conventional restraint system.

Another reason for the improvement of safety functions is the demographic change (aging society). Older people usually withstand only lower restraint forces than younger people do. Owing to the fact that the correlation between displacement and force is physically limited, it is reasonable to use a compromise between displacement and restraint force in all kinds of accidents. Adaptive restraint systems can help to optimize this compromise.

At this point, it should be mentioned that the age of the occupants is not a relevant parameter for designing the safety systems. The aim should always be to offer the lowest possible occupant loads for all kind of passengers. Owing to this, a decision between older or younger passengers is not required.

4 SENSOR TECHNOLOGY

To accommodate the use of the various restraint systems, several sensors are present in the vehicle to measure relevant parameters. In this case, the sensors that can be used in the BMW 5 series of the model year 2012 will be described as typical for current premium vehicles. The following sensors are present in the restraint system and relevant for a frontal crash:

- Acceleration sensors measure whether the vehicle's acceleration level exceeds a certain value, meaning the vehicle is in a crash situation.
- Buckle sensors measure whether an occupant is belted or not.
- A sensor in the seat foam of the passenger seat determines whether an occupant is present. The sensor gives three possible outputs: no occupant seated, child seat mounted, or occupant seated.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- A seat position sensor recognizes whether the seating position is in the front. Therefore, the occupant may be a 5th percentile female or smaller.

Integrated safety will play an important role in the further improvement of vehicle safety (Dannenberg, 2004; Heudorfer and Meissner, 2008; Bogenrieder *et al*., 2007). A future car is, therefore, likely to contain sensors to measure crash conditions and occupant characteristics, such that optimal protection is possible for each occupant.

Currently, research focuses on vision systems, occupant classification, and tracking sensors and wireless communication between cars and infrastructure.

4.1 Restraint system sensors

4.1.1 Object detection

To be able to accurately detect an oncoming crash, automotive manufacturers have been working on various solutions for object detection such as radar- and camera-based systems. For example, the Mercedes S-class (model year 2012) currently can be equipped with short- and long-range radars (two 24 GHz radar devices and one 77 GHz radar device, respectively) to detect upcoming vehicles and obstacles (Schittenhelm, 2009). The BMW 7 series of the model year 2013 uses a sensor system of one combined mid- and long-range 77 GHz radar sensors and a mono-video camera. Infrared sensors for obstacle detection at night (Jerzembek, 2008) are available for some premium vehicles.

It is expected that the costs for sensors for object detection, particularly for video- and radar systems, will decrease significantly in the near future, so that it is safe to assume that these systems will be present in future nonpremium cars as well (Whydell, 2010).

4.1.2 C2X communication

Next to the development of vision systems, wireless car-to-car and car-to-infrastructure communications (in short, C2X-communication) could also contribute to a safer vehicle. These systems would be able to warn the driver about a possible oncoming hazard; for example, when a vehicle a few cars ahead suddenly performs emergency braking. With car-to-infrastructure communication, a traffic light could provide data predicting when the red phase will begin, so that a driver who fails to stop could receive a timely warning (Kompass, 2008). Currently, several tests are being conducted to develop a system that functions reliably between cars from different manufacturers and different kinds of infrastructure (Badstübner, 2008; Herrtwich, 2008). Car manufacturers and scientists agree on the potential of C2X communication for improving traffic safety, and it is, therefore, likely that this technology will be part of future vehicles (Hartenstein *et al*., 2004). In the sim^{TD} research project, car-to-x communication and its applications are being tested in a large-scale test field around the German city of Frankfurt am Main (www.simtd.org, 2012).

4.1.3 Occupant sensing

Finally, an occupant-sensing system is needed to trigger adaptive restraint systems. This system needs to be able to classify an occupant in terms of weight, size, and seating position, measure the motion of the occupant, and provide information on the possible type and severity of injuries of the occupant. With this information, the adaptive restraint system can provide optimal occupant protection in case of a crash. However, unlike the vision and communication systems mentioned earlier, automobile manufacturers and scientists have not reached consensus on a reliable occupant-sensing system concept.

It is very likely that future cars will be able to predict an oncoming crash and that this information can be used to adapt the restraint systems to this specific crash scenario. It is expected that in future, vehicles information on crash severity will be available before the crash occurs.

5 EFFECTIVENESS ANALYSIS

In the development of adaptive safety systems, attention should be focused on the true effectiveness in real accident situations with respect to avoided collisions and reduced severity. However, this assessment is difficult to extract from statistics, as completely avoided accidents ("near misses") are not recorded in accident databases, and injury accident statistics do not provide data on complete avoidance of injuries. Moreover, it is important to assess whether a proposed safety measure will have a positive effect on accidents before introduction of the measure. For this reason, virtual methods of safety assessment are key elements in the entire development process for integral safety.

Large variances are inherent in the spectrum of relevant accident and risk situations and in the influence of driver reactions and responses. These variances considerably complicate the assessment of integral safety system effectiveness. No definitive standard test cases have yet been established, and system design needs to be oriented to effectiveness in the field—rather than optimized for testing. In order to achieve reliable assessment, a linked framework including driving dynamics, system operation, and crash

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

simulation is needed. Standards for determining the quality of these simulations have not yet been established and are also needed.

Stochastic simulation (also known as *Monte Carlo simulation*) offers a method to assess the effectiveness of safety systems rapidly—while considering the spectrum of traffic situations in which the systems might be triggered, the variability of possible driver responses, and other variable factors. A target scenario is simulated a large number of times with stochastically varying characteristics (on the order of one million runs). All relevant quantities (e.g., the braking force of a driver after a warning) are drawn anew in each run from appropriate, calibrated frequency distribution models. Owing to the large number of computational runs, a large variety of possible combinations of influence factors are drawn, including unusual but critical combinations. Simulation results vary correspondingly: most runs involve enough favorable factors to avoid an accident; a small proportion of runs—generally involving several unfavorable parameters—result in virtual accidents of varying severity or in near misses. If the distributional model parameters and the process model are close to the real scenario, then the distribution of accidents and severities should resemble the corresponding data in reality. This similarity can be verified by studying appropriate accident databases. Now, a novel safety system can be modeled and introduced into the virtual simulation environment in order to assess the effectiveness in a controlled virtual experiment by comparing the changes in accident frequency and severity with and without the system.

In order to compute a useful metric from stochastic simulation, injury severity distributions need to be generated from the state variables describing the virtual occupants and the virtual collision. Currently, these distributions are usually derived from statistical injury risk curves (usually obtained from logistic regression models) based on accident databases. However, the level of modeling detail is severely limited because of the statistical power and possible sampling biases of existing databases.

If a more precise or differentiated (i.e., by body part) assessment of injury probabilities is desired, a crash simulation with its corresponding computational effort could be utilized. However, even this method does not generally consider the motion of the vehicle and the occupants before the crash; for example, if the vehicle goes into a skid or braking is very strong. Appropriate simulation tools can of course be implemented to include vehicle dynamics and occupant motions resulting from the vehicle dynamics as well. The challenge lies in combining the various simulation domains, which typically have different time and spatial resolutions as well as modeling depth. By appropriate tools for cosimulation of different models, a comprehensive toolkit can be generated. A comprehensive simulation sequence enables assessment of integrated safety systems with active and passive elements on the basis of injury severity as a common metric. There is still a need for standardization of requirements on simulation models for effectiveness analyses.

Figure 2 illustrates a computation with a simulation sequence as described earlier. Simulation of vehicle dynamics provides a representation of the vehicle's

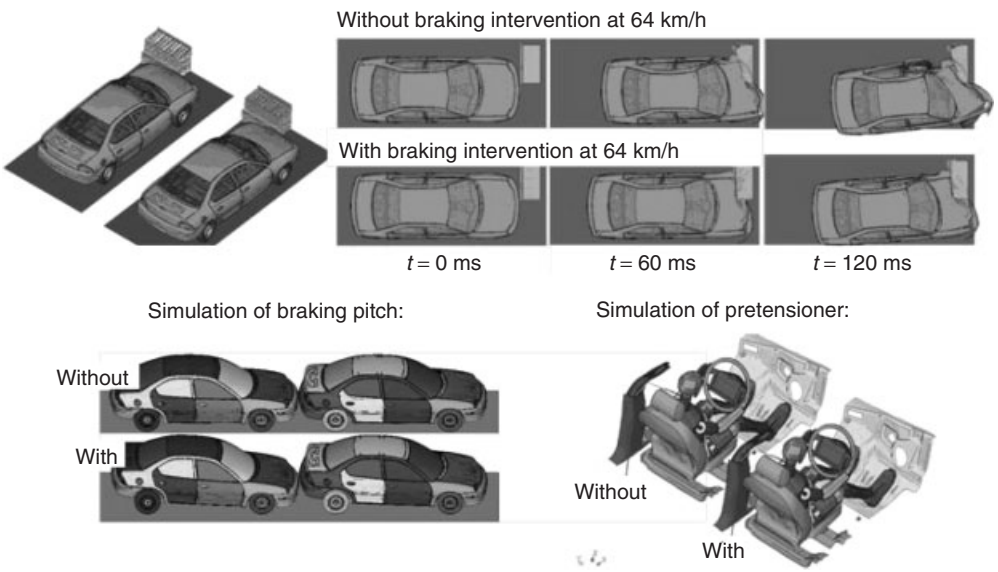

Figure 2. Simulation of offset frontal crash with braking intervention and precrash seatbelt pretensioning.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259

shift in orientation during braking. At the same time, forward displacement of the occupants with and without pretensioners can be shown. The starting configuration of the crash simulation varies correspondingly; the subsequent crash simulation then provides the computed occupant forces.

Any simulation requires validation, however. Validation is implemented using testing in a real environment. However, there are as yet no standardized methods established for testing adaptive and integral safety systems.

Currently, vehicle safety is dominated by passive safety measures. Correspondingly, test procedures are designed to assess the effectiveness of passive safety measures, which by definition begin with the crash itself. Thus, the benefits of any safety measures that work by preconditioning are not assessed by laboratory crash tests, although these measures could exhibit a high effectiveness in real accidents.

An example is reversible electromotive belt pretensioners. Their effectiveness is essentially attributable to the pretensioning of seat belts before the impending collision. They allow pretensioning before the collision has even taken place because they are reversible if the collision in fact does not occur. In real accidents, a large number of drivers will brake strongly before the collision (Figure 3), leading to forward displacement of occupants.

A conventional crash test (constant speed) without forward displacement thus underestimates the system's effectiveness. This assessment deficit causes an unnecessary disincentive for introducing such systems.

In the future, vehicles will be increasingly equipped with systems that warn the driver of an impending rear-end collision and support braking. These systems may institute automatic emergency braking if there is an unavoidable collision and the driver fails to react. Owing to the sharp braking of the vehicle, the occupants will normally experience forward displacement. This can lead to an occupant position closer to the airbag, so that the space available to move forward during the crash becomes smaller.

A reversible electromotive pretensioner can be activated as soon as an environmental sensor detects that the distance to the preceding vehicle is so small that an immediate crash seems imminent. Strong braking by the driver or an unstable driving state can also activate a reversible electromotive pretensioner. This activation couples the occupant tightly to the restraint system. In the event that the collision does not in fact occur, the pretensioning can be reversed. The consequences were shown in a crash test considering the effects of reversible systems.

It has not yet been possible to test the effectiveness of forward-looking occupant protection systems by crash tests with test rigs used up to now. However, innovations in vehicle safety will be introduced in increasing numbers of vehicles in coming years. For this reason, we need test methods capable of reproducibly testing the effectiveness of precrash functions. To this end, it would be advisable to develop a policy for implementing novel technical functionalities of traffic safety within currently valid standards.

A demonstration test was developed in a cooperative effort between DEKRA and BMW that showed how the effect of forward-looking protective systems can be evaluated in a crash test (Berg, Rücker, and Domsch, 2011).

A BMW 530d prepared especially for this test was able to determine the distance to the relevant target (in this case, the crash block) as well as the relative velocity, on the basis of radar sensor data from the ACC (active speed/distance control device). In this way, it was possible to record the

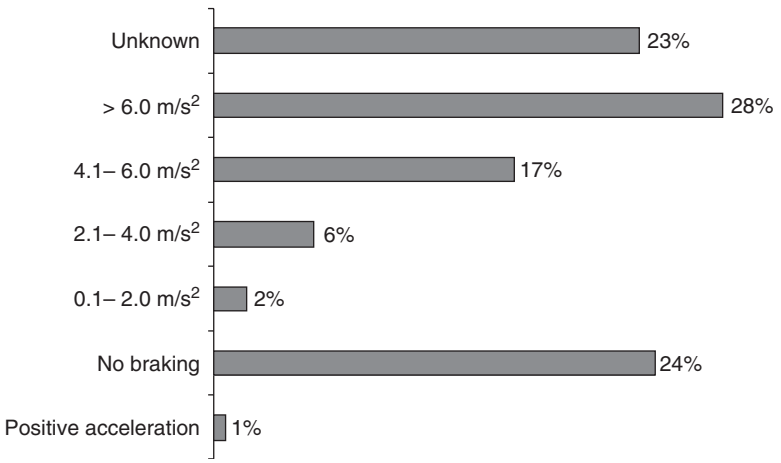

Figure 3. Frequency distribution for braking decelerations during the precrash phase ($N = 1492$ accidents, (GIDAS).)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto259

entire signal sequence starting from the sensor right up to the safety system reaction (i.e., triggering of automatic emergency braking). The response of the safety system in the test thus corresponded precisely to the corresponding response in a comparable real accident scenario.

While the vehicle was approaching the crash block, various safety functions—in some cases, prototypes—were activated. In addition to the ACC radar sensor with special object detection, identification, and selection capabilities, a stability control system (electronic stability program, ESP/dynamic stability control, DSC) with prototypical functions was required to implement an automatic emergency stop under full braking. In addition, the vehicle was equipped with reversible electromotive belt retractors for the driver and the passenger. The strategy for warning the driver and initiation of emergency braking was also implemented as a prototype. Finally, precrash deactivation of the fuel pump was implemented. The automatic emergency calling function corresponded to the standard BMW assist production version ("advanced emergency call") and was also utilized.

In the course of the test, the "point of no return" was reached, where a collision was no longer physically avoidable by any driver reaction (neither braking nor swerving). The automatic emergency braking function was initiated at this moment, producing the maximum vehicle deceleration possible on the basis of the traction between the tires and the road.

An initial speed of 64 km/h was selected for the crash test run, corresponding to the initial speed of the Euro NCAP or IIHS unbraked frontal offset tests. As in the Euro NCAP and IIHS frontal offset tests, there was a 40% overlap of the vehicle front with the deformable barrier. The driver and the passenger were represented by belted, instrumented dummies (Hybrid III 50th percentile male). Child dummies were not used.

In contrast to normal test procedures, in which precrash systems are not permitted to be activated, they were intentionally activated here. After the vehicle had been accelerated to the test speed, it approached the crash block with constant velocity. The sequence of safety measures was defined as follows: At a TTC of 2.1 s (TTC = time to collision, defined assuming the vehicle maintains its current velocity), the driver is warned optically of the impending rear-end collision. This warning is displayed as a red warning symbol on the instrument panel and as a warning symbol in the head-up display. Thus, the driver sees the symbol directly in his or her field of view. At the same time, the brakes are prefilled, and the triggering threshold of the brake assistant is lowered. In the system configuration presented here, an acute warning is given to the driver at TTC of 1.7 s, in which the optical warning is accompanied by an acoustic alarm. The reversible belt pretensioners are activated at TTC = 1.1 s, in order to avoid forward displacement of the occupants during braking. Automatic emergency braking is initiated at TTC = 0.9 s. In the test, the speed was reduced from 64.8 to 40.4 km/h (−38%).

The test rig controller was designed to detect the automatic precrash vehicle deceleration and reduce the speed of the towing cable correspondingly.

Even in the unbraked crash test, the production BMW 5 series vehicle had exemplary safety behavior. These results are highlighted by outstanding assessments in US-NCAP, EURO-NCAP, and IIHS test procedures. In the test with precrash braking, because of the reduced speed, the measured forces on the occupant dummies were further reduced by considerable amounts compared to the 64 km/h unbraked crash. The relative changes of several characteristic force values for the driver and the passenger dummies are displayed in Figure 4

6 EFFECTS OF UNNEEDED ACTIVATION

Adaptive restrain systems can contribute to a minimization of the risk of occupant injuries. However, it is important to understand what effects can occur in case of an unneeded activation. The following discussion illustrates the influence of a one-sided optimization.

To this end, consider an adaptive restraint system optimized for a 50 km/h crash into a rigid barrier. Suppose that the restraint system can be adapted using available data from the precrash phase of the situation. Now, the precrash phase data could be subject to errors for various reasons. This consideration raises the question of what influences uncertain or faulty data could have on the effectiveness of the system.

One example of an unneeded activation will be investigated: the velocity of a full overlap rigid barrier crash is wrongly detected and the settings of the restraint system are, therefore, not optimal for the situation. Two simulations are performed: one with a velocity of 40 km/h and the other with a velocity of 60 km/h. The restraint system settings are selected to be optimal for the case of

Table 1. P values in (%) for standard and unneeded activated restraint systems.

	P_{Standard} (%)	P_{Unneeded} (%)	Relative difference (%)
40 km/h	12.7	8.5	−33
60 km/h	14.9	45.2	+203

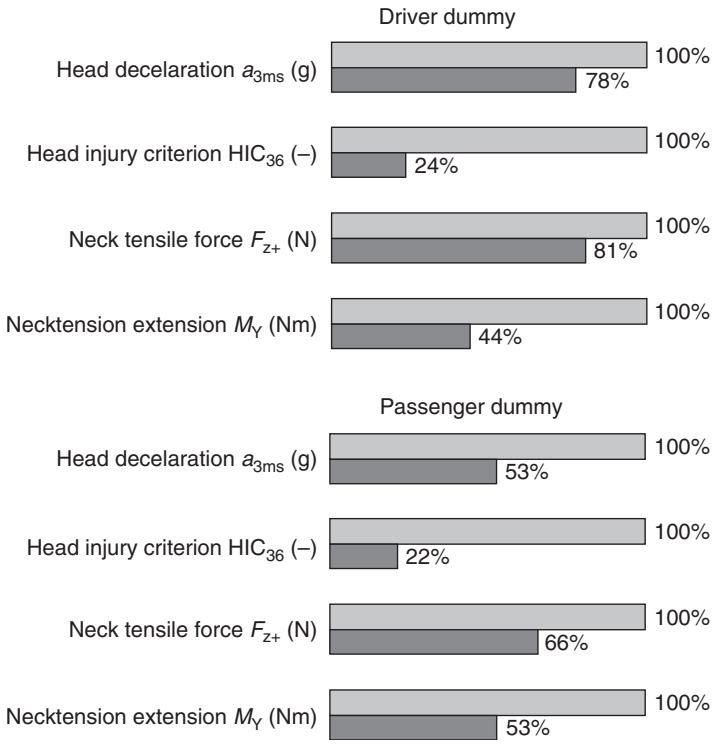

Figure 4. Comparison of relative injury measures to driver and passenger dummies in a braked crash test at 40 km/h collision speed compared to an unbraked crash test at collision speed of 64 km/h (normalized to 100%).

50 km/h. The dummy's injury level is compared with that of simulations with the standard restraint system at the same velocity.

The resulting *P*-values are shown in Table 1 for the standard restraint system ("standard") and the adaptive restraint system ("unneeded"). Each component of the *P*-value is displayed in Figure 5, together with the values of the various crash simulations.

If the relative difference is considered, it is clear that the *P*-value increases significantly for a velocity of 60 km/h. This is caused by the fact that the dummy hits the steering wheel with its head, which leads to a high probability of severe head injury ($P_{\text{Head}} = 35\%$) as can be seen in Figure 5a.

However, in the case of 40 km/h, the *P*-value is improved by 33% relative to the standard case. This is caused particularly by decreased values of chest deflection (Figure 5b) and Nij (Figure 5d).

Summarizing, measurement errors in adaptive restraint systems can lead to more serious injuries, particularly if the accident severity is considerably higher than forecasted. This conclusion implies that further development is required both to reduce errors to a minimum and to make sure that errors do not have negative effects on occupant injuries.

7 CONCLUSIONS

Traffic safety has made great strides in recent years, but the development of conventional, strictly passive safety devices is approaching a point of diminishing returns.

Adaptive restraint systems can contribute substantially to reduction of forces on the vehicle occupants during crashes. By combining these systems with integral safety systems that precondition the vehicle and its occupants or trigger additional appropriate vehicle responses, one can further reduce injury risks in serious accidents. This reduction is due to avoidance of some accidents entirely, decreased relative collision speeds, and individualized and accident-specific optimization of structures and restraint systems; the protective effect is adapted both to the occupants characteristics and to the details of the collision dynamics.

In system development, the problem of false positives is an important consideration. The collision is 100% certain according to vehicle sensors only at the moment of contact. As a prediction of collisions and their dynamics become increasingly uncertain with increased time to collision, in many cases, reversible protective measures are the only viable options. Even then, a careful coordination is

required, because the driver should under no circumstances be hindered in driving.

Active dynamic control of restraint systems during a crash promises high effectiveness, although further research will be needed in the areas of actuators and sensors. In particular, faulty measurements need to be intensively considered; a falsely interpreted sensor signal must not lead to increases in occupant stresses under any circumstances.

The design of safety measures should be optimized with respect to accidents and traffic scenarios as they occur in the field. To this end, simulative methods should be further developed and validated, in order to achieve rapid and reliable assessment of effectiveness.

1 INTRODUCTION TO TRAFFIC INJURIES

In recent years, society has gradually become aware of this epidemic problem. Administrations have reacted to this by incorporating requirements for the certification of vehicles, demanding the use of restraint systems, indicating the way vehicles should move on their highways, and educating their citizens. Other entities such as automobile and suppliers companies have prioritized safety as the main requirement in every new model design. All these developments have led to greater protection inside the vehicle during the accident, leaving the behavior of the vehicle for the rest of entities that coexist with it. This will become, among others, the bone of contention in the near future:

- Vehicle compatibility: the way the vehicle behaves compared to other vehicles during the event of impact, without pursuing the protection of the occupants whatever the price.
- Pedestrian protection: There is a need to study the problem of pedestrian casualties and fatalities and how can they be mitigated.

2 EPIDEMIOLOGY AND CHARACTERIZATION OF PEDESTRIAN ACCIDENTS

The World Bank estimates that between 41% and 75% of all road traffic fatalities worldwide are pedestrians (World

Bank Group, 2006) and that nearly 35% of all pedestrian fatalities are children (World Bank Group, 2002). According to Japanese data, pedestrians are four times more likely to be killed in a traffic accident than vehicle occupants (ITARDA, 2004). Like most of the approximately 1.2 million road traffic fatalities occurring each year, the majority of all pedestrian fatalities occur in developing nations where traffic volume exceeds the infrastructural capacity and the latest safety countermeasures are not yet available (World Bank Group, 2002). Pedestrian fatalities occupy a lower, yet still substantial, percentage of road traffic fatalities in industrialized nations: 11% in the United States, 12% in France, 14% in Australia, 21% in the United Kingdom, 32% in Japan, and nearly 50% in South Korea (NHTSA, 2006; ATSB, 2007; CARE, 2007; NPA, 2006; Youn *et al*., 2005). While pedestrian fatalities are a considerable problem, the number of pedestrians surviving vehicle impacts with injuries far exceeds the number of fatalities. In the United States (US), for instance, there are more than 13 injured pedestrians that survive vehicle impacts for every pedestrian fatality (NHTSA, 2006).

3 THE PEDESTRIAN, THE ENVIRONMENT, AND THE VEHICLE

Three factors are important to fully understand a vehicle–pedestrian collision. The environment, the vehicle, and the pedestrian contribute to accidents and determine their outcome (Haddon, 1980). Further, the accident can be divided into three parts on a time-scale; pre-, in-, and post-crashes. In each of these time events, the environment, vehicle, and road user are more or less influential factors important to consider.

The pre-crash phase describes the sequence leading up to the accident. In this phase, the road design, rain, lighting conditions, vehicle condition, the pedestrian, and driver behavior all interact, and if one or more of these parameters are faulty or unfavorable, a dangerous situation can emerge. If the risk parameters are not minimized, the dangerous situation can lead to an accident. Examples of poor road design could be sight obstructions or lack of safe pedestrian crossings (Figure 1). Poor vehicle brakes and lack of stability control (ESC; electronic stability control) are examples of vehicle factors. Distraction and alcohol intoxication of the driver or pedestrian are road user factors that can contribute to risky situations. When the accident is unavoidable, the vehicle impacts the pedestrian and the accident proceeds to the in-crash phase. During this phase, vehicle design and speed are examples of vehicle-influencing factors (Figure 2), whereas pedestrian vulnerability is an influencing factor for the road user and surface rigidity for the road. Finally, in the post-crash phase, rapid, emergency care can influence the outcome of pedestrian injuries.

Figure 2. Example of vehicle designed without pedestrian protection requirements. (Photo reproduced by permission of Carlos Arregui.)

4 THE VEHICLE–PEDESTRIAN COLLISION, INFLUENCING FACTORS

4.1 Pedestrians' age distribution

Two differentiated groups monopolize most of the leading role in pedestrian accidents: those younger than 12 years old and those older than 65.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto260
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

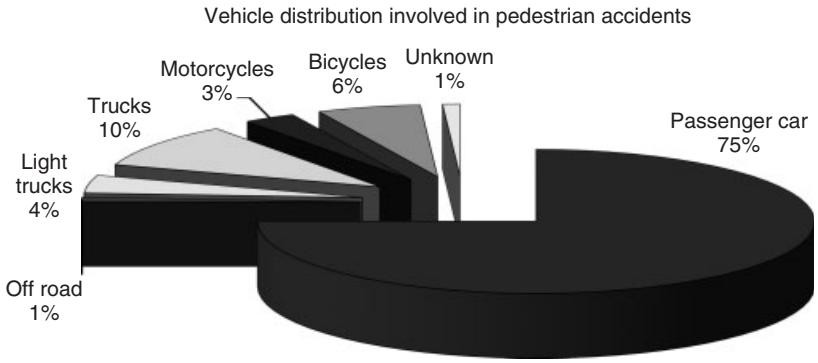

Figure 3. Vehicle type distribution, based on GIDAS database.

Some of the causes that make children a group of risk are (Montoro *et al*., 2000)

- limited visual field due to their low stature
- problems of outlying vision, reduced field of vision
- audition deficiencies (shown up to the age of 7)
- lack of attention
- ignorance of rules and risks.

Some of the causes that make elderly people a group of risk are (Montoro *et al*., 2000)

- sensory problems
- smaller attention to the environment
- muscular and bony degeneration.

4.2 Vehicles involved in pedestrian accidents

Passenger cars are responsible for 70–80% of all pedestrian accidents in developed countries, varying this percentage depending on the world area studied, followed by trucks, slight trucks, and pick-ups, being responsible for 85–90% of all pedestrian with injuries. Figure 3 presents the distribution of types of vehicles with an injury of AIS 1+.

Currently, the automotive industry and the administration focus their efforts on passenger cars, with little or no research carried out by other vehicle types.

4.3 Speed of collision

The speed between vehicle and pedestrian is one of the main causes responsible for the seriousness of the pedestrian injuries. Figure 4 presents the impact speed

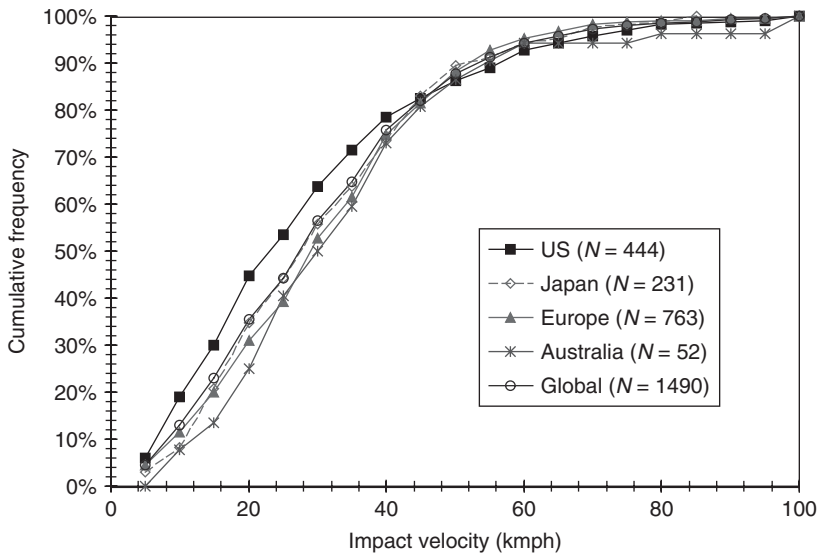

Figure 4. Impact velocity distribution. (Based on Mizuno, 2002.)

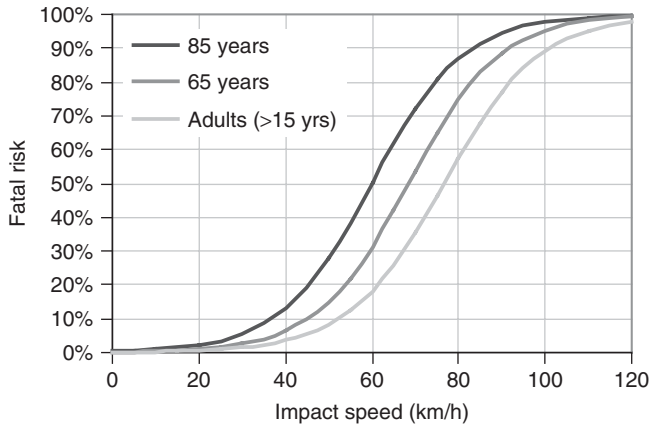

Figure 5. Fatality risk as a function of impact speed for different ages of pedestrians. (Based on data from Rosén and Sander (2009).)

and the accumulative frequency, with data collected from USA, the European Union, Japan, and Australia. For all of them (maybe with the exception of USA, where the frequency is slightly higher), it can be noticed that approximately 70–75% of pedestrian accidents take place up to 40 km/h.

Rosén and Sander (2009) presented an injury risk curve describing the relationship between vehicle impact speed and risk for fatal outcome for the pedestrian in a vehicle frontal impact. This was based on 490 accidents representative to Germany. The study showed that the risk for fatal outcome in a 50 km/h impact was twice as high as an impact at 40 km/h and four times higher than an impact at 30 km/h, indicating the importance of impact speed to determine outcome (Figure 5).

Older pedestrians are over-represented in severe and fatal pedestrian crashes with a higher injury and fatality risk (Henary, Ivarsson, and Crandall, 2006; Loo and Tsui, 2009; Rosén and Sander, 2009). Henary *et al*. found in 552 US vehicle-to-pedestrian accidents that pedestrians 60 years or older had an almost threefold higher mortality rate compared to adults 19–50 years old. Loo and Tsui found, in a study of 4290 accidents in Hong Kong, a 3.6 times higher mortality rate for pedestrians 65 years or older compared to 15–64-year-old pedestrians. Rosén and Sander (2009) presented a pedestrian injury risk function where they concluded that age and speed were the two most important parameters for risk of fatal outcome. The risk function was used to extract risk functions for different ages, compared to average adults, in figure. Males are reported as more frequently involved in pedestrian crashes, but no gender difference has been found for the fatality risk (Rosén and Sander, 2009; Zhang *et al*., 2008).

4.4 Kinematics of pedestrians: the injury pattern

Before analyzing the distribution of injuries suffered by a pedestrian, it is important to point out what can be understood by the term *pedestrian accident*. Obviously, all accidents are different and all external elements add more entropy to understand an already turbulent scenario. Nevertheless, there are common elements or patterns.

Figure 6 shows the occurrence of the impact direction on a pedestrian. It can be concluded from them that the most probable direction is the lateral. This fact is extremely important in understanding what impactors are used as a tools for developing cars with pedestrian protection countermeasures in a crash laboratory.

4.4.1 The sequence of a pedestrian accident (adult case)

In the event of a pedestrian–vehicle collision, the first contact takes place between the bumper and the lower extremity. Later on and as a consequence of the impact produced below the pedestrian's center of gravity because of the speed of the vehicle, a wrap around the body on the vehicle takes place. The second contact occurs between the front part of the vehicle and the area of the thigh and

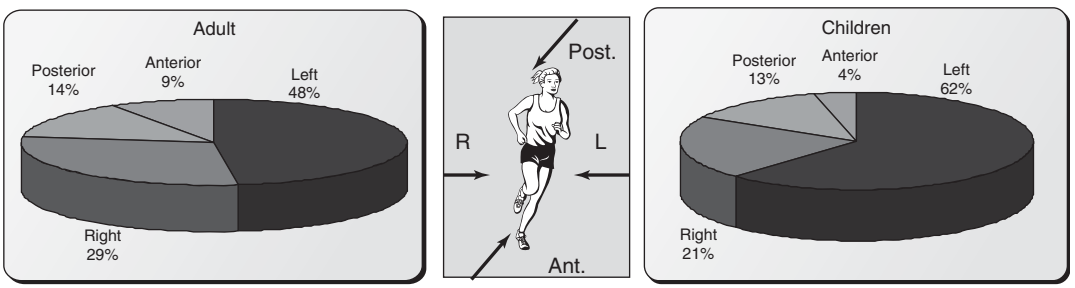

Figure 6. Impact direction occurrence. (Based on data in Sakurai *et al*., 1994.)

DOI: 10.1002/9781118354179.auto260
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

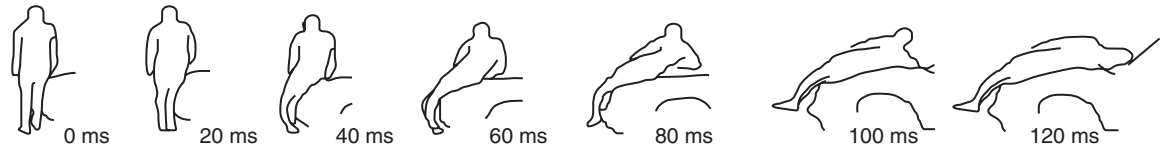

Figure 7. Adult pedestrian kinematics.

hip. The third impact corresponds to the pedestrian's torso and the vehicle's hood, and finally, the head hits against the hood or windshield, depending on several variables (Figure 7).

Once the collision against the automobile is over, the possibility of increasing the pedestrian's injuries does not disappear, which is known as the *second impact*. This second impact involves the pedestrian's collision against the road or the elements found in the scenario, and it is interesting to point out its great randomness and the unforeseeable nature of the injuries suffered. Generally, it is not possible to dissociate absolutely the lesions suffered at the first impact from those sustained at the second impact.

Likewise, pedestrian kinematics will be affected by the geometry of the vehicle, the vehicle speed, the pedestrian's anthropometric measures, the possibility of braking, the direction of the impact, the internal structure of the front part of the vehicle, and so on.

For instance, in Figure 8, different types of kinematics are represented according to the vehicle's geometry.

If a deeper investigation needs to be performed, accident reconstruction or finite element model analysis is not the right research tool; in that case, pedestrian test

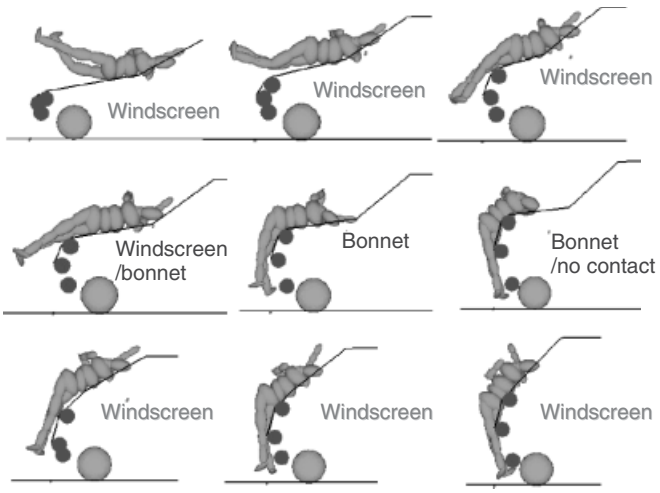

Figure 8. Pedestrian–vehicle different kinematics depending on vehicle profile. (From Mizuno, 2002. Reproduced by permission of Y. Mizuno.)

should be conducted in suitable laboratories. Kerrigan *et al*. performed 12 PMHS (postmortem human subject) tests, with three sedan-type cars and small to tall pedestrians (154–187 cm), the wrap around distance (WAD) to head impact was between 60 and 540 mm greater than the pedestrian stature in each test (Kerrigan, Arregui, and Crandall, 2009; Kerrigan, Crandall, and Deng, 2007; Subit *et al*., 2008).

A pedestrian body versus hood-sliding effect is visible in pedestrian tests with sedan-type cars. The pelvis slides up onto the hood surface after the impact of the thigh to the hood leading edge. This is related to sliding motions of similar distances. In similar tests with sports utility vehicles (SUVs), with a higher hood leading edge, the sliding effect was less pronounced, with an 85–90 mm difference in WAD to stature (Kerrigan, Arregui, and Crandall, 2009). This indicates a higher WAD-to-head impact in collisions with sedan-type cars compared to collisions at same impact speed with vehicles with higher front ends such as SUVs, or in vehicles with a more vertically inclined hood surface as in small compact cars.

High speed video images from a PMHS are given in Figure 9 for sedan-type vehicle and Figure 10 for SUV vehicle.

Accident data was used to investigate this sliding effect. Fredriksson and Rosén (2010) used German (GIDAS) accident data to derive a head impact WAD equation, where WAD depended on pedestrian stature and car impact speed. Using their equation to calculate the sliding effect (head impact WAD—body height) for three body heights, the following dependence on impact speed could be derived (Figure 11).

Head impact speed relative to the car can be both higher and lower than the initial car impact speed. Kerrigan *et al*. reported, in 10 PMHS tests with sedan-type cars, head impact velocities ranging from 68% to 130% of the car impact speed (Kerrigan, Arregui, and Crandall, 2009; Kerrigan, Crandall, and Deng, 2008). There seems to be a trend that a higher impact velocity ratio is recorded when the head impact is to the windshield compared to the hood.

Head impact times are dependent on car type, pedestrian stature, and impact speed. Kerrigan *et al*. and Subit

et al. reported, in their 12 tests with sedan-type cars at 40 km/h, head impact times ranging from 107 to 151 ms from first car-to-pedestrian impact, with the shorter times for shorter pedestrians. Four SUV tests have been performed with differing stature adult PMHS to measure head impact time (Kerrigan, Arregui, and Crandall, 2009; Schroeder, Fukuyama, and Yamazaki, 2008). The head impact times ranged from 90 to 116 ms. Subit *et al*. (2008)

performed two tests with a small compact car and reported impact times of 91–94 ms for one short and one tall adult PMHS.

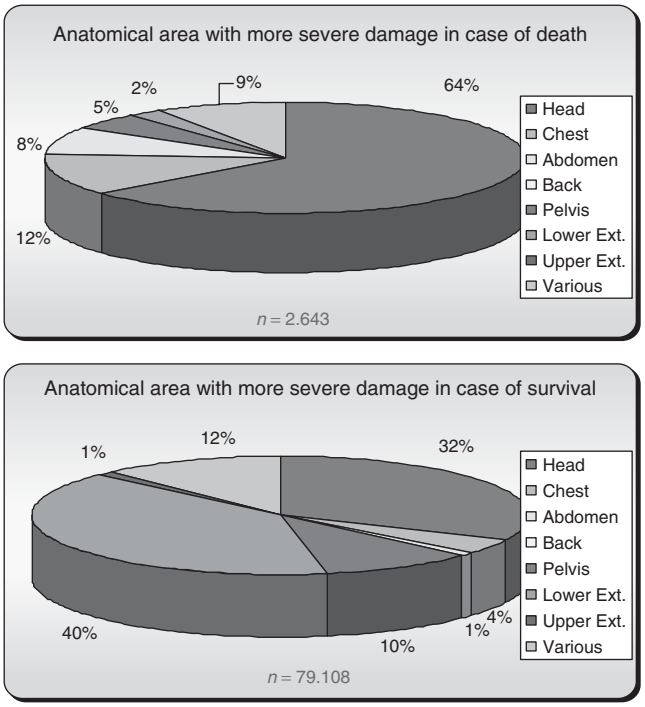

Figure 12. Pedestrian accidents divided into fatalities and survivals. (Based on Matsui, 1998.)

5 DISTRIBUTION OF PEDESTRIANS' INJURIES

In case of a pedestrian–vehicle collision, almost every anatomical area is exposed to sustain injuries. Table 1 shows the injury distribution according to anatomical areas. It can be observed that head and lower extremities are the most frequently injured anatomical areas. Another remarkable aspect is the similarity of data collected in USA, the European Union, and Japan.

Nevertheless, more precise information can be obtained by analyzing this type of data in detail. For instance, if pedestrian accidents are divided into fatalities and survivals and represented graphically (Figure 12), it can be appreciated that in the event of fatality, the head is the most injured structure, followed far away by chest and abdomen, and legs have a minor representation. In case of survival, the scenario is completely different; legs are mainly represented as the most injured area followed by the head. It is important to point out that in spite of the little influence of the lower extremities for survival, injury to this region can have serious and lasting effects on the quality of life.

Table 1. Injury distribution related to anatomical areas.

(For AIS 2–6) Injury Location	$n = 1342$ US (%)	$n = 1140$ Europe (%)	$n = 360$ Japan (%)	$n = 163$ Australia (%)	$n = 3305$ Global (%)
Head	32.7	29.8	28.6	39.0	31.3
Face	3.7	5.3	2.4	4.4	4.3
Neck	0.0	1.8	4.5	0.5	1.3

The fact that the most damaged structures are head and lower extremities explains the policy dictated by the WG 10–17 (groups of work that study pedestrian protection) of EEVC (European Enhanced Vehicle-Safety Committee), and consequently focused on head, femur, and lower extremities impactors.

6 VEHICLE STRUCTURES RESPONSIBLE FOR PEDESTRIAN INJURIES

One of the goals of accident research consists of being able to discern what elements of the automobile have caused certain lesions to the pedestrian. From Table 2 for pedestrians older than 15, with a damage of AIS 2+, it can be seen that the area of the vehicle that most frequently injures the head is the windshield, the thorax is damaged by the rear part of the hood, the abdomen and the pelvis by the line of the hood, the femur practically in the same way by the line of the hood and the bumper, and finally the knee and the low leg are damaged mostly by the bumper.

Considering the previous table for an age group up to 15 years old for a damage equal to AIS2+ (Table 3) can be concluded that the hood is the structure that most frequently damages the head, chest, and pelvis, the line of the hood damages the abdomen, and the bumper is responsible for most of the damages in the femur, knee, and lower extremities (tibia, fibula).

The explanation of these results lies in the difference of height between children and adults, giving a different impacted area. Children are more frequently damaged by the front part and the hood in its frontal area, as for adults the front area injures the lower extremities and pelvis, the head being impacted against more rearward structures by the simple fact of the body wrap around. Figure 13 reproduces the main car structures involved in a pedestrian collision.

7 THE CONSEQUENCES OF THE SECOND IMPACT

The second impact can be defined as the impact suffered by a pedestrian once he or she leaves contact with the vehicle. This definition brings some problems, especially one found in literature and known as *run over* (pedestrian accident in which a large vehicle, such as SUV, or pick-up is involved). In this scenario, the pedestrian's contact surface contains his or her center of gravity, so that he or she is projected frontward. Later on or at the same time of the second impact, a run over can take place, producing visceral squashing and pneumatic tattoos.

D. Otte studied in 2001 a total of 293 pedestrians throughout more than 20 years of accident research

undertaken at the Medical University of Hanover in Germany. Figure 14 reproduces the frequencies for $n = 293$ pedestrians distinguishing between primary and secondary impacts and indicating 100% of each injured region.

This figure shows that most of the frequencies are superior in the first impact, with the only exception of upper extremities. Furthermore, the existence of a first impact does not avoid the second one from happening. Similarly, the study determines injury severity, as shown in Figure 15, and shows that injuries are more serious during the first impact.

The conclusion is that it is essential and necessary to pay attention to the design of the frontal part of the vehicle, and also performing more research on the second impact.

8 INJURY BIOMECHANICS

8.1 Pedestrian head injury

Many factors should be considered in order to understand properly how a mechanical input to the head can result in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto260
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

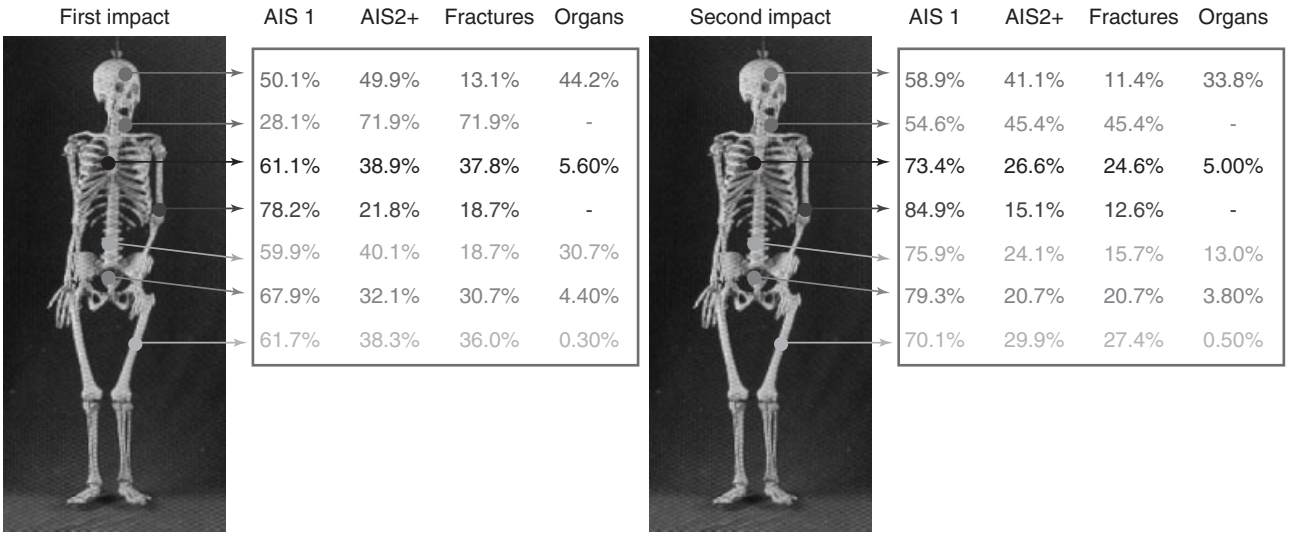

Figure 15. Injury categorization for pedestrians distinguishing between primary and secondary impacts. (Based on data in Otte and Tohlemann, 2001.)

a determined type of head injury: the severity, the nature of the mechanical input, the impact location, the direction of this input, the age of the patient, his or her gender, anthropometrics, and previous state, and also the treatment and recovery of the patient.

Head injuries are either the most or second most commonly reported injuries to pedestrians struck by vehicles (Mizuno, 2003; Zhao *et al*., 2010). Furthermore, among serious or life-threatening injuries, head and brain injuries far outnumber injuries to all other body regions (Fildes *et al*., 2004). Previous studies have shown that head and neck injuries sustained by pedestrians account for almost 60% of all harm to pedestrians (Fildes *et al*., 2004).

As explained previously, in an effort to mitigate the risk of head (and other) injuries to pedestrians, researchers have developed tools, such as pedestrian dummies and computational models, to further understand the dynamics of vehicle–pedestrian impact (Untaroiu *et al*., 2008). While the local stiffness of the individual vehicle structures involved in head-to-vehicle impact is a primary concern in decreasing the risk of head injury, impact simulations with pedestrian dummies and computational models allow for examination of other factors that affect head injury risks. For instance, the magnitude of the accelerations sustained by the head in head-to-vehicle impacts is dictated not only by the vehicle stiffness but also by the impact velocity and impact angle, which dictate the magnitude and duration of the impact forces applied to the head. In addition, Okamoto and Kikuchi (2006), in a study that involved vehicle-pedestrian impacts with the Polar II

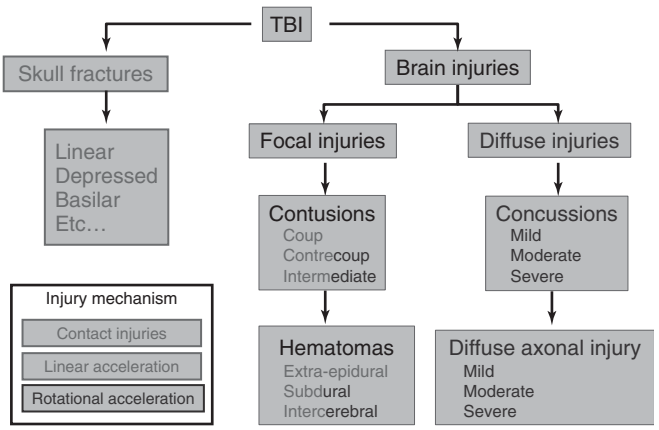

Figure 16. Head injuries related to injury mechanisms. (Based on Gennarelli, Spielman, and Langfitt, 1982, 2002.)

pedestrian dummy, used the dummy's neck instrumentation to explore the magnitudes of forces applied to the head through the neck during impact. As their goal was to compare pedestrian dummy impacts to those of headform impactors, Okamoto and Kikuchi used neck forces to examine similarities and differences between the dummy and the impactor, without examining how neck forces directly affect impact kinematics and estimates of injury risk. Figure 16 summarizes the main head injuries and their injury mechanisms.

Contact injuries are related to a direct impact between the head and the vehicle, linear and rotational accelerations are due to the head impact and/or the head kinematics during all the event of a pedestrian–vehicle collision.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto260
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Twenty-three percent of all head injuries analyzed have the translation acceleration as a single injury mechanism; in 40% of all cases, rotational acceleration is the only injury mechanism and in 37% of the cases, rotational or translational acceleration can be the injury mechanism for the sustained head injury (Arregui-Dalmases, 2006).

8.2 Pedestrian lower extremity injury

By combining both the frequency and the severity of pedestrian lower extremity injuries, pedestrian lower extremity injury mitigation priorities could be described as

- diaphysis fractures of the tibia and fibula,
- soft tissue injuries and fractures of the knee joint,
- femoral diaphysis fractures,
- malleolar (ankle) fractures.

As injury tolerance is a function of loading mode, the mechanisms associated with these lower extremity injuries must be considered if injury countermeasures are to be designed specifically to prevent these injuries.

Previously it was showed that the majority of pedestrians were struck laterally by the vehicle and the majority (65%) of pedestrians were in mid-stance gait (one foot in front of the other) when struck (Kam *et al*., 2005). Accordingly, most pedestrian lower extremity injury mechanisms are derived from direct loading to the lateral or medial side of the lower extremity (Figure 17).

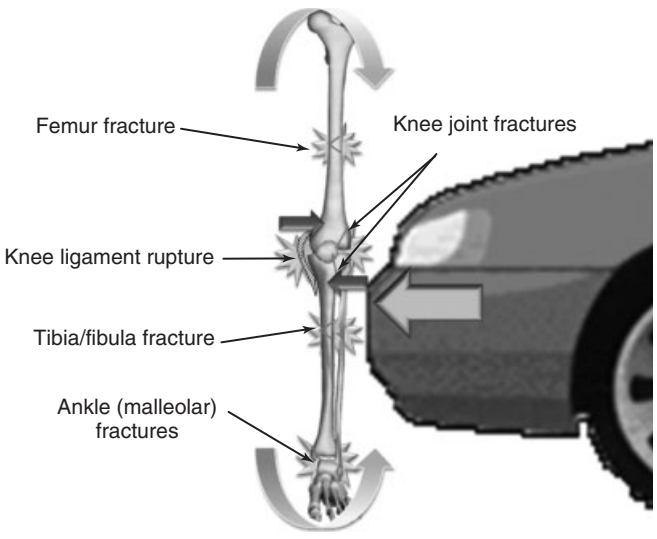

Figure 17. Schematic diagram predicting lower extremity injuries as a result of vehicle front-end loading causing bending and shear in the lower extremity components.

Direct loading of the vehicle bumper in the area of the knee joint can cause the knee to experience bending loads and shearing loads if the vehicle's geometry is such that the vehicle loads the proximal leg without loading the distal thigh, or vice versa (Yang, 2005). In addition, even when the knee joint is subjected to pure (four-point) bending, shear displacements can still occur as a result of the complex geometry of the tibial and femoral epiphyses (Bose *et al*., 2008). Thus, lateral shearing and bending have been recognized as the two most important knee injury mechanisms (Yang, 2005). Yang (2005) and many others have explained that lower extremity long bone (diaphyseal) fractures, as well as both fracture and soft tissue injuries to the knee joint, are the result of lateral bending of the entire lower extremity owing to vehicle bumper and hood leading edge loading of the lateral aspect of the lower extremity (Figure 17). Biomechanics experiments using PMHS lower extremities loaded laterally by vehicles or vehicle-like structures have produced

- long bone fractures (Pritz *et al*., 1975; Cesari *et al*., 1980; Bunketorp *et al*., 1981; Ashton, Cesari, and Van Wijk, 1983; Bunketorp *et al*., 1983; Kallieris and Schmidt, 1988; Schroeder *et al*., 2000; Snedeker *et al*., 2005; Kerrigan, Crandall, and Deng, 2008),
- knee joint fractures (Pritz *et al*., 1975; Cesari *et al*., 1980; Bunketorp *et al*., 1981; Ashton, Cesari, and Van Wijk, 1983; Bunketorp *et al*., 1983; Kallieris and Schmidt, 1988; Untaroiu *et al*., 2007; Kerrigan, Crandall, and Deng, 2008)
- soft tissue injuries (Cesari *et al*., 1980; Bunketorp *et al*., 1981, 1983; Schroeder *et al*., 2000; Untaroiu *et al*., 2007; Kerrigan, Crandall, and Deng, 2008), and
- ankle injuries (Cesari *et al*., 1980; Bunketorp *et al*., 1981, 1983; Untaroiu *et al*., 2007; Kerrigan, Crandall, and Deng, 2008).

The majority of pedestrians are struck laterally, whereas their lower extremities are positioned in gait-like stance, which dictates the mechanisms of the most common injuries. Diaphyseal fractures of the long bones are expected to occur as the result of lateral bending loads applied to the lower extremity. Knee joint injuries, including soft tissue injuries and epiphyseal fractures, are expected to occur as a result of either pure bending (valgus on the struck-side limb or varus on the contralateral limb) or a combination of bending and lateral-medial shear loading. Finally, ankle fractures are expected to occur as a result of either eversion (struck-side limb) or inversion (contralateral limb).

9 PEDESTRIAN TESTS AND RESEARCH TOOLS

9.1 Regulation and consumer test, pedestrian impactors

The striving of car manufacturers to perform well in car safety consumer tests has led to a rapid development of safety systems and improved safety for car occupants during the 2000s.

In 2005, the first legal requirements for pedestrian protection were introduced in both Europe and Japan. The EEVC WG 17 impactors and test methods were adopted by the European directive (EC, 2003). The lower legform is launched horizontally toward the vehicle bumper at 40 km/h (Figure 18). Requirements were set for tibia acceleration as well as knee bending and shearing. For higher front-end vehicles, the upper legform is used in a vertical orientation to assess bumper performance, using requirements of force and bending moment. The upper legform for the front hood edge is used only for monitoring purposes where the impactor mass, impact angle, and speed are dependent on vehicle geometry. The child and adult headform tests are performed at the front and rear sections of the hood area, respectively, determined by the WAD but limited to the hood area. Injury is assessed by the head injury criterion HIC_{15}. The headform impact speed in the directive was reduced to 35 km/h, which was argued to reflect a car impact speed of 40 km/h. The WG17 based its conclusions on AIS2+ injuries and, to a limited extent, AIS3+ injuries.

The Japanese directive includes the head-to-hood tests only, using the headforms developed by ISO. The impact angles are different from the European directive and depend additionally on vehicle geometry, divided into three vehicle categories. The headform impact speed is 32 km/h, lower than the European directive.

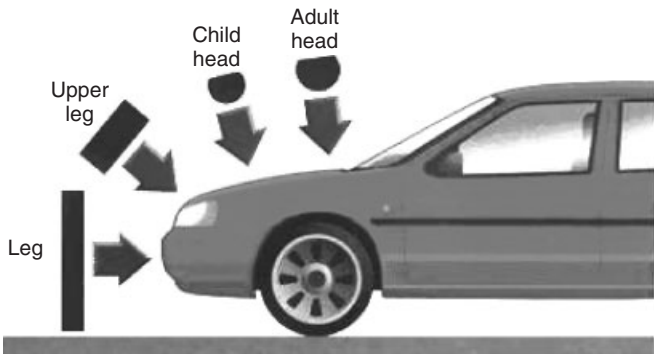

Figure 18. Pedestrian impactors, based on EEVC WG 17. (Reproduced from Euro NCAP. © Euro NCAP.)

A second phase of the European directive was introduced in 2009 (EC, 2009). It was basically harmonized with the global technical regulation (GTR). The two headforms, of 2.5 and 4.8 kg, were replaced by the ISO child headform of 3.5 kg. The injury criteria were raised to a slightly higher level. Further, a requirement of equipping the vehicle with a brake assist system, to assist the driver to brake optimally, was introduced.

In 2009, a GTR to harmonize pedestrian protection was introduced (UN, 2009). It was almost identical to the second phase of the EC regulation, with legform-to-bumper and headform-to-hood tests based on a crash speed of 40 km/h, but did not require brake assist and included the possibility of raising the upper vehicle mass limit to 4.5 tons if so decided by the individual country. The EU regulation is limited to 2.5 tons. Further, the GTR plans to adopt the FlexPLI legform to replace the WG17 legform used by the EC regulation and as an intermediate solution in the GTR. In the early phase of the GTR development, the intention was to include the windshield area, but this part of the test was removed owing to feasibility issues. It was considered unfeasible to design a pedestrian-friendly windshield frame while meeting other vehicle stability requirements. Further, it was concluded that the glass impact caused a spread in the test results for identical windshields but that this was not yet fully understood (UN, 2009). In addition, the GTR includes a test method for deployable hood systems. Part of this test method uses numerical pedestrian models, a new method to assess pedestrian protection in a regulation. The GTR was based on AIS2+ pedestrian injuries.

In 1997, the European consumer organization Euro NCAP introduced pedestrian protection assessment of the most sold vehicles in Europe. They adopted the EEVC WG17 impactors and test methods, including the lower legform, upper legform, and child and adult headforms. In contrast to legal tests, they did not limit the headform tests to the hood area, but included the windshield area to a WAD of 2100 mm. They also retained the headform test speed of 40 km/h (Euro NCAP, 2011). The pedestrian rating of the car was initially excluded from the overall rating of the car. In 2009, Euro NCAP changed their assessment protocol to include pedestrian protection in the overall rating (Euro NCAP, 2009), which has led to a rapid development of the secondary (passive) pedestrian protection of cars.

The regulations and consumer pedestrian tests have been driving forces in the introduction of pedestrian safety measures, such as pedestrian bumpers and hoods in production cars.

9.2 Full-body dummies and models

As early as the 1980s, pedestrian-specific test devices were developed. Aldman *et al*. (1985b) developed a rotationally symmetrical pedestrian dummy (Figure 5). In the early 2000s, Autoliv and Chalmers University developed pedestrian dummies in adult and child sizes. The adult dummy, a 50th percentile adult male, was based on existing frontal and side impact dummy parts with new parts designed for the lumbar spine and knee joints (Björklund and Zheng, 2001). The child dummy, equivalent to a 6-year-old child in size and weight, was based on a Hybrid III dummy with a redesigned neck, lumbar spine, and knees (Renaud and Tapia, 2004; Renaud *et al*., 2005). Both dummies were tested at three different impact speeds and two car types and were compared to the Chalmers Madymo pedestrian model (Yang and Lövsund, 1987). The intention of these dummies was limited to study kinematics, not injury assessment. Honda and Gesac developed the Polar dummy, based on the Thor dummy (Akiyama *et al*., 1999, 2001). The Polar dummy was a more advanced pedestrian dummy, designed for both kinematic and injury assessments. The most important features were a flexible lower spine, deformable knee structures including ligaments, and a deformable tibia with properties including fracture, and the Polar II version was validated against PMHS tests (Figure 18) (Kerrigan *et al*., 2005a, 2005b). The Society of Automotive Engineers (SAE) pedestrian dummy task group developed a performance specification for an adult pedestrian dummy (SAE, 2009). The performance specification was based on PMHS tests using a mid-sized sedan and compared to the existing Polar II dummy in a report by SAE (2008). The Polar dummy is still under development to Polar III, where new properties and injury assessment are under consideration (Figure 19) (Akiyama *et al*., 2009; Okamoto, Akiyama, and Takahashi, 2009; Takahashi *et al*., 2009).

The main advantages of the pedestrian dummy are:

1. The assessment of dummy kinematics interaction with the vehicle in a global way.
2. Assessment of the EEVC subsystems.
3. Previous evaluation and comparisons with human cadavers.
4. Avoiding problems of excessive focus on the subsystems.
5. Testing with another type of vehicles.
6. Study the second impact, etc.
7. Collision identification systems for pedestrians to activate all the passive safety mechanisms incorporated in the vehicle.
8. Increase knowledge on injury biomechanics and injury causes.

10 CURRENT STRATEGIES USED BY THE INDUSTRY TO PROTECT THE PEDESTRIAN

10.1 Passive safety system, thorax and head protection

Secondary or passive safety systems have been developed for the vehicle front, focusing on the bumper, hood edge, hood, and windshield areas.

To mitigate thorax injuries to the hood edge in impacts to vehicles with higher front ends, such as SUVs, an airbag was proposed for the front hood edge (Fredriksson *et al*.,

The main advantages of the pedestrian dummy are:

1. The assessment of dummy kinematics interaction with the vehicle in a global way.
2. Assessment of the EEVC subsystems.
3. Previous evaluation and comparisons with human cadavers.
4. Avoiding problems of excessive focus on the subsystems.
5. Testing with another type of vehicles.
6. Study the second impact, etc.
7. Collision identification systems for pedestrians to activate all the passive safety mechanisms incorporated in the vehicle.
8. Increase knowledge on injury biomechanics and injury

Figure 20. Pop-up bonnet. (Reproduced with permission from Autoliv. © Autoliv.)

2007). The hood, wings, and wiper engines have also been passively redesigned to improve energy absorption (Belingardi, Scattina, and Gobetto, 2009; Han and Lee, 2003).

Even if the hood surface design is optimized for energy absorption, there may not be a sufficient deformation distance available to underlying parts in the engine compartment. It has been theoretically and experimentally proved that deformation distances of 60–70 mm can be sufficient to achieve HIC values below 1000 (Okamoto *et al*., 1994; Zellmer and Glaeser, 1994). A solution for this is to lift the hood in case of pedestrian impact. Active hoods, pop-up hoods, or deployable hoods are different names for the concept of lifting the hood surface, usually by actuators in the rear corners of the hood (Fredriksson, Håland, and Yang, 2001; Nagatomi *et al*., 2005). These systems are currently (2012) in production in 20 car models from 14 different car brands. They lift the rear hood part between 50 and 120 mm to enable energy absorption of the head impact preventing a second "bottoming out" impact to structures underneath the hood in the engine compartment. Fredriksson *et al*. 2009 showed, in a combined experimental and finite element study, that an under-hood distance of 100 mm reduced both skull fracture-related and brain-related injury criteria to acceptable levels in 40 km/h headform impacts. The same study with dummy tests using Polar II and a real vehicle showed a large reduction in head loading by a deployable hood system compared to a standard hood. For deployable hoods to be activated in accidents, they are connected to a sensor and an actuator, which must make the decision and perform the lifting motion within a short time period. Dummy tests and simulations have shown that the deployed hood for a standard sedan-type passenger car must be in position within less than 60 ms after the first leg impact to the front of the car at a crash speed of 40 km/h. For the lower part of the windshield and the a-pillars, airbags have been proposed to enhance head protection (Autoliv annual report, 2002, 2010; Crandall, Bhalla, and Madeley, 2002; Maki, Asai, and Kajzer, 2003). A windshield airbag typically needs 90–100 ms for the same type of car, whereas a car design with a more vertical hood and front (e.g., multi-purpose vehicles MPVs or vans) requires positioning significantly earlier of both the deployable hood and airbag. A pedestrian airbag needs more energy absorption distance than a deployable hood, owing to the limited energy absorption capability in the first phase of the airbag impact. A typical airbag thickness is 200 mm and the volume can vary between 80 and 140 L depending on the car size, roughly similar to a passenger side occupant airbag. The first airbag of this kind, called *Pedestrian Airbag Technology* (*PAT*), was entered into production in 2012 in the Volvo V40 model (Figures 20 and 21).

The following figures reproduce main current strategies used for protecting the thorax-head (Figures 22–31).

10.2 Passive Safety System, Lower Extremity Protection

In recent years, a rapid development in car bumper design has been seen. While the average car scored low in the legform-to-bumper test in 2004, most cars were rated "green" (full score) in Euro NCAP tests in 2009. The distance between the bumper and the bumper beam has been increased, the bumpers were redesigned with solutions such as thicker foam and an extra lower stiffener below the bumper to reduce loading of the knee, which typically impacts at bumper height for an average adult. Airbag solutions have also been proposed to distribute and reduce the load on the lower extremities (Pipkorn, Fredriksson, and Olsson, 2007) and headlights have been redesigned to be more energy absorbent (Lucas, 2000). Modern cars have a more aerodynamic design leading to a lower, less protruding, front hood edge with a lower risk of pelvis and thigh injuries (Figures 32–34).

11 REQUIREMENTS INCOMPATIBLE WITH PEDESTRIAN PROTECTION IN NEW DESIGN VEHICLES

Unfortunately, the desire to include a new requirement in an existing product comes into conflict with of existing requirements and regulations. Among these requirements opposed to pedestrian protection the following stand out:

- Decreasing the vision field; increasing the distance between hood and engine hinders the driver's visibility, and conflicts with EC 77/649–90/630. This also increases the coefficient of friction C_x, which contributes to vehicle consumption.
- Modifying lock stiffness conflicts with FMVSS 113, 401. The lock must withstand the aerodynamic force of the vehicle and always work properly. On the other hand, in the vehicle design, there are also internal requirements such as misuse (using the vehicle in an inappropriate manner), for instance the bonnet slam test it is performed, consisting of opening and closing the bonnet 5000 times without resulting in large deformations or cracks.
- Modifying windshield stiffness conflicts with EC 92/22–2001/92. It must have enough resistance against the objects penetration. It should also break without projecting parts.
- A-pillar stiffness (EC 96/79–99/98). It must have enough rigidity for a good behavior in a frontal crash, oblique crash, and rollover. This is one of the worst places to impact against in case of pedestrian accident, and one of the most challenging to modify.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto260
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 24. Deformable elements in case of wing impact.

Figure 26. Increase distance from bonnet to still structures.

Figure 25. Deformable windshield wiper axis.

Figure 27. Engine at the back (trunk) would help to increase deformation distances.

- Internal structures weakness, hinges, and so on have to fulfill all their functions and be able to collapse during a pedestrian impact.
- Difficulty for processes, these new elements tend to have less stiffness than those of the previous vehicles. This results in added difficulties for production, handling, keeping the geometry, and so on.
- Bumper and bumper beam weakness to absorb low speed structural crash test. RCAR (Research Council for Automobile Repairs).

One of the most important points is client's satisfaction, because excessive loss of stiffness in the hood or wings will seem to imply low quality. An example of this restriction can be the sensation of the client; if when the client opens the bonnet, he or she feels that the hood is weak, which could create dissatisfaction.

12 ACTIVE SAFETY SYSTEMS

Primary or active safety systems have been introduced to either aid the driver in reducing speed or automatically reduce the speed of the impacting car in a pedestrian crash. The "brake assist" system in the brake pedal senses the braking intention of the driver and automatically optimizes braking performance. The brake assist systems were

Figure 31. Rain trough without rigid structures.

mandated in new vehicles in Europe in 2008. Infrared systems detecting living creatures such as animals or pedestrians and displaying the image on a screen to the driver were introduced in the early 2000s (Cadillac, Lexus) and were later followed by systems that additionally warned the driver (BMW, Audi, Honda, Mercedes, and Toyota). As brake assist systems are dependent on driver action, they were estimated to be activated only in 50% of accidents (Hannawald and Kauer, 2004). It is then natural to develop this system into an automatic system without driver intervention. A system was introduced in 2009 that detected pedestrians and gently applied the brakes if no driver action was noticed after a warning (Lexus, 2011). Recently, an auto-brake system was introduced that detects pedestrians and automatically applies full braking before an imminent impact (VolvoCars, 2010). This system has been claimed to be able to brake to a full stop from 25 km/h and thereby completely avoid low speed pedestrian crashes. At higher speeds, crash energy can be substantially reduced (Figure 35).

The pre-crash, or primary, safety measures and the in-crash, or secondary, safety measures can be combined into integrated systems. Integrated pedestrian systems have not been introduced in production cars. It is unclear whether an integrated system would be more effective than a single primary system such as autonomous braking. When

Figure 32. Increase distance between the bumper and the bumper beam.

Figure 33. Plastic frontal elements, increase distance to stiff elements.

developing an integrated system, it is also important to study how the two parts of the system interact. This can be performed using full-body impacts, and introducing both primary and secondary countermeasures.

12.1 Effectiveness/potential of countermeasures

Studies have tried to estimate the effectiveness of pedestrian protection systems. Lawrence *et al*. (2006) estimated the effectiveness of reducing fatally and seriously injured pedestrians, by introducing brake assist systems, to 10%.

Figure 34. Aerodynamic new designs.

If the vehicle could brake autonomously, the effectiveness of the system would be increased. Rosén *et al*. (2010) estimated that an auto-brake system, activated for all visible pedestrians within a forward-looking angle of 40° one second before impact, would reduce fatalities (when struck by car fronts) by 40% and seriously injured by 27%.

It is unclear whether primary safety measures, such as automatic braking, can be enhanced by secondary safety measures. Fredriksson and Rosén (2010) studied 54 representative, severely head injured (AIS3+) pedestrians in detail to estimate the potential of theoretical primary and secondary systems and the potential of combining them into an integrated system. The primary safety system was assumed to brake (up to 0.6 g, depending on road friction) for all visible pedestrians one second before crash. The secondary system consisted of a deployable hood system and a lower windshield/A-pillar airbag covering up to 2.1 m WAD, estimated to be fully effective (when impacted) in avoiding AIS3+ injury up to 40 km/h and then have a linearly decreasing effectiveness. The research concluded that the passive (secondary) system could protect 34% of the severely head injured (AIS3+) and the active (primary) system 44%. If combining the systems into an integrated system, it protected a significantly higher number, 64% of the pedestrians, from severe (AIS3+) head injury (Figure 36).

Although the Fredriksson and Rosén study showed theoretically that primary and secondary systems complement each other to increase the protection potential, there is a need to further study the potential of integrated systems including information from real tests or simulations with the countermeasures.

Automotive Applications for Magnesium

Roger Grimes and Vit Janik

University of Warwick, Coventry, UK

1 INTRODUCTION

Magnesium is the lightest of all structural metals having a density of 1.74 g/cm^3 compared with 2.7 g/cm^3 for aluminium and 7.8 g/cm^3 for steel. Thus, it might be expected to find major use in the construction of motor vehicles, particularly in an era where there are major concerns over fossil fuel consumption and environmental damage. Probably, the best-known automotive application of magnesium alloys was their introduction, in 1936, into the cylinder block and gearbox housing of the Volkswagen Beetle. This was very successful and, over the life of the model, consumed large quantities [42,000 tonnes per annum at its peak in 1971 (Friedrich and Schumann, 2001)] of magnesium alloy. Despite this success, there has, until relatively recently, probably been a perception that magnesium alloys are only appropriate for use in exotic vehicles.

The fuel crises of the mid-1970s led in the United States to major efforts to reduce their dependency on imported oil (35% in 1973) and, particularly, to reduce the consumption by automobiles. In 1978, legislation was introduced in the form of the Corporate Average Fuel Economy (CAFE) regulations to force the vehicle builders to construct more fuel efficient vehicles and, in consequence, smaller vehicles were introduced together with new construction techniques and greater use of lightweight materials. This resulted in a dramatic reduction in the average weight of a North American car between 1977 and 1980, followed by a slower reduction between 1980 and 1986. However, from 1986 onward, and despite the growing use of low density materials, average weight has increased by about 1% per annum (Figure 1). In Europe, a similar pattern of weight creep has been observed. Here, the major driver for mass reduction has been the concern for the environment, and targets for reduced CO_2 emissions were reached by voluntary agreements between the vehicle builders. But, as in the United States, despite the greater employment of low density materials and the introduction of improved construction methods, average car weight has continued to rise.

Between 1960 and the fuel crises of the mid-1970s, the aluminium content and the plastics content of passenger cars remained roughly constant and averaged about 2%. With the search for lighter vehicles, these contents had risen to about 10% and 15%, respectively, by the year 2000. The magnesium content of the Lincoln LS, a midsize vehicle launched in 2000, was only 0.3% (aluminium 12% and plastic 10%). Thus, in the early efforts to reduce vehicle mass, magnesium hardly figured at all, probably because of a variety of unfavorable perceptions such as corrosion, flammability, cold workability, and, particularly, cost. However, from about this time onward, there has been a steady growth in the range of vehicle applications

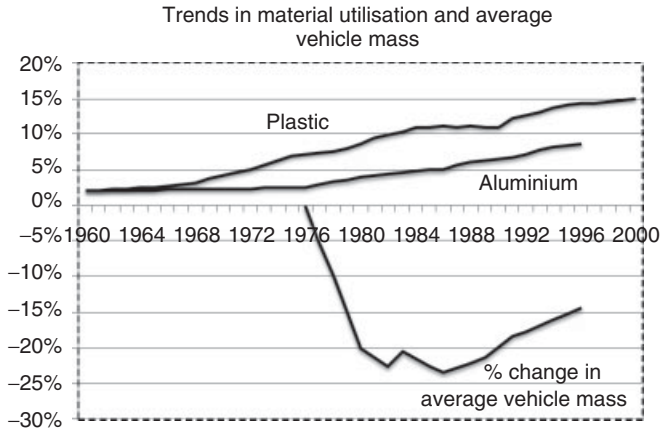

Figure 1. Trends in material utilization and average vehicle mass.

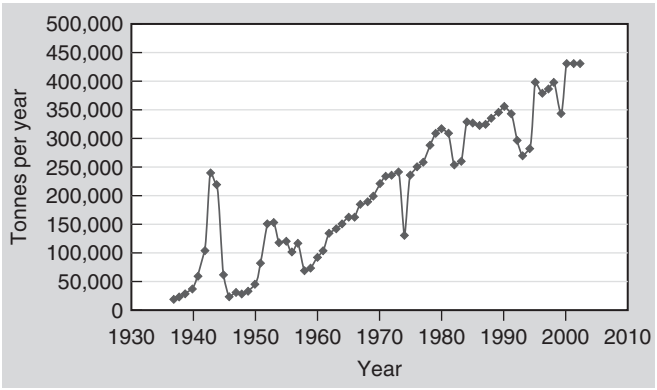

Figure 2. Virtually linear growth in primary magnesium production. (Reproduced from JOM, 59(2), 2007, 30–38, The evolution of technology for light metals over the last 50 Years: Al, Mg, and Li, J.W. Evans, Figure 1. With kind permission from Springer Science and Business Media.)

that has been taken over by magnesium and a dramatic increase in R&D activities investigating means by which the weight-saving potential of magnesium alloys may best be practically exploited. At present, the growth in actual applications has, virtually completely, been in castings and, particularly, high pressure die castings (HPDCs) and the actual average magnesium content remains at a very low percentage of the vehicle mass. Nevertheless, it seems likely that the combination of the mass reducing potential that magnesium alloys provide with the environmental pressures on vehicle manufacturers will lead to significantly greater use in the coming years.

The following sections of this chapter outline the history of magnesium, its manufacture, its availability, the properties that make it attractive for vehicle construction, and likely developments in cast and wrought applications and attempt to forecast future progress.

2 HISTORY

The existence of magnesium was proved by Davy in 1808, and the separation of elemental magnesium was achieved by Busy in 1828 (Polmear, 1999). He achieved this by reducing magnesium chloride with potassium. Subsequently, two industrial processes were developed, one based on electrolysis of molten magnesium chloride and one on reduction of the magnesium salt with ferrosilicon and derivatives of these processes form the basis of all the primary magnesium production systems in use today. Magnesium is the eighth most abundant element in the Earth's crust and is found in numerous well-distributed minerals as well as in sea water at about 0.2%. It is most frequently extracted from dolomite ($MgCO_3 \cdot CaCO_3$) or from $MgCl_2$ derived from brine. However, several other minerals could be employed and are currently under consideration as the magnesium source in some new, possible, extraction operations (see the following sections).

Magnesium alloys found some application in early motor vehicles but, for many years, the largest use for magnesium was as an alloying addition to aluminium and the growth in magnesium production was largely driven by the growth in the consumption of aluminium alloys containing magnesium. Significant quantities are consumed in desulfurizing steel but, for the past 15 years, or so, there has been a steady growth in the quantity of magnesium being used for the manufacture of die castings for motor vehicles such that roughly equal quantities of magnesium are now consumed in alloying aluminium and in automotive castings. While the growth in production of primary magnesium has fluctuated considerably, particularly peaking during wars and dropping back thereafter, over the past 60 years, growth has been virtually linear (Figure 2) and now stands at close to 600,000 tonnes per annum. The use of wrought magnesium alloys has consumed a very small fraction of this total and although, from time to time, there has been some automotive consumption of sheet and extrusions, current actual applications are negligible.

3 PRODUCTION OF MAGNESIUM ALLOYS

3.1 Extraction of primary magnesium

The separation of magnesium from its ores inevitably consumes large quantities of energy. While several extraction variants exist, essentially, two processes

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto273
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are currently employed: either electrolysis of molten magnesium chloride, in a process that is basically similar to that used to separate aluminium from alumina, or thermal reduction of magnesium oxide. The former is more environmentally friendly but relatively capital intensive and, compared with aluminium extraction, has the disadvantage that the molten magnesium is less dense than the electrolyte from which it has been separated and so floats on the surface of the cell and must be protected from the atmosphere. Aluminium is more dense than the electrolyte and so collects on the bottom of the cell from where it can be periodically tapped off. The energy involved in the electrolytic part of the extraction of the two elements is fairly similar and can be about 13 kWh/kg (Evans, 2007) for either, albeit older designed cells may have significantly higher power consumption. Unfortunately, the most commonly used protective gas in the magnesium primary industry is sulfur hexafluoride (SF_6) with global warming potential 23,000 times higher than CO_2 (Ramakrishnan and Koltun, 2004). Even though the magnesium industry uses relatively small amounts of SF_6, the overall current contribution of SF_6 to global warming is estimated to be 0.2% annually, with a further potential rise because of the increased utilization of magnesium in the automotive industry. Several alternative cover gases with lower warming potential than SF_6 have been introduced recently (United States Environmental Protection Agency, EPA, 2008). The leading candidates for further application in magnesium primary production and recycling include sulfur dioxide, 1,1,1,2-tetrafluoroethane cover gas known as *AM-cover*® developed by Advanced Magnesium Technologies, and fluorinated ketone fluid available under the commercial designation Novec™ 612 supplied by 3M™.

The thermal reduction of magnesium oxide was developed by Pidgeon and Alexander (1944) and is a batch process in which the magnesium oxide is reduced by ferrosilicon:

$$2(CaO \cdot MgO) + FeSi \rightarrow Mg_{(g)} + 2CaO \cdot SiO_2 + Fe$$

Calcined dolomite, or magnesium oxide, is charged together with ferrosilicon into retorts and heated to about 1200°C under vacuum. Magnesium vapor is formed, as indicated in the preceding reaction, which condenses in the cold part of the retort. Not only is the process energy intensive during the reduction phase but the production of the ferrosilicon employed in the reduction process is also a high temperature, energy-intensive operation.

Ramakrishnan and Koltun (2004) compared the energy consumption involved in electrolytic extraction with that required for thermal reduction when all the steps of the extraction processes were included. They concluded that in energy terms the electrolytic process was significantly better than the thermal process requiring 174 and 284 MJ/kg Mg, respectively.

The geographic distribution of primary magnesium production has undergone dramatic changes since the year 2000 and these are considered in Section 7.1. These changes have, however, led to new producers considering entering primary production and to the consideration of employing new, or evolved, processes for the production. It seems appropriate to consider the new processes in this section.

Probably, the nearest to actual production is the SilMag operation, a joint venture between the Norwegian company Hydro and the German Advanced Metallurgical Group (AMG). The actual extraction of magnesium is to be fairly conventional electrolysis of magnesium chloride using the cells at Porsgrunn from the mothballed Norsk Hydro plant. The intention is to use olivine, a magnesium iron silicate with a magnesium content up to about 33% and found in abundance on the west coast of Norway, as the starting mineral. The ore would be treated with hydrochloric acid to produce magnesium chloride and silica. Annual capacity is predicted to be about 34,000 tonnes of magnesium with a similar quantity of silica. SilMag believe that energy consumption would be about 25 kWh/kg Mg and there would be virtually no CO_2 produced. Production should commence in 2014 (Willekens, 2012).

The Zuliani process, being developed by Gossan Resources, is a variant of the thermal reduction of calcined dolomite with ferrosilicon but operating continuously at atmospheric pressure to produce a high purity, liquid product. The major power source would be hydroelectricity from Manitoba where the prices are both stable and very low. Modeling and bench-scale operations have indicated a potential green house gas (GHG) emission of only 9.1 kg CO_2/kg Mg. However, while there are plans for a 5000 tonnes per annum pilot plant, at present, the process has only been demonstrated on a bench scale (Zuliani and Reeson, 2012).

Another variant of thermal reduction has been under investigation since 2003 by CSIRO in Australia (Prentice, Poi, and Haque, 2010). They have improved on previous attempts to use carbothermic reduction of the magnesite by employing extremely rapid quenching of the reaction products and, thus, suppressing the reversion reaction and allowing the magnesium to condense and solidify.

$$MgO_{(s)} + C_{(s)} \leftrightarrow Mg_{(v)} + CO_{(g)}$$

GHG emissions would lie between 6.4 and 21.3 kg CO_2/kg Mg and, thus, at worst, be roughly equivalent to

the best operations of the Pidgeon process in China at 25 kg CO_2/kg Mg (Ehrenberger *et al*., 2008). The CSIRO version of carbothermic reduction is called *MagSonic*™ and detailed analysis of the costs of running the new process compared with either electrolytic extraction or the Pidgeon process has been conducted (Prentice and Haque, 2012). Their paper concluded that, potentially, of the three processes, MagSonic™ would be the least labor intensive, have the lowest global warming potential, and be only marginally more capital intensive than Pidgeon. However, thus far, the MagSonic™ process has only been operated as a laboratory batch process, whereas continuous industrial operation is envisaged.

3.2 Production of magnesium alloy sheet

At present, commercial magnesium alloy sheet is manufactured by the traditional route of employing vertical, semi-continuous, direct chill (DC) casting to produce a rectangular cross-section ingot that, after appropriate scalping and heat treatment, is hot rolled to an intermediate gauge on a reversing mill before reheating and warm rolling to final gauge and temper. While facilities exist that are capable of producing large quantities of sheet by this route, the demand for magnesium sheet is very small and thus the price is, inevitably, high. If magnesium sheet is to find significant application in volume motor vehicles, it is likely to be in competition with aluminium alloy sheet and must be able to compete with aluminium on a price basis. Given that any sheet structure fabricated from magnesium will be lighter than the comparable aluminium structure, it has been estimated that, to be competitive, magnesium sheet should be no more than 1.3 times the price of aluminium (Zuliani and Reeson, 2012). Currently, it is suggested that the price of magnesium sheet is five times that of aluminium (US AMP Magnesium Vision 2020, 2006).

The suggestion is that a sheet production system based on twin-roll strip casting (TRC) could reduce the cost and simplify manufacture to the extent that the cost of magnesium alloy sheet would be not more than 20% higher than that for aluminium alloy sheet (US AMP Magnesium Vision 2020, 2006). Detailed modeling by Herling and Carpenter (2005) of the likely cost of magnesium alloy sheet produced via TRC suggested a reduction to US$4.34/kg from US$9.92/kg for conventionally cast and rolled magnesium sheet. This was for a 10,000 tonnes per annum operation producing 1.5 mm gauge sheet at a width of 1 m.

The first of the current investigations into the potential of TRC for the production of magnesium alloy sheet was that of CSIRO in Australia (Liang and Cowley, 2004). Starting in about 2000, they developed a casting system capable of producing 300 mm wide strip by 3 mm gauge and estimated that full-scale production by this route would save 60% of total production costs and reduce associated GHG emissions by 50%. They also suggested that sheet made via TRC should, because of the rapid solidification, have superior properties together with reduced segregation and preferred crystallographic orientation compared with that made via conventional casting. The technology developed is available but has not led to a sheet manufacturing operation. More major developments of TRC sheet production systems are taking place in Korea and Germany.

In Korea, in 2002, the Pohang Iron and Steel Company (POSCO), in conjunction with the Research Institute for Science and Technology (RIST), initiated planning for diversification into a magnesium business (The Korea Herald, 2011). By 2008, they were able to produce 600 mm wide by 3 mm strip in coils up to 1220 mm diameter and by 2011 had increased the cast strip width to 2000 mm (Park *et al*., 2011). POSCO plans to have an integrated magnesium sheet production line, initially supplying thin-gauge, narrow strips for application in electronic devices on a pilot plant basis but providing wide sheets for automobile applications in due course. While the TRC equipment for producing 2 m wide coils is being moved from RIST to the POSCO plant at Suncheon, the warm rolling mill that will be necessary to complete the integrated line has not yet been installed but some 1500 mm wide coils cast at RIST have been successfully rolled to strip at Magnesium Elektron North America (MENA) (Choo *et al*., 2012). In June 2010, POSCO entered a collaboration agreement to exchange technology with the Thysen Krupp Stahl subsidiary Magnesium Flachprodukte GmbH (MgF).

In Germany, research into the potential for greater application of magnesium alloys in motor vehicles had been underway since the 1990s, and in 2001, Thysen Krupp Stahl, in conjunction with the University of Freiberg, formed the organization Magnesium Flachprodukte GmbH to accelerate the project. In 2002, MgF acquired a TRC machine capable of casting 700 mm wide strip of magnesium alloys in gauges between 3.5 and 8 mm (Figure 3) (Kawalla *et al*., 2008). Sheets cut from the TRC coils were individually hot/warm rolled but, in late 2009, the plant was augmented with a hot strip rolling mill, thus making possible accurate simulation of a full-scale production operation.

In Turkey, the Materials Institute TUBITAK MRC has developed a TRC capable of producing strip up to 1.5 m wide and in the gauge range 4.5–6.5 mm (Kaya *et al*., 2008; Duygulu *et al*., 2009) and has found the resulting warm-rolled strip to be appreciably less anisotropic than comparable strip produced via the ingot route (Duygulu *et al*., 2009).

Figure 3. Twin-roll casting plant of the MgF Magnesium Flachprodukte GmbH in Freiberg. (From Kawalla *et al*. (2008). Reproduced by permission of Croatian Metallurgical Society.)

In China, Taiwan Mach has made significant magnesium investment in Shandong Province including a cast-rolling line said to be operational in late 2012. Its capacity is expected to be 2000 tonnes per annum, but strip dimensions are not disclosed (Metals Week, 2012a).

As the overwhelming majority of magnesium alloys have a close packed hexagonal crystallographic structure, they have very limited slip systems on which to deform at ambient temperature and, hence, very limited ductility. Rolling has to be carried out either hot or warm and this tends to produce strong basal plane crystallographic textures that add to the difficulties in subsequent forming operations. While strip casting reduces the overall strain involved in strip production, textural problems can remain. Various techniques, such as equal channel angular extrusion (ECAE), have been employed to modify and refine the structure of magnesium alloys, but the majority of such techniques could not be employed on an industrial scale. However, it has been shown that the redundant work introduced by asymmetric (or shear) rolling can greatly modify the resultant strip microstructure (Cui and Ohori, 2000) and this technique might be applicable on a large scale. Kim, Kim, and Wang (2009) applied this technique to ZK60 and found that the grain size could be refined to $1-2\,\mu m$ by a single pass, although the experiment was performed on a relatively small scale with material that had been extruded before rolling. An alternative route leading to significant reduction of undesirable basal texture after rolling of magnesium alloys can be achieved by modification of their microstructure with rare earth (RE) elements, the most powerful options being cerium, neodymium, or yttrium (Hantzsche *et al*., 2010).

A joint project between Oak Ridge National Laboratory and MENA was duly set up to investigate the extent to which shear rolling could be employed to produce magnesium alloy sheet with improved cold formability (Randman *et al*., 2011). The five tasks in the project scope included design of a shear mill, alloy selection, and demonstration of component fabrication. Shear rolling did not dramatically refine the grain structures that were generally fairly uniform apart from thin ($\sim 20\,\mu m$) surface layers of refined structure, while the basal texture was tilted away from the sheet normal and toward the rolling direction. In the course of the development, an experimental rolling mill was designed and built at Oak Ridge National Laboratory with cooperation from Hunter Fata Inc., enabling detailed investigation of the shear rolling process (Oak Ridge National Laboratory, 2012). This has now enabled Hunter Fata to design a new magnesium reversing warm rolling mill (Passoni *et al*., 2012) for producing large wide coils from a twin-roll caster. The mill incorporates features designed to overcome the limitations of previous magnesium warm mills so that hot coilers are placed on either side of the rolling stand and are able to carry out intermediate annealing as well as allowing reheating. The mill drive system is capable of either conventional rolling or shear rolling.

Thus, while at present there is no magnesium producer capable of manufacturing wide, thin magnesium sheets in the volume (and at the price) that would be required for significant use in volume vehicles, the technology for casting and rolling such a material does exist.

4 PROPERTIES OF MAGNESIUM

It is obviously not appropriate to attempt comprehensive listing of the properties of magnesium alloys in a chapter like this and readers seeking such information are referred to publications such as the ASM Speciality Handbook *Magnesium and Magnesium Alloys* (Avedesian and Bake, 1999) or manufacturers', such as Magnesium Elektron, web sites (http://www.magnesium-elektron.com). This section will simply give a brief summary of the alloy designation system and some of the more widely used alloys. Although not formally recognized internationally, the American Society for Testing Materials (ASTM) alloy descriptions are widely used. In this system, the first two letters of the designation indicate the major alloying elements, while the numbers indicate the alloy content, rounded to the nearest whole number. Table 1 indicates the element code letters used in the ASTM system. Table 2 gives a brief summary of the properties of some of the main sheet materials competing for structural vehicle applications. The listed magnesium alloy, AZ31B, seems at present to be the sheet alloy of choice, although it was developed long ago and there are current development activities to produce improved alloys. It is likely that for superplastically formed applications, AZ31B would be in competition with the aluminium alloy AA5083, whereas if the aluminium alloy had been conventionally formed, it would be likely to be a stronger alloy, such as AA6022. Magnesium and its alloys have a significantly lower modulus than either aluminium or steel, which give them a considerable advantage in reducing noise, vibration, and harshness (NVH) problems and in improved dent resistance but give the disadvantage that if magnesium sheet is substituted for aluminium sheet in stiffness critical applications, there has to be an increase in the gauge of the magnesium alloy to compensate. Magnesium has excellent machining behavior and can be readily recycled if one is dealing with clean segregated scrap. However, when dealing with end-of-life vehicles and postconsumer scrap recycling, the situation becomes much more difficult and more work is needed (Fechner, Hort, and Kainer, 2009).

The cold forming capability of magnesium is severely restricted, so that the manufacture of the body panels would have to be either by warm conventional forming or

by superplastic forming or some derivative thereof. Most magnesium alloys appear to be capable of superplastic forming with little, or no, modification to their manufacturing route (Grimes, 2011). For low volume niche vehicle manufacturing, the material condition after TRC is suitable for direct manufacturing by nonconventional routes such as superplastic forming, allowing more freedom in design and significant part consolidation and weight reduction (Figure 4). It is believed that the combination of TRC and superplastic forming of magnesium sheet could be attractive to the high end automotive market and be competitive with carbon fiber processing technology for panels and closures.

5 APPLICATIONS OF CAST MAGNESIUM

The combination of low density and excellent casting behavior makes substitution of steel or aluminium components with magnesium castings an attractive means of making significant mass reduction and it is this that has, over the last decade or so, resulted in the considerable growth in magnesium alloy consumption. This weight saving will improve the performance of the vehicle because of a reduction in the rolling resistance and energy of acceleration, allowing lower fuel consumption and also reduction in the greenhouse gases (Mordike and Ebert, 2001; Blawert, Hort, and Kainer, 2004; Kim and Han, 2008).

Factors inhibiting wider utilization of magnesium castings in various areas of vehicles are chiefly related to the higher cost of primary magnesium and with a lack of knowledge and experience with magnesium. Magnesium alloy castings are currently largely restricted to the top-end, low volume automotive market, where the cost penalty is not significant and high performance is required. However, legislative pressure for low carbon vehicles and also voluntary commitments from manufacturers to reduce the average fuel consumption of their cars seem likely to lead to a significant increase in magnesium-related applications and expansion of magnesium into high volume automotive production (Blawert, Hort, and Kainer, 2004; Robinson, 2011).

Cast magnesium alloys can be classified into those suitable for less demanding applications [body-in-white (BIW), interior, and chassis] and those suitable for the more demanding applications in the powertrain that carry a higher requirement for high temperature stability.

Areas of typical applications of magnesium alloys in motor cars have been suggested as follows (Luo and Sachdev, 2012; Kulekci, 2008):

- Structural applications—interior, chassis, and BIW: requirements for castability, room temperature strength, joining ability, corrosion resistance, damping capacity, and low cost; additional requirements for chassis and BIW components include crash worthiness, fatigue strength, and durability. High surface quality and increased corrosion resistance is necessary for exterior parts.
- Powertrain applications: with additional requirement for mechanical properties at elevated temperatures, creep resistance, fatigue resistance, and corrosion resistance under wear.

5.1 Applications of magnesium alloys for interior, chassis, and body-in-white

Apart from the high specific strength and good rigidity of magnesium alloys, the chief advantage of magnesium compared to aluminium or steel is its low dynamic vibration response together with the ability to absorb energy (Cole, 2011a). Improved corrosion resistance of magnesium alloys can be achieved by maintaining the content of impurities in solid solution to a maximum of 0.002 wt% for Ni and Fe and 0.015 wt% for Cu. AZ91 is the preferred choice for automotive designers because of its high die castability and good room temperature strength. AZ91 can be applied in a wide range of common low-demanding structural applications in the automotive interior where it can substitute for aluminium alloys and compete with polymeric or composite materials. AM50A and AM60B are alternative alloys with better ductility than AZ91; these alloys are generally utilized in applications exposed to possible crash scenarios where the chief design parameter is the energy absorption of the component (Sadayapan and Luo, 2011). Alloys AE42 and AE44 are slightly stronger at elevated temperatures and more creep resistant than AZ and AM alloys; the microstructure of AE alloys is reinforced by a complex precipitation of RE-containing particles.

Examples of interior applications of magnesium alloys include the steering wheel and steering column system, where lighter magnesium is favored to compensate for the increased weight of the integrated airbag assembly. Instrument panel, door handles, pedals, radio and airbag housing, and other smaller interior trims and features are also frequently made of magnesium AZ91 (Abbott, Easton, and Caceres, 2003). Alloys AM20, AM50A, and AM60B are further applied for seat frame and supporting construction, and bracket shells (Schumann and Friedrich, 2006). A summary of common grade alloys is provided in Table 3.

Compared to the interior, current utilization of magnesium alloys in the automotive chassis is limited to engine

cradles (front or rear) of high performance vehicles (Corvette Z06, Audi R8 GT Spyder) or front-end carrier structures of light trucks (Ford F-150). Alloys AE44 and AM60B have been utilized in these applications. The relatively high price of these components is, however, the main factor restricting wider penetration in the high volume automotive segment (Luo, Sachdev, and Powell, 2010; Luo and Sachdev, 2012). Examples of recent structural components manufactured from magnesium castings for the 2013 Range Rover are shown in Figure 5.

Currently, the most widespread application of Mg alloys in BIW and automotive closures is the instrument panel cross beam, first introduced by Audi as long ago as 1989 (US AMP Magnesium Vision 2020, 2006). To a lesser extent, components for tailgate, hood or door inner assembly reinforcement, bonnet inner parts, and frames for convertible roof tops or "bow top" are also manufactured in magnesium chiefly from AM- and AZ-type magnesium alloys using HPDC process (Blawert, Hort, and Kainer, 2004; Luo and Sachdev, 2012).

The HPDC process is predominantly used for casting of structural applications because of good die castability of common grade AZ- and AM-type magnesium alloys (Schwam, 2011). HPDC technology is able to produce complex thin-walled castings with acceptable surface quality, low porosity or cracking, and minimum need for further machining or joining. For lightweight BIW components or doors, a magnesium inner reinforcement (usually AM50 or AZ31 alloy) is integrated with sheet aluminium outer frame to form optimized hybrid lightweight structure. One of the latest examples of this method is the HPDC window frame for the Porsche Panamera that is manufactured from AM50 alloy and is attached to the cast aluminium door frame (Danisch, 2009).

(a) (b)

However, due to galvanic corrosion occurring in areas where aluminium skin panels and magnesium reinforcement make contact, additional surface protection of the magnesium is required. Sand casting of AZ91E alloy is a popular option for manufacture of the wheels of racing cars or high performance low volume passenger vehicles. Vacuum-assisted casting processes, originally developed for aluminium castings, are currently considered as an alternative to HPDC process for thick-walled castings; alternatively, the low pressure die casting (LPDC) process is especially attractive due to its ability to produce thick-walled pore-free hollow castings with high strength and improved ductility (Luo, Sachdev, and Powell, 2010). Semisolid casting (SSC) processes such as thixomolding are now accepted commercially and are broadly adopted in manufacturing of smaller parts, thanks to faster cycle times, good surface quality, and net-shaping ability (Carnahan and Decker, 2011).

5.2 Powertrain applications

Magnesium alloys in powertrain applications have recently gained popularity not only because of their good combination of low density, elevated temperature strength, and good die castability but also thanks to the progress in the die casting technology that is allowing manufacture of hybrid Al/Mg parts. AZ- or AM-type alloys could be used for castings in the powertrain system that are not exposed to temperatures above 125°C under load, such as cylinder head covers, intake manifolds, and some other less demanding components (Kulekci, 2008). In this area of application, the chief competitors for magnesium are currently thermoplastic manifolds that provide the cheapest option with similar performance and lightweight characteristic to magnesium or aluminium; however, in the luxury automotive segment, the high noise and vibration reduction combined with lightweight offered by magnesium is preferred. For other powertrain applications, operating at elevated temperatures and high external stresses for extended periods, medium grade Mg–Al-based alloys or highly creep-resistant Mg–RE-based alloys are available as a possible alternative to the currently dominant, creep-resistant Al–Si–Cu die casting grades A380 or A360.

There are two possible ways to improve the creep resistance of magnesium alloys (Pekguleryuz and Celikin, 2010): one is through alloying of the Mg–Al binary system with RE elements or alternatively relatively cheaper additions including Ca, Si, or Sr; another way is to completely eliminate aluminium and adopt complex alloying with Y, Zn, Ag, or RE, and up to 0.75 wt% Zr used for grain refinement. Previously popular creep-resistant alloys containing thorium (H-type alloys applied in military and aerospace industry) are not in automotive use because of the radioactivity of thorium. Alloying with high amounts of RE elements would lead to significantly increased costs and might also reduce die casting ability.

Medium grade Mg alloys based on the Mg–Al system with various modifications are widening the application window for magnesium die casting up to 175°C (Aghion *et al.*, 2003). Typical applications of modified Mg–Al alloys are die cast or gravity cast automatic or manual transmission housings and clutch housings, engine front covers, or oil pans. Mercedes Benz 7G-tronic automatic transmission uses die-cast AS31 high purity alloy housings; Porsche Panamera V6 and V8 engines contain two camshaft covers, front cover, and the oil module from AE44 alloys (Figure 6); various VW/Audi, BMW, GM (General Motors), and Ford models are equipped with similar components based on AJ52x/62x or MRI153M/230D HPDC alloys (Kulekci, 2008). Another example of magnesium HPDC is

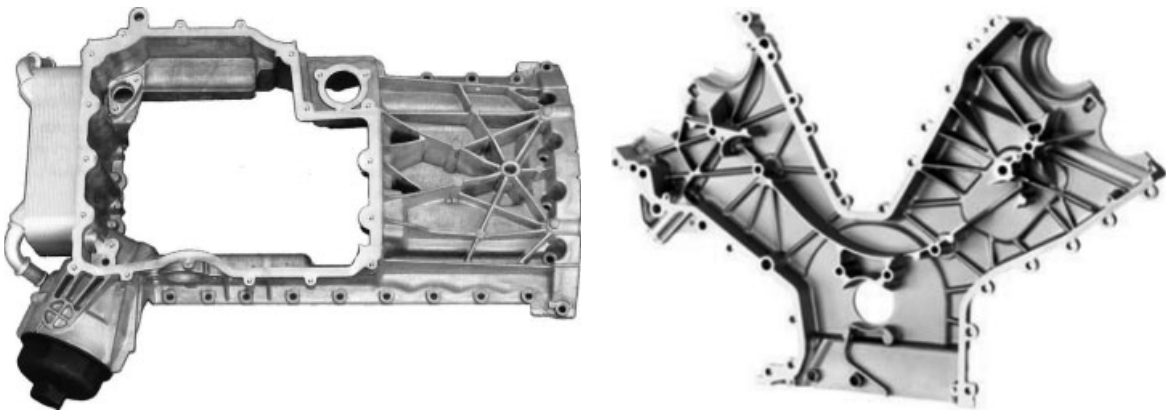

Figure 6. Examples of HPDC parts for V6/V8 engines of the Porsche Panamera; (a) oil module; (b) front cover.

the hybrid cylinder block for the BMW N52 engine, where severely loaded regions of central cylinder parts (cylinder cores, coolant passages, and bolt and stud anchors) are cast in aluminium, whereas outer shell and lower crankcases are cast in the medium grade Mg–Al AJ62 alloy. Apart from up to 24% in weight savings, the Mg/Al hybrid casting technology allows reduced engine noise and vibrations (Hoeschl, Wagener, and Wolf, 2006). For specifications and tensile properties of medium grade magnesium alloys, see Table 4.

Creep-resistant, peak-aged Mg–RE–Y–Zr-based alloys, originally developed for aerospace and military equipment and containing a combination of various expensive RE elements, are currently the only option for automotive engine components working at high external loads at temperatures above 180°C. Regrettably, even though intensive research has been carried out to develop low cost creep-resistant Mg alloys suitable for high volume automotive manufacturing, existing options are still characterized by high price and poor castability. The original duo of military alloys, WE43 and WE54, has in recent years been joined by a variety of slightly cheaper equivalents, such as MRI201S and MRI202S from Dead Sea Magnesium or several grades from Magnesium Elektron: Mg–Zn–RE-based alloys including Elektron 21, ZRE1, and RZ5 and Mg–Ag–RE-based alloys including EQ21 and MSR-B. Finally, Advanced Magnesium Technologies developed Mg–RE-based alloys AM-SC1 and AM-HP2 and successfully demonstrated their applicability for gravity and die-cast engine blocks (Pekguleryuz and Celikin, 2010). Specifications, chemical composition, and tensile properties of creep-resistant magnesium alloys are listed in Table 5; mechanical properties of selected magnesium alloys at elevated temperature are listed in Table 6.

Owing to the poor die-casting ability of creep-resistant magnesium alloys without aluminium, alternative casting methods such as gravity permanent mould casting (GPMC), squeeze casting, or SSC have to be employed. To reduce porosity and improve the creep resistance of alloys suitable for applications in cylinder heads or engine blocks, the squeeze casting process is considered and might gain more interest from automotive manufactures in future, even though squeeze casting is not as productive as HPDC (Kasprzak, Lo, and Jekl, 2011).

It remains to be seen if any of these alloys will be able to find utilization in a volume vehicle market. To the authors' knowledge, apart from aerospace castings for helicopter gearboxes and other high performance military applications, this group of alloys is currently being used only for engine blocks of racing cars.

6 APPLICATIONS OF WROUGHT MAGNESIUM

The development in Germany in about 1925 of flux covers for molten magnesium enabled production of good quality castings and, in turn, allowed development of magnesium alloy wrought products (Brown, 2002). In the period from the 1920s through the late 1950s, magnesium alloy forgings, extrusions, and sheet found widespread use in major structural roles in a large number of aircrafts and performed

satisfactorily in these roles. Wrought magnesium alloys were also used in several quite mundane land vehicles, such as the body of the Metro-Lite delivery truck that was largely constructed from magnesium sheet and extrusions. However, from the late 1950s until the present, there has been virtually no significant use of wrought magnesium in automobile construction.

The demands on current vehicle builders for performance, safety, and comfort are such that despite its attractions of low density, high specific strength, and good dent resistance, the drawbacks of very limited cold forming capability, galvanic corrosion behavior, availability, price, and price instability have been perceived as too great to warrant its use in volume cars. Use of magnesium sheets in automobile structures has been restricted to a small number of limited-series vehicles. Nevertheless, numerous development programs have been underway for, at least, 10 years. Objectives include developing alloys with improved cold formability and improved corrosion behavior, developing forming and joining techniques, developing protective coatings, and considering recycling procedures. Friedrich and Schumann (2001) (of Volkswagen) suggested that there would be a "New Age of Magnesium" in the automotive industry and that this would include castings, forgings, extrusions, and sheet and they also suggested that the necessary development programs would take more than 10 years to achieve practical implementation. Sheet applications were judged farthest from implementation and in their then state failed to meet either corrosion requirements or the surface quality required for exterior panels. Nevertheless, a bonnet structure had been satisfactorily formed from AZ31B sheet and this had performed in a manner similar to aluminium in an offset deformable barrier crash test (Moll *et al*., 2005) (Figure 7).

Progress toward actual use of magnesium alloy sheet in series production seems to be being made by GM who have recently announced (GM Press Release, 2012) that they have developed a forming process for magnesium sheet that is conducted at 450°C and combined with a proprietary anticorrosion treatment. They have formed a trunk lid inner panel and subjected it to severe tests without problems. It seems probable that the experimental panel was formed by the so-called Quick Plastic Forming process that GM developed for forming aluminium panels (Krajewski and Schroth, 2011). Krajewski is quoted (Magnesium Monthly Review, 2012) as saying that magnesium sheet inner door

and trunk lid panels will be installed on 50 test vehicles by the end of the month (October 2012).

In the United Kingdom, the Morgan Motor Company is managing a collaborative program with funding from the UK Technology Strategy Board to investigate use of wrought magnesium as a chassis construction material. The partners are Magnesium Elektron, Superform Aluminium, Penso Consulting, and Coventry University. Initially, fears centered around flammability but were dispelled by the absence of ignition during severe burning tests and it is also believed that the corrosion behavior is superior to that of steel and no worse than that of high strength aluminium, provided due note is taken of galvanic issues. It is possible that the forthcoming Morgan Eva GT Coupé will have wrought magnesium in its chassis as a consequence of this program (Eureka Magazine, 2012).

Of the potential magnesium sheet manufacturers, POSCO is probably nearest to being able to produce production quality sheet in production quantities. At the conference that POSCO hosted to celebrate the commencement of production of magnesium ingot at the Okgye plant, they reiterated that they plan to deliver magnesium sheet to Renault, Samsung, and Hyundai and Kia Motors Corporation (HKMC) by March 2013. HKMC uses magnesium seat frames fabricated from castings in some of its luxury vehicles and has also been developing seat frames employing magnesium extrusions (Kim and Han, 2008). POSCO have themselves been developing magnesium seat frames that they hope to export to European vehicle builders (Japan Metal Bulletin, 2012).

7 THE FUTURE

7.1 Sourcing of magnesium

Before the year 2000, the great majority of primary magnesium production was conducted in the west and most was extracted using the relatively environmentally friendly electrolytic process. Western production (plus CIS) was about 415,000 tonnes per annum and Chinese production 115,000 tonnes per annum, the Chinese material being largely produced by the labor-intensive and environmentally unfriendly Pidgeon process. Over the next decade, there was huge growth in both the volume produced in China and in China's production capacity (Patzer, 2010) such that by the end of 2009 over 75% of global magnesium production was in China (Figure 8). Western producers could not match Chinese prices and the United States was left with US Magnesium LLC as their sole primary producer. By 2011, it has been estimated that Chinese primary magnesium capacity had risen to almost 2 million tonnes per annum with an actual production of 600,000 tonnes (The CM Group, 2012). Although the great majority of this capacity was for production by the Pidgeon process, the growth was accompanied by significant improvement in the efficiency of the process, by the operation of generally larger plants and by the closure of many small plants. These changes in the location of primary production initially led to a considerable reduction in the metal price, but in the intervening years, increasing labor, energy, and material costs in China have resulted in price increases and price uncertainty. However, the development by Qinghai Salt Lake

Group of an electrolytic plant employing hydro power to extract magnesium from Qarhan Lake brine, with an eventual capacity of 100,000 tonnes per annum, should result in materials of lower cost (The Hatch Report, 2012). Figure 9, taken from Zuliani and Reeson (2012), shows the changes in magnesium price over the past 15 years and emphasizes its instability.

In 2005, the US International Trade Commission (ITC) imposed punitive tariffs on imports of magnesium to the United States from China and Russia. This met with protests from US magnesium die casters who claimed that their volumes were being reduced as a direct result of the tariffs. In consequence, after review, the ITC revoked the punitive tariffs on Russian imports but retained them for Chinese imports. In turn, this decision was appealed by the US Magnesium LLC with the argument that the ITC should have considered the cumulative effects of imports from China and Russia rather than considering each country separately. Certainly, the result is that the ratio of magnesium price to aluminium price is far more favorable to magnesium in China and in Europe and favorable to aluminium in the United States (The CM Group, 2012) and both the number of magnesium die casters in the United States and the volume of their business have progressively declined since 2005 (Twarog, 2012).

Despite the closure of so many western primary magnesium plants and China's current dominance, new plants have opened outside China and more are under consideration. CVM Minerals in Malaysia set up a Pidgeon plant in Perak to utilize the high grade dolomite that is found there and this started operation in late 2010. When fully operational, this plant is expected to produce 15,000 tonnes per annum (www.cvmminerals.com/ceo.html) but, in due course, a second 15,000 tonnes per annum line is planned.

POSCO, also, has constructed an extraction plant and although delays were experienced because of a dispute over electricity supply cables (Metals Week, 2012b), these have now been resolved and commercial production has recently started (Magnesium Monthly Review, 2012). The plant extracts magnesium from locally mined dolomite and has an initial capacity of 10,000 tonnes per annum but expansion of output to 100,000 tonnes per annum by 2018 is planned (Japan Metal Bulletin, 2011). Extraction employs POSCO's own development of vertical thermal technology with ferrosilicon imported from China.

7.2 Continuing growth

A large proportion of the substantial growth in primary magnesium production has been driven by the growth in the utilization of magnesium alloy castings in motor cars. Nevertheless, the actual percentage of magnesium in a typical current motor car remains very small (<1%), whereas the USAMP study of 2006 suggested that by 2020, 155 kg of magnesium could replace 285 kg of ferrous plus aluminium structure, provided that the significant necessary development programs were conducted (US AMP Magnesium Vision 2020, 2006). In fact, if all of the magnesium components that were in use on a variety of north American cars at the time of the USAMP investigation had been installed on a single vehicle, the weight saving would have been 175 kg, so that the 155 kg target for 2020 does not seem unduly optimistic. Also, the 175 kg would not have included any wrought material. In the intervening years, large development programs have been continuing in Asia, the United States, and Europe and there is considerable collaboration between continents, countries, and companies. The Korean government is allocating 1 trillion won (US$864 million) to its World Premier Materials framework between 2010 and 2018. This consists of 10 consortia involving over 220 enterprises and institutions but, in particular, a "Magnesium Research and Development Project for Ultralight Vehicles" to be led by POSCO but involving Helmholtz-Zentrum Geesthacht, Wrought Magnesium Alloys Group. Major programs to develop sheet continue at MgF in collaboration with the Technical University Freiberg. In the United States, three of the DOE's (Department of Energy) national laboratories have magnesium-related activities. Most of the world's major car builders have magnesium programs. Each year, the annual TMS gathering includes a Magnesium Technology Symposium at which some 100 papers are presented and, in addition, each year there are several other national, or international, conferences devoted to the development of magnesium. Thus, given the huge effort being devoted to magnesium alloy technology, there seems reason to be optimistic that satisfactory solutions to outstanding problems should be found.

In a world where there are growing environmental concerns, however, magnesium's carbon footprint is a cause for concern. Neither the LCA performed by Ehrenberger *et al*. (2008) nor that performed by Das *et al*. (2009) showed magnesium in a particularly good light, although the point was made that the situation would probably have been considerably better had a scrap recycling system been in place. The Pidgeon process invites particularly unfavorable comments for its environmental damage (Ingarao, Di Lorenzo, and Micari, 2011; Cherubinia, Raugei, and Ulgiati, 2008) but, as it is far and away the dominant process currently employed for magnesium extraction and the cheapest, it seems unrealistic to suggest that utilization of magnesium components in motor vehicles should await availability of some, yet to be proved, cheaper and more environmentally friendly process.

It is now well established that a wide range of structural castings can be satisfactorily made from magnesium alloys while conferring significant weight savings. There seems every reason to suppose that both the range of such castings and the number of vehicle builders employing them will increase. As far as wrought alloys are concerned, the technology to produce industrial quality sheet via TRC now exists at POSCO and MgF so that the obstacles to implementation of magnesium sheet in vehicle structures seem, very largely, to be commercial.

Plastic Trim

Kylash Makenji and Ruth Cherrington

University of Warwick, Coventry, UK

1 INTRODUCTION

The inherent features of plastics such as good mechanical properties, light weight compared to metals, ease of decoration, and ease of fabrication in creating aesthetically pleasing but technically acceptable surfaces that are the major drivers for use in vehicle interiors. Manufacturers have used the materials to attain quality finish and aesthetic styling of the interior trim to set them apart from their competitors. Other considerations include light weight, lower tooling costs for high volumes, and the possibility for them to be fabricated as single complex components. The plastic content of a vehicle is typically 8% of the total weight. The interior comprises ∼48%, the exterior ∼27%, and the under hood ∼14% of the total plastics used (Vidhyaa, 2012). This chapter looks at the plastics that make up the vehicle interior.

ISBN: 978-0-470-97402-5

There are many different components used to make up the interior trim of the cabin and some premium manufactures use traditional materials such as wood, leather, and metal inserts to enhance the aesthetics, as illustrated in Figure 1. Each component is required to pass stringent legal performance and durability standards, be produced at the right cost, and meet the customer's expectations of quality.

The vehicle interior is typically zoned in a number ways to enable the manufacturer to focus the styling around different features; this approach enables them to select the appropriate materials and manufacturing methods in their facilities or their supply chain. This chapter discusses the different zones or areas of the vehicle trim, the materials, and the manufacturing methods employed.

1.1 The zones of the vehicle interior trim

The typical zones of vehicle interior trim identified by manufacturers are outlined below:

1. The roof pillars and body-in-white (BIW). Traditionally, these areas are aesthetically clad to cover the unsightly bodywork.
2. The instrument panel (IP) and central console. The IP houses all of the vital user dials and gages, providing the user with intelligent vehicle data. Systems such as in-car entertainment, climate controls, and safety airbags are also found here. The central console houses driver controls such as gearshifts and emergency handbrake, as well as drink holders and similar fixtures. Plastic versions of these were first introduced into vehicles in the mid-1960s (Maxwell, 1994).
3. The door panels. There is a need to clad these surfaces to make them look attractive, while housing audio speakers,

Figure 1. Vehicle interior.

locking mechanisms, and occupant impact protection beams.

There are others areas of "soft" trim in the vehicle such as the seats, carpets, and headliners. However, while these are vital to the look and feel of the vehicle interior, they will not be considered in this chapter.

2 PLASTICS USED TO MANUFACTURE THE INTERIOR TRIM

There are a number of different types of plastics used in the makeup of the vehicle interior. These include polypropylene (PP), acrylonitrile butadiene styrene (ABS), polycarbonate (PC), polyvinyl chloride (PVC), polyethylene (PE), and thermoplastic poly olefin (TPO). In 2005, approximately 275 million kilograms (kg) of commodity thermoplastic was used in the interior of vehicles, this is predicted to grow by 2.8% per annum (Vidhyaa, 2012).

The drive to improve styling and to meet the durability performance standards and end-of-life recycling targets has led to an increasing popularity in the use of PP in vehicle interiors. PP is a cost-effective commodity semicrystalline thermoplastic that can easily be formed to create the high quality surface and color finish required by the automotive industry. It replaces ABS, which has inferior performance and is more costly. It is also replaces PVC, which was used considerably in vehicle interiors but due to issues with fogging and cracking, its use has gradually declined (Helps, 2001).

The IP is commonly made from TPO. TPO is a plastic blend, usually consisting of fractions of PP, PE, and block copolymer PP. It is applied to a hard or soft PP or ABS substrate to provide a soft-touch feel (Helps, 2001) that is desirable to the customer. Some of the inserted panels fitted to the IP may be manufactured from ABS or PC/ABS blends for styling, decoration, or performance requirements.

3 PERFORMANCE TESTING

Interior automotive components must comply with aesthetic and safety standards. Vehicle manufacturers test the performance of components to ensure that they are able to withstand the user and environmental requirements it is likely to experience during its lifetime.

The materials are subjected to rigorous environmental and substance-resistance testing to establish their suitability for the demands of the everyday motorist. The trim is subjected to sunlight (112–3609 kJ/m^2, depending on location), heat (−40 to 100°C), humidity (5–95% RH), impact (4.5 kg at 610 mm), and chemical substance testing (Ford, 2009). The plastic trim panels will also have to comply with head impact testing, based on Federal Motor Vehicle Safety Standard 201 (FMVSS 201, 1989), regulated by the National Highway Traffic Safety Administration (NHTSA). All areas contactable by the form within the "head impact area" must be tested. The test is used to determine that the trim is constructed using energy-absorbing material that deflects or collapses to within a specified limit of a rigid subsurface without permitting contact with any rigid material.

4 FITTING PLASTIC TRIM TO THE BIW

The trim is designed to consider how it is assembled within the BIW. On the assembly line, the plastic trim has to be fitted in a few seconds, without any damage to the visible exterior surface. It also has to meet a service requirement for removal and refitting such as access, service, or repair, up to five times during the life of a vehicle. Originally, the plastic trim would have been fitted with screws; however, this is unsightly and requires more equipment and time to assemble. Most modern plastic trim is fitted using blade, low or high friction metal clips that are preassembled to the trim on the interior surface, as illustrated in Figure 2. Low friction clips are used where the frequent removal of the trim is required. This system is also used to install an airbag behind the trim. The trim is ejected during airbag deployment; in this arrangement, the trim is tethered to prevent injury to the occupant. These methods of trim retention enable the vehicle interior to have clean styling lines.

Plastic trim linearly expands and contracts ($25–200 \times 10^{-6}$) more than the steel BIW ($10–13 \times 10^{-6}$) that it is attached to. To allow for the greater expansion and the

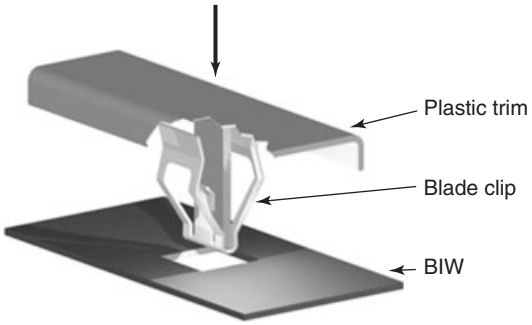

Figure 2. Metal clips used to fix the plastic trim to the BIW. (Reproduced with permission from JETPRESS.com. © JET PRESS.)

varying build tolerances of the BIW structure, the trim is designed with overlapping slip joints where required and positioned depending on the intended method of interior trim assembly on the vehicle assembly line.

5 MANUFACTURING METHODS

Injection molding is a commonly used process to manufacture plastic trim parts for a range of sizes and complexities. Parts can be produced direct from raw plastic materials with minimal further operations. The production time is fast and can be automated to produce high volumes of the same part.

The injection molding machine consists of a clamp and injection unit; these are assembled to the machine frame. The injection unit consists of a reciprocating screw, a heated barrel, and a nonreturn shut-off valve. The function of the injection unit is to plasticize a fixed volume of material ready for injection. The screw flight geometry can be optimized for the type of plastic being processed; however, most machines are installed with general purpose designs.

The clamp unit is used to open and close the mold tool and to create high pressures to hold the mold tool shut during injection molding (DIN 24450, 1987). The moving platen provides the opening and closing movements of the machine; it typically runs along four tie bars on the bed of the machine frame. The main designs of clamp units are toggle and hydraulic, however other types of design also exist.

There are a number of different forms of injection molding where a second or third plastic is injected in the same or a secondary process to create different colors or effects on components. The different techniques of molding are core-back multimaterial, cavity transfer, and co-injection (Goodship and Love, 2002). The secondary plastics need to be compatible to the main one; however, they can be a different type of plastic, grade, or color, or they can be soft.

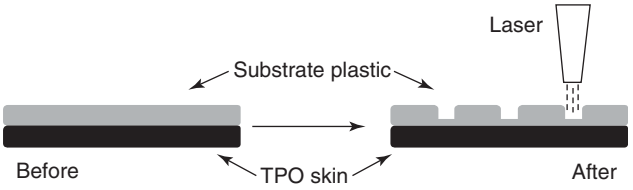

Figure 3. Laser cutter to remove the substrate material.

The IP and door panels typically have a soft-touch TPO skin on the exterior surface of the trim, to provide the driver and passengers with a quality tactile surface. The TPO skin is laid into the mold and the plastic is flowed onto the rear surface of the skin, before the mold is fully closed. This process is known as *injection compression* and it is used to prevent damage to the TPO skin from the high injection pressures of the injection molding machine.

Where this molding system is employed and airbag deployment is required, the rear of the molded article is made weaker to allow the airbag to deploy in a controlled manner. This is completed by using a laser cutter to remove the substrate material without affecting the visible interior trim surface TPO skin, as illustrated in Figure 3.

The injection mold tooling is made from standard components enabling easier manufacture and maintenance. The tooling is typically made from pretoughened steel and the form of the trim is cut directly from the computer-aided design of the part with a compensation factor for plastic shrinkage, cooling channels, and an ejection mechanism. For interior trim products, the surface finish of the tool is designed to the type of decoration required (Menges, Michaeli, Mohren, 2001).

6 DECORATING VEHICLE INTERIOR TRIM

6.1 Color-pigmented plastics

This method is the most common method of decorating plastic trim parts and provides a very durable result. The pigment or dye is uniformly dispersed throughout the plastic using an appropriate mixing technique. Dyes are easy to disperse into the plastic because they dissolve into the resin. The pigments are dispersed through the mechanical energy provided by the mixing technique, so that their particle size is reduced and the plastic can penetrate the surface of the pigment. Color match of trim components that may have been manufactured from different suppliers

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

using different techniques may also be an issue. This is partially overcome by the use of different colors, gloss levels, and surface texturing, and using a single source of compounded materials. Color and gloss are defined and controlled very stringently by the vehicle manufacturer.

The concentrate pigment is dispersed into a carrier substance and is added to the plastic at 1–5% addition to the natural plastic resin. The natural resin can be purchased in high quantities and is only colored when required at the processing stage of the plastic (Margolis, 1986). The colors of the pigments or dyes can be stock or color-matched to individual requirements; metallic effects can also be produced by the addition of metal flakes (Wheeler, 1999). This method of decorating plastics can result in low gloss and weld and flow lines from the flow into the mold tool.

6.2 Spray painting of plastic parts

Spray painting is commonly used in automotive interior trim where metallic, solid-colored, high gloss, or soft-touch finishes are required. This is especially true where color matching of the component is desirable to a mating part. Paint can be applied to complex geometries without contacting the part and can form thicknesses of 12–25 μm, depending on the application method. The spraying technique is very common where the aesthetic appearance as well as the physical properties, for example, abrasion and scuff resistance, require changes. The surface of the plastic material must be cleaned before to paint application. Some materials such as polyolefins require special treatment to activate the surface. This can include flame treatment or corona discharge. Some plastics may also require a primer to promote the adhesion of the paint to the surface of the plastic.

There are two main categories of spray paint products: solvent-based and water-based. Solvent-based paints contain solvents that evaporate following application onto the part. Depending on the application, these types of paints can be made up of up to 80% by weight of solids (60% of which can be pigments). They typically contain high levels of volatile organic compounds (VOCs), toxins that are limited under the Environmental Protection Act (Tromans, 1991). As a result, the use of solvent-based systems has been in decline and the amount of VOC content released into the atmosphere is reducing (Love, 2002; Sherman, 2004; Smith and Easterlow, 1996).

Water-based paint systems have typically low levels of VOC. They were developed in the 1950s with a view to replace traditional paint systems and to eliminate toxicity and combustion concerns. With these paint systems, water is used as a direct replacement of the traditionally used solvent. Owing to the nature of water, (high boiling point and high latent heat of evaporation), the paint requires more time and heat dry (Margolis, 1986; Stoye, 1998). Paint application can be completed by air atomization, airless atomization, centrifugal spray heads, and electrostatic assists.

6.3 Pad printing, (tampo printing)

Pad printing is a process that enables complex and flat geometry parts to be printed onto the surface. The process is suitable to be used on a variety of surfaces and textures without modification, it is commonly used to decorate or identify automotive decals and instrumentation. A variety of materials can be printed onto surfaces using the process, including thermoplastics, thermoset plastics as well as natural materials such as wood and leather. Some substrate materials may require pretreatment prior to the application of the ink. Cyan, magenta, yellow, and key (CMYK) (black) colors can be printed; different shades enable the whole spectrum of colors to be achieved (Berins, 1991; Gilleo, 1995, Muccio, 1999).

6.4 In-mold decoration (IMD)

In-mold decoration (IMD) is a technique widely used for the application of a film to an injection molded part to create decorative, technical, or wood grain finishes. IMD is one of the most efficient and cost-effective ways to decorate a part. It removes the inconvenience of on-site surfacing with paints or outsourcing to a third party. IMD provides rapid and easy surface changes and also provides the opportunity for significant cost reduction through component integration. This process relies on chemically compatible materials to act as substrates, allowing for remelting to occur during the injection molding process and ensuring material fusion takes place at the IMD film and plastic interface. The use of IMD as a decorative medium has several benefits including

1. Cost—the utilization of IMD techniques assists in the overall reduction of component piece cost (Raphanaud, 2004).
2. Environmental impact—removal of an entire manufacturing step results in reduced energy use and carbon emissions.
3. Styling—the technique provides a high quality finish that can incorporate unique company branding and identity, which improves the salability of new items.

There are a number of different IMD films on the market such as Soliant, Senoplast, 3M, Lakeside Films,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

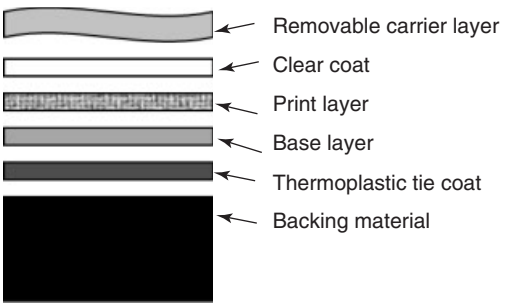

Figure 4. Typical structure of IMD film.

Sabic, Nissha, and Autotype. The films can be applied to a number of substrates such as PP, TPO, ABS, PVC, and PC; however, the compatibility of the injected plastic must be considered (Sherman, 2004).

Films in automotive interiors have been used since the 1970s. The materials have been developed to be durable enough for exterior use, while providing a suitable high quality gloss and color finish. The in-mold films are predominately multilayered structures as shown in Figure 4 (Nastas, 1994; Love, 2002).

The carrier layer is a flexible, formable, and heat-resistant sheet, normally polyethylene terephthalate, with a thickness of 25–75 μm. The clear coat is a cast coating of acrylic poly-vinylidene difluoride, materials such as poly-methyl methacrylate, PVC, and materials based on fluorocarbons. The typical film thickness for the backing material is 25–50 μm (Love, 2002). Data indicate that to make IMD a cost-effective process, the minimum volumes are ~22,000 p/a (Goodship, 2008).

Real wood veneers can also be used in an IMD process; thin sheets of the veneer can be preformed as inserts and placed into the injection mold tool. The injection molding process then follows, enabling a component to be manufactured with a visible real wood surface. Jaguar cars currently use this process to produce interior trim components for their vehicle range (Makenji *et al*., 2006; Makenji *et al*., 2007).

7 FUTURE TRENDS

The interior trim of the vehicle will continue to be manufactured from thermoplastic materials; however there is a trend for increased BIW replacement. Polymers with high temperature and modulus performance will be used further to replace steel materials and improved vehicle light weighting. As end-of-life recycling targets increase and the drive to use more recycled content in the vehicle picks up, the trim will also need to meet these demands; this can be executed by using similar types of plastics throughout. The trend of integration and modularization will escalate so that more assembly, decoration, and installation of subcomponents are completed during the primary manufacturing phase. This impacts the vehicle assembly method, reducing time and labor content. Engel, Austria have developed a one-step process to producing auto interior parts with a pleasing tactile surface known as *Dolphin*. The process uses physical foaming with the Mu-Cell microcellular process from Trexel Inc., Wilmington, Mass., together with a core back process that Engel calls "*reverse compression*." The Dolphin process is not only simpler than other methods of producing soft-surface interior parts but it also allows for complex geometries and undercuts (Anon, 2012a, 2012b). Another area that will increase is the demand for mass customization; in other words, decorating the interior to meet the customer's individual tastes and requirements. Dye sublimation is one such process, which shows fantastic potential; the technology will be developed to meet the tough performance requirements of the automotive industry (Makenji, 2011).

One area that is under the spotlight is the use of printed electronics with interior trim components. The ability to print circuit millimeters thin on thin substrates overcomes traditional wiring and packaging issues with electrical systems. The 2013 model of the Ford Fusion uses T-ink "plywood electronics" replacing the overhead instrument cluster. Different printing methods such as screen, offset, gravure, pad, flexo, rotary, and spray are employed, mainly using carbon and silver inks (Anon, 2012b). There is already a "proliferation of touch screen devices," increasingly printed on the vehicle interior trim. Research at the University of Warwick has enabled the manufacture of electroluminescent surfaces during injection molding. This process allows the vehicle trim to act as direct lighting surfaces or allows the OEM to create secret-till-lit areas in the cabin (Middleton and Goodship, 2012).

Metal Matrix Composites: Automotive Applications

Krishnan K. Chawla[1,2] and Nikhilesh Chawla[2]

[1] *University Alabama at Birmingham, Birmingham, AL, USA*
[2] *Arizona State University, Tempe, AZ, USA*

1 INTRODUCTION

A composite material is a manufactured material that consists of two or more physically and/or chemically distinct, suitably arranged phases with an interface separating them; the composite has characteristics not shown by any of the components in isolation (Chawla, 2012). In this chapter, we provide a brief account of the processing, characteristics, and use of metal matrix composites (MMCs) in automotive vehicles. The term "*automotive vehicles*" includes passenger cars, sport utility vehicles, vans, trucks, buses, recreational vehicles, and so on. Reinforcements can be in the form of fibers, particles, or flakes; detailed information about fibrous reinforcements can be found in Chawla, 1999.

2 PROCESSING OF MMCS

2.1 Liquid-state processing or casting

This is one of the common methods of processing MMCs, particularly, particle-reinforced composites. One of the important variables in the process is the viscosity of the liquid metal. The important fact to take into account is increase in the viscosity of the liquid metal by the addition of the ceramic particles (Chawla, 2012, 1999; Chawla and Chawla, 2006). This fact makes the commonplace gravity casting less attractive. Instead low pressure or squeeze casting is more effective. This involves the preparation of preform of the reinforcement (particle or short fiber plus organic binder material) and then forcing the liquid metal through the preform. Binder burnout is a significant problem. Reinforcement–matrix compatibility is another problem in liquid-state processing of MMCs. This has two components, a chemical component that has to do with an undesirable reaction at the interface, for example, reaction between carbon and aluminum to form Al_4C_3, which is a very brittle and highly hygroscopic compound. The second is a physical component. This involves the problem of poor wettability of the ceramic reinforcement by the liquid metal and the mismatch in the coefficient of thermal expansion of the metal and ceramic. The problem of wettability can be reduced by matrix composition modification or by applying pressure during processing.

2.2 Powder processing

Powder metallurgy (PM) or powder processing is a very versatile route. Ceramic particles are difficult to wet

by molten metal. The PM route obviates that difficulty. Practically, any ceramic particle species can be mixed with any metal or alloy powder to produce a composite.

Metallic powder can be elemental or prealloyed atomized powder (20–40 μm). Rapidly solidified ribbon chopped into flakes can also be used. The metal matrix powder and the ceramic particles are blended into a homogeneous mixture, that is, no agglomerates should be present in the final blend. The size of the powder is perhaps the most critical parameter in this regard. It was observed that in the case of SiC_p/Al, the SiC particle/Al particle ratio of 0.7 gave a more uniform reinforcement distribution than a ratio of 0.3 (Dinwoodie *et al*., 1985). Frequently, metal powders have hydrated oxide films on them. These water molecules must be removed by heating in order to avoid gas evolution and porosity in subsequent processing. The final step is vacuum consolidation to obtain a 95%+ dense composite. Hot pressing can be done below the matrix alloy solidus or in the liquid/solid region. Working in the liquid/solid region can give faster kinetics but there can also lead to an unwanted reaction between the reinforcement and the metal.

Secondary processing can be used. Generally, consolidated composites are subjected to extrusion (extrusion ratio between 15 and 20) to break the oxide film. The oxide film is present between metal powder particles as well as on ceramic particles. The extrusion process results in a plastic flow of the metal matrix and breaks down any clusters of ceramic particle, giving a better distribution of ceramic particles.

Advantages:

1. Any reinforcement/metal combination can be obtained.
2. Reaction between reinforcement/matrix can be minimized in a solid-state process.
3. There is essentially no limit on the volume fraction of ceramic particles that can be incorporated in a metal.
4. Nonequilibrium alloys, for example, those produced by rapid solidification, can be used as the matrix.

Disadvantages:

1. The PM process is generally complex and the product forms are somewhat limited.
2. Highly reactive, potentially explosive powders can be involved.
3. The PM process is quite expensive *vis-à-vis* liquidtate processing methods.

3 AUTOMOTIVE APPLICATIONS OF METAL MATRIX COMPOSITES (MMCS)

MMCs are used in a variety of automotive applications. The main reasons for this are enhanced strength and stiffness, coupled with low density. In addition to these properties, under certain circumstances, we have improved cyclic MMCs, for example, in pistons, cylinder liners, connecting rods, powertrain and suspension components, brake rotors, and calipers. An early and successful engine application was that of selectively reinforced aluminum pistons in the Toyota diesel engine (Donomoto *et al*., 1983). In this application, an alumina–silica chopped fiber preform was incorporated into the ring groove area of the piston during pressure casting of the aluminum. The conventional diesel engine piston has an Al−Si casting alloy with a crown made of a nickel cast iron. The main property requirement was increased wear resistance in this area. The previous approach used a Ni-resist ring that increased weight and differed in coefficient of thermal expansion from the aluminum alloy piston material. Aluminum matrix materials reinforced with SiC particles have also been used in piston applications, primarily in drag racing cars. In this case, the lower coefficient of thermal expansion of the MMC compared to that of conventional aluminum allowed reduced clearances between the piston and cylinder wall leading to improved performance.

Another early MMC application in an automotive engine was a hybrid particulate-reinforced Al matrix composite used as a cylinder liner in the Honda Prelude (Figure 1). The composite consisted of an Al–Si matrix with 12% Al_2O_3 (short fibers for wear resistance, and 9% carbon for lubricity). Both the reinforcements were in the form of short fibers. The composite was integrally cast with the engine block, had improved cooling efficiency, and exhibited improved wear and a 50% weight savings over cast iron, without increasing the engine package size. While this concept was initially implemented in the Honda Prelude 2.3 L engine, it has also been used in the Honda S2000, Toyota Celica, and Porsche Boxster engines (Hunt and Miracle, 2001). Toyota's 2ZZ-GE engine is another example where MMCs have been incorporated in the cylinder walls. These composites are made by high-pressure casting and use ceramic particles and fibers. It is worth recalling that a reduction in the weight of the automobile is a major factor in increasing fuel efficiency. Conventionally, this is done by replacing the heavy cast iron engine block with aluminum. Cast iron liners, however, are still used in aluminum engine blocks because of their superior wear resistance. Piston liners made of MMCs can replace cast

iron liners. The 2ZZ-Ge engine does that. It contains MMC liners that contain 5% alumina–silica fibers (95% alumina, 5% silica) and 10% mullite particles (12 μm) (Fujine *et al*., 2000).

Figure 2. Particulate MMCs for use in brake drums and brake rotors, as a replacement for cast iron (courtesy of D. Miracle). The high wear resistance and thermal conductivity coupled with 50–60% weight savings, make MMCs quite attractive for this application. (Reproduced from *Metal Matrix Composites*, 2006, N. Chawla and K.K. Chawla. With kind permission of Springer Science+Business Media.)

Particulate MMCs, particularly Al-based MMCs, have been used in brake drums and brake rotors as a replacement for cast iron (Figure 2). The high wear resistance and thermal conductivity coupled with 50–60% weight savings, make MMCs quite attractive for this application. An intensive development effort was carried out using cast 359Al/SiC/20_p composite. While the costs for this rotor are somewhat higher than those for cast iron, the benefits were justified in a number of specialty vehicles, such as the Plymouth Prowler, Lotus Elise, and others (Hunt and Miracle, 2001).

One of the disadvantages of MMCs with a ceramic reinforcement is that they are typically more difficult to

machine than the unreinforced alloy. In centrifugal casting, optimal placement of the reinforcement can be achieved by using a centrifugal force during casting, which results in a gradient in reinforcement volume fraction (Divecha, Fishman, and Karmarkar, 1981; Tsunekawa *et al*., 1988). In brake rotors, for example, wear resistance is needed on the rotor face, but not in the hub area. Thus, in areas where reinforcement is not as crucial, such as in the hub area, machining would be easier without the reinforcement. Figure 3 shows the microstructure at different points in a centrifugally cast brake rotor, showing a pure aluminum alloy matrix region, interface region, and reinforced region. The process is relatively inexpensive, with a potential for composite materials at as low as \$2/kg. Thus, use of "selective reinforcement," whereby the hard SiC particles are used precisely where high strength and wear resistance are required would appear to be quite attractive.

An important application of MMCs in the automotive sector is the driveshaft. The key limitation in this case arises from the critical rotational speed at which the component becomes dynamically unstable. Use of MMCs reduces the inertia which in turn allows the critical speed of the driveshaft to be increased. The critical rotational speed (N_c) is given by (Hoover, 1991)

$$N_c = \frac{15\pi}{L^2}\left[\frac{E}{\rho}\left(R_o + R_i\right)^2\right]^{\frac{1}{2}}$$

where L is the length of the driveshaft, E is the Young's modulus, ρ is the density, and R_o and R_i are the outer and inner radii of the shaft, respectively. The take away

message from this equation is that the material parameter that controls critical speed is the specific modulus, E/ρ. One of the requirements of the driveshaft is that it be welded to a yoke. Thus, SiC reinforcement is precluded from material selection, because of the harmful reaction products formed between Al and SiC in liquid-phase processes. Duralcan has used a $6061/Al_2O_3/20_p$ composite, which exhibits a 36% increase in specific modulus over steel (Figure 4) (Allison, Jones, Davis, 1997). The modulus of the composite increases with the volume fraction of the reinforcement (fiber or particle). As an example, we cite the fact a particle-reinforced MMC can have the same modulus as gray cast iron. Thus, in a modulus-based design, sections can have thicknesses that are the same as that of cast iron and less than that of aluminum sections. This could be a great advantage in terms of E/ρ.

Another important potential replacement of steel by SiC particle-reinforced Al matrix composite is in the connecting rod (Figure 5). The connecting rod requires high fatigue resistance at temperatures as high as 150°C. A lighter connecting rod would result in (a) 12–20% reduction in secondary shaking force, (b) 0.5–1% improvement in fuel economy (with lightweight piston and pin), (c) 15–20% increase in peak RPM, (d) decreased bearing width (package improvement), and (e) increased bearing and crankshaft durability. Initial attempts at developing an MMC connecting rod used hot-pressing followed by extrusion, commonly used to fabricate aerospace components. This technique proved to be too costly in the automotive sector (where production volume is much larger than in the aerospace industry) because of the large amount of wasted material. Near-net-shape sinter forging was used to fabricate MMC connecting rods with tensile and fatigue properties comparable to those of extruded materials (Koczak *et al.*, 1993). A prototype model of this rod is shown in Figure 6.

weight savings was achieved with the MMC rod, with a moderate increase in cost. In addition, it is estimated that for every 1 kg of weight removed from connecting rods, 7 kg of supporting and counterbalancing structure can be eliminated (Hunt and Miracle, 2001). Other demanding powertrain applications are intake and exhaust valves. These components must have good high cycle fatigue performance at elevated temperature, good sliding wear resistance, and creep resistance. Austenitic stainless steel was replaced by a TiB_2-reinforced Ti matrix composite in the Toyota Altezza (Hunt and Miracle, 2001).

MMC foams have also been developed for damping/energy-absorbant applications in automobiles (Leitlmeier, Degischer, Flankl, 2002). A $6061Al/Al_2O_3/22_p$ composite foam was has been used in Ferrari cars. Figure 7a shows the three-dimensional microstructure of the foam obtained by computed X-ray tomography. The pores are a few millimeters in diameter and are homogeneously distributed. Figure 7b shows the microstructure of the composite (Babcsan *et al*., 2004). The SiC particles stabilize the wall thickness (Figure 7b), and segregate to the cell wall (Figure 7c). The thickness of the cell walls is about twice the SiC particle diameter.

4 CONCLUSION

In summary, MMCs find applications in automobiles as niche applications. This stems from their high modulus, high strength, and superior wear characteristics. It has to be admitted that compared to polymer matrix composites, the penetration of MMCs in the automotive sector is not as extensive. The high cost of MMCs would appear to be a major factor.

Voltage Control and Frequency Control

Christian Rehtanz, Johannes Rolink, and Willi Horenkamp

TU Dortmund University, Dortmund, Germany

1 INTRODUCTION

Electric vehicles (EVs) are nowadays treated as potential candidates for providing ancillary services. Owing to their storage capability, they are able to store energy in times of overproduction, especially from renewable energy sources, and to restore it, for example, when the volatile feed-in is low. Thereby, EVs can help to maintain and improve the quality, reliability, and stability of the supply system.

Ancillary services are services that the grid operator provides for power consumers in addition to electricity transmission and distribution. Ancillary services include (VDN, 2007a):

frequency control;
voltage control;
restoration of supply;
system/operations management.

These services are not usually provided using low voltage power sources. This may change in the future.

This chapter looks at *frequency control* and *voltage control* services in connection with EVs. For the analysis, the German perspective is chosen. First of all, voltage control is discussed briefly. This is followed by an overview of the current regulatory framework for providing frequency control in Germany. Eventually, a basic analysis of the technical potential of EVs is presented considering different types of control power. Most of the following results can be generalized for the territory of the former UCTE.[1] Unfortunately, this is not completely possible because of national regulatory aspects.

2 VOLTAGE CONTROL

Low voltage supply systems experience excessively low voltage conditions when they have long lines and high consumption. Excessively high voltage conditions are increasingly being seen in rural areas of Germany in connection with photovoltaic systems. Supply system voltage can be kept within specified tolerances by upgrading the system or reducing the consumption or output of grid-connected power sources.

EVs can help support voltage control in low voltage supply systems. For example, they can supply or consume reactive power. This must be done locally, as reactive power cannot be transported over long distances. Given the primarily resistive nature of low voltage lines (R/X ratio of 2.57 with NAYY^2 $4 \times 150\,\text{mm}^2$ and 50 Hz) and the restricted power factor (VDEW, 2001), power factor correction has only a limited impact (also see Impact of Electric Vehicles on Low Voltage Supply Systems). Power factor correction also requires larger charging converters. The most effective way to regulate voltage in the low voltage supply system is by adjusting overall current; this also changes the active current component. This can be

done, for example, by consuming locally generated power near the point of generation or generating power near the point of consumption. EVs with bidirectional converters can handle both options, allowing them to be used to both raise and lower system voltage. However, owners of consumption and generation equipment in the low voltage supply system are currently under no obligation to actively support voltage control.

3 FREQUENCY CONTROL

Temporary deviations between generation and load are offset using control power, which stabilizes system frequency and returns it to the scheduled value. Deviations occur as a result of generation loss, major grid disturbances, maintenance, incorrect load and generation forecasts, and schedule changes. There are three forms of control power in Germany: primary, secondary, and tertiary controls. They differ in their response times and duty durations. Primary control power is activated automatically and locally. It is supplied mainly by fossil fuel-fired steam power plants. As primary control power must come online quickly, the only alternative to thermal power stations is battery storage (VDE, 2008). Secondary control power is activated automatically and centrally using the network characteristic method (UCTE, 2009). This form of control power is supplied by hydraulic storage power plants and steam power plants. Pumped storage power plants are ideal suppliers of secondary control power, because they have such high rates of change of power. Tertiary control power ("minute reserve") is activated manually, usually by phone. It is supplied by hydroelectric plants, fast-start gas turbines, and thermal power plants operating below full capacity.

3.1 Regulatory environment

Several codes and regulations define the regulatory environment for providing control power. One is the Operation Handbook, which defines technical standards for the territory of the former UCTE (2009). Nationally, the Operation Handbook is supplemented by the Transmission Code (VDN, 2007a) and the prequalification conditions (VDN, 2007b). The procurement of control power is governed by the German Grid Access Regulation (StromNZV) (German Government, 2011), which is interpreted and supplemented by resolutions passed by the German Federal Network Agency.

The transmission system operators (TSOs) require providers of control power to maintain certain availability factors and capacity factors (VDN, 2007b). TSOs in Germany procure control power on a shared internet platform (German Transmission System Operators, 2012). On the platform, the tenders can be either symmetrical or asymmetrical. Symmetrical tenders require bids to cover equal amounts of positive and negative control powers. Asymmetrical tenders, by contrast, treat positive and negative control powers as separate products. Compensation is based on energy and/or demand tariffs. Bidders have to meet minimum lot sizes and bid on specific periods (time slots) during the day (German Federal Network Agency for Electricity, Gas, Telecommunications, Post and Railways, 2011). Table 1 summarizes the various parameters for each type of control power.

If EVs are used to provide control power, a sufficient number of them will have to be pooled together to meet the minimum lot size requirement. In addition, the vehicles will have to be coordinated, so that they comply with the availability and capacity factor requirements. This results in different requirements for the vehicles' communication systems. Primary control power, for example, is automated locally and automatically; therefore, information about how many EVs are contributing to the primary control reserve should be available centrally. The technical units in the secondary control reserve, by contrast, are connected to a closed-loop control circuit with a control cycle of no more than 4 s (VDN, 2007b). The pool operator has to independently assign the set point signal from the secondary

Table 1. Parameters for types of control power.

	Primary	Secondary	Tertiary
Availability factor	100%	95%	100%
Capacity factor	n/a	100%	100%
Tender	Symmetrical	Asymmetrical	Asymmetrical
Compensation	DT	DT + ET	DT + ET
Minimum lot size	±1 MW	±5 MW	±5 MW
Time slots (work day)	1	2	6
Procurement	ACA	ACA	ACA

DT: Demand tariff
ET: Energy tariff
ACA: Across control areas (Germany-wide).

DOI: 10.1002/9781118354179.auto283
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

controller to the various technical units within the cycle time. The operator also needs to know the availability and capacity factors for the vehicles. The communications link between the pool control center and the secondary controller should be a redundant point-to-point connection (VDN, 2007b). While tertiary control power still tends to be requested by phone, in the future, the EVs will have to be activated automatically because of the expected pool sizes. Here, too, the pool control center and the vehicles will have to exchange measurement and control signals as well as information on availability and capacity factors in order to coordinate the vehicles.

3.2 Contribution to control reserve

EVs can essentially contribute to control reserves in a variety of ways. First, they can be operated as changing loads during the charging process. This can include load shedding. In this case, the maximum power contribution varies depending on the number of vehicles being charged in the course of the day. This approach only provides positive control power. It is, however, also possible to vary charging output within a fixed symmetrical control range for each vehicle. This would provide access to both positive and negative control reserves. As the number of charging vehicles fluctuates in the course of the day, neither approach can provide a constant range of power throughout the day (cf. Figure 1, Impact of Electric Vehicles on Low Voltage Supply Systems).

EVs can also be used outside of the charging process to store power. This allows them to provide both negative and positive control powers. To provide positive control power, they would need a charging converter that can operate in both directions. If each vehicle is required to meet a certain capacity factor, part of the vehicle battery will have to be set aside as an energy reserve for the duration of the time slot while maintaining a constant power range. This operating mode depends on the vehicles' availability factor and is thus unaffected by fluctuations in charging vehicles in the course of the day. Figure 1 clearly illustrates this: it shows the availability factor for EVs charging at 3.7 kW at work or at home on a workday. The two lines show the availability factors when vehicles that are not mobile during the day are classified as not available (−NM) or available (+NM) (Rehtanz and Rolink, 2010).

Vehicles that only serve as a negative control reserve will have to maintain adequate reserve capacity at the start of each time slot. This approach is ideal for EVs that are used every day: when users drive their vehicles, they consume the energy stored in the vehicle batteries, thereby restoring the vehicles' ability to absorb power as part of the negative reserve (i.e., the capacity factor). When providing a positive control reserve, the batteries must be adequately charged at the start of each time slot. This approach is ideal for vehicles that are rarely used.

3.3 Power and energy reserve

3.3.1 Primary control

Primary control is a proportional control. To include electrical vehicles in primary control, each vehicle will need

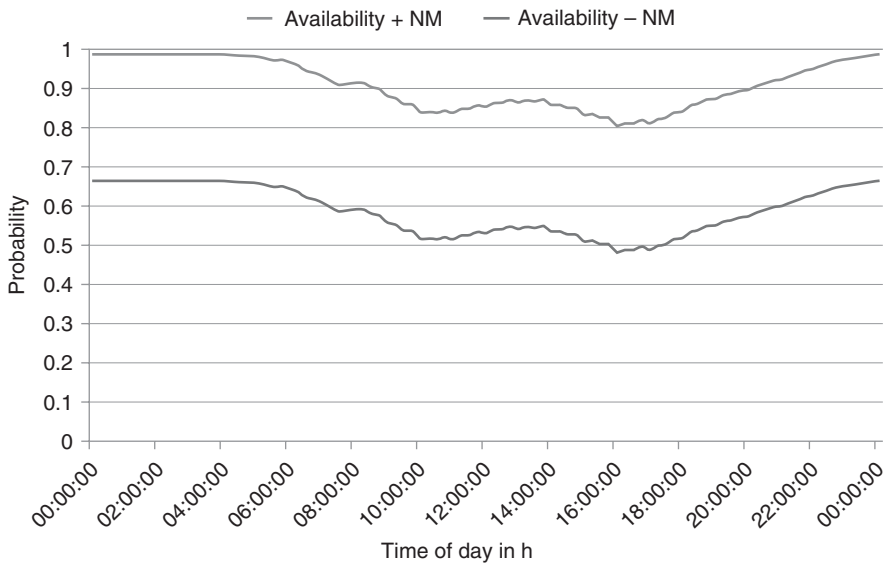

Figure 1. Vehicle availability factor on a workday.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto283
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to be assigned a certain power frequency characteristic K. This power measure is calculated as follows:

$$K = \frac{\Delta P}{\Delta f} \tag{1}$$

It describes the power difference ΔP of the technical unit divided by the frequency deviation Δf from the target value ($f_t = 50$ Hz). The full primary control reserve must be activated when the frequency deviation is $|\Delta f|_{max} = 200$ mHz (UCTE, 2009).

Assuming a control range of 5% of nominal power per vehicle ($P_N = 3.7$ kW) in bidirectional operation, the symmetrical control range would be $\Delta P_{EV} = \pm 185$ W per vehicle. According to Equation 1, this translates to a power frequency characteristic of $K_{EV} = 925$ W/Hz. With only one million vehicles and a minimum availability factor of 50% (Figure 1), the possible control reserve could reach 92.5 MW, or roughly one-seventh of the primary control reserve maintained in Germany.[3] Given the high availability factor requirements and essentially continuous use of the primary control reserve, the next step is to determine the energy reserve required per vehicle.

Utility frequency is used as a reference signal for timekeeping. As utility frequency fluctuates, there are timekeeping errors. To compensate, utility frequency is regulated in order to keep network phase time synchronized with coordinated universal time (UTC) over the long term. This is done by adjusting the secondary controller. The grid control center in Laufenberg (Switzerland) is responsible for monitoring and corrections. The difference between UTC and synchronized time should not exceed $|\Delta t|_{max} = 30$ s (UCTE, 2009). The phase error $\Delta\theta$ resulting from the time deviation Δt is calculated as follows:

$$\Delta\theta = 2\pi f_t \Delta t \tag{2}$$

The maximum phase error can be calculated as $|\Delta\theta|_{max} = 9424.8$ rad. The relationship between the phase error and the energy E_{PRL} consumed or generated by the vehicle is calculated as follows:

$$E_{PRL} = \frac{K_{EV}}{2\pi}\Delta\theta \tag{3}$$

If we use the power measure as calculated in Equation 3, the necessary energy reserve per vehicle works out to $E_{PRL} = \pm 0.385$ kWh. Analyses of actual frequency curves have confirmed that this magnitude is correct and show that phase error fluctuations span several days, that is, the maximum energy is not reached within a single day. Therefore, a reserve of 0.77 kWh per vehicle is sufficient to provide primary control power under the above conditions.

3.3.2 *Secondary and tertiary control reserves*

To estimate EVs' contribution to secondary and tertiary control reserves, we will assume that the control reserve buffer in the vehicle batteries is sizable enough to provide the full amount of reserve power for at least 4 h.[4] The vehicles are assumed to only participate in one time slot a day. We also assume that the provider pools are homogeneous, that is, they do not simultaneously provide positive and negative secondary and tertiary control powers within a single day. This is done for two reasons: first, providers have to meet different requirements in each pool. Second, combining both options would double the required control reserve buffer.

Drivers' mobility requirements should be the main priority when determining vehicle power and energy reserves. Power set aside for the control reserve should have only a moderate impact on the charging process during the time slot. Similarly, the EV should only have to maintain a moderate amount of energy for positive/negative energy reserve purposes. The amount of power set aside and the energy reserve will have to be chosen based on availability and capacity factors, daily vehicle consumption, battery capacity, and charging power.

In Germany, the average daily consumption of a vehicle that is mobile during the day is assumed to be 6 kWh (Rehtanz and Rolink, 2009). A common battery capacity for modern electric-only vehicles is roughly 30 kWh.[5] Thus, a control reserve buffer of 3 kWh is equal to one-half the assumed daily consumption or 10% of stated battery capacity. If a vehicle with this control reserve buffer supplies or consumes control reserve power during a 4 h time slot and the capacity factor is 100%, the maximum control reserve buffer per vehicle is $P_{max} = 0.75$ kW. Thus, with one million vehicles, the total control reserve would be 750 MW. The maximum energy provided by a vehicle pool of this size is 3000 MWh. As the control reserve must be available during the entire time slot, this might reduce the charging output by 20% during the charging process (Rehtanz and Rolink, 2010).

4 SUMMARY

EVs can be used to provide ancillary services. To ensure greater flexibility and effectiveness, however, the vehicles must be equipped with a bidirectional charging converter. Voltage and frequency controls were investigated. The investigations showed that EVs can make only a limited

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto283
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

contribution to voltage control, because most of the load on low voltage lines is resistive. They can, however, help in integrating additional EVs in certain circumstances. In order to participate in voltage control of low voltage supply systems, the vehicles cannot be allowed to operate autonomously. Instead, they need to be integrated into a management system that coordinates vehicles in response to the electricity supply system's current condition.

At first glance, EVs appear able to make an enormous contribution to provide control power. One million EVs could cover a significant portion of Germany's primary control reserve requirements. Each vehicle would only need to set aside a small portion of its battery for this purpose. However, the actual impact depends largely on vehicle availability. EVs must be coordinated in a pool in order to meet the high availability and capacity factor requirements. The technical requirements for secondary control power are particularly high. However, even primary control, which is activated locally, would require some form of data communications in order to indicate the vehicle's status.

EVs can be involved in primary control and in power factor correction. This requires the development of sound business models for vehicle owners. If none are developed, it may be possible to compel them to provide these services through technical terms of service.

Impact of Electric Vehicles on Low Voltage Supply Systems

Christian Rehtanz, Johannes Rolink, and Willi Horenkamp

TU Dortmund University, Dortmund, Germany

1 INTRODUCTION

Electricity supply analyses with focus on electric vehicles (EVs) started in the early 1980s (Heydt, 1983; Boonekamp and Wakkerman, 1993; Rahman and Shrestha, 1993). However, the impact of EVs on power grids has only recently become a significant object of research (Clement-Nyns, Haesen, and Driesen, 2010; Taylor *et al*., 2009; Richardson, Flynn, and Keane, 2010; Babaei *et al*., 2010). EVs are relatively large household loads, and their widespread, mass deployment will have a significant impact. The key questions of this chapter are how many vehicles can the current public power grid handle in Germany and what grid upgrades will be needed over the long term in connection with EVs?

One difficulty is that research findings cannot be fully validated. EVs are few in number and usually deployed locally. While multiple projects have been conducted, the resulting data are too sparse to draw universal conclusions about distribution systems. This makes it even more important to thoroughly describe and discuss what methods are used to estimate grid impacts to gain a more concrete understanding of how EVs will affect the grid in the future.

The research findings depend on many unknowns. For example, it is too early to say whether most EVs will be charged at home, public charging points, or battery swap stations. Another unknown is user behavior. We do not know how most drivers—especially consumers—will behave in the future. Many researchers simply apply the mobility behavior of conventional vehicles to EVs. However, any statements about users' future charging behavior are purely speculative.

Analyses of grid impacts pose a dilemma. If we analyze individual, concrete grid topologies, the results cannot be readily generalized. If we adopt a more general approach using supply system models, the analysis cannot be applied to concrete scenarios, but will only outline general trends. Given the lack of knowledge about EVs' future charging behavior, the general approach seems to be the better choice. Integrating EVs into the low voltage supply system will likely increase the load on the grid even more. Thus, the first logical step is to consider what operating parameters limit connections of EVs to the grid and observe how these limitations come about and where they apply.

This chapter analyzes the impacts of EVs on the low voltage supply system in Germany with respect to its capacity. The analysis focuses on reference supply systems

that are identified using structural data. It first determines the simultaneity behavior of EVs based on uncontrolled charging processes. Next, it explains the methodology used to determine the reference supply systems. Then, it describes the main bottlenecks to connect EVs to the power grid. Finally, it analyzes the capacity of the low voltage supply system. Sections 2–4 are intended for readers keen to learn about the underlying methodology. Readers who are more interested in the results should turn directly to Section 5.

These findings were obtained as part of "e-IKT—Integration of Electric Vehicles into Tomorrow's Power Grids," a project supported by the German Federal Ministry of Economics and Technology.

2 SIMULTANEITY CURVES OF CHARGING ELECTRIC VEHICLES

To analyze the ability of low voltage supply systems to handle EVs, we have to look at the simultaneity distribution during the charging process. The simultaneity distribution is expressed by the simultaneity factor. The expected load on the grid P_{tot} produced by n loads is calculated based on the peak load portion P_s of the individual loads and the simultaneity factor $g(n)$ (Kaufmann, 1995).

$$P_{tot} = g(n) \cdot P_s \cdot n \tag{1}$$

In this chapter, simultaneity curves are generated like household patterns of consumption and used to model the charging load of EVs. As comprehensive information is not available about public charging station use, this analysis only considers EVs that are charged at home. Data on home-charging behavior is derived from conventional car data collected in "Mobility in Germany 2008" (MiG, 2008), a study commissioned by the German Federal Ministry of Transport, Building, and Urban Development (BMVBS). To simplify things, the analysis also assumes that driving patterns on the various days of the week remain the same throughout the year.

Rehtanz and Rolink (2009) described how to estimate charging patterns for uncontrolled EVs based on the MiG study. Figure 1 shows the average charging load curve for EVs that are driven during a workday and only charged at home. The three curves represent different charging outputs.

A comparison of the charging profile of the EVs with the German VDEW standard load profile for households (H0 profile) shows peak loads between 17:00 and 20:00 for both households and EVs. These simultaneous load peaks are essential if we wish to use simultaneity factors for both household loads and EVs.

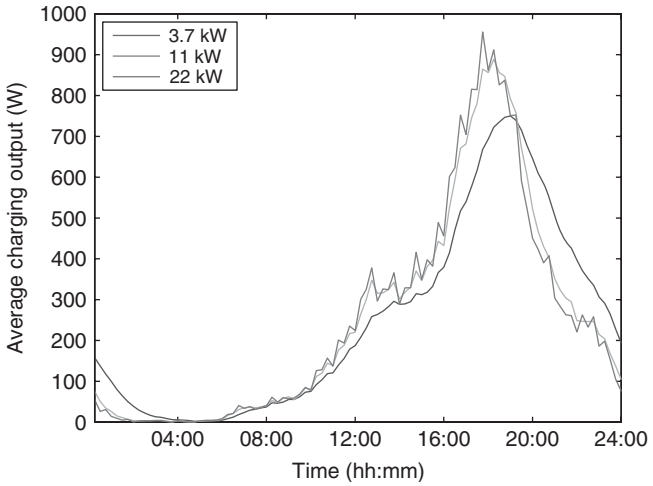

Figure 1. Charging curves for different charging outputs.

To compute the simultaneity curves, we first take 25 random sample populations from all the available "distance traveled" data. The simultaneity curves of these samples are used to determine the simultaneity factor for a given number of vehicles n. Maximum values are used to obtain a conservative estimate for the simultaneity curves.

To simplify matters, the computed simultaneity curves are approximated using a function. Household loads are usually estimated using the function

$$g_1(n) = g_\infty + \frac{(1 - g_\infty)}{n^k} \tag{2}$$

(Approach 1) (Kaufmann, 1995). This result is compared to the result obtained from the exponential function.

$$g_2(n) = g_\infty + (1 - g_\infty) \cdot e^{-k \cdot n} \tag{3}$$

(Approach 2). The simultaneity factor g_∞ describes the behavior of a very large number of dwelling units or EVs. In both functions, the parameter k is chosen to enable the computed simultaneity curve to be approximated as closely as possible using the least squares method. The total error (distance d) between the computed curve and the approximated curve is minimized using an optimization method. Table 1 shows the resulting exponent k and computed distances for various charging outputs.

The smaller distances show that the exponential approach describes the simultaneity curve much better for all three output levels. Figure 2, for example, shows the computed and exponentially approximated simultaneity factor curve for a charging output of 3.7 kW.

3 SELECTING REFERENCE SUPPLY SYSTEMS

This section describes the methodology used to select reference supply systems. Reference supply systems provide the data used in subsequent analyses and should reflect differences in the low voltage supply system as accurately as possible. As the analyses focus on purely residential areas, reference supply systems are selected using residential structural data provided by the Berlin Senate, which contains information on city blocks in Berlin. These blocks are consolidated into groups based on selected parameters. Then, a block is chosen that best represents the set of blocks within each group. Structural data from these representative blocks supply the parameters used in the reference supply systems.

3.1 Choice of methodology

As the data set has a large number of blocks, it makes sense to group them using portioning clustering. This method uses a predetermined number of clusters. Each cluster has a predetermined cluster center. Elements (city blocks) are assigned to whichever cluster has the center that is most similar or least dissimilar to them. An optimization algorithm tries to maximize heterogeneity between the clusters and homogeneity between the elements in each cluster (Backhaus *et al.*, 2006).

Cluster variable selection is extremely important. Variables have a significant impact on cluster composition. Highly correlated variables can overweight certain characteristics because of the redundant information, so variables should be as uncorrelated as possible. These variables can be identified using a correlation analysis. Typical parameters used to describe residential structures and low voltage supply systems include floor space, building footprint, building density, residential density, and the number of dwelling units per service (DPS) entrance (Kaufmann, 1995). A correlation analysis identified floor space and building density as ideal cluster variables.

We can obtain the optimal number of clusters by treating the F-value as a quality measure. The F-value is the quotient of the variance of a variable between clusters and the variance of the variable within the clusters. The higher the F-value is, the greater will be the heterogeneity between clusters and the homogeneity between elements within the clusters. The PRE-value can also be used to determine the number of clusters. It describes the improvement in variability provided by k clusters compared to $(k-1)$ clusters. Using the F-value and PRE-value, the optimal number of clusters was determined to be $k=8$ (Bacher, 1996).

3.2 Selecting representative blocks

After clustering, there are several different ways to identify the best representative for each cluster. One way is to select the block with the most "neighbors." A neighbor is defined as a cluster object whose distance from the reference object lies within a defined range. Obviously, the results vary depending on the limits of the range. Moreover, local accumulations tend to skew the choice of representative (Bacher, 1996). A more global approach is to choose whichever block is the least distant from the cluster center. However, this approach is extremely sensitive to outliers. For this reason, the medoid is used as the representative. The medoid is the block in each cluster with the least average distance (i.e., dissimilarity) from all other objects in the cluster.

The average house distance, average rate of car motorization per household (m), and the average number of DPS entrance are needed to set the reference supply system parameters for subsequent analyses. Table 2 shows the reference supply system parameters.

8	17.9	10.33	0.391

4 SUPPLY SYSTEM CONSTRAINTS

This section describes the constraints on power distribution systems' ability to support EVs. The main constraints are the load ratings of the *transformers* and the *cables*. This section also examines voltage control and the interrupt condition for feeder fuses.

4.1 Equipment load rating

Load ratings for distribution transformers are mainly determined by thermal operating limits. Exceeding load limits will reduce the transformer's expected service life. Transformer load rating depends on load duration and the temperature when the load begins to rise (Helling *et al*., 1988). Both oil and dry-type transformers are used in Germany to step down voltage from the medium- to the low voltage supply system.

Oil transformers can handle up to 1.3 times their rated load in continuous operation and up to 1.5 times their rated load during peak load periods (Kaufmann, 1995; Helling *et al*., 1988). The large variety of dry-type transformers makes it difficult to generalize their ability to handle above-rating loads (Vosen, 1997). Dry-type transformers are classified into different temperature classes based on their insulation systems. Overtemperatures are defined for each temperature class in the German VDE 0532-76-11 (EN 60076-11) standard. A resin-encapsulated transformer rated above 400 kVA can handle a load of up to approximately 110% in continuous operation and 120% for half an hour at an ambient temperature of 20°C (Kaufmann, 1995).

VDE 0289-8 defines the current-carrying capacity of cables as the maximum current allowed in given operating conditions. Current-carrying capacity is also limited by the maximum permitted operating temperature. Other operating conditions that affect cables' current-carrying capacity include the depth of installation, type of installation, type of soil, soil temperature, and operating mode.

VDE 0276-603 specifies current-carrying capacity for various cable cross sections under reference conditions. Local deviations from the reference conditions (parallel installation of cables) can be accounted for using conversion factors from VDE 0276-1000. Cables can also be overloaded briefly depending on the previous load situation (VDEW, 1986).

If the load rating given in the standards is used for an item of equipment ignoring local operating conditions, it should be noted that the values obtained under reference conditions are only general guidelines. Only a detailed assessment of the actual condition of an item of equipment can determine if it is actually overloaded. As this is normally not done, operators of low voltage supply systems do not know exactly when an item is overloaded. As a result, they do not have any information on remaining equipment capacity in any given load situation.

4.2 Voltage control

IEC 60038 specifies voltage levels for low voltage supply systems. However, devices connected to these supply systems are designed for a certain voltage range. This range must be maintained to preserve device functionality. Under EN 50160, the voltage drop (10 min average) in the medium- and low voltage supply system may not exceed 10% of the rated voltage in 95% of the cases on average for the week. As the 10% encompasses both the low and the medium-voltage supply systems, the maximum permitted voltage drop in the low voltage supply system is usually around 5% of the rated voltage (Heuck, Dettmann, and Schulz, 2007).

4.3 Interrupt condition for feeder fuses

Figure 3 shows the fuses for a secondary substation. A high voltage, high breaking-capacity fuse (HV-HBC fuse) is located on the high voltage side. Low voltage, high breaking-capacity fuses (LV-HBC fuses) are located on the low voltage side. A transformer fuse (LV-gTr) may also be located on the low voltage side. In addition, every feeder on the low voltage side has its own fuse (LV-gL) (Helling *et al*., 1988).

The interrupt condition states that the feeder fuse must be selected to reliably de-energize the line at the smallest expected fault current (single-phase short circuit) (Heuck, Dettmann, and Schulz, 2007), that is, a short circuit between phase and neutral. The maximum line length should thus be chosen to allow the LV-HBC fuse to operate within a certain timeframe at a given current. This value is specified by the conventional fusing current I_f.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto284
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

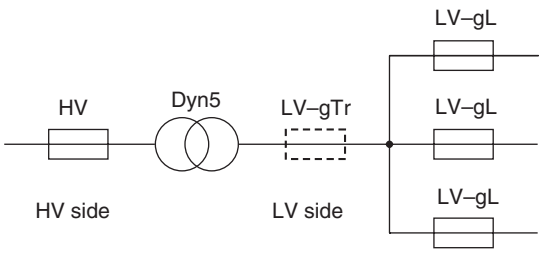

Figure 3. Fuses in a secondary substation.

It is possible to calculate the maximum line length that still maintains the interrupt condition for a minimum fault current. The line length limits the number of connections and affects the maximum permitted voltage drop. For a NAYY[1] $4 \times 150\,\text{mm}^2$ low voltage cable equipped with a 315 A LV-HBC fuse, a transformer with an apparent power rating of $S_N = 100$ kVA and a subtransient short-circuit power of $S_k'' = 50$ kVA at the transformer, the maximum line length is 583 m. This value increases only insignificantly with higher transformer power ratings.

5 ANALYSIS OF THE CAPACITY OF LOW VOLTAGE SUPPLY SYSTEMS

This section examines the capacity of low voltage supply systems to absorb EV charging. In this case, capacity depends on what percentage of vehicles in a particular segment of the supply system can be replaced by EVs, not the absolute number of EVs that the segment can support. This percentage is expressed as the penetration rate p, which is calculated by dividing the number of locally replaceable vehicles by the total quantity of vehicles. The analysis uses the reference supply systems. This section first explains the model assumptions underlying the supply system analysis. Then, it presents the capacity analysis.

5.1 Creating the model

The system capacity analysis relies on several basic assumptions that are required to analyze equipment loading and the voltage drop. A general approach is used to reduce complexity. Several simplifying assumptions are made. Special local circumstances are ignored.

This analysis focuses on home charging. In other words, it generally assumes that EVs will be charged at home and ignores commercial users of EVs. This represents a worst-case scenario from the perspective of a low voltage supply system, which predominantly supplies dwelling units. The vehicles are plugged into an AC or a three-phase power outlet. Charging devices are integrated in the vehicles. DC charging stations are not considered, as the sojourn times at home are supposed to be generally long enough for charging, especially over night. Therefore, the high charging power offered by DC charging stations is not requested. The charging output is assumed to be 3.7, 11, or 22 kW based on VDE 0122-1 (EN 61851-1). The analysis assumes that all vehicles use the same charging output. It does not consider combinations of different charging outputs in order to reduce the complexity of the investigations. The analysis assumes that vehicles being charged on a single phase with 3.7 kW of power are symmetrically distributed among the various phases, so they can be treated like three-phase burdens. Charging rectifiers are assumed to be operated with a power factor of $\cos\varphi_{EV} = 1$, that is, 100% active power, and constant charging current. This assumption is widely valid for many of the currently available EVs.

Exemplary, all the consumers are assumed to be households with an electrification level (EL) of 2. In other words, electric power is used for cooking and other applications, but not for heating or generating hot water. The parameters for the simultaneity function (2) are set to $g_\infty = 0.15$ and $P_s = 8$ kW (Kaufmann, 1995). A conservative power factor of $\cos\varphi_{HH} = 0.9$ (ind.) is used for the household loads (German Government, 2010). The analysis assumes that all the supply systems have a noninterconnected radial topology. This leads to long cables and consequently to high voltage drops. A low voltage cable is assumed to be installed on each side of the street where service entrances are located. Thus, the average distance between the house connections can be assumed according to Table 2. The analysis also assumes that equipment is not loaded past its rated capacity.

The capacity analysis is performed based on expected peak loads. Equipment loading is estimated using a value called *base-level load*. The base-level load is the peak equipment load before the load from the EVs is added. In our model, the base-level load is solely produced by household loads. As this value varies widely depending on local conditions and equipment, it is set up as a variation parameter. The number of households is determined using the simultaneity function (2). The remaining reserve capacity is then incorporated into (3) to calculate the maximum number of EVs that can be connected without violating any operating limits. The number of dwelling units and the number of EVs are used to calculate the maximum penetration p_{max}.

5.2 Analysis of secondary substations

The German VDE 0532 series of standards specifies preferred values for distribution transformer ratings. This

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto284
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

analysis assumes a rated output of 400 kVA. To minimize costs, utilities generally aim for distribution transformers to have an initial load of around 70% (Kaufmann, 1995). As such, the base-level load varies between 60% and 90% of the rated output. The analysis ignores any voltage effect for connected loads, and so the number of low voltage feeders and the line lengths are irrelevant.

Figure 4 charts maximum penetration levels (p_{max}) against base-level loads for the various reference electricity supply systems at a charging output of 11 kW. At a base-level load of 70%, the penetration level ranges from 30% to 80%. This value sinks, as the base-level load rises. Indeed, it is less than 6% in all reference supply systems once the base-level load reaches 90%.

Analyzing the penetration level at different charging outputs shows that only a fraction of the conventional vehicles can be replaced by EVs, given a relatively high base-level transformer load. Even at low loads, it is impossible to completely replace all the vehicles in most cases. The lower the vehicle charging output is, the more vehicles the supply system can support. Supply systems 2, 6, and 8 tend to have higher values because of their lower motorization levels.

Transformers' overload capacity can be used when integrating large, individual loads in the low voltage supply system. If the transformers' overload capacity is exceeded, more powerful transformers can be installed in their stead. If, however, loads are integrated throughout the electricity supply system, it makes more sense to add transformers to the new high load areas and create new supply system segments by relocating the segmentation points. In Germany, the grid was resegmented in this manner in the 1960s when many off-peak storage heaters were connected to low voltage supply systems. Section 5.3 explores the extent to which low voltage power cables limit the ability to connect EVs to the grid.

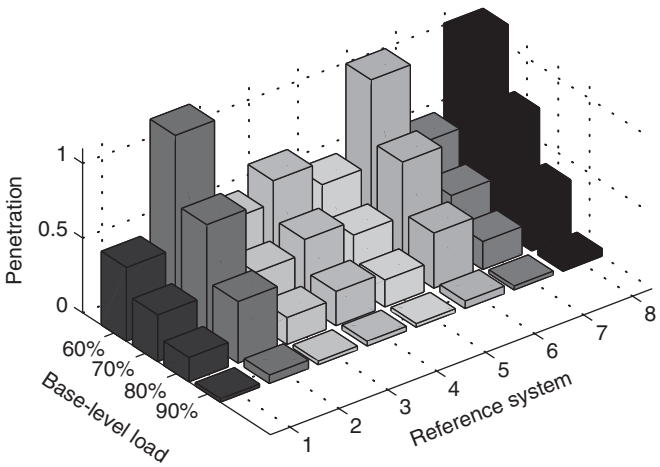

Figure 4. Maximum penetration at a charging output of 11 kW.

5.3 Analysis of low voltage cables

A capacity analysis of low voltage cables requires a different approach, as it needs to consider equipment load, voltage control, and interrupt conditions. This is illustrated by the flow chart in Figure 5. First, the maximum penetration level $p_{max,I}$ is calculated based on current-carrying capacity. The next step is to determine whether the value is restricted by the voltage range limit. This is done by deriving the line length from the number of households. If the interrupt condition is violated for the computed line length, the algorithm aborts. If the interrupt condition is met and no voltage problems occur, the algorithm ends. In this case, the maximum penetration level is determined by current-carrying capacity. If the interrupt condition is met and an unacceptable voltage drop occurs, the number of vehicles is reduced until the voltage limits are met. The maximum penetration level is then outputted as $p_{max,U}$.

This analysis uses NAYY $4 \times 150\,mm^2$ low voltage cables. Their maximum current-carrying capacity is assumed to be $I_z = 275\,A$. A maximum load utilizes around 50% of the cables' capacity, assuming an optimum grid design (Heuck, Dettmann, and Schulz, 2007). The following analyses vary the base-level load of the main lines between 50% and 80%.

5.3.1 Analysis of current-carrying capacity

Figure 6 shows the maximum penetration level at a charging output of 11 kW. At a base-level load of 50%, it is possible to replace at least 80% of all existing vehicles. The penetration level falls rapidly once the base-level load exceeds 50%. At a base-level load of 80%, this value is only between 6% and 15%. Supply systems 2, 6, and 8, by contrast, have higher penetration levels because of their low levels of motorization.

As long as the base-level load remains below 50%, EVs can replace all the vehicles in the reference electricity supply systems for all three charging outputs. This changes at higher base-level loads. While a charging output of 3.7 kW per car leaves plenty of leeway to integrate EVs, this leeway diminishes as the charging output increases. The supply system's capacity becomes extremely constrained when the base-level load exceeds 60% and the charging output is 22 kW per EV.

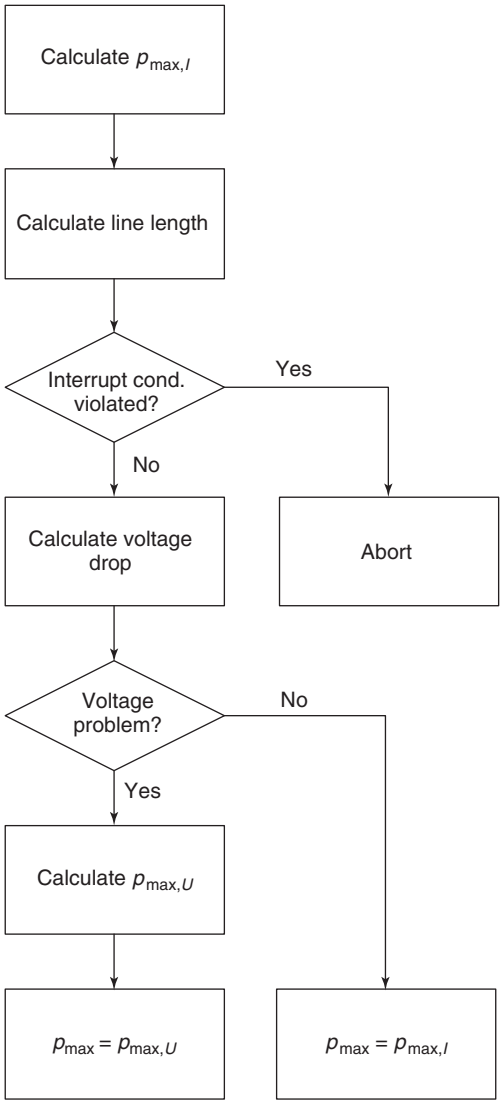

Figure 5. Procedure for analyzing capacity.

5.3.2 *Analysis of voltage control*

This section analyzes voltage control for various load situations. Locally supplying reactive power can increase the grid's transmission capacity (VDEW, 2001). For that reason, the analysis also considers the impacts of having EVs supply capacitive reactive power. First, the general process is explained, starting with the fundamentals. Then, the results are presented.

The voltage drop is estimated mathematically instead of performing a more precise power flow study. The analysis only looks at nonbranching lines—the worst-case scenario in terms of voltage control. In keeping with VDEW (2001), the power factor is assumed to be $\cos\varphi_{EV} = 0.9$ when the EVs supply capacitive reactive power.

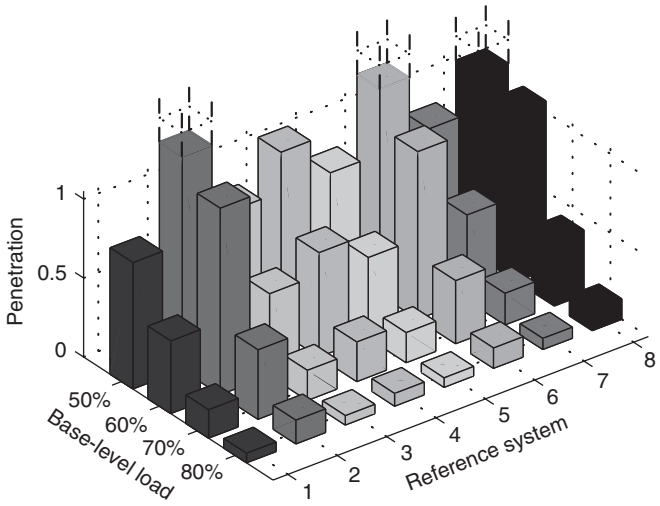

Figure 6. Maximum penetration at 11 kW charging output.

5.3.2.1 Fundamentals. In radial grids, loads spaced along a line can be converted to a lumped load located at the end of a virtual line with a length of $l' = \varepsilon \cdot l$, where it produces the same voltage drop as is observed at the end of the line in the original grid. The conversion factor ε depends on the local load distribution and the size of the individual loads. The maximum allowable line length l_{max} for a given load current I and a maximum voltage drop ΔU_{max} can be approximated by the following function (Nagel, 1994):

$$l_{max} = \frac{\Delta U_{max}}{\sqrt{3} \cdot \varepsilon \cdot I \cdot (r \cdot \cos\varphi + x \cdot \sin\varphi)} \tag{4}$$

In this function, r and x represent the specific line parameters. The load current $\overline{I}$ of the lumped load can be represented as the sum of all individual currents $\overline{I}_i$ at the service entrances:

$$\overline{I} = I \cdot (\cos\varphi + j \cdot \sin\varphi) = \sum_{i=1}^{h} \overline{I}_i \tag{5}$$

The individual currents are approximated based on the complex apparent power consumed by the loads at nominal voltage. The parameter h describes the number of service entrances. The analysis assumes that household and vehicle loads are evenly distributed along the line and that the connected loads are approximately identical. The conversion factor ε can thus be estimated as follows (Nagel, 1994):

$$\varepsilon = \frac{h+1}{2 \cdot h}, \quad \text{for} \quad 0.5 < \varepsilon \leq 1 \tag{6}$$

DOI: 10.1002/9781118354179.auto284
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.3.2.2 General approach. The following approach was used to analyze voltage control. First, the line length l_{HH} is calculated for the reference electricity supply system without the vehicle loads. This requires the number of dwelling units to be determined based on the base-level load of the line. The line length can then be calculated based on the average number of dwelling units per service entrance and the average distance between houses (Table 2). The analysis ignores scenarios that violate the interrupt condition. The maximum line length l_{EV} is calculated using (4) for the load scenario with EVs. If the inequality 7 is true, there is a voltage control problem.

$$l_{EV} < l_{HH} \tag{7}$$

If a voltage control problem is found to exist, the next step is to determine the maximum penetration level $p_{max,U}$ that breaches the voltage range limit. This is done by reducing the number of EVs until the voltage falls within the allowable range. This is an iterative process, as the voltage situation has to be reexamined after every reduction. Finally, the maximum allowable penetration level p_{max} is defined as:

$$p_{max} = \min\{p_{max,I}, p_{max,U}\} \tag{8}$$

To ensure comparability, the active component of charging output was retained in the power factor correction, and an additional capacitive reactive component was added to the charging current. This is a more expensive approach, as it requires a larger charging converter. Problems can also occur if equipment limits are reached at a power factor of $\cos\varphi = 1$.

5.3.2.3 Findings. Reference supply systems 2 and 7 have voltage problems. Reference supply system 2 also violates the interrupt condition and so is not included in the analysis. Table 3 shows maximum penetration levels for reference supply system 7 at various base-level loads and charging outputs. Penetration levels are not constrained until the base-level load exceeds 50%. As the table shows, power factor correction improves the maximum penetration level. Given a base-level load of 60% and a charging output of 11 kW, penetration improves from $p_{max,U} = 20\,\%$ to $p_{max,Q} = 39\,\%$. It does not, however, improve penetration indefinitely. The improvements become insignificant once the base-level load reaches 70%.

Table 3. Maximum penetration for reference supply system 7.

Charging output		Cable base-level load			
		50%	60%	70%	80%
3.7	$p_{max,I}$	1.6	1.00	0.61	0.28
3.7	$p_{max,U}$	1.6	0.67	0.03	0.00
3.7	$p_{max,Q}$	1.6	0.85	0.05	0.00
11	$p_{max,I}$	0.93	0.54	0.20	0.07
11	$p_{max,U}$	0.93	0.20	0.00	0.00

6 SUMMARY

This chapter examined the impact of EVs on the low voltage electricity supply system in Germany. It determined simultaneity patterns for charging EVs, identified reference supply systems for analysis and addressed supply system constraints. These findings were then used to identify general tendencies for the ability of low voltage supply systems to support EVs. The analyses focused on purely residential areas. Our findings suggest that the German federal government's goal of one million EVs by 2020 should cause relatively few problems.

Distribution transformers tend to be the limiting factor for EV deployment. Where transformer loads are high, EVs can replace only a fraction of the conventional vehicles. Indeed, replacing all the vehicles will be hard to achieve, even when loads are low. It is, however, usually fairly easy to replace transformers with more powerful units (Meyer, 1982). For that reason, this analysis looked particularly closely at low voltage power lines.

Line capacity tells a more optimistic story. At line loads of up to 50% of total capacity (not counting EV loads), it is possible to replace all the vehicles associated with dwelling units connected to a particular line in every scenario. Higher loads reduce line capacity—in some cases, by a significant margin. At a charging output of 3.7 kW per car, the electricity supply systems were able to handle the replacement of a large number of conventional vehicles with EVs.

Voltage problems caused by EVs are only likely to occur in unusual cases. In most situations covered in this analysis, EVs exceed the lines' current-carrying capacity before breaching the voltage range limits. Some constraints should be expected if long lines are already heavily loaded before EVs are added. If voltage range limits are violated, EVs equipped with charging converters can provide capacitive reactive power to raise supply system voltage. This increases the percentage of vehicles that can be replaced by EVs. However, this kind of power factor correction only offers improvements within a narrow range.

Until now, low voltage supply systems have been designed to handle expected peak loads. Equipment capacity cannot, however, be fully utilized, as the utilities

do not know their equipment's operating conditions in detail. Moreover, reserves freed up in low load periods are rarely used. These reserves can only be used to charge EVs if the supply system's condition is monitored and charging processes are coordinated. Homes and places of work are ideal charging sites, because the vehicles are parked for long periods at a time.

Ceramic Sensors for Power Train ECU Systems

Akira Fujii, Takehiro Watarai, and Akitoshi Mizutani

DENSO Corporation, Kariya, Japan

1 INTRODUCTION

Although there is currently no fixed definition of the term *ceramic*, it generally refers to an *inorganic compound* comprising two or more materials such as metallic, metalloid, or nonmetallic elements. Under this definition, it should be possible to precisely control the chemical composition, microstructure, microshape, and manufacturing processes of the ceramic materials to achieve the desired function. However, there are exceptions to this general definition. For example, diamond, which consists only of carbon (C), as well as silicon carbide (SiC) and aluminum nitride (AlN) may be referred to as a *semiconductor* or a ceramic depending on the application (Table 1).

These types of ceramic materials have a wide range of properties and are widely used in vehicles both as structural materials and as sensors. Table 2 shows the general properties and applications of ceramic materials.

Materials used for automotive sensors (particularly powertrain sensors which is installed in engine body and exhaust pipe) commonly use ionic bonded oxides formed between metals and nonmetals. This is because the electrically biased bonds created by ionic bonding have many useful electrical properties. These oxides are regarded as a special genre of materials with high mechanical strength that can also withstand high temperatures. This chapter describes the required functions and detection principles of these ceramic sensors. It also outlines the basic technologies that enable the practical adoption of ceramic materials as sensors, and some of the key products. These issues are addressed focusing on typical powertrain sensors such as the O_2 sensor, air/fuel (A/F) sensor, NO_x sensor, temperature sensors, and knock sensors in gasoline and diesel engines, which represent the two main forms of combustion used in vehicles. In this way, the aim is to clearly identify categories of sensors falling under different combustion methods based on variations in installation position and environment, detection objects and methods, as well as the forms of sensor products.

2 CERAMIC SENSOR APPLICATIONS IN GASOLINE ENGINES

2.1 Overview

Figure 1 shows the installation positions of some typical ceramic sensors in a gasoline engine.

A gasoline engine functions by compressing and combusting intake air and injected fuel in a combustion chamber. The combusted waste gas is then directed to a catalytic converter through the exhaust manifold and exhaust pipes to treat toxic components. Along this route, an A/F sensor or an O_2 sensor is provided immediately

Table 1. Relationship of compound categories and ceramic materials.

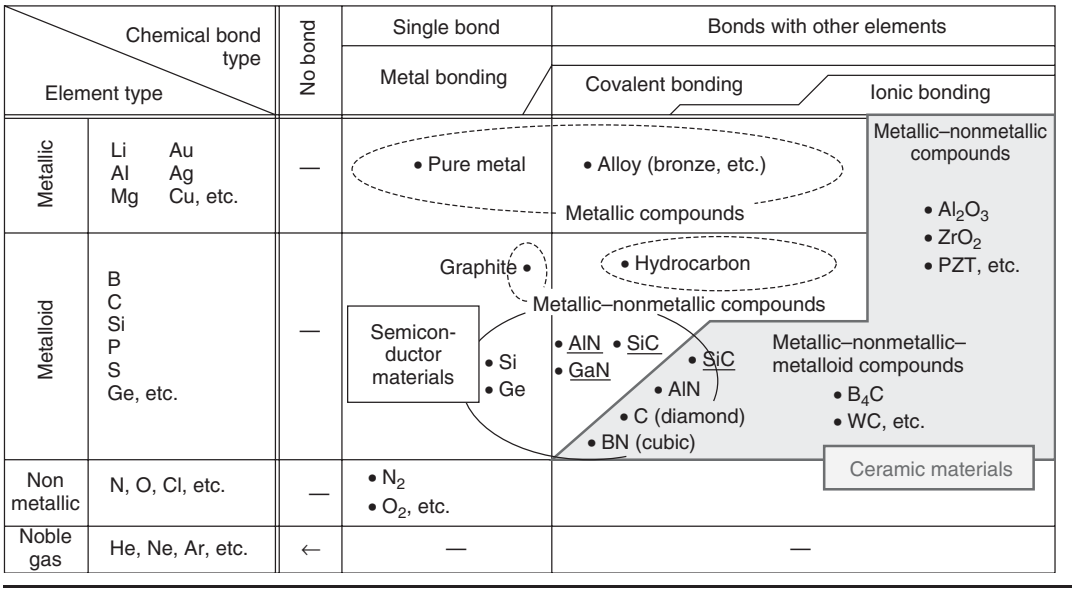

Table 2. Functions of ceramic materials and automotive applications.

Properties		Functional capabilities	Applications
Mechanical		- High-strength - Light - Deformation resistant	- Turbo rotors - Substrates for catalyst carriers - Particulate filters - Heat sink
Thermal		- High melting point - Little thermal expansion - High or low thermal conductivity - Converts heat energy to electrical energy	
Electrical	Ionic conductivity	- Ions conduct as carriers	- O_2 sensors, A/F sensors, NO_x sensors
	Thermistor properties	- Resistance changes due to heat	
	Piezoelectricity	- Mechanical $\Longleftrightarrow$ electrical energy conversion	- Temperature sensors
	Pyroelectric and thermoelectric	- Thermal $\Longleftrightarrow$ electrical energy conversion	- Knock sensors
	Varistor properties	- Resistance changes due to electric field strength	- Varistors
	Electron conductivity	- Conducts or acts as semiconductor	- Semiconductors
	Dielectric properties	- Insulates from electricity - Stores electricity	- Plug insulators, - Capacitors
Magnetic		- Becomes magnetized	- Magnets for motors
Photo		- Transmits and absorbs light - Converts light to electricity	- Ultra-violet ray blocking glass

below the exhaust manifold, and another O_2 sensor is installed after the catalytic converter. The purpose of the A/F sensor or O_2 sensor immediately below the exhaust manifold is to control combustion by detecting and transmitting the concentration of oxygen in the exhaust gas so that toxic components can be efficiently eliminated by the catalytic converter. Either type of sensor is used based on differences in the required format of the oxygen concentration signal.

In contrast, the sensor after the catalytic converter is almost always an O_2 sensor because of the required signal format and the moist environment in this location. This O_2

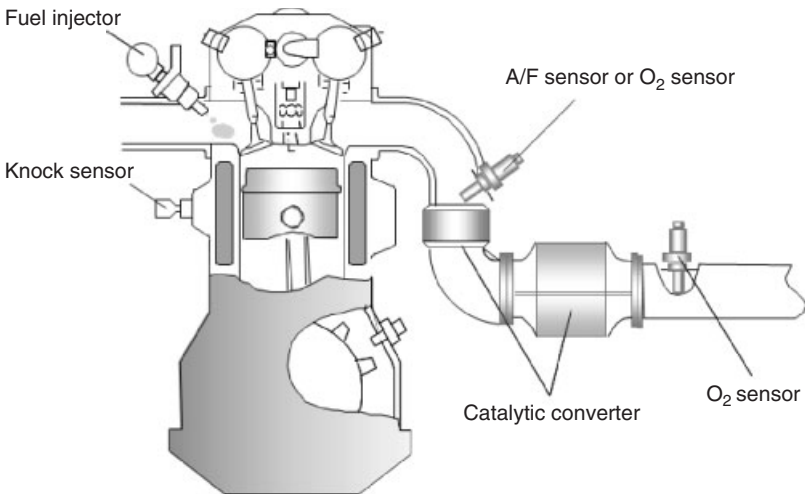

Figure 1. Installation positions of ceramic sensors in gasoline engine.

sensor uses oxygen concentration to detect small quantities of NO_x and hydrocarbons (HCs) that leak from the catalytic converter as the catalyst degrades. However, as a result of continuing advances in research, further optimized sensors are beginning to enter the market (Ito, 2011).

The knock sensor is installed on the engine block close to the combustion chamber. If the combustion frequency is in a range equivalent to that generated by engine knocking, the knock sensor converts the mechanical vibration into a direct electrical charge and transmits this value to the electronic control unit (ECU). The ECU then controls combustion to prevent knocking.

The sensors described earlier are installed in the necessary locations to obtain the signals for controlling combustion or treating the exhaust. These positions are optimized factoring in the restrictions of the environmental conditions. The following sections describe each sensor in more detail.

2.2 O_2 sensor

2.2.1 *Required functions*

In a gasoline engine, O_2 sensors are used to control combustion. The power of a gasoline engine is determined by the amount of fuel supplied with respect to the intake air volume. The mass of air divided by the mass of fuel in the mixture is referred to as the *A/F ratio*. The actual combustion reaction in the cylinder is defined by the following formula:

$$C_xH_y + \left(x + \frac{y}{4}\right) O_2 \rightarrow xCO_2 + \frac{y}{2}H_2O$$

This chemical reaction formula shows that there is an optimum A/F ratio at which the fuel is completely combusted and converted into carbon dioxide and water. For a gasoline engine with 100% octane fuel (C_8H_{18}), 14.7 g of air are necessary to completely combust 1 g of gasoline. This means that the optimum A/F ratio is approximately 14.7. The A/F ratio that satisfies this relationship is known as the *theoretical* A/F ratio. The amount of deviation from the theoretical A/F ratio is called the *excess air ratio*, which is generally depicted using the lambda symbol (λ). This is defined as follows:

$$\lambda = \frac{\text{actual A/F ratio}}{\text{theoretical A/F ratio}}$$

When λ is calculated, a state with a relatively high amount of fuel compared to the theoretical A/F ratio (i.e., $\lambda < 1$) is referred to as the *rich* condition and a state with a relatively low amount of fuel (i.e., $\lambda > 1$) is referred to as the *lean* condition. Under theoretical A/F ratio conditions, $\lambda = 1$.

In a conventional gasoline engine, combustion is controlled so that $\lambda = 1$, which represents the most efficient range for exhaust treatment. To achieve this A/F ratio, a ceramic O_2 sensor with ionic conductivity is installed directly under the exhaust manifold. This sensor examines exhaust gas directly after combustion and transmits the postcombustion oxygen concentration to the ECU.

2.2.2 *Detection principle*

Figure 2 shows an outline of the element used in an O_2 sensor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto285
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

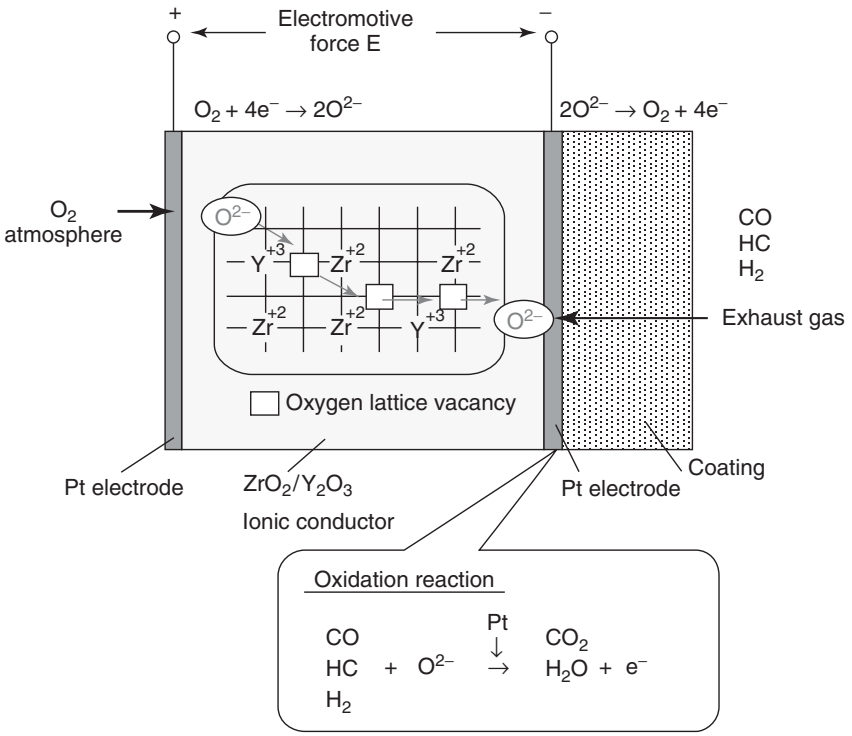

Figure 2. Outline of O_2 sensor element.

In this sensor, the material used to detect the oxygen concentration is a solid solution of zirconia and yttria (ZrO_2/Y_2O_3). This material is placed between platinum (Pt) electrodes to form the element. At high temperatures of approximately 300°C when a difference in oxygen concentration occurs between the electrodes on each side, oxygen ionizes because of the catalytic action of the Pt and transfers through oxygen vacancies in the zirconia crystal lattice. The movement of these ions is detected as a voltage. The resulting electromotive force E is then applied in accordance with the following Nernst equation:

$$E = \frac{RT}{4F} \ln \frac{(P_{O_2})_I}{(P_{O_2})_{II}}$$

F : Faraday constant

R : gas constant

T : absolute temperature

$(P_{O_2})_I$: oxygen partial pressure on atmosphere electrode side

$(P_{O_2})_{II}$: oxygen partial pressure on exhaust electrode side

The electromotive force E exhibits different aspects under lean and rich conditions. Under lean conditions, virtually no electromotive force is generated because there is hardly any difference between the oxygen concentrations at the atmosphere side (approximately 20%) and exhaust side electrodes. In contrast, under rich conditions, unburned HC, CO, and H_2 are combusted at the exhaust side electrode by the oxidative action of the Pt. Consequently, electromotive force E is generated in excess of the Nernst equation. This oxidation reaction continues until the combustion reaches chemical equilibrium and the O_2 concentration in the exhaust gas drops promptly after the reaction is completed. As a result, electromotive force increases dramatically at the rich side when lower than theoretical A/F ratio conditions. This electromotive force acts as the output of the O_2 sensor. Figure 3 shows the relationship between the A/F ratio and the sensor output and catalyst treatment efficiency. When electromotive force is generated, the ECU judges that the state has switched from lean to rich and outputs a fuel injection signal to recover the lean conditions. Therefore, the ECU control uses changes in the signal from the O_2 sensor as a trigger to increase or decrease the fuel injection quantity. In this way, the combustion is constantly controlled to a state close to the theoretical A/F ratio,

and the exhaust gas treatment rate is kept high at all times.

2.2.3 *Technology and product overviews of O_2 sensor*

Figure 4 shows the structure of the detection element in a cup-type O_2 sensor.

The detection element uses a cup-shaped zirconia/yttria ionic conductor as the base material, enclosed on the inner and outer sides by Pt electrodes. The outer electrode is exposed to the exhaust gas and the inner electrode acts as the atmosphere electrode. The outermost shell of the exhaust side electrode is coated to protect the electrode from the exhaust gas. Figure 5 shows the structure of the O_2 sensor.

An O_2 sensor consists of an element for detecting the A/F ratio, a heater for the zirconia, element covers to protect the sensing portion from exposure to items such as condensation in the exhaust pipe, and a case that outputs the sensor signals and the like. As O_2 sensors operate within the exhaust gas, the operating environment is subject to high temperatures, vibration, and foreign substances. For this reason, material selection and structural design from the element to the case must consider resistance against heat, vibration, and foreign substances. Sealing performance is also a critical design requirement to prevent external leaks

of exhaust gases. Figure 6 shows the appearance of an O_2 sensor that satisfies these technological and design requirements.

2.3 A/F sensor

2.3.1 Required functions

In contrast to an O_2 sensor, which outputs a trigger signal using the theoretical A/F ratio ($\lambda = 1$) as the threshold value, an A/F sensor meets strict low emission vehicle (LEV) exhaust regulations by outputting a continuous signal over a wide range of exhaust gas atmospheres and activating immediately after engine start. These two features enable even more precise combustion control. The key points for realizing these two features are how to make the ionic conductor trigger into a continuous action and how to activate the sensor as quickly as possible. Although the material, characteristics, and functions of the ionic conductor are the same as described in Section 2.2.2, the detection principle and product configuration of the A/F sensor to achieve these two features greatly differ from that of an O_2 sensor.

Recent requirements of A/F sensors include the detection of variations in combustion between cylinders and greater robustness with respect to H_2 generated by engine combustion. Research and development of A/F sensors that satisfy these requirements has been published (Su *et al*., 2011; Yamamoto *et al*., 2010; Suzuki *et al*., 2010).

2.3.2 Detection principle

In the same way as O_2 sensors, A/F sensors also use the conduction of oxygen ions for detection. However, A/F sensors utilize a different element structure to detect the A/F ratio continuously under the principle of early activation (Figure 7).

The A/F sensor detection element has a rectangular external shape. The internal structure is layered with cavities and dense structures. The cavity in the center of the element allows the inflow of the atmosphere. The zirconia ionic conductor and two Pt electrodes are located between that cavity and a diffusion resistance layer that allows inflow of the exhaust gas. The diffusion resistance layer performs the same role as the O_2 sensor coating. However, it also has an upper shield layer that provides a certain distance and resistance for the exhaust gas flowing to the exhaust gas side electrode. A heater is embedded in the bottom portion of the element. The heater, which mainly comprises Pt on an alumina-base (Al_2O_3) material, heats the zirconia by conduction. This structure enables the A/F ratio to be detected continuously and immediately after engine start.

In an A/F sensor, under rich conditions, voltage is applied (in a process known as *pumping*) so that the atmospheric oxygen in the internal cavity is transported electrochemically as oxygen ions. This is carried out to calculate the necessary O_2 volume for reacting with the unburned gas under rich conditions. This O_2 volume is called the *pump current* (*IP*). This current is virtually proportional to the concentration of unburned gas, that is, the A/F ratio. In this control, it is necessary to limit the movement of unburned gas using the level of pumping performance. For this reason, a diffusion resistance layer is formed. In contrast, under lean conditions, a voltage is applied to expel excessive O_2 that passes through the diffusion resistance layer. The direction of applied voltage is reversed in either rich or lean conditions using the theoretical A/F ratio as a threshold.

Under rich conditions, IP does not increase in accordance with the applied voltage but reaches saturation because the diffusion resistance layer limits the diffusion of the exhaust gas components. This saturated current is called the limit current (IL). In contrast, under lean conditions, the O_2 volume that passes through the diffusion resistance layer

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

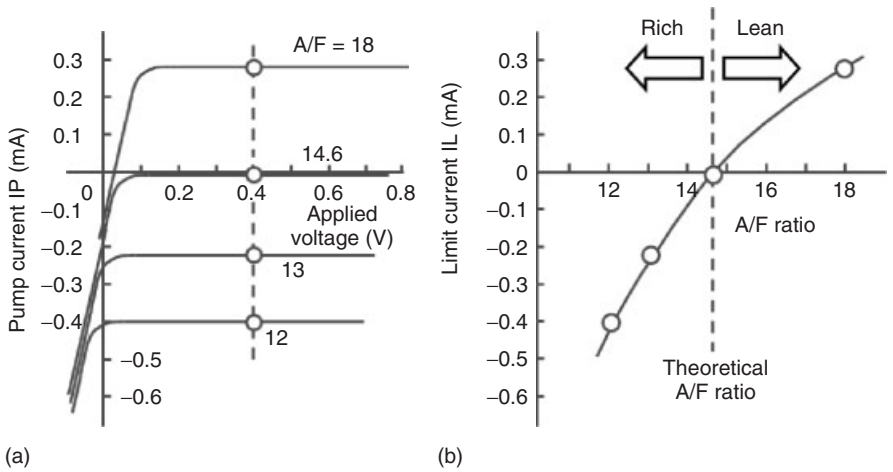

Figure 8. Control and output characteristics of A/F sensor. (a) Relationship between applied voltage, IP, and A/F ratio. (b) Relationship between A/F ratio and IL.

is detected as the emitted current. Therefore, the A/F ratio can be detected continuously in a wide range from A/F = 10 to A/F = atmosphere by measuring IL in both rich and lean conditions. Figure 8 shows the output characteristics of the A/F sensor.

The control and output of the A/F sensor described earlier starts to be obtained when the element temperature is maintained at around 700°C. For this reason, the element is embedded with a conduction heater mainly composed of Pt, which enables early activation of the sensor immediately after engine start. Activation takes only a few seconds.

2.3.3 Technology and product overviews of A/F sensor

Figures 9 and 10 show the structure and appearance of an A/F sensor, respectively. The sensor consists of a rectangular detection element, a cover to protect the sensing portion from exposure to items such as condensation in the exhaust pipe, and a case that outputs the sensor signals and the like.

2.4 Knock sensor

2.4.1 Required functions

In a conventional gasoline engine combustion process, the mixture is ignited by a spark plug, which then spreads throughout the cylinder by flame propagation. However, self-ignition of mixture around the outside of the cylinder before the conventional flame propagation process results in the generation of a shock wave. Cylinder block vibration caused by this shock wave is then transmitted to the atmosphere. This phenomenon is referred to as *knocking*.

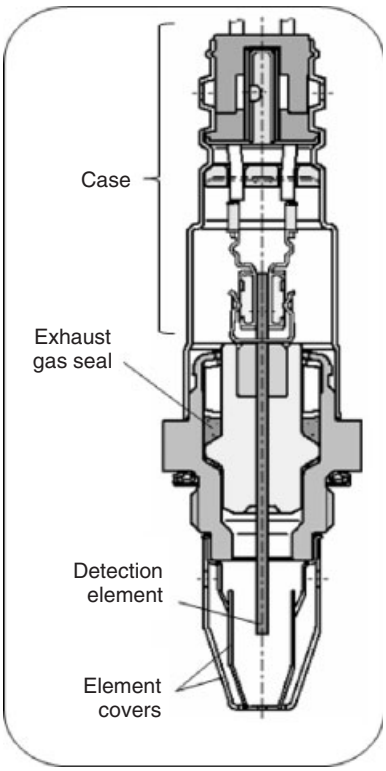

Figure 9. Structure of A/F sensor.

Figure 10. Appearance of A/F sensor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto285
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In a knock control system, the knock sensor is directly attached to the cylinder block. Piezoelectric ceramic material provided in the knock sensor detects the vibration caused by knocking and transmits it to the ECU as a voltage signal. The purpose of the knock control system is to improve both engine power (output torque) and fuel efficiency by controlling the ignition timing to a position extremely close to the engine knock region, without actually entering that region. It accomplishes this control by retarding and advancing the ignition timing in accordance with the degree of knock.

2.4.2 *Detection principle*

The detection element built into the knock sensor is mainly composed of lead zirconate titanate (PZT), a compound that is expressed by the following chemical formula: $Pb(Zr \cdot Ti)O_3$. The sensor uses the piezoelectric properties of this material (Table 2) to convert the applied vibration into electrical charge, which is then output to the ECU. Figure 11 shows the crystalline structure of PZT.

The PZT compound shown in the figure has a cuboid crystal lattice that is referred to as *tetragonal*. Each unit of this crystal possesses a quantity of electricity called *spontaneous polarization* because the position of the central Zr or Ti ion is displaced from the lattice center. However, if this material is left in a bulk-sintered state, the direction of the spontaneous polarization shown by the arrow in the figure becomes random. As a result, the total quantity of electricity possessed by the bulk may cancel itself out. Although the material cannot be used as a detection element in this state, the spontaneous polarization direction can be aligned by applying a high voltage to the bulk so that the bulk possesses a quantity of electricity. If mechanical displacement is applied to the detection element, the total quantity of electricity possessed by the bulk changes, which enables the admission and release of electrical charge. This property is called the *piezoelectric effect*. Figure 12 illustrates a state in which electrical charge is generated by compression.

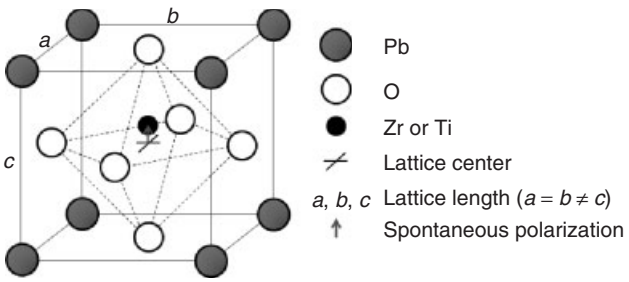

Figure 11. Crystalline structure of PZT.

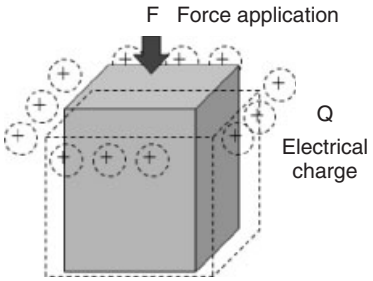

Figure 12. Piezoelectric effect.

Although the electrical charge generated by mechanical displacement is small, a sizeable charge can be obtained if the frequency of the applied vibration matches the resonance frequency as determined by the mass, dimensions, and Young's modulus of the PZT bulk, as resonant vibration causes the mechanical displacement to increase. The knock sensor generates its electrical charge after exposure to displacement caused by the resonance of the assembly. Therefore, the resonance frequency of the detection element (which is determined by the total frequency generated by the components used to fix the knock sensor, the weight used to increase the mechanical displacement, and the physical properties of the surrounding parts) must either be designed to match the frequency of engine knocking (i.e., a resonant knock sensor) or a large enough detection element or additional weight must be provided so that a sufficient electrical charge is generated even without resonance (i.e., a nonresonant knock sensor). Conventional detection elements have an outside diameter of several millimeters and a thickness of approximately 0.5 mm in the case of resonant knock sensors. Nonresonant knock sensors are cylindrical and have an outside diameter of several tens of millimeters and a thickness of approximately 5 mm. Both types have a silver electrode coated on the top and bottom surfaces of the PZT material to extract the charge. A hole is provided in both types to facilitate the fixing of the sensor.

In a resonant knock sensor, the detection element consists of a piezoelectric ceramic material adhered to a plate that acts as a diaphragm. The detection element is embedded in the sensor and generates voltage because of the resonance that occurs when the knock frequency matches the natural frequency of the diaphragm. In contrast, a nonresonant knock sensor combines the piezoelectric ceramic material with a weight to form the detection element. Vibration from the engine changes the force on the weight (i.e., generates acceleration), which compresses the piezoelectric ceramic material and generates the voltage. This type of sensor has flat frequency characteristics without a resonance point in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto285
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

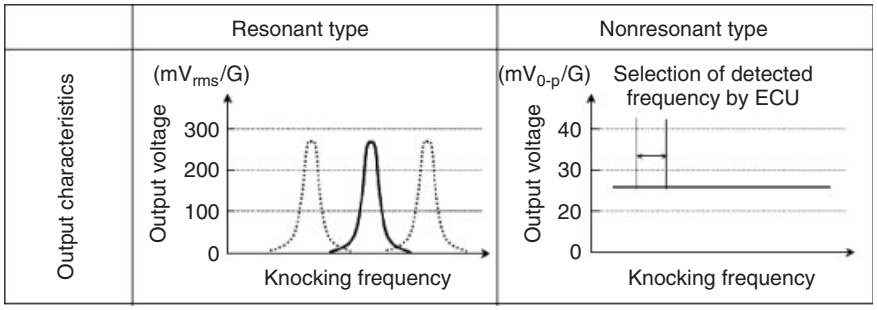

Figure 13. Output characteristics of knock sensors.

the detection frequency range. Figure 13 shows examples of the output from both types of knock sensors.

It should be noted that the output voltage on the vertical axes in Figure 13 differ in accordance with the size of the device and the permittivity (equivalent to the capacitance) of the material, as well as the size of the resonance gain and acceleration. Therefore, the absolute output value of a particular knock sensor may differ from that shown in the figure.

Nonresonant type sensors have several merits. The use of this type of sensor allows the system to electrically select the desired signal frequency and to change the selected frequency in accordance with the engine load. This reduces the work hours required to adapt the sensor to the engine and also improves the accuracy of the system. For these reasons, nonresonant knock sensors are the most commonly adopted type. The output of a nonresonant knock sensor is expressed by the following equation:

$$V = \frac{m \bullet a \bullet g_{33}}{C}$$

V output voltage
M mass of weight
a acceleration
g_{33} piezoelectric constant
C capacitance of PZT.

2.4.3 *Technology and product overviews of knock sensor*

The knock sensor is directly attached to the engine cylinder block to detect knocking. Figure 14 shows the structures of a resonant and nonresonant knock sensor.

A resonant knock sensor contains a thin circular element pierced with a hole that is adhered onto a plate to adjust the resonance frequency to the engine knocking frequency. In contrast, a nonresonant knock sensor has a thick cylindrical element pierced with a hole that is attached to a base along with a weight. Both types must be attached with care as the adhesion and tightening conditions as well as the state of the part itself affect the resonance frequency and output characteristics. Figure 15 shows the appearance of a nonresonant knock sensor and Figure 16 shows its attached state.

3 CERAMIC SENSOR APPLICATIONS IN DIESEL ENGINES

3.1 Overview

Diesel engines are more thermally efficient than gasoline engines and, therefore, have lower CO_2 emissions. However, because diesel engines with high power and low emissions are more complex than gasoline engines, a more sophisticated system configuration and more sensors are required. This section describes the NO_x sensor and exhaust gas temperature sensor (EGTS) as examples of ceramic sensors used in a diesel engine. Figure 17 shows the installation position of these sensors.

3.2 NO_x sensor

3.2.1 Required functions

A diesel engine has a larger intake air volume than a gasoline engine. It compresses this air in the cylinder, creating a high temperature that causes directly injected fuel to self-ignite and combust. However, incomplete combustion leads to the generation of soot, and NO_x is generated if the combustion temperature is too high. A NO_x sensor detects the concentration of NO_x to the order of parts per million (ppm) generated by diesel engine combustion. It is used to control and run diagnostics on the exhaust emission control devices.

3.2.2 Detection principle

Figure 18 shows the detection element of a NO_x sensor. The element comprises a pumping cell for expelling oxygen and a sensing cell for detecting NO_x. The electrodes of the former are Pt, whereas the latter is mainly rhodium (Rh). The cells are connected to a heater that enables early activation by electrical heating.

The detection principle is similar to the A/F sensor. O_2 and NO_x enter a chamber through the diffusion resistance layer. O_2, which enters the chamber in the order of parts per hundred (percent) as opposed to NO_x that enters as ppm, undergoes ionic conduction faster than ppm NO_x. As a result, this O_2 blocks NO_x detection and causes noise. Therefore, NO_x is reacted by itself at the detection electrode after the O_2 is expelled by the oxygen expulsion electrode. The detection electrode uses an Rh catalyst to separate NO_x into N_2 and O_2. Ionic conduction is performed within the zirconia, and the O_2 quantity is detected as an electrical current to measure the NO_x concentration.

3.2.3 Technology and product overviews of NO_x sensor

The structure of a NO_x sensor consists of a detection element, covers to protect the sensing portion from exposure to items such as condensation in the exhaust pipe, and a case that outputs the sensor signals and the like. In addition, to enable the detection of NO_x at the ppm level, the sensor is integrated with a circuit to output the detection results. More recently, the size of the control circuit is becoming smaller to improve mountability. Figure 19 shows the structure of a NO_x sensor.

3.3 Exhaust gas temperature sensor (EGTS)

3.3.1 Required functions

Vehicles use a wide variety of sensors to measure the temperature of coolant, oil, intake air, exhaust, and the like. Of these, an EGTS is used in several systems, such as for diesel particulate filter (DPF) control, NO_x catalyst control, urea SCR (selective catalytic reduction) control,

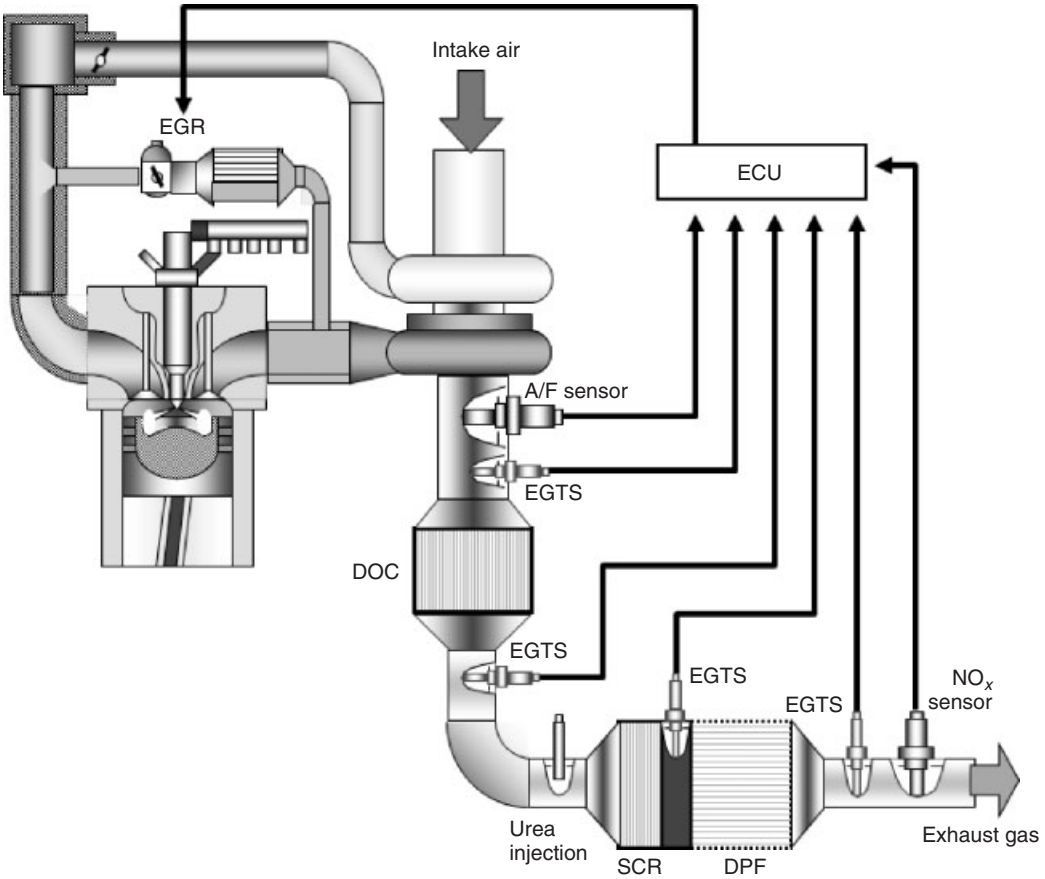

Figure 17. Installation positions of ceramic sensors in diesel engine.

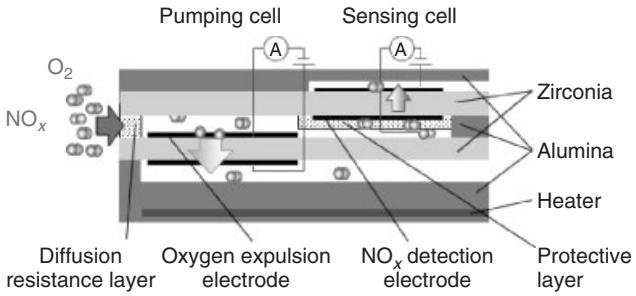

Figure 18. Detection element of NO_x sensor.

turbocharger protection, catalyst on-board diagnostics (OBD), and the like. For this reason, an EGTS is required to measure a much wider temperature range (from low temperatures to approximately 1000°C) than a normal temperature sensor. It is also required to measure temperature highly accurately with a fast response to enable precise exhaust gas temperature feedback control. Another requirement is the durability to resist both high temperatures and vibration. Although some automotive EGTS use the temperature characteristics of metal resistors or a thermocouple, ceramic sensors use the characteristics of a thermistor (Table 2).

3.3.2 *Detection principle*

A thermistor is a type of resistor with an electrical resistance that varies widely in accordance with changes in temperature. Some thermistor materials are categorized as having a positive temperature coefficient (PTC), in which the resistance increases as the temperature rises. Others have a negative temperature coefficient (NTC) in which the resistance decreases as the temperature rises. NTC thermistors are widely used for automotive EGTS.

The relationship between temperature and resistance in an NTC thermistor is expressed by the following equation:

$$R = R_0 \exp\{B(1/T - 1/T_0)\}$$

where R is the thermistor resistance at the absolute temperature T, R_0 is the thermistor resistance at the

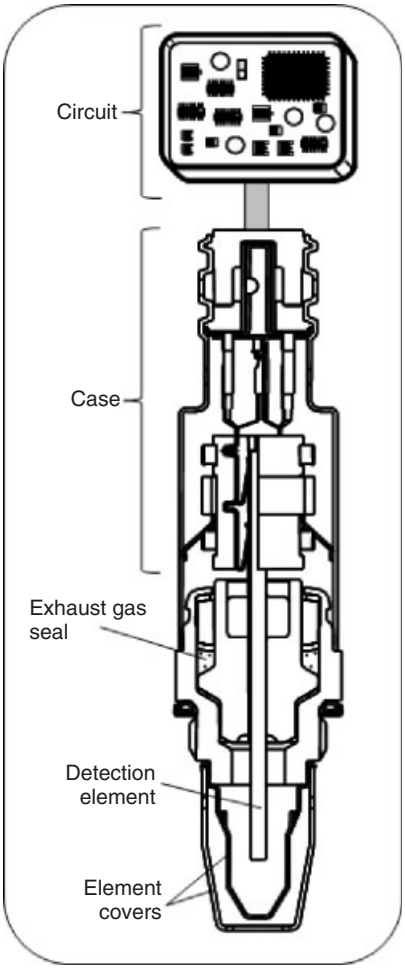

Figure 19. Structure of NO_x sensor.

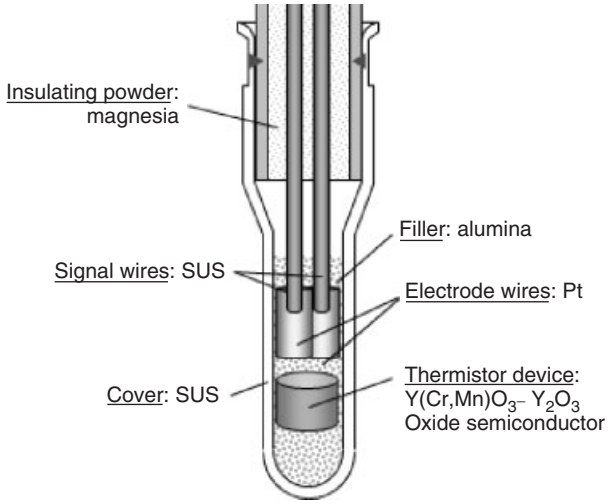

Figure 20. Detection element of EGTS.

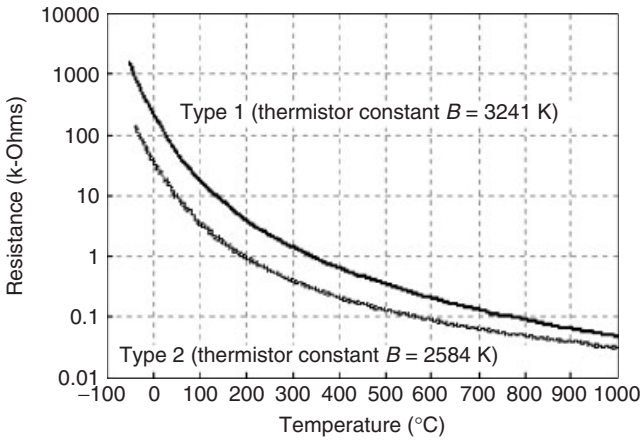

Figure 21. Typical thermistor characteristics.

absolute temperature T_0, and B is the thermistor constant. The thermistor constant B expresses the sensitivity to temperature and differs depending on the thermistor material.

Conventional thermistors satisfy the requirement for high temperature durability by using perovskite oxide semiconductor materials because of their excellent stability at high temperatures. Homogenous mixing and extra-precision molding technology of thermistor materials enable highly accurate measurement as well as the development of smaller thermistors and faster response by reducing the size of the temperature-sensitive portion. Figure 20 shows the configuration of the temperature sensing detection element of an EGTS.

The thermistor material is a mixture consisting of a $Y(Cr \cdot Mn)O_3$ oxide semiconductor material and a Y_2O_3 insulator. The proportion of the mixture can be varied to adjust the thermistor resistance and the thermistor constant B can be adjusted by changing the ratio of Cr and Mn in the semiconductor material. Figure 21 shows the typical characteristics of a thermistor. Type 2, which has a smaller thermistor constant B, is capable of measuring a wider temperature range than type 1.

3.3.3 *Technology and product overviews of EGTS*

The detection element shown in Figure 20 is provided with a cover to prevent degradation because of exposure to the exhaust gas. It also has a ceramic filler (alumina) inside the metal cover that holds the thermistor device to prevent vibration from fracturing the electrode wires (Pt). These measures ensure that the EGTS satisfies the requirement for high durability.

Figure 22 shows the basic structure of an EGTS. It is screwed to the exhaust pipe by a boss attached to the pipe

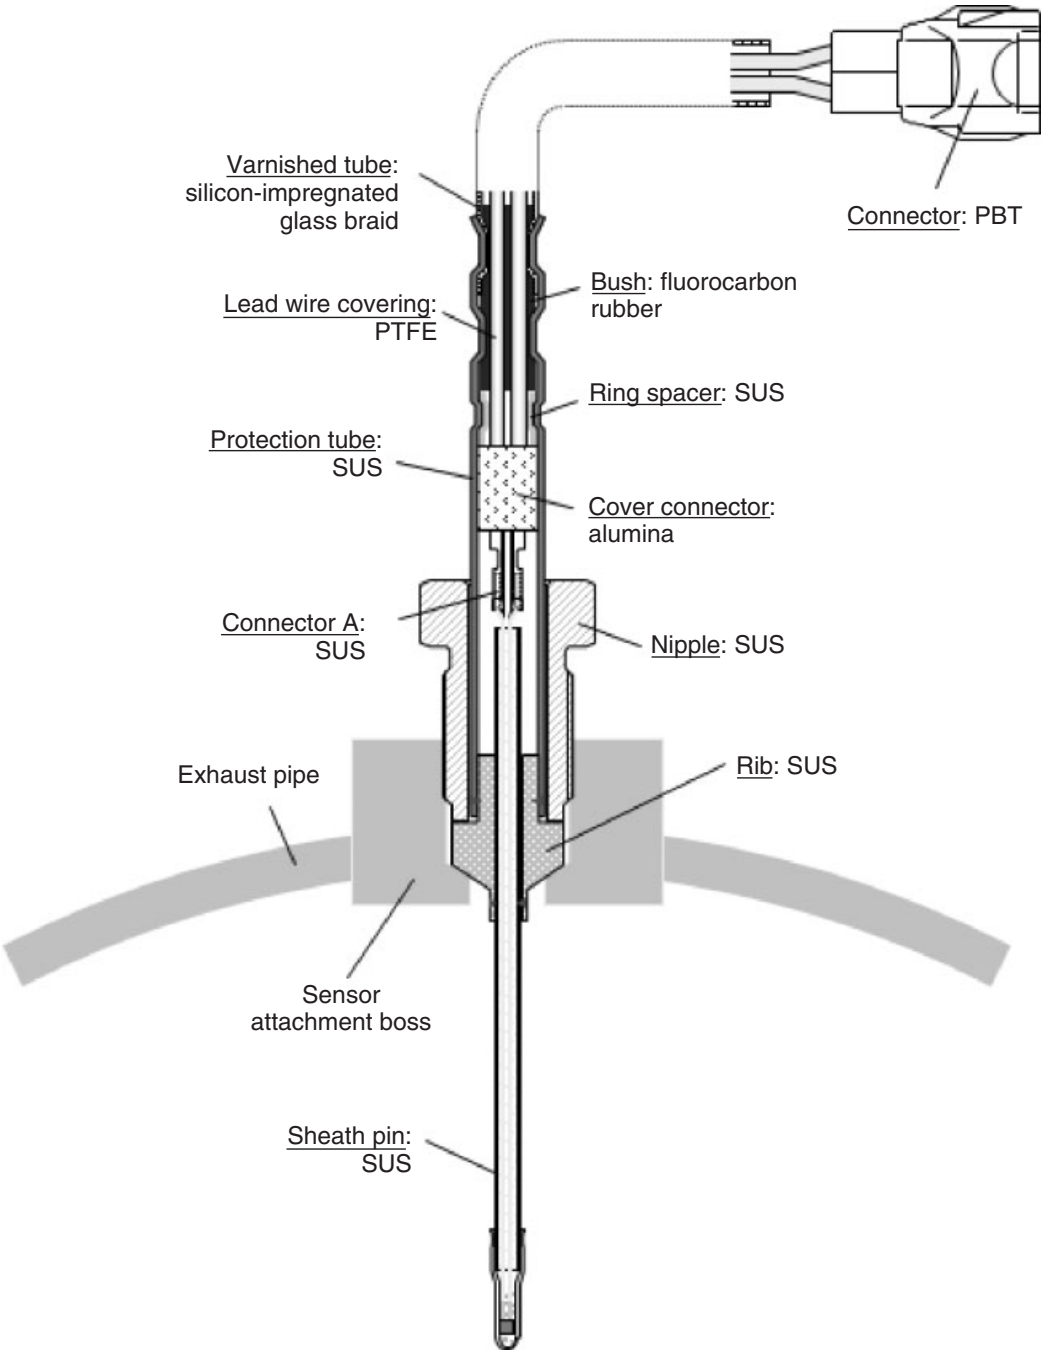

Figure 22. Basic structure of EGTS.

and a nipple. A caulked rubber bush acts a waterproof protection tube. Generally, the EGTS protrudes into the exhaust pipe by 30–50 mm.

Figure 23 shows the appearance of a general EGTS and a long-type EGTS. There is increasing demand for the long-type EGTS because of the recent requirement for more accurate measurement of the temperature in the center of the DPF to improve the efficiency of DPF regeneration. As increasing the length of the EGTS has a major negative effect on durability, a long-type EGTS with the vibration-damping structure shown in the figure has also been developed (Hori and Todo, 2009).

4 THE FUTURE OF CERAMIC SENSORS

Engine control is likely to become even more sophisticated and complex as demands for CO_2 reduction and the depletion of fossil fuel resources intensify. Consequently, the number of required parameters will increase, making detection more difficult. The detection of new parameters is another likely requirement in the future. Smart sensor functions that use communication to increase the efficiency of development and adoption work and sensor simulations compatible with model-based development are also beginning to enter the mainstream.

Ceramic sensors are currently being used in locations that best fulfill their capabilities, such as those that require the unique functions of ceramic materials and high durability. However, many ceramics are expensive or use toxic materials, and some are difficult to obtain a stable supply. Other methods will have to be considered unless sensors can be developed that meet the requirements of the customer at a reasonable cost.

Further research is required to enable wider future acceptance of ceramic sensors capable of playing a key role in society and to ensure that ceramics are not left behind as development trends change.

Body Design, Overview, Targeting a Good Balance between All Vehicle Functionalities

Gerhard F. K. Tecklenburg

Hochschule für Angewandte Wissenschaften (HAW), Hamburg, Germany

1 INTRODUCTION

Comprehensive and careful planning is required to meet the numerous conflicting design and manufacturing constraints in the development of a new passenger car that is to be produced in large batches.

Is it necessary to update a vehicle in production (facelift) or to develop the replacement of a successful car? Does it make sense to fill a market niche with a novel vehicle concept or to develop a new market (e.g., emerging markets such as China or India)? Which basic model and which derivates on the basis of which platform should be developed of which should a platform be developed? A number of duties and responsibilities are generated for development, production, and sales from the answers to these questions.

Sales influences the decision-making process for every new vehicle. Therefore, before and parallel to the development process, detailed actions of market and competition analysis are taken up to define and approve vehicle characteristics (e.g., body shape, variants of equipment) and the exact competition positioning (e.g., market segment, customer orientation) in complete lists of objectives for design (styling) and concept development. From these lists of objectives, lists of requirements are elaborated in full detail by project management, advanced design (styling), and concept development for all vehicle areas and assemblies.

Internal and external, national and international driving tests with competitor and company cars in the early concept phase are part of the competition analysis to systematically compare, for instance, full vehicle integration, interior, and access to the vehicles and/or components. Disassembling of competitor vehicles delivers detailed information regarding material, weight, manufacturing sequences, part and tooling costs, and so on.

Furthermore national and international car clinics are organized in the different phases of development to confront potential customers with latest design models, seating mock-ups, concept cars, or prototypes, and to conduct, record, and evaluate detailed interviews.

Toward the end of the concept development phase, sales defines the ideal variants of equipment together with technical development, design (styling), finance, and production according to technical, creative, and, in particular, financial arguments.

According to market launch strategies, for example, for the exploration of a new market niche, show cars are presented on motor shows more than two years before start of production (SOP) to selectively evaluate the resonances of potential customers, dealers, and specialized press. Sales develops adequate communication/ advertising and market launch strategies with, for instance, extensive press and dealer presentations with pilot series vehicles under support of digital processed material before SOP.

To start the development according to the preparations of sales, all relevant initial strategic plans are chalked out by a product strategy committee. The overall responsibility is assumed by a member of the chief executive committee of the original equipment manufacturer (OEM) or by a management representative appointed for the project. Once the product strategy committee has decided to launch a new automobile project, the product evolution process (PEP) is prepared, comprising product planning, product development, and production planning. For this purpose, the OEM has defined master processes permitting the detailed planning of the project and the reliable validation of the maturity levels. The nature of the development project (e.g., a face-lift or a completely new passenger car) determines the duration and the details of the development and planning scope of the required product development processes.

Independent of a specific automobile project, the OEM and system suppliers continuously monitor the market. This often leads to general investigation and research projects that are independent of specific car or system developments. The PEP comprises analyses, definitions, and coarse and detailed design steps, which are iteratively performed, often jumping back and forth within the steps, and finally leading to optimized solutions.

The development of a new automobile is generally performed independent of the powertrain development. Several other modules and components such as front seats or axles and suspension systems are rarely developed with reference to a specific car project, that is, they remain unchanged in their basic design and are only adapted to the special requirements of the car project.

The tasks of product development of the automotive body and full vehicle integration are shared between different technical disciplines (Figure 1) situated at the OEM, the suppliers, and engineering services working for the OEM. In the discipline of systems layouts, the main engineering task is to develop the electric and electronic concepts for driving, comfort, operating, display, infotainment, air-conditioning systems, and so on, with efficient energy management and most intelligent logic. Important boundary conditions are cost efficiency, design space, ability for diagnoses, and safety. The main tasks of engineers working for the discipline of functional layouts are to lay out or proof and optimize components of sub- and total systems according to loads and strains defined for driving performance, active and passive safety, emissions, climatic and acoustic comfort, and so on, by legislation, institutions for consumer safety assessment, or the OEM itself. The main boundary conditions are to minimize the use of material, design space, energy, weight, and so on, and to maximize the performances. The automotive body engineers working for the discipline of geometrical forms and functions layouts

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are responsible for laying out the shape and safeguard the geometrical functions of parts and assemblies of the automotive body, exterior and interior systems, accounting for ergonomic requirements, styling demands, and existing platform and modularization concepts. Relevant requirements are defined by legislation, the geometric function of the parts and assemblies, as well as tooling and assembly (Albers, 2012).

Besides the layout work, automotive body engineers are responsible for the fulfillment of all system, functional, and geometrical requirements for the components they authorize. Body engineers control the PEP for their components from the early packaging and styling phases to the mass production phase after SOP according to reliability, completeness, and currentness of the components, while the contribution of the other divisions (e.g., powertrain, seating systems) to the PEP often is set as temporary but highly sophisticated auxiliary and supporting work (Albers, 2012).

The majority of development tasks for styling, design, calculation, or simulation, for example, are supported by virtual product development tools implemented in different software and hardware platforms. The advantage of these virtual tools is the early verification of design requirements. Their disadvantage is the rudimentary or nonexistent interaction between the virtual systems. This leads to several parallel modeling efforts of the same geometry or part. The leading system for geometry definition and verification is parametric associative design (PAD). While in the 1950s only a few automotive body engineers were involved in the development of a new automotive body, working on one project, today a large number of engineers from different disciplines are involved in each project, and they are all working on several projects in parallel. The resulting complex interrelations and interdependencies in product development process cannot be controlled by one technical discipline with the aid of its approved discipline-specific methods. Consequently, the automotive industry uses approaches and methods of systems engineering. After elicitation and analysis of all relevant requirements for the system or product to be developed, a reasonable architecture or product structure is conceived. At the same time, well-defined interfaces between subsystems or components belonging to different technical disciplines are identified. The detailed design of the discipline-specific components takes place under consideration of these interfaces and the existing interrelations. It requires continued cooperation of the different technical disciplines. In many aspects, this development principle corresponds with the principles of methodic design. But the principles of systems engineering are not limited to addressing classic questions of mechanical design. They also imply important aspects of project management, reliability, and risk assessment (Abulawi, 2012).

2 MASTER PROCESSES FOR THE PEP

The master processes for the development of the automotive body and the integration of powertrain and chassis describe and control the different maturity processes in the product evolution, for example, the maturity processes for the automobile packaging, the styling, the module definitions, the prototype phase, or the mass production phase based on the analysis of several independent publications (e.g., Braess and Seiffert, 2007a). The master processes of three German OEMs (BMW, Daimler, and Volkswagen) are shown in Figure 2 and can be compared. According to publications, the duration of the master process of a conventional automobile development is approximately 48–60 months. The project timing is structured with the aid of defined phases and milestones (Volkswagen), quality gates (Daimler), or synchronization points (BMW). The milestones are defined control points (often documented in project reports) at which certain results or findings must be available and a certain product maturity level must be achieved. It is the objective of the master processes to define the maturity level validation (to ensure the reliability) in the PEP. Phases and milestones are defined for each new project before the project is kicked off.

Nowadays, most OEMs have adopted platform strategies for deriving different models and production lines from a standardized design basis. Generally, a platform is defined as the reusable design of the floor pan components, which is of indirect influence on the styling and design of the visible parts of the body-in-white (BIW) but has uniform reference points for the automotive body production (e.g., part breakdown, clamping and positioning points, and conveyor adaptation) and for attaching powertrain components such as engine, transmission, and wheel and suspension system. The sophisticated process of defining platform concepts is based on comprehensive analyses and research projects carried out by all OEMs. The consequence of the platform strategy is that the early phases of car body design can and must use a set of carryover parts (COPs) that are available as 3D computer-aided design (CAD) models. The selection of the correct platform components for the product family must occur at the beginning of the design project and must be verified and validated as soon as possible with the highest achievable reliability. BMW subdivide their master PEP, which follows the strategic product planning phase, into the following two major phases: “preparatory phase” and “serial (detailing) phase,” each of which is allowed to take approximately the same number of months. Both major

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

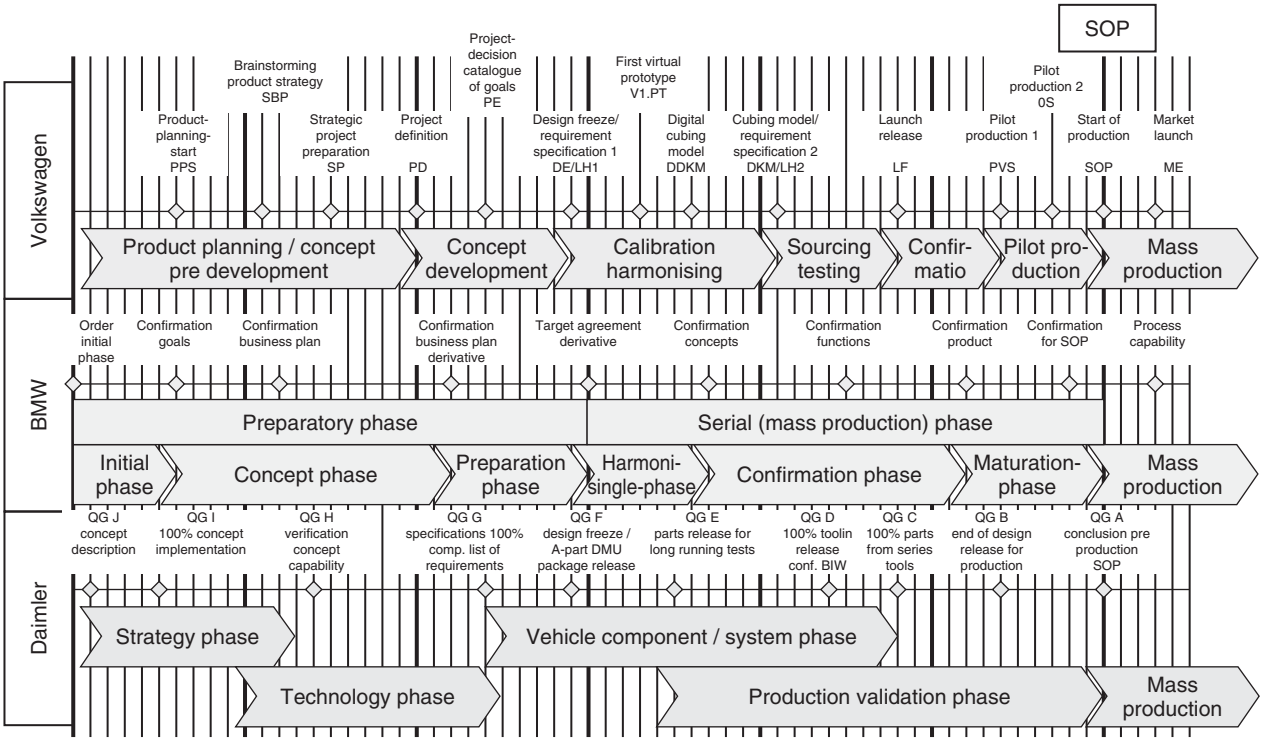

Figure 2. Comparison of master product evolution processes (PEPs).

phases are split up into three subordinate phases. The preparation phase is broken down into "initialization phase," "concept phase," and "design phase," and the detailing phase is broken down into "agreement phase," "confirmation phase," and "maturity phase" (Figure 2).

The objectives of the first major phase, the preparatory phase, are as follows (Figure 3):

- Investigate, define, agree, and verify design, technology, and innovations of the basic model of the new car family.
- Investigate, define, agree, and verify design, technology, and innovations of the cars to be derived from the basic model (this process begins after the basic model has been defined).
- Determine timing and responsibilities for the serial phase.
- Eliminate initial conflicts between design objectives as far as possible.
- Accomplish and freeze package and styling.
- Derive the engineering bill of materials (BOMs).
- Elect development partners.

This phase is responsible for defining about 75% of the product costs, and it has a major impact on the company's profit of the next decade.

In the process of converging packaging, styling, and engineering, which is a part of the preparatory phase, the approach is from interior to exterior (with the focus on technical constraints, i.e., "form following function") as well as from exterior to interior (with the focus on styling, i.e., "form following emotions") (Braess and Seiffert, 2007b). The design freedom of the car body is restricted by the styling-oriented exterior shape of the car and the function-driven package. This leads to numerous conflicting and contradictory objectives that must be resolved in multidisciplinary convergence processes.

The objectives of the second major phase, the serial (mass production, detailing) phase, are listed as follows:

- harmonization of the development output (i.e., the results of the preparatory phase) with current legislative requirements, standards, competitive situations and research conclusions;
- detailed design of individual parts and zones, and their optimization and verification in the context of the complete car design through calculation, simulation, testing, and prototype investigation;
- accomplishment of the homologation legislation and type approval; and
- planning and production of series of production tools and fixtures, and their maturation through sample inspections and pilot production to ensure the capability of all production.

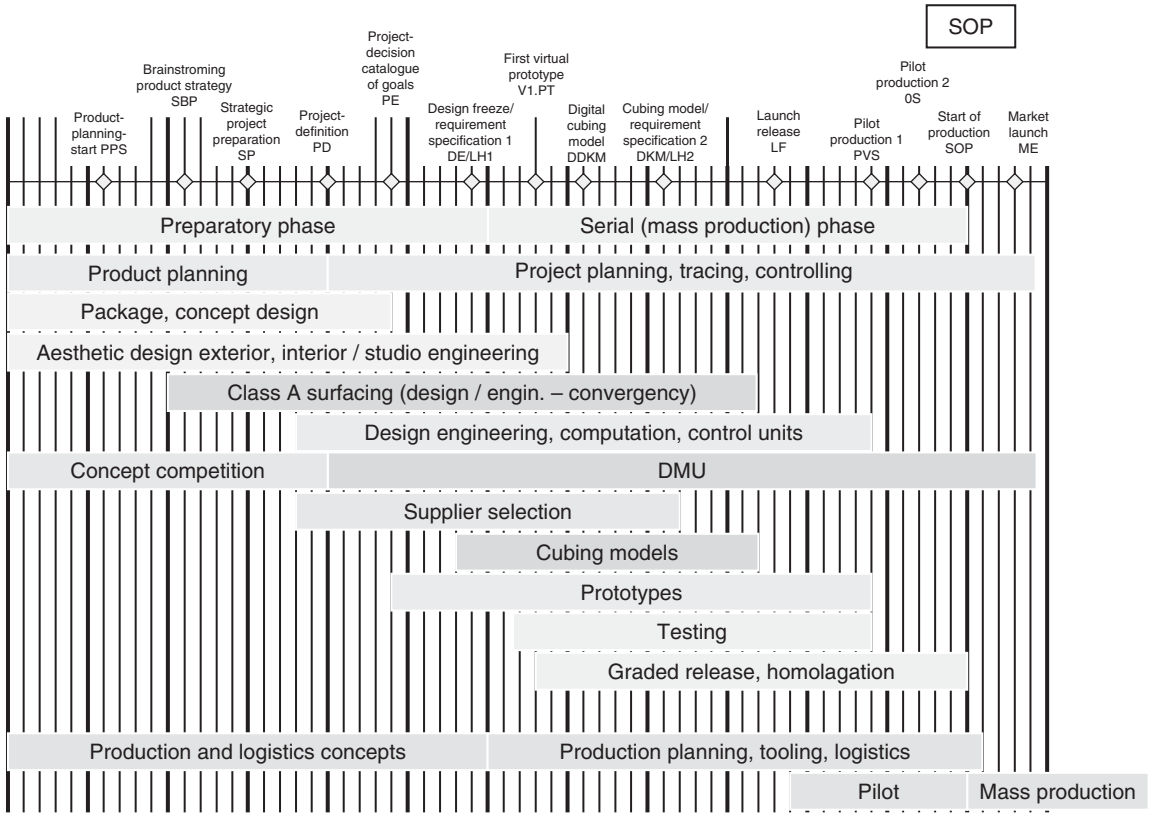

Figure 3. Distributed tasks in PEP.

In the following section, the most significant steps of this second major phase in the evolvement of a new passenger car are described and analyzed from the design engineer's point of view.

3 PACKAGING/ERGONOMICS PROCESS AND CONCEPT DEVELOPMENT

"The packaging process manages and harmonizes the requirements of component locations, ergonomics, and the overall characteristics of a car. It is a multidisciplinary process which accompanies the complete product evolvement cycle, from the first ideas to the end of production. The administration of all geometric data of the car and the control of all associated documents (to safeguard that each document is up to date) also belongs to the responsibilities of the packaging process". (Grabner and Nothhaft, 2006)

It is the objective of the packaging process to control and harmonize the interior of the passenger compartment (e.g., the arrangement of the seats) and luggage compartment, the location of powertrain components, and resulting characteristics such as wheel base, front and tail section, and ground clearance. The basic car concept defined at the beginning of the development phase is continuously substantiated as the development progresses; package plans, styling concepts, and subassembly designs are now getting more and more detailed and refined. In the past, this process of converging package, styling, and design was a two-dimensional (2D) process. Today, the availability of digital 3D tools (3D CAD, computer-aided styling system (CAS), large-scale projections, power wall, virtual reality (VR) caves, five-axis milling machines, rapid prototyping, etc.) has led to a dramatic acceleration and improvement of the development process.

In the first phase of the packaging process, according to 60 months duration, about 60 to 54 months before SOP, initial objectives are defined on the basis of strategic specifications derived from market analyses and predictions as well as project-independent results of technical investigations and research. The resulting concept package is the first 3D package, which initially comprises only about 15 components of powertrain, wheel and suspension system (including their interfaces with the car body), the locations of passenger seats and the driver's fields of vision, and the envelope of the luggage compartment. It is supplemented

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

with components from previous car projects, permitting rapid qualitative visualization of the new car concept. In addition, this concept package documents the resulting basic car dimensions such as overall length, height, width, and the location of the engine and the axles, as well as the anticipated positioning of the driver and the other passengers. On this basis, a dimensional design concept is derived that contains a preliminary course of hard points. In this phase, between five and six competing concepts are developed in parallel, for example, with varying wheel base. Additionally, predevelopment issues are defined, which must be tackled and solved to ensure the realization of the package concepts.

Once the initial design objectives have been determined, the second phase (about 54 to 40 months before SOP) is devoted to the preparation of a correct and marketable overall car concept. All major open issues contained in the initial concept are resolved to obtain the first draft concept already containing about 50 subassemblies of the new car. Conflicts between styling and package are resolved by compromises (convergence), leading to an agreed plan of hard points.

Furthermore, the engineering concept of the automobile project is determined in this second phase, to permit the verification of the package of wheel and suspension system and powertrain. With the aid of up-to-date manikins (virtual anatomical models of the human body), ergonomic investigations are made to validate seating positions, viewing angles, and access to the car (Figure 4). The virtual analyses are verified with the first physical seating mock-up.

On the basis of the initial design objective, the automotive body development process prepares a concept for the automotive body structure. The overall car concept, which is prepared in the concept phase, is aligned with these first automotive body analyses. Initial finite-element method (FEM) calculations are made to verify the overall car concept with respect to structural strength and stiffness. Additionally, concept analyses are performed in all domains of the automotive body development, to harmonize the overall car concept with the structural concept. If the initial design objectives are proved to be feasible, the second development phase leads to the confirmation of these objectives. The final plan of hard points and the first vehicle integration plan are the output of this phase.

The vehicle integration plan, which is documented in engineering drawings (scale 1 : 1), tables, and written descriptions, contains all major interior components such as seats, steering wheel and other cockpit elements, as well as the Society of Automotive and Aeronautical Engineers (SAEs) manikins and seating reference points (SgRPs). The space occupied by the powertrain and wheel and suspension system is visualized in the three main views. Furthermore, all major dimensions, driver viewing angles, nominal loads, slope angles, and so on, are documented in this plan. In the past, the resulting 2D geometry was the basis of the styling tape plans. These tape plans (scale 1 : 1) were used to optimize styling geometries and to initiate the 3D design process.

Today, packaging is a completely 3D process, permitting the ideal integration of the development of initial styling geometries (main curves and guide curves) and the generation of principal sections describing package and component envelopes through boundary surfaces into the overall process. Package functional surfaces are 3D surfaces, describing the space occupied by individual components (e.g., diesel engine with its envelope surface determined for idle vibrations or the front wheel with the envelope surface of permissible steering and suspension movements, arm reach envelopes of the passengers according to legal and ergonomic specifications or viewing pyramids).

50 months before SOP, the principal sections are created in 3D models using standard locations in the car coordinate system, with standard names for the geometric elements. To begin with, cross sections of previous and other cars

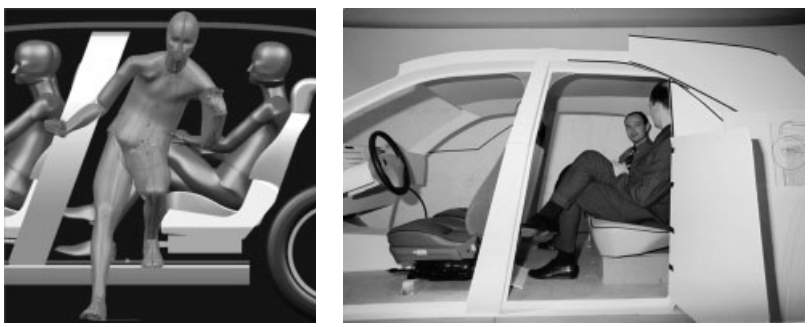

Figure 4. Validation of ergonomics with virtual (RAMSIS) and physical seating mock-ups on the Rolls-Royce Phantom (Lindermaier, 2006). (Reproduced by permission of Lindermaier/BMW AG.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

from the OEM product portfolio are used to obtain a coarse description of the topology of the zones and compartments to be developed. This coarse description is used to reach agreements and compromises between conflicting objectives with all departments involved in the car evolvement process. Subsequently, the principal sections positioned at standard locations in the car coordinate system are replaced by actual development sections derived from the functional surfaces of the package, styling data, and concept development results. These development sections are used for documenting relevant problems, reaching agreements between the design departments, and creating primary design surfaces.

In the third phase, approximately 40 to 30 months before SOP, the vehicle integration plan is detailed further. In the middle of this phase, the package of the basic car model of the desired product family is officially released (package freeze). In the meantime, about 150 subassemblies of the car would have been entered into the package plan. It is the main goal of the packing process to generate the geometric evidences that all legal and other requirements and specifications including OEM-specific regulations and standards are met and all conflicts resolved, and to keep the number of design variants to a minimum. Examples of such issues are the seating layout, luggage compartment layout, direct and indirect views of the driver, head clearance and head impact zones, accessibility of control elements, access to car, location and layout of restraint systems, pedestrian safety, bumper heights, ground clearance, and slope angles.

With the aid of CAD and digital mock-up (DMU), the packaging team continuously checks virtual design surfaces, module and part designs against hard points and envelope surfaces, and possible collisions of components. This way, the configuration of the car is verified more and more in the 3D models. In this phase, the first physical models of the future subassemblies are produced, for example, milled from hard foam. These physical mock-ups are used for experiments and tests, backing up the virtual validation processes, for example, with ergonomic investigations performed by test persons, and with manufacturability studies. After package freeze, the overall geometric data of the car is prepared according to internal standards and Global Car Manufacturers Information Exchange (GCIE) Group, and simplified overall car plans according to GCIE are prepared for exchanging data with other OEMs.

Even during the detailing phase, design modifications and adjustments accounting for current research results may occur. Consequently, the packaging team remains responsible for the validation and verification of all such changes with respect to legal and other requirements. In the mass production phase (detailing phase), the ergonomics team assumes the responsibility for the fine-tuning of control element surfaces and locations, operating forces, and paths.

At the close of the serial phase, production part homologation processes and type approval are carried out, supported by the packaging team.

4 TECHNICAL SUPPORT OF AESTHETIC DESIGN (STYLING) EXTERIOR AND INTERIOR

The most important function in aesthetic design is to give the product a soul of its own. This soul is not alone created by technical development neither package or with the decoration; the product soul can only be created by a stylist who is able to combine aesthetic, style and emotion.

In the competition for market dominance the manufacturers (OEM) have to satisfy customer's demands in ever increasing market segments. Parallel to the daily complex demands in customer lifestyle and the increasing number of products on the market, styling and "product soul" are growing in importance. You can't just glue on "product character", nor is it achieved by just using the logo symbols and colors of corporate identity. The combination of brand identity and "product soul" is achieved by the interplaying of aesthetic design, interior and exterior, of colors, shapes and materials. Thus aesthetic design defines the brand. (Ostle, 2003)

The aesthetic design process was the last manual layout process that has changed enormously through the developments in the virtual world. With the aid of computers it is possible to serve better process integrations and to have a greater variety of styling layouts in a shorter time span. Years ago, the pure development of design ideas with manual sketches, renderings, tape renderings, clay (Plastilin) modeling, synthetic wood (Epowood, Uriol), or hard foam were in the forefront. Today, the whole design process is developed in a new order with reduced numbers of format and media discontinuations aided by 3D CASs with a large variety of import and design functions supported by large-screen projections and 3D VR visualization (power wall, cave; Figures 12 and 13).

Sketchboards including software for sketching, rendering, and airbrush techniques are available for freehand sketching. It is thus possible to underlay a 3D package while using the 2D sketcher, which leads to the exact and correct proportions and perspectives. It is also possible to scan background photographs or handmade sketches to be used for a 2.5D styling process. Today, the shift from milled and hand-finished design models into the computer (redesign) is possible with the use of modern scan and import functions. High-resolution real-time

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

visualizations and animation of 3D design models enhance the efficiency of the styling process.

Aesthetic designers are still skeptical toward the new process: "Digital models tend to have a more optimistic appearance on the screen and on power walls. Only the physical and tangible model will give you the best impression. It is true that the CAD models save a lot of money. It is however fact that a car factory sells real cars. Because of this fact it is necessary in the phase of deployment to work on real cars." (Kraus, 2007)

4.1 Core areas of aesthetic design (styling)

"The exterior is love at the first sight. The interior is the marriage." (Sielaff, 2004)

The basic form of organization of aesthetic design is advanced design, exterior design, interior design, and color and trim. These areas are supported by modeling, studio engineering, and studio management. Some OEMs assign ergonomics and the Class-A surfacing also to aesthetic design.

Advanced design and concept design follow rules similar to those in early project concept developments of assembly groups within the technical design process. Both are often independent of the core project. The characteristic of concept design and advanced design is to collect ideas and visions without regard to whether they can be integrated into the technical design process. Advanced aesthetic designers track down new design trends based on the information of trend research. The results of their creativity are translated to design models or even show cars for car exhibitions.

Exterior aesthetic design creates the specific visual character of a vehicle by designing proportions of painted panels, glass, and light surfaces. In addition, character lines, highlights, and graphic elements determine the visual character. Thus brand image is created by the typical styling of the front and rear end or the shaping of the C-pillar. Aerodynamics plays an important driving force for composition work of the exterior over the last decades. The recent legislation for pedestrian's protection has influenced the arrangement of the front end considerably during the last years.

Interior aesthetic design must also include haptics, scent, and the auditory sense, besides the visual language of shapes. Not only seating package but also ergonomics and passive safety influence the interior process. Also issues such as seat design and arrangement, accessibility of operating units, and vision of instruments are of great importance. The aim is to offer the customer a comfortable, functional interior and a safe and secure feeling. The selection of materials for the interior components largely influences this point (Figure 5).

In close cooperation with paint, textile, and plastics industries, color and trim develops color and material combinations for the interior and exterior, texture of plastic parts, fabric and leather for seats and trim, and so on, all of which have to correspond to future fashion trends. Careful selection of materials must also meet all requirements for quality and durability.

The roles of designers and modelers often fuse together during the aesthetic design process. In the conventional process, modelers have largely been occupied mostly to convert sketches, renderings, and tape plans into clay models. They optimized the process in close cooperation with the aesthetic designers. Because of their artistic skills and excellent capacity to think in three dimensions, modelers are today occupied with aiding 3D styling models on CAS work stations. Following this, the virtual styling models are milled in clay and are completed and optimized by the modelers. Then the virtual model is updated with the latest design in a redesign process by scanning and surface modeling.

Studio engineers play an important role within the design process. They mediate between the aesthetical and technical design process. Similarly to the modelers, studio engineers must be able to understand and interpret the emotions and motivation of the stylists. Their task is to demonstrate the possibilities and technical limits to the stylist. They are also authorized to represent the stylist's claim to the engineers of the other development departments. Studio engineers continually compile the latest information about working

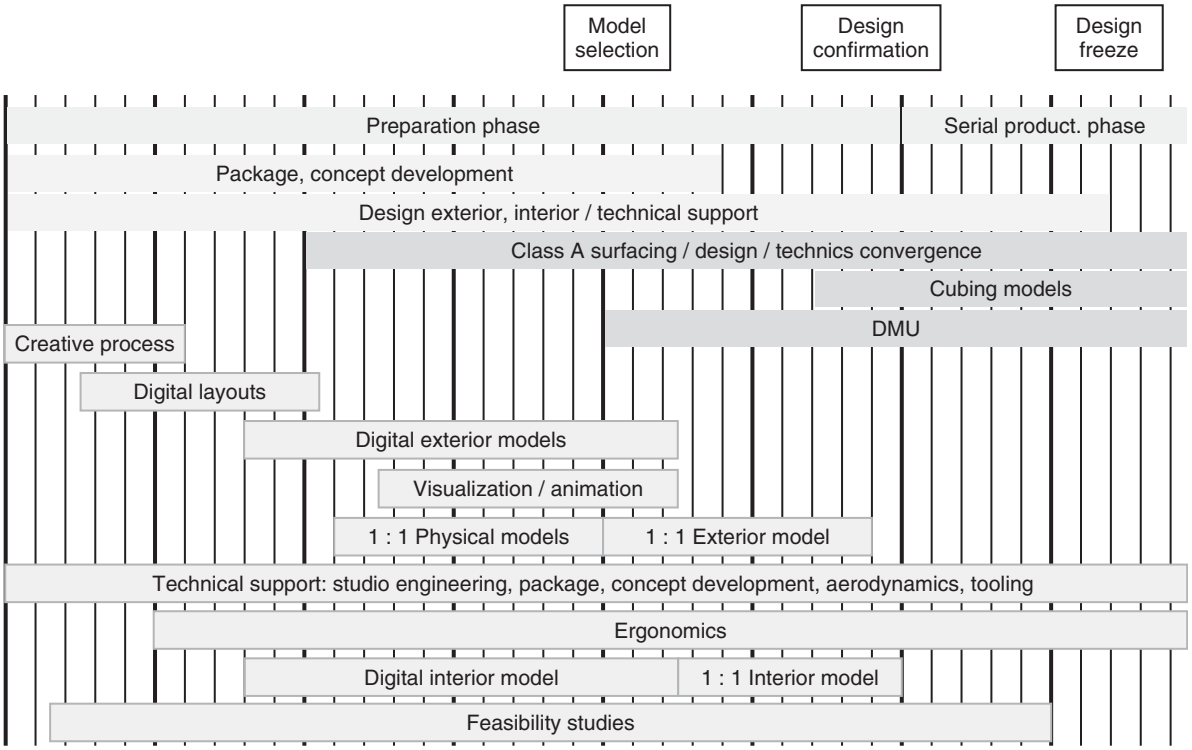

Figure 6. Digital aesthetic design (styling) process.

methods, production processes, materials, legal requirements, and so on, and they develop new technical ideas. The aesthetic designers are continuously informed by them about the possible innovations and consequences for the styling process. Studio engineers are responsible to guarantee the first functional feasibility of a styling by the use of principle sections, layouts, and model building. They conduct aerodynamic tests of design models. Together with method planners, studio engineers take production realization into consideration at this early stage. As "ambassadors" of aesthetic design, studio engineers present the new styling to the other departments of development. They conduct the design and the development from the beginning of the PEP, briefly until the SOP stage.

4.2 The new digital styling process

After a phase of discussion and interpretation of the list of goals of the new project, the styling process begins with a contest of ideas. Every aesthetic designer involved displays his individual interpretation of the project in layouts and sketches. Within the styling process, which consists of creative phases, presentations, discussions, and decisions, several competing aesthetic designs are studied at the same time. At the end of this process, there is one styling concept that combines the essential details of these competing styles (see Figure 6).

At the start of the aesthetic design process, the artistic and creative work comes to the fore. First of all, it is important to let the design ideas ripen. The package/aesthetic design convergence process starts afterward. Thus the artistic process of the tracked topic begins with freehand sketches of free chosen perspectives. Note that until the second step, these handmade sketches are digitally edited with the support of sketch boards and are converted to the proportions of the underlaid 3D package. For that purpose, freehand sketches can be scanned to reshape and to change those on the sketch boards.

In the second phase of the aesthetic design process, the conversion, the refinement of proportions and composition of details are carried out by 3D modeling in CAS. Orthogonal 2D outlines can be used as the basic framework for modeling and designing within the 3D model (sketch mapping). The stylists and modelers develop precisely tailored surfaces on the CAS system. The shapes and proportions of the model can be modified efficiently and the 3D data is available anytime so that a constant surface data flow to the development is possible. In the first instance,

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 7. Samples of painted exterior clay models and the chosen model. (Reproduced by permission of Daimler AG.)

five or more competing concepts are tracked. The concentration on two concepts is carried out shortly thereafter. Physical clay models of these two concepts are manufactured in a scale of 1 : 1. The precise refinement work often takes place at milled partial models, which can be added with assembly components from rapid prototyping or else from mass production.

Within the handcrafted process, renderings and tape plans have been the prestage for the physical model. Alongside the multifarious possibility of inspection and the possibility to animate styling models on a screen or a silver screen for visualization and discussion, renderings (Figure 5) and tape plans are nowadays derived afterward from 3D models of the CAS system.

The redesign process turns out to be demanding. The scanning data of physical models, which have been milled from CAS data and have been changed and optimized, are interpretable and sometimes redesigned surfaces do not reflect the styling idea of the optimized physical models. After closing off the second phase, the aesthetic design of the vehicle is largely detailed, and one final concept is chosen.

The finish of aesthetic design takes place within the third phase. The exterior and interior models merge into one model (Figure 7). Parallel to the second phase, the Class-A surfacing already begins to optimize the surfaces of the design models in CAD. The definition of the gaps in position, width, and producability as well as the quality of the surfaces has to be adjusted between aesthetic design and Class-A surfacing together with the demands of the technical conversion. The designed Class-A surfaces are tuned with the aesthetic design by using physical data control models (DCMs) of the interior, exterior, and the complete vehicle (cubing models) and are finally determined. Stylists accompany the technical design of the assembly components from the concept development until the detailing phase. They ensure the accurate conversion of their aesthetic concept, especially in cases of the often required compromises within the development and the production preparation.

5 CLASS-A SURFACING/STYLING/ TECHNIQUES CONVERGENCE

"Today the Class A surfaces are the geometrical representation of all surfaces that are visible for the customer both interior and exterior under consideration of all technological and shape aesthetical demands." (Lender, 2001)

The former manual Class-A process originally derived from shipbuilding. In the search for flow-enhancing designs of hull shapes, it was possible to design grid sections (length sections = vertical frames, breadth, and height sections) through the hull under support of long, flexible splines made of homogeneous material. These splines are kept in desired form with the use of spline weights (Figure 8). By alternately raising the weights, curves with smooth curvatures developed, which were free of dents, waves, or any kind of inconsistencies. Thus surfaces were clearly defined along the sections; however, the areas between the sections were not defined. Up into the 1990s, automotive Class-A surfaces were designed by this wire frame method of grid sections and 3D curves. Today, however, without exception, the Class-A surfacing is completed with the

aid of special CAD programs, for example, ICEMSurf (Dassault) or ALIAS (Autodesk). All these programs are based on the principles of curve and surface algorithms of de Casteljau and mathematics of Bèzier (Figure 9).

The Class-A process is a major component of the PEP. Its primarily importance lies in its early position in the development process and thus the big influence of all the following processes that are continuously dependent upon up-to-date surface data. With the introduction of Class-A surfacing into the early stage of PEP, a dynamic loop process of surface and gap modeling and adjustment under support of all relevant specialists begins to harmonize the demands of styling and technical design. Class-A development is completed with the release of the DCMs, which is followed by the release of all customer-relevant surface data of interior and exterior vehicle surfaces.

The process of surface development is based on scanning data that are generally available as a mesh of polygons originating from a cloud of scanned points. For better orientation, the polygon mesh is added by relevant grid sections. The area that has to be developed is "divided" in the mind into primary surfaces and secondary surfaces. Primary surfaces are those surfaces that are used as the principal or basic surfaces for the adaptation of further geometry, for example, offset surfaces or character curves. Secondary surfaces are those surfaces that are based on primary surfaces or add further details to the primary surfaces, such as bent portions, blend surfaces, or fillets.

As an example, contact points on each of the primary surfaces are used to hustle surface patches of low order (Figure 9) onto the primary surfaces. By careful and equal manipulation of the polygon points, the surface patch will closely resemble the scanning data. The primary surfaces (patches = unbounded surfaces) are larger than the styling surfaces. Character curves can be achieved and smoothened from the scanning data or intersection curves can be gained in combination with other primary surface patches. The patches (unbounded surfaces) are bounded by the curves and become faces (bounded surfaces). Any discrepancies in the scanning data or in the styling model at hand will be interpreted by the Class-A surfacing engineer to harmonize them with the aesthetic design. Surface data that the Class-A surfacing department provides includes all visible surfaces including first bent portions and first radii.

The visible surfaces of the interior and the exterior are interrupted by gaps whereever component parts meet. Gaps are an important stylistic element for an aesthetic designer. While designing the gaps, functionality of movable components and highlights on surfaces have to be taken into account. The unbounded visible surfaces and the curves defined by the aesthetic design and safeguarded by technical design, are the basis for the Class-A design of the gaps. For the development of a gap (Figure 10) the visual constant appearance of the gap, seen from the customer's typical point of view, is to be defined instead of defining a theoretical constant gap. In critical areas, the surface position in the area of the gap is moved within height (displaced) and/or the theoretically arranged gap varies in breadth.

The virtual world offers a multitude of possibilities to evaluate the quality of surfaces. Highlights are a

common method used. In theory, light sources are reflected under various angles to the free form surface. Lines of constant brightness (highlights, isopodan) are the geometric positions where the angles between light beams and surface normals are identical. A further virtual and even practical method used is the projection of a panel with parallel light sources onto the free form surfaces (Figure 11).

The Class-A department starts with its work as soon as the aesthetic design reduces the number of possible styling concepts to two. The styling models are milled and modeled in precise detail in Plastilin in the scale of 1 : 1 for the first time. To be able to evaluate the models virtually and to make the surface data available to the following departments as quickly as possible, the two models are scanned. Within the Class-A surfacing process, concept surfaces are created out of the 3D cloud of points from the scanning. The concept surfaces do not yet comply with the final requirements because of their quality, curve progression, and continuity. These first CAD models primarily act for judgment and confirmation by the department of aesthetic design, although the departments of technical design already use these concept surfaces as the foundation for the assembly group design.

The criteria for evaluating the Class-A surfaces are

- producibility,
- optical quality,
- compliance with package dimensions, concept coherence, COP concepts, and design variants.

With the choice of the styling model (model selection; Figure 6) by the management, the number of exterior and interior models decreases to one. Shortly thereafter, the design confirmation, including the incorporation of all open points and leadership issues into the model, takes place. The current development status is now harmonized with regard to package, concepts of technical design, aerodynamics, ergonomics, and occupant safety. Hence the technical stage of maturation has proceeded to the point where the development of the final Class-A surfaces begins. With that, a process of virtual and physical DCMs and master gauges begins, which conducts the PEP till the SOP and which safeguards Class-A surfacing and the technical design of components that follows (prototype parts as well as mass production parts). In an automotive project between 600 and 800 interior and exterior components relevant for visible surfaces get processed in Class-A surfacing. Gray zone surfaces, which cannot be seen until the customer

Figure 12. Virtual validation of the interior at the power wall. (Reproduced by permission of Daimler AG.)

opens a door or a lid, and a lot of surfaces of the interior are first designed as functional surfaces within the concept development phase and are at last finished in Class-A surfacing.

The design confirmation (Figure 6) means to "freeze" the current aesthetic design model. From now on, it is no longer possible for the styling department to shape the physical model and the design subject is completely assigned to the follow-up CA processes. Class-A surfacing is the leading department to make modifications and to visualize them. At this stage, all styling subjects are completely displayed. This includes, for instance, all mounting parts of the exterior, for example, handles or trim strips as well as panels or electric components of the interior. Furthermore, a detailed gap plan is defined, which can be adjusted to a minor degree. Even so, the stylists still have the possibility to place change requests within Class-A surfacing. Henceforth, the areas of aesthetic design and Class-A surfacing closely work together with the aid of visualization (Figures 12, 15) and CA tools.

The design freeze (Figure 6) is the next milestone within the Class-A process. At that time, the aesthetic design area finishes a styling adventure model (Figure 7) that contains interior and glass surfaces. All open issues, which were detected at the confirmation of aesthetic design, are incorporated in the Class-A surfaces. This is the base for the digital DCM that assures the design and the visible surfaces within the virtual process. The digital DCM describes the final condition of the visible surfaces in every detail, for example, varnished metal sheet areas, colored and textured interior components, or configuration variants. Thus it can also be used to safeguard the match-up of color and material combinations (Figure 12). Weeks before the completion of the first physical DCM, the virtual evaluation and the certification of all visible components takes place. Parallel to the Class-A surfacing process, a digital controlling of functions continuously takes place in all development areas. Functions, such as kinematics or overpush effects of lids, the air distribution of the air vents, or the head impact zones of the instrument panel are checked in detail (see Digital Prototyping and Digital Mock-Up (DMU)).

The result of the first physical data control model (DCM = Feasibility Cubing) is a complete and full-scale milled model on the basis of CAD surface data. The DCM or else the master pattern controls the Class-A surfaces; it resembles the design model and represents the decision made by the executive committee. Today, the DCM is created by high-performance milling machines that allow varnish-capable surfaces. The assembling takes place on the basis of synthetic woodblock material (Uriol) supported by aluminum beams. Final surface refinements demand accompanying Class-A surface design operations and lead to the point of release for the last milling loop of the final DCM.

The functional cubing models of the exterior and interior complete the safeguarding of all Class-A surface data. The BIW and all mounting and trim components of interior and exterior are displayed as a buildup that is geometrically equivalent to the final product. All exterior and BIW components are made from aluminum. The interior is displayed by Uriol or laminated components. Similarly to a real car, doors and lids can be opened by using realistic kinematics. In addition, the original boot is displayed. Cubing models of mounting parts of the exterior and interior are fixed the same way as in mass production. For example, the functional cubing interior is verified to check if the mounting and assembly components are able to be installed at their fixing points, at the clips holes, and if these fit together. The executive committee affirms the complete field of visible surfaces of the automobile, including secondary surfaces as well as visible gray zone surfaces between interior and exterior.

6 DIGITAL PROTOTYPING AND DIGITAL MOCK-UP (DMU)

The development of a product roughly takes place within the phases of design and simulation, laboratory work on physical models and road testing (Figure 13). Calculation and simulation leads to an early safeguarding of design data. It also allows physical prototypes with a high maturity and an optimized testing. Alongside the early safeguarding by simulation, the testing of physical prototypes within the development process is indispensable (Breitling, 2007). DMU is the virtual replacement of physical mock-ups using 3D computer graphic techniques to support the product engineers validating the designs of the complex assemblies.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

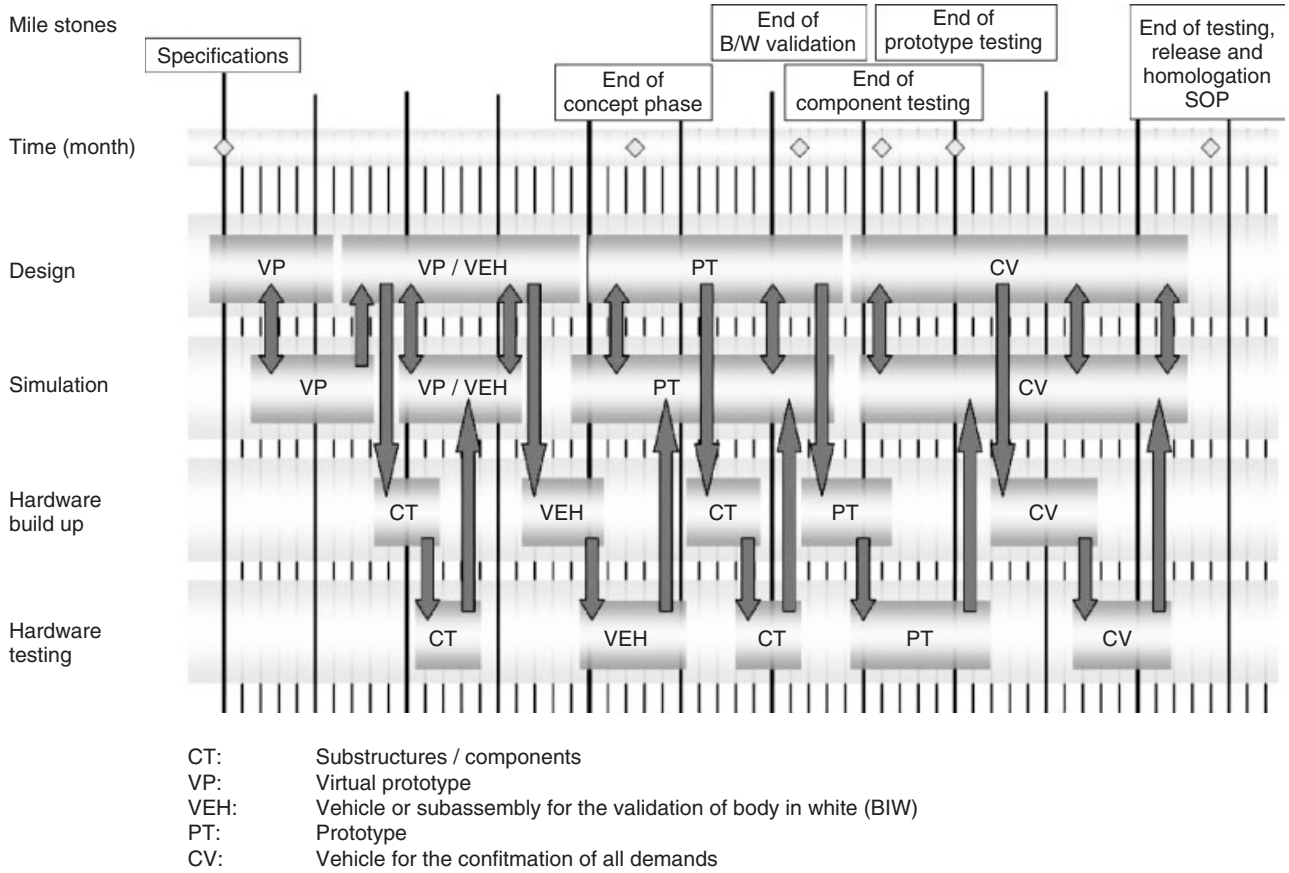

Figure 13. Virtual and physical arrangements for the validation of passive safety. (Reproduced by permission of Rodolfo Schöneburg, Daimler AG.)

The term *DMU*, the digital build of prototypes, no longer describes the full breadth of tasks for the support of visualization and simulation within the PEP. Within the automotive industry, terms such as digital prototyping (DPT) or digital engineering visualization (DEV) are in use.

In automotive body design, several verifications of the 3D geometry take place. In former times, verifications were performed under support of extensive 1 : 1 mock-ups (e.g., seating mock-up for ergonomic examinations or mock-ups built from deep-drawn plastic sheets to verify the assembly of BIW parts). Today we find a mixture of CAD-driven, product data management (PDM)-driven, and special isolated applications for DMU. These DMU-supported technologies evaluate diverse development concepts of the early phase and often can validate different design variants. Today the following fields among the application areas of visualization and simulation are important for the safeguarding of body design:

package layout and homologation (Figure 14);
visualization of design data and Class-A surfacing (Figure 15);

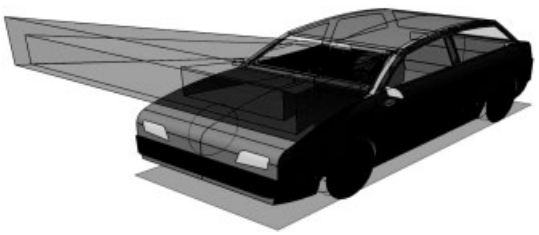

Figure 14. CAVA-software for packaging and homologation.)

aerodynamics;
structural load cases;
kinematic functions of mounting parts;
deformation of parts within production or in common handling;
tolerance management with its effects on surface and gap design as well as within production (Figure 16);
assembly, disassembly, and handling/filling of assemblies;
all crash load cases;
durability of load-bearing components;
noises, vibrations, and harshness (NVH) a passenger feels;

thermal functions of the heating/ventilation and air conditioning unit (HVAC);
thermal comfort inside the car;
loads caused by cataphoretic painting process.

Forsen (2003) classifies the activities of DMU into four main areas:

"GI: Geometrical Integration: All CAD-driven and powerless verifications belong to the area of steric geometric applications, such as: Interference Checking, Available Space Analysis, Cinematic Clearance Checks, Tolerance Simulations, and Ergonomic Examinations etc." (Forsen, 2003). Geometrical integration already includes several functional integrations (FIs) such as ergonomics examinations, kinematics of closures and other adjustable body assemblies, lighting, and so on.

FI (Functional Integration): The area of FIs includes all power integrated calculations in the field of DMU, such as: Crash Simulations, Stiffness Calculations, Aerodynamic Simulations, and Driving Dynamics Calculations etc.

PTI (Production Technology Integration): The term of PTI includes all verifications to safeguard manufacturing processes, such as Installation and Dismantling Studies, Deep Draw Simulations, Simulations of Jigs and Fixtures or Spot Welding etc.

EI (Electronic Integration): A strongly growing rate of electronic components in vehicles intensifies the poor design of mechanical components up to the handling of complex functional contexts, controlled by electronic devices. DMU therefore must be enhanced by simulation methods for EIs. (Forsen, 2003)

The design stages (status management) and design variants (variants management), which can only be organized for digital calculation and simulation process under support of intelligent CAD software (PAD) and/or PDM systems, are very important subjects within development and analysis. It is typical to analyze and rate a large number of alternatives within the early project phase. The main part of DMU data is taken over from 3D CAD data. The DMU simulations listed under GI can be verified in the CAD programs themselves. Visualization and rendering of large assemblies or dynamic cross sectioning often is handled within PDM systems. PDM-integrated applications also support verifications in a development process with multi-CAD use. Special solutions of FI often have special data formats that may course problems with feedback of data into the design processes.

At all times, the amount of data confines the actionability of design and simulation. The DMU data format JT (Siemens PLM Solutions) has becoming the new interface on behalf of the digital development process. Besides tessellated data with several levels of detailing, for instance, to visualize design data effectively, the JT format delivers exact geometric data (NURBS), for example, for measurement aspects, after the conversion. It also delivers metadata such as the product structure or attributes such as dimensions, tolerances, reference point system (RPS) points, or welding spots. Thus it is possible, for instance, to represent the complete environmental geometry within JT format while designing an assembly unit in a complex environment. The transmission of design history between OEM and system suppliers or different design departments is not needed.

Analysis of the complete vehicle with configuration and creation of DMU data in real time is not possible nowadays because of the high volume of data and different

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

data formats. For these verifications, DMU data are collected externally and converted overnight into JT or other exchange formats. The preparation of FEM meshes based on this exchange format cannot be done completely automatically, and takes another one to 3 days for an assembly and up to several weeks for a complete vehicle. The results of these verifications are not therefore up to date and often do not deliver all versions (Hagenah and Klar, 2006). The evaluation of constructed space in "Design in Context" applications requires a connection between the DMU and the BOM systems (PDM). Modern, parametric, associative CAD systems with connection to PDM system have taken over the main duties from DMU: to safeguard the continuous consistent management of versions and primarily interference-free development of assemblies.

7 CONCEPT DEVELOPMENTS ON THE EXAMPLE OF CLOSURES

The design of geometry and safeguarding of functions in concept and detail development is performed in several phases and is interrelated in diverse ways. According to the product vision (catalog of goals) declared, design and simulation work is divided from the whole vehicle into the single part of the vehicle body and reassembled several times.

For the concept and package phase, as a general rule, specialists from different areas of the vehicle body development, from package, styling, design, and simulation are concentrated in a project team to develop, organize, and decide about development work for the basic approach within a short period of time and to declare their centers of competence directly. Innovative concepts and new technologies developed independent from a special project are adapted to the new project in this phase. For every goal, several alternative concepts are explored and developed to one optimum concept. While the suppliers and engineering suppliers were involved in the detail development in early years only, they are often integrated from the early phase of concept development now. Project management of design and simulation work is often performed by experienced body designers of the OEM.

Detail development takes place under supervision of the centers of competence responsible for the special areas of the vehicle body. Most part of the engineering work is done by engineering suppliers. During this phase, parts and assemblies are developed in detail and their detail functions (e.g., weight, producibility, comfort, crash) are further optimized. While in the concept phase, simulation for the safeguarding of functions is executed on the basis of unripe CAD models, analog models, or computer-aided engineering (CAE)-modeled geometry in the detail phase simulation safeguards the development on the basis of ripe CAD data. But even in this phase, new cognitions (laws, competition situations, mistakes in early phase, etc.) can lead to a switchback into concept development. As definite project steps are appointed until SOP, expenditures are multiplicated in such situations.

The activities described in the previous chapters will be interpreted in this chapter on the example of side doors. Even here, the explanations can deliver only a small view into the multifarious field of closure development.

Side doors as well as front and rear lids belong within the system "vehicle body" to the subsystem "mounting components exterior" while the structural parts of the vehicle body define the subsystem "body structure." In the organizational structures of some OEMs, the interior trim of closures is also part of closure development.

A closure is a device that allows access to a compartment. Examples are the access to the passenger compartment, the boot, and engine compartment.
A door protects the passenger compartment against climatic influences, noise, unauthorized access, and so on.
Important elements of a swinging door, for instance, are, besides the door structure, the hinges, the latch, and the sealing gaskets.

The side door is one of the most complex assemblies of the vehicle body and must fulfill lots of requirements. In this chapter, requirements are described that can be categorized as follows:

Handling functions
Passive Safety
Quality impressions
Misuse
Durability.

Side doors are designed according to different concepts. During the last years, the frame door concept was established in mass production (Figure 17).

Handling functions are functions that have to be guaranteed for the daily use of the door. Nowadays, handling comfort and safety play an increasing role.

Legal requirements, directives, and specifications (e.g., ECE, FMVSS), the crash test procedures defined by consumer organizations (e.g., Euro NCAP, IIHS), as well as in-house rules and regulations for passive safety are multifaceted and influence the design of side doors and side-wall structures extensively. Side doors must support the safety of passengers at both side and front impacts. In all cases, side doors must guarantee the rescue of the

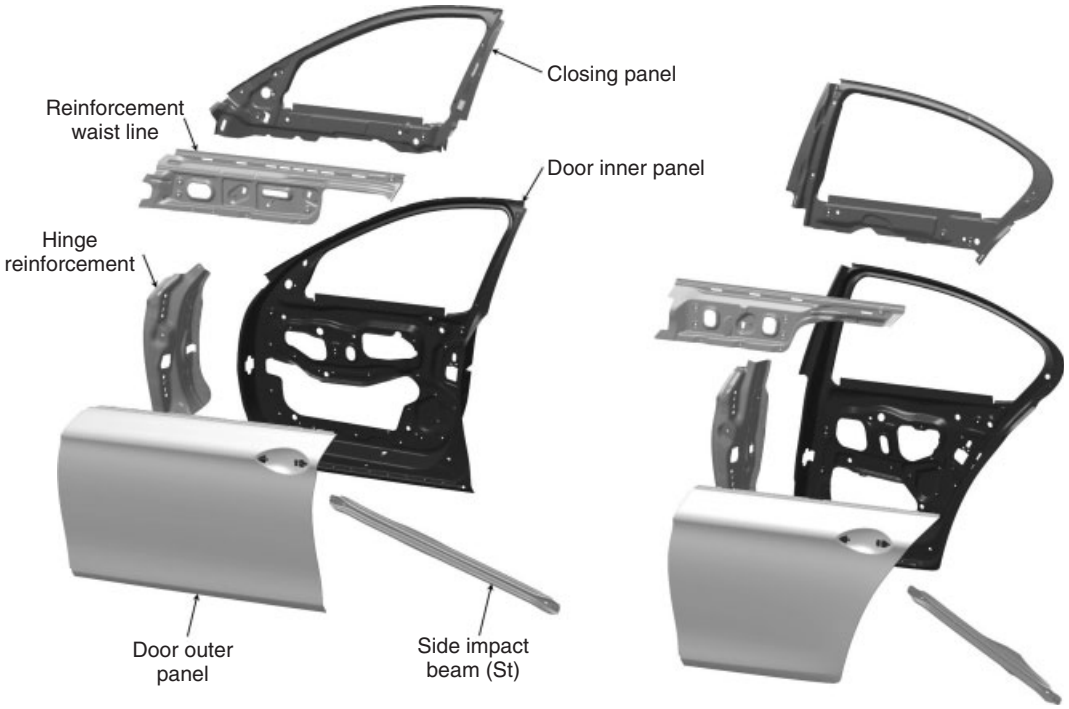

Figure 17. Frame door concept in an aluminum layer-built design. (Reproduced by permission of BMW AG.)

passengers after an accident. As examples from a multitude of designs, the waist rail of the door, which defines a load path for frontal impact, the side impact beam, and the side airbags in the doors, or padding arrangements in the door trim can be appointed. A lack of quality comes up when during polishing, for instance, the elastic deformations of the outer door panel lead to a noisy oil-canning tendency. This effect and plastic deformations are not allowed. Other examples for quality issues are the stiffness of the arm rest and the map case or door-closing noises.

Misuse loads are defined as soon as normal handling loads exceed the expectations. Doors must bear misuse loads up to certain limits. Examples of such conditions are as follows:

When the load case door sags; here, a load is defined that represents a heavy person leaning on the door body.
When a third person tries to get into the car by forced pull on the partially opened door window;
When a door is slammed with partially opened door glass with up to 30*g*.
When the open door is overpulled, this extremely stresses hinges, door stop, door panels, and pillar.

If the occurring loads do not exceed regular working loads, but occur in a great amount of cycles during the vehicle life span durability, load investigations are necessary. Typical examples are the endurance tests "door opening and closing" or "window opening and closing" where wearing parts like sealing gaskets, latch, hinges, door stop etc. are examined.

The following examples show some design requirements in more depth.

7.1 Hinge axis positioning

The hinge axes of passenger cars are positioned within the side wall. This leads to the situation that a part of the door turns into the side wall when the door is opened. The depths of turn in amount depend on the distances between the outer surface and hinge axis as well as front corner of the door and hinge axis (Figure 18).

The hinge axis is inclined marginally to lift the lower rear corner during opening and to allow comfortable opening and closing moments. The position of the hinge axis is defined by the curvature and inclination of the outer surface, the size and distance of the hinges, the general design of the door panels, and connections and the adjusting ranges for tolerance compensation. The hinges used are often COPs. The mounting of the hinges parallel to the planes of the vehicle axis system allows the adjustment within all three directions of the coordinate system. This is necessary to adjust flush outer panels and parallel gaps. Doors are nowadays often reassembled after painting, to enabling separate final assembly. Hence, in most cases, the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

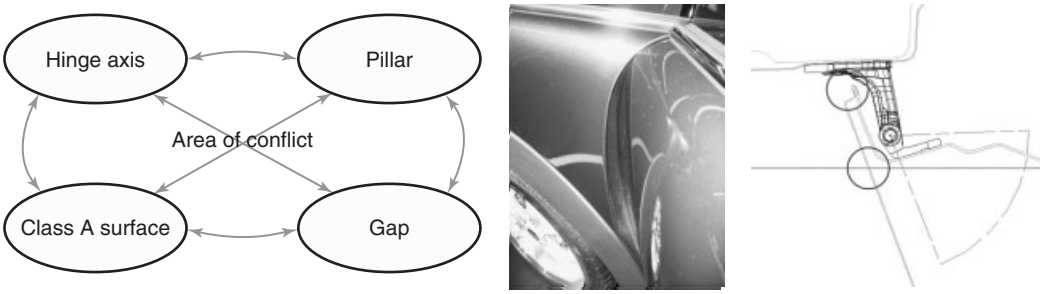

Figure 18. Conflicts during gap and hinge axis definition.

hinges are designed according to a two shear connections to unhinge and hinge the door. The travel needed for the unhinge operation has to be taken into account when the door gap is defined.

The door gap in the hinge axis area has to be safeguarded several times during the development process. As soon as the first 3D styling surfaces have been defined, the studio engineers can check in critical positions on the basis of principle sections, whether the gap defined by the stylist allows opening the door. Or the studio engineer defines limiting points and curves for the stylist to show a bandwidth for the definition of the gap. The first limiting curve and possible front corner of the door is defined when the outer surface of the opened door intersects the outer surface of the closed door at a defined opening angle (Figure 18). The second limiting curve for shaping and positioning of the outer pillar surface is defined by the front corner of the opened door. The more the stylist stays away from the first limiting curve, the more the front corner of the door turns into the side wall and prevents a suitable side-wall structure.

In the concept development, the hinge axis is safeguarded again on the basis of Class-A surfaces and gaps. Under consideration of the parts mentioned above and critical tolerance positions, a 3D corridor for the final position of the hinge axis is defined by three limiting surfaces on basis of the styling gap. From the first concept development stage of the door to the completely detailed door, the designs of the parts will be optimized in several loops. This will lead to several adjustments for the safeguarding of the hinge axis and gap.

7.2 Latch positioning

For low noise emission and wear out of the latch positioning, the latch plane has to be defined normal to the turning circle of the door. The second angle of inclination of the latch plane is defined parallel to the breadth (XZ) sections of the basic slanted surface connecting the inner and outer side walls in the latch area. This is the best way to allow the smallest possible constriction of the pillar, whereas in former designs, the latch often was positioned perpendicular to the plane view.

The basic slanted surface of the door connecting the inner and outer surfaces of the side wall is defined by the travel line of the door glass and the slanting angle necessary to open and close the door. While this functional surface is defined planar at the beginning of concept design, all surfaces of the gray zones except mounting surfaces have to be designed slightly convex at a later stage for manufacturing and aesthetical reasons.

The height of the latch depends on whether the door outer handle fits the latch directly or indirectly. The latch and all its components are positioned within the lower door case. For operation between latch and striker, a slot is necessary in the corner between the inner door surface and basic slanted surface of the inner panel of the door, and in some designs, in the inner door trim as well.

To allow the movement of the door glass, there must be a recess in the basic slanted surface. The size of modern latches with all their comfort functions need large recesses on the doors and corresponding pillar surfaces constricting the pillar structure. Some OEMs define the recess and its slope surfaces locally, only from the waistline down to the sill.

Optimization of the side-wall structure according to passive safety requirements often leads to changes and redesigns in the latch area.

To guarantee the hinge and latch functions, depending on the locking position of the latch, legal requirements define longitudinal and transverse forces. These forces are simulated in designed position in a ridged portal and door environment as soon as the first concept geometry for hinge and latch position is defined.

7.3 Drop glass

When the side door area is defined in styling, it must be ensured that the curvature and inclination of the greenhouse

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

area correspond with the dimensions of the lower door case. On the basis of longitudinal sections (cross sections, ZY) and principal sections of the package, the size, shape, and positioning of the door glass is safeguarded.

As the door glass of former cars were plane or curved cylindrical, nowadays most door glasses are part of a large rotational surface. Measured data of two or more longitudinal sections through the styling model are the basis to define the axis of rotation. As the rotational surface is made more or less elastic, the glass must pass the slot between the waist rails, and limit ranges; and combinations for the curvatures of the glass normal (R 1000 to R 2500) and radial (R 20,000 to R 150,000) to the axis of rotation are defined from experience. Modern CAD programs allow the mathematical optimization of the door glass according to points of interest on the styling model.

The door glasses of the front and rear doors are guided along the B-pillar. The inclination of the front and rear corners of the B-pillar defines a movement of the door glass as a combination of rotation and translation. The daylight area of the door is enlarged in the waist area by supporting and adjustment surfaces. Form and positions of the door glass must match up with the panels of the door, for example, in the sill area and the mounting parts such as door stop movement, side impact beam, and latch. Minimum distances between rigid, flexible, or moving parts have to be considered.

When the first concept design of the door panels is finished, the door can be simulated and optimized with the following load cases:

door glass opening and closing with and without stopper in opened position;
door slam with door glass partially opened with an acceleration of more than 30*g*;
forced entry through the window with a pulling force of 1000 N on the slightly opened door glass.

7.4 Door frame

The door frame defines the upper corner of the door. The nearly flush door glass is guided and sealed on the door frame. The sealing gasket situated on the welding flange of the side-wall structure seals against the seal surface of the door frame. The sealing gasket situated on the door frame seals against the seal surface on the side-wall structure.

The door frame is built by a deep-drawn door inner panel designed from sill to roof rail (Figure 17) and includes the cutout for the door glass. A stiff box section for the door frame combined with a deep-drawn closing panel reaching from roof rail to the upper hinge/latch area is defined..

Contrary to the design concept with, for instance, a constant extruded or rolled frame profile, the deep-drawn inner panel can be designed with variable profile depths. Even here, most OEMs keep the frame constant in the directly visible area of A-pillar and roof rail, and define the variable profile depth in the area of the B-pillar only.

In the front, the door frame ends in the mirror triangle; and in the rear, the door frame ends in a blunt corner with the waist rail. Additional panels may reinforce the changeover from frame and lower door case in the area of the waistline.

The aerodynamic pressure distribution under driving conditions leads to a high vacuum in the joint area of A-pillar and roof rails. The load level can be increased by separate excitations of road and engine. The sealing gaskets and the corresponding surfaces on body or door frame must always overlap each other and only reduced relative deformation of the structures are expected. Otherwise, loud wind noises in the area of the passengers head would occur when the air leaves the car through short-term gaps.

The stiffness of the door frame and its connection to the door case must be defined in a way that preloads of the sealing gaskets, wind loads, and other excitations are over compensated. OEMs therefore overbend the door frame in the joint area of the A-pillar and roof rails. When the door glass lies on the door frame, the door glass is overbent too. The disadvantage of this design is that the closing loads of the door and door glass is increased for the customer as the overbent door frame must be pressed back into its styling position when the door is closed.

"Usually, complex dynamic loads affect the closures and therefore the doors of a vehicle body. Reducing this complex real time behavior to the most important factors and defining appropriate load cases is usually a great challenge for any simulation engineer. The static linear simulation of the window frame stiffness is an example of such degradation. Here, the aerodynamic wind loads, as well as the road and engine excitations, lead to complex vibration during the vehicle operation. These dynamic events can be reduced to a static load case, in which forces are applied to the front and rear window frames. From experience, the resulting stiffness required for satisfactory behavior is known. The method allows fast and reliable identification of information needed for the designer to dimension the door structure (Lauterbach and Dick, 2007)."

7.5 Waist rail

The waist rail covers an important part of the stiffness of a door and safeguards passive safety during frontal, rear, and side impacts (Figure 19). Especially for cabriolets, the waist

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

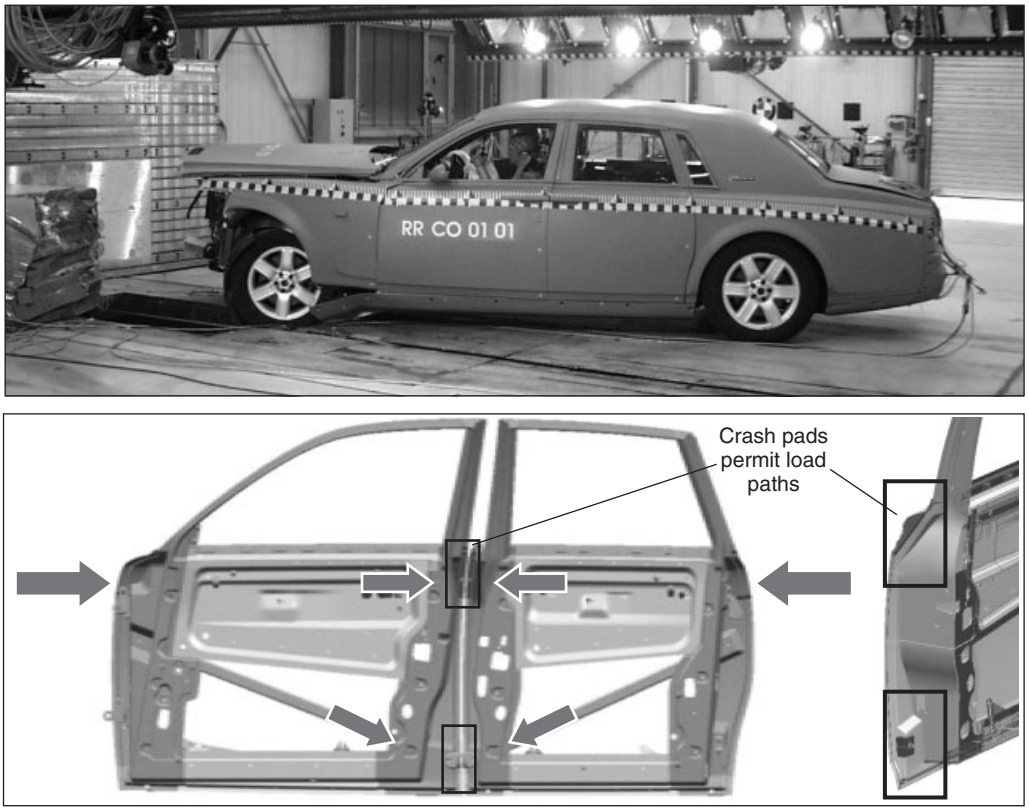

Figure 19. Crash pads permit load paths through side doors (Lindermaier, 2006). (Reproduced by permission of Lindermaier/BMW AG.)

rail defines an important load path for frontal impact. For the local reduction of gaps between doors and pillars in the load paths, beads are designed or crash pads are mounted. The window regulator system (WRS) is pivoted to the inner waist rail to allow the improvement of sealing and guidance by adjustment of the door glass and door frame in the *Y*-direction by adjustment screws between the WRS and inner panel in the sill area. The inner and outer seals are supported by the inner or outer waist rail to protect the inner door from water and dust. The stiffness of the outer waist rail must protect the door from forced opening through the waistline.

The door glass divides the waist rail into an inner and outer profile. The sophisticated design of the front and rear joints under consideration of door functions, producibility, stiffness, and safety is complex. The inner panel and the one-piece inner waist rail panel easily define a closed profile because welding operations are mainly covered by the inner door trim. The outer waist rail must be defined by two separate panels as it is not possible to define a force fit between a single panel and the visible outer panel. So at the outer waist rail assembly, the order and definition of the contacts between rail panels, and inner and outer door panels are a lot more demanding than in the inner side.

Nonlinear dynamic simulation of the whole vehicle is ambitious and time consuming. The goal is to optimize one of certain variants modeled in different ways. So it is not useful to start with the simulation of the whole vehicle. The early layout of the body structure is often carried out under support of partial structures such as the door inner panel combined with the inner and outer waist rails. The geometry of these separate models can be easily defined, meshed, and optimized. According to Lauterbach and Dick (2007) and Hänschke (2007), this approach reduces development time considerably and leads to reliable complete vehicle models. As CAD geometries in the early phase of the product development do not exist or are incomplete, CAE engineers model their partial structures themselves, use body structure libraries of former body structures, or work with parametric structures defined in special CAE tools.

8 CONCEPT COMPETITION AND SUPPLIER INTEGRATION

"After mass production in the 1920s and 'lean production' in the 1980s, the automobile industry is undergoing a

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

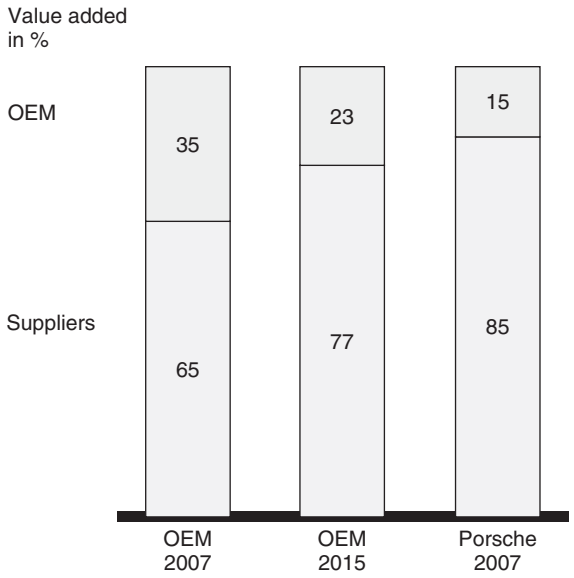

Figure 20. Change of added value between OEMs and suppliers acc. to Wyman (2004) and Binder (2007).

new revolution. By 2015, automotive suppliers will have taken over large parts of R&D and production from the automobile manufacturers, achieving total growth of 70% in this process. During the same period, the auto makers will give up 10% of their current value creation, even though their output will increase by 35%." (Wyman, 2004; see Figure 20)

The cooperation between OEM and suppliers has changed dramatically. The early integration of systems suppliers in the vehicle concept phase, distribution of responsibilities and partnership between all partners involved, concept competitions, target prices set by the OEM, focus of OEMs on core competences, and related reduction of development depth for supplier components have defined a completely new qualification profile for suppliers during the last 15 years.

Hundreds of OEM–supplier relations from concept development to delivery of components for mass production take up subordinate roles in the vehicle development process. Besides OEM and systems suppliers, the engineering suppliers take over most of the design work and a lot of simulation work. According to the master process (PEP) of the OEM, they all follow the same goal and have to be coordinated from the technical and commercial standpoints of the OEM. The basis for most technical communications and simulation processes are 3D CAD models, which always have to be kept up to date and described precisely according to the requirements and maturity defined. Failures in subprocesses endanger the overall goal (SOP) and lead sometimes to superheated catch-up games.

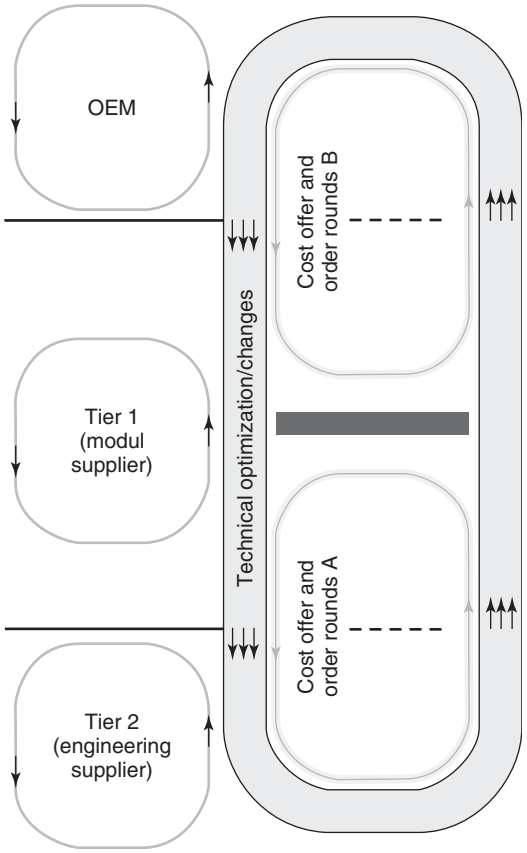

Figure 21. Contradictions in dynamic cooperation between OEM and suppliers.

For the promotion of a number of technical ideas, creativity, and innovation, OEMs define concept competitions at the start of a new project. In every competition, several competitors are invited to apply their technical product proposals. The bases for the proposals are according to the enquired assembly, a list of requirements defined by the OEM, as well as package space restrictions and concept surfaces.

For the OEM, this proceeding requires an extensive supplier management with assessment, development and risk management measures. The suppliers need to be integrated efficiently in suggestion gathering, creativity workshops, and concept competitions and, finally, in the concurrent engineering process.

The technical cooperation between OEM and suppliers is a stringent dynamic process on a high level of outsourcing for engineering work. Otherwise, reduction of time in the development processes would not be possible. The commercial administrative process usually is neglected and often leads to depressive moods in technical cooperation (Figure 21).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto286
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For the systems supplier, the reorientation of the OEMs leads to a new development strategy. While formerly the development of the systems suppliers was realization of the product developed by the OEM, nowadays, besides actual system development innovation management, fundamental research and independent predevelopment of substandard and standard components becomes their responsibility. The independent predevelopment may start 6 or more years before the component goes into mass production. The development of project-defined assemblies starts with the concept competition of an OEM about 3 years before SOP. According to the complexity of the assembly, about 6–12 month are needed to launch and guarantee a safeguarded mass production.

In the context of concurrent engineering of vehicles and their necessary components, an OEM expects from their suppliers at least the same competency and professionalism as their own R&D center. In addition, a high level of communication ability is expected. These abilities not only include the CAD, CAE, and data management systems but also up-to-date testing and analyzing equipment, as well as a high level of technical competence and performance. As long as the capacity of a systems supplier is insufficient, engineering suppliers are assigned to completely or partially develop components in a close coordination with the systems supplier and OEM.

Besides engineering suppliers, the systems supplier engages subsuppliers for the development and delivery of subcomponents. Other suppliers of systems are companies specializing in production equipment and machines. These suppliers play an important role when the product is launched before SOP. The cooperation between all subsuppliers has to be carefully managed and synchronized by the systems supplier in cooperation with the OEM. The systems supplier takes over the entire responsibility for the results of product development, product launch and delivery, and the absolute fulfillment of the list of requirements and target costs defined by the OEM.

9 SUMMARY

This chapter gives a small insight into the various development works of stylists, automotive body designers, CAE engineers, and related partners. Every unit of the automotive body is developed with several variants with the objective of improvement toward one optimum. Every single development step of every variant of every unit needs automotive body design of often complex 3D geometries for its evaluation.

It must be the goal for the future to upgrade product knowledge in the early phase of product development by improvement and systematization of design of 3D geometry supported by PAD and the improvement of the distribution of design and calculation/simulation work especially within the concept phase, and also through the whole development process supported by the approaches of systems engineering.

In the following chapters, several approaches for the styling, interior design, and the validation of the automotive body development will be described in more depth.

Batteries

Jun Furukawa

The Furukawa Battery Co., Ltd., Fukushima, Japan

1 INTRODUCTION

A power supply system in a vehicle electrical system is composed of three basic functions: power generation function represented by an alternator, power supply–storage function represented by a battery, and power distribution function represented by a wire harness. In this chapter, we introduce the battery as a function of power supply–storage.

2 OUTLINE OF AUTOMOTIVE BATTERY

The lead acid battery was invented by Planté in 1859. Thanks to its excellent practicality, this battery has been widely used even now 150 years later, not only for automobiles application but also in the industrial field, for instance, in emergency power supply, electric vehicle (EV) field such as electric fork-lift truck, and so on. Furthermore, this battery is expected to be used as means for global warming prevention, such as energy storage for load leveling and grid interconnection of the micro grid that utilizes renewable energy such as solar power. Especially, the lead acid battery in automotive application has been in an indispensable position for high durability in the high temperature environment under the hood, cold starting capability, and low cost.

In about 1920, almost 20 years after the introduction of EVs, the lead acid battery started to be used in automobiles equipped with internal combustion engine. Automobiles in those days were equipped with far less electrical devices than today. Electric loads were only the starting system, lighting system, and ignition system. Then, the electrical system voltage of vehicles was half of the current voltage, 7-V (with a 6-V battery), and the automotive battery was called a *starting, lighting, and ignition* (*SLI*) *battery* taking initials of three systems mentioned earlier. In the 1950s, the electrical system voltage was raised to the current of 14-V (with a 12-V battery) because of the increase in electric load. After that, the number of electric equipments and electric load of automobiles increased rapidly because of the pursuit of safety, comfort, convenience, and economy. For instance, electrical equipments for body systems are over 100; various motors are used for opening and closing of windows, mirror adjustment, opening and closing of slide doors, audio-visual equipments, and the navigation system. Chassis and power train equipments, such as electric power steering, electro-hydraulic brake, and even idling stop-start systems, are added to that. In such a trend of electric load increase, lack of electric power supply became an urgent issue mainly in the European luxury vehicles, and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto287
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

as a result, a 42-V electrical system (with a 36-V battery) began to be advocated. In 1996, an MIT (Massachusetts Institute of Technology) consortium presided over by MIT began full-scale activity in the United States. Coupled with the mass reduction of the enlarged wire harness, the 42-V electrical system investigation started. However, there were big problems concerning parts, system reliability, and cost in the once in 50 years technical innovation of the 42-V electrical system. Furthermore, significant improvement of electric generation capability, due to the progress in alternator technology, reduced the demand for a 42-V electrical system, which stemmed from the lack of power supply. But, hybrid power systems of 14-V and 42-V were already introduced in some automobiles, for instance, partial voltage step-up using DC/DC converter was applied to electric power steering, keeping electrical system voltage at the conventional 14-V. Hence, 12-V is still the mainstream automotive battery. But it is expected that in near future, the days of two batteries with 36-V and 12-V and one 36-V battery will be introduced.

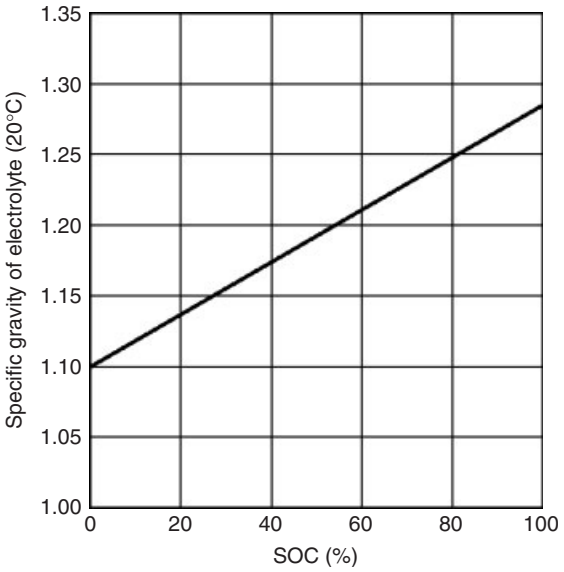

Figure 1. Relation between SOC and specific gravity of electrolyte.

3 THE PRINCIPLE OF LEAD ACID BATTERY

The overview of the lead acid battery is shown in the following sections.

3.1 Discharge reaction of lead acid battery

A lead acid battery has lead dioxide (PbO_2) as positive active material (PAM), spongy lead (Pb) as negative active material (NAM), and dilute sulfuric acid as electrolyte (H_2SO_4).

Equation (1) describes discharge electrochemical reaction of lead acid battery:

$$PbO_2 + Pb + 2HSO_4^- + 2H^+ \rightarrow 2PbSO_4 + 2H_2O \quad (1)$$

Lead dioxide changes to lead sulfate and water at positive electrode, and lead changes to lead sulfate at the negative electrode. In each reaction, active materials generate lead sulfate reacting with sulfuric acid, which is an electrolyte. This means, sulfuric acid density is decreased in the electrolyte with the progress of discharge reaction. Utilizing this behavior, state of charge (SOC) of lead acid battery can be found by measuring the specific gravity of the electrolyte (Figure 1).

On the other hand, as lead sulfate, which is a product due to the discharge, shows little or no electric conductivity, so the crystalline morphology of lead sulfate, at the electrodes in the discharge process, has a big influence on the subsequent charge reaction and the battery characteristic. Especially in the case of the lead acid battery, the situation called *sulfasion* is one of the typical degradation modes. In this situation, lead sulfate accumulates in the electrodes as coarse crystals and after that passivation occurs. This phenomenon makes charging most difficult.

3.2 Charge reaction of lead acid battery

Lead sulfate, a product due to the discharge, is oxidized to lead dioxide at the positive electrode and reduced to lead at the negative electrode. Equation (2) describes this process:

$$2PbSO_4 + 2H_2O \rightarrow Pb + PbO_2 + 2HSO_4^- + 2H^+ \quad (2)$$

After the battery is fully charged, if charging continues, oxygen from the positive electrode and hydrogen from the negative electrode are generated by electrolysis of the water in the electrolyte. So, ignition sources should be kept away from overcharged batteries.

3.3 Open circuit voltage (OCV) of lead acid battery

A lead acid cell has approximately 2-V of OCV (open circuit voltage); this is a very high value for a cell using a water-based electrolyte. This is based on the characteristic that the oxygen overvoltage of lead dioxide at the positive

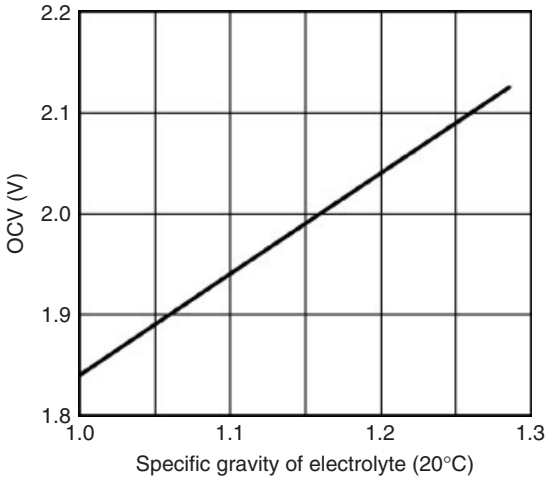

Figure 2. Relation between specific gravity of electrolyte and OCV.

electrode and the hydrogen overvoltage of lead at the negative electrode are high and water electrolysis is more difficult to cause than for other metals and compounds. The OCV of a lead acid battery has a good correlation with the specific gravity of the electrolyte. The relation between specific gravity of electrolyte and OCV is shown in Figure 2. The simplified way to find the OCV is to add 0.84 to the specific gravity of the electrolyte; this gives a nearly equivalent OCV value.

4 STRUCTURE, MANUFACTURING METHOD, AND TYPES OF AUTOMOTIVE BATTERIES

4.1 Structure of automotive battery

Structure, components, and materials of a typical automotive battery are shown in Figure 3.

In an automotive battery, positive plates, inserted into an envelope like polyethylene separator, and negative plates are stacked, and current collectors at the positive and negative plates are welded respectively to plate connectors. This is called *plate group* that configures a 2-V cell as the basic elements of a battery. The plate groups are respectively inserted into six cells in a container that is made of injection-molded polypropylene. Each cell is connected by resistance welding between the direct cell connectors provided on the plate connector. And a polypropylene lid, which is embedded with terminal posts made of lead alloy, is bonded to the container by a hot molding process. Positive and negative poles provided on the plate connector at the first and sixth cells are welded to terminal posts of the lid. Sulfuric acid aqueous solution, with a specific gravity of approximately 1.28, is poured as electrolyte.

4.2 Manufacturing method of automotive battery

An outline of an automobile battery manufacturing method is discussed in the following paragraphs.

Generally, the positive and negative plates of an automotive battery are manufactured by the following procedure, though the type of additive and manufacturing conditions may be different. First, lead oxide powder, the raw material, is manufactured by the ball mill method, which oxidizes lead balls by using the heat generated by the friction between lead balls struck mutually, or by Barton pot method, which oxidizes the pulverized molten lead. Water, sulfuric acid aqueous solution, and additives are added to the lead oxide powder and mixed to a paste form. And lattice-shaped battery grid, which is made of trace elements added lead alloy, is pasted with the paste mentioned earlier, and the surface is dried. Mainly Ca and Sn are used as trace elements for both positive and negative battery grids, even though added amounts are different between the two. Note that, in case of heavy duty application such as trucks, buses, taxis, and construction vehicles, Sb added lead alloy is generally used for the positive battery grid. After that, electrochemical reactivity and mechanical strength are increased by the chemical reaction in high temperature and high moisture atmosphere, called *curing process*, and unformed (uncharged) plates are finished.

The assembly process using the unformed plate is mentioned later (explained in Section 4.1): (i) positive and negative plates stacking, (ii) current collectors welding, (iii) plate group insertion into a container, (iv) welding between the cells, (v) bonding the lid and the container, and (vi) welding between poles and terminal posts.

The electrolyte is poured into the assembled 12-V unformed battery with repeat charge and discharge in the electrochemical conversion process called *formation process*. Thus, charged automotive battery is completed.

As explained earlier, the PAM is made of lead dioxide and the NAM is made of lead. In addition, all the metallic conductor parts, such as battery grids, connecting parts, and terminals, are made of lead alloys. Then, lead acid battery is easy to recycle. Furthermore, the polypropylenes used for the lid and the container and sulfuric acid as electrolyte are recyclable. So, more than 90 mass% of the components of automotive battery can be recycled.

Thus, automotive battery can be ecofriendly products.

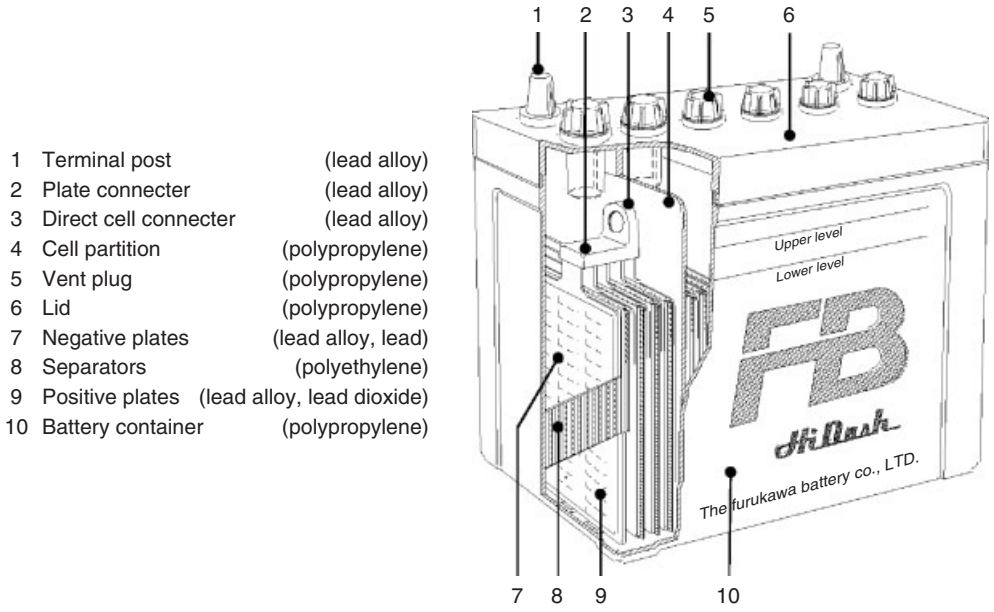

Figure 3. Structure, components, and materials of automotive battery.

4.3 Maintenance-free (MF) battery

At the beginning, lead-antimony alloy, which has excellent mechanical strength, was used as the battery grid alloy for the lead acid battery. But, as antimony significantly lowers the hydrogen overvoltage of lead, so water loss was induced, due to hydrogen gas generation, when used for the negative battery grid. Then, frequent water addition was required and self discharge was significant. In the 1970s, low antimony alloy, which has lower antimony content, was developed as one step toward maintenance-free (MF) batteries. Around the same time, lead-calcium alloy, which had higher hydrogen overvoltage, was developed and MF proceeded largely to today's type. MF batteries are of two different types. One is the calcium type, which uses lead-calcium alloy for both positive and negative battery grids; another is a hybrid-type, which uses lead-low antimony alloy for the positive battery grid and lead-calcium alloy for the negative battery grid. The hybrid type increases hydrogen gas generation while in use, because of the positive battery grid antimony moving to the negative electrode. This type is less MF than the calcium type. But, by using lead-antimony alloy for the positive battery grid, durability of the positive electrode is improved during deep discharge due to the antimony effect on PAM, and longer life is obtained. So the hybrid type is applied to heavy duty applications such as trucks, buses, taxis, and construction vehicles that have repeated deep discharge and recharge. On the other hand, for this heavy duty application, the use of the lead-calcium alloy for the positive battery grid shortens the life. This phenomenon is called the *antimony-free effect*. Nowadays, improvement has been promoted in various ways. Thus, the calcium type and the hybrid type are differently used depending on the applications. Each characteristic of the MF batteries are shown in Table 1.

Table 1. Comparison of maintenance-free lead acid batteries.

Items		Hybrid-Type	Calcium-Type
Grid alloy	Positive grid	Lead-antimony	Lead-calcium
	Negative grid	Lead-calcium	Lead-calcium
Life cycle	Light load life	Excellent	Excellent
	Heavy load life	Excellent	Moderate
Maintenance	Self-discharge	Poor	Excellent
	Maintenance free	Poor	Excellent
Applications		Commercial vehicle Bus	Passenger car

4.4 Valve-regulated lead acid (VRLA) battery

In Sections 4.1, 4.2, and 4.3, descriptions are made of the flooded-type lead acid batteries (open ventilated type), which have abundant electrolyte. Recently, the VRLA (valve-regulated lead acid) battery has been widely introduced in luxury vehicles in Europe. In comparison with the sealed type of batteries, such as small size nickel-cadmium battery or nickel-metal hydride battery, the VRLA battery is a type with extremely low valve opening pressure. VRLA batteries are designed to utilize the recombination reaction at the negative electrode for consuming oxygen gas generated from the positive electrode whilst charging. Any extra oxygen gas that cannot be consumed is released to the outside. The recombination reaction means a series of cycles, that is, "Oxygen gas generated at the positive electrode while overcharging, reacts with the spongy lead at the negative electrode and makes lead oxide. The lead oxide reacts with sulfuric acid in the electrolyte and makes lead sulfate. The lead sulfate is reduced to lead by charging again." This cycle continues while in charging, so the sealed condition can be maintained. But an abundant electrolyte, such as in the flooded type of lead acid battery, suppresses the movement of oxygen gas. Thus, a fine glass fiber separator, called *absorbed glass mat* (*AGM*) separator, is applied to the VRLA battery so as to limit the electrolyte amount, which can be absorbed by the separator. With these treatments, VRLA battery facilitates the oxygen gas movement to the negative electrode. Furthermore, this battery has the following features. As the electrolyte amount is limited, electrolyte does not leak even when the battery trips over. As separators like felt compress the plate group, the positive electrode is hardly degraded and the long life span is expected. On the other hand, owing to limiting the electrolyte amount, the VRLA battery has weak points. Its capacity is smaller than that for the same size of flooded-type lead acid battery. As its heat capacity is small, it is easy to cause the battery temperature to rise. By using it for a long term at high temperature, the recombination reaction causes thermal runaway and the battery is overheated. Thus, when a VRLA battery is loaded into an engine bay, sometimes countermeasures such as a thermal barrier, similar to housing in a battery box, may be needed.

5 CHARGE AND DISCHARGE CHARACTERISTICS OF AUTOMOTIVE BATTERY

A charge and discharge characteristic of an automotive battery is shown in Figure 4. Discharging was performed for 5 h at rated current and charged for 10 h rated current.

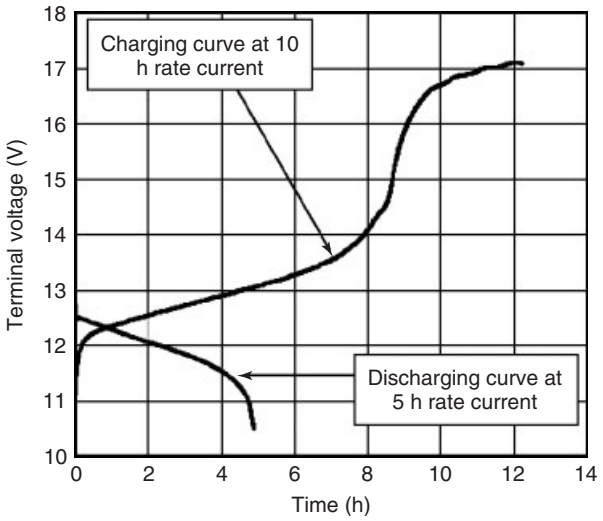

Figure 4. Charge and discharge curve of lead acid battery.

The terminal voltage before discharge began was approximately 12.8 V. A rapid voltage drop caused mainly by internal ohmic resistance occurred right after the start of discharge. After this, the voltage dropped gradually, and rapidly dropped again after 5 h because of depletion of reactants. In the case of charging, immediately after the start of charging, the voltage increased rapidly because of the internal ohmic resistance and polarization. After that, the voltage increased gradually. At the end stage of charging, the voltage increased rapidly and got into the overcharge region, when oxygen and hydrogen gases were generated.

Figure 5 shows the relation between discharge current and time for complete discharge.

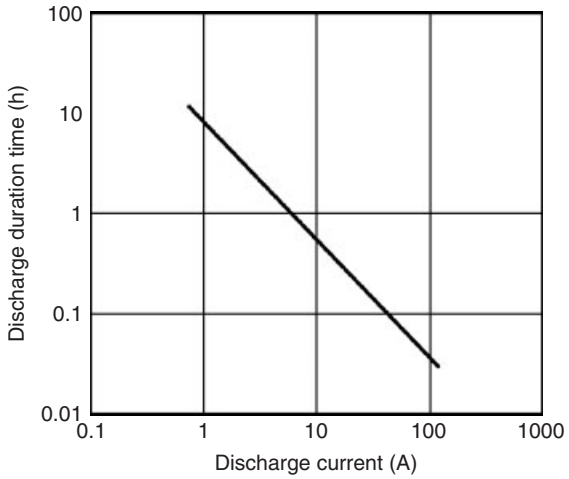

Figure 5. Relation between discharge current and discharge duration.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto287
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

From Figure 5, we can find that the discharge duration (capacity) decreases with an increase in discharge current. The relation between discharge current (or discharge rate) and discharge duration can be expressed by the Peukert equation described in Equation (3):

$$t = C \times I^n \tag{3}$$

where I is the discharge current and t is the discharge duration time. C and n are coefficients obtained from plot of I and t in Figure 5.

6 DEGRADATION MODES OF AUTOMOTIVE BATTERIES AND COUNTERMEASURES

A variety of degradation modes of lead acid battery exist depending on operating conditions. Here, we show the typical degradation modes of automotive battery and countermeasures.

6.1 Passivation of the interface between PAM and positive grid (premature capacity loss-1: PCL-1)

In the 1970s, after lead-calcium alloy for the positive battery grid had started to be used instead of lead antimony alloy, a capacity reduction phenomenon frequently occurred because of low conductivity passivation forming in the corrosion layer of the interface between the PAM and the grid. This was improved by adding Sn (tin) to the lead-calcium alloy and forming high conductivity Sn (tin) dioxide layer in the interface between the PAM and the battery grid. On the other hand, the theory mentioned later is also influential. If the adhesiveness of the interface between the PAM and the battery grid is not enough, the electrolyte penetrates into it, and forms a passivation lead sulfate layer or causes a break in the corrosion layer in the interface. Thus, a review of improvement in corrosion resistance of the positive battery grid alloy and improvement of the manufacturing process is now performed. Figure 6 shows scanning electron micrograph (SEM) observation results on the interfaces between the PAM and the positive battery grid after life-cycle tests using a conventional alloy and a new alloy (Furukawa, Nehyo, and Shiga, 2004). The corrosion layer breakage is suppressed in the case of the new alloy shown in Figure 6.

6.2 Softening and shedding of PAM (premature capacity loss-2: PCL-2)

In the charging and discharging reactions of lead acid batteries, PAM and NAM dissolve as Pb^{2+} ion, and this ion precipitates as lead sulfate, lead, or lead dioxide. And repetition of charge and discharge process directly influences the change in the morphology of the active material. Softening of PAM is the phenomenon described later. Owing to above-described dissolution and precipitation reaction and mass transfer of the solid phase, an initial aggregate of fine lead dioxide particles gradually changes to an aggregate of coarse particles. As a result, contact between the particles is reduced and cohesion becomes weaker. This state is called *softening*. Softening is suppressed by adding some kind of metallic ion to PAM. Figure 7 shows SEM observation results of the change in particle size before and after the life-cycle test with and without additives. Coarsening of particles is suppressed by the new additive.

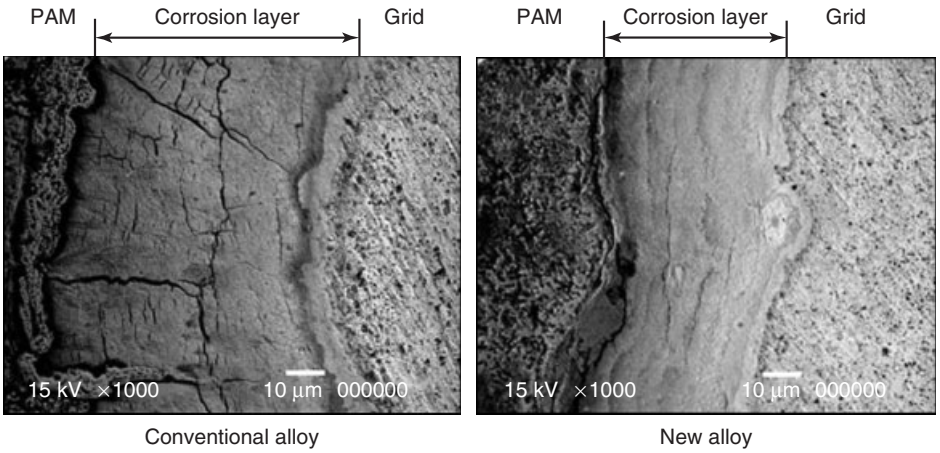

Figure 6. SEM observation results on interfaces between PAM and positive battery grid.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto287
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

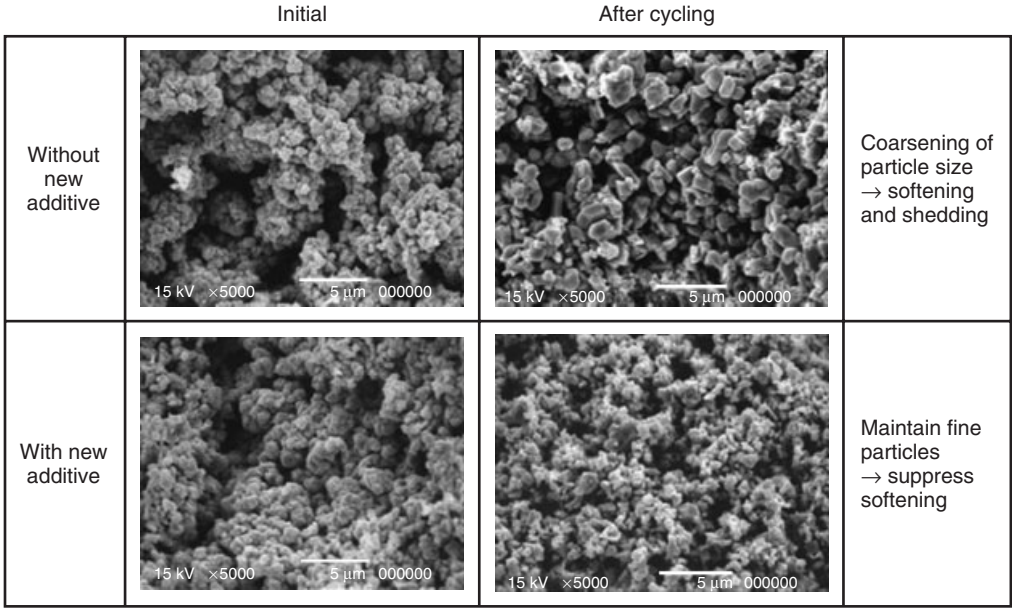

Figure 7. Change in particle size of lead dioxide (PAM) before and after the life-cycle test.

Apart from this, the following theory is also influential. A lot of gel zones, which include hydroxyl group and hydrate water, exist in the initial lead dioxide crystals and act as the glue that connects the crystals. After repeating the charge and discharge process, these crystals change, reducing the glue function and then softening is caused.

6.3 New type of sulfation of negative electrode (premature capacity loss-3: PCL-3)

It is known that when charging, different sulfation occurs because of coarsening of the lead sulfate crystal, a by-product of discharge, in the case of leaving the lead acid battery in a discharged state for a long time. This is caused by the following phenomenon. Owing to a slight lead sulfate dissolution into the electrolyte, initially chargeable fine particles are gradually bound together by the Ostwald ripening effect. Then, the initially fine particles change to more difficult-to-charge coarse particles. Moreover, this new type of negative electrode sulfation can occur within a relatively short time, by repeating rapid charging and discharging in a half way charging state called *high rate–partial state of charge* (*HR-PSOC*). In itself, this HR-PSOC is the battery charge/discharge process of hybrid electric vehicles (HEVs). Similar operating conditions are expected in the case of regenerative braking of enhanced micro-HEVs, which is getting a lot of attention as the next-generation vehicles with idling stop, and mild-HEVs in which the start assist function is added to micro-HEVs. So,

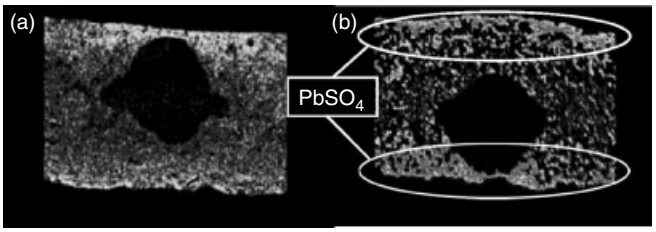

Figure 8. (a,b) EPMA measurements results of lead sulfate density distributions in the negative electrode.

performance improvement of lead acid batteries is needed urgently. In this type of sulfation, stonewall-shaped lead sulfate grows on the surface layer of the negative electrode and impedes the charge and discharge reaction at the negative electrode by blocking the electrolyte movement inside the negative electrode. Figure 8 shows electron proved micro analysis (EPMA) measuring results at the negative electrode cross section during an HR-PSOC life-cycle test and after the test (Takeshima *et al.*, 2004). Bright parts are the high concentration sulfur region in the lead sulfate. This shows that the high concentration of lead sulfate is distributed around the negative electrode surface.

An increase of conductive carbon added in the NAM and the addition of new carbon material has been effective in impeding this sulfation, and more development focused on carbon is now underway.

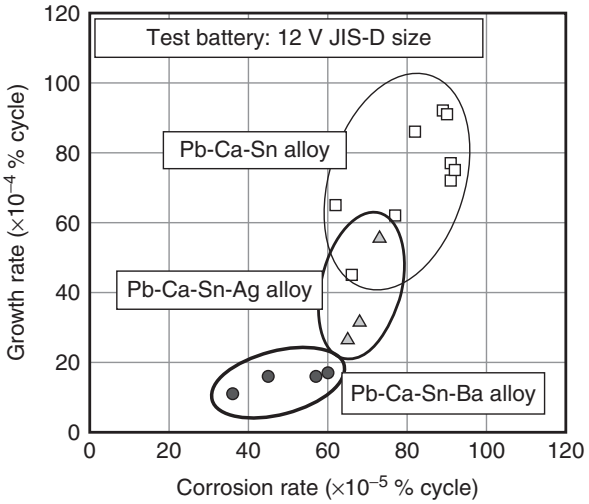

Figure 9. Relation between corrosion rate (weight loss) and growth rate of positive battery grid alloys.

6.4 Corrosion and growth of positive battery grid

Corrosion and growth of the positive battery grid is the most commonly observed degradation mode of automotive batteries that are placed in the high temperature atmosphere under hood and overcharged. Therefore, many lead-calcium alloys to improve corrosion resistivity and growth resistivity have been developed. Lead-calcium-tin alloy with a small amount of barium is a possible alloy that has excellent features in corrosion resistivity and growth resistivity. In addition, lead-calcium-tin alloy with a small amount of silver is used mainly in the United States. The relation between corrosion rate (weight loss) and growth rate of the positive battery grid alloys is shown in Figure 9 (Furukawa, Nehyo, and Shiga, 2004).

7 THE CURRENT STATE OF AUTOMOTIVE APPLICATIONS

7.1 Lead acid battery for idling stop vehicles and micro-HEVs

Vehicles using charging by regenerative braking, in addition to idling stop function, are called *micro-HEVs*. These vehicles have electrical system voltage of 14-V (battery voltage is 12-V). Since 2007, the production of these vehicles has expanded in Europe was more than 25% of the 13.5 million new vehicles manufactured in Europe in 2010. This figure is predicted to reach 60% by 2015 (Fraser-Bell and Prengaman, 2010). Expansion in Japan is predicted as well, but there are some limitations at this time.

As a lead acid battery for idling stop vehicles needs to supply electric power during the no engine idle stop, high durability for deep discharge is required. Also, a large current discharge is necessary for restarting the engine. Thus, low and stable internal resistance is required to ensure reliability on engine restart. Moreover, improved charge acceptance is required for quick recovery of the discharged electricity. For improved deep discharge and internal resistance, the following countermeasures have been developed: increase of PAM density, improved durability for the charge and discharge cycle by the additive described in Section 2.5.2, and optimization of battery grid potential distribution by computer-aided engineering (CAE). Charge acceptance of the lead acid battery is subject to negative electrode performance, so the improvements described in Section 2.5.3 such as an increase of conductive carbon, added to NAM, are performed. As a result, a lead acid battery for idling stop vehicles when tested achieved 60,000 cycles, twice as much as 30,000 cycles target, for idling stop life-cycle test (Takada, Monma, and Furukawa, 2006; Takada and Furukawa, 2008).

Next, it is assumed that the lead acid battery for micro-HEVs is operated under PSOC condition, which means 80% SOC, so as to efficiently receive charge by regenerative braking. For this purpose, suppression of the negative electrode sulfation described in Section 2.5.3 is very important. In addition to this, some kind of additive is needed to suppress crystal growth of the lead sulfate in the negative electrode, and practical application is in progress. Figure 10 shows SEM photographs of observation of the influence on the crystalline morphology of lead sulfate by additive effects (Takada and Furukawa, 2008). It is found that lead sulfate crystal becomes randomized in form and maintains the condition for easy charge.

In addition, although the lead acid battery type may be different depending on the type of vehicle, the flooded-type lead acid battery, which is low cost, tends to be used in compact and standard-sized vehicles, and the VRLA battery, which has higher durability but at a higher cost, tends to be used in high end luxury vehicles. And the VRLA battery tends to be used when improved fuel economy is needed.

7.2 Capacitor hybrid type lead acid battery

The capacitor hybrid-type lead acid battery "UltraBattery" combines an asymmetric capacitor and a lead acid battery in a unit cell, without extra expensive electronic control (Lam and Louey, 2006; Lam *et al*., 2007; Furukawa *et al*., 2010).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto287
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

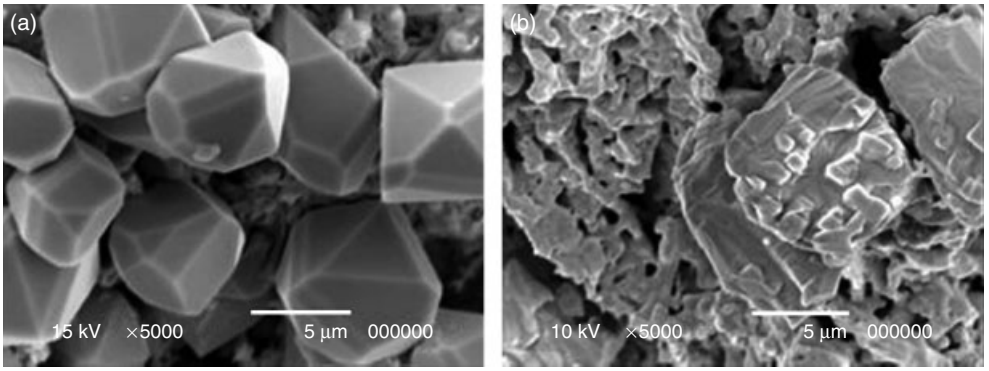

Figure 10. (a,b) Influence to crystal morphology of lead sulfate caused by an additive.

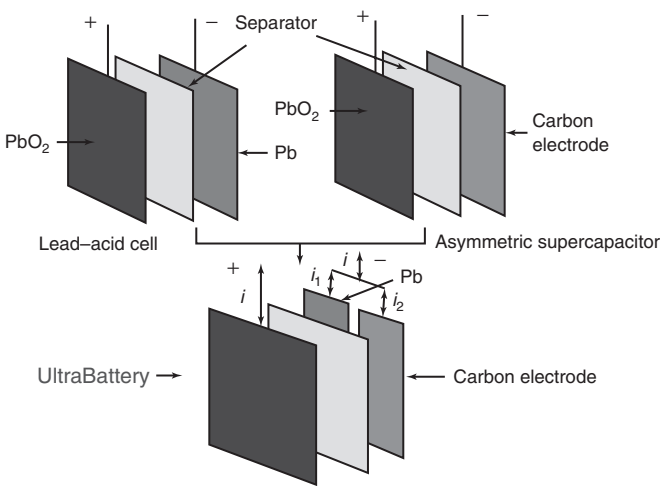

Figure 11. Configuration of UltraBattery.

Figure 12. Prototype of valve-regulated UltraBattery.

Thus, the UltraBattery alone can be used as an electric power source for idling stop vehicles, micro-HEVs, and mild-HEVs in harsh operating conditions, which combines PSOC and large current pulse discharging and charging. The conventional lead acid battery has been difficult to be applied to this condition. The configuration of the UltraBattery is shown in Figure 11.

A normal lead acid cell comprises one lead dioxide positive electrode and one spongy lead negative electrode. In contrast, an asymmetric super-capacitor is composed of one lead dioxide positive electrode and one carbon-based negative electrode (i.e., capacitor electrode). As the positive electrode in the lead acid cell and the asymmetric super-capacitor have a common composition, these two devices can be integrated into one unit cell by internally connecting the capacitor electrode and the lead acid negative electrode in parallel. So, both electrodes can share the electrical load with the lead acid positive electrode. With this design, during discharge and charge, the total current of the combined negative electrode is composed of two components. One is the capacitor current. The other is the lead acid negative electrode current. Accordingly, the capacitor electrode can act as a buffer to share the discharge and charge currents with the lead acid negative electrode and, thus, prevent it by being discharged and charged at the full rates required by HEV duty. Figure 12 shows a prototype valve-regulated ultra battery with the battery sized for motorcycles (5 h rate capacity 8.5 Ah).

For a vehicle demonstration held at the proving ground of GM in Millbrook in the United Kingdom, a Honda Insight HEV was equipped with a 144-V pack, which connected 12 prototype UltraBatteries in series, instead of its usual nickel-metal hydride battery pack, The actual vehicle in the demonstration is shown in Figure 13.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto287
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 13. 100 k mile (160 k km) achievement in the UltraBattery demonstration by a Honda Insight HEV.

This was the world's first 100 k mile (160 k km) driving achieved in a vehicle demonstration with lead acid chemistry without charge recovery, which is mandatory for the conventional lead acid battery. In addition, equivalent results to vehicle equipped with nickel-metal hydride battery pack were obtained in driving feeling, fuel consumption, and carbon dioxide emission. As described earlier, the UltraBattery is expected to expand its application to the next generation vehicles such as micro, mild, and high voltage HEVs, for which application the conventional lead acid battery has been considered to be too difficult.

8 FUTURE OUTLOOK OF AUTOMOTIVE BATTERIES

In 1997, Prius—a HEV available from TOYOTA—was launched. It employs an internal combustion engine and an electric motor in combination and successfully achieved less CO_2 emission and fuel consumption than ever before. Until then, "automobiles" meant two types of vehicle, that is, vehicles powered by an internal combustion engine or EVs. The Prius employs an over 200-V high voltage nickel-metal hydride battery pack with a high energy density and power density as a power source for an electric motor, and a 12-V lead-acid battery as an auxiliary power supply. Various hybrid electric vehicles (*x*-HEV) have been introduced after the appearance of Prius. They are called as *strong-HEVs* including Prius, medium-HEVs with an approximate 100-V electrical system, mild-HEVs with a 42-V electrical system (refer to Chapter 1), and micro-HEVs with a 14-V electrical system (refer to Chapter 7), in accordance with hybrid features for reduced CO_2 emission and fuel consumption such as idling stop, regenerative braking, power-assisted driving, and EV driving. Meanwhile, plug-in HEVs with an increased battery capacity for longer EV driving distances appeared as hybrid vehicles closer to EVs. However, the vehicles that require larger amounts of electrical energy involve larger battery mass and volume. So, to meet the need for batteries with a higher energy density and power density, lithium-ion batteries have been developed. Although lithium-ion batteries are expensive, lithium-ion batteries are replacing nickel-metal hydride batteries not only in EVs and plug-in HEVs that require reduction of battery mass and volume but also in strong-HEVs and medium-HEVs that have employed nickel-metal hydride batteries, and it is expected that eventually lithium-ion batteries will replace nickel-metal hydride batteries. Meanwhile, lead-acid batteries are predominantly employed in micro-HEVs with 14-V electrical system (with 12-V battery) because of their limited CO_2 emission and corresponding low fuel consumption. However, a combination of lead-acid batteries with lithium-ion batteries or electric double-layer capacitors is under consideration for reducing cost and improving fuel efficiency. Although, as explained, the predominant main power supplies for automobiles will be classified into lithium-ion battery and lead-acid battery HEVs, in which a 12-V lead-acid battery is mounted as an auxiliary power supply, providing continued use of lead-acid batteries.

Semiconductor Sensors (3): Optical Sensors

Shoji Kanda

DENSO Corporation, Kariya, Japan

1 OPTICAL SENSORS

1.1 Principle of the optical sensor (photoelectric effect)

The photoelectric effect phenomenon was first discovered by Hertz and Hallwachs in 1887. Figure 1 shows the principle of a photodiode (PD). When light that has more energy than the silicon (Si) bandgap (Eg) is radiated onto the P–N junction layer, the light produces electron–hole pairs within the Si crystals. The electrons and holes diffuse in accordance with the concentration gradient of the P–N junction. When these reach the depletion layer the accelerated electrons move to the N-layer, while the holes move to the P-layer.

Consequently, the current flows from the N-layer to the P-layer owing to the connection to an external load. In other words, it flows in the opposite direction of the P–N junction. The electrons and holes produced close to the P–N junction are converted efficiently into current, but the electrons and holes that are produced further away from the P–N junction tend to recombine until they reach the depletion layer and are unable to contribute to the production of current.

Light energy is expressed as $E = h\nu$. If the radiated light energy is considered to be equal to the Si energy band gap (Eg = 1.12 eV), then from $h\nu = 1.12\,\text{eV}$ and $\nu = c/\lambda$, the energy becomes $\lambda = hc/1.12$. This equals 1.24/1.12, which is approximately 1100 (nm). Therefore, Si possesses sensitivity up to a wavelength of approximately 1100 nm.

1.2 Relationship between optical sensors and wave length

Figure 2 shows the relationship between the bandgap of each type of semiconductor and light wavelengths.

Owing to the photoelectric effect, the energy of the light in excess of the bandgap is absorbed (i.e., the shorter wavelength light) and the energy below the bandgap passes through the semiconductor (i.e., the longer wavelength light). In the case of a gallium phosphide (GaP) semiconductor, light in the color range from red to yellow passes through as it absorbs light with a wavelength of 564 nm (2.2 eV) or less. For this reason, GaP semiconductors appear to have an orange color. Si and gallium arsenide (GaAs) semiconductors appear black because these materials absorb light up to the infrared light range (however, surface reflection makes the actual crystals appear silver). Zinc sulfide (ZnS) semiconductors allow all light from the visible range to pass and therefore appear transparent. Furthermore, the light absorbed by these materials may also have an effect on the material properties. Light radiated onto the P–N junction of a Si integrated circuit (IC) has an adverse effect as it causes the generation of electron–hole pairs. For this reason, black is selected for the color of molding packages. Si is widely used for optical

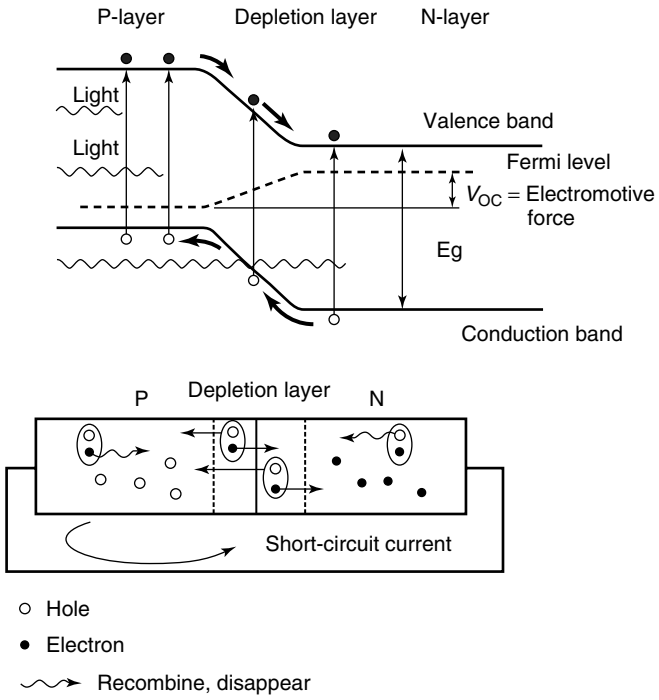

Figure 1. PD principle.

sensors as these sensors are required to detect light in a range extending from visible to infrared rays. Furthermore noncontact temperature sensors that detect infrared light generated from high temperature objects are also required to react to light in the far-infrared range. Ceramic sensors that utilize the pyroelectric effect are generally used for this purpose. However, this type of sensor falls outside the scope of this chapter, which focuses on semiconductor optical sensors.

2 APPLICATIONS OF OPTICAL SENSORS

Examples of optical sensors include automatic headlamp control sensors and sunlight sensors that help to improve air conditioning performance. However, as these sensors are installed close together and share the same basic technology, light sensors that combine both these functions are now the mainstream type of optical sensor. The following sections describe the principles of light sensor operation. Section 2.1 details the structure of a light sensor and Section 2.2 outlines each system used for the headlamps and air conditioning.

2.1 Structure of a light sensor

Figure 3 shows the external appearance and structure of a light sensor and a top view of a sensor chip.

Circular and semicircular PDs are formed on the sensor chip. The aperture is smaller than the PDs on the sensor chip. This structure is capable of detecting the direction and amount of radiated light. Section 2.2 describes the details.

2.2 Characteristics of a light sensor

Figure 4 shows an outline of the systems that use light sensors.

The headlamp control system automatically turns the headlamps and tail lamps on and off in accordance with the brightness of the surrounding environment to improve convenience and safety. However, it also has a function to detect light radiated from the headlamps of oncoming vehicles to prevent the headlamps of the driver's car turning off because of the lights of other cars. Another function of

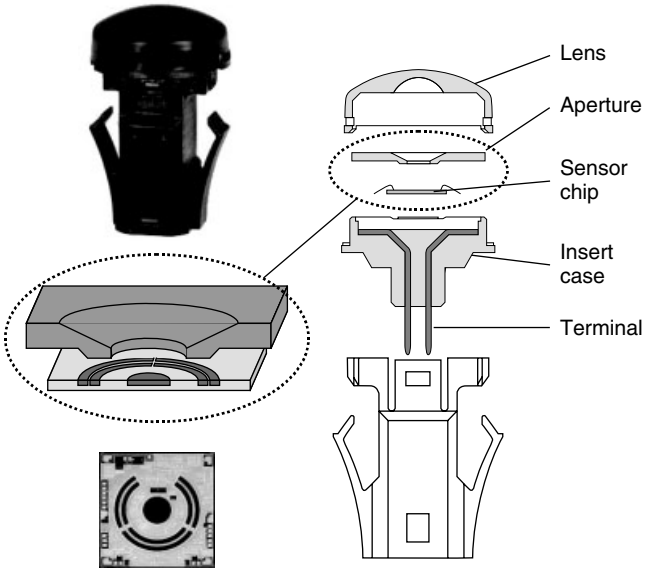

Figure 3. Structure of a light sensor.

this system prevents the driver from forgetting to turn off the headlamps.

The temperature and flow strength of the air conditioner are generally determined on the basis of the difference between the external and internal temperatures. However, as contact with direct sunlight has the effect of making vehicle occupants feel warm, air conditioners may be equipped with light sensors. These detect the direction and amount of sunlight, and improve comfort by independently controlling the air flow strength and temperature at the driver and passenger seats. Figure 5 shows the operating principle of a light sensor system.

Figure 6 illustrates the outputs from the light sensor to the headlamp control and air conditioner.

A two-direction sunlight-sensing function is necessary to simultaneously detect the amount of solar radiation coming from the left and right toward the driver's seat and the front passenger's seat. Sunlight passes through the aperture plate, and the amount of received light that is radiated onto a separate PD is detected to determine whether the light is coming from the left or the right. Figure 5 also shows the circuit that is used to realize the elevation characteristics for the sunlight function. A current is output that is proportional to the amount of light radiated onto the ring-shaped light-receiving section. This current is then subjected to arithmetic processing so that it corresponds to the elevation characteristics of the sunlight sensor and the desired elevation characteristics are obtained.

Different elevation characteristics for automatic headlamps are achieved by dividing the PD pattern on the chip so that the center is for the function for automatic headlamps, while the circumference is for the sunlight sensing function. The output is uniform in all directions owing to the ring-shape of the PD in the same way as it is for the two-direction sunlight-sensing function (Honda, Michiyama, Onoda, 2004).

3 IMAGE SENSORS

Nowadays, cameras are being installed at the front and rear of automobiles, and there has been an increase in automobile systems that use these cameras to monitor the area around the vehicle during driving and backing up. This is being done in consideration of safety around the automobile. The type of sensor used in these cameras is an image sensor.

Charge-coupled device (CCD)-type as well as complementary metal-oxide semiconductor (CMOS)-type image sensors are available now; of these, CMOS sensors are cheaper and consume less power. For these reasons, CMOS-type image sensors are in widespread use in mobile media devices such as cell phones, and they have also become the main type of automotive image sensors. The following sections therefore focus on the principle and applications of CMOS-type image sensors.

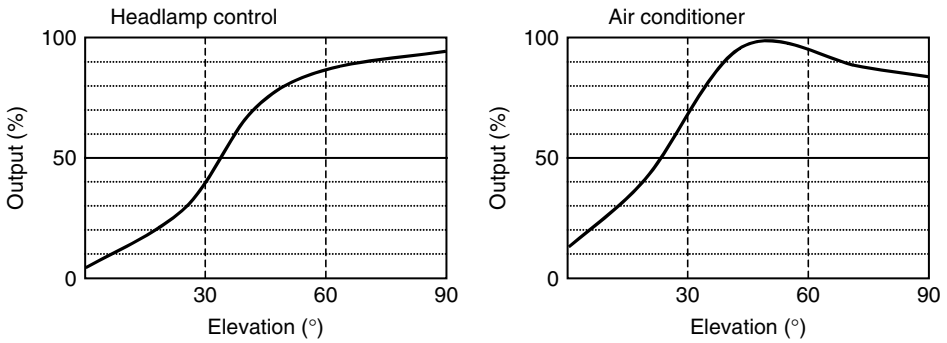

Figure 6. Characteristics of a light sensor.

3.1 Principle of CMOS image sensors

Figure 7 shows the cell composition of a CMOS image sensor, Figure 8 shows its pixel composition, and Figure 9 shows the principle of the sensor.

Since an image sensor obtains images in two dimensions, it uses a matrix layout of cells structured as shown in Figure 8. Each cell is sequentially layered with red, green, and blue filters that allow only the corresponding light to pass. The PD of each cell generates a charge that corresponds to the amount of light radiated onto it in a certain period of time. The image sensor outputs this charge as the light amount of each color. Row and column decoders are provided to acquire the charge from each two-dimensionally laid-out cell without interference. The signal acquisition sequence is as follows. Serial data is outputted by selecting the decoder for each line and each column. This operation is repeated for a single screen. This enables the image signals from the two-dimensional matrix to be outputted as serial data for a single screen. The actual red/green/blue filter layout, sequence, and know-how are proprietary knowledge of each company.

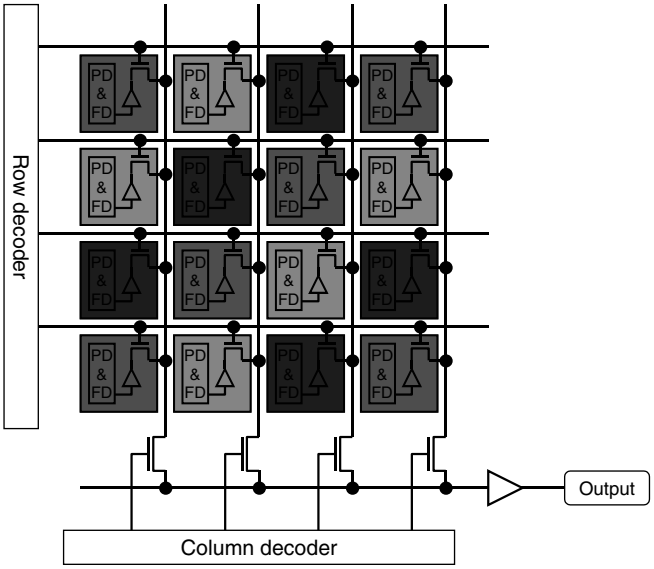

Figure 7. Cell composition of a CMOS image sensor.

Each cell operates as follows. The basic principle is the same as that of a PD, and an electric charge is produced in accordance with the amount of light received by the PD. A transistor (Tr_1) then transmits the electric charge to a floating diode (FD). As shown in Figure 9, voltage sensitivity is increased by transferring the charge from a PD with a large area to a PD with a small area.

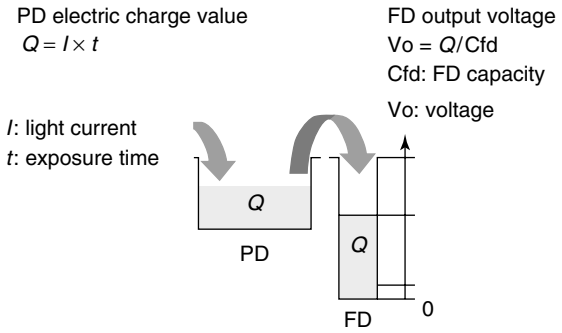

Figure 9. Principle of electric charge transmission.

Next, the charge in the FD is converted into voltage by the electric charge–voltage conversion transistor Tr_3. This voltage signal is then read by the selection transistor Tr_4. Finally, the electric charge in FD is reset by the resetting transistor Tr_2.

Infrared sensors that can detect up to the far-infrared region are classified as thermal sensors that measure infrared rays as heat. These sensors include thermopiles, which utilize the thermoelectric force effect, pyroelectric sensors, which utilize the pyroelectric effect, thermistors, which utilize the thermoelectric effect, and bolometers. There are also quantum sensors that measure infrared rays as light (Tabet, 2002; Fossum, 2008).

Figure 10. Vision sensor for safety systems.

3.2 Applications of CMOS image sensors

Figure 10 shows an illustration of a vision sensor equipped with a CMOS image sensor. This sensor is installed behind the rear view mirror. It supports safe driving by using an in-built algorithm to judge recognized images in front of the vehicle. Recognition targets include lane markings, road signs, preceding vehicles, objects, pedestrians, and the like. This sensor is currently installed in lane-departure warning (LDW) systems, which help to reduce accidents caused by vehicles leaving their lane, and automatic high beam (AHB) control systems. AHB systems help to improve driver vision at night and prevent the dazzling of drivers in other vehicles by automatically switching between high and low beams based in the presence of a preceding or oncoming vehicle. In the future it is also likely to be adopted for road sign and pedestrian recognition during driving.

Image sensors are installed close to the top edge of the windshield. This is a prominent position that easily attracts the eyes of vehicle occupants and creates a sense of crowding. Therefore, the sensors must be reduced in size to help alleviate these issues. This installation position also tends to become very hot. Therefore, other issues include developing sensors with lower power consumption and packaging with greater heat discharge capabilities.

4 CONCLUSION

This chapter has described how optical sensors are used as PDs to help improve air conditioner performance, control headlamps, and so on. In the future, the number of optical sensors installed in each vehicle will increase because of the rapidly expanding demand for image sensors in the safety field.

As the demand for these sensors increases, technological innovation of hardware is likely to lead to the development of sensors with greater performance (i.e., the improvement of sensitivity, resolution, and compactness). Software innovation is likely to result in the development of improved built-in algorithms. Consequently, sensors installed with image sensors will continue to evolve and new systems will be developed that integrate image sensors with laser radar, millimeter wave radar, sonar, and other peripheral monitoring functions. Ultimately, this technology will help to increase the feasibility of autonomous vehicles in the future.
