Possibilities of Coil Springs and Fiber-Reinforced Suspension Parts

Joerg Neubrand

Chassis Technologies—Mubea Fahrwerkstechnologien GmbH, Attendorn, Germany

1 INTRODUCTION

As early as over 400 years ago, the first helical compression springs (coil springs) were already used for wheel suspensions of a wagon body, and at the very latest since the invention of the wheel suspension strut (McPherson), they have represented the best spring design for the vertical dynamics of passenger cars. They took over suspension functions and because of their advantages regarding weight and installation space, replaced leaf springs almost completely. The necessary suspension arms to carry the coil springs may be regarded as a disadvantage, but their design enables exceptionally good road holding and safety.

Springs will be deformed elastically and during this process, they take up potential energy, which will be released when relieved. They will have to live up to such duties also during repeated and dynamic loads and considerable deforming processes. For this reason also, steel continues to be an ideal material to make springs.

Over the past few years, resource-saving weight reduction has assumed growing importance. Assuming that the weight of a smaller middle class car was kept constant, the weight of a chassis support spring was reduced by about 55% since 1992 (Figure 1). Such weight reductions were brought about by higher loads, underpinned by optimized manufacturing technologies and new types of steel, without any reductions in robustness.

One example of the developments in manufacturing technology is the high performance process (HPP) developed by the Mubea company, as a result of which the load-bearing strength of helical compression springs was increased by more than 10%. This method was first introduced in 2003, and it has been used as the global benchmark since 2004.

Moreover, in future, there will be increasing demands by car builders as regards CO_2 reductions, lower vehicle weights, and a reduction of unsuspended sections and the robustness of springs, particularly as affected by corrosion. This means that optimum use of materials employed will play a decisive role, underpinned by efficient design. In addition to that, alternative materials, such as composite materials, may be increasingly important when used for suspension purposes.

2 CALCULATION OF COIL SPRINGS

In general, the equations of the German DIN standard 2089 can be used for an initial estimate of the dimensions and stresses of a cylindrical compression coil spring with a constant wire diameter. Figure 2 shows the definition of calculation values for one deformable coil ($n = 1$).

Spring work is defined as:

$$W = \frac{F \cdot s}{2} \tag{1}$$

where s is the spring stroke.

Spring force can be calculated as follows, considering G as the shear modulus:

$$F = \frac{G \cdot d^4 \cdot s}{8D^3 \cdot n} \tag{2}$$

Spring stiffness is given by

$$c = \frac{F}{s} = \frac{G \cdot d^4}{8D^3 \cdot n} \tag{3}$$

Shear stress may be calculated using the following equation:

$$\tau = \frac{G \cdot d \cdot s}{\pi \cdot D^2 \cdot n} = \frac{8F \cdot D}{\pi \cdot d^3} \tag{4}$$

Such stress equation is valid for a straight wire and torsion stress only. In coil springs, the wire is curved and the stresses on the inside are higher than those on the outside of the coil. Torsion and shear forces will have to be added. Moreover, the same force is being applied to a smaller area on the inside of the coil (Figure 3).

Therefore, stress has to be corrected by the factor k, depending on w, the ratio of the coil diameter to the wire diameter.

$$w = \frac{D}{d} \tag{5}$$

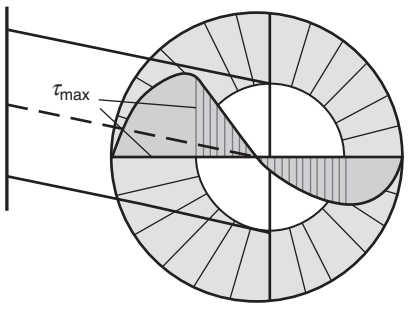

Figure 3. Stress increase on the inside of a coil. (Reproduced from Carlitz and Neubrand, 2008. With kind permission from Springer Science+Business Media.)

DOI: 10.1002/9781118354179.auto001
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$k = \frac{w + 0.5}{w - 0.75} \tag{6}$$

Corrected stress may then be calculated as follows:

$$\tau_k = k \cdot \tau \tag{7}$$

When designing a spring, the maximum stress τ_{max} is most important for minimizing the weight of a spring. Assuming a uniform deflection without any disturbing side forces, the mass of a cylindrical coil cannot be lower than a certain minimum mass m_{min} (Brandt, Kobelev, and Neubrand, 2007). This mass m_{min} is calculated according to Equation 1 with ρ as the density of the spring wire material and G as the shear modulus. The force F_{max} is the load at full jounce height. The coil spring mass m_{min} is reciprocally related to the maximum shear stress τ_{max}.

$$m_{min} = 2\rho \cdot G \frac{F_{max}^2}{c \cdot \tau_{max}^2} \tag{8}$$

In general, there are two ways to reduce coil spring weight:

1. Shape optimization for decreasing the load stress along the coil spring wire.
2. Increasing maximum allowed stress τ_{max}.

Until quite recently, it was common practice to decrease spring weight by increasing the stress level of suspension springs (Figure 1) and keeping robustness with certain measures regarding material and process optimization.

In real-life springs, load stresses are distributed nonuniformly along the coils. Therefore, it is necessary to calculate springs using a finite element analysis (FEA) as described, for example, in Georges (2000).

Owing to tremendous progress in calculation methods and corresponding production technologies, shape optimization is now possible for increasing the material usage by stress homogenization.

3 SIDE LOAD SPRINGS

The concept and design of a vehicle axle mainly defines the shape of a suspension coil spring. Moreover, the loads occurring and packaging are important factors. Two types of loads can be differentiated. First, the coil over shock, where both ends of the coil spring travel in line with each other, spring and damper form a single device. The second load application is to place one end of the coil spring on a suspension arm. Here, this end travels along a spatial curve, which leads to a nonuniform stress distribution along the spring profile and causes a distortion of the spring body (Carlitz and Neubrand, 2008).

The McPherson strut is a special case of the first kind of load. Owing to the conceptual axle design (Figure 4), unwanted moments occur, resulting in side loads at the

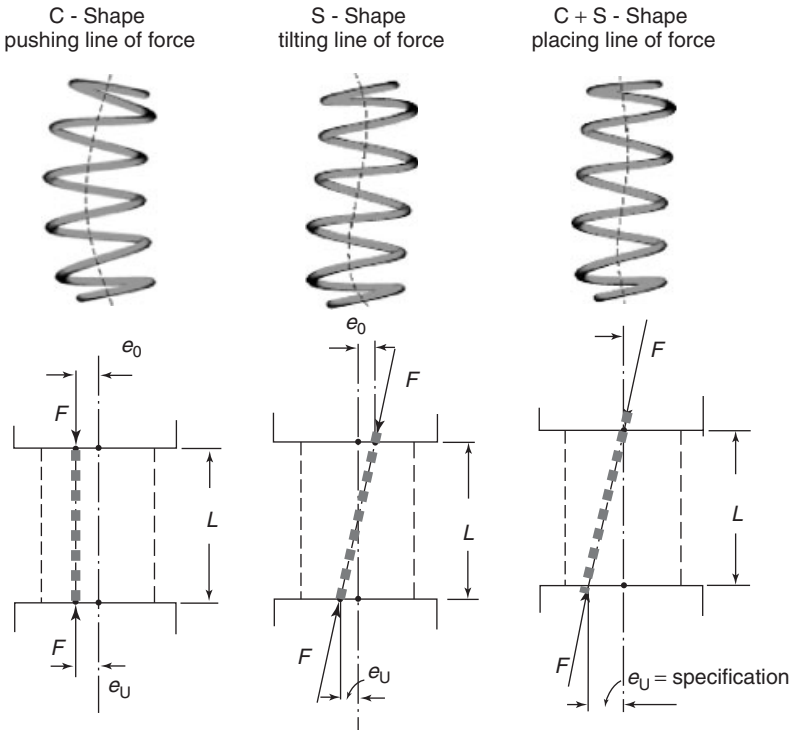

Figure 5. Adjustment of the load vector through spring shape. (From Neubrand *et al*., 2010. Copyright © 2010 SAE International. Reprinted with permission.)

damper rod and therefore, to an increased friction along the damper rod and damper piston bearings. This friction does not only generate increased wear and tear of the damper piston and seals but driving comfort may also be reduced. A slip–stick effect is noticeable especially at very small damper travels.

Until the late 1980s, this problem had been solved by tilting a huge cylindrical coil spring on a McPherson strut, which offered compensation for such unwanted moments. However, as packaging space for suspension components becomes ever smaller, this solution was soon obsolete because of the voluminous coil springs needed to allow for tilting.

For this reason, the development of side load (SL) springs had been started (Muhr and Schnaubelt, 1991; Kobelev *et al*., 2002; Brandt and Neubrand, 2001). These counteract the unwanted moments within a small package because of geometrical intelligence. These springs are showing an S-shaped centerline in unloaded condition, which leads in loaded condition to a tilted load vector and fully compensates the unwanted moments around the McPherson strut (Carlitz and Neubrand, 2008; Muhr and Schnaubelt, 1991; Kobelev *et al*., 2002; Brandt and Neubrand, 2001).

Furthermore, the load vector of these coil springs can be further attuned by adjusting spring geometry, without having to change spring seat designs. Moreover, spring seats can be minimized, because SL coil springs are mostly designed as double-pig-tail springs.

The principle of control of the load vector is shown in Figure 5, and the load vector offset can be "pushed" by a C-shape and "tilted" by a pure S-shape. A combination of these two adjustments leads to a typical SL spring, where the load vector can be "placed."

The technology of the SL spring as explained earlier triggered the development of multiple versions and modifications of spring designs and as of today side load technology is used in more than 70% of all McPherson strut applications worldwide.

Moreover, the ability for controlling the load vector of coil springs could also be used for additional functions, such as height leveling systems as described in Carlitz, Neubrand, and Hengstenberg (2005).

4 NEW GENERATION COIL SPRINGS

Nonparallel coil spring deflection leads to a nonuniform load stress distribution along a coil spring. Even though an SL coil spring is a coil over shock, the deflection is nonparallel. The load vector is inclined relative to the axis

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto001
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

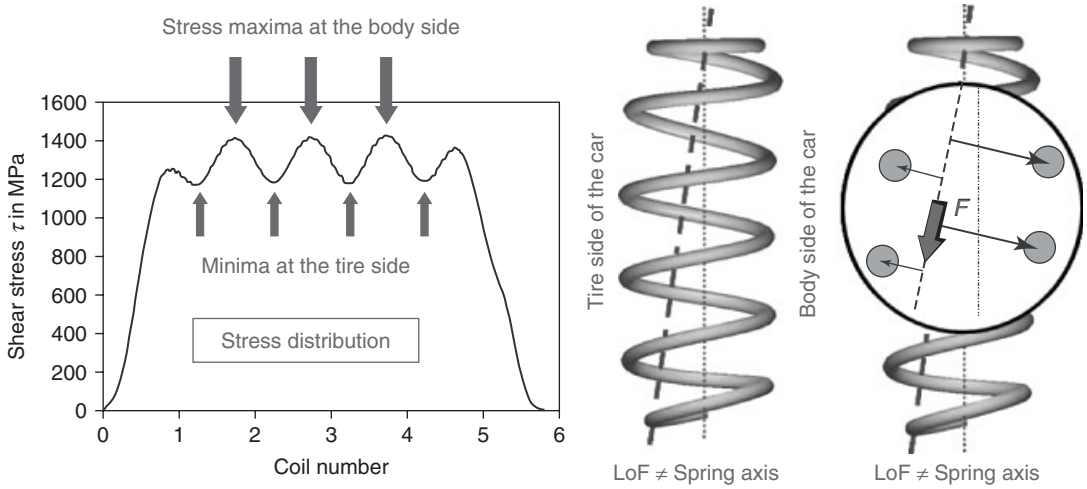

Figure 6. Stress distribution of a conventional SL spring with inclined load vector. (From Neubrand *et al*., 2010. Copyright © 2010 SAE International. Reprinted with permission.)

of the damper and this is causing a nonuniform distance of coil spring wire to the load vector. Distances from the wheel are smaller than the distances on the opposite side of the load vector (Figure 6).

The distance from the coil spring wire to the load vector also reflects the moment arm of the moment around the coil spring wire centerline. Thus, nonuniform deflection of the spring and an inhomogeneous stress distribution occur under load (Figure 6). This leads to local stress minima at the coil position toward the wheel and local maxima toward the vehicle body. Hence, material utilization is not at its best and spring weight is too high, considering maximum stress τ_{max} as the limiting factor.

Therefore, a significant weight reduction and optimal materials utilization may be achieved by homogenizing stress distribution. Modern FEA methods as well as corresponding manufacturing processes are offering such a chance.

The following equations are used to describe the true shape of a suspension spring (Figure 7; Neubrand *et al*., 2010).

$$\underline{r_g} = \left[\cos(n) \cdot R(n) \quad \sin(n) \cdot R(n) \quad z(n)\right]^T \tag{9}$$

$$\underline{r_m} = \left[x(z) \quad y(z) \quad z(n)\right]^T \tag{10}$$

$$\underline{r} = \underline{r_m} + \underline{\underline{T}} \cdot \underline{r_g} \tag{11}$$

These equations can be used for a numerical determination of local stresses of the whole spring wire during deflection. Latest FEA software offers an optimized coil spring shape respecting all restrictions such as package, load vector, rate, and maximum stresses and the shape is automatically translated into required computer-aided design (CAD)

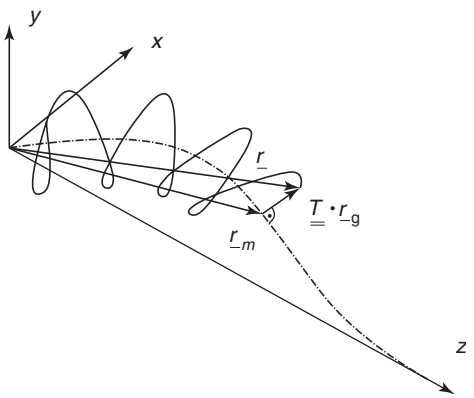

Figure 7. Parametric description of an SL coil spring. (Reproduced from Neubrand *et al*., 2001. © R. Brandt and J. Neubrand.)

formats. Automated pre- and postprocessing as well as parametrical definition of the spring shape allow for systematic adjustment of coil spring parameters while solely focusing on the FEA output.

Using this powerful method, it is possible to automatically generate the uniform load stress distribution of a new generation spring (Figure 8). Coil spring geometry is optimized in a way that preserves the defining spring characteristics, while load stress is uniformly distributed along the coil spring profile. Hence, the lowest possible spring mass m_{min} has been numerically calculated.

This new generation spring still offers all advantages of a traditional SL spring regarding side load compensation within small package space and furthermore, a huge weight reduction due to perfect material utilization.

This method of design may also be applied to other kinds of coil springs. The following example shows a rear

axle coil spring, where the spring seats deflect along a spatial curve (Figure 9). The light gray springs show a conventional cylindrical spring at rebound and full jounce condition, whereas the dark gray spring shows a new generation spring at full jounce condition.

Spring deflection in such a system is highly nonuniform; deflection extremes even change from one direction (at rebound height) to the other side (at jounce height). The result of this nonuniform deformation once more is an inhomogeneous load stress distribution along the coil spring profile (Figure 9). Furthermore, coil clearance issues particularly at jounce height may occur.

Applying the same methods employed for new generation spring design and relying on the same principles as were employed for strut application, uniform deflection, and load stress distribution can be achieved. Just like for strut applications, significantly better steel utilization results in welcome weight reduction while load stress limits have not been increased.

The idea of stress homogenization by new generation design and, therefore, better material utilization offers a weight reduction of more than 10% without increasing maximum stress and/or better robustness.

Coil springs are being produced by hot or cold forming. In recent years, cold forming won significant market shares because of the high flexibility in forming complex shapes. The latest production processes can transfer the FEA design into the forming operation and plastic as well as elastic deformations during manufacturing may be anticipated.

Coiling programming systems have been developed to efficiently produce most complex coil spring designs with the highest possible dimensional capability.

5 MATERIALS AND ROBUSTNESS

Spring materials must have superior properties regarding storing and releasing huge amounts of elastic energy. Therefore, materials with high shear and elasticity modulus are showing the best properties for springs. Furthermore, materials should have high strength and high elasticity to withstand high loads without any plastic deformation (Neubrand, 2004). Properties such as corrosion resistance, sag loss resistance, and dynamic fatigue strength are very important; in addition, superior toughness is also important, which is increasing resistance against notches and cracks.

In general, steel is still fulfilling most of these required properties as best in class. Several alloy elements can be added for improving the steel. Until the late 1980s, CrV steels were commonly used for coil springs. Nowadays, SiCr steels represent a major part of vehicle suspension springs because of their very good properties, such as high toughness at great strength and high settling strength, even at higher temperatures.

Until the late 1980s, material impurities such as inclusions represented a major problem for springs regarding durability, especially in case of high cycle fatigue. Super clean steels were developed as the superior material for valve spring applications, avoiding critical inclusions as far as possible (Neubrand, 2004) by creation of deformable, low melting inclusions.

Continuously decreasing packages, increasing vehicle weights and higher demands regarding component lightweight design caused a significant increase of tensile strength and hardness. The inductive tempering represents a milestone of improvement in this direction, because it provided an excellent fracture toughness for tensile strength higher than $R_m = 2000\,\text{MPa}$. In addition to that, corrosion robustness is assuming ever greater importance. This is the result of combining higher stresses with high tensile strength material under corrosive environmental conditions, when the topic of stress corrosion cracking is assuming ever more relevance. In principle, a distinction is made between two corrosion mechanisms: corrosion in the presence of oxygen (rust), where corrosion scars will be formed by a local dissolving of iron and corrosion under the influence of acids, which is better known as *hydrogen embrittlement*, that is to say, the material will get brittle when cathodic hydrogen will be formed along the grain boundaries (Carlitz and Neubrand, 2008).

These two processes may be counteracted by a number of steps:

- turning the layer of rust into a covering layer by alloying metals such as Ni, Mo, or Cu, thus reducing the speed of corrosion;
- forming hydrogen traps with the help of V (vanadium) or Ti (titanium), where hydrogen will be held up and where there will be less hydrogen embrittlement as a result.
- bringing up fracture toughness by fineness of grain formers such as V, so that tension peaks at corrosion scars can be more easily reduced as a result of plastic distortion.

Using such modifications of materials, such steels as the so-called HPM190 were developed by changing chemical composition on the basis of classical 54SiCr6. Especially in Japan, other alloys were also developed. However, they always limited the strength of steel, so that it was not possible to use the weight reduction potential to the full. Over and above, such modifications of materials using alloy elements are very expensive and they very often result in "special steels." These can only be used for individual spring or car factories and they will not be made in sufficient quantities to gain a sustained foothold in the market.

Over the past few years, a number of very interesting techniques were brought to series production that increase toughness at high strength. Thermomechanical treatment offers one case in point. Here, material will be formed during the austenitic stage in such a way that a very fine grain structure will be produced during the martensitic state that results in very good mechanical properties.

Classical tempering in various types offers additional methods to bring about very small grain sizes. The temperature for austenitization is quite important for the grain size evolution. An adequate method to create a fine microstructure in the rim of a wire could be a heating at high temperatures for hardening the whole wire section, followed by an austenitization at low temperatures just within the rim to create a fine microstructure (Liu, 2011). Other methods such as intensive mechanical working by multiple drawing processes as well as subsequent simple or multiple tempering were investigated. Here, a multitude of nuclei generated by mechanical working will be used to produce small grains. Shaping and tempering parameters need to be very finely balanced for all these methods. Surface layer modification is a procedure of its own (Neubrand and Hartwig, 2009), in that it combines a tough lower strength marginal layer with the hard core of the wire. Giving it some thought, this method can be integrated into inductive wire tempering processes, which makes it very economical (Figure 10).

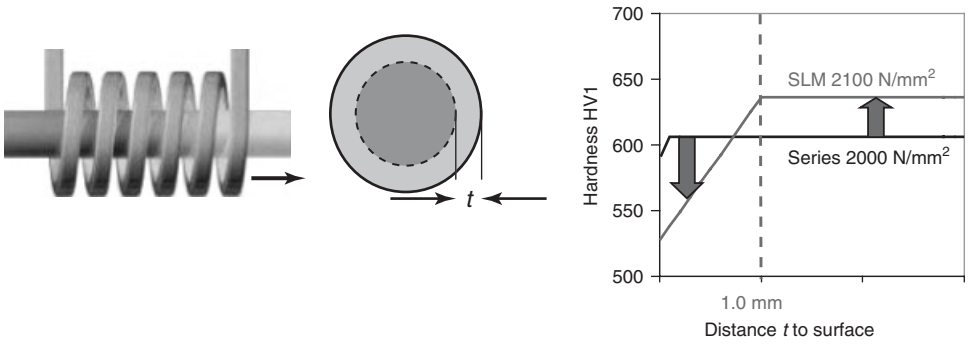

Figure 10. Mubea surface layer modification.

Over the past decade, alternative materials have been investigated to a large extent but could not really move from applications in racing and exotic cars to volume car manufacture. Some particular mass production applications occurred on and off, such as titanium springs for the VW Lupo FSi (Schauerte *et al*., 2001) and composite leaf springs for the Daimler Sprinter and VW Crafter, but the main reason against greater usage in volume cars can be defined as poor cost competitiveness compared to steel springs. Nevertheless, steel still has some further potential for improvement, but the properties are going to reach a certain limit and therefore, new material will become of greater importance, also in the spring world.

6 COMPOSITE SPRINGS

From the materials point of view, composite materials harbor specific potential. Of practical relevance are combinations of glass and carbon fibers with pressure setting plastics material. Thermoplastics materials are also gaining importance as matrix materials; however, because of technological restrictions, they have been unable so far to meet suspension challenges at high dynamic loads. Glass fibers represent a better material for spring application because their lower elasticity module compared to carbon fibers is favorable regarding high strokes and deforming requirements. Given their high specific strength and the stiffness of composite materials, it becomes in principle possible to achieve weight reductions ranging from 30% to 70%. While reducing unsuspended masses it is also possible to reduce driving dynamics and also as regards noise, vibration, and harshness (NVH) behavior, composite materials may offer advantages when compared to steel, because their material amplitudes are very much higher. In view of high corrosion resistance and resistance against the influence of other environments, surface protection mostly is something that can be discarded, but special protection will be needed when it comes to possible damage by rocks. Studies into the comprehensive energy input for making compound components have shown that their CO_2 footprint is larger than that for steel making (Geuder, 2004). However, this may be compensated for partly or wholly in view of the considerable reduction in quantities required during operational cycles.

However, the potential of this group of materials is also limited by serious disadvantages, which have so far prevented the use of fiber composite materials in large quantities. The load transmission is demanding special designs. Typically, quite frequently high loads come up cross-wise to the main load direction so that the material is not taking up a load in an ideal way and following the direction of the fiber, so that only medium loads may be imposed on the matrix. In addition, allowances will have to be made when it comes to large series production and available manufacturing processes when comparing these with units made of steel. At present, these represent the focal point of research and development efforts all over the world.

Continuous reinforced compound fiber materials as they are used for structural elements in car-making reveal strong anisotropic, that is to say, direction-dependent properties. Fibers employed will be oriented as to the loads occurring so that they take up tension and pressure, if possible. Typical fiber volume percentages for structural elements reach about 60%.

When it comes to suspension, leaf springs made of composite fibers represent an application offering high potential for glass-fiber-reinforced plastics in the chassis section that may bring about industrialization and large quantity manufacturing (Figure 11).

Predominant bending requirements for leaf springs offer a possibility to align fibers in one direction only. When compounded, their elasticity modulus may reach about 45,000 MPa. Compared to conventional multi-leaf springs made of steel, it is possible to score considerable reductions

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto001
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 11. Tension leaf spring made from glass-fiber-reinforced plastics (Schürmann and Keller, 2010).

in weight, amounting up to 70%. The number of leaves in a multi-leaf spring may be reduced; sometimes springs may be replaced by a one-leaf spring only. Tension leaf springs (Schürmann and Keller, 2010) represent a specific development, which might replace multi-leaf springs. Over and above reduced weight, it might also be possible to set up progressive spring characteristics.

Using fiber compound materials, it may also be possible to improve damping properties. Contrary to steel leaf springs, spring eyes will not be shaped, they have to be linked to the interfaces with a wedge. A number of different types emerged for steel leaf springs, and they come in differing width and breadth. Such structural shapes may also be offered in glass-reinforced fibers. The simplest shape is a rectangular spring with a constant cross section. Other shapes of cross sections lead to (approximate) constant bending stress, which means a constant use of material employed. Hyperbola-shaped springs may easily be manufactured of glass-fiber-reinforced plastics. In this type of spring, there is a linear reduction of width from the center, whereas the cross-sectional area remains constant. For springs of this type of manufacture, no cut fibers need to be used and it is quite easy to make a blank, or a preform, of various sections. There is a constant width for parabolic springs and their width will be adapted to the load course. Given their varying cross sections, different quantities of fibers will be needed over the course of the spring. This is equivalent to more input in complex manufacture; on the other hand, parabolic springs are weight-optimized structural types, and constant width is in keeping with the installation space situation in a car (Franke, 2004). It is also possible to bring about a compound-fiber compromise between a rectangular and a parabolic spring, by designing a smaller change in width than for the parabolic spring, which may be achieved by a variable fiber volume percentage (Götte, 1989), so that fibers will not have to be cut. Variations in the range 45–65% in the fiber volume would be possible. In practice, however, such low fiber volume percentages may lead to unequal distribution of fibers over the entire cross section.

There is a large number of manufacturing methods for the production of fiber-plastics compounds. Because of the resulting good properties at dynamic loads, the prepreg method stood the test of time for leaf springs. Prepreg processes produce optimum bond strength (Schürmann, 2007).

Component manufacture here first involves impregnating fibers with resin so that subsequent parts of the process may work with strip sections easy to handle (Figure 12).

An impregnated semifinished product represents the first step (preimpregnated fibers). To make it, the resin system and the fiber will be brought together on backing paper while adding some heat. The cross-linking reaction of the resin begins when a prepreg is made. This process, however, may be interrupted by cooling, which means that a weakly cross-linked stage will be reached, and the resulting material may be stored when cooled down. Afterward, prepreg strips will be cut and a blank will be prepared. The blank will then be put into a compression mold and cured at high pressure and temperatures between 110°C and 170°C. Springs will then be subject to mechanical postprocessing.

It is also possible to manufacture leaf springs using a resin injection process. For this resin injection process,

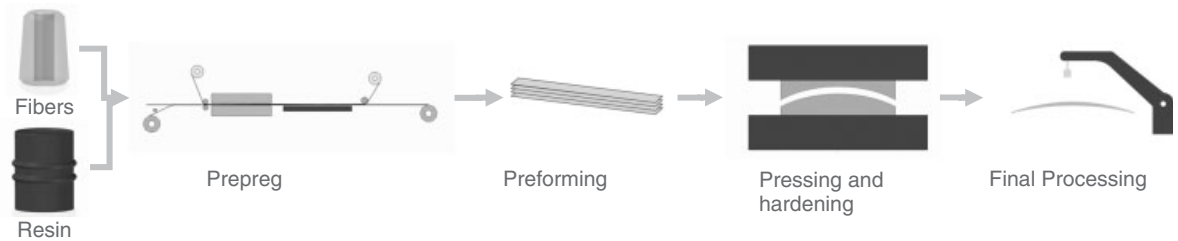

Figure 12. Sequence of operations during spring leaf manufacture, using the prepreg process. (From Müller, 2012. Reproduced by permission of David Müller, Mubea © Mubea.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto001

a fiber structure will first be manufactured of the dry reinforcing fibers, which follows the component geometry required. Structural cohesion may be achieved as needed using textile methods, such as sewing processes or involving binder, gluing fibers together. Such fiber structures are known as *preforms*. This preform will then be inserted into a pressing tool, which may be used to inject the resin system. The tool has the jets required and the resin system will be fed into this unit by a mixing device. Resin injection comes in a large number of varieties, distinguished primarily by the type of injection used. Pressure, vacuum, and combined processes are used to achieve the desired results. There are also variations of closing the tool and applying press pressures. The term *resin transfer molding* (*RTM*) is used for the group of pressure-supported resin injection methods (Mitschang and Neitzel, 2004). Compared to prepreg methods, resin injection processes use resins with considerably lower viscosity, as fibers will have to undergo a wetting process as complete as possible within a very short time frame. This is decisive for resultant compound properties and at the same time, this is also the decisive disadvantage for this particular process when manufacturing thick-walled components.

Conventional suspension springs, used as helical suspension springs, offer another field of application for fiber compound materials. Such helical compression springs are mainly made of steel today. Figure 13 shows different types of suspension springs, which are currently investigated regarding feasibility in fiber composites. Specific properties of fiber compound materials are integrated into their design in various types of manufacturing (Müller, 2010). In the case of a mere materials substitution when comparing a steel spring and a helical compression spring (Sardou, 2002), the direction of the fibers must be chosen in such a way that torsion loads may be borne by the spring in an appropriate manner. A classical orientation is to position fiber layers interchangeably in $+45^\circ$ and -45° directions. This corresponds to the direction of the main normal tension in cases of pure torsion.

For spring cross sections, both a circular cross section and a circular ring cross section similar to a tube have been proposed. The circular ring cross section not only offers additional weight-saving potential but it also involves more installation space for the finished product. A significantly reduced shear modulus of compound fiber materials using a $\pm 45^\circ$ layering when compared to steel results in the fact that the spring geometry of a steel spring cannot be transferred, but that it must be rethought. Composite fiber materials have a low compressive resistance. Therefore, the spring interfaces must differ from those for steel springs, and the design of these must consider the reduction of surface stresses.

A bellows-type spring structure offers one possibility of materials-adapted design (Marquar *et al*., 2010a).

As opposed to a conventional helical spring, this spring element bears loads by bending and membrane tension. Thus, it is possible to make full use of fiber strength.

A third type of design is the meander-type spring (Kobelev *et al*., 2008). It is almost exclusively bearing bending loads, which means that it may also be used effectively for compound fiber applications. Subdivided into two elements, this type of spring may also be placed around a shock absorber.

First concepts are also available for designing wheel-bearing units and shock absorbers to be made of compound fiber material. Because of high stiffness demands, carbon-reinforced plastics are given preference here (Marquar *et al*., 2010b). Compound fiber material is very appropriate for such complex components, because the number of elements may be brought down and additional functions

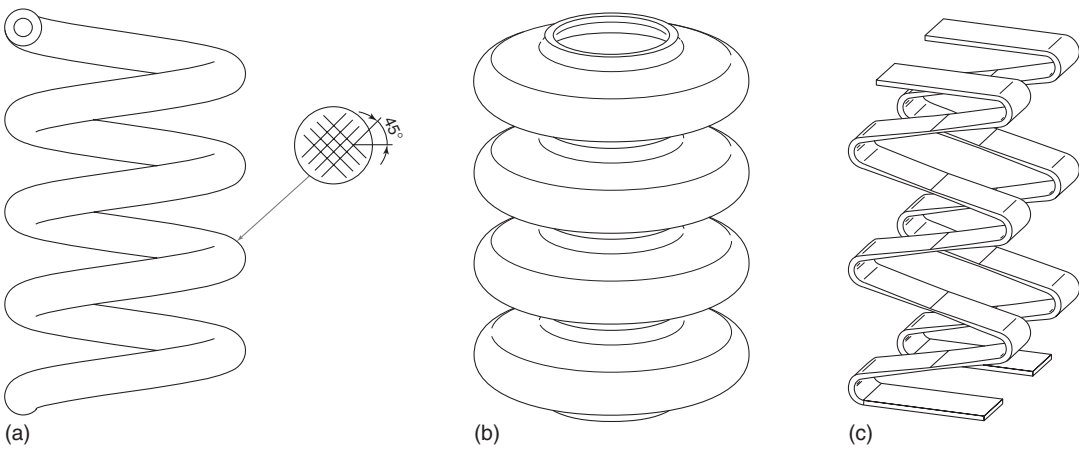

Figure 13. Different types of composite springs: (a) coil spring, (b) bellows-type spring, and (c) meander-type spring.

can be integrated. As already known from air transport, it is for instance possible to integrate sensors directly into such material, so as to protect them against external stress.

A significant disadvantage of compound fiber materials is to be seen in that manufacturing technologies lack sufficient flexibility to represent various forces and constants as taken up by springs. Given a large platform, a great diversity of brands, engine types, and configurations must be implemented for the same installation space with similar connection concepts. This means that quite readily one may need over one hundred different spring force/spring constant combinations for one platform and for one axle at each platform. For the present compound fiber concepts, this would need a new tool for every new component number to produce the exact spring geometry. In case of steel, an isotropic material, this can be achieved fairly easily by varying wire diameters, the number of active windings, or the diameters of coil windings.

Suspension Arms, Steel versus Aluminum, Where are the Benefits?

Dirk Adamczyk, Markus Fischer, and Klaus Schüller

ZF Friedrichshafen AG, Friedrichshafen, Germany

1 INTRODUCTION

Suspension arms or links connect the wheel or the wheel carrier with the vehicle body, usually via a subframe, and allow with respect to the vehicle chassis the controlled motion of the wheel. They have to transmit the loads from braking, cornering, vehicle acceleration, and impacts from the road surface. There are even strong crash requirements for the suspension arms. Crash or controlled buckling and durability are key targets for suspension arms. In special axle types, the suspension arm has to transmit the loads from vertical acceleration and "carry" the vehicle load. In this case, the spring is directly or indirectly assembled to the arm (Heißing, 2011).

Owing to the fact that the control arm is assembled to the wheel carrier, the mass of the arm is at least partially unsprung mass. On the basis of this, lightweight is one of the most important design targets for a suspension arm as it supports two design targets on vehicle level:

1. General low vehicle weight to reduce CO_2 emissions and
2. To improve the vehicle performance, for example, improved vehicle acceleration and improved vehicle safety and comfort by reducing the unsprung mass (Adler, 1991).

Suspension arms are highly integrated in the overall vehicle package. Main drivers are the required wheel or tire clearance and the ground clearance. As on the one hand, wheels are getting bigger and bigger with every new vehicle model, and on the other hand, engines and especially hybrid engines require more and more package space, the allowable space to package suspension arms gets more and more limited.

Beside all functional and packaging requirements, there is a very strong focus on costs and the manufacturing/assembly process. As suspension arms have a critical function for the vehicle, it is essential to have a strong focus on quality and robust production processes that have to be globally available for worldwide vehicle platforms.

1.1 Where are the benefits?

We have to take aluminum to get the best weight and steel to get the best cost.

Of course, it is not as simple as this. Although for many applications, the sentence is true.

Considering the material data (Table 1), it is easy to imagine that there is no simple answer to the question: Steel versus aluminum – where are the benefits?

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002

Table 1. Mechanical properties of steel and aluminum.

	Steel	Aluminum
Young's modulus	210 Gpa	70 GPa
Density (ρ)	7850 kg/m^3	2700 kg/m^3
Tensile strength (typical high end)	800 MPa	Up to 380 MPa

Some thoughts about ratios between the material properties of aluminum and steel:

$$\frac{\text{density (steel)}}{\text{density (alu)}} = \frac{7.85\frac{\text{g}}{\text{cm}^3}}{2.70\frac{\text{g}}{\text{cm}^3}} = 2.91 \quad (1)$$

$$\frac{\text{young's modulus (steel)}}{\text{young's modulus (alu)}} = \frac{210\,\text{Gpa}}{70\,\text{Gpa}} = 3.00 \quad (2)$$

$$\frac{\text{Tensile strength (steel)}}{\text{Tensile strength (alu)}} = \frac{800\,\text{MPa}}{380\,\text{MPa}} = 2.11 \quad (3)$$

One of the main drivers for using aluminum in automotive business is its weight reduction potential. The density of aluminum is 2.91 times lower than for steel (1). At the same time, the tensile strength is lower as well, but only 2.11 times lower (3). This means, if tensile strength is essential for the design, it is still possible to achieve a major weight reduction.

An example that considers previous material facts is calculated (Figure 1), based on a simple tension rod. A tension load of 40 kN was chosen, as it is an average force in today's mid-sized passenger cars.

This simple assumption of a rod tension loaded by a one-axis static load shows the aluminum weight-saving potential of 27.7%. In both cases, the tensile strength of the respective material is on the high level of the forging alloys that are typically used in the automotive industry for chassis components (380 vs 800 MPA).

If the stiffness is essential for the design, with the Young's modulus being the relevant key parameter, then there are some slight advantages for steel regarding weight, as the Young's modulus of aluminum is even 3.00 times lower than the Young's modulus of steel (3).

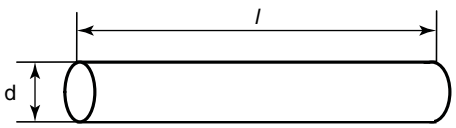
For most of the control arms, the required buckling load is important for design and weight. A basic factor for the buckling load is as well the Young's modulus. Taking a simple straight control arm, the following ideal example shows that the steel version is even lighter than the aluminum version – at least the middle section (Figure 2).

For the buckling calculation, there are different buckling conditions (Figure 3), but for typical suspension arms, the mode (2) has to be used.

For the calculation in the example, the following extended equation will be used. The equation includes bending/offset (Figure 4) to cover, for example, tolerances.

$F_{\text{Buckling}} = \frac{\delta_{\text{steel/alu}}}{\frac{e+f}{W}+\frac{1}{A}}$; based on offset [$e$]; additional displacement/bending [f] under load [F]; maximum stress for steel or alu [δ]; resistant torque [W]; cross section [A].

F_{max} = 40 kN (Load applied to the rod)
l = 300 mm (Total length of the rod)
$R_{\text{m steel}}$ = 800 MPa (Ultimate tensile strength)
$R_{\text{m alu}}$ = 380 MPa (Ultimate tensile strength)



$$\sigma = \frac{F}{A} = \frac{F}{\frac{\pi d^2}{4}} \quad \text{(Stress)}$$

$$d = 2\sqrt{\frac{F}{\sigma\pi}} \quad \text{(Required rod diameter)}$$

$$m = \frac{d^2\pi}{4}\, l\, \varrho \quad \text{(Mass of the rod)}$$

$$d_{\text{steel}} = 2\cdot\sqrt{\frac{40\text{ kN}}{800\text{ MPa}\cdot\pi}} = 8.0\text{ mm};\ m_{\text{steel}} = \frac{(0.8\text{ cm})^2\cdot\pi}{4}\,30\text{ cm}\cdot 7.85\,\frac{\text{g}}{\text{cm}^3} = 118.4\text{ g}$$

$$d_{\text{alu}} = 2\sqrt{\frac{40\text{ kN}}{380\text{ MPa}\cdot\pi}} = 11.6\text{ mm};\ m_{\text{alu}} = \frac{(1.16\text{ cm})^2\,\pi}{4}\,30\text{ cm}\cdot 2.70\,\frac{\text{g}}{\text{cm}^3} = 85.6\text{ g}$$

Figure 1. Example: a mass comparison of a steel rod and an aluminum rod under the same load requirement.

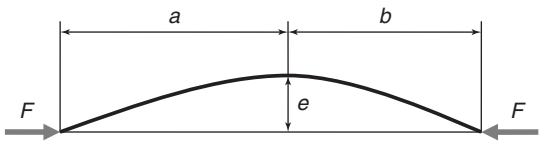

Figure 4. Buckling including offset.

$$f_{\text{buckling}} = -\left[\frac{e+W\left(\frac{1}{A}-x\right)}{2}\right] \pm \sqrt{\left(\frac{e+W\left(\frac{1}{A}-x\right)}{2}\right)^2 + W \cdot e \cdot x};$$

displacement [f] under buckling load [F]; $x_{\text{buckling}} = \frac{\delta_{\text{steel/alu}} a \cdot b}{3 \cdot E \cdot I}$; distance [$a$]/[$b$] (Table 2).

The simple comparison (Figure 5) shows that aluminum does not necessarily lead to the best weight solution. In this case, the steel design is approximately 11% lighter than the aluminum design. This example is also a very simplified case based on only one requirement – in reality, further boundary conditions such as interfaces and packaging requirements between suspension arm, subframe, and knuckle have to be considered. Considering all the packaging requirements, the picture will likely change and a weight advantage for the aluminum design can be expected.

There are additional aspects that further influence weight (and costs). In typical sheet metal applications, there are weld seams that reduce the material properties significantly. For forging and casting parts, the tolerances of the raw part (e.g., thickness) have to be considered.

The existing applications show a typical weight-saving potential of 10–50% by the use of aluminum. The more complex a part is and the more it is effected by fatigue, the higher the weight-saving potential is. For the cost side, it is more or less the opposite.

The following sections show the typical influencing factors for the design and the choice of the best material and the manufacturing process for suspension arms.

2 KEY FACTORS FOR THE DESIGN OF SUSPENSION ARMS

2.1 Weight and environmental aspects in suspension design

Looking at today's vehicle fleet, vehicle simulations indicate that fuel consumption is reduced by 0.25 l/100 km or

Given geometry data:
s length = 300 mm
$a = b$ = 150 mm
e = 0.5 mm
d_{max} = 18 mm (R_{max} = 9 mm)

Given data for a steel tube:	Given data for an aluminum rod:
R_{steel} = 9 mm	R_{alu} = 9 mm
r_{steel} = 7.5 mm	r_{alu} = 0 mm
A_{steel} = 77.7 mm^2	A_{alu} = 254.5 mm²
I_{steel} = 2668 mm^4	I_{alu} = 5153 mm^4
W_{steel} = 593 mm^3	W_{alu} = 1145 mm³
$R_{e\ steel}$ = 680 MPa (δ_{steel})	$R_{e\ alu}$ = 330 MPa (δ_{alu})

Results steel tube:	Results aluminum rod:
$x_{steel} = 0.0091 \frac{1}{mm^2}$	$x_{alu} = 0{,}0069 \frac{1}{mm^2}$
f_{steel} = 0.77 mm	f_{alu} = 3,87 mm
F_{steel} = 45 kN	F_{alu} = 43 kN

Conclusion:	
The mass comparison for aluminum and steel version: ($F_{buckling}$: $F_{alu} \approx F_{steel}$)	m_{steel} = 183 g m_{alu} = 206 g $\Delta m \approx$ 11%

Figure 5. Calculation including offset.

even up to 0.4 l/100 km and 0.5 l/100 km (an improvement of ca 1 mile per gallon) for light trucks per every 100-kg weight reduction (Cheah, Heywood, and Kirchain, 2010; Goede, 2007). This figure shows the increasing need for the reduction of weight and in consequence fuel for all vehicle types – vehicles with combustion engine, vehicles with hybrid engine, or electric vehicles. This requirement of weight reduction puts a lot of pressure on new designs and challenges current production processes regarding improvements and optimizations.

The goal of weight reduction nowadays can be realized by the utilization of high strength steel, standard and high strength aluminum, higher strength ductile iron (DI), and the advancement of plastics. Nevertheless, the most common material for weight-optimized links is still aluminum. There are solutions for nearly all imaginable control arm applications, using forging, casting, and performance casting processes as well as cast–forge with various alloys. Only strongly limited package spaces in combination with the need to maintain a certain maximum load level

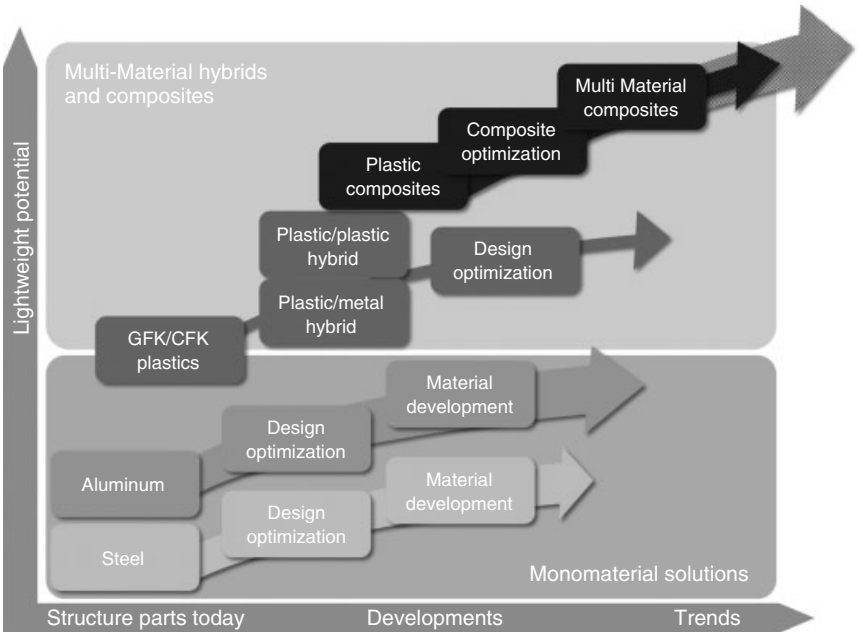

Figure 6. Material mixture as trend for lightweight concepts. (Reproduced with permission from ZF.)

would not allow using the light metal, from a functional point of view.

On the other hand, the energy balance producing aluminum generally speaks against this alloy: the amount of energy used – throughout the process from the raw material to the final product – is higher compared to that used for the processing of steel products.

Nowadays, not only the amount of energy used to produce an alloy is considered but also, seeing the global warming, a more holistic approach is chosen: more and more attention has to be paid to the overall CO_2 emission – not only during the usage of the vehicle but also under cradle-to-grave aspects. A study on a front end of a 2007 Cadillac CTS, for instance, came to the result that the aluminum design achieves the break-even distance from energy use and GHG (greenhouse gas) emission perspectives earlier within the vehicle lifetime (Dubreuil *et al*., 2010). This achievement in overall environmental friendliness has further potential for improvement. It can be reached by considering the capability of aluminum to be recycled indefinitely, which requires only 5% of the original energy to be put back into use (Heidi and Thomas 2011).

Apart from the well-known disadvantages of steel arms compared to aluminum – such as higher weight and the need for corrosion prevention – the steel producers and manufacturers push toward high strength material and smart material mixes. This is to improve weight and fight the losses caused by aluminum and upcoming composite applications. Steel control arms using sheet metal, forging and cast iron alloys, and processes are still being used widely; especially in mid- and low-sized vehicles with standard engines, they show an increasing market share. Reason for this is the focus on cost in this market segment as main driver for design selection, and other considerations have lower priorities.

Figure 6 shows an overview about trends in lightweight solutions similar to the trend we see for the vehicle body (Goede *et al*., 2008). Beside momo-material solutions, multi-material solutions will offer further lightweight potential for chassis.

2.2 General design aspects

Control arms are typically designed for two load conditions – fatigue load cycles and misuse load cases: load duty cycles (fatigue load or "dynamic" load): this is a combination of a number of single load events or block cycles. These loads are generated during "normal" driving conditions.

Single load events (the so-called quasi-static):

(a) Loads that appear frequently: these can be taken out of a load spectrum, as the load level is below the maximum, which means there are no special events or maximum loads included. The criteria are no crack or fracture, no or only minimal plastic deformation.
(b) Loads that appear just a few times over the vehicle life, such as special events and misuse. These load

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

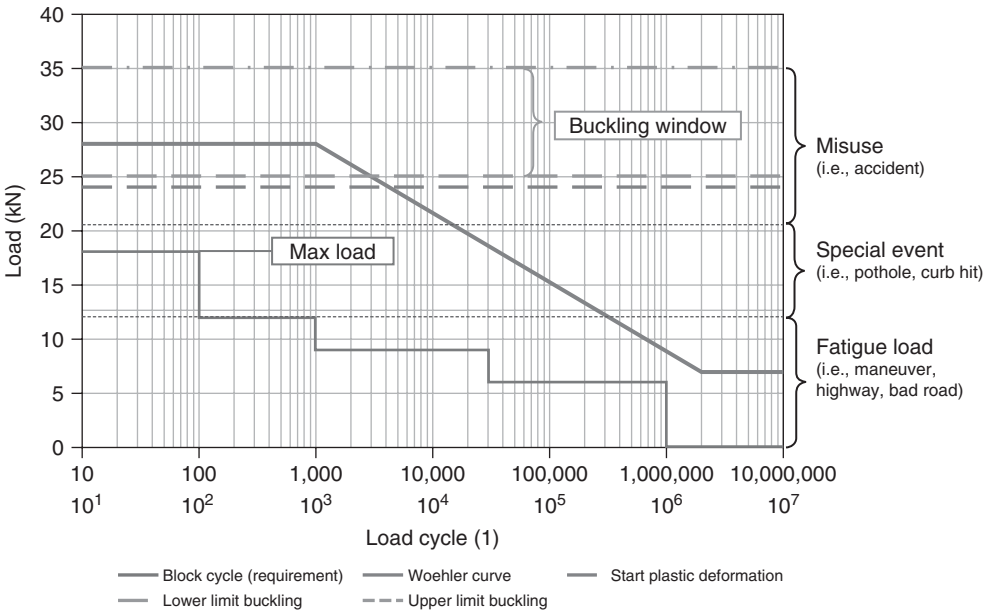

Figure 7. Relation between the load cases fatigue load, special event, and misuse.

cases are usually given through "Nastran-load-decks" (an input data format for finite element calculations) or "Adams-loads" (a software to simulate the kinematic and kinetic vehicle/component function) if not available out of real road load data measurements with test vehicles. They cover various driving maneuvers according to certain load philosophy rules such as "brake over railway tracks," "obstacle overdrive," and "washboard braking" just to name a few possible events. These loads are generated or simulated/calculated through pothole braking, curb impacts, crash (like through an accident) events, and some more. The load level reaches up to the maximum load expected from all relevant events. Depending on customer and design targets, it might be expected that after a special event full fatigue life is still ensured.

The relationship between the different load cases is shown in Figure 7.

Simulation tools check the dimensional layout of control arms before physical prototypes are built. As a standard, linear and nonlinear finite element analysis (FEA) calculations are used for the "quasi-static" cases and fatigue life FEA if needed. In most cases, it is not required to perform a fatigue life FEA because design rules for maximum strength will cover it. Structural or surface-related iteration tools such as "Optistruct" as one example support optimizations of complex structural parts considering the load requirement optimizations.

At the beginning of the design process, the following pieces of information are typically available.

The material selection or –request (material or weight target), load data and calculation requirements (i.e., for instance "Abaqus Skin"). FEA parameters such as bearing constraints (i.e., "RBE" = rigid body elements). Assessment requirements such as a maximum plastic elongation under a permissible load, maximum damage rate for fatigue life or stiffness and buckling requirements.

For suspension arm design, the following aspects are to be considered if applicable:

- Structural related: concept model constraints, special tolerances, target weight, specific section modulus or cross-sectional constraints, and stiffness. A control arm package is sometimes given as a CAD model with all applicable component contacts in worst condition, by minimum distance faces or a kinematics model (Figure 8). The kinematics model contains the kinematics points of all components and distances, as well as parameters for jounce, rebound, and steering, including stiffkinematic (structural components without elasticity content) and elastokinematic (elasticity added, such as from rubber bushings). The kinematics analysis should also consider interim movement positions to catch all possible positions that could touch minimum package requirements. Some defined steering overtravel might be required as well. In addition, it is closely to be judged and decided whether full jounce and rebound of the strut should be reduced to a reasonable amount.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

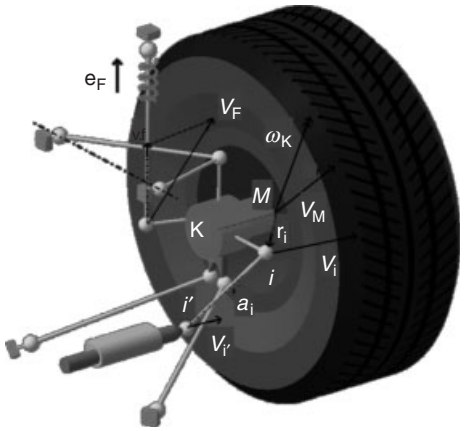

Figure 8. Kinematics model. (Reproduced with permission from ZF.)

Special care should be given to not create any stress raiser notches. Not only radii of main structures can be designed too sharp but also tight transitions to bushing bosses, mold part sections, mold part markings, and surface imperfection due to manufacturing process constraints. This is especially important not only to fulfill the fatigue lifetime requirements but also at fastener connections and for the application of coatings. In addition, pockets that can collect dirt or water have to be avoided or drainage solutions have to be found. Material raw part properties impact the function of a control arm through their mechanical, chemical, and grain conditions; material tolerance ranges; work hardening stiffening; and fracture behavior, which is different from push to pull direction. Furthermore, the geometrical tolerance chain from the raw part over the machining contour and the assembly components has to be considered in the common locator scheme at all production stages to avoid unnecessary machining or assembly effort or conflicts.

Smooth and "flowing" blended transitions are intended to achieve a consistent stress distribution under load. Special attention has to be given to avoid flat, straight, and even control arm structures, which would provide an unintended so-called close-to-Euler buckling case that reacts sensitively – small changes in typical tolerance windows of manufacturing processes would lead to large buckling load variations. Especially, this design rule contradicts the target of minimum weight because "leaving" the direct kinematics line will add weight. As a compromise, structural pinching dedicated to certain load directions can be a solution for cases that cannot allow for "buckling friendly" bending.

In some rare cases, it might be required to design a minimum natural frequency (nuisance avoidance) or minimum energy consumption (crash characteristic).

Table 3. Examples for aluminum.

	High Performance Aluminum Casting	Aluminum Forging Design
Material	SAE A 356-T6	SAE J 454-6082-T6
Yield strength	220 MPa min	240 MPa min
Ultimate strength	290 MPa min	290 MPa min
Elongation	8% min	10% min

Table 4. Examples for steel or iron.

	Ductile Iron Casting	Steel Forging Design
	Example Middle Range	Typical
Material	EN-GJS-500-7	30MnVs6 + P
Yield strength	320 MPa min	560 MPa min
Ultimate strength	500 MPa min	820 MPa min
Elongation	7% min	14% min

- Load related: maximum allowable stress for specific load cases, misuse requirements such as lateral and longitudinal buckling windows (minimum and maximum permissible buckling load) considering push and pull direction. This can be in conjunction with a required defined minimum plastic deformation limit and the direction to ensure the detection of a misuse event by a steering misalignment for instance or a defined travel of control arms relative to other components. In the case of a front impact, the requirement can be to provide a certain limited wheel travel, which must not block the doors for instance. Consequences of plastic deformations in case of hits or accidents may apply to the ball joints as well. It is to be considered that even a defined control arm bend would not separate the ball joint – in order to provide permanent wheel and/or steering control.

Example: Typical mechanical material properties of different manufacturing processes (Tables 3 and 4).

The expression "high performance casting" contains various processes such as counterpressure casting (cpc), vacuum riser-less casting (VRC), pressure riser-less casting (PRC), and cast forge (Cobapress) with high mechanical properties.

2.2.1 *Optimization of suspension arms*

Figure 9 shows the typical design process for forged and cast control arms starting with package model and the specification (step 1), initial optimization, for example, with

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

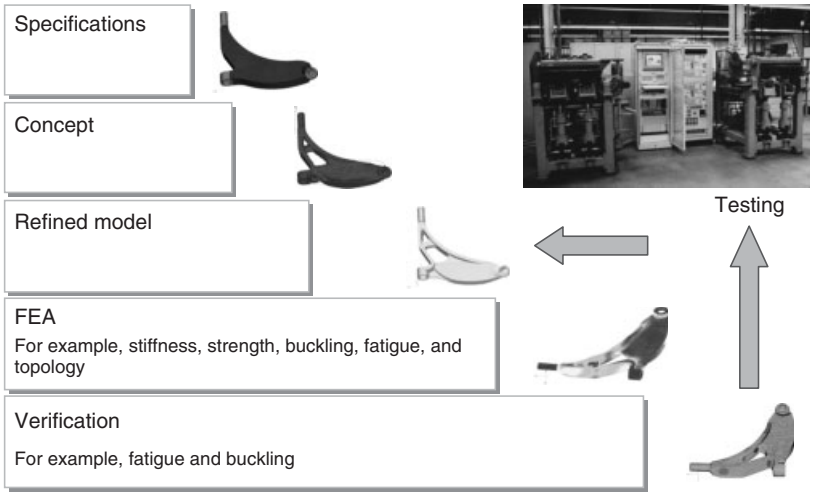

Figure 9. Typical development optimization process via simulation.

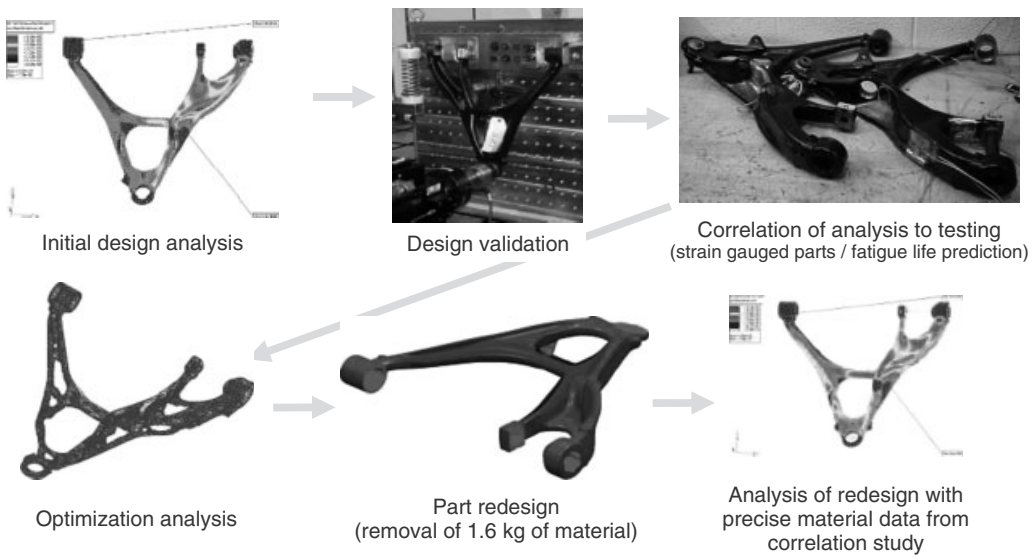

Figure 10. Development optimization including correlation study.

Optistruct® (step 2), optimized design (step 3), FEA (step 4), verification by fatigue simulation (step 5), and finally verification by testing (step 6). In some cases, a shape optimization will be done on top to further optimize some design details. In Figure 10, there is a special process shown to even consider design- and process-specific material behavior based on initial verification tests.

The above-mentioned process takes the optimization process even one step further. Real part material properties depend not only on the alloy but also on the raw part manufacturer and their production processes and variation of mechanical properties. On the basis of this knowledge, parts have been produced, strain gauged and real stress in critical areas of the part have been measured. These data have been used in FEA to further optimize the design based on a selected foundry process and tool design. This approach could reduce the weight by another 1.6 kg over the original FEA with typical material properties for the shown example of a front lower control arm (ZF).

2.3 Buckling and failure chain

Compact and light axle arrangements lead more and more to extraordinary challenges for the design to cover multiple

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

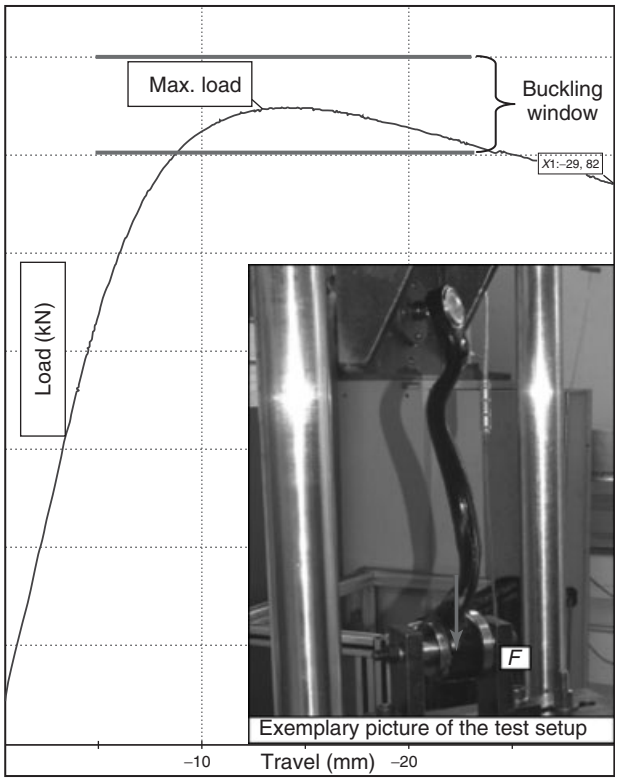

Figure 11. Typical buckling curve measured in compression direction.

load requirements for various load directions. On top of that, the so-called damage chain is defined for the vehicle. The damage chain describes the cascade of misuse load through the chain of components linked to each other, leading to a recognizable failure of single defined components. This follows the principle "leak before break" and means that a driver for instance recognizes a wheel misalignment after hitting a curb with too high speed.

The damage chain would be cascaded down from the major vehicle weight and ability requirements down to each component. For a side impact at the front end, the tie rod needs to deform first to protect the steering gear, and typically a control arm needs to buckle before the knuckle or subframe is damaged. The suspension arms are usually relatively easy to be replaced and therefore lead to low repair costs in case of minor misuse cases. However, this depends also on the manufacturing damage chain philosophy. These components are therefore the so-called sacrificial or victim parts, which act like a mechanical fuse. The damage chain defines the maximum permissible load for structural parts and for link attachments and screw connections. Figure 11 shows an example for a control arm. The buckling window describes the range for the maximum permissible load.

3 SUSPENSION ARM TYPES

3.1 Front axles

Requirements toward a chassis are high and complex and have to be a compromise among but not limited to driving dynamics, ride comfort, safety, weight, cost, reliability, durability, allowable space, crash behavior, and environmental friendliness. Owing to these requirements, the following suspension principles and modifications within those are typical for modern vehicles and SUV as front suspension (Figure 12; Elbers *et al.*, 2004)

3.1.1 Suspension arms for McPherson axles

The McPherson suspension type (Figure 13) is the preferred solution on passenger cars up to the luxury segment – thanks to the simplicity of design, associated cost effectiveness, and cross-car installation space. Nevertheless, this type of suspension has still limitations due to the fact that the shock has to transfer additional loads besides the vertical ones, which can add friction to the system and therefore influences the performance of the suspension. In today's cars and crossover vehicles, the typical design is a rear or front facing L-arm, manufactured out of stamped steel (single and double shell), DI,

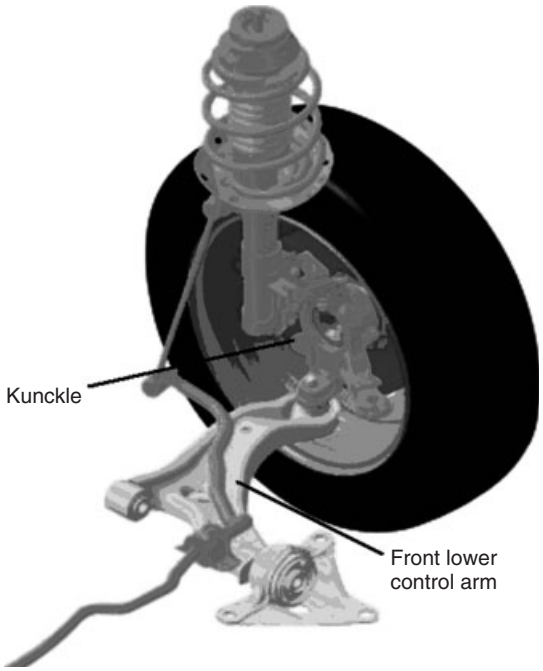

Figure 13. McPherson axle.

aluminum forging, and aluminum casting (Figure 14). From the design perspective, vertical loads are not too high, but the fore-aft and cross-car loads plus the crash performance have to be considered during the design as well as the space requirement for tire envelope, ground clearance, and stabilizer bar.

Figure 15. Strut front suspension with two lower suspension arms.

The figures above show examples for the different technologies for L-shape suspension arms. Application in the vehicle depends on requirements such as loads, packaging space, and cost. Therefore, all of the above-mentioned samples are feasible and production intend.

3.1.2 Two separated arms

To improve the freedom to position the lower hard point (virtual hard point) and therefore also to move the upper shock mount further out, the lower control arm can be replaced by two links (Figure 15 – links are marked red), typically called *tension* and *lateral* or *compression link*. These arms are typically designed out of forged steel or forged aluminum, but, if clearance and deformation requirements allow casting or tubular, weld designs are also feasible (Figure 16).

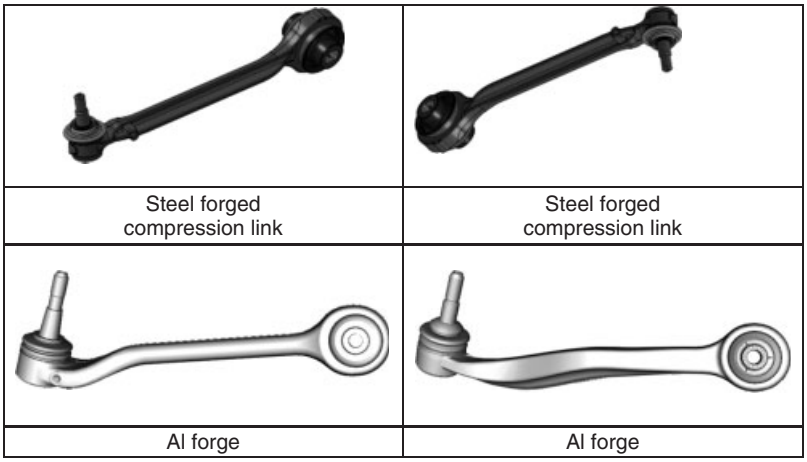

Figure 16. Examples: front lower compression and tension links.

Figure 17. McPherson suspension with revolute joint.

A special modification of the McPherson suspension is the revolute joint (Figure 17), which improves the scrub radius and the king pin offset; it therefore can be used for high powered front-wheel-drive vehicles.

3.1.3 Suspension arms for double wishbone

The double wishbone suspension or SLA (short long arm) is typically used on SUVs, pickup trucks, and luxury passenger cars. The big advantage of this suspension is that the shock absorber is decoupled from the wheel guiding function. The lower control arm carries the vertical forces in addition to driving loads and the upper control arm on an SLA suspension has to provide clearance for the strut mount.

3.1.4 Lower triangle arm, A-arm, and V-arm

Lower arms can be made out of DI, steel forging, aluminum casting, or complex multipiece stamping. All of those have to provide attachments for shocks and springs, which can be torsion bars or coil springs (Figure 18).

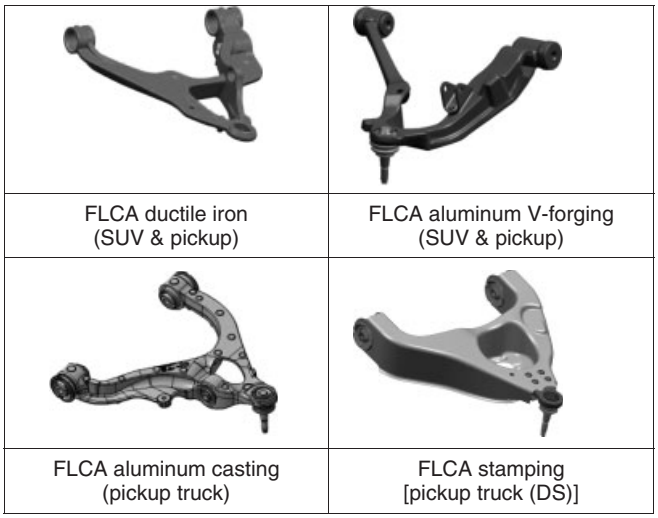

Figure 18. Example: SUV front lower control arms of double wishbone suspension.

3.1.5 U-shape arm

The upper control arm of a double wishbone suspension (Figure 19) has a typical "U-shape" to provide clearance for the strut assembly, which makes it sometimes difficult to achieve the required stiffness values. Owing to the position of the arm, the vehicle loads are low, but the arm has to be built short to allow space for the engine compartment. Therefore, the ball joint and the bushings have high requirements regarding working angles especially on SUV and pickup trucks.

3.1.6 Separated arms (preloaded arm and wheel-guiding arm)

Similar to the strut suspension with two arms, a double-wishbone axle can be designed with two arms on the lower and/or upper level for the same reason (Figure 20).

Figure 22. Rear axle types.

3.1.7 Preloaded suspension arms

For multilink axles, one of the control arms has to carry the load of the spring/strut as a permanent static preload (Figure 21).

3.2 Rear axles

The typical modern suspension can be a multilink rear suspension, for smaller vehicles a twist beam axle and for pickup trucks – due to high payload – a rigid rear axle (Figure 22).

3.2.1 4-point suspension arm

Especially, for premium rear axles with higher loads, we can often find suspensions with a 4-point suspension arm. Owing to the size of the arm, there are a lot of aluminum solutions available for this kind of control arms. Owing to high stiffness requirements and complex load conditions, the hollow cast solution offers the best weight-saving potential (Figure 23).

4 SUSPENSION ARM TECHNOLOGIES

Today's independent passenger car and truck suspensions use either ferrous material or aluminum. Within those materials, forging, casting, and stamping are the prime choices in ferrous design; casting and forging, potentially extrusion, are the choices in aluminum design. Castings, especially new riser-less technologies, provide freedom to design sections on the suspension with a minimum of unused material (sprue and flash). Forging and sheet metal can provide higher strength materials, but typically the rate of nonutilized material is higher than with casting technologies (flash, trim-off, and raw part net weight vs weight of the forged part).

The different technologies stay in constant competition; the technologically and commercially best solution has to be found for each application, based on vehicle goal and target requirements (Figure 24).

4.1 Integrated ball joint

What is special about suspension "die-based" technologies such as forging and casting is the possibility to integrate the ball joint directly into the structural component element. Although this is a common technology, ZF (Figure 25)

has improved the functional performance of such joints to implement low or, if needed, high motion torques with small tolerance range on the one hand and lifetime wear resistance in each driving condition on the other hand. Furthermore, the position of the hard points to each other is kept extremely tight with minimum tolerances. Special ball joint types cover different needs such as suspension- or compression-loaded variations.

In general, this is different to sheet metal, which requires a separate bolted, riveted, or pressed-in ball joint solution. It is obvious that an integrated ball joint has advantages compared to others. Pressed-in ball joints can be just right from a functional performance point of view but, when assembled, the press fit can have negative impacts on the motion torque of the ball joint. This is caused by the design of the press fit with the respective tolerances and the selected stiffness of the hub. A press fit has to be chosen to maintain a minimum of press-out to withstand vehicle loads, which can as a result double or triple the motion torque of the ball joint.

To provide the advantages of integrated joints to sheet metal control arms as well, ZF has developed and patented

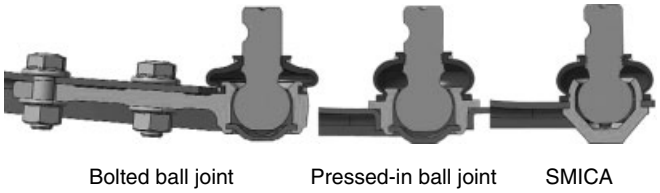

Figure 26. Ball joint types for sheet metal control arms.

the so-called sheet-metal-integrated control arm (SMICA) solution. The unique solution with the robustness of a conventional integrated joint contains a complete ball joint with a steel housing, welded by laser as a cartridge into the arm. The advantages of this technique are a smaller package space to the knuckle, less parts, and less weight compared to all other solutions; this brings the steel solutions a little closer to the weight saving that light metal solutions can offer (Figure 26).

4.2 Ferrous material

4.2.1 Castings

Like all casting technologies, DI casting gives a lot of freedom in design (shape, change of cross sections, and potentially coring). The freedom to distribute material where it is needed in a shape that is most efficient to support loads or the stiffness requirement is the big advantage of the casting process. All this is possible without the need of putting too much material in flash that has to be trimmed, which results in a good material usage. Furthermore, small draft angles can be realized and portions can be cored to reduce the raw material usage.

The typical DI alloy used in suspension components is DBC 450 (Rm = 450 MPA), optionally DBC 550 (Rm = 550 MPA), which both offer a compromise between strength and ductility.

SiboDur® is a material for use in chassis components subject to high levels of stress as typically seen in control arms and steering knuckles. SiboDur has been developed by Georg Fischer Automotive on the basis of spherical graphite cast iron. The name SiboDur is derived from the two materials silicon and boron and from the English word durability. SiboDur makes it possible to produce lightweight cast iron parts.

Tempered ductile iron (ADI) is a heat-treated form of cast DI. It improves the strength of the DI and maintains the ductility to a certain degree. Sizes of the parts and packaging densities in the heat treatment furnace have to be considered to develop a cost-effective part.

Overall, with its flexibility in design, its potential to core certain areas, and considering its mechanical properties, DI offers a high potential to design chassis components such as control arms and knuckles efficiently and cost effectively.

4.2.2 Forgings

4.2.2.1 General. Steel forging had been the most common production process for control arms for decades until the weight factor became more and more demanding. Even today, it still can be efficiently used in axles with specifically tight package areas and high load requirements leading to mostly locally concentrated yield strengths way above 360 MPa or ultimate 400 MPa and up.

The damper and spring as well as the spring tower for the upper arm and the lower arm, especially with separated arms on the outbound ends of the control arms – because of the additional ball joint and the special kinematics with a virtual center for the steering axis, limit the package on double wishbone corners. At the inbound end of a control arm, it is sometimes tight for the bushing bosses in combination with large bushing diameters driven by desired stiffness and allowable space, limited by available space to the subframe. Further examples are on lower L-arms with a spike pin bushing attachment; the transition from the pin to the structure of the arm is a weak point for bending stress. This can be handled more easily with forgings. In general, it is a big benefit if the packaging and the loading are specified correctly with little potential of change during the program: so a decision for a particular material and process selection can be made with high confidence.

Even though – from a functional standpoint – quenched and tempered material is generally more desirable for a control arm design because of its high ductility and more preferable impact behavior, it has been nearly completely eliminated from the control arm market. As the 1990s, microalloy steel has been the only option in use. Inventions on these specific material types were driven in the 1970s already, especially because of their cost efficiency for crankshafts. The cost efficiency lies in the forge–temper–rework process chain: the final raw part reaches its mechanical properties just by controlled air cooling on a conveyor after forging and trimming with least thermal. Additional advantages are a delayed tendency to crack under fatigue life, a far better machinability because of its specific grain structure and a smaller border-to-core hardness decrease compared to quenched and tempered material. However, the disadvantages are a faster crack progress, once a crack is induced, and a worse notched-bar impact works (Wegener, 1998). So, it is possible to meet the demanded combination of best function and least possible cost.

The most popular alloy in Europe is 30MnVS6 +P, in the typical range 560-MPa yield and 800-MPa ultimate

strength. The alloy is also available on the Asian and American market or can be purchased with very close similar chemical properties such as 15V24.

The process and the cost with some major aspects drive the forging design. Two-point arms with straight and easy routing as well as small cross sections with easy geometry are the most desirable ones. The more complex the geometry gets and the wider the projected area in forging direction is, the less likely it is to find a cost-effective design (Figure 27). If steel forging is needed in particular sections of the arm, then large arms will be hybrids out of sheet metal or aluminum-plus-steel combinations.

The material consumption on a steel-forging arm surely depends on the arm's size and complexity, but there is a general disadvantage with this process. The flash extension required to fill the cavity of the mold properly is large compared to that required in casting processes. It is extraordinary on flat arms with a wide extent but significantly lower on straight thin arms. A rate factor larger than 2 for the operational weight in proportion to the final part weight is borderline in terms of cost efficiency. In addition, the larger and more complex the arms are, the bigger is the height and mold shift tolerance impact with its effect on the function of the part, like buckling. Aluminum forgings of a similar size and complexity are easier to control, compared to steel (Figure 28).

4.2.3 Sheet metal (1-shell, 2-shell)

Sheet metal is widely used in vehicle suspensions and on all types of vehicles from passenger cars over SUVs up to pickup trucks (Figure 31). Depending on load case, the stampings can be single shell, double shell, or fabricated and welded together out of multiple different sheet

metal parts and reinforcements. The more complex the stamping gets, the more efficient it might be to substitute it by a casting. During the past years, new higher strength sheet metal alloys with good formability have been developed to enable lightweight stampings (Figure 29). This development was feasible because of dual and multiphase steel alloys that provide a soft ferrite grain matrix with a bainitic or martensitic second-phase deposit at the grain borders, which work hardens through the plasticization of the grain (ThyssenKrupp Steel AG, 2008). Although such applications are in production, there are still some huge disadvantages: high steel cost, lack of steel market volume, and missing availability on the global market. In view of increasing global platforms, it appears to be more advisable to accommodate widely used, common alloys of the range up to 600-MPa UTS.

ZF investigated the possibility to produce a single-shell L-arm in a high strength steel grade for vehicles in the C/D class. The aim of this study was to avoid any welds with the exception of welds needed for the ball joint integration. The study showed that single-shell control arms can be utilized up to typical loads for C-segment vehicles; formability of

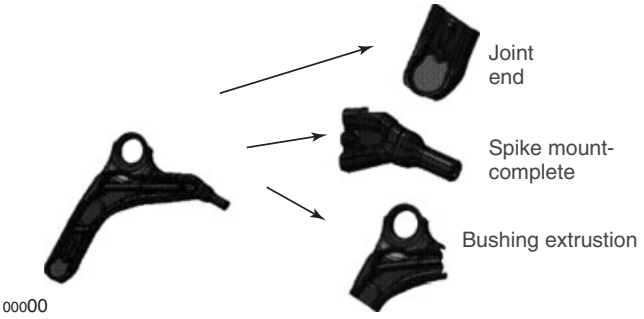

Figure 30. Study of a single-shell L-arm.

the boss hole for the vertical bushing plus the forming of the pin for the rear facing bushing could be realized. Furthermore, the production process could be optimized so that the part can be coated after stamping and then all additional processing can be done in the production line (ball joint integration and bushing assembly). The welding method to integrate the ball joint was developed, so that the ball joint can be integrated at precise position without any negative effects on the ball joint torque and performance and with minimum space requirements to the brake disk and knuckle.

Figure 30 demonstrates the steps of the study: to assure that the single-shell L-arm was feasible, the most critical areas regarding the degree of deformation such as ball joint end, spike mount, and bushing extrusion have been developed as sections. After those successful trials, the whole control arm was formed to demonstrate design feasibility (Figure 31).

4.3 Aluminum

4.3.1 Aluminum casting

Despite intense research and in contrast to sheet metal technology, the alloy used for aluminum suspension parts has not changed over the past 10 years and is out of the 3xx.x series with the elements silicon, copper, and/or magnesium; commonly A 356 is used with the T6 heat treatment (solution heat treated and artificially aged). Even though the casting alloy for control arm applications has not changed, a development process took place on the casting production process side: a variety of performance casting processes has been developed such as squeeze casting, VRC/PRC, Cobapress™, Vacural®, CPC, and others. These performance castings could be used in the chassis application as they provide low porosity parts with good mechanical properties and sufficient elongation values (T6 heat treatment).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

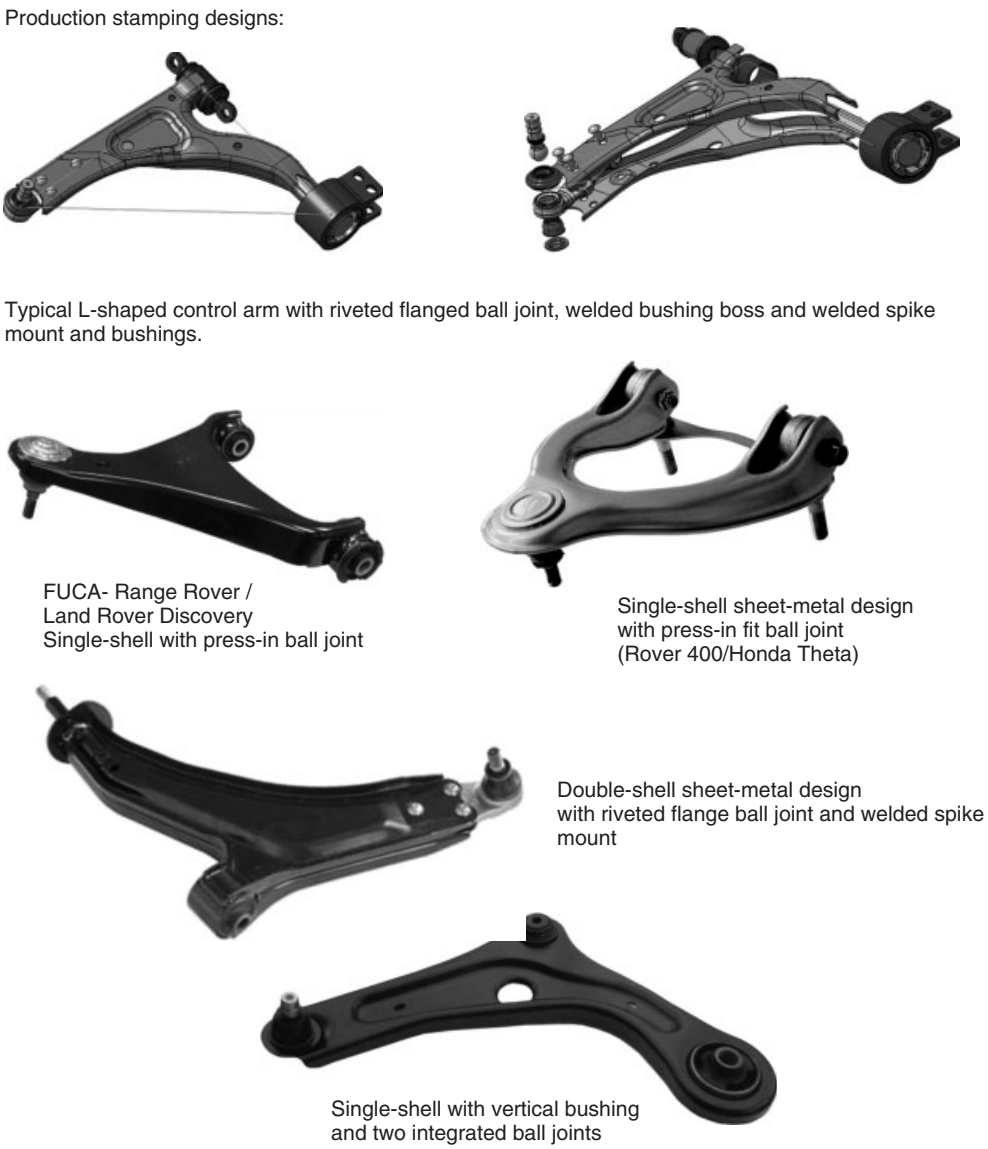

Figure 31. Examples for sheet metal control arms.

Owing to the need to further reduce weight, an increasing focus on the potential for hollow cast is seen; currently, different chassis parts such as control arms and knuckles (Figures 32 and 33) are under development. The usage of cores allows a box section in the part that gives an ideal shape for stiffness (Figure 34); in addition, local reinforcements can be casted into the part. Furthermore, reduced heat transfer to the core may allow thinner walls and may reduce mold complexity as no mold pulls are required; designs may be possible that cannot be realized with pulls. In addition, a core can be designed without a draft angle or even undercut, which would create mold lock in a typical casting process.

4.3.2 Aluminum forging

4.3.2.1 General. Aluminum forgings do not share the fate with steel forging, which is more and more decreasing. As weight has become more important and therefore strength and ductility, aluminum is in favor. The market share of aluminum forgings is still increasing; an aluminum forging is the best functional solution with the best process capability. Despite the fact that aluminum forgings come with relatively high costs, they are still very popular at OEMs especially for front axle applications, as casting processes require expensive quality controls such as X-ray checks.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

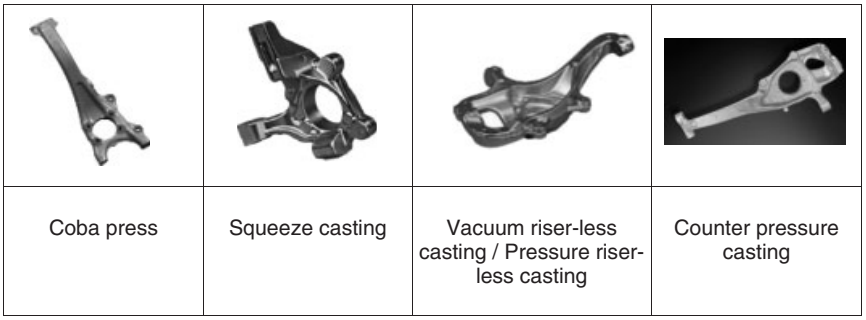

Figure 32. Example Knuckles in Al casting.

Figure 33. Examples: suspension arms in cast technology.

Figure 34. Example: BMW X5 RLCA: VRC/PRC with sand core (hollow cast).

If the design constraints described in the steel chapter allow for softer material, then aluminum forge will be the best choice of all, if the comfort ability of best fit and function can be afforded. What has been said about steel forging is also valid for aluminum: the production process is very stable and reliable; high end forging is for instance controllable by fully automated high speed lines.

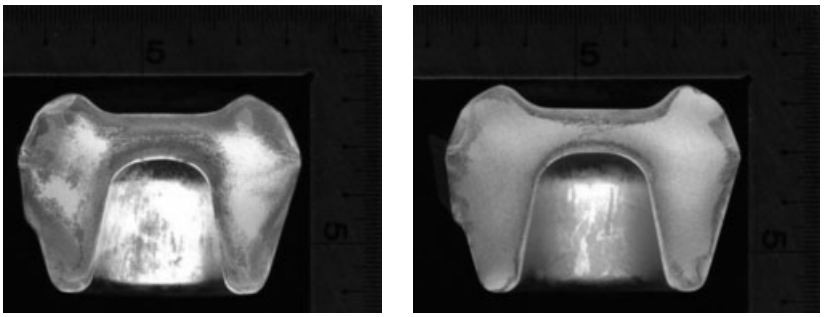
Compared to steel, aluminum material provides some additional advantages beside weight reduction, which support the decision to use it. Very obvious is the optical appearance, a dull or even shiny silver like surface with smooth roughness. The functional aspect of the smooth surface is the lack of roughness notches acting as stress raiser on fatigue life. However, the disliked effect with aluminum is that it does not show a constant long life fatigue strength level. Therefore, assumptions need to be made like setting a minimum cycle number of 2×10^6 for long life criteria.

Similar to casting materials, forging material ranges of the alloy SAE J 454–6061 (yield 260 MPa, UTS 300MPA, and elongation 10%) and SAE J 454–6082 (yield 310 MPa, UTS 340MPA, and elongation 10%). Depending on the specific company alloy composition and heat treatment, a level of yield 390 MPa with UTS 410 MPA is possible especially for two-point links.

It is very important for aluminum arms to maintain the rule of providing as little coarse grain as possible.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5



Example for coarse grain deep through the cross section.

Example for coarse grain mostly at the skin only.

Figure 35. Cross section of forged aluminum suspension arms (grain structure).

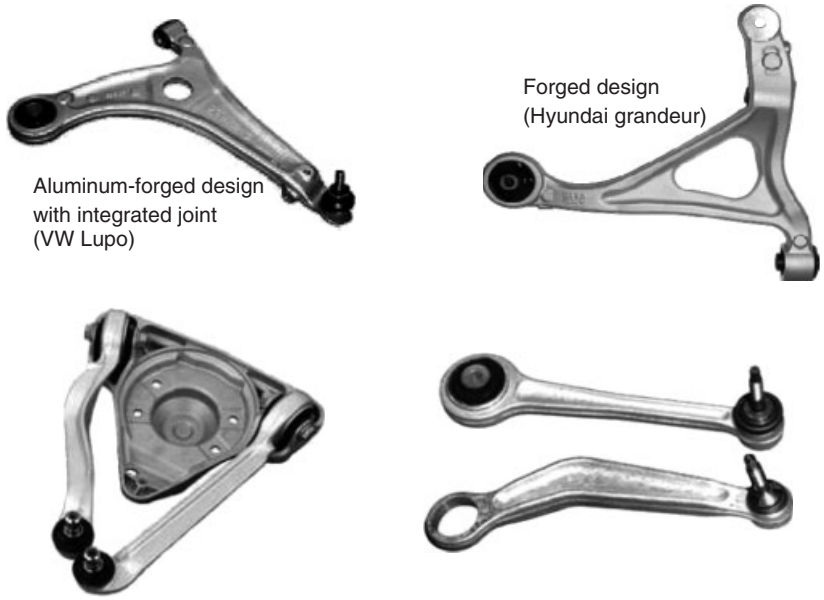


Figure 36. Examples: aluminum forging.

On typical arms, only a thin layer of coarse grain is allowed at the skin to enable the desired deforming and fatigue life behavior as well as the formability after machining – allowing the integration of ball joints (Figure 35).

In addition to the description in the design chapter, the aluminum forging process generally provides the same restrictions as the steel forging process. The advantages versus steel are hidden in details such as smaller draft angles or sharper radii. The loss of material in the flash extension is less (thinner), and, as a rule, the scrap material is completely used for company-internal recycling, as mentioned in chapter 2.1.

5 DESIGN MATRIX (JUDGMENT OF TECHNOLOGIES FOR DIFFERENT SUSPENSION ARM TYPES)

5.1 L-shape front lower control arm for McPherson suspension

L-shape control arms are currently the preferred FLCA (front lower control arm) for McPherson suspensions; they are typically designed to lateral and traversal stiffness, ground clearance, crashworthiness, clearance for tire envelope and drive shaft, stabilizers, and so on – Owing to those requirements with regard to space and performance,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

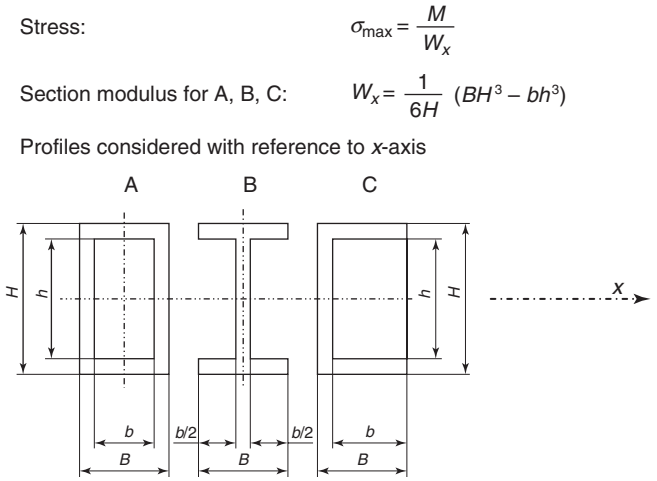

Figure 37. Shape (cross section) of control arms.

not only one material or process is applied. L-arms are rather produced in aluminum and steel forged, stamped, or casted parts.

The following arm was designed as double-shell control arm during early development stages with regard to fore-and-aft stiffness and lateral stiffness. Considering the fore-and-aft stiffness in a simplified way, the design engineer, while keeping the bending stress in mind, has to find the best section modulus and therefore the best cross-sectional shape suitable for the intended manufacturing process.

The different cross sections in Figure 37 have the same sectional modulus (based on reference to the *x*-axis) and therefore the same maximum stress and the same weight. This means that the H profile, typical for casting processes, and the box profile, typical for double-shell stampings, can be designed competitively for the relevant processes.

The following front lower control arm (Figure 38) shows a production design for a high volume application. The numbers below show the ranking – "1" for best in this category down to "4" worst in this category. The design was in competition with a double-shell stamping. Before deciding for this aluminum performance casting, the following other options have been considered by the vehicle manufacturer.

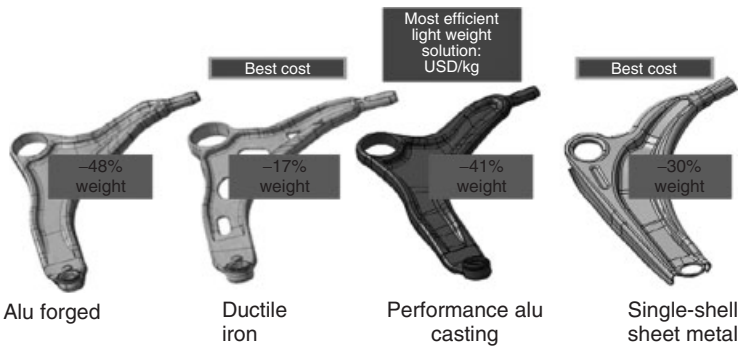
Fulfilling customer requirements for stiffness, packaging, and durability, the above table shows the performance of the different materials. In this case, a performance aluminum casting process (vacuum riser-less casting/pressure riser-less casting) was chosen for series production, as it offered the customer a weight advantage at a reasonable cost.

5.2 Front upper control arms

Front upper control arms for a double wishbone suspension with a long knuckle (goose neck) are currently the typical design, because of space and kinematic advantages over the McPherson strut suspension. The upper arm is typically designed to allow space for the strut module assembly; it provides short length to limit cross car space and for stiffness. Furthermore, the arm has to allow for jounce and rebound travel and tire clearance. The following example is taken from a design competition against a steel forging.

For the new vehicle, requirements have been updated regarding lateral and fore-and-aft stiffness; different designs in stamping, DI, and aluminum have been analyzed including a ranking (see above) (Figure 39).

In this case, none of the investigated parts could fulfill the upgraded stiffness requirements – even not the incumbent



Weight	1	4	2	3
Stiffness	2	3	1	4
Cost	4	2	3	1

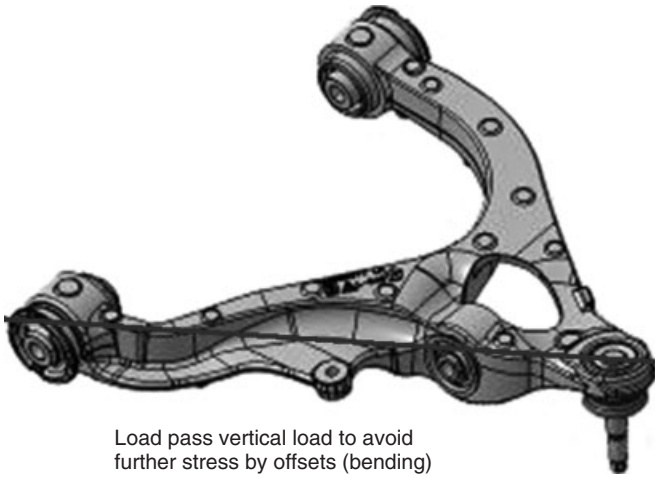

Figure 40. Example: A-shape FLCA.

forged steel design. With reduced stiffness, it appears that a stamping or an aluminum cast could provide the best compromise between cost and desired performance.

5.3 A-shape front lower control arms (FLCA) for double wishbone suspension

These are in the market in all different materials and processes. Besides all the requirements previously discussed for the L-arm, FLCAs of a double wishbone suspension have to additionally carry the vertical force. The following suspension arm (Figure 40) was developed for a pickup truck. The first generation had a multiple piece double-shell stamping design, which was – for cost reasons – replaced by a DI control arm with torsion bar attachment. The next model changed from a torsion spring to a normal strut-mounted coil spring (due to crash performance), and the design was carried out in DI as the previous arm. During the last refresher, weight and fuel economy came into focus – a lighter design had to be developed for nearly identical requirements as to loads, clearance to tires, and drive shaft. As the DI cast part had already been optimized for maximum allowable packaging space and clearance, the aluminum casting could only be designed in the same space. Moreover, material could

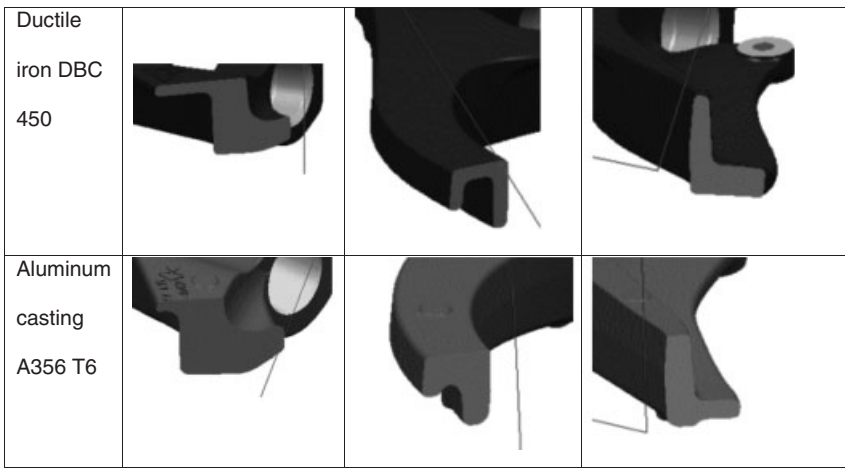

Figure 41. Cross-sectional variation possibility in casting process – ductile iron versus aluminum casting.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto002
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

only be added in areas that are not as efficient to create force-carrying capability (Figure 41).

The development history shows that for similar applications different processes and materials have been in production, based on overall vehicle goals, which resulted in aluminum casting with the main focus on weight at reasonable costs. With the replacement of DI – which had been the cost effective solution – by aluminum casting, a weight saving of 5.3-kg per control arm was achieved, resulting in an overall weight saving of ca. 40% for the complete assembly.

6 SUMMARY AND OUTLOOK

Suspension arms, steel versus aluminum, where are the benefits? Coming back to the initial question, this chapter shows the overall tendency that aluminum applications offer the best weight whereas steel offers best cost. Owing to the fact that designs for suspension arms are often driven by stiffness and/or buckling requirements, the individual solution might lead to different results – so in the end, it depends on the application. For other chassis parts, for example, knuckles, the direction is more constant.

Sheet metal solutions already have a big market share and, based on ultrahigh strength steel, there is further weight reduction potential. Key for a good sheet metal design is the design of the weld seem. Or, the other way round, the best material properties do not support a lightweight design if we have to weld too much in critical areas. Owing to cost advantages and the possibility of weld reduction, one-shell solutions (if feasible) seem to be most interesting for sheet metal solutions.

Steel forging has more and more become a niche process for volume products. For heavy and small packages and high loads (heavy vehicles) it will remain an important technology for suspension arms.

DI solutions are often seen as old-fashioned heavy solutions. This chapter has shown some examples where DI is the best option or compromise among stiffness, package, and cost. There are alloys on the market that even offer very good elongation properties to fulfill the buckling/bending requirements of automotive industries. Depending on the market situation, DI can lead to the best-cost solution at a competitive weight.

Aluminum forging seems to offer low weight but high cost. Competitive costs can be reached for designs with a good material utilization of the aluminum preform to avoid as much machining as possible and as much aluminum scrap due to flash as possible. The machining of aluminum is cheaper than the machining of steel, and in some chases, this more or less compensates for the higher material costs for aluminum. There are materials on the market with much higher strength than standard steel.

High performance aluminum cast solutions and combined cast forge solutions are becoming more and more interesting. The market offers an increasing number of special production technologies that support a good stable quality of the material and material properties with high strength. This leads to best-cost lightweight solutions. Depending on the axle concept, we have to pay special attention to the overall crash concept because of limited elongation properties of cast solutions.

Owing to the upcoming endless range of fiber-reinforced plastic applications especially for vehicle bodies, the interest in plastic applications for chassis components has increased, too. There is still some skeptics regarding plastics for chassis application, but it becomes a more open discussion. For some chassis parts, there are already solutions in series production, for example, the leaf spring for GM Corvette or Volvo 940 and the anti-roll bar links for several BMW and GM vehicles. The complex structure of suspension arms with their high load and crash requirements make it much more difficult to substitute traditional suspension arms. So to overcome hurdles and find different axle layouts that better support plastic applications will take some time.

In other words, the question of "Suspension arms, steel versus aluminum, where are the benefits?" will survive some more years.

Designing Twist-Beam Axles

Veit Held and Rüdiger Hiemenz

Adam Opel AG, Rüsselsheim, Germany

1 INTRODUCTION

When the twist-beam axle was introduced in 1974 in the Audi 50, in the VW Golf, and later in the Scirocco, it became a rapid success. Historically, this concept can be seen as a further development of the trailing arm axles that were widely used in front-wheel-driven vehicles. The immediate forerunner was the non-driven rear suspension that was launched in the DKW Junior, 1959–1962 (Figure 1). While this axle connected the trailing arms with a slotted axle tube, which did already work as a stabilizer, the longitudinal control arms were still flexible and a Panhard rod was needed to take the lateral forces.

In the Audi 50, we find all the typical elements of a twist-beam axle that work in the way, as we know it today (Figure 2).

Today, twist-beam axles or, as they are also referred to, compound crank rear suspensions, have by far the largest volume on the global passenger car market of all rear suspension types (Table 1). It can be expected that, with the growth of the small and compact car segment, the demand for the twist-beam axle type will increase.

Twist-beam rear suspensions dominate the mini to lower medium passenger car segments (Table 2). Typical models in the mini category are the Toyota IQ and Peugeot 107. In the small car segment, we find the Opel Corsa, the Ford Fiesta, and the VW Polo, and in the lower medium category, we find vehicles such as the Honda Civic (EU) and the Renault Megane.

The reasons for this widespread usage have been summarized in numerous textbooks, for example, in Heißing, Metin Ersoy, and Gies (2007). The main advantages and disadvantages of this simple, but very effective axle are listed in Table 3.

2 THE FUNCTIONAL PRINCIPLE OF A TWIST-BEAM AXLE

Apart from the usual design elements that apply to any axle (such as the positions of dampers and springs), the twist-beam axle has the following characteristic components that define the specific properties of this concept (Figure 3):

1. the torsion beam
2. the front bushing or, as it will be called in the remainder of this chapter, the “A-bushing”
3. the left and right trailing arms

This highly integrated design takes all forces and moment which are applied to the tire and wheel during driving. Its mechanical parameters allow tuning both ride and handling

behavior as well as the noise isolation of this suspension. The small number of components requires each of them to serve several functions, unlike the links in a multilink suspension that have dedicated functions and dominating load directions.

The torsion beam (1) is the key element that differentiates this axle from all other concepts. All side forces that act on the wheels try to turn the whole body of the axle around a vertical axis. This creates internal stresses in the structure, particularly in the crossbeam, which has to provide a stiff coupling of the wheels. The higher the bending stiffness of the profile, the better is the control of the pivoting moment by tuning the elasticity of the A-bushings. With respect to the roll response during cornering, the torsion profile has exactly the same role as the stabilizer bar in independent suspensions.

Table 3. Advantages and disadvantages of twist-beam axles.

Advantages of the Twist-Beam	Disadvantages
• Very simple design—essentially, it takes one body plus two rubber bushings • Excellent packaging, that is, needs little space and has a very flat shape (exceptions: housing the dampers and accommodating the vertical movement of the crossbeam during suspension movements) • Easy to assemble • Stabilizer function included • Small unsprung mass • Enables damper ratios around one (damper can be placed vertically at the wheel center) • Roll steering independent of the load • Good compensation of pitching during braking • Small changes of track width under load	• Load peaks at the joints between the rigid trailing arms and the crosslink • Lateral force steer needs toe-correcting bushings • Limited side force stiffness due to deflecting moments in torsion beam and control arms. Compensating measures (e.g., toe-correcting bushings) affect road harshness • Difficult to enable all wheel drives • High axle loads difficult to achieve because of undue stress on welds • Conflicting targets of ride comfort, noise isolation, and handling are difficult to meet because all forces have to be taken by the front bushings

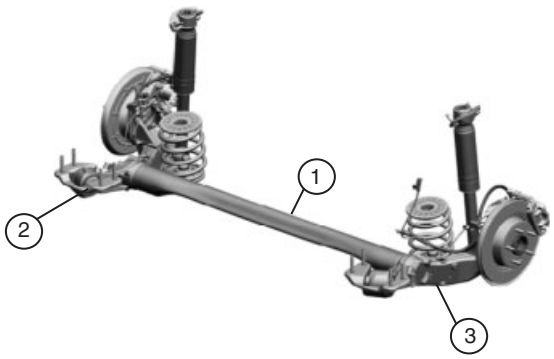

Figure 3. Key elements of the twist-beam axle. (Reproduced by permission of Adam Opel AG, Germany.)

The A-bushing (2) takes all lateral and longitudinal forces. The orientation and the spring rates of the bushing have a huge impact on the steering behavior during lateral loading.

The trailing arms (3) carry the brake force, the side loads during cornering, and the resulting moments, which are mainly the bending moments around the lateral and the vertical axis plus the twisting moment around the roll axis. Therefore, the stiffness of the trailing arms in all directions and around all axes controls the deflection and orientation of the wheel and tire under loads. Stiff welded sheet metal structures or cast profiles are established design solutions.

These three components will be discussed in more detail in the following sections.

2.1 The torsion beam

Understanding the twist-beam axle means understanding the torsion beam. In the case of most other concepts, the movement of the wheel is defined by the geometry of the bushings and the links. In the case of the twist-beam axle, the roll center, the camber angle, and the toe-in are largely defined by the twisting behavior of the beam.

When driving over a wide obstacle such that the left and right wheels move in parallel, the twist-beam axle works exactly like a rigid axle. The situation is more complex under lateral loads or when the car is rolling. If one wheel is raised while the other one is lowered, then the beam gets twisted around its lateral axis, which induces shear forces in the profile. As a consequence of these internal forces, the beam will twist around the shear center of the profile (Figure 4).

If the left and right wheels are moved vertically in opposite directions, then the shear centerline will pivot around its center point in the middle of the car (Figure 5). This means that the intersection of the shear centerline with the middle of the car defines one pivoting point of the left and right half-axles; the second one is the respective A-bushing. In Figure 5, the dashed line marks the axis around which the left wheel turns upward. Apparently, a twist-beam axle behaves like a semi-trailing arm axle with the same A-bushing as the twist-beam and a central bushing at the intersection of the shear centerline with the middle of the vehicle. Figure 5 depicts this relationship in the top view.

The designer can position this "virtual center bushing" by moving the beam backwards or forwards. This "virtual bushing" can also be moved up or down by choosing the profile and the orientation of the beam such that the shear center is located at the desired height. Moving the shear center above the A-bushing will result in a roll understeer behavior, moving it below will result in roll oversteer behavior (Figure 6).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto003
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

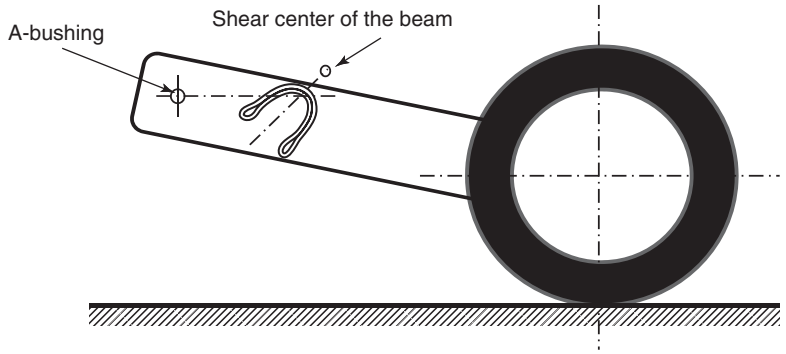

Figure 4. The torsion of the beam is defined by the shear center of the profile.

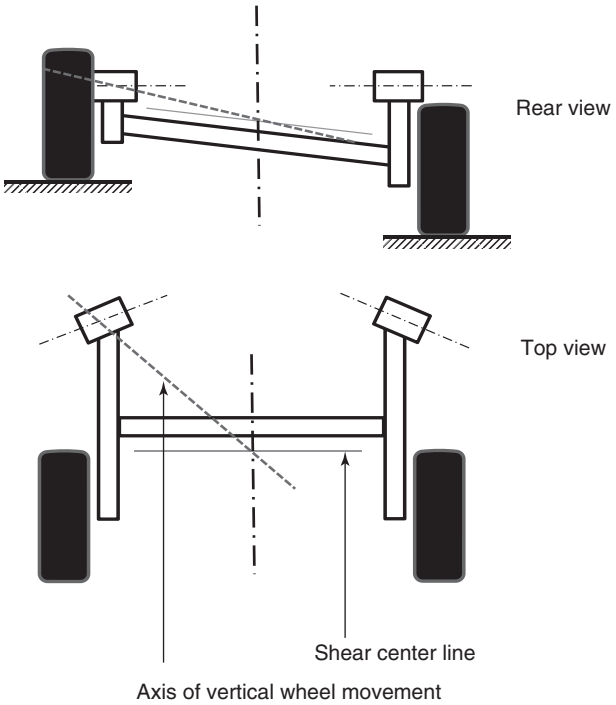

Figure 5. Wheel movements when the vehicle is rolling.

To define both the torsional rate and the position of the shear center, the designer can select the material and the shape of the profile (Table 4).

2.2 The A-Bushing

The A-bushing of the twist-beam has to resist longitudinal and lateral forces and the resulting moments. There are multiple conflicting design goals that make the design of the A-bushing critical. On one hand, the bushing should be soft to absorb the noise and vibrations from the road and to reduce the impacts from obstacles. On the other hand,

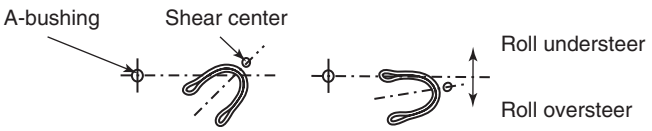

Figure 6. Positioning the shear center will define roll under- and oversteer.

the bushing needs to be stiff to create a precise handling behavior and determine the desired over- or understeer behavior due to side forces or rolling movements. To meet these requirements, the designer needs to define the vertical and horizontal spring rates of the bushing and the orientation.

2.3 The trailing arms

Because all side forces have to be transferred to the A-bushing, these arms have to be very rigid. Most commonly, sheet metal arms are chosen to save cost and mass. Another option is to use cast aluminum, which allows for topology optimization. One of the biggest challenges is to design the link between the trailing arm and the torsion beam, in particular, if different materials have to be combined.

3 THE PROCESS OF DESIGNING A TWIST-BEAM AXLE

In the previous chapter, the main design elements of the twist-beam axle were introduced. In the following chapter, the main steps will be summarized to develop a specific twist-beam axle for a particular carline.

The first step in the design of any rear axle is to do the "concept selection", which means to find the right axle type for a given vehicle. In this phase, all alternative concepts

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto003
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 4. Commonly used profiles to define torsional stiffness and shear centerline.

Shape	Design	Property
	Closed section in U- or V-design, made from tube	High torsional/roll stiffness
	Open section in U- or V-design, made of sheet metal	Low torsional/roll stiffness
	Open section in U- or V-design, made of sheet metal	Additional stabilizer bar for increased torsional/roll stiffness

will be evaluated. Apart from the traditional chassis requirements, there are many other boundary conditions to be met. Some of the primary drivers are the packaging constraints, which are imposed by the required trunk space and fuel tank volume, and the ground clearance. All these requirements have to be evaluated against the allowable system cost.

3.1 Essential design parameters and system characteristics

The twist-beam axle has a specific set of design parameters that can be selected or tuned to achieve the desired handling behavior, ride comfort, and noise isolation. These parameters are marked in Figure 7 and the impact on the targeted properties is listed in Table 5.

Table 5. Design parameters of twist-beam axles.

No.	Parameter	Impact
(1)	Position of the crossbeam Torsional stiffness	Roll center height, Stabilizer rate
(2)	Position of the shear center	Roll center height, Roll steer
(3)	Angle of the A-bushing	Lateral force steer
(4)	Compliances in *x*- and *z*-direction, Compliance in *y*-direction	Impact harshness, Lateral force steer, Road noise, Lateral force compliance
(5)	Side view swing arm angle	Wheelbase change and hence impact in harshness Anti-dive angle

3.2 Understeer contribution

The performance of a twist-beam axle depends on how well the conflicting requirements for the overall steering behavior of the axle and the ride and noise refinement can be balanced within the given package constraints. A typical design iteration process starts with the understeer contribution that the rear axle has to deliver in the context of the desired overall vehicle handling trim.

The rear axle understeer contribution is the sum of roll steer, lateral force compliance steer, and vehicle roll rate fore/aft distribution. Each element relates to a design factor with its own package constraints that limits the amount of total steer that can be derived from the single element. Consequently, the design process of a twist-beam

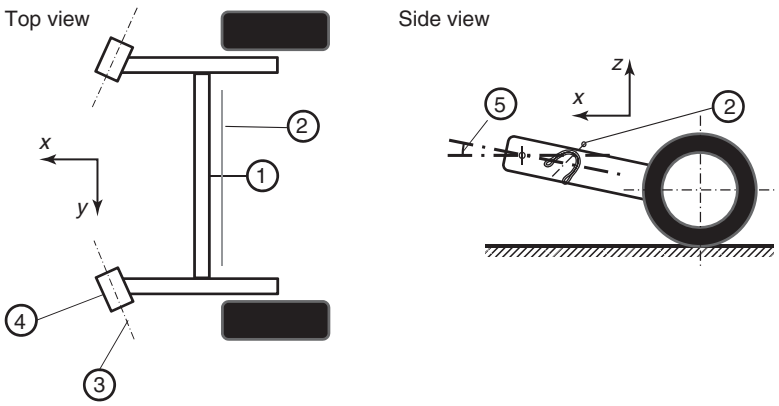

Figure 7. The design parameters of the twist-beam axle.

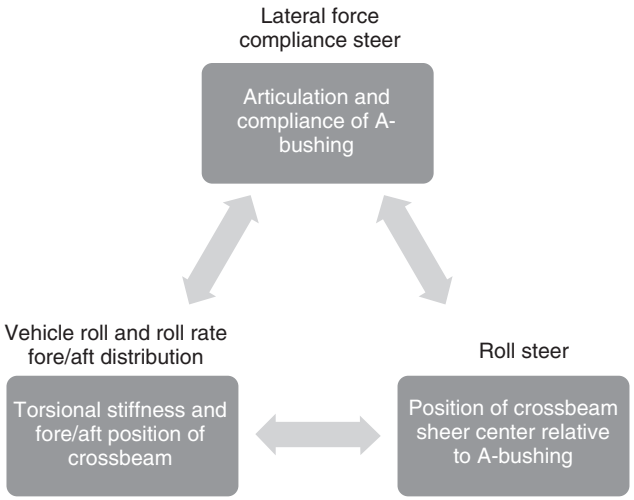

Figure 8. Main elements that contribute to the total axle steer.

axle makes best use from all three factors in combination (Figure 8).

The design evolution starts with the definition of the total vehicle understeer and its distribution to the front axle and rear axle.

3.2.1 Lateral force compliance steer

By its nature, the twist-beam axle goes into toe-out (oversteer) during cornering. Oversteer is caused by the moment that is generated by the side forces acting on the tire contact point longitudinally behind the A-bushings. The moment twists the axle into the direction of the acting side force, that is, oversteer (Figure 9a).

Mainly, three factors control the amount of inherent oversteer. To reduce the amount by which the axle is turned into toe-out by cornering loads, one can shorten the distance between the tire contact point and the A-bushing, choose a wider track width, or increase the fore/aft stiffness of the A-bushing. Of the three main factors, one can assume track width to be a program-given constraint that cannot be used as a design variable to control steer.

The control arm length can be chosen more freely. However, if the arm becomes too short, then the twist-beam is too close to the tire contact point in the fore/aft direction. As a result, the twist-beam is predominantly bent by the loads and not twisted anymore. In this case, the axle behaves more like a rigid axle—with all the known disadvantages. The fore/aft position of the twist-beam is furthermore restrained by the underfloor package where tank, muffler, rails, and foot space leave a small window for the suspension.

The fore/aft stiffness remains the main free parameter that can be tuned to control oversteer. Unfortunately, the fore/aft stiffness not only controls side force oversteer but also affects the noise isolation. Hence, the fore/aft stiffness is a compromise to meet both requirements. The acceptable fore/aft rates alone do not allow to provide sufficient oversteer control.

For this reason, a kinematic trick has become standard in modern twist-beam axles. The pivot line of the A-bushing is not perpendicular to the longitudinal axis of the car, but is angled towards the front.

If the bushing has sufficient axial compliance, then the cornering force pushes the axles sideward up the ramp on the side with the higher side force and down the ramp

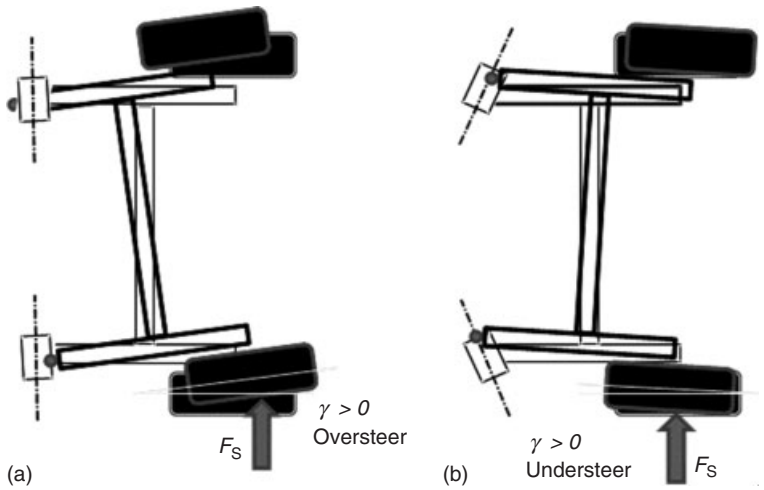

Figure 9. (a) Typical side force oversteer effect caused by the rotation of the axle within the fore/aft constraint of the bushing. (b) Partial compensation by twisting the A-bushing such that the axle slides along the ramping angle, thus inducing a turn.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

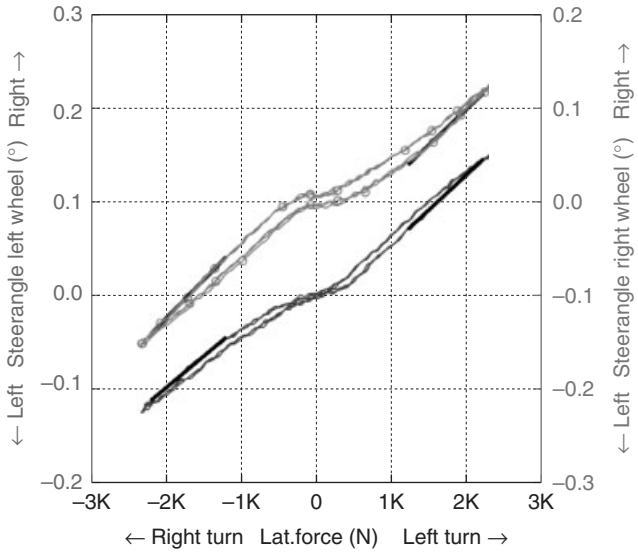

Figure 10. Typical side force steer curves.

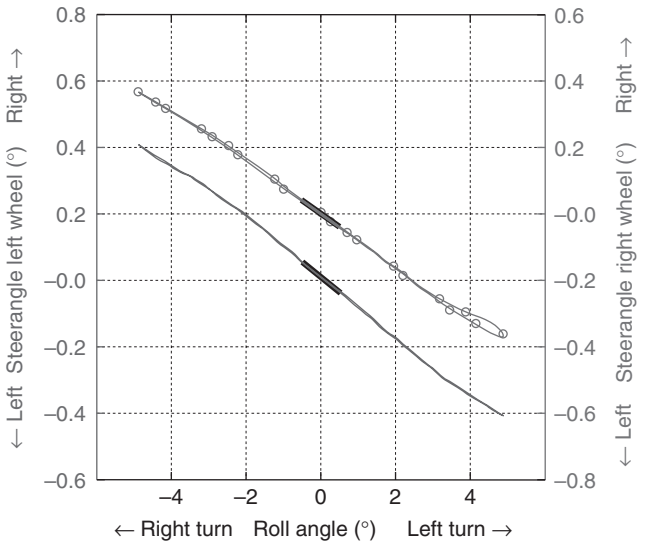

Figure 11. Typical roll steer curve.

on the other side. Effectively, the whole axle is turned into understeer (Figure 9b). The exploration of this effect is limited by the need for directional control of the rear axle that is compromised by the lateral compliance in the bushings. Figure 10 shows a typical curve for the steering angle of the rear axle as a function of the lateral force.

3.2.2 *Roll steer*

As shown in the last chapter, a particular characteristic of the twist-beam axle is the dependency of roll steer from the position of the shear center of the torsion profile relative to the pivot line of the axle. To further compensate for the remaining compliance oversteer tendency, most passenger cars require a roll understeer contribution from the rear axle (Figure 11).

Maximum roll understeer is gained if the open sections of U- or V-shaped profiles point downwards such that the shear center is above the pivot line of the axle. The optimal vertical position of the A-bushing would be low for understeer; however, for impact smoothness a high position is desirable. The amount of understeer to be gained is limited mainly by packaging restrictions and conflicting performance requirements.

The more the A-bushing is raised, the higher the torsion profile must be situated to provide understeer. Naturally, the underfloor height and the exhaust routing limit the vertical packaging space for the torsion beam. Hence, roll steer will always be a compromise with the influencing factor "harshness".

Twist-beam axles with a tubular interface to the trailing arm offer a marvelous opportunity. With identical crossbeams and trailing arms, the location of the shear centerline can be positioned simply by turning the beam and welding the joint at different angles to the crossbeam (Figure 12). This feature allows tuning the roll steer of an axle to the mass and the mass distribution of the vehicle.

3.2.3 *Vehicle roll and roll rate fore/aft distribution*

The roll rate of a twist-beam rear axle is defined by the crossbeam torsion stiffness, possibly by the twist rate of an additional stabilizer bar and by the suspension spring rate. The roll rate distribution front to rear together with the axle load distribution front to rear affects the overall steering behavior of the vehicle. The effective roll rate of the crossbeam is a product of its diameter and wall thickness and the fore/aft position of the beam.

By selecting an appropriate effective torsion stiffness as a function of the axle load distribution, the overall steer behavior of the vehicle can be tuned to meet the specification. Furthermore, the steering behavior can be maintained constant for all model variants despite different axle loadings.

The concept of the crossbeam connecting both rear wheels has earned the twist-beam axle the label "semi-independent". In respect to its "copying behavior" of excitations from one side to the other, this notion is misleading. The copying effect is no different to that of an independent suspension that utilizes a stabilizer bar to create roll stiffness. This stabilizer bar does exactly the same thing

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto003
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

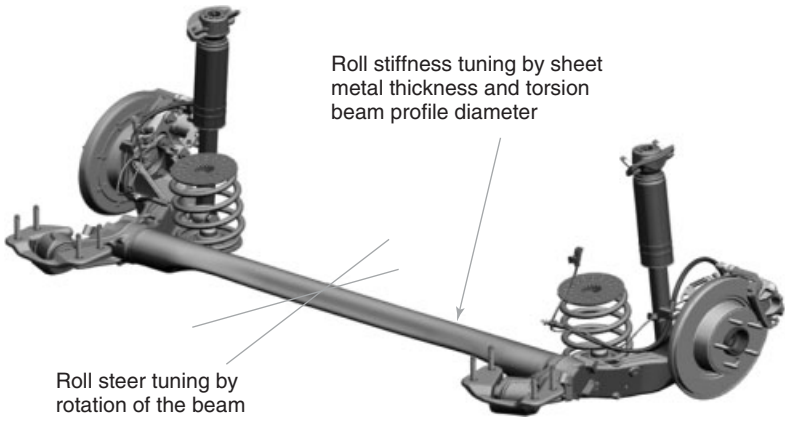

Figure 12. Tuning flexibility of a twist-beam axle with tubular crossbeam.

Figure 13. Main elements that contribute to the impact compliance.

as does the crossbeam of a twist-beam axle: it transfers loads and excitations from one side to the other regardless whether intended (to control body roll) or unintended (if caused by road irregularities). A certain fore/aft transfer of road excitations, however, is inherent to the twist-beam, yet far less apparent than the mutual vertical interference that is common to suspension with a high roll stiffness.

3.3 Impact compliance

The main factors that influence the ability of a wheel to elude road irregularities have already been mentioned in connection with understeer control (Figure 13).

3.3.1 Brake force compliance

Forces that are induced by braking have the same effect as any other forces that are generated from an uneven road. In both cases, the tire/wheel moves backwards against the effective compliance of the A-bushing. High fore/aft compliance of the A-bushing allows the wheel to swing back rather freely while contacting a road input such as a crack or a bump.

Although high fore/aft compliance of the A-bushing is desirable for impact isolation, it is undesirable for side force oversteer as shown in the previous section.

3.3.2 Side view swing arm angle (SVSAA)

Side view swing arm angle (SVSAA) is the angle between the horizontal and the line through the wheel center and the A-bushing. The influence of the SVSAA can be easily envisaged by picturing the overcoming of a step with a wheelbarrow. Pushing the wheelbarrow forward into the step results in a high impact, whereas pulling the wheelbarrow instead, while holding the handles high, results in a smaller impact and a more smooth negotiation of the step. This is because the wheel is kinematically guided away from the step, instead of being pushed into it.

Likewise, the A-bushing should be above the wheel center (positive SVSAA) for minimal impact sensitivity. The optimal solution regarding impact compliance, however, is very often not feasible due to interference with the body rails or the foot space in front of the rear seats. In this case, minimal negative SVSAA should be considered.

Since fore/aft compliance is limited by side force oversteer, and SVSAA is limited by packaging constraints, the achievable impact comfort is a compromise. This drawback is inherent to conventional twist-beam axle concepts.

3.4 Roll camber/camber stiffness

Common multilink suspensions have the property that the upper point of the wheel moves inboard when the wheel gets pushed upwards. This implies that the camber angle deteriorates when the vehicle rolls in a corner and the tire can take less side forces. This effect is almost negligible in the case of twist-beam axles.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto003
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

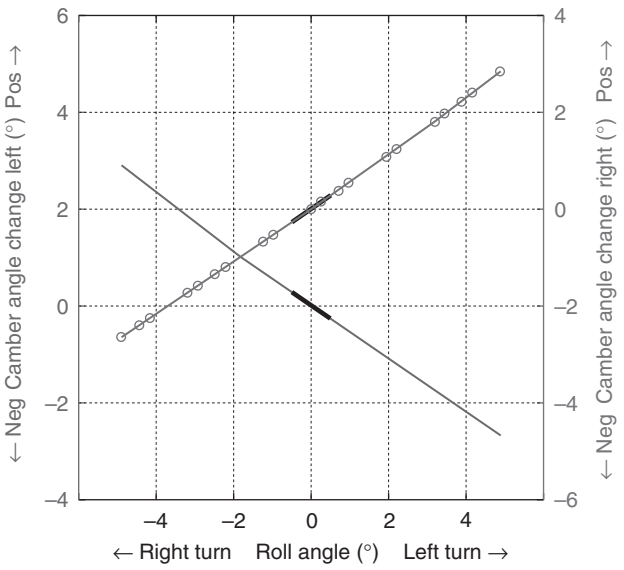

Figure 14. Typical roll camber curve.

Kinematic camber loss is minimal due to the nature of the connection of the axle to the body by the A-bushing that constrains the axle in roll and heave like a hinge with one rotational degree of freedom. Figure 14 shows a typical curve of the camber angle as a function of the roll angle.

Compared to multilink suspensions that suffer from higher kinematic camber loss, the twist-beam axle has significantly better camber compensation.

The second relevant aspect of camber is side-force-induced camber loss. The side force during cornering creates a moment that tilts the wheel in the direction of positive camber. The amount of this effect is predominantly controlled by the torsional stiffness of the trailing arm. Modern cast iron or box-type sheet metal designs provide excellent torsional resistance; hence, twist-beam axles have minimal side-force-induced camber loss.

Sufficient camber compensation and high camber stiffness lead to high residual camber during cornering. This helps grip and rear axle stability.

3.5 Summary: typical design parameters of a twist-beam axle

The said mutual interdependencies and restrictions of the design parameter of twist-beam axle as well as the packaging constraints define a solution space. Most twist-beam axles in the compact and small car segment fall into the bandwidth shown in Table 6.

4 FURTHER ADVANCEMENTS OF THE AXLE CONCEPT

Lately, the usage of the twist-beam axle has been extended to applications that go beyond the conventional performance expectations or use cases of this suspension. New materials and further enhancements to its mechanics show that the limits of the twist-beam axle have not yet been fully explored.

4.1 Twist-Beam with Watts linkage

It has been shown that the twist-beam axle has big advantages to other axle types with respect to camber stiffness, camber compensation, and jounce hysteresis. Lateral force steer and fore/aft compliance, however, are known weaknesses. The A-bushing cannot control the latter three

Table 6. Typical performance attributes of existing twist-beam axles.

Performance Attribute	Phys. unit	From	To
Swing arm length	mm	375	460
Swing arm angle	deg	−6	+10
Ride rate	N/mm	17	35

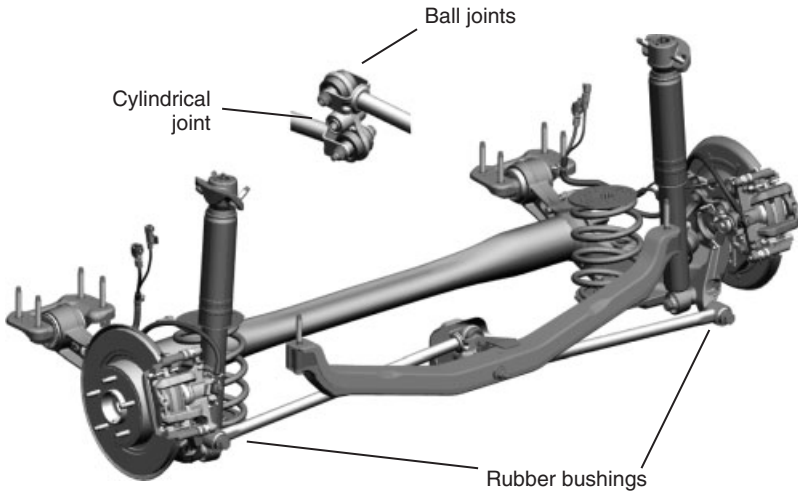

Figure 15. Rear view of a twist-beam with Watt linkage.

characteristics in an optimal way. The compromise lies in moderate, hence safe side force oversteer for the price of relatively harsh impact response and a certain lateral softness.

In 2009, Opel presented the Astra J with a twist-beam axle that was upgraded by two lateral links with a third "differential" link (Harder and Ohligschläger, 2010; Hiemenz and Harder, 2010). This mechanism is called *Watt linkage*. The Watt linkage serves the purpose to maintain the inherent advantages of the twist-beam axle while effectively solving the contradicting requirements for lateral force and steer and fore/aft compliance.

Watt link suspensions for normal front-wheel drive cars have been used before, particularly, in racing together with live axles or with pure torsion beam axles (torsion beam positioned between the wheels). Compared to the historical designs, the attachment for the Watt linkage in the environment of a twist-beam axle has to be reversed. The differential link is attached to the body through an additional subframe and the two lateral links are attached to the axle (Figure 15).

The Watt linkage essentially allows separating the longitudinal support from the lateral support. The lateral forces are reacted by the Watt linkage with minimal lateral displacement. However, if the complete side forces are being compensated by the Watt linkage, then there is still a remaining moment around the vertical axle that will turn the axle into oversteer while cornering. Lateral compliance and lateral force steer are negligible with the Watt linkage. Since the A-bushing is relieved from the support function against side loads and resulting twisting moments, it can be made very compliant in fore/aft direction. This results in an excellent impact behavior and low road noise.

Table 7. Comparison of twist-beam with and without Watt linkage.

	Compound Crank	CC w Watt Link
		
Lateral force steer	0	+
Lateral force deflection	0	++
Camber stiffness	0	0
Camber compensation	0	0

Lateral compliance at wheel center	mm/kN	1.00	1.50
Brake force steer	deg/kN	−0.10	−0.20
Fore/aft compliance	mm/kN	1.00	1.50

Figure 16. Four-wheel-drive-capable twist-beam axle. (Reproduced by permission of Adam Opel AG, Germany.)

drive and four-wheel drive. Vehicle size, performance specifications, and cost targets suggest the usage of a twist-beam axle in this segment. Packaging, however, is a severe issue as the crossbeam of the twist-beam normally blocks the space needed for the rear drive module and the propeller shaft.

A bended twist-beam has been found to be a performance-compliant and cost-effective solution that allows the application of a twist-beam axle with both front-wheel drive and four-wheel drive (Figure 16).

In this case, the twisted beam is formed like an arc over the rear drive module. The design does not dictate the static suspension metrics as shown in Table 8. It must be noted, however, that roll steer tuning by rotation of the beam around the *y*-axis is limited to a few degrees because of the interference of the beam with the driveline.

5 SUMMARY

Starting with the historical designs, the development of the twist-beam axle and its main design parameters that control roll stiffness and roll steer are explained. Chassis designers can take this chapter as a guideline for their own work. Several data samples and additional design hints are offered to help designing such an axle.

The latest developments of twist-beam axles show that some of the intrinsic limitations could be overcome and a modern twist-beam axle is able to have a defined steering behavior and is even able to be used as a driven axle. This will enable the chassis designer to use this lightweight and inexpensive axle for future applications.

Air Suspension Systems—What Advanced Applications May Be Possible?

Friedrich Wolf-Monheim
Ford Motor Company, Aachen, Germany

1 INTRODUCTION

Air suspension systems offer various advantages compared to conventional suspension systems, featuring usual coil or leaf spring elements, leading toward improvements in terms of the ride comfort, the vehicle dynamics performance, and the driving safety. The advantages of air suspension systems in general relate mainly to the practicability of a vehicle body leveling functionality, the technical feasibility of a constant eigenfrequency independent of the loading condition of a vehicle, and the flexibility in terms of the tuning potential of the force versus travel characteristics of the air spring elements by shaping the rolling pistons.

Using air suspension systems, the distance between the vehicle body and the road surface can be varied within the limitations given by the available wheel travels with the aid of the defined supply and exhaustion of pressurized air to and from the air spring elements. On the one hand, the vehicle body can be raised compared to the design height to generate a greater ground clearance between the vehicle underbody and the road surface under severe off-road driving conditions. On the other hand, the vehicle body can be lowered compared to the design height to allow for an unimpeded ingress and egress for all vehicle passengers when the vehicle is standing still. Similarly, the lowering of the vehicle body can enable the reduction of the aerodynamic driving resistance at higher vehicle speeds, for example during highway driving. At the same time, the body lowering improves the road holding abilities of the vehicle, the vehicle handling stability and finally the brake stability of the vehicle. A well-known possibility to reduce fuel consumption and to maintain stability at high speeds is changing the vehicle body pitch angle (lowering the vehicle body height at the front axle only). This functionality is currently used in the Bentley Continental GT.

In the same way, the vehicle body height can be maintained constant independent of the loading condition of the vehicle by varying the air pressures in the individual air spring elements. As a result, also the body eigenfrequency remains unchanged as the air spring stiffnesses can be adapted to the loading conditions. This effect improves the ride comfort for the vehicle passengers.

Furthermore, the geometric design of the rolling pistons can be used to adapt the force versus travel characteristics of the air spring elements to the specific tuning needs over a wide range. Compared to conventional coil or leaf springs, highly nonlinear curve characteristics can be accommodated.

Basically, all air suspension systems consist of air spring modules as primary suspension force elements, a pneumatic compressor in order to ensure the supply of pressurized air, an electronic control unit to handle the control tasks, one or more sensors to detect the ride height and the tilting of the vehicle body as well as pneumatic and electrical connection lines. Some air suspension systems also include a compressed air reservoir in addition to the pneumatic compressor in order to supply the air spring modules with high air mass flow rates if required.

In contrast to the commercial vehicle sector, almost exclusively rolling lobe air spring modules are used for passenger cars. With regard to the ride comfort of air suspended vehicles, the initial dynamic response of the individual air spring modules is particularly important (Wallentowitz, 2005). The contribution of the air spring module stiffnesses with decreasing excitation amplitudes to the total wheel suspension vertical stiffnesses plays a major role in this context. Increasing the wheel suspension vertical stiffnesses results in higher vertical body accelerations with a negative impact on the ride comfort for the vehicle passengers. In the field of automotive engineering, the increase of the wheel suspension vertical rates with decreasing excitation amplitudes is usually referred to as the *harshness effect* (Puff, 2009). Figure 1 illustrates the dynamic air bellow[1] stiffness differences between comfort bellows (one axial fiber layer) and conventional bellows (two crossed fiber layers) with respect to the excitation amplitude.

The frequency dependency starts already slightly above 5 Hz. Thus, the passengers can feel the stiffening of the air bellows. This reduces the driving comfort. Several car companies therefore decided to use comfort bellows and designed air spring systems with externally guided bellows. These differences are explained in more detail in the following: essentially rolling lobe air spring modules can be divided into those that are externally guided and those that are not. From a technical point of view, air spring modules without external guiding can be best executed with cross-ply lobes. Cross-ply lobes normally consist of two or more layers of rubber-coated rayon or nylon cord laid in a cross-ply manner in an angular arrangement with respect to the direction of motion of the air spring unit with an outside layer of abrasion resistant rubber and sometimes an additional internal layer of impermeable rubber to minimize the loss of air (Heisler, 2002). The cross-ply design enables the stability of the geometrical outer shape of the air spring lobe, even under high internal air pressure, without an external guiding tube, as it allows the lobe to carry not only the axial acting force components but also the radial acting force components of the internal air spring pressure. Naturally, cross-ply lobes show greater wall thicknesses compared to axial lobes with external outer guiding tubes. This is the reason for the higher bellow stiffness in Figure 1. In addition, the hysteresis of these bellows during jounce and rebound motions of the suspension is larger compared to the hysteresis of comfort bellows. It is well known that the more friction and hysteresis there is in a suspension system, the less the system deflects for small road irregularities, giving rise to the vehicle riding on its tires rather than on its suspension; this leads to a "busier" secondary ride and to what the Americans call "boulevard jerk". The behavior of former diagonal tires compared to the behavior of radial tires of today is in some way comparable to the behavior of air bellows, which is discussed in this chapter.

The lobes of air spring modules with external outer guiding tubes can be designed with lower wall thicknesses compared to cross-ply lobes without external outer guiding tubes, as the external outer guiding tube carries the circumferential forces. Usually, axial lobes are made from one

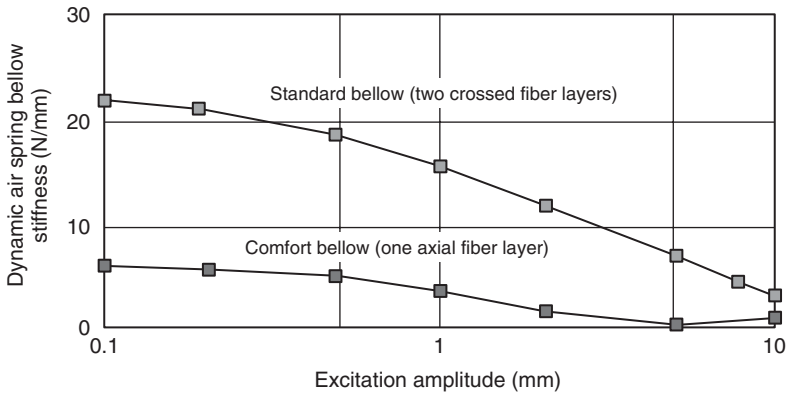

Figure 1. Differences in the dynamic stiffness of one-layer axial air spring bellows and two-layer cross-ply air spring bellows, indicating harshness differences.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

layer of rubber-coated rayon or nylon cord in a parallel arrangement with respect to the direction of motion of the air spring unit with an outside layer of abrasion resistant rubber and sometimes an additional internal layer of impermeable rubber to minimize the loss of air (Heisler, 2002). Owing to the lower wall thicknesses of air spring lobes with external guiding tubes, the harshness effect is usually significantly lower compared to air spring lobes without external guiding.

Generally, air spring modules with outer guiding are more limited in terms of the allowable cardanic movements between the upper and lower ends within a given suspension architecture compared to air spring units without outer guiding. This disadvantage can be compensated by alternative guiding concepts of the air spring lobe, for example, the use of pivoted rolling pistons. Next to the design of air spring modules, also the history of the modules (aging) influences the harshness characteristics. In terms of the air spring module design not only the external guiding elements of the air spring lobes but also the upper and lower connecting joints (ball joints, bearings, bushings, etc.) as well as the dimensions of the modules themselves influence the harshness performance. In the area of air spring lobe design, the influencing factors are the fiber orientation of the different layers, the fiber material, the fiber diameter, the elastomeric material and the air spring lobe wall thickness. These are additional contributors to friction and hysteresis. With regard to the aging of air spring lobes, various environmental influencing factors such as ozone in the ambient air, the combination of ultraviolet light and oxygen, reactive metals such as copper, oils and fats play a key role in terms of the harshness effect. In addition, the air spring module loading history (temperature, force and pressure) has an effect on the harshness characteristics (Puff, 2009).

2 STATE OF THE ART—FOUR-CORNER AIR SUSPENSION SYSTEMS

Vehicles equipped with a four-corner air suspension system are characterized by the fact, that all suspension springs are air spring modules. Four-corner air suspension systems can be divided into two distinct classes: Those without switchable additional volumes and those with switchable additional volumes. Already in the 1960s, vehicles as for example the Borgward P100 and the Mercedes 600 were equipped with four-corner air suspension systems. Even today, four-corner air suspension systems are mainly offered in the premium passenger car segment of the upper and middle classes because of the high cost of such systems. The air spring modules of today's state-of-the-art four-corner air suspension systems are usually equipped with air spring bellows with small wall thicknesses and outer guiding tubes to optimize the ride comfort for the vehicle occupants. Generally, the systems incorporate comprehensive functionality with regard to automatic leveling. This functionality comprises for example the speed-dependent lowering of the vehicle body to reduce the aerodynamic driving resistance or to increase the dynamic driving stability and the hoisting of an SUV body to improve the off-road capabilities. The functions are available to the driver either fully automatic or on demand of the driver.

Figure 2 shows the Jaguar XJ front suspension with the air spring modules of the four-corner air suspension system integrated into a double-wishbone-type front suspension as an example of application. Driven by the front suspension architecture of the Jaguar XJ, air spring modules with outer guiding tubes can be used because no significant bending moments need to be carried by the air spring and damper assemblies. For air sprung strut type front suspension architectures, the bending moments on the damper are usually compensated with the aid of asymmetric shaped air spring bellows without outer guiding elements. Alternatively, it is possible to use rotationally symmetrical air spring bellows that are angularly arranged with respect to the dampers to achieve a side force compensation. Four-corner air suspension systems as in the Jaguar XJ are often combined with adaptive damping systems. The switchable damper units are usually centrally arranged inside the air spring modules to optimize the vehicle package.

Four-corner air suspension systems with switchable additional volumes are semiactive systems. By connecting switchable additional volumes to the individual air spring modules, the air spring rates can be varied depending on the driving condition without changing the pressure levels inside the air spring modules. By opening the pneumatic connections between the individual air spring modules and

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

their corresponding additional volumes, softer air spring rates can be achieved because of the volume increases of the different air spring modules. This results in an improved ride comfort for the vehicle occupants. In the case where the pneumatic interconnection lines between the air springs and their additional volumes are closed, the driving stability and therefore the driving safety during lateral dynamic driving maneuvers are increased because of the resulting higher air spring rates. Therefore, air suspension systems with switchable additional volumes are a potential enabler to defuse the conflict of goals between the driving safety and the driving comfort. Depending on the specific geometric design of the pneumatic interconnection lines, including the electromechanical valves between the air springs and the additional volumes, four-corner air suspension systems with switchable additional volumes can generate damping forces caused by the airflow processes between the air volumes through the interconnection lines, as energy is dissipated by the system. For very high suspension travel velocities and/or unfavorably designed pneumatic interconnection lines between the air springs and the additional volumes, the additional volumes can uncouple dynamically from the air springs. The dynamic uncoupling is driven by the fact that the pressure equalization between the volumes significantly deteriorates because of the dynamics of the suspension excitation and/or the pneumatic interconnection line designs. These decoupling effects can be avoided by a sufficient system design with respect to the fluidic system layout. The general design rule is to use short interconnection lines with large cross-sectional areas. However, interconnection lines with large cross-sectional areas need to be combined with suitable electromagnetic valves with similar cross-sectional areas and adequate air tightness. From a technical point of view, pneumatic valves, which are suitable for use in high volume production, are limited in terms of the maximum switchable cross-sectional area. In addition, the weight and the cost of these valves increase with increasing switchable cross-sectional areas of the interconnection lines. The integration of the individual additional volumes into the air spring modules offers the opportunity to reduce cost and weight of the entire system. At the same time, the lengths of the interconnection lines between the air spring volumes and the additional volumes can be minimized and the airflow between the volumes can be improved accordingly.

In Figure 3, the front suspension air spring module with integrated additional volume of the Porsche Panamera is shown. Air spring bellows with a small wall thickness and an outer guiding tube are used to improve the harshness characteristics of the air spring module. In the upper part of the module, the integrated switchable additional volume (1) is depicted. In the comfort setting of the air suspension system, the additional volume can be added to the base volume (2) by operating a pneumatic valve (3). The base volume is arranged in the lower part of the air spring module. The adaptive damping system with switchable valve unit (4) is coaxially integrated into the air spring module.

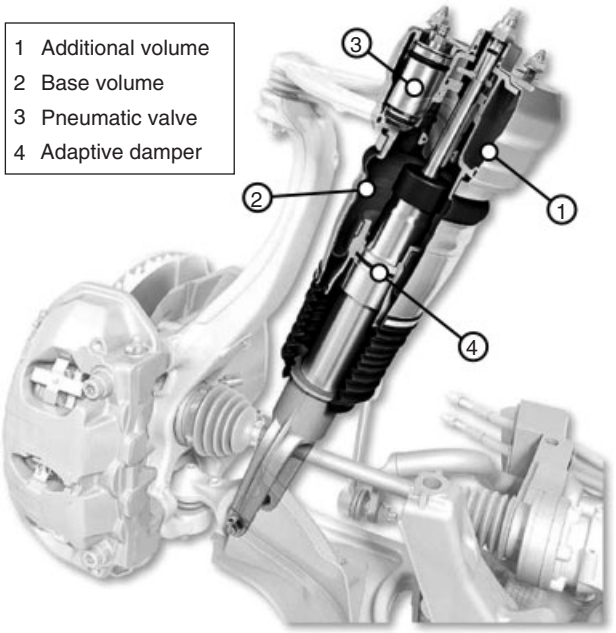

Figure 3. Semiactive four-corner air suspension system—Porsche Panamera front suspension air spring module with integrated switchable additional volume. (Reproduced by permission of Porsche Aktiengesellschaft.)

3 CONTINUOUSLY VARIABLE AIR SUSPENSION SYSTEMS

Usually, four-corner air suspension systems with one switchable additional volume for each air spring module allow only the implementation of two discrete force versus travel characteristics per module. In contrast to these systems, continuously variable air suspension systems enable the individual, seamless transition of the air spring module stiffnesses over a large adjustment range without changing the amount of air in the different air spring modules. In general, two different design approaches for the air spring modules of continuously variable air suspension systems are known. On the one hand, the air spring volumes or the additional volumes can be actively varied to generate continuously changing air spring rates. On the other hand, the effective areas of the air spring modules can be actively increased and decreased over specific roll

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

areas of the air spring bellows over the rolling pistons to generate seamless changing rates of the air spring modules. The interrelationship between the effective area A and the stiffness c of an air spring is shown in Equation 1

$$c = \frac{n \cdot p_i \cdot A^2}{V} \quad (1)$$

On the one hand, the polytropic exponent n and the internal pressure p_i cannot be influenced by the air spring design. On the other hand, the volume V and the effective area A can be influenced by the air spring design within the given package constraints.

As an example for a continuously variable air spring module, Figure 4 shows the Active Air Suspension module from Meritor, Inc. The design of the Active Air Suspension module with coaxially integrated adaptive damper unit (3) is similar to the design of a conventional air spring module. In addition to the main air spring bellow (1) of the module, an additional smaller bellow (2) is mounted directly to the rolling piston to enable the continuous variation of the air spring module rate. This second air spring piston bellow has hermetically sealed interfaces with the rolling piston on the upper and lower ends.

The filling of the air spring piston bellow with compressed air is independent from the filling of the main air volume of the air spring module. By varying the amount of air in the air spring piston bellow, the shape of the rolling piston in the roll area of the air spring bellow changes. Owing to the diameter variation of the air spring piston bellow mounted to the rolling piston with the pressure change inside the air spring piston bellow, the characteristic of the effective area as a function of the air spring module travel can be continuously varied. As a result of the variation of the effective area versus travel characteristic, the air spring module rate can be changed continuously. Because of the high sensitivity of the air spring module rate to the effective area, already relatively small variations of the air volume of the air spring piston bellow can generate large air spring module rate changes. As a result of this correlation not only quasi-static but also fast dynamic air spring module rate variations are possible. For example, at a static air pressure of 9 bars inside the main air spring bellow, the air spring module rate can be varied from 16 to 36 N/mm by changing the air pressure of the bellow mounted to the rolling piston from 1 to 14.4 bars.

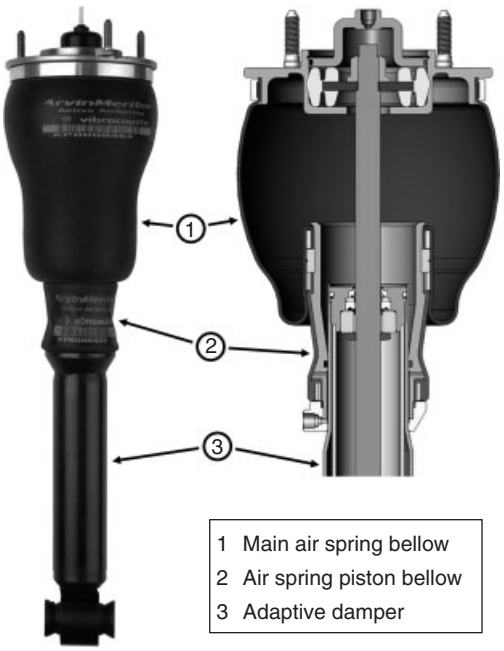

Figure 4. Continuously variable air spring module. (Reproduced by permission of Meritor, Inc.)

4 AIR SPRING DAMPER SYSTEMS

The particularity of air spring damper systems is, that not only the spring forces but also the damping forces are generated with the aid of air as the working fluid. The spring and the damper functionalities are combined in one single functional component. In this manner, the use of conventional hydraulic damper units can be dispensed with. Conventional hydraulic damper modules, used within four-corner air suspension systems with switchable additional volumes, are usually semiactive adaptive units to enable the variation of the damping force versus velocity characteristics of the damper units, in addition to the spring force versus travel characteristics of the air spring modules with switchable additional volumes, depending on the driving situation. However, adaptive hydraulic damper modules are technically more complex in comparison to conventional hydraulic damper units as they require switchable valve elements. In case of air spring damper modules, the damping functionality is achieved with the integration of throttle elements. During the bump and rebound motions of the air spring damper modules, the air is forced to flow through these throttle elements. This leads to the generation of damping forces. Fundamentally, air spring damper units can be distinguished into air spring damper units with two air volumes and air spring damper units with three air volumes. For air spring damper modules with two air volumes, only one maximum of the damping work occurs in the frequency domain that can be aligned with the vertical eigenfrequency

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the vehicle body. With the aid of air spring damper modules with three air volumes, two separate maxima of the damping work can be implemented in the frequency range. To achieve the optimum system performance for an air spring damper system, the first maximum of the damping work can be adjusted to the vertical eigenfrequency of the sprung mass respectively to the vehicle body mass and the second maximum of the damping work to the vertical eigenfrequencies of the unsprung masses. Theoretical and practical investigations with regard to air spring damper modules and systems are documented in Kranz (1934) and Gold (1973).

Currently, in the fields of passenger cars, no applications of air spring damper systems are known for series production. In the fields of motorbikes, a series production application of an air spring damper system is known on the single arm rear suspension of the BMW HP2 Enduro. This air spring damper module is supplied by Continental and shown in Figure 5 (Müller *et al*., 2005).

The module is based on a compact aluminum part with integrated guiding for a hollow aluminum piston rod, which is shown in the upper part of Figure 5. A damper piston with integrated throttle elements is rigidly mounted to the piston rod. In the lower part of Figure 5, a fabric reinforced rolling lobe is shown, which can roll up and down in direct contact to a cone-shaped rolling piston as the air spring damper unit moves in bump or rebound direction.

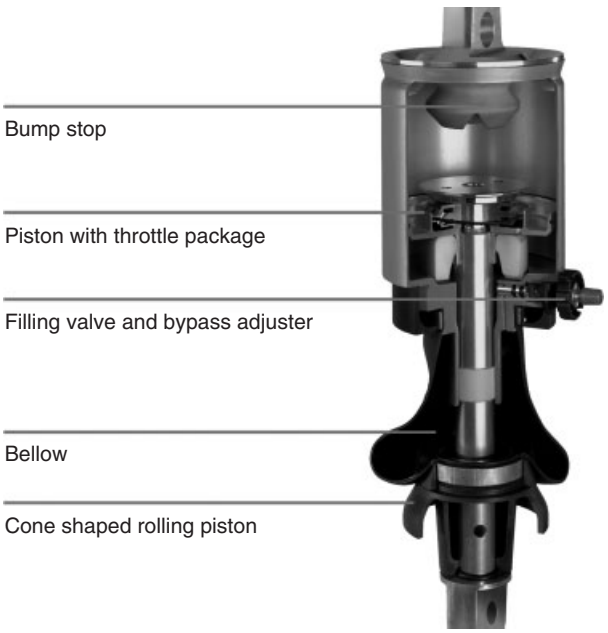

Figure 5. Cutaway view of the BMW HP2 Enduro air spring damper module. (Reproduced by permission of Continental.)

One bump and one rebound stop made of polyurethane rubber provide the necessary progressivity of the air spring damper module in the extreme ends of the available module travel. Conventional asymmetric shim stacks are used as throttle elements in the rebound and compression motion directions. The shim stacks generate annular gaps as a function of the pressure difference over the damper piston. With the aid of the bypass adjuster, which is integrated into the filling valve, two different settings can be applied to the module to avoid extreme damping force peaks. This damping force limitation enables an improvement of the driving comfort.

During the assembly process of an air spring damper module, the mounting tolerances between the base part and the dividing piston do not need to be as narrow as with conventional hydraulic damping units, because the leakages through the seals are not very sensitive to the generated damping forces. This means, that the leakages on the seals do not immediately lead to a reduction of the generated damping forces. This is based on the fact, that the transported air volumes of air spring damper modules are much higher compared to the transported oil volumes of conventional hydraulic damper units. As a result, the outer diameters of air spring damper modules are usually larger compared to the outer diameters of conventional hydraulic damper units. This leads to an increased package space demand of air spring damper modules, that needs to be considered as a part of the full vehicle layout process.

5 INTERLINKED AIR SUSPENSION SYSTEMS

In Wolf-Monheim (2011), a semiactive interlinked four-corner air suspension system, which is based on a conventional four-corner air suspension system with switchable additional volumes, is analyzed. The system enables an improved ride comfort for the vehicle occupants without neglecting the driving safety aspects. The semiactive interlinked four-corner air suspension system is currently not in series production. To analyze the system performance in terms of the ride comfort improvement for the vehicle occupants, the system was installed into a Volvo XC90 prototype vehicle. The semiactive interlinked four-corner air suspension prototype system consists of four air spring modules with switchable additional volumes as well as two pneumatic pipes routed from the left side to the right side of the vehicle to interconnect the two front suspension air spring modules with one another and the two rear suspension air spring modules with one another. Depending on the current driving condition, the pneumatic interconnection lines between the air spring modules can be switched

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

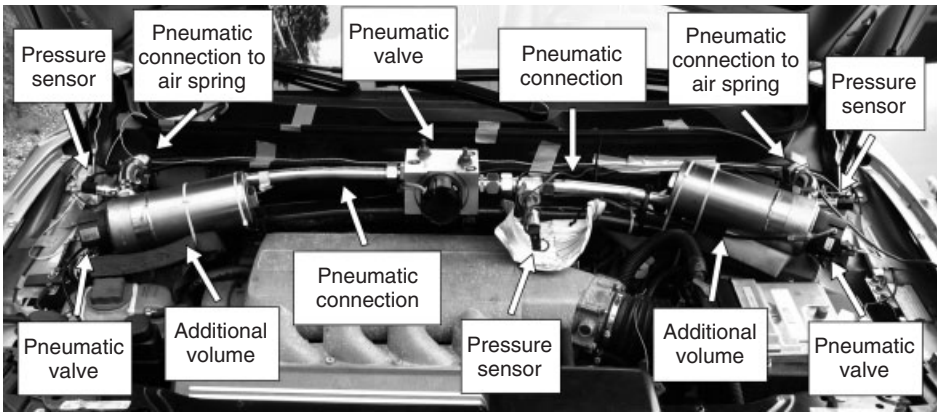

Figure 6. Interlinked air suspension system—Volvo XC90 front suspension. (Reproduced by permission of Wolf-Monheim, 2011. © Wolf-Monheim.)

on and off with the aid of electromagnetic pneumatic valves.

A pneumatic connection between the front and rear suspension air spring modules is not shown in Wolf-Monheim (2011). Within semiactive four-corner air suspension systems, a front to rear connection can be used to reduce the pitch angles of the vehicle body while driving over single impacts and to reduce the pitch angle oscillation accelerations while driving on uneven road surfaces. Within active four-corner air suspension systems, a pneumatic connection between the front and rear suspension air spring modules can be used to allow for an active anti-lift and/or anti-dive pitch angle compensation during acceleration and braking maneuvers.

The achievable improvement in terms of the ride comfort for the vehicle passengers of the semiactive interlinked four-corner air suspension system shown in Wolf-Monheim (2011) results from the fact, that the roll stiffness of the vehicle can be adapted to the individual driving conditions. In this manner, both high roll stiffness during high lateral acceleration driving maneuvers, such as while driving around bends, and low roll stiffness to improve the driving comfort for the vehicle passengers while driving straight ahead on uneven road surfaces can be achieved. Furthermore, semiactive interlinked four-corner air suspension systems can specifically generate roll damping by the appropriate design of the pneumatic interconnection lines and the electromagnetic pneumatic valve geometries as well as by the controlled variation of the cross-sectional areas of the electromagnetic pneumatic valves. Specifically, in combination with switchable additional volumes and continuously variable hydraulic damper modules, the interlinked semiactive four-corner air suspension system can independently influence the roll, pitch and bounce oscillation accelerations of the vehicle body.

In Figure 6, the semiactive interlinked air suspension system with two switchable additional volumes of the prototype vehicle front suspension is shown. Figure 7 shows the equivalent semiactive interlinked air suspension system with two switchable additional volumes installed into the rear suspension of the prototype vehicle. The flows of the pressurized air through the pneumatic interconnection lines between the left and right air spring modules of the front axle and those of the rear axle, respectively, can be interrupted with the aid of electromagnetic pneumatic valves. The additional volumes are connected to the air spring modules with the smallest possible distances and can also be switched on and off separately by means of electromagnetic pneumatic valves. The lengths of the pneumatic interconnection lines of the front and rear suspensions are approximately 1 m. Owing to packaging restrictions, the pneumatic interconnection lines on the front and rear suspensions have some curvatures.

The semiactive interlinked four-corner air suspension system enables a significant improvement in terms of the ride comfort for the vehicle passengers compared to a conventional passive four-corner air suspension system. Compared to a semiactive four-corner air suspension system with switchable additional volumes the ride comfort improvement of the interlinked air suspension system without switchable additional volumes is on a similar level. However, the required package space of the interlinked four-corner air suspension system is significantly lower in comparison to the four-corner air suspension system with switchable additional volumes. Compared to the four-corner air suspension system with switchable additional volumes, the interlinked four-corner air suspension system enables a significantly greater reduction of the body roll oscillation accelerations. The body roll oscillation accelerations are particularly uncomfortable for the vehicle passengers

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

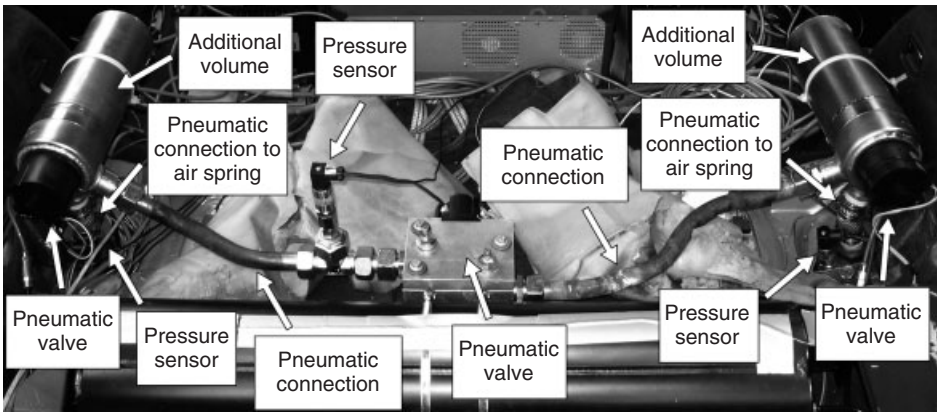

Figure 7. Interlinked air suspension system—Volvo XC90 rear suspension. (Reproduced by permission of Wolf-Monheim, 2011. © Wolf-Monheim.)

compared to the other translational and rotational oscillation accelerations of the vehicle body (Ilgmann, 1979; Kenneth and Griffin, 1978; Parsons, Whitham, and Griffin, 1979).

The vibration intensities introduced to the vehicle body can be further reduced by the combined use of the pneumatic interconnection lines and the additional volumes. Finally, the biggest advantages of the semiactive interlinked air suspension system with switchable additional volumes can be shown in combination with a semiactive adaptive damping system. As mentioned earlier, up to now the semiactive interlinked air suspension system was realized as a prototype system installed into a prototype vehicle only. For future applications of the system under series production conditions, further development work is needed. When the semiactive interlinked four-corner air suspension system with switchable additional volumes is applied to a particular vehicle, it is important that the specific characteristics of the system are aligned with the specific characteristics of the other chassis and suspension systems and components, especially with regard to the driving dynamics. Especially in this context, the tuning of the anti roll bars of the front and rear suspensions should tend toward softer rates whereas the rates of the air spring modules of the front and rear suspensions should tend toward higher rates, as the semiactive interlinked air suspension system allows for a variation of the body roll stiffness. In addition, the air volumes of the pneumatic interconnection lines on the front and rear suspensions should be considered when the air spring modules are designed.

In Wolf-Monheim (2011) various driving test measurement and simulation results on full vehicle bases are presented and analyzed using a prototype vehicle with semiactive interlinked air suspension systems with switchable additional volumes installed on the front and rear suspensions. Initially, simulation and measurement results are analyzed while driving on a ride comfort test track with firstly a sinusoidal profile on one vehicle track only and then secondly with sinusoidal profiles on both driving tracks of the vehicle. During the test drives with only one driving track of the vehicle on the ride comfort test track with the sinusoidal road profile, the other driving track of the vehicle runs on a flat road surface. The results of the test runs with a single track driving on the sinusoidal test track road profile show that the resulting dynamic air spring module stiffnesses can be significantly influenced by the diameters of the pneumatic interconnection lines and by the vehicle driving velocity. Furthermore, the resulting body roll oscillation accelerations and the resulting seat rail vertical oscillation accelerations in relation to the excitation frequencies are studied. The influence of various system designs on the respective effective accelerations is analyzed. With the aid of suitable analysis models to describe the ride comfort as perceived by the vehicle passengers, weighting functions are selected and applied to the simulation as well as the measurement results. In this context, parameters not only for the individual vibration severities but also for the total vibration severities are determined for the various designs of the semiactive interlinked four-corner air suspension system with switchable additional volumes. For the vehicle with opened pneumatic interconnection lines with diameters of 19 mm compared to the prototype vehicle with a reference system design with closed pneumatic interconnection lines and disconnected additional volumes driving with one single track on the ride comfort test track with sinusoidal road profile, the vibration severities of the vehicle body roll oscillation accelerations and the seat rail vertical oscillation accelerations sensed by the vehicle passengers can be reduced by 24%. On various ride comfort test tracks with a wide range of different stochastic unevenness distributions, the potential of the semiactive interlinked air

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

suspension system with switchable additional volumes to reduce the vibration intensities introduced to the vehicle body is also analyzed. In the first place, the potential for variations with regard to the vehicle body control with opened pneumatic interconnection lines of different diameters on the front and rear suspensions, respectively, and with different additional volume sizes is analyzed in the frequency range up to 10 Hz in comparison to the reference vehicle configuration as described earlier.

In this context it becomes evident, that the body roll motions can be influenced by opening the pneumatic interconnection lines to a far greater degree compared to the connection of the additional volumes. The vehicle body roll motions are perceived more clearly by the vehicle passengers compared to other vehicle body motions, such as the vehicle body pitch motions, the vehicle body yaw motions or the vehicle body bounce motions. The reason for this observation can be explained as follows. The road profile excitation content of the left and right driving tracks, primarily leading to vehicle body roll oscillations, results in less dynamic wheel load fluctuations between the two front and two rear wheels, respectively, for the vehicle configuration with opened pneumatic interconnection lines on the front and rear suspensions and disconnected additional volumes in comparison to the vehicle configuration with closed pneumatic interconnection lines on the front and rear suspensions and connected additional volumes.

This is due to the fact that in the case of opened pneumatic interconnection lines on the front and rear suspensions and antiphase travel excitations of the wheels of each axle, the pressure differences between the two front and two rear suspension air spring modules, respectively, can be equalized because of the air mass exchanges through the pneumatic interconnection lines. This results in almost constant forces of the air spring modules of one axle.

In contrast to the aforementioned, the level of the bounce oscillations of the driver's seat as well as the level of the pitch oscillations of the vehicle body can be better varied by connecting or disconnecting the additional volumes compared to switching the pneumatic interconnection lines between the left and right sides of the vehicle. The greater efficiency of the switchable additional volumes, with regard to the bounce and pitch angle degrees of freedom, follows from the fact, that the road profile excitation content of the left and right driving tracks, primarily leading to bounce and pitch angle oscillations of the vehicle body, can only influence the forces introduced into the vehicle body and therefore the vehicle body bounce and pitch angle oscillations in the case, when the additional volumes on the front and rear suspensions are varied respectively switched with the resulting variations of the base rates of the individual air spring modules.

The pneumatic interconnection lines between the air spring modules of the front and rear axles, respectively, have only a minor influence on the resulting air spring module forces, when the road profile excitation content of the left and right driving tracks primarily leads to bounce and pitch angle oscillations of the vehicle body. This can be explained by the fact, that the base rates of the air spring modules are equal for opened and closed pneumatic interconnection lines between the left and right sides of the vehicle for almost identical road profiles of the left and right tracks.

In a similar way, the oscillation acceleration reduction potential in the enhanced frequency range of up to 100 Hz is analyzed for different design variants of the semiactive interlinked air suspension system with the switchable additional volumes, in comparison to the reference vehicle configuration with closed pneumatic interconnection lines and disconnected additional volumes. These tests are based on acceleration measurements on the outer seat rail of the driver's seat and on the steering wheel. In addition to the analyses of the influence of the pneumatic interconnection lines and the switchable additional volumes on the ride comfort for the vehicle passengers, also the influence of a semiactive adaptive damping system is analyzed. The results are evaluated in various individual frequency bands. For all tests, the percentage reductions of the root mean square values of the power spectral densities (PSDs) are determined.

For opened pneumatic interconnection lines, the PSDs of the seat rail vertical oscillation accelerations can be reduced in comparison to the reference vehicle configuration by up to 9.6%, depending on the individual frequency range. The PSDs of the steering wheel oscillation accelerations can also be reduced significantly (by 15.6%) with opened pneumatic interconnection lines in comparison to the reference vehicle configuration. In case the additional volumes are connected, instead of opening the pneumatic interconnection lines, the PSDs of the seat rail vertical oscillation accelerations as well as the PSDs of the steering wheel oscillation accelerations can be reduced by a similar magnitude. On the seat rail of the driver's seat, the PSDs can be decreased by up to 11.3% and on the steering wheel by up to 12.7%, depending on the frequency range.

The combined use of the pneumatic interconnection lines and the additional volumes enables the further increase of the ride comfort perceived by the vehicle passengers. In this case, the PSDs of the seat rail vertical oscillation accelerations can be diminished by up to 15.4%, depending on the frequency band. The PSDs of the translational steering wheel oscillation accelerations can be reduced by up to 19.8%.

A further improvement of the vibration comfort felt by the vehicle passengers is possible if a semiactive adaptive damping system is used in addition to the opened pneumatic interconnection lines between the air spring modules of the front and rear axles, respectively, and the connected additional volumes.

In comparison to the reference vehicle configuration with closed pneumatic interconnection lines between the left and right sides of the vehicle, disconnected additional volumes, and inactive adaptive damping system, this system configuration enables the reduction of the PSDs of the outer seat rail vertical oscillation accelerations measured at the driver's seat of up to 24.6%. In addition, it is possible to decrease the PSDs of the translational steering wheel oscillation accelerations by up to 29.5%.

Subsequent publications referring to semiactive interlinked four-corner air suspension systems are Wolf-Monheim *et al*. (2008a), Wolf-Monheim *et al*. (2008b), Wolf-Monheim *et al*. (2008c), and Wolf-Monheim *et al*. (2009).

6 ACTIVE AIR SUSPENSION SYSTEMS

From a physical point of view, active air suspension systems can be based on either an active air mass change or an active air volume change in the individual air spring modules. Next to the ride height control functionality of conventional semiactive four-corner air suspension systems with and without additional volumes, active four-corner air suspension systems also enable additional functionalities, for example, active roll and/or pitch angle compensations. On the one hand, an active air suspension system based on dynamic air mass change can be realized, for example, by means of high pressure air reservoirs and air compressors. If required, the air masses can be shifted actively from the high pressure air reservoirs to the air spring modules. On the other hand, an active air suspension system based on dynamic air volume change can be made, for example, with the aid of hydraulic, pneumatic, or electromechanical actuators. To minimize the energy consumption of the actuators used within the system layout, the static loads generated by the sprung mass can be carried partly or fully with the help of passive spring elements. This means, that only the requested dynamic force variations are demanded from the actuators.

In Zhang (2006), three different active air suspension systems based on dynamic air volume change are presented and compared with one another with the aid of complex numerical simulation models. All the three systems documented in Zhang (2006) are based on a driven double-acting cylinder, which moves two additional connected mechanical two-chamber cylinders. These mechanical two-chamber cylinders are used to supply pressurized air to one air spring module and remove pressurized air from another. With the help of appropriate valve technology, the active air suspension system can be switched between roll angle compensation mode for lateral acceleration maneuvers and anti-lift and anti-dive pitch angle compensation mode for acceleration and braking maneuvers, respectively, depending on the driving situation. For the fully pneumatic system (Figure 8), a pneumatically operated double-acting drive cylinder is used, whereas a hydraulically operated double-acting drive cylinder is utilized within the hydropneumatic system (Figure 9). The third system is referred to as the *fully hydraulic system* (Figure 10), as in this case, a hydraulically operated double-acting drive cylinder moves two additional connected hydropneumatic two-chamber cylinders. In this system, four additional passive cylinders with one hydraulic and one pneumatic chamber are needed to realize the active air volume change of the individual air spring modules.

For the fully pneumatic active air suspension system, two key advantages in comparison to the other two systems can

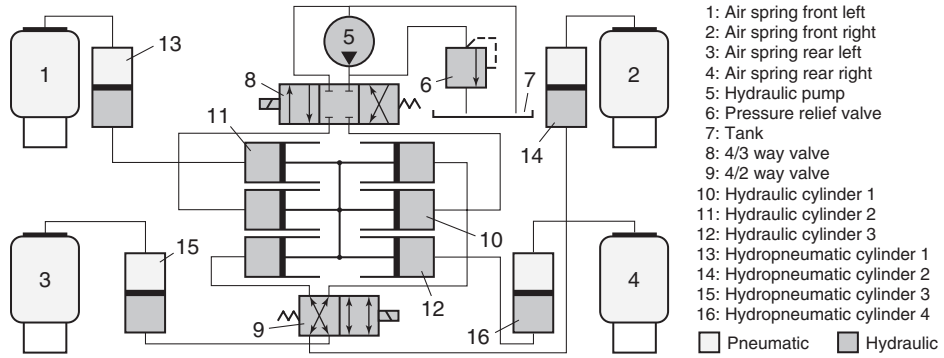

Figure 10. Active air suspension system—fully hydraulic system. (Reproduced by permission of Zhang, 2006. © Zhang.)

be mentioned. On the one hand, only pressurized air is used in this case as the working fluid and hydraulic oil can be avoided to improve the environmental friendliness of the system. On the other hand, the actual design and development of the system is relatively easy. However, the disadvantage of the fully pneumatic active air suspension system is that it tends to oscillate because of the compressibility of the pressurized air as the working fluid. This results in difficulties in terms of the precise position control of the individual actuators.

In contrast to the fully pneumatic active air suspension system, the fully hydraulic active air suspension system can be controlled in a stable way as it features only a small amount of volumes filled with pressurized air. However, it is technically more complex and demands more packaging space compared to the fully pneumatic and the hydropneumatic active air suspension systems. In addition, it is also more expensive compared to the other two systems. The hydropneumatic active air suspension system is implemented and tested in a prototype vehicle.

A further active air suspension system is presented in Kranen (1996). In the system presented here, a volume exchanger is utilized as the actuator to shift the pressurized air between the air spring modules. The power steering device supplies the energy needed to actuate the system.

7 SUMMARY

This chapter gives an overview of advanced air suspension technologies and applications based on current state-of-the-art four-corner air suspension systems. In the introduction, the main advantages and base functionalities of air suspension systems as well as the available design variants of air spring modules are presented.

Section 2 deals with the two key distinct categories of the state-of-the-art four-corner air suspension systems. The first category covers air suspension systems without switchable additional volumes and the second category systems with switchable additional volumes.

Continuously variable air suspension systems presented in Section 3 offer the advantage to vary the force versus air spring module travel characteristics of the individual air spring modules and therefore also the air spring module stiffnesses in a continuous way. For these systems, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto004
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

stiffness variations can be generated by varying either the effective areas or the air spring module respectively additional volumes.

Air spring damper systems as discussed in Section 4 do not only provide a springing functionality but also a damping functionality based on pressurized air as the working fluid. The air damping is achieved with the aid of pneumatic throttle elements integrated into the air spring damper modules where the pressurized air is forced to flow through while dissipating energy. Compared to conventional hydraulic damping elements, air spring damper units avoid the use of hydraulic oil as a working fluid and therefore improve the environmental friendliness.

In Section 5, interlinked air suspension systems, characterized by pneumatic interconnection lines between the individual air spring modules, are described. Semiactive interlinked four-corner air suspension systems offer enhanced possibilities to tune the vehicle body bounce and roll stiffness properties independently from one another, depending on the current driving condition. In addition, the vehicle body pitch angles can be influenced while driving over single impacts or on uneven road surfaces.

Finally, active four-corner air suspension systems are introduced in Section 6. Active four-corner air suspension systems enable additional functionalities, for example active vehicle body roll angle or anti-lift and/or anti-dive vehicle body pitch angle compensations during lateral acceleration or longitudinal acceleration and braking maneuvers.

ENDNOTE

1. The use of "bellow" should be understood as a flexible bladder or bag containing pressurised air.

ULSAS—Suspension, A Comparison of Rear Suspension Design

Henning Wallentowitz

RWTH Aachen University, Aachen, Germany

1 INTRODUCTION

Chassis engineering basically refers to the designing of axles and chassis suspension systems and their vehicle integration. A company unique driving performance shall be achieved. Chassis suspension systems, especially those of passenger vehicles, can be categorized by dividing into rigid axles, semirigid axles, and independent suspensions. Figure 1 shows this classification.

Ever since the intensive use of aluminum in vehicle construction, there have been widespread discussions about materials used in the chassis suspension systems. Those discussions are still on-going. Owing to the differentiation between sprung masses (body mass) and unsprung masses (axle parts), the lightweight layout of the unsprung masses with regard to driving comfort, weight, as well as kinematics, is considered in the design of suspension parts. Axles should be as light as possible, hence higher grade steels, lightweight metals, or even synthetics, for example, fiber composites, provide possible solutions, at least on first sight.

Ten years ago, the international steel industry gave an assignment to Lotus engineering to do a survey on lightweight chassis suspension systems. The weight-based competitiveness of steel should be shown for these applied usages. The design proposal, which became known as the *ULSAS-study* (*Ultra light Steel Auto Suspension*) (Lotus, 2000; World Auto Steel, 2012; Stahl-Informations-Zentrum, 2012), focused on rear axles and came up with interesting solutions. This study will be partly reviewed in the following article. For front axles, this volume of the Encyclopedia contains the detailed report "Lightweight front suspension, a comparison" (see Light Weight Front Suspensions, a Comparison) by Mrs Dr. Chang (2006).

2 STARTING SITUATION WITH REAR AXLE SUSPENSION SYSTEMS

The engineers at Lotus started working on the ULSAS study by analyzing existing car chassis suspension systems. They focused on the four most important axles. Figure 2a–d summarizes those axles.

Figure 2a shows the so-called Double Wishbone axle (often known as *Short-Long Arm* suspension in the United States) with a body-connected longitudinal control arm, which is made from a deep-drawn steel plate. The two lower transverse control arms are mounted to a small rear suspension subframe and they are made of forged steel. The front lower transverse control arm carries a suspension strut that is directly held up at the body at its upper end. The knuckle is forged as well and is shaped to follow the contour of the tire until it reaches a ball joint, to which

ISBN: 978-0-470-97402-5

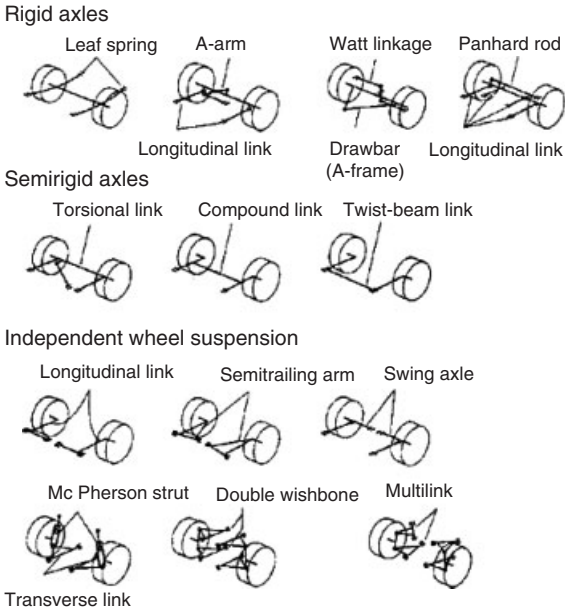

Figure 1. Systematic classification of chassis suspension of passenger vehicles. (Reproduced with permission from ika RWTH Aachen University. © ika Aachen.)

the upper transverse control arm is mounted. This upper control arm is also forged and is directly attached to the body at its other end with an elastomeric bush. According to the ULSAS study, the mass of the axle is 39.8 kg. This nondriven suspension assembly is fitted to the rear of the Honda Accord.

Figure 2b shows a driven rear axle of BMW, the so-called integral axle. The large suspension subframe is made of hydroformed aluminum. Welded consoles, also consisting of aluminum, are the connections to the upper transverse control arms. These control arms are made from forged aluminum. The lower control arm consists of a large box section, which is made up of metal sheet, and is mounted to the suspension subframe with two bearing connections and with one ball joint to the wheel carrier. The so-called integral connecting rod connects the wheel carrier with the large box section transverse control arm (Matschinsky, 1998). The "integral rod" reduces elastic rotational deformations during acceleration and braking. This reduces the so-called wind-up of the wheel carrier that otherwise may lead to wheel hop or "tramping" [reasons are changes in friction (slip) between the tire and the road because of the wind-up of the wheel carrier].

Suspension is done through suspension struts, which are not shown in Figure 2b. Those struts are directly mounted to the wheel carrier. The large suspension subframe enables the connection of the axle in the area of the vehicle's stiff longitudinal chassis beam. This suppresses the transmission of noises into the body, created by the tires or the rear axle differential. The differential is supported in the suspension subframe by elastomeric bushes, as is the suspension subframe in the body. That is why this is called a *double-elastic bearing*. The mass of this BMW integral axle is stated at 46.67 kg in the ULSAS study (aluminum axle).

Axle 2c is a lightweight suspension strut rear axle. It was taken from a Ford Mondeo. Via a tension strut

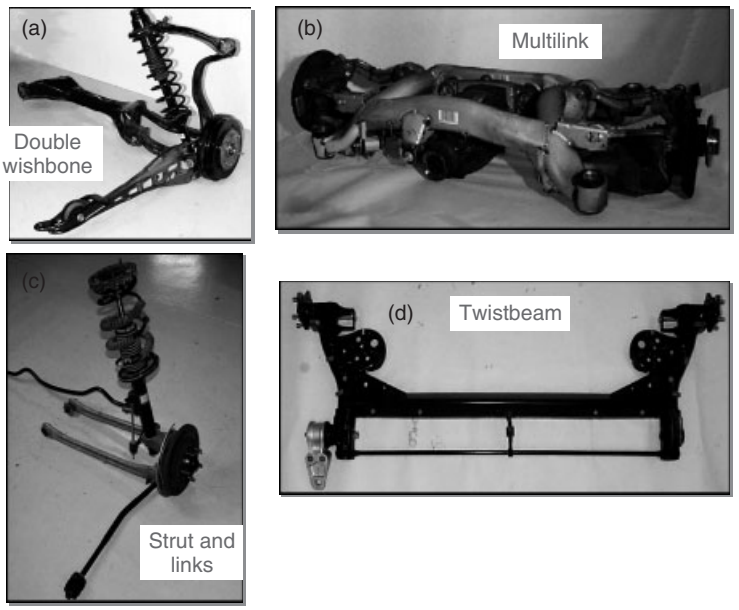

Figure 2. (a–d) Most important axles. (Reproduced from World Auto Steel. © World Auto Steel.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto006
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and connected rubber bearings, the longitudinal forces are transferred from the wheel carrier into the car body. The transverse forces are transferred to the body through two lower transverse control arms (forged aluminum parts) and the upper suspension strut bearing. This upper suspension strut bearing additionally transmits the vertical forces from spring and damper.

Owing to the upper suspension strut bearing having to brace side forces, the piston in the damper and the piston rod bearing have to handle lateral forces. The induced torque by the vertical forces can be compensated by the inclined function line of the coil spring within the design position of the wheel suspension. This "trick" to compensate torque is used commonly on front suspension McPherson struts, but it can also be applied in rear axles. To achieve a high stabilizer conversion ratio, the stabilizer (or antiroll bar) is mounted to the suspension strut using a rod.

To provide adequate clearance between the tire and the damper strut, the bottom mount of the strut into the hub carrier (often clamp design or welded) is offset laterally inward. To carry the torque between wheel hub and damper, the hub carrier is designed as a cast or forged part to accommodate this. This suspension strut rear axle is designed as a nondriven axle. The ULSAS study quotes a mass of 39.7 kg.

The twist-beam axle that is shown in Figure 2d, and which originates from the Volkswagen Golf, is made from steel plates to achieve the required stiffness. Longitudinal control arms, connected via the twist beam, carry the wheel carrier and the brakes (which are not shown in Figure 2d). The longitudinal arms are mounted directly to the body via rubber bearings. The springs and dampers are then connected to the longitudinal control arms via brackets. As the connections of the brackets, as well as the connections between the longitudinal control arms and the twist beam, are usually achieved by welding, the stiffness is limited through the welding seams. Additionally of disadvantage is the fact that, during cornering, the lateral forces tend to cause the whole axle assembly to turn about a vertical axis, thus the sideslip angles are reduced. The wheels are steering into the turn; this generates an oversteering tendency. The mass of this twist-beam axle is 33.4 kg (without brakes) according to the ULSAS study.

For illustrating the results of the survey, the Lotus engineers used the so-called spider charts. The performance ratio of the four axles in view of certain demand aspects is evaluated. This ratio is then marked on the chart. The higher the ratio, the better is the performance of the axle. Figure 3 shows the spider chart for the four analyzed axles.

The greatest differences can be observed in the categories of cost, manufacturing, and the space demands each individual axle poses to the vehicle structure. The multilink axle is superior to all other axles in respect of "ride and handling" and "refinement (NVH)" performances (NVH, noise–vibration–harshness). The better ride and handling performance is due to the better wheel control afforded by the multilink design, and the better NVH performance is a result of the double-elastic bearing as mentioned earlier. The implemented mass is rated the same with all four axles.

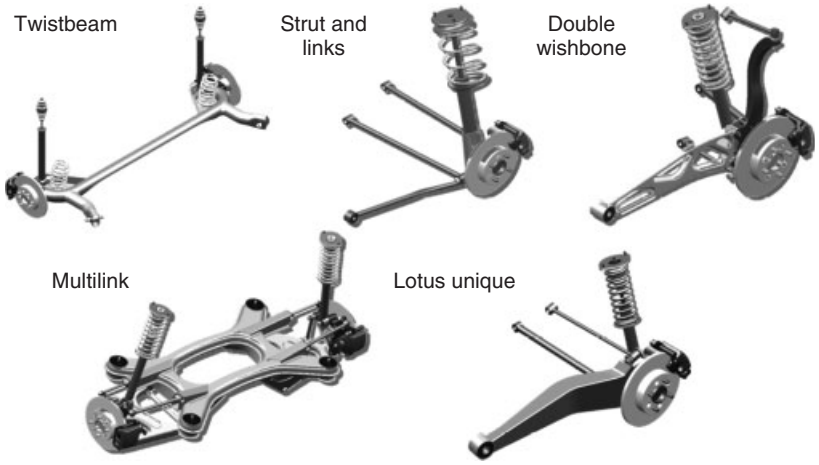

Figure 4. Steel axles as proposed by Lotus engineering. (Reproduced from World Auto Steel. © World Auto Steel.)

3 REAR AXLES DEVELOPED BY LOTUS

Within the development done by Lotus, the engineers proposed rear axles made of just steel. However, different grades of steel were used. The development target was to

1. decrease the mass of the steel-made axles by at least 20% without increasing the costs.
2. achieve the same mass as the aluminum-made axles but using steel instead, and at the same time decrease the costs by at least 20%.

To accomplish these targets, five new axles were developed. They were worked on in design engineering as well as using simulation technology (finite element analysis). Figure 4 shows a compilation of those proposals. In addition to the axles used in practice, there is also another solution shown, called *Lotus Unique*.

Furthermore, they were able to achieve the set goals of reducing the mass, as shown in the comparison (Table 1), illustrating the masses of current axles and the new developments.

Table 1. Mass comparison of the analyzed and the newly developed axles.

	Realized (kg)	ULSAS (kg)	b.	Car
Double wishbone	39.80	32.88	17%	Honda Accord
Multilink	46.67	48.00	3%	BMW 5er
Strut and links	39.70	29.87	25%	Ford Mondeo Taurus
Twistbeam	33.40	27.30	18%	VW Golf
Lotus unique	39.80	26.49	34%	Honda Accord

The differences in cost and the production studies performed by the ULSAS study are not examined any further in this report because of them being rated differently today. However, axle developers are advised to take a closer look into the study, as it is full of interesting suggestions.

3.1 Double wishbone axle

This axle matches the analyzed axle's basic buildup. However, there are differences in some parts. Figure 7 shows these parts; especially the longitudinal chassis beam that is explicitly shown as pressed steel plate made of high grade steel.

The housings for the rubber bearings are tube sections, which are welded; the transverse control arms are also steel tubes with rubber bearings on the end. This enables a connection to the wheel carrier on the one end and to the body on the other end. Whether there is supposed to be a suspension subframe in between the body and the transverse control arm or not is left unanswered in Figure 5. The wheel carrier itself consists of very high grade forged steel. A ball joint connects the upper transverse control arm to the knuckle. The control arm itself consists of only a tube. The suspension strut is directly screwed to the wheel hub and the connection to the body is done conventionally using suspension strut mounts.

The overall rating of this axle was entered into a spider chart as shown in Figure 6. It shows the rating as compared to the other, currently used axles, which were set out as benchmarks. The indications ULSAS D&P refer to are the vehicle classes the axles are intended to be used within. Vehicle class E will be looked at later (Figure 10).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

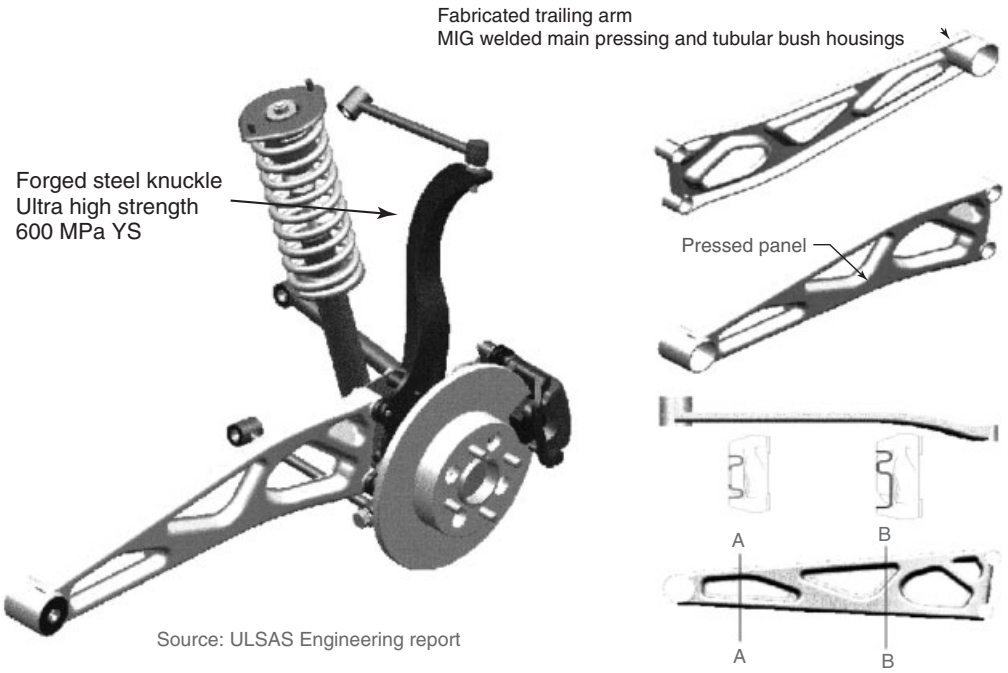

Figure 5. Lightweight construction double wishbone axle. (Reproduced from World Auto Steel. © World Auto Steel.)

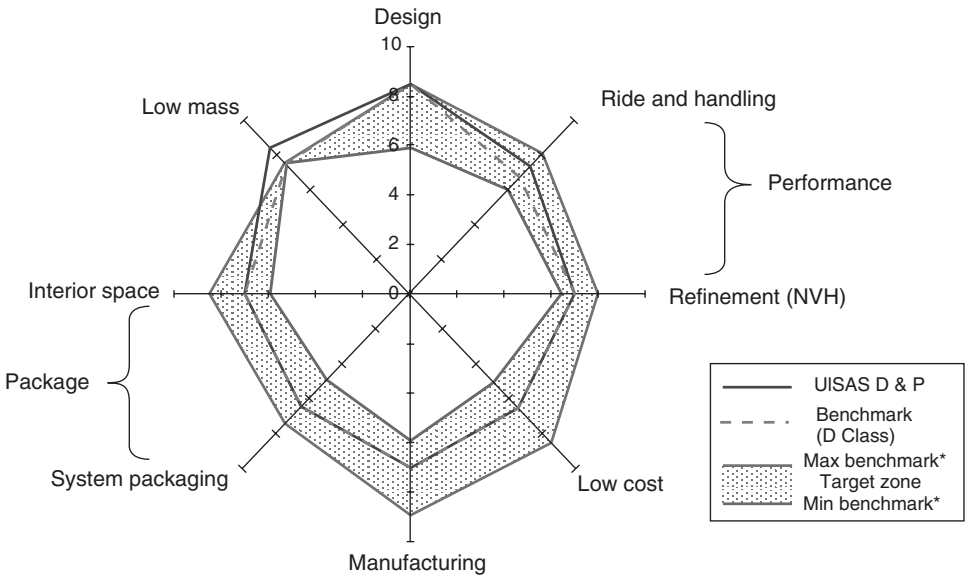

Figure 6. Classification of the double wishbone axle into the benchmark zones as determined before. (Reproduced from World Auto Steel. © World Auto Steel.)

As a result of this classification, it shows that especially the mass could be reduced without creating additional costs. The behavior of the axle (ride, handling, and NVH) competes very well within the competitor class, as well as the other characteristics also staying within the benchmark parameters.

3.2 Multilink rear axle

The multilink rear axle, which in the analyzed integral axle version was equipped with an aluminum suspension subframe and taken from an upscale vehicle class, will also feature a suspension subframe in its steel version.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 7. Multilink rear axle. (Reproduced from World Auto Steel. © World Auto Steel.)

Figure 9. View of a multilink rear axle. (Reproduced from World Auto Steel. © World Auto Steel.)

This suspension subframe will, however, not be created by hydroforming but by pressing two sheet metals into frames that are then welded together. The study suggests using 250–500 MPa YS steel. The connectors for the transverse control arms are welded onto the sheet metals of the suspension subframe. These connectors are simply created through angled sheet metal. Figure 7 shows this axle in detail.

Further elements made of steel plates are the lower transverse control arms. They were also designed in a clamshell way. Their production is recommended using 250 MPa YS steel. Figure 8 contains special production instructions for these transverse control arms. Especially important is the flange depleted welding of the two half shells.

The tubular wishbones can be seen clearly in Figure 9. The vehicle-based side has rubber bearings; the wheel-based side has a ball joint. Figure 9 also features the integral link as a connection between the wheel carrier and the lower wishbone.

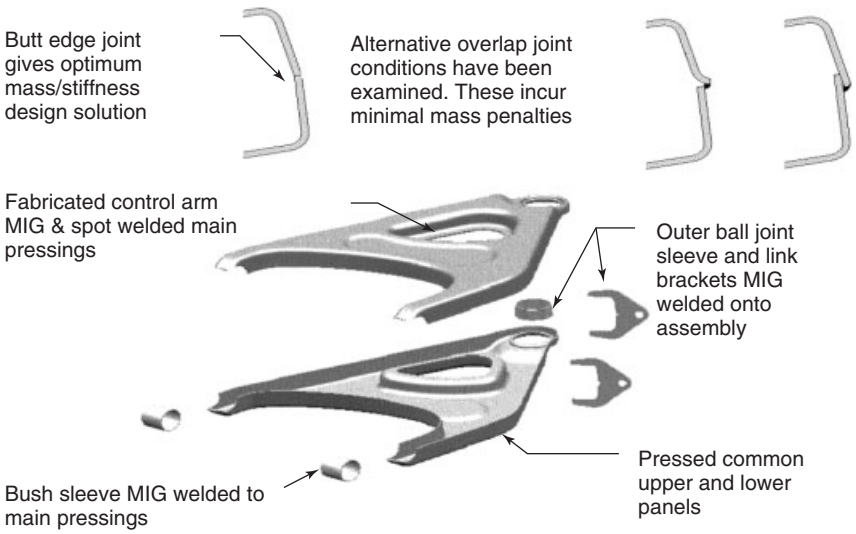

Figure 8. Production instructions for the lower transverse control arms of the multilink rear axle. (Reproduced from World Auto Steel. © World Auto Steel.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto006
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

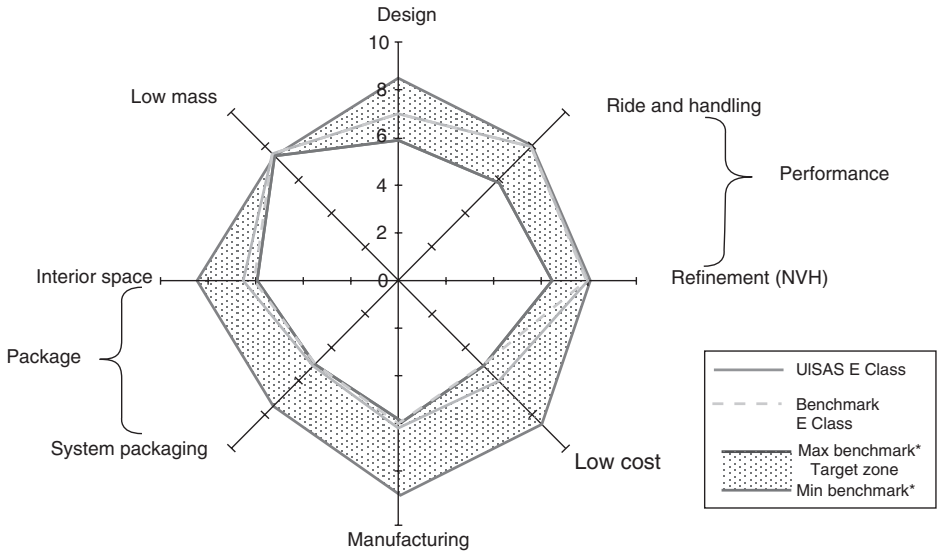

Figure 10. Spider chart of the multilink rear axle. (Reproduced from World Auto Steel. © World Auto Steel.)

The wheel carrier is forged of 750 MPa YS steel; the wishbone tubes consist of 250 MPa YS steel. The engineers at Lotus put the performance data of the axle into a spider chart once again. Figure 10 shows this chart.

It shows that only a minor weight reduction could be achieved, but a significant 30% cost reduction was realized. Performance and packaging match the evaluation criteria of the axles.

3.3 Strut and links rear axle

This axle type was designed for light- and heavyweight vehicles. Figure 11 shows the suggestion for the lighter vehicle. The applied constructions only differentiate in the connection of the tubular longitudinal support beam to the wheel carrier. Instead of connecting to the frontal wishbone, the solution for heavyweight vehicles applies the connection

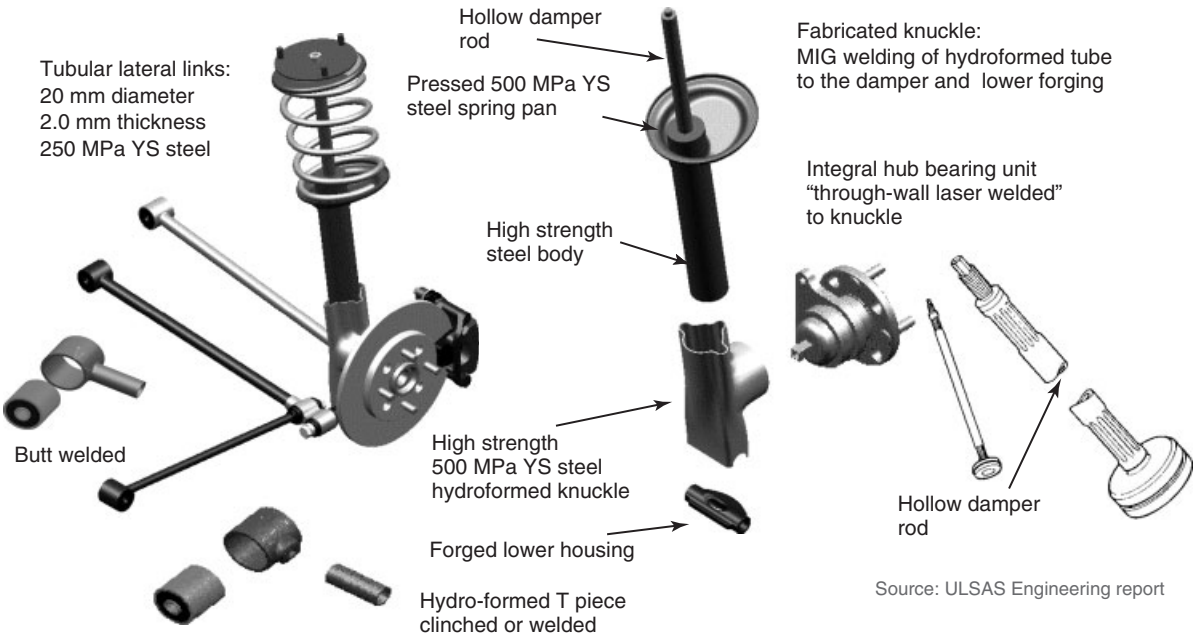

Figure 11. Overview over the suggestions of the strut and links rear axle. (Reproduced from World Auto Steel. © World Auto Steel.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto006
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the longitudinal support beam to the knuckle. Then, the "forged lower housing" part is altered.

Essential for utilizing the lightweight potential of this axle is the creation of the wheel carrier, which is produced from a hydroformed tube. The hub bearing units, as "finished parts," are welded into the metal sheet knuckle. A special "through penetration welding by laser process" is applied as the laser beam bonds the hydroformed part directly to the lower casing of the wheel hub unit. Accordingly, the steel part, which represents the lower end of the hydroformed wheel carrier, is welded into place as well. This part is welded onto the shock absorber tube. The wheel hub unit also carries the brake caliper mounts. The wishbones are produced as tubes onto which are welded smaller tubular parts that serve as housings for the rubber bearings.

The piston rod for the damper is suggested to be a hollow pipe, which, for stiffness reasons, is manufactured with longitudinal grooves but not in the areas that cross the sealing.

The mass comparison, as given in Table 1, indicates a weight reduction of 25% as compared to contemporary state of technology.

The estimation of performance of the axle for both the light- and heavyweight vehicles is shown in Figure 12. It shows that the mass, but not the costs, could be reduced. Especially ride and handling experience a positive influence with this type of axle construction. Otherwise, the axle is within the benchmark parameters.

3.4 Twist-beam rear axle

With lower and middle class vehicles, which usually have front wheel drive, the rear axle of choice is typically the twist-beam axle. The analysis showed that its welding seams limit the capacity of this axle. Hence, the Lotus engineers put the task on themselves to reduce those seams as much as possible. Figure 13 shows the suggested design and the applied steel grades.

Figure 13 underlines that both the longitudinal control arms and the twist beam are made from one piece of pipe. To achieve the torsion softness of the twist beam, the pipe is cut open with a plasma cutter and the edges are bent a little. This enables only the trailing arm toward the bearing, the spring base, and the mount for the wheel bearing to be welded. The bolted wheel bearing construction then enables the connection of the brakes to the axle. The angling of the rubber bearing in plan view, between the axle and the body that enables some compensation of side force oversteering, can be achieved by simply twisting the trailing arm. This trailing arm is produced by hydroforming. The housing in which the rubber bearing is mounted to the trailing arm can be manufactured by rearranging the trailing arm tube.

In addition, the position of the shear center, which together with the bearings of the longitudinal control arms determines the kinematic data of the axle, can be chosen freely (within a certain range) with this type of design. It only matters as to which side the cross profile is cut open,

or rather which lengthwise angle is used for welding these longitudinal control arms to the twist-beam tube.

The functionality of the axle is shown in Figure 14.

Especially remarkable are the weight reductions; the cost reductions are less impressive. Design and behavior is even better than the benchmark, whereas production and packaging both meet the benchmark standards.

3.5 Lotus unique rear axle

In addition to the various types of axles considered, the engineers at Lotus also presented their own axle suggestion. This axle can be used as both a driven and a non-driven axle.

A massive body-trailing arm is connected to two tubular wishbones. Thus, the mechanism is statically defined and the spring and damper combination does not have to take any shear forces.

To a certain degree, the different lengths of the wishbones enable an influence on the wheel kinematics (for example, there is no track width alteration in the area of design position of the car). The distinctiveness in the construction of the trailing arms lies in the usage of "Tailor Welded Blanks." Steel plates of different thickness and grade are welded together and are then deep-drawn. Using the strain data available that the specific parts have to withstand enables a strain-related construction. Figure 15 shows these modifications. The trailing arm is welded together from two panels, each of which was manufactured individually. These measures help to achieve the aim of reducing the weight as only as much material as needed is used for production.

These Tailor Welded Blanks can also be used for other axle constructions. By now, there are production techniques that allow rolling metal blanks with varied thickness. The varying stiffness within one part can be achieved by tempering.

The evaluation of the Lotus unique axle by the engineers can be seen in Figure 16. This construction achieved significant reductions in both cost and weight. The packaging demands are evaluated to be adequate; production and assembly is easy. The performance is perceived to be good as well.

The evaluations in Figure 16 show that this axle is positioned in the middle to the upper level of the benchmark. It is therefore advisable to have a closer look at this construction.

4 CONCLUSION

Entering the evaluation figures of all five axles into a spider chart, as done in Figure 17, the advantages of the axles become clearly visible.

This chart exemplifies that the aims to reduce cost and mass were achieved. The multilink rear axle is superior to all others in terms of driving behavior and NVH. Since it is a steel-made axle, it also features a cost advantage in comparison to the axle produced out of aluminum.

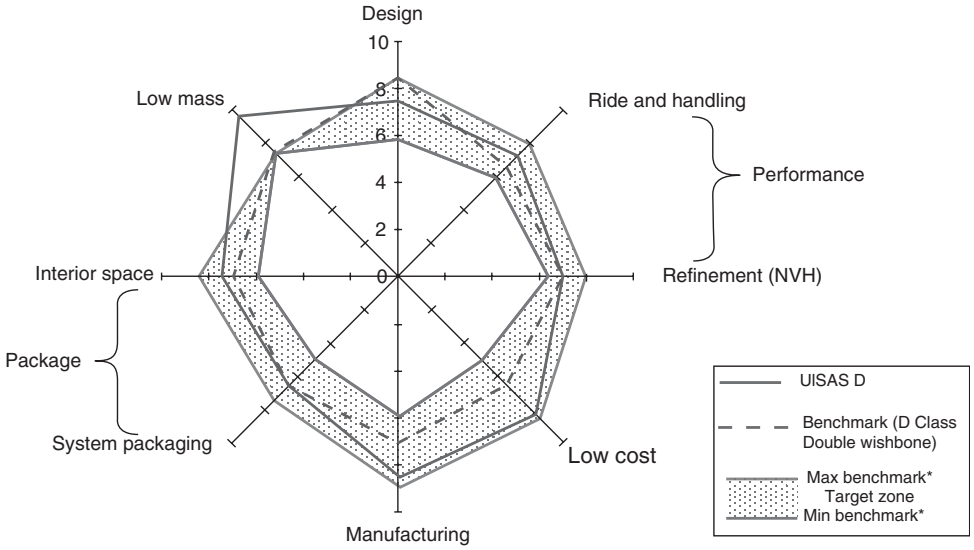

Figure 16. Evaluation of the Lotus unique axle. (Reproduced from World Auto Steel. © World Auto Steel.)

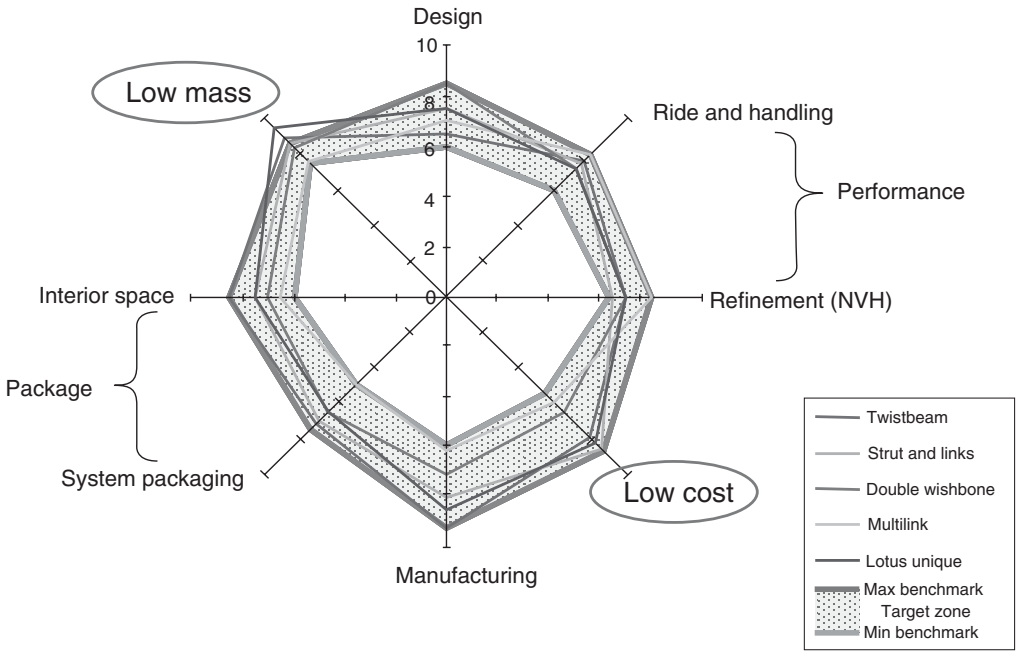

Figure 17. Summary of the different axles. (Reproduced from World Auto Steel. © World Auto Steel.)

Concluding the ULSAS-study, it can be determined that using the suggested steel-axles a mass reduction of up to 34% could be achieved without creating any additional cost. With steel-axles, matching the mass of aluminum-axles there were also no further costs created.

None of the axles compromised the driving performance.

Improved qualities of steel made this progress possible. Since these advancements in steel continued over the last 10 years, a revision of the suggested constructions with contemporary steel qualities and production methods, like flexible rolling and further improved joining technology, is highly suggested. For chassis-developers, there are still

some very interesting and innovative ideas left in the ULSAS-study that are still awaiting implementation.

Active Front Steering for Passenger Cars

Matthias Wiedmann
AUDI AG, Pfaffenhofen, Germany

1 INTRODUCTION

For manyyears now, power steering has been an indispensable feature of our automobiles and has almost completely replaced mechanical steering. One of the difficulties when selecting power steering settings is deciding on the correct steering ratio, so that the driver enjoys a comfortable driving feel and a sense of safety in all driving situations, from parking to high speed driving. When parking, the driver expects low effort at the steering wheel and easy maneuverability at low speeds, without losing a sense of complete control at high speeds.

This classic conflict of objectives can be solved by a superimposed steering system. A controlled additional angle is superimposed on the steering wheel angle chosen by the driver. In this way, both a variable steering ratio and other functions, such as steering stabilization, can be incorporated.

2 HISTORY

The first patent applications for superimposed steering systems were filed in the early 1970s (Pilon, Sattavara, and Schechter, 1972). Practical implementation was unsuccessful then because such complex mechatronics were not available. The patent already contained all the components of a modern superimposed steering system, for instance secure mechanical through-drive with provision for steering angle superimposition. In this case, the superimposition itself was obtained from a double planetary gear set with the ring gear turned by an electric motor through a worm gear drive.

This patent and the further development (Karnopp, 1990) reached series production in 2003 (Köhn *et al*., 2002), but a year earlier an alternative concept (Musser, 1955) reached series production in which the angle superimposition was obtained by means of a harmonic drive. The functionality will be described in the following chapters.

3 GENERAL FUNCTIONAL PRINCIPLE

All the systems for active front steering in series production are based on superimposing an additional angle on the steering wheel angle chosen by the driver. Other functional principles can be envisaged, for example displacement of the steering system in relation to the vehicle or altering the length of the tie rods, but these technologies have not so far progressed beyond the patent application stage (Mouri, 1992).

Different to pure steer-by-wire systems, superimposed steering systems have a through mechanical drive to

the vehicle's road wheels. As the steering system now possesses a further degree of freedom, an additional motor angle δ_M can be superimposed on the driver's chosen steering angle δ_H. The total angle present at the steering system input δ_S can then be calculated with the simple formula

$$\delta_S = \delta_H + \delta_M \quad (1)$$

As torque equilibrium is present in the entire system, the motor must withstand all the torques that occur during vehicle operation. This is done by the high gear ratio (1 : 50) between the electric motor and the gearbox housing. In addition, this design satisfies package and weight requirements.

In the case of vehicle maneuvers with no active contribution from the driver by turning the wheel, for example side wind compensation or vehicle stabilization by electronic stability control (ESC), the driver always has to hold up or compensate for the steering torque that arises from the angle superimposition system.

4 CONSTRUCTION

Three systems differing in their gear-set technology and installed position on the vehicle are currently in use for active front steering. In principle, superimposed steering needs the following components:

(a) superimposition gears;
(b) electric motor;
(c) motor angle sensors; and
(d) a lock to restore the through mechanical connection from the steering wheel to the steering gear in the event of a fault or loss of electric power from the system.

Two types of gear drives have been established on the market:

1. the double planetary gear set as used by BMW/ZFLS[1] and
2. the harmonic drive gear set (in series production at Audi/ZFLS and in a slightly modified form at Lexus/JTEKT[2]).

The main gear-set requirement is a high ratio, so that minimum electric motor torque is needed to withstand steering torque, and the motor can therefore be of small size. In addition, the gear set should (if possible) operate without slack to ensure precise initial steering response. Acoustical considerations also have an increasingly important role to play, when determining the gear set's design ratings, as these steering systems are mostly installed on high quality vehicles that are correspondingly quiet.

In view of the high demands, they must satisfy in respect of control quality and performance, the electric motors are in all cases of the permanent magnet synchronous type (brushless electrically commutated DC motors). One of the main factors to be considered when determining the motor rating is high power density, so that the desired torques are reached with a satisfactorily dynamic action and torque ripple is as low as possible, in order to avoid feedback that can be felt at the steering wheel.

With the aid of a rotary position sensor, the actual position of the rotor in the electric motor is measured as a means of determining the actuating signals and phase currents for the individual motor phases. The closed-loop control circuit thus eliminates deviations between the actual and the desired motor positions.

The locking device is a solenoid that, when its power supply is interrupted, locks the system by means of a preloaded spring. This lock must satisfy the most stringent safety requirements, as it is the system's mechanical fail-safe device. Rapid, reliable locking in all environmental conditions and extremely high failure protection are needed. Among the measures adopted to ensure this are redundant springs to actuate the locking pin.

4.1 Types of system

4.1.1 Hollow-shaft harmonic drive

The actuator is notable for its hollow-shaft concept. The permanent magnet synchronous motor is located concentrically around the input shaft. The other components such as the gear set and motor position sensors are also mounted on a joint shaft. The gearbox technology consists of a harmonic drive gear set with a ratio of 1 : 50. This type of gear set needs very little space and provides a high gear ratio with complete freedom from play (without special measures having to be taken) and excellent torsional rigidity. The gear set is also suitable for high torques, which makes it capable of withstanding misuse situations (parking close to the curbstone and turning the steering wheel with full torque) reliably.

The harmonic drive (Figure 1) operates by means of a flexible thin-race ball bearing (a flex-bearing), which is pressed onto the elliptical motor shaft and thus acquires an elliptical shape as well and acts as the wave generator (WG). This elliptical ball bearing changes the shape of the gearwheel connected to the steering wheel (flexible spline, FS). Thanks to its elliptical shape, the FS (which has 100 teeth) is able to mesh with the circular spline (CS) or ring gear, which has 102 teeth. The output shaft leading

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

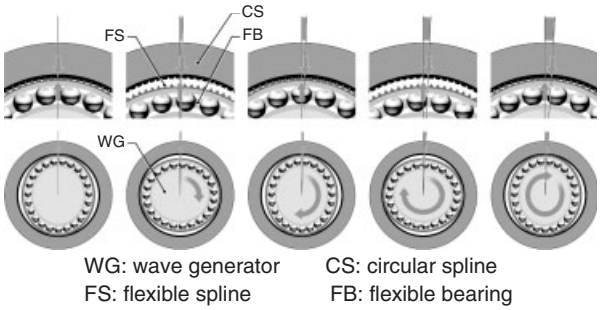

Figure 1. Function of harmonic drive.

to the steering system itself is attached to the circular spline.

When the motor shaft revolves through 360°, the 100 teeth of the FS rotate within the 102 teeth of the circular spline and thus generate a gear ratio of 1 : 50 and therefore a superimposition of 7.2° per revolution of the motor. This is added to the angle reaching the circular spline by way of the input shaft and FS.

When the vehicle is parked or if a system fault occurs, the motor shaft is locked by way of the lock ring and locking pin; this inhibits one of the degrees of freedom of the gear set and ensures that the through mechanical drive to the wheels remains operational.

This compact design can be installed in the upper part of the steering column and therefore in the car's interior, which has advantages above all in meeting the environmental requirements that the system must satisfy (temperature and humidity), whereas this might be more difficult if the system is installed in the engine compartment. At the same time, however, acoustical requirements and also questions of crash protection have to be considered when the actuator is located in the passenger compartment.

The superimposition steering system, which is used in the Audi A6 and which is installed in the steering column, is shown in Figure 2. Explanations are given in Schwarz and Dick (2007), whereas another design can be found in Rothmund *et al*. (2006).

4.1.2 Double planetary gear set

A characteristic of this system is that the actuator is mounted directly on the steering system. The superimposition function is performed by a double planetary gear set (Wallbrecher, Schuster, and Herold, 2008). This position on the steering system behind the torque sensor/hydraulic valve has the advantage that effects such as friction and feedback because of the motor's mass moment of inertia can be compensated for by the power steering assistance, thus reducing possibly unwanted feedback at the steering wheel. As an additional reduction gear stage to the electric motor, which is also an electronically commutated, permanent magnet synchronous motor, the planetary gear set has a worm gear. This provides a very high overall reduction ratio and also a degree of self-locking. This self-locking produces a certain degree of redundancy in the locking action. It enhances the safety concept. In addition, the electric motor is prevented from rotating by a locking device (falling pin) when the system is inactive and in the event of a fault.

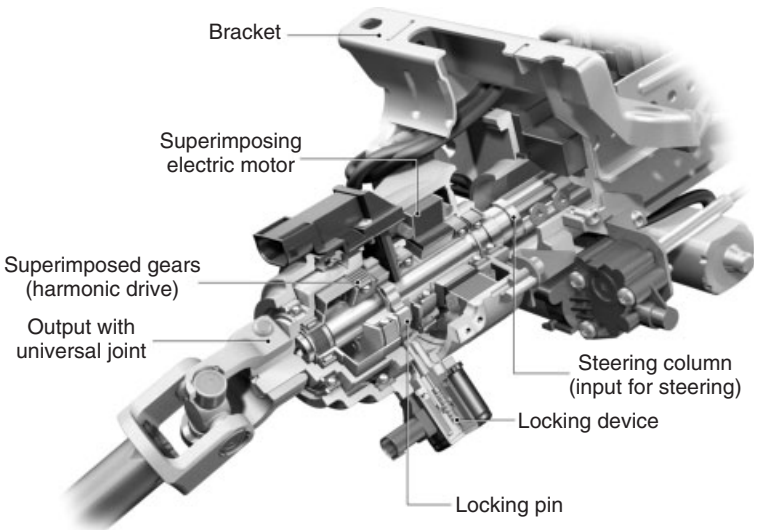

Figure 2. Construction of Audi dynamic steering system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The actual superimposition is obtained from two planetary gear stages with different ratios. The first of these ($i_1 = 15/12$) has an input shaft (ring gear) with 15 teeth and planet wheels with 12 teeth. The second stage ($i_2 = 13/14$) has an output shaft (ring gear) with 14 teeth and planet wheels with 13 teeth. The two sets of planet wheels are linked by a planet wheel carrier (spider) and therefore always rotate at the same speed. If the electric motor causes the planet wheel carrier to perform a single revolution, the ratio of output to input shaft rotation is 1.35 : 1 ($i_{ges} = \frac{15/12}{13/14}$). As manufacturing tolerances mean that the teeth in these gear sets can never be entirely free from play, the individual planet wheels must make a sprung connection in order to prevent play in the steering. This measure, however, can lead to increased friction in the system.

4.1.3 Harmonic drive with rotating housing

In the same way as the system described in Section 4.1.1, this system is based on a harmonic drive assembly, but unlike that system, the housing also turns with the steering. In addition, there are slight differences in the gear set itself, for instance the circular spline is divided into two rings. One ring has 100 teeth and is connected to the steering wheel and the other has 102 teeth and acts as the output to the steering system. The two rings are linked together by the FS, which also has 100 teeth and is coupled to the electric motor. Here too this is a permanent magnet synchronous motor. In this system, when the electric motor performs one revolution, there is a difference of two teeth between the steering wheel and the steering system. The gear ratio is therefore once again 1 : 50. As the housing also rotates, it is not necessary for components such as the motor and the locking device to be constructed with a hollow shaft. To make the assembly as compact as possible radially, the locking device is integrated into the housing and connected by a pivoting lever. This concept can have the disadvantage of requiring more installation space and also that electric power has to be transmitted by a volute spring.

As this system too is installed ahead of the steering system, additional measures are needed to improve the acoustics and minimize unwanted feedback that would be felt at the steering wheel. A ‘Hardy’ flexible-joint disk therefore decouples the system.

4.2 Adaptations to the vehicle

Using Audi Dynamic Steering as an example, it can be seen which additional components on the vehicle need to be adapted in order for the superimposed steering to operate safely and conveniently to its full extent.

4.2.1 Steering system

As superimposition increases steering angle speeds at the steering system, especially when performing stabilizing movements, dynamic steering requirements are higher. In the case of hydraulic systems, for example, pumps with increased displacement are needed to ensure that the necessary volumetric flow is reached. In view of the increased energy consumption and therefore the higher hydraulic fluid temperature, electronically regulated pumps are often used, with an electrically energized valve to regulate the flow volume. A power steering oil cooler of larger capacity may also be needed.

Similar requirements apply to vehicles with electromechanical power steering (EPS). If axle loads and therefore the forces acting on the tie rods are high, the electric motor rating and possibly even the supply voltage may have to be modified.

The demands imposed by superimposed steering must also be considered when choosing the steering ratio. In combination with superimposed steering, it is best to adopt the most direct possible basic gear ratio (for example 1 : 13.5), so that assistance from the actuator, especially when parking or driving slowly, is kept low (1 : 12). This improves particularly the acoustics and the amount of feedback felt by the driver in this critical range. However, this approach is subject to limits, as the driver must be capable of supplying the necessary level of passive fail-safe effort in the event of a defect. This applies to the overall steering ratio and also to the sudden jump in the effective ratio if a fault happens.

4.2.2 Acoustic requirements

In particular when parking and driving slowly, the superimposition must not cause any noise that could be regarded as unpleasant. However, a mechatronic system with gears and an electric motor can never be entirely noiseless, and additional measures must therefore be taken. When deciding-g on these measures, a distinction has to be made between structure-borne noise and airborne noise. Airborne noise can be reduced by suitable encapsulation. To prevent the propagation of structure-borne noise, damping elements must be installed. One that has already been mentioned is the “Hardy” flexible disk between the actuator and the steering wheel, but damping elements can also be installed between the actuator and the steering column if the system uses steering-column actuators. A disadvantage of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

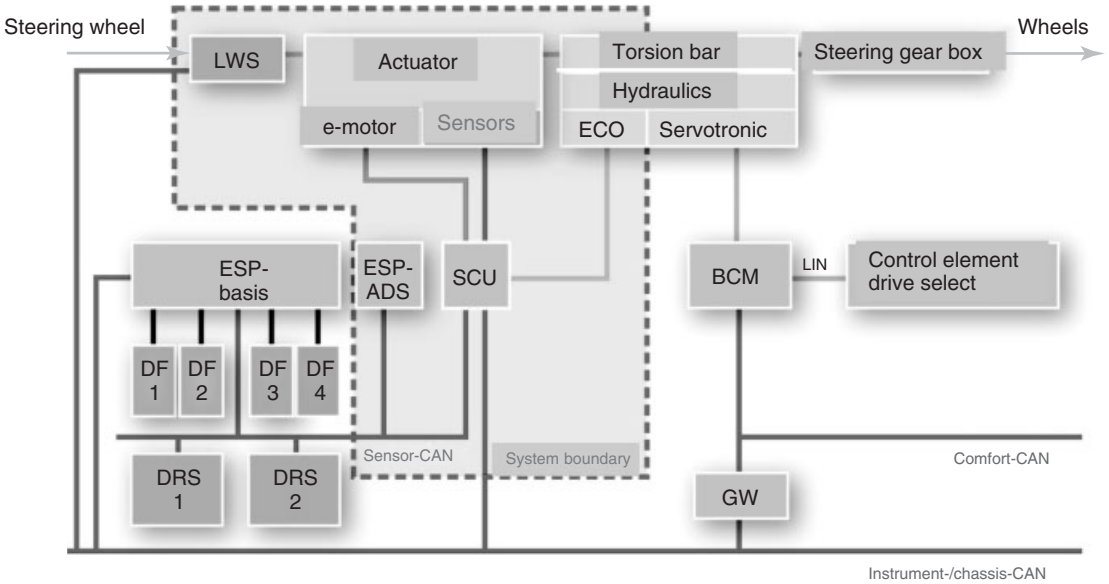

Figure 3. In-car system networking.

these additional measures is that they reduce rigidity. This influences steering response, for instance, and the ability to achieve the required eigenfrequency in the steering column.

It is therefore advisable for the acoustic requirements not to be disregarded when the concept is chosen. Major factors in the selection process are the type of gear set chosen and the gear ratio, though classic conflicts of objective arise here, as the gear ratio also affects the size of the motor and the maximum torque that can be withstood.

4.2.3 Networking adaptations

As superimposed steering effectively communicates with all the vehicle's systems that need steering angle information, networking is accordingly complex. Additional systems supply the input values for the system, for example a driving program switch for the selection of different vehicle dynamics characteristics. If in particular there is also a vehicle stabilization function, this will call for intensive data exchange with the ESC. The ESC itself must satisfy more stringent demands, for example yaw rate-sensing redundancy. If EPS is installed, there will also be a communication with this system, so that further functions such as steering performance limiting can be realized.

Figure 3 shows this signal networking. Networking in such systems is also dealt with in Knoop, Flehming, and Hauler (2008).

5 CUSTOMER FUNCTIONS

5.1 Variable steering ratio

The variable steering ratio is the basic function of a superimposed steering system. This function makes it possible to avoid the compromise that is always present in conventional steering systems between stability at high speeds and avoidance of excessive steering-wheel effort at low speeds. This can be achieved by way of the steering angle (in a similar manner to a variable-ratio steering rack, but with a greater spread of ratios possible) or by way of road speed. The steering ratio can be varied over a wide range between a more direct ratio (for optimal vehicle agility and maneuverability) and a less direct ratio (for high vehicle stability).

The various driving situations can be approximately classified under three headings:

1. Low speed driving (city traffic/parking),
2. Medium speed driving (regular out-of-town roads), and
3. High speed driving (freeways, etc.).

When selecting settings in these three categories, it is important to maintain a harmonious steering ratio characteristic so that the driver does not encounter any unexpected vehicle reactions.

Figure 4 shows the AUDI realized gear ratio function for different vehicle dynamics variants in dependence of the driving velocity.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

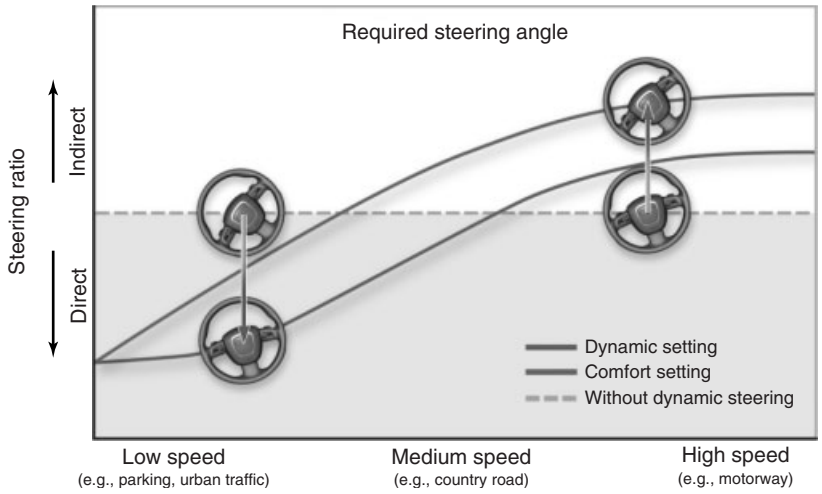

Figure 4. Steering ratio characteristic.

5.1.1 Low speeds

At low speeds, the aim must be to keep driver effort at the steering wheel to a minimum. The steering is normally rated to permit the driver to control the vehicle's direction without having to reposition his or her hands on the steering wheel. Possible factors limiting the degree of directness could be the high degree of superimposition needed, the associated noise, and the driver's ability to adjust to what is felt at the steering wheel. When parking, a superimposed steering system permits the effort required at the steering wheel to be reduced to between one and a half and two turns from lock to lock.

5.1.2 Medium speeds

In this speed range, the vehicle's agility and ease of handling are the decisive criteria. Agility can be described by the increase in the vehicle's yaw rate. The aim in AUDI is to choose a more direct steering ratio than the standard value, one that builds up yaw rate gain plotted against the vehicle's road speed more rapidly (Figure 5). A deeper description can be found in ATZ-Automobiltechnische Zeitschrift (2008).

5.1.3 Road behavior at high speeds

At high speed, a less direct steering ratio is chosen so that the vehicle can be driven in a relaxed manner at high speed. It reacts calmly and less nervously to steering wheel movements. In the BMW superimposed steering even countersteering is installed. At high speed, the drivers steering input is reduced by the electric motor to make the car more stable.

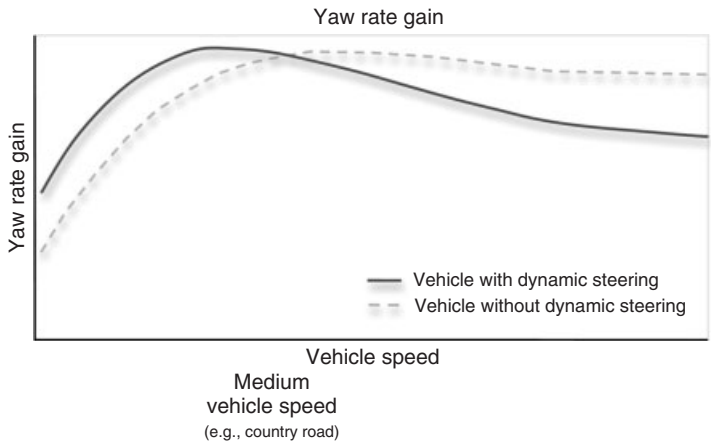

Figure 5. Yaw rate gain plotted against road speed.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.1.4 Change between characteristics

As the steering ratio can be tuned, the characteristic of the steering gear ratio can be coupled to a driving program switch if this is installed in the vehicle. This gives the driver another means of influencing the steering in addition to the manual torque exerted at the steering wheel. Furthermore, with the aid of a superimposed steering system, it is relatively simple to provide entirely different steering and therefore vehicle characteristics, for example, on a sport model within a model line. This is difficult to achieve with conventional steering systems, as a separate version has to be developed for a limited number of vehicles. The arising costs are prohibiting this. The superimposed steering makes this differentiation possible.

6 STEERING STABILIZATION

As a means of moving the road wheels independently of the steering wheel is now available, it is possible to stabilize the vehicle in critical situations by turning the steering. Until now, vehicle stabilization was only possible with ESC, by applying individual wheel brakes, but as any form of brake application naturally slows the vehicle down, the subjective sense of sportiness is reduced.

At high road speeds, the superimposed steering system demonstrates its advantages most clearly in the form of reaction times that are distinctly faster than any brake application and they are much more comfortable. Steering correction stabilizes the vehicle, whereas the brake application reduces its dynamic performance in an equivalent situation.

At slower speeds or in less critical situations, it may in certain circumstances even be possible to dispense entirely with brake applications. In view of this, a vehicle with steering stabilization maintains its progress more smoothly than one that is only stabilized by means of the brakes. This is especially obvious when friction in the form of tire grip is low. If brake applications are still necessary in such situations, they can be less powerful or will only be needed at a later stage in the critical situation.

Stabilization is effective to a differing degree according to steering performance, which is limited by the actuator. A parameter for this is the steering angle gradient for the stabilizing action. However, the maximum gradient that can be adjusted not only depends on the actuator's performance but also on how it is networked on the vehicle. It is essential to ensure that a superimposition angle that has been called for incorrectly does not lead to a critical safety situation. The latency time of the bus system, for example, also has a decisive part to play.

The decision as to which form of intervention will bring the desired result—brake application, steering stabilization, or a combination of both—is also an important factor for stabilization quality. Comprehensive evaluations of stabilization procedures are reported in Baumgarten *et al*. (2004) and Holle (2003).

6.1 Oversteer

If a vehicle oversteers, an experienced driver will sense its reaction and apply an opposite steering input at the steering wheel. To make this situation easier for less experienced drivers as well, the superimposed steering can apply the opposite steering actively if oversteer occurs, and in this way achieve the optimal front-wheel steering angle. Thus, undesirably high vehicle yaw reaction can be reduced in effect or entirely canceled out. At high vehicle speeds, in particular, the vehicle's fast reaction to the steering angle allows the brake application to take place later and more harmoniously.

Figure 6 demonstrates this behavior of a car. In case of Figure 6a, the brakes are applied only. If the active front wheel steering is added to the stabilization procedure of the car, the brake intervention can be reduced. This is shown in Figure 6b. In addition, it becomes obvious that the total steering effort for the driver is reduced as soon as the superimposed steering is applied.

6.2 Understeer

A vehicle that is understeering is driving more straight ahead at the front wheels, because the maximum force that the tire contact patches on the front axle can transmit has been exceeded (Figure 7). This limits the effect of any action taken through the front steering. The aim must therefore be to provide the driver with access to the maximum adhesion point for as long as possible. When action is taken in this situation, the steering ratio is made less direct so that the steering does not pass the point of maximum friction too quickly.

6.3 μ-Split

μ-Split is the term used to describe a situation in which the amount of grip on one side of the vehicle is noticeably different from the other side. This occurs in the autumn or winter, for example, when one side of the road is covered with wet leaves and the other is dry. When the brakes are applied in this situation, the difference in effective braking force generates a yaw moment that causes the vehicle to turn toward the side with the higher grip. To

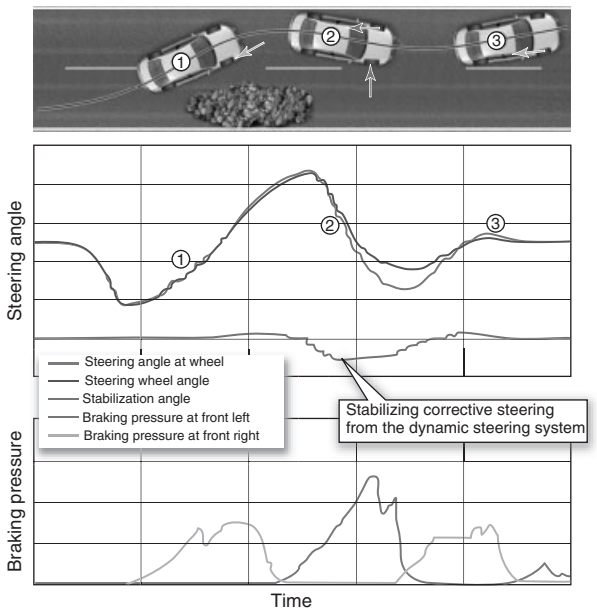
(a) Brake application only



(b) Brake application and superimposed streeing cooperate (reduced braking)

Figure 6. (a,b) Oversteer intervention.

keep the vehicle moving in the chosen direction, the driver has to steer toward where tire grip is lower. To give the driver sufficient time to react, braking pressure is built up relatively slowly.

With superimposed steering, it is possible to select the correction angle at the steering automatically. All the driver has to do is turn the steering wheel in the correct direction, and as the superimposed steering system reacts quickly,

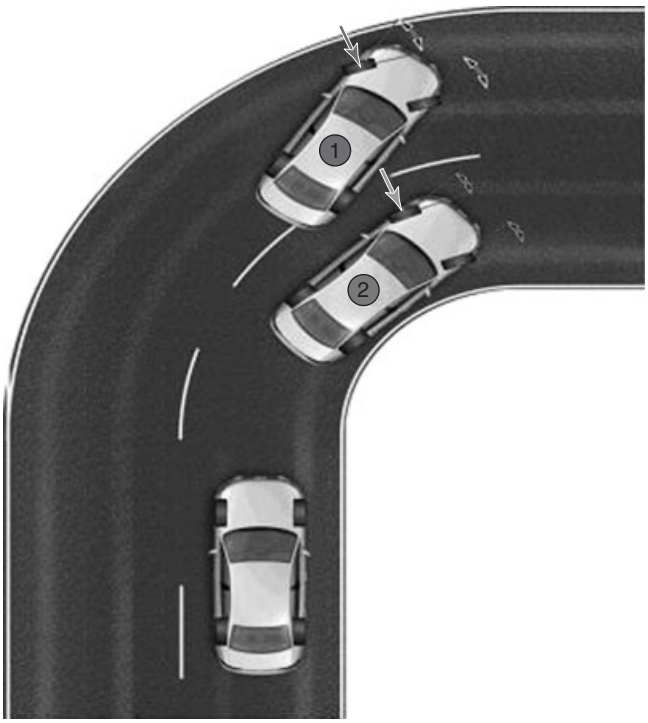


Figure 7. Understeer intervention.

braking pressure can be built up more rapidly as well, so that the braking distance can be shortened. The yaw movement will be reduced or even avoided. Figure 8 gives an insight into the brake forces and the steering angles. The brake pressure on the high friction side can be higher than on the low μ side. The front wheel on the high μ side produces side forces to counteract to the yaw moment, which is generated by the different brake forces. The superimposed steering system generates these side forces.

7 SAFETY

Like other mechatronic steering systems, the superimposed steering system is a product with safety relevance. The primary development objective must therefore be to avoid potentially critical situations. These can include

- Preventing reversible or irreversible errors that could be caused by the control unit, the electric motor, or the motor position sensor.
- Monitoring externally computed stabilizing interventions and initiating suitable measures to prevent maximum permissible positioning errors from being exceeded.
- Ensuring that in the event of an error the maximum tolerable gear ratio jump is not exceeded.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

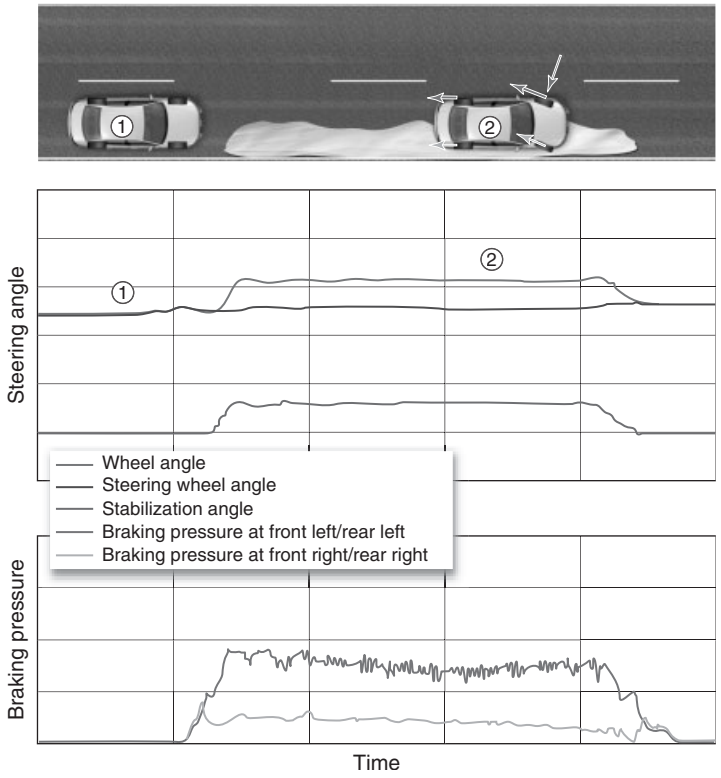

Figure 8. μ-Split braking with and without superimposed steering.

- Preventing any situation in which steering movement is uncontrolled.

Figure 9 shows the three-level steering control unit (SCU) safety concept adopted for the Audi dynamic steering system. All the functionally necessary software modules are integrated into layer 1, including signal plausibility checks and error strategy. All critical paths that could lead to a malfunction are calculated in a diverse manner in layer 2. This ensures that system errors (for example, programming errors) or sporadic RAM defects cannot result in a malfunction. Diverse means that the computer hardware and the used software in layer 2 should be different from layer 1. If possible, different persons should do even the engineering. Layer 3 ensures the correct program sequence, for example, and checks by way of question–answer communication that the set of commands has been carried out correctly (watchdog function).

The difficulty that arises with computing in a diverse manner is achieving the same result in the diverse path with other algorithms as in the main path. Two principal measures enable this:

1. Under error-free conditions, it is possible to achieve the same results with the main function and the diverse function with no relevant time delay. The reason is that the variable steering ratio functions follow feed forward control rather than feedback control.
2. For position control, including sensor evaluation, both paths are monitored in layer 2 by read-back and checking of the motor position signal in relation to its desired angle, as shown in Figure 10.

To ensure high availability, AUDI follows a stepwise degrading of system functions, depending on the error that has occurred:

- Selection of a constant steering ratio (as on vehicles with standard steering) if vehicle velocity information is lacking.
- Inhibition of external stabilizing interventions if reduced performance is to be anticipated, for example, because of vehicle power supply fluctuations.
- If an error is suspected, deactivation of the system, just when the steering wheel angle is zero, in order to prevent the steering wheel from having a constant angle deviation. Other companies are using this constant steering wheel error as a hint of the failed system. The

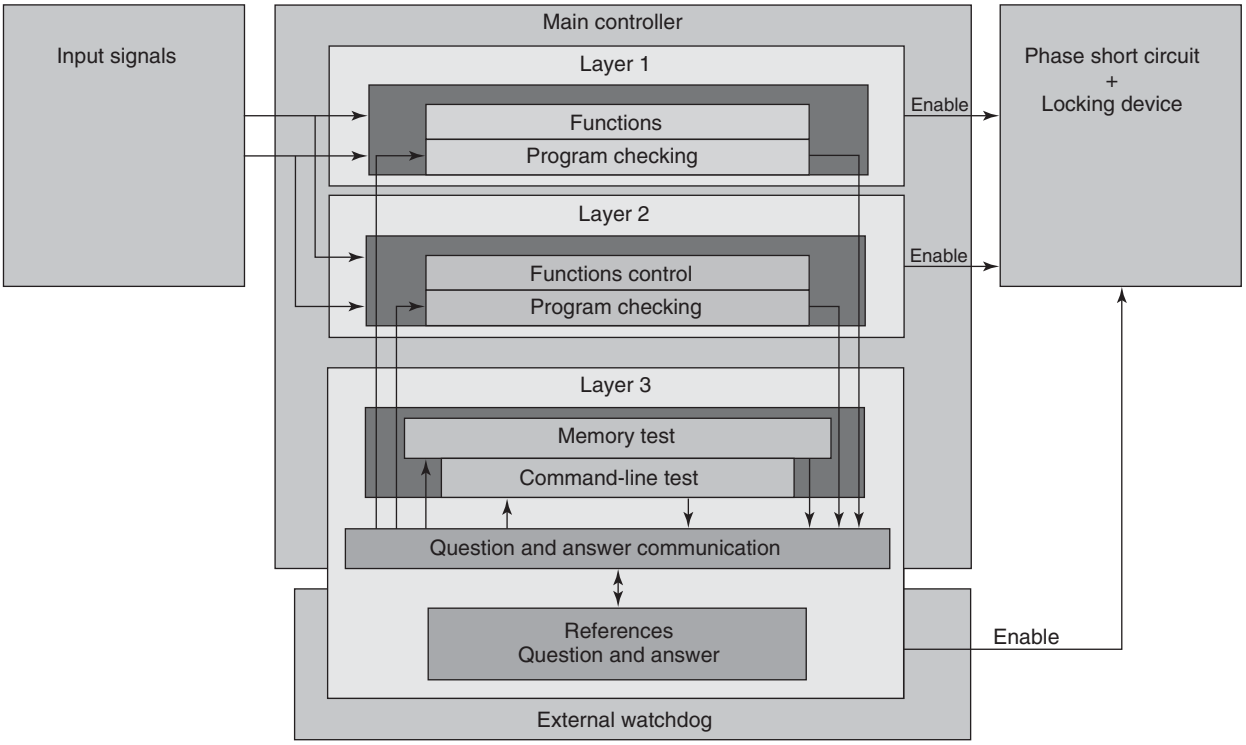

Figure 9. Monitoring levels.

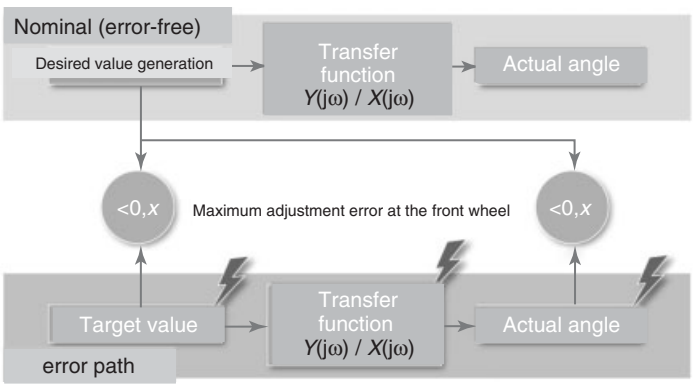

Figure 10. Position control error path.

customer should be advised to go to a workshop and to take the car for repair.

- Immediate, complete deactivation in the event of severe faults.

In the AUDI system, the integrated integral index sensor makes it possible to restart the system without having to take the car to a workshop even if a severe error has occurred, for instance, the loss of electric power. For this purpose, the motor angle is reset in an initializing phase.

The SCU output signals must also satisfy the relevant safety criteria, as other vehicle systems with safety relevance, for example, ESC, react to them. In Jakobi (2011), there are intensive discussions about fallback behaviors of the steering system.

8 SUMMARY

One of the latest mechatronic systems in cars is Active Front Steering. This means that in addition to the driver's

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto007
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

steering input an electric motor can steer the front wheels of a car. Driver and the electronical system are normally working in cooperation. The amount of automated steering depends on the car speed, a selected control program, and the driver's steering input.

At present, there are two technical solutions used, the double planetary gear set and the harmonic drive gear set. The systems are described and the different positioning in the steering shaft is mentioned. In addition, the requirements in acoustics and in the oil supply are mentioned. The Active Front Steering is connected to the safety network of the car.

For normal driving, it is possible to use different steering ratio characteristics. The individual driver's wish can be fulfilled. Some examples are explained in this contribution and the basic support for vehicle dynamics is mentioned.

Special requirements for such a system are demanded by the system's safety. The SCU and the used sensors must be diverse. This means that hardware and software must function in different ways. This makes the system more complex. On the other hand, there is so much benefit for the drivers that this effort is justified.

New Electrical Power Steering Systems

Mathias Würges
NSK Deutschland GmbH, Ratingen, Germany

1 INTRODUCTION

Following the introduction of the first steering systems with an electromechanical servo unit (electric-power-assisted steering, EPAS) at the end of the 1980s, they have become more and more widespread in recent years. This development is driven by the necessity to economize on energy and thus reduce CO_2 emissions. Depending on vehicle type and driving style, EPAS systems contribute to a reduction in fuel consumption of between 0.3 and 0.5 L/100 km.

The global EPAS market in 2010 already totaled 26 million units, and it is expected to almost double by 2015. This trend stems from the rapidly increasing technological development of electrical and electronic components and safety concepts, which can be used in small-range to top-of-the-range vehicles, and from the expansion of EPAS technologies in high growth markets such as China and Brazil.

2 ELECTRIC-POWER-ASSISTED STEERING

Nowadays, there are different EPAS systems on the market, which are used according to the vehicles' boundary conditions and the vehicle manufacturers' technological philosophy. Significant technical factors in the selection of suitable systems are the necessary steering rack force and the steering ratio, that is, the ratio between steering wheel angle and the steering rack stroke or the corresponding front wheel steer angle (Figure 1).

In spite of the different designs of the various EPAS systems, they all share the most important functional requirements:

- Safe operation in all driving situations and a very high level of availability
- Highly dynamic response characteristics in the most varied driving situations
- A sufficient level of steering assist for the driver in the case of intensive actuation forces, for example, parking maneuvers
- Minimal noise during all steering maneuvers. As for this vehicle functions, acoustic feedback is not desirable
- High quality steering characteristics in line with the philosophy of the vehicle brand
- More and more steering functions are being integrated into modern EPAS system, which improve safety or comfort for the driver and can be correspondingly marketed by the vehicle manufacturers.

However, the introduction of EPAS systems—and with it the substitution of hydraulic steering systems—was primarily driven by the reduction in fuel consumption. As it is crucial for the steering assist to respond highly dynamically in every driving situation, the oil pressure

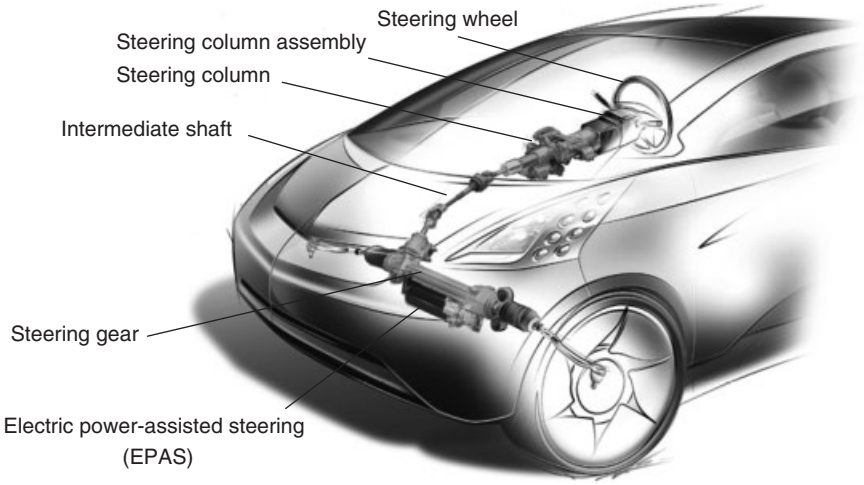

Figure 1. Electric-power-assisted steering (EPAS) system.

in hydraulic systems must be maintained at all times. This results in power dissipation through the continuous operation of the pump and therefore to a high demand for energy. Meanwhile, EPAS systems convert electrical energy from the vehicle power supply, drawing only the amount needed for the length of time required by the respective steering requirement. A further advantage of EPAS is its simple installation and dismantling, because the EPAS actuator system can be connected simply by attaching the power and signal plug connectors. There is no time-consuming handling of hydraulic fluids.

Further advantages of electromechanical steering are its good control capability, the incorporation of the EPAS control unit into the vehicle communication network, the system's highly dynamic properties, and its most temperature-independent characteristics. These properties are also used to introduce new (steering) functions, which increase safety and comfort levels when steering.

The exacting safety demands made of a steering system require the development and validation of extensive safety functions, as well as the application of standardized quality processes. The universal IEC 61508 safety standards for electronic safety-related systems originally applied to the application of safety concepts. However, the new safety standard ISO 26262 specifically for safety-related electrical and electronic systems in road vehicles, which came into force in November 2011, will be the standard for future developments.

2.1 General functions of EPAS systems

The driver applies a manual steering torque to the steering wheel. This is detected by a torque sensor and is transmitted as an analog or digital signal to the electronic control unit (ECU) of the steering system. The ECU calculates the necessary assist torque, considering the driving situation. The drive status is determined using system-internal and system-external information, such as the vehicle speed. The ECU controls the electric motor correspondingly via the power electronics. The steering torque accumulated from the manual torque and assist torque is converted into an actuation force by a pinion on the steering rack and transmitted to the wheel unit via the tie rod (Figure 2).

To minimize loading of the vehicle electrics—and thus the demand for energy—the steering system must operate

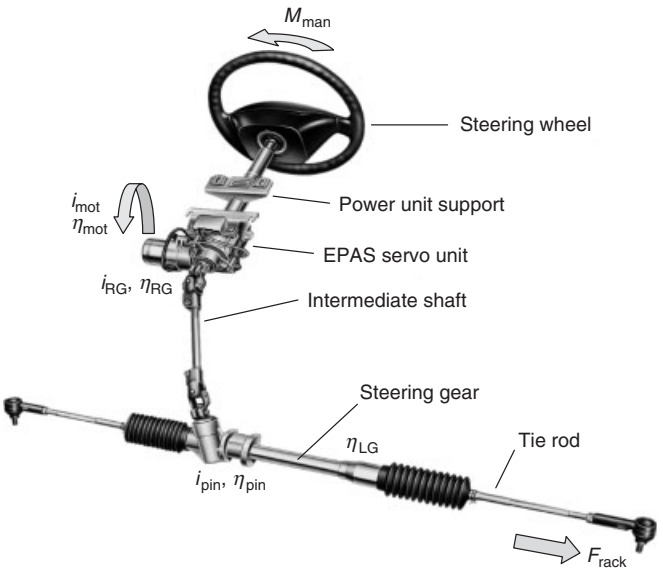

Figure 2. The equilibrium of forces in steering column EPAS.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as efficiently as possible. The system design makes a significant contribution to this with low mechanical friction losses as well as efficient motors and transmission trains. The following equation shows the definitive mechanical influence variables in an example of a steering column electric-power-assisted steering (C EPAS) system

$$F_{\text{rack}} = i_{\text{pin}} \times \eta_{\text{pin}} \times [M_{\text{man}} + (\eta_{\text{mot}} \times M_{\text{mot}}) \times i_{\text{RG}} \times \eta_{\text{RG}}] \times \eta_{\text{LG}}$$

F_{rack}	Actuation force on the tie rod
i_{pin}	Gear ratio of the pinion on the steering column to the steering rack of the steering gear
η_{pin}	Efficiency of the rack-and-pinion gear
M_{man}	Manual steering torque applied by the driver
η_{mot}	Mechanical efficiency of the motor
M_{mot}	Mechanical torque of the motor
i_{RG}	Gear ratio of the reduction gear
η_{RG}	Efficiency of the reduction gear
η_{LG}	Efficiency of the steering gear

This equilibrium of forces clearly illustrates that the manual steering torque is influenced directly by changes to the controlling torque of the motor. Speed-dependent regressive steering assist draws on this principle. At low vehicle speeds, such as when parking, the EPAS motor is activated with a relatively high current (assist current), so that smooth steering is achieved. At high speeds, only small steering movements are generally carried out and the driver requires precise tactile feedback; therefore, a smaller level of steering assist is provided by the EPAS system in this case (Figure 3).

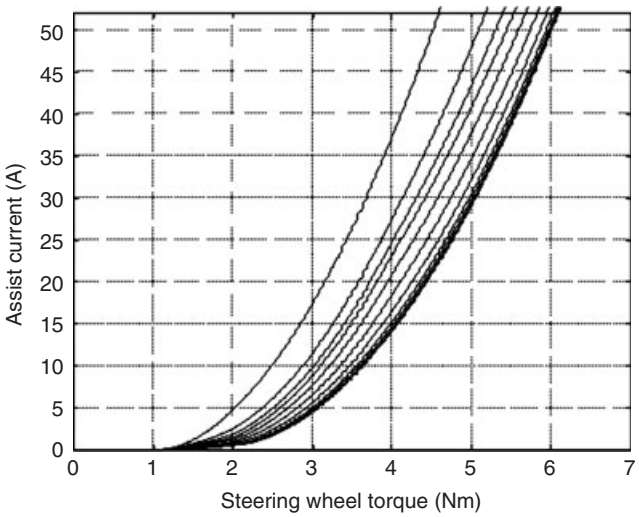

Figure 3. Regressive steering support.

Highly dynamic drives are used in EPAS systems, so that the necessary assist torque can also be provided when completing fast steering movements, for example, when parking or conducting quick evasion maneuvers. Generally, EPAS systems are capable of providing full assist torque, even at angular velocities of 360°/s.

2.2 EPAS technologies

2.2.1 Steering column EPAS

Steering C EPAS is used primarily in small and compact vehicles. Thanks to further enhancements to the technology used for the electric motor, the (power) electronics, the component stiffness, the reduction gears, and the control software; however, modern steering C EPAS is also used in all classes of vehicle, small-range to top-of-the-range models.

In case of steering C EPAS, the motor/control unit and the torque sensors are integrated into the steering column. By means of a reduction gear, the motor transmits a supporting torque to the steering column. As the technology is incorporated into the vehicle interior, this type of EPAS can be configured for relatively moderate ambient conditions.

As the servo unit is integrated directly into the steering column, modern EPAS systems must be small enough to adapt flexibly to the vehicle installation space. Owing to its close proximity to the driver, the servo unit must be very quiet at all steering speeds. The high demands made of the steering feeling are satisfied by the stiff mechanics of the steering column and the intermediate shaft (I-shift), as well as by corresponding control algorithms (Figure 4).

A look at the product portfolio of the globally active Japanese steering manufacturer NSK clearly shows the wide

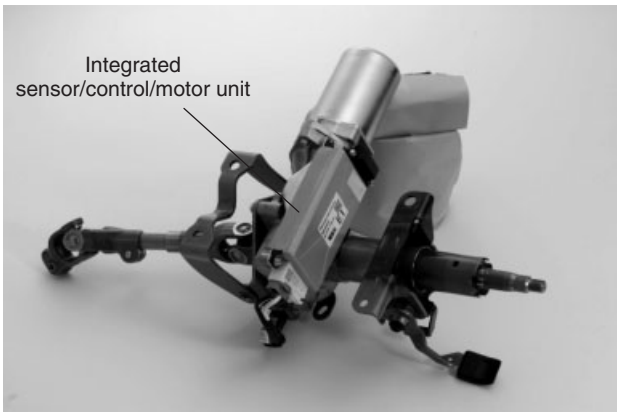

Figure 5. Small package Toyota iQ steering column EPAS. (Reproduced by permission of NSK Deutschland GmbH.)

range of possible applications for steering C EPAS systems. Figure 5 shows the smallest system currently available on the market, which is used in the Toyota iQ. With its steering system for the new Toyota Sienna, NSK sets the standard worldwide for the performance and power density of C EPAS systems. This system provides a steering assist of 12.5 kN rack load and is thus a classic example of an alternative to hydraulic steering assist that can be used for various vehicle classes, from small vehicles to cars with over 3-L engines. At 8.5 kN, the highest performance C EPAS on the European market was also developed by NSK. It is used in models including the Renault Mégane Scénic.

2.2.2 *Single-pinion EPAS*

In case of the single-pinion EPAS, the servo unit is positioned directly on the steering pinion. Integrating the torque sensor, servo unit and reduction gear into the steering pinion housing results in a compact EPAS system, which, however, has a relatively inflexible layout. Single-pinion EPAS is used in small- and middle-range vehicles.

As they are located in the engine compartment, single-pinion EPAS and the following systems are exposed to higher ambient temperatures than C EPAS systems (up to 135°C) and must be designed accordingly, especially as regards the electronic components. Its positioning also means that the EPAS system is exposed to dirt particles and moisture; therefore, the casing construction must be sealed (Figure 6).

2.2.3 *Double-pinion EPAS*

As the name suggests, this type of EPAS system features a second pinion. This second unit contains the electric motor, the controls, and the reduction gear as well as the pinion. Because of the principle used, the torque sensor is integrated into the pinion unit on the steering column, similar to the single-pinion EPAS, so that a separate signaling line is routed to the electrical control unit. Compared to the single-pinion concept, double-pinion EPAS offers a greater level of flexibility in the arrangement of the servo unit and thus its placement within the limited space available in the engine compartment. As it is independent of the steering pinion ratio, the gear ratio of the reduction gear can be optimized for applications with somewhat higher controlling torque (Figure 7).

2.2.4 *Axially parallel EPAS*

Axially parallel drive systems are used in vehicles with medium to high axle loads and are presently enjoying strong growth, as hydraulic systems are now being replaced with electric servo systems in this vehicle class too as EPAS systems becoming increasingly mature.

The unit, which is composed of an electric motor and an ECU, is arranged axially parallel to the steering gear. A pinion on the motor shaft drives a toothed belt, which transfers the torque to the nut of a ball screw drive, whose spindle is on the steering rack. Owing to the effective transmission stages, toothed belt, and ball screw drive, this

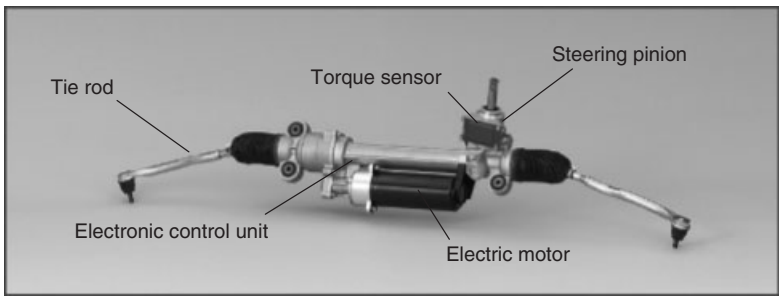

Figure 8. Axially parallel EPAS. (Reproduced by permission of NSK Deutschland GmbH.)

form of EPAS has a high overall efficiency, which enables it to control large steering forces. The torque sensor is in turn integrated into the steering pinion unit and connected with the servo unit via a signaling line (Figure 8).

2.2.5 Rack-concentric EPAS

Rack-concentric EPAS systems are used in vehicles with high axle loads and a correspondingly high actuation force requirement. However, they are still not very widespread today.

With this system, the rotor of the electric motor is seated directly on the ball screw nut. The torque of the electric motor is converted into an actuation—force acting on the steering rack by the ball screw. As the system includes only one transmission stage, the electric motor must provide a very high torque (Figure 9).

3 SYSTEM COMPONENTS

3.1 Mechanics of the steering column in column EPAS

The steering column mechanics have the primary task of absorbing the steering torque applied by the driver and

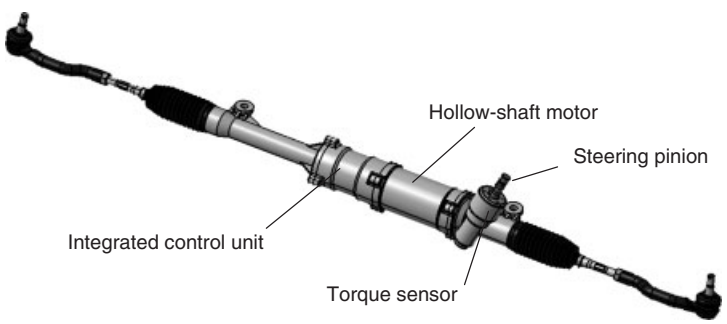

Figure 9. Rack-concentric EPAS.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

transferring it to the I-shift with the lowest possible friction losses. As the steering must always be available as a top-priority safety system, the design of the steering mechanics is correspondingly robust and subject to intensive tests. In the case of a crash, the steering column also has the task of absorbing the impact energy by means of a controlled collapse rate should the driver be thrown against the steering wheel.

The steering column has the following mechanical interfaces to the driver/vehicle system (Figure 1):

- Steering wheel (torque input)
- I-shaft (torque transfer)
- Cross car beam (fixing)
- Instrument panel (package interface).

The mechanics of a steering C EPAS system include a divided steering shaft, whose two parts are connected by a torsion bar. Depending on the torsion bar stiffness, typical values are between 2.0 and 25 Nm/°, this design ensures a rotation angle difference of the input and output shafts relative to the manual steering torque. This angular difference is used to detect the steering torque (Section 3.3.1; Torque sensor). The accumulated torque from the manual steering torque and the servo assist torque is transmitted, via an I-shaft, to the steering pinion and translated into the resulting steering rack force.

A distinction is made between the following steering column types based on their adjustability:

- A steering column that cannot be adjusted individually to the driver position is known as a *fixed steering column*.
- For enhanced comfort, the height of some steering columns can be adjusted. In this case, the steering column is released using a lever and set to the right height for the driver's position.
- The third type of steering column can be adjusted for height and reach. This allows the steering wheel position to be moved up or down and in or out.

The adjustable systems feature a divided steering shaft, which is compatible with a clamp system to fix the steering column in position. A special version features electrically adjustment for height and reach. This is mainly found in premium vehicles. Such electrical adjustment systems are made using an electromechanical system separate from the steering actuator system (Sections 3.1.1–3.1.3).

3.1.1 Manual height adjustment

When vehicles are developed, the steering wheel position is designed for a driver of a certain height. Depending on the actual anatomy of the driver and his or her individual seat position, a height-adjustable steering column can increase the level of comfort. Height-adjustable steering columns pivot at their lowest mounting suspension point. The steering column is guided along a slot on the upper fixing, which determines the possible tilt of the steering column (approximately ±20–25 mm is typical). A clamping system guarantees that the steering column is fixed securely in the selected position, even when it is exposed to loads, such as the driver pulling himself or herself up, using the steering wheel. Both friction-based mechanical systems and positive locking are established options.

3.1.2 Manual reach adjustment

A further adaptation of the steering wheel position can be achieved by adjusting it for reach, that is, changing the distance between the driver and the steering wheel. There are two types of reach adjustment, which are used, based on the philosophy of the vehicle manufacturer and the space available.

Type 1: During reach adjustment, only the inner steering column tube is moved, leaving the upper cardan joint of the I-shaft in position.

Type 2: The entire upper steering column is moved, including the upper cardan joint. A sliding mechanism in the I-shaft compensates for this movement in the system.

For both types, reach adjustment is guided by a slot, which defines the possible adjustment (approximately ±20 mm is typical). The steering column is fixed in position using friction clamping or positive locking. The system must be designed to ensure that the forces applied by strong drivers do not accidently alter the steering wheel position. This comfort-enhancing option is generally combined with height adjustment, so that the driver can be optimally adjusting the system.

3.1.3 Steering column with electric height and reach adjustment

Some premium vehicles have electrically adjustable systems. These systems have one electromechanical actuator system for height adjustment and one for reach adjustment, allowing the driver to adjust the steering wheel position within the permitted range by activating the corresponding switch. The mechanism is controlled by a separate system, independently of the EPAS control unit.

These systems are not only used to adjust the steering wheel position when driving, but they also perform additional functions. For example, when the driver exits the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

vehicle, the steering wheel can be lifted automatically to make getting out easier. After the driver gets in, the steering wheel is automatically returned to the specific position stored for the respective driver.

3.1.4 Passenger safety in the case of a collision

As part of the passive safety system, the steering system includes mechanisms for the protection of the driver in the case of a vehicle collision. If the driver is thrown against the steering wheel, the steering column should absorb energy and thus decrease the forces acting on the driver. Basically, a vehicle collision—in particular a head-on collision—can be divided into two phases, the primary and secondary collisions.

During the primary collision, the vehicle hits the obstacle and the engine compartment is deformed. Because of this, the engine is pushed back, which would move the steering wheel toward the driver. This relative movement between the steering gear and the steering wheel is compensated by a sliding mechanism in the I-shaft—the same as that used for reach adjustment (Figure 11).

The secondary collision refers to the rapid deceleration of the vehicle and its passengers and the reaction of the steering system. The air bag is released and the driver is flung against the steering wheel. The steering system now protects the driver by absorbing largely the impact energy. Defined counterforces are generated here, whose characteristics can be represented in three phases.

As already mentioned in the description of reach adjustment (Section 3.1.2), the steering wheel can also be subject to high loads exerted in the direction of the steering shaft during operation. For example, the steering wheel is often used for support when the driver moves or changes the position of his or her seat. In these cases, the steering column must not collapse, that is, high initial forces acting parallel to the axis of the longitudinal column must be absorbed (typically 1.5–2.5 kN) in order to initiate the first phase of the absorption system. In constructive terms, this breakaway force is represented by crash elements, which activate the collapse of the steering column at a defined force. The crash elements are connecting elements between the carrier bracket and the steering column, which allow movement parallel to the axis above a predefined force threshold. This function can be realized by means of a friction force-oriented design. However, this is generally dependent on the tightening force of the bolts during vehicle assembly. Alternatively, a capsule can be used, whose predetermined breaking points allow the steering column to collapse if the predefined force threshold is exceeded. The properties of this capsule are independent of the vehicle assembly.

In the second phase, the steering column is slid together against a relatively constant force level. One way to absorb the force is to use a design, which generates a defined friction between the internal and external steering column tubes. For instance, ribs can be pressed into the internal steering column tube, which generates almost a constant friction force between the tubes. This phase can be overlaid by additional elements, which allow the counterforce characteristic to be set individually (tuning). This option is particularly interesting in the case of platform applications for steering columns, where it may be necessary to adapt the mechanism to the various models in the design series.

In the third phase of the defined collapse of the steering column, the system reaches its limit, meaning that the residual kinetic energy is absorbed by elasticity in the steering system and in the vehicle. The counterforce rises sharply as a result.

3.1.5 Reduction gear

The reduction gear has the task of converting the fast rotating movements of the electric motor's drive shaft into the rotation of the steering column shaft. As well as the purely functional requirement of converting this power, the EPAS gear has a significant influence on the acoustic and tactile characters of the power steering.

Steering C EPAS systems typically use worm gears as reduction gears (Figure 10). The worm interlocks with the motor shaft and the casing contains roller bearings. The bearing arrangement is elastic, so that the system is constantly subject to a defined preload. The preload, combined with the precise manufacturing process used for the friction partners (the worm and worm wheel), leads to a quiet, uniform transmission of energy. Worm gears are used in steering C EPAS, single-pinion EPAS, and double-pinion EPAS systems.

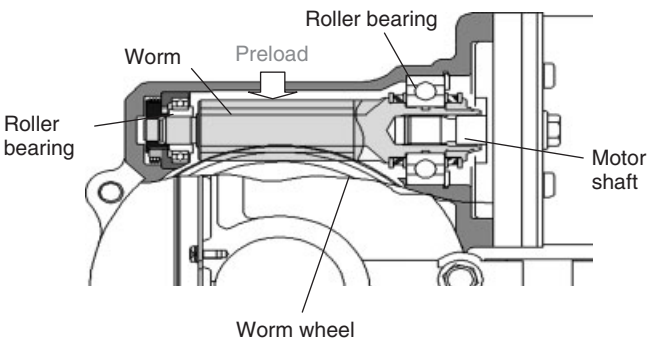

Figure 10. Worm wheel gear in steering column EPAS.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As the reduction gear acts directly in the torque flow of the steering mechanics, any jamming or mechanical damage must not block the steering. A low coefficient of friction in the reduction gear ensures that the driver is also still able to steer the vehicle manually if the steering assist is switched off. As the mechanics are permanently in action, the construction must also prevent any blocking of the motor (Section 5).

3.1.6 Intermediate shaft

The I-shaft uses a positive fitting design to transfer the steering torque from the upper steering column to the pinion of the steering gear.

The dimensions of the I-shaft depend on the steering torque to be transferred and the respective load profile of the steering system. In the case of steering C EPAS, both the manual steering torque applied by the driver and the assist torque of the servo unit must be transferred. The I-shaft of EPAS systems that are integrated into the pinion gear or into the steering gear only need to transfer manual steering torque. On the basis of their application, I-shafts must be designed to meet demanding vehicle-specific or platform-specific load profiles throughout their service life and to cope with the maximum force requirements. As well as safety requirements, stiffness and play tolerance values must be considered in the construction of the I-shaft, depending on the vehicle-specific requirements for steering feeling.

Figure 11 shows an intermediate shaft for an EPAS system. Cardan joints are used at the interfaces to the steering column shaft and to the pinion on the steering gear side, in order to balance the angle and the axis offset between these component parts. An equalizing mechanism compensates for relative movements between the upper and lower cardan joints as they occur, for example during vehicle assembly, in the case of a crash, when adjusting the steering wheel reach, or when driving as a result of elasticity.

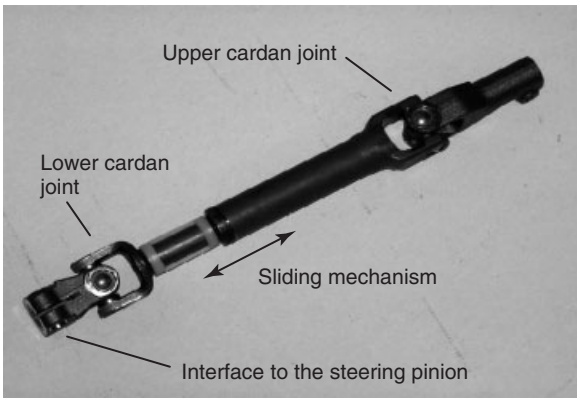

Figure 11. Intermediate shaft. (Reproduced by permission of NSK Deutschland GmbH.)

3.2 Electromechanical system

The main task of the electromechanical system for EPAS is to identify the driver's steering requirements and reliably provide assist torque. Various analyses and secondary functions are integrated into the software to perform this task conveniently and reliably. Additional steering functions are increasingly being incorporated into EPAS systems, which are not perceived directly by the driver, as are functions, which offer more obvious benefits, such as parking assistance. The most important functions are described in Section 4.1.

The electrical components of a modern steering C EPAS system are shown in Figure 12. The torque sensor, ECU, and electric motor are the core components of all forms of EPAS. To identify the driver's steering requirements, the manual steering torque is registered by a torque sensor and transmitted in the form of an electric signal to the ECU. As well as this internal signal from the EPAS system, vehicle data—such as the vehicle's speed or the rotational speed of the combustion engine—can be supplied to the ECU by means of a CAN or FlexRay bus. From this input data,

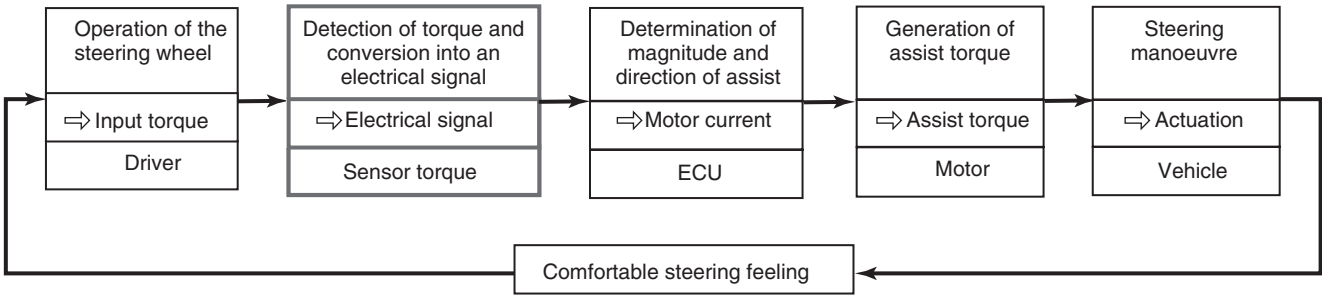

Figure 12. Workflow of the electrical system of an EPAS.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the ECU's processor unit determines the necessary assist torque, and the phase currents are computed for the electric motor and injected into the phases via the power electronics. The engine torque provided is converted by the reduction gear and supplements the driver's manual steering torque.

Knowledge of the absolute position of the steering wheel angle is necessary for different steering functions. The necessary signal can be registered by an external steering angle sensor and made available to the EPAS system via the interface to the vehicle communication. In modern EPAS systems, the absolute steering angle can be calculated using the existing wheel speed signals by means of an integrated electrical hardware system or a complex algorithm. The absolute steering angle position is used not only for different steering functions but also for other vehicle systems such as ESP. As both the steering and the ESP system must satisfy the highest safety demands, the signals are developed according to standardized safety norms (see also Section 6 on functional safety).

The subsystems, which make up the electromechanical system, are described in the following sections.

3.3 Sensor technology

3.3.1 Torque sensor

The steering torque exerted by the driver is a crucial input variable for the calculation of the electrical steering assist. High demands are therefore placed on the torque sensors for EPAS systems. These exceptional requirements are described in the following list:

Exact—In order to be capable of calculating the assist torque required by the driver, a torque sensor with high resolution of about 0.1° at high angular speeds up to 2500–3200°/s and good signal quality is used.

Safety—The safety of the steering system relies on the magnitude and direction of the steering movement being recorded and the correct signals being transmitted. The construction of the system must safeguard this. Sending incorrect information to the control unit can lead to unwanted steering assist or countersteering. These are major safety-related faults. Such faults must be prevented and/or identified using reliable error detection. Suitable action must be taken to avoid situations, which could lead to accidents.

Reliable—The technology used and the design in question must have a high level of reliability, that is, very low failure rates, even when subject to external influences such as vibrations, high temperatures or fluctuations of temperature, and under the influence of electromagnetic radiation.

Low friction—As modern EPAS mechanics are constructed using a very low friction design, this requirement must also apply for the subsystems, such as the torque sensor. Therefore, low friction systems or systems without contact are used.

Figure 12 shows a simplified control circuit, which illustrates the function and importance of the torque sensor. The sensor acts as the EPAS system's interface to the driver by registering the steering requirements and the steering torque applied and converting these into an electric signal. On the basis of the signal, the necessary assist power or current is calculated in the control unit, considering the driving conditions. The generated actuation force itself initiates a vehicle reaction, which in turn causes a steering action by the driver.

A mechanical system, which generates a physically measurable variable dependent on the torque, forms the basis for the detection of the steering torque. To achieve this, the steering shaft is divided into an input shaft and an output shaft. The mechanical connection for the force transfer is realized via a torsion bar with a defined stiffness. The manual torque input twists the torsion bar, changing the angle between the input and output shafts. This angle is used to calculate the steering torque. Similar arrangements are used in hydraulic power-steering systems.

Figure 13 shows the torque sensor module assembly of a steering C EPAS system. The torque from the input shaft is transferred to the torsion bar via a toothed profile. In order to enable relative movements to be absorbed, for example, in the case of reach adjustment, the input shaft can be displaced axially with respect to the torsion bar. While the assist torque is transmitted to the output shaft directly by the EPAS, the manual torque is transmitted by the torsion bar to the output shaft via a pressed-in pin. A secure mechanical

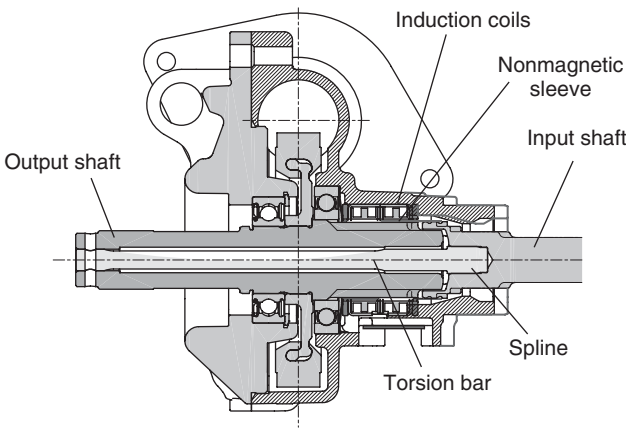

Figure 13. Integrated torque sensor.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

layout and intensive validation ensure that the system is extremely reliable. However, even if the torsion bar or its connections fail, a mechanical stop between the input and drive output shaft ensures that the vehicle can be steered manually.

In the system shown, a nonmagnetic sleeve is fixed to the input shaft. The sleeve has windows, which are rotationally offset with constant phase angles. The relative movement of the output shaft's tooth profile in relation to the sleeve changes the magnetic flux in the coils, which causes a change in the coil impedance. This change in the coil impedance is converted by the sensor electronics into an electric signal and transmitted to the ECU. This electric signal is a measure of the required torque assist.

3.4 Motor angle sensor

For the brushless motors used in many systems, as well as for induction generators, the respective motor angle and the motor angular speed are required as a basis for the control algorithm. The motor angle sensor has the task of converting the relative angle position into an electric signal and transmitting it to the ECU. In order to avoid any friction, contact-free principles, such as magnetoresistive (MR) technologies or resolvers, are used in modern EPAS systems.

3.5 Steering angle sensor

The control unit, based on the information supplied by the motor angle sensor, considering its resolution, the mechanical gear ratios, and the mechanical tolerance stack can calculate the relative steering angle. As the motor angle sensors are not multiturn capable, that is, the position can only be determined within one revolution (360°) of the motor shaft, the absolute position of the steering shaft cannot be determined. However, some steering functions require the absolute steering angle, such as the parking assistant.

One way to determine the absolute steering angle without any additional electrical hardware is using an algorithm, which can calculate the straight-line progress using the wheels' rotational speeds. This learning algorithm uses the wheels' rotational speeds determined by the anti-lock brake system (ABS) after the engine is started, in order to index the position of the straight-line progress. By means of the EPAS system's motor angular speed signal, the absolute steering angle can be calculated on the basis of this information. In principle, this process requires a certain driving distance, which is dependent on the steering profile and the road. For most steering functions, determining the absolute steering angle position in this way is sufficient.

However, ESP systems in particular require high precision, rapidly available signals. The so-called true power-on systems provide the absolute steering angle position as soon as the steering system control unit boots up when the engine is started.

The ECU is the distribution center of the electromechanical steering system. All signals arrive here and the suitable assist torques and power flows are computed for the respective driving situation then outputted to the electric motor. The system states and the active processes are monitored by the ECU in a complex safety structure, and appropriate action is taken if a fault is detected (Figure 14).

The input circuits of the signal electronics convert the torque sensor signals from the vehicle power supply and the angle position of the motor into electric signals, which can be processed by the ECU. To generate suitable steering assist, the central processor unit (CPU) uses this information to calculate the current to be injected into the individual motor phases. To activate the motor phases, the CPU sends a control current to the gate driver, which in turn activates the field-effect transistors (FETs) in the power output stage, which is arranged in an H-bridge. As well as the resistive losses, switching losses also occur in the power electronics, which lead to a high level of heating in the component parts. For this reason, the power electronics are placed directly on the housing of the control unit for optimal heat dissipation and the construction ensures that heat is effectively transferred to the steering gear housing.

The monitoring of the CPU is a key component of the safety concept for an EPAS system, because incorrect outputs can lead to fatal faults. The calculated results and/or the computing capability of the processor and the control algorithms must be checked independently. For instance, important calculated results are checked by independent parallel algorithms within the CPU, which have to considerably differentiate from the basic control algorithms. Furthermore, the system diagnostics monitor the software and the electrical hardware of the control unit by running calculations in two independent computer units. Some of the monitoring is completed in the central processor, whose results are checked by a further processor (sub-CPU). If, in the comparison calculations, differences are diagnosed outside of a stipulated tolerance range, which can lead to faults with safety implications, the system goes into safe mode.

Depending on the type of fault identified, the system can revert to replacement actions, which only reduce the level of steering comfort or the degree of steering assist. If a more severe fault is identified, power-assisted steering is switched off and the vehicle must be steered manually. As modern EPAS systems are extremely reliable, these interventions by safety functions are extremely rare occurrences, however.

4 STEERING FUNCTIONS

All functions, which are provided by means of software algorithms within an EPAS system, are referred to as *steering functions*. A distinction can be made between functions, which can be incorporated into the EPAS system and functions, which are supported by the EPAS but are activated by other control units in the vehicle. Generally, the functions, which can be implemented via the EPAS system, serve to support the driver and keep providing him or her with appropriate feedback on the driving situation. However, the driver remains responsible for decision-making regarding the steering. Tactile feedback from the steering system should also place the driver in a position to identify faults in the vehicle, such as a badly balanced wheel or tire pressure loss.

4.1 Basic steering functions

4.1.1 Steering assist

The steering assist provided by the servo motor is the elementary function of an EPAS system. As described in Section 3.3.1, the steering assist is outputted primarily based on the manual steering torque applied by the driver, steering requirements, and the vehicle's speed. The characteristics of the steering assist are extensively coordinated in test runs by vehicle manufacturers and steering suppliers, and these characteristics determine the character of the steering in the respective range of vehicles. The philosophy of the engineers, responsible for coordinating steering in a certain manufacturer's vehicle, reflects the driving feeling that the driver associates with a brand, regardless of the platform in question.

4.1.2 Damping

During operation, the steering system is subject to various influences, which tend to affect the stability of the steering system in a negative manner. In the ideal case of a straight-line drive, no steering intervention and thus no servo assistance would be necessary. In reality, however, acceleration is continuously present from external disturbance variables, such as the stimulation from the road surface or the small steering movements made by the driver, so that these influences do not lead to instabilities in the steering activation, these disturbance variables are detected by the system and dampened in a speed-dependent manner. The character of the damping can be defined by corresponding parameterization in the vehicle coordination phase.

4.1.3 Friction compensation

In the electromechanical steering system, friction losses arise at different points, which have a corresponding influence on the steering characteristics. A supplementary assist torque and a corresponding compensation current are calculated to compensate for the friction and added to the basic steering assist.

4.1.4 Inertia compensation

Steering a vehicle is a dynamic process, which—considering the transmission ratios typical of EPAS systems—is disturbed by the inertia of the relatively large masses moved. Without further measures, the driver would have to continuously steer against the resulting forces. Inertia compensation means that the driver no longer has to do this and gives him or her the sense that the steering responds immediately and exactly to his or her actions.

4.1.5 Reduction of the assist power

If the driver steers into an obstacle, such as a kerb, the wheels are blocked, so that no further steering movement is possible. As long as the driver continues to exert a steering torque, however, the EPAS system will provide a powerful assist torque, which will generate very high power dissipation, leading to heating of the system. In order to reduce this loading and to protect the system, an algorithm is implemented that identifies any blocking and reduces the assist power.

4.2 EPAS steering functions

A great advantage of EPAS systems is the option of going beyond basic steering features by integrating further steering functions via software algorithms without the need for extra hardware. Section 4.2.1 describes functions, which can be realized by the EPAS system using existing information in the vehicle network.

4.2.1 Active return

In a high quality steering system, the driver expects the steering wheel to return clearly to the center position depending on the vehicle speed. This means that, when cornering, he or she expects a uniformly increasing counterforce before the steering is reset on the next straight stretch. Furthermore, the neutral position of the steering wheel should be unambiguously reached and maintained as long as the driver exerts no steering torque. On the whole, modern chassis kinematics are no longer designed with this focus in mind as the axle construction considers the option of active return via the EPAS system and the mechanics are optimized with regard to other aspects.

The active return function calculates the necessary active return torque through the EPAS system, considering the steering wheel torque, the vehicle speed, the absolute steering angle, and the steering angle speed. Without steering torque input by the driver, in relation to the vehicle speed, the vehicle automatically goes back to traveling in a straight line after cornering.

4.2.2 Soft end stop

Very high rack forces and steering speeds can occur in an EPAS system, depending on the steering requirements. If no other measures are implemented, the steering gear can reach its end stop and be exposed to very high mechanical loading as a result. The mechanics must therefore be designed robustly, which drives up weight and costs.

To optimize the mechanical system, a function can be introduced that can reduce the EPAS assist before it reaches its mechanical end stop, or even oppose the driver's residual manual steering torque. For the realization of this function, knowledge of the absolute position of the steering is necessary, calculated from the absolute angle position of the steering wheel. As well as the mechanical design optimization possibilities offered by this function, the driver also perceives steering toward the end stop as significantly softer, which further enhances comfort.

4.3 Vehicle functions

The technical possibilities of EPAS systems enable different comfort-enhancing functions to be introduced at vehicle level. Other control units in the vehicle manage overall functionality, and the necessary function of the EPAS system is called up via the vehicle communications. However, responding to requirements remains the responsibility of the EPAS system. Many of these additional driver assistance functions lead to an immediately perceptible increase in tactile comfort for the driver, and they can be marketed correspondingly. It is expected that greater use will be made of such assistance functions in the coming years. Some of them are described in the following sections.

4.3.1 Lane keeping assistance

If a vehicle changes or leaves its lane following an action such as use of the indicators or an unambiguous steering movement, it is clearly the driver's intention to do so. However, if the vehicle slowly drifts out of its lane, this

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

could be caused by inattentiveness on the part of the driver and could lead to an accident.

Unintentional departure from a lane is generally detected by means of camera systems and feedback about the driver's actions. In order to make the driver aware of this situation, the EPAS system can send tactile feedback to the driver, for example, by making the steering wheel vibrate briefly. However, the driver is still responsible for taking any action to correct the vehicle's direction. This function is also known as *lane departure warning*.

Before active support can be provided to avoid unintentional lane departure, several safety criteria must be met. The driver must be able to override the active steering intervention at all times and the system must always be able to identify whether the driver has his or her hands on the steering wheel by evaluating the manual steering torque. If these prerequisites are met, any active correction by the EPAS system using information from the camera system can be activated.

EPAS can also actively support safety by giving the driver a steering torque recommendation. If oversteering or understeering is registered at vehicle level, or the vehicle skids after braking on μ-split condition, the driver can be encouraged to counteract this by means of short torque pulses to the steering wheel. Here too, the driver must retain ultimate control over the steering, that is, it must also be possible to override these steering pulses.

4.3.2 *Parking assistance*

Parking assistance helps drivers with parallel and reverse parking. Different types of parking assistance are available, which differ in the degree to which the vehicle's acceleration is automated (accelerating and braking). Steering is always taken over by the vehicle. Autonomous steering places special demands on the steering system in that different steering requirements are communicated by an external signal via the vehicle communication, instead of via the system's internal torque signal. As the driver still has to keep control of the procedure, any possible intervention on the steering wheel is identified by the EPAS system and is responded to appropriately, for example, by terminating the parking procedure.

5 ELECTRIC MOTORS FOR EPAS SYSTEMS

The electric motor in an electromechanical steering system primarily has the task of converting electrical energy into the required mechanical assist torque. Its effect on the character of the EPAS system becomes clear when the most important requirements are considered in more detail:

Performance: From small steering angle speeds to speeds of one steering wheel revolution per second, an EPAS system must be able to make the maximum nominal torque available. Load profiles, which consider the frequency and scales of the assistance provided, are used to design the layout of the motor. For instance, the maximum steering torques only ever have to be made available on a short-term basis and a low level of performance is all that is usually required during operation.

Dynamics: The size and direction of the steering assist changes highly dynamically during steering operations. The motor is therefore required to have the lowest possible rotor inertia and very dynamic response characteristics.

Efficiency: As electric steering uses a comparatively large amount of power, the system must be highly efficient in order to make optimum use of the limited energy available from the vehicle power supply. A high level of efficiency, in combination with a high power density, is also necessary to enable EPAS systems to be positioned in the confined spaces available in the vehicle.

Acoustics: The electric motor for an EPAS system should be as quiet as possible. Any residual noises should be "pleasant," that is, in a relatively low frequency band. Low levels of mechanical friction, the avoidance of resonance, and a good electric design, as well as corresponding motor control, contribute to achieving these objectives.

Tactile properties: A uniformly running rotor with low torque fluctuation results in a high quality steering feeling.

Safety: When considering the functional safety of EPAS systems (Section 6), the focus is on self-steering and blocking in particular. In principle, any blocking of the rotor by a foreign body in the motor can lead to blocked steering. The system is therefore constructed so as to exclude foreign bodies during manufacturing and/or prevent the release of particles during operation. Electric short circuits must also be avoided by constructive means, because these can lead to inadmissible braking torques.

Robust against environmental impacts: EPAS motors are exposed to vibrations and a large ambient temperature range, as well as to different media depending on where they are installed. The motor module assembly must be designed robustly to withstand these influences and provide the required performance reliably throughout the vehicle's service life.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Costs: Costly materials are used in electric motors, such as copper fillings and various magnets. Ongoing improvements to the design and materials utilized for electric motor development reduce motor costs and thus contribute to maintaining the overall costs of EPAS systems at a competitive level.

5.1 Motor types

In EPAS systems, DC motors or brush motors (brushed DC) are used for a mechanical power in the region of 500 W, asynchronous motors (ASMs) are used for 300–500 W, and brushless motors (brushless DC or BLDC) are used up to approximately 900 W.

5.2 Structure of the brushless DC motor

Even though brush motors continue to have their areas of application, BLDC motors are preferred for modern EPAS systems because of their low inertia, long service life, high efficiency, and high power density. The structure of this motor type, which is also designated as a permanent magnet synchronous motor (PMSM) or electronically commutated (EC) motor, is described later.

In order to achieve a high power density, high energy magnets (approximately 360 kJ/m^3) made of neodymium iron boron (NeFeB)—the so-called rare-earth magnets—are used for BLDC motors. During manufacturing, the magnetic powder is pressed, sintered, and then cut into the respective application shape with diamond tools. Ring or segment magnets are used in EPAS motors, which are fixed on the surface of a laminated core. In order to prevent the motor from being dangerously blocked by particles released from the brittle magnetic material, the magnets are bandaged. Rectangular pocket magnets, which are inserted into corresponding pockets in the laminated core, are another magnet construction design. The laminated core with the magnets is pressed onto the motor shaft. This combination forms the rotor, which is supported by roller bearings in the motor housing and in the housing cover.

EPAS motors of the newer generation are generally structured with technology using individual tooth winding. This enables the spatial separation of the phase windings, in line with the safety objective of preventing short circuits between the phases. The running properties of the motor are determined by the combination of the number of slots and the number of poles. 9/6 (9 slots/6 poles), 12/8, and 12/10 motors are frequently used in EPAS systems. As in the case of electrical machines with slotted stators, an undesired cogging torque occurs due to the varying magnetic resistance associated with the change from stator tooth to stator slot. This effect is countered constructively by skewing the rotor or the stator.

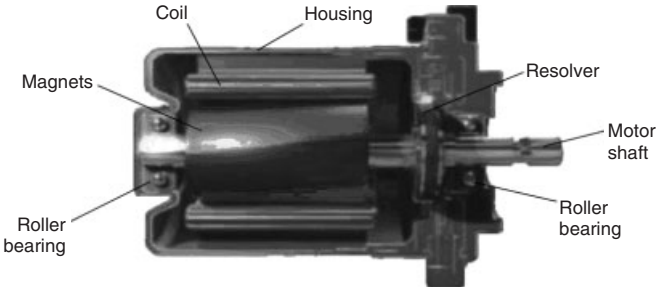

Figure 15. Motor structure of a synchronous motor.

BLDC motors in EPAS systems are commutated electronically in relation to their position. Resolvers integrated into the motor module assembly, or MR measurement methods, are used to determine the rotor position. In line with the rotor position, a stator current is injected via the power electronics of the control unit to create the stator magnetic field (Figure 15).

6 FUNCTIONAL SAFETY IN EPAS SYSTEMS

To put it simply, the steering system should always follow the requirements of the driver, that is, the steering torque should be exerted as requested in terms of both magnitude and direction and the requested steering angle should be set. Similarly, it is important that no steering assist is provided when it is not requested and that the system is always steerable.

In order to ensure product safety, the systems are based on standards, which cover the entire life cycle of safety-related electrical and electronic systems. Systematic development in defined processes forms an elementary component of these standards.

The IEC 61508 standard "Functional security of safety-related electrical/electronic/programmable electronic systems" originally dates from 1998 and is used for the development and evaluation of EPAS systems. It covers "all safety-related systems that include electrical, electronic, or programmable electronic components (E/E/PES)." Depending on the risk to persons and the environment, the systems considered are classified into Safety Integrity Levels SIL1 to SIL4. A steering system is classified as SIL3, which corresponds to the highest safety level in the automotive sector and requires the system to be approved by independent third parties.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

While IEC 61508 for safety-related electrical/electronic systems covers a range of power systems including EPAS, a specific standard (ISO 262629) has now been developed for automotive electrical/electronic systems on the basis of IEC 61508. This has been officially valid since the end of 2011. This standard will replace IEC 61508 in the development of electrical steering systems, which will affect the product generation process and the product design.

Corresponding to the IEC norm, ISO 26262 also classifies systems using Automotive Safety Integrity Levels from ASIL A to ASIL D. On the basis of an analysis of the system risk, EPAS systems are classified in the highest category, ASIL D. As mechanical aspects are not considered in the standard, fault-free mechanical systems are always assumed in case of the electromechanical systems analysis.

6.1 Identification of the safety hazard

In the risk analysis, the possible safety-related effects of faults are identified in the overall system considered. For an EPAS system, the following safety-related faults are considered:

- *Self-steering*: The servo unit assists in magnitude or direction, which does not correspond to the driver's requirements.
  Self-steering is caused by incorrect torque assist from the electric motor, which is incorrectly activated, for example, by an incorrect signal from the torque sensor, a fault in the electrical circuit or a software error.
- *Steering blocking*: A distinction is made between two scenarios.
  (a) The steering is blocked mechanically. As only the electrical system is considered in IEC and ISO, this case is reduced to a blockage of the electric motor.
  (b) The steering is so stiff that the vehicle can no longer be safely steered. This fault can be caused by a phase short circuit in the motor or in the motor control circuit. In this case, the motor is operated as a generator, so that a corresponding electromagnetic braking torque acts against the steering movement.

6.2 Safety objectives

ISO 26262 requires the application of a redundancy and diagnostics concept, which also guarantees that the system enters safe mode in the case of an error. Measurable target values are defined using special metrics, which are divided into three categories:

- Isometrics give the target value for the maximum acceptable probability of occurrence for safety-related faults. This target value is defined for the occurrence of a fault with reference to the operating time (failure in time, FIT);
- Single point of failure (SPF) refers to errors that lead directly to a safety-related fault;
- Latent faults are undetected faults that, in combination with a further fault, lead to a violation of the safety objective.

In order to ensure that these objectives are met, EPAS systems are developed strictly according to the automotive SPICE model, in combination with further measures from the ISO standard.

6.3 Functional safety in use

The consideration of functional safety includes all components of the electrical system, which have an influence on the actuation force and are capable of causing blocking. The sensor technology, the electrical hardware, the software, and the motor must be considered. Depending on their impact on functional safety, external information is also verified again in the EPAS system.

The top priority is to develop components with a very high level of reliability, that is, to avoid faults in operation. Nevertheless, as there are chances for a fault occurring in operation, a fault identification mechanism must be in place, which analyzes the fault and classifies it according to criticality.

If a fault with a possible impact on safety is identified by the diagnostics, a system response is triggered. Depending on the type of fault, substitute reactions are initiated that, as far as possible, are not perceptible to the driver or are only perceptible to a small degree. In some cases, a gradual reduction of the assist power is necessary to make the vehicle safe. With every fault detection and the corresponding system response, a defining factor is that the driver remains control of the vehicle at all times.

For development test drives and homologation (certification for road use), the results are finally evaluated from the process of developing the electric subsystem and also from the approval tests of the electromechanical overall system before approval.

7 SUMMARY

Modern EPAS systems will continue to become much more widespread in the coming years, with the different systems being used in top-of-the-range vehicles and in small- and middle-range models. While basic functions,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto008
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

reliable operation, and safety were the focus when developing the first generation of EPAS, modern EPAS systems will feature new steering functions, reduced weight, and a more compact design. However, the introduction of the new ISO 26262 standard for functional safety will also lead to further development of the electronic concepts. In order to optimally exhaust the possibilities for further development, it is crucial to develop the system in an integrated way, ensuring compatibility between mechanics, electrical hardware, and software. The global steering manufacturer NSK is one company, which combines a deep knowledge of steering column mechanics with an expansion of the development of steering-specific control units. Such kind of system competence leads to modern safety architectures and steering functions to meet future needs for steering systems.

Steer-by-Wire, Potential, and Challenges

Lutz Eckstein, Lars Hesse, and Michael Klein
RWTH Aachen University, Aachen, Germany

1 INTRODUCTION

Since the invention of the automobile in 1886 by Carl Benz, vehicle technology has rapidly evolved multiplying performance, efficiency, and safety of today's vehicles compared to those of more than 125 years ago. Nevertheless, some technical solutions seem to be immune to technological progress: after a few attempts to steer a vehicle by a crank-like device, the steering wheel commonly, and almost exclusively, became the operating device used to influence the vehicle's direction. The first step to improve the complex vehicle operation back then was made by Alfred Vacheron in a redesigned 1893 Panhard 4 hp driven in the race Paris-Rouen in 1894 (Alexandre, 1894; Dick, 2004). The main reason for the steering wheel's success was the steering gear, which offered an ideal force transmission realizing an effortless set and hold to the vehicle's course.

Regarding the steering system, which translates the driver's steering command into a change of the vehicle's direction and—at the same time—provides an adequate feedback in order to support the stability of the driver–vehicle control loop, the predominant solution in street legal passenger and commercial vehicles is still based on a mechanical transfer of forces and torques. Numerous inventions created an evolution from purely mechanical linkages via power-assisted (see Active front steering for passenger cars; New Electrical Power Steering Systems) steering to electromechanical steering systems offering additional but limited functionalities regarding vehicle stabilization and driver assistance.

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

1.1 Motivation

The motivation for introducing steer-by-wire systems can be attributed to three aspects:

- functionality,
- vehicle architecture, including benefits in production and costs, and
- human factors.

The three-level model for driver assistance systems classifies the vehicle operation into the levels of navigation, guidance, and stabilization. While today's electromechanical steering systems enable functionalities such as speed-dependent power assistance on the level of vehicle stabilization and lane-keeping assistance regarding vehicle guidance, the mechanical part of the system restricts the functionality because of the transfer of torque between steering wheel and steering system. In case of a fixed steering ratio, an operation of the steering actuator yields both a change in steering wheel angle and angle of the steered wheels.

The idea of superimposing an additional angle to the steering wheel angle while having a mechanically safe operating mode was patented for the first time in 1972 (Pilon *et al*., 1972). However, after another 30 years, Toyoda Machinery Works and Lexus, as well as ZF-Lenksysteme and BMW, have introduced a superimposed steering system into the market (Köhn *et al*., 2002; NN, 2003). Active front steering introduced by BMW superimposes an electronically commanded steering angle in addition to the steering wheel angle using a planetary gearing. This principle clearly enables additional functionality such as a variable steering ratio and improves driving stability but is still limited by the fact that the driver needs to compensate the change in steering torque resulting from the (see New Electrical Power Steering Systems) actuation of the active front steering (Köhn *et al*., 2002).

The second motivation for steer-by-wire is given by the fact that the mechanical integration of the steering system has a large effect on the vehicle package, as the steering column needs to connect the steering wheel with the steering gear in right- and left-hand-drive vehicles. The geometry of a conventional steering system also limits the vehicle variants that may be derived on a modular basis, as the ergonomically required position and angle of the steering wheel largely changes with the different postures of the driver, for example, in a limousine versus a sports utility vehicle. Introducing steer-by-wire yields a robust package of the steering system and engine compartment and maximum spreading of vehicle variants on one technical platform.

The third motivation also plays a major role in the history of aviation: with increasing aircraft size and performance, the pilot's ability to control the aircraft without significant auxiliary forces and flight control systems rapidly decreased. Moreover, the classical control column in front of the pilot consumed a large amount of valuable space and surfaces in the cockpit that were needed to integrate additional controls and instrumentation. Consequently, the entire cockpit layout has changed with the introduction of fly-by-wire incorporating compact joysticks instead of large column sticks. In addition, in a road vehicle, the cockpit layout can be significantly improved by introducing by-wire controls in terms of human factors, design, active safety, and passive safety (Eckstein, 2001).

1.2 Definition

A steer-by-wire system uses an electronic communication replacing the mechanical linkage between the operating device (e.g., steering wheel) and the steering system, as stated by the term *by-wire*.

Extended definitions of steer-by-wire systems found in literature (Binfet-Kull, 2001) also include other nonmechanical connections between the steering control and the steering actuator(s), for example, hydraulic or pneumatic systems. This broad definition is not adopted here, as these systems significantly differ in terms of technology and functionality.

Consequently, a steer-by-wire system comprises at least one sensor in order to sense the input, an electronic control unit calculating a steering command and one actuator influencing the angle of the steering system.

The exact technical solution depends on the individual requirements concerning operating device, functionality, steering actuation, steering feedback, and system integrity. In order to keep up the steering functionality in case of a system fault, a fallback mode is required that clearly distinguishes pure by-wire systems with an electrical/electronical redundancy from those systems incorporating a hydraulic, pneumatic, or mechanical backup.

2 HISTORY OF STEER-BY-WIRE SYSTEMS

Braess (2001) points out that since the 1950s, the demands on steering systems have increased because of increasingly high engine powers, improved road surfaces, and hence higher vehicle velocities. Consequently, the design of conventional steering systems was largely improved by, for example, introducing hydraulic power-assisted steering, electrohydraulic (see New Electrical Power Steering Systems) power-assisted steering, electric power steering (EPS), or superimposed steering. (see Active front steering for passenger cars Similarly to the introduction of fly-by-wire systems, the next step would be the introduction of steer-by-wire systems with a for example, mechanical, hydraulic, electric, or integrated fallback (Figure 1).

The first series production of hydraulic power-assisted steering systems started in the Chrysler models New Yorker and Imperial in 1951. The principle itself had already been filed in a patent by F.W. Davis in 1920s and was ready to go into serial production of GM's Cadillac by 1933 (Davis, 1927). However, owing to the world economy crisis, GM planned to sell only 15,000 vehicles, leading to cost-intensive machine tools in production. Finally, the introduction of the system into the market was stopped. During World War II, American and British army forces equipped military vehicles with Bendix–Davis hydraulic power-assisted steering systems and the market for heavy-duty vehicles started to develop. Series production started in 1951; by 1956 already every forth vehicle in the US market was equipped with a hydraulic-assisted power steering system. Right from the beginning, the servohydraulic steering gear has been supplied by a hydraulic pump, which has been directly driven via a belt drive by the combustion engine. Sporadically, steering systems have been equipped with electric motors driving the hydraulic pumps due to packaging reasons. The automotive R&D departments have always been focusing on designing energy-efficient steering systems. At the end of the 1990s, electrohydraulic power steering systems have been introduced into series production. The development of electric motors and pumps brought forth improved degrees of efficiency and the control of the pump rotational speed decreased the total power demand (Pfeffer, 2011; Rixmann, 1962). Following hydraulic and electrohydraulic power-assisted steering systems, EPS systems have decreased energy consumption and broadened the horizon of steering functionality. The patent from Bayle and Ecquevilly (1972) presents an early example for the idea of an electromechanical steering system. This solution shows an electric motor integrated into the steering column. The first vehicle having an EPS system was the Suzuki "Cervo" in 1988. This system developed by Koyo (Japan) has an electric motor as a component integrated in the steering column. As the front axle wheel load was small, the electric motor only needed an input power of 240 W and was connected to the steering shaft via a worm drive with a gear ratio of 1 : 16 (Stoll, 1992). The next innovation in steering design was the superimposed steering system, which has been patented in 1972 (Pilon *et al*., 1972). In 2002, ZF Lenksysteme and BMW, as well as Toyoda Machinery Works and Lexus, presented a superimposed steering in series production (Köhn *et al*., 2002; NN, 2003).

Regarding the functional motivation, *automation* was one key driver in research on steer-by-wire systems in close analogy to the aviation industry. Since the 1960s, research activities concentrated on the idea of autonomous driving. At the same time, the Concorde was the first civil airplane to perform, in 1969, its first flight with analog fly-by-wire technology. Three years later, NASA's Vought F-8 Crusader flew with a digital fly-by-wire system (Brockhaus, Alles, and Luckner, 2011; Henke, 2010).

The Eureka project PROMETHEUS (PROgraMme for a European Traffic of Highest Efficiency and Unprecedented Safety) and its successive project MOTIV, initiated by German car manufacturers, bundled the activities of many European companies and Universities starting from 1987 (see Automated Driving). In the same year, the Airbus A320 had the first completely digitalized fly-by-wire system. The electronic system was designed with redundancies. A mechanical pitch elevator and yaw rudder pedals served as mechanical backup (Brockhaus, Alles and Luckner, 2011; Henke, 2010). In addition to the PROMETHEUS project, similar projects have been initiated (e.g., NAHSC, IVI, and AHSRA) (see Automated Driving) (Stiller, 2007; Sun, Bebis, and Miller, 2006).

The conceptual idea of intelligent vehicle highway systems (IVHSs) started in the General Motors Pavilion at the 1939 World's Fair. The automotive future was presented by relaxing drivers in self-driving cars (Fenton, 1994). In recent years, the US Defense Advanced Research Projects Agency (DARPA) organized the Grand and Urban Challenges, which were intended to boost US research activities (see Automated Driving). Broggi *et al*. (2010) presented the VisLab Intercontinental Autonomous Challenge (VIAC), where four electric vehicles aimed to drive autonomously along a 13,000-km trip from Italy to China (see Automated Driving).

Apart from these competitions and races, many car manufacturers investigate the potential of driver assistance systems, which not only support the driver on the longitudinal driving task, such as adaptive cruise control, but also provide steering support. Such a system would offer autonomous driving in defined scenarios, such as traffic on motorways, and constitute an important step toward full autonomous driving.

While there is little official available information on the second key motivation for steer-by-wire, namely benefits regarding vehicle architecture, modularity, and production, the third key driver of research on steer-by-wire, *safety and human factors*, was also inspired by progress in aviation technology. Before the invention of the airbag in 1951 (Linderer, 1951) and its final breakthrough in the Mercedes-Benz W126 in 1980 (Patzelt, Schiesterl, and Seybold, 1971; Kramer, 2009), the steering wheel and column often caused severe injuries and many deaths. Already in 1959, General Motors presented a research vehicle based on a Chevrolet Impala, which had a door-integrated joystick to control the longitudinal and lateral vehicle dynamics (Bidwell and Cataldo, 1958). General Motors designed the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto010
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

vehicle stick displacement to be proportional to lateral acceleration at velocities >10 or 15 mph. As there have been no mechanical connections between stick and the controlled vehicle, the freedom in designing the most suitable steering response characteristics was one principal challenge. The joystick feeds back the car's motion to the driver. According to Bidwell (1958), the vehicle's path stability in critical situations was improved while the control knob acted as an accelerometer and also the sensitivity to wind gusts was decreased. The GM Firebird III was presented at GM's Motorama in the same year. This vehicle concept, which was inspired by the space age, had an integrated single joystick like that of the GM Impala replacing steering wheel, gas, and brake pedal (Bidwell, 1959; Davis 2004).

In recent two decades, numerous research prototypes and concept cars with steer-by-wire systems have been built and as such, only a few examples can be mentioned in this chapter. A concept car, the Saab 9000, having an active joystick with force feedback control was presented in 1991. The sidestick concept, originally developed for a military aircraft, was moveable in lateral direction, whereas a passive spring–damper combination and an electric motor applied the feedback force (Bränneby *et al*., 1991). The DaimlerChrysler F200 Imagination, presented in 1996 at the Paris Motor Show, was a research vehicle featuring a steer-by-wire system with two hydraulic sidesticks instead of a steering wheel. Eckstein (2000) carried out substantial research on control algorithms and human factors resulting in a Mercedes-Benz SL 500 (R129) prototype with two active joysticks (Figure 2). The control commands for steering, throttle, and brake were based on force transducers, whereas the displacement of the sidesticks provided an active feedback in lateral direction; in longitudinal direction, the joysticks were isometric. In 2002, General Motors presented the GM Hywire, a steer-by-wire concept where steering was achieved by gliding up or down the steering device handgrip creating a feeling similar to that of a conventional steering wheel. In 2003, DaimlerChrysler published a steer-by-wire concept in the F500 Mind on the Tokyo Motor Show.

3 STATE OF THE ART

3.1 Classification of steering systems

The oldest steering system is the turntable steering, which still can be found nowadays in truck trailers. Here, the drawbar connects the rigid axle and the turntable. The articulated-frame steering is another concept in the heavy equipment sector. In this case, the vehicle bends around a joint in the middle. Both designs are not applicable for passenger cars driving at high speeds because of high steering forces, the performance of the steering kinematics, and the required packaging space (Stoll, 1992).

Single-wheel steering and axle-pivot steering are known as *Ackermann steering systems*, which can be distinguished by the way the steering force is generated (Stoll, 1992):

- *Manual Steering System*. The driver has to apply the steering-wheel force. Only the steering gear reduces the force to a manageable level.
- *Power Steering System*. The driver is assisted in the steering task by additional components reducing the required steering wheel torque.

DOI: 10.1002/9781118354179.auto010
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- *Full-Power Steering Equipment*. The required steering forces are provided solely by one or more energy supplies ECE Reg. 79 (2005).

One potential of steer-by-wire systems is the freedom in designing both the steering torque assistance and the steering ratio. Steering systems can also be classified by the type of force transmission between steering control and steered wheels (Stoll, 1992) as

- mechanical steering systems,
- hydraulic steering systems,
- pneumatic steering systems, and
- electrical steering systems.

Steering systems can also be distinguished by the type of steering gear:

- translational movement (rack-and-pinion steering gear),
- rotational movement (cam-and-roller (Gemmer) or ball-and-nut steering gear), and
- wheel individual steering actuators.

The rack-and-pinion steering gear converts the rotational movement of the steering wheel angle into a translational motion of the tie rod. In contrast, the second type of steering gear transmits the rotational movement of the steering column to a rotation of the pitman arm. Wheel individual steering actuators are often used in specialized on-road and off-road vehicles on the basis of a hydraulic system.

3.2 Steer-by-wire system architectures

In recent decade, many steer-by-wire system architectures have been proposed. This chapter gives an overview of the system architectures without making a claim to be exhaustive. In addition, means to improve system safety are presented.

Steer-by-wire systems do not have a mechanical linkage between the steering control (e.g., steering wheels and joysticks) and the steering system. A basic system configuration comprises a sensor for detecting the driver steering input, an electronic control unit, and an actuator for the operation of the wheels and adequate means for communication between the system elements. Integrating an additional actuator at the control element enables feedback information to the driver, depending, for example, on the steering angle of the wheels or the lateral acceleration of the vehicle. The force feedback actuator thus generates a haptic feedback, which aims at easing vehicle control. The steering actuator is linked to or replaces the conventional steering gear and operates the wheels (Wallentowitz and Reif, 2006). This system is able to provide almost all the functions described in Chapter 4 Potentials in Steer by Wire, Potential and Challenges. Splitting the steering tie rod and adding single-wheel steering actuators increases functionality again. However, in case of a fault in the E&E architecture, this extended basic configuration does not achieve the reliability of conventional steering systems. Of course, also the electric power source has to be considered in the respective analysis for system integrity. As steering systems are considered to be safety critical, the system safety has to be guaranteed in all operating conditions and over vehicle lifetime. As a one-channel electronic control unit and mechatronic subsystems do not have a failure occurrence of $<10^{-7}$ per hour (Wallentowitz and Reif, 2006), a system without redundancy would not be sufficient for safe operation. In aviation industry for example, the Joint Aviation Authorities (JAAs) have specified that failures in primary control systems, such as fly-by-wire systems of large airplanes, should have a failure occurrence of $<10^{-9}$ per hour to be considered as improbable (Joint Aviation Authorities Committee, 1989; Reichel, 2004). Thus, in order to make a steer-by-wire system as safe as a conventional steering system, the system architecture has to allow single electric and electronic faults in each of its mechatronic subsystems without leading to loss of control by the driver (Wallentowitz and Reif, 2006).

Hayama *et al*. (2008) show the development of a basic steer-by-wire to a fault-tolerant architecture without considering the electric power source and required sensors. The baseline steer-by-wire architecture (Figure 3) consists of one steering wheel angle sensor, one reaction torque actuator, one steering actuator, one tire angle sensor, two controllers, and one battery. Considering the state

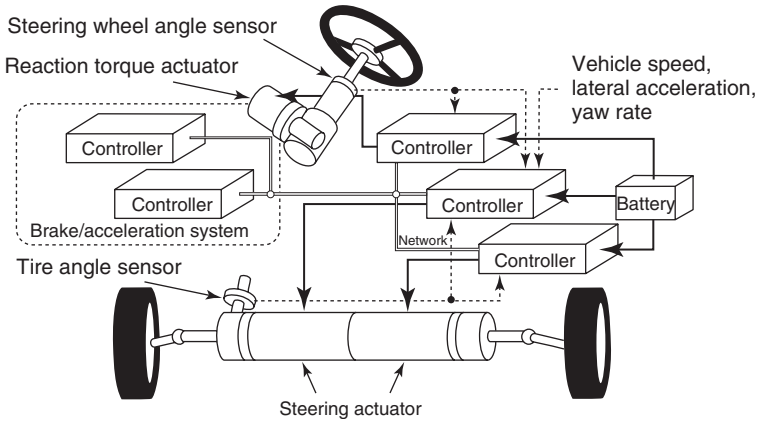

Figure 4. Integrated control steer-by-wire architecture. (From Hayama *et al*., 2008. Copyright © 2008 SAE International. Reprinted with permission.)

transition of different steer-by-wire architectures, Hayama *et al*. (2008) suggest an integrated steer-by-wire architecture (Figure 4). Compared to the baseline structure, the integrated control architecture has two redundant steering actuators and a controller. In addition, the steering system has an interface to the braking and accelerating system in order to generate a yaw momentum by an appropriate wheel torque distribution, thus supporting the driver's steering intention.

Wallentowitz and Reif (2006) have presented another fault-tolerant architecture that can be used for steer-by-wire systems. The idea is to combine two fail silent units (FSUs) to one fault-tolerant unit (FTU) in order to increase system integrity. (Fail safe means that a system is in a safe state, even in case of a failure; fail silent means that the system does not generate adverse effects, by still being active). The superior fault-tolerant architecture (FTA) consists of one sensor, controller, and actuator FTU. Moreover, the power supply is redundant. The strategy to guarantee system integrity is based on local redundancies for E/E subsystems. Figure 5 shows the E/E architecture of the proposed steer-by-wire architecture. The hand wheel and front axle actuator are designed as FTU with two motors, three sensors on one single shaft, and two electronic control units. Each control unit processes the data of two different sensors and controls one actuator. Two electronic control units representing the central electronic control unit as FTU are connected to the actuator FTUs via a fault-tolerant real-time data bus system. This bus transfers the data of the sensor signals, the actuator set point commands, and the system status.

These two examples show that there is no general solution for a steer-by-wire architecture. The design depends on many factors such as system integration, steering functionality, and vehicle properties but will always comprise some degree of redundancy, which leads to additional costs.

3.3 Current steering systems relevant for steer-by-wire

This chapter gives an overview of steering systems that provide steer-by-wire functionality to some degree and that have already been introduced to the market. So far, no true steer-by-wire system has been presented beyond concept vehicles and prototypes; thus, the presented steering systems only fulfill the extended definition of steer-by-wire, for example, with a hydraulic or electrohydraulic linkage between steering control and steering system.

In the heavy equipment sector, for example, agriculture, construction, and forestry, vehicles with steer-by-wire functionality have already penetrated the market because legal regulations allowed such steering systems for vehicles with low maximum speeds at an early time. The main technical driver for the introduction of hydraulic steering systems without mechanical fallback in this sector have been huge vehicle dimensions resulting in high steering torques also due to heavy-duty tires. Moreover, autonomous driving plays an important role in some off-road applications.

In the agriculture sector, John Deere has presented the ActiveCommand Steering (ACS™) system. The ACS steering system offers a wheel-offset control, a variable steering ratio, and torque and eliminates steering wheel drift. The system consists of a power supply, a feedback unit, two controllers, control valves, and an electric-driven backup pump. In case of a lack of oil, the latter one supplies the oil to the steering system and brakes. The feedback unit applies light feedback in field use, slightly heavier feedback in transport mode and cornering at high speed. The system is able to correct minor tire angles, for example, when forward driving, to reduce necessary driver corrections. Considering the sensor technology, the system comes with a gyroscope to measure the tractor yaw

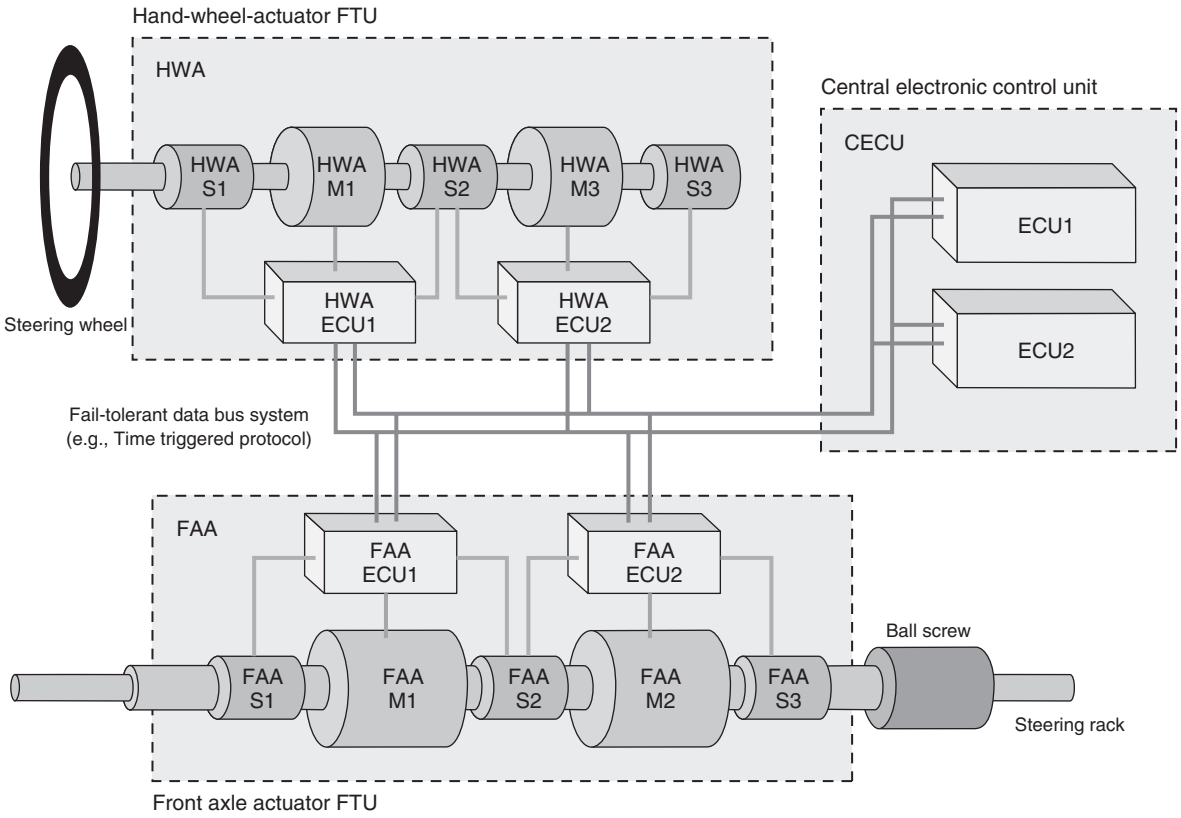

Figure 5. Fault-tolerant steer-by-wire architecture. (Reproduced from Wallentowitz and Reif, 2006. With kind permission of Springer Science+Business Media.)

rate, wheel angle sensors, and steering wheel angle sensors. The ACS is designed to fail operational. Basically, every function is backed up by another component. Thus, the primary controller is replaced by the second one in case of a fault. If the alternator power fails, the battery takes over. The electric-driven backup pump resumes control and supplies hydraulic oil to the system if the engine quits running (NN, 2012).

Other well-known examples are specialized heavy-duty vehicles for transporting, for example, production plants, which comprise several actively steered axles. In these applications, the angle and vertical travel of each wheel is controlled individually and actuated hydraulically.

In aviation technology, fly-by-wire systems are already state of the art. Besides the reduction of weight and volume, fly-by-wire systems offer the possibility of a variable computer-aided flight control. Binfet-Kull (2001) describes, among other advantages, the ability to handle the steering input feeling and the electrical transmission of pilot input signals along short to long distances within a short period of time at minimal energy. In addition, saving time-consuming adjustments of the mechanical steering system reduces assembling and maintenance costs. Binfet-Kull (2001) points out that the demands on steer-by-wire systems compared to fly-by-wire systems differ in major aspects. Examples are the danger potential, the highly trained operation personnel, and the maintenance intervals. First, if a fly-by-wire system fails, this breakdown could directly affect hundreds of human lives. Second, in comparison with normal car drivers, pilots are highly trained personnel who learned in many flight simulator hours how to react if technical faults cause worst-case scenarios. Finally, airplanes are subject to numerous inspection and maintenance intervals, the so-called letter checks, which secure its proper operation.

4 POTENTIAL

Steer-by-wire systems are able to resolve many compromises that occur during the conventional layout process of a steering system. These potentials are widely discussed throughout literature. Binfet-Kull (2001) provides a complete list of the potentials unlocked by steer-by-wire systems:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto010
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- Free configuration of steering ratio and steering assistance
- Improvement of active and passive safeties
- Maximum potential of functionality
- Suspension design without regarding steering feedback
- Improved package situation
- Reduction of variants
- Simplification of assembly
- Introduction of new human–machine interfaces (HMIs).

These aspects can be categorized into functionality potentials, package and production potentials, and HMI potentials. These categories are discussed in detail in the following sections.

4.1 Functionality potentials

Steer-by-wire inherently allows a simple implementation of any kind of steering function. Additional hardware is not necessary and communication with other systems can improve overall vehicle functionality beyond the steering system. Several related functions of these categories such as basic steering, vehicle dynamics, advanced driver assistance, and autonomous driving are introduced in the following sections.

4.1.1 Basic steering functions

The basic functionality of a steering system can be divided into two different aspects. On the one hand, the driver needs to set the trajectory of the vehicle. On the other hand, a feedback of the current state of the steering system or the vehicle dynamics can be provided to the driver.

As in a steer-by-wire system no mechanical connection between the steering wheel and the wheels exists, traditional conflicts in the layout process can be resolved. Transmission ratio and operating force can be chosen independently and individually. Thus, the functions of a conventional steering system "variable steering assistance" and "variable steering ratio" are inherently available in a steer-by-wire system. This allows, for example, a freely designed steering feedback, which could inform the driver of a significant change of the operating force when vehicle dynamics limits are about to be reached. As the correlation of steering wheel and wheel movement depends on software only, it can be adapted depending on the actual driving situation or personal preference of the driver.

4.1.2 Vehicle dynamics control

On the basis of a steer-by-wire system, yaw-rate and sideslip angle control can be realized. As no brake forces are utilized, as would be the case in conventional electronic stability control (ESC) systems, control intervention is possible in less critical driving states and is regarded less invasive by drivers. Yih (2005) derives that, in an oversteering situation, control intervention by means of the steering system is more efficient. On the one hand, this is due to the fact that the resulting lever arms from the tire contact patch to the center of gravity are longer, thus influencing the yaw behavior of the vehicle more than a brake force. On the other hand, both tires of the front axle contribute to the stabilization when the invention is realized by the steering system.

Breuer and Bill (2006) show the potential of an active steering system when braking on a μ-split surface. In this situation, the driver of a conventional vehicle is required to compensate the yaw momentum by operating the steering wheel to stabilize the vehicle. The standard driver will likely lose control of the vehicle. To reduce the yaw momentum, the brake force on the μ-high side can be reduced by the antilock braking system (ABS) leading to a longer braking distance. By controlling the steering angle, the yaw momentum can be compensated and maximum possible traction can be used to obtain the minimum braking distance. Results from the EU-project PEIT (powertrain equipped with intelligent technology) (Maisch *et al.*, 2005) show that these advantages can also be transferred to commercial vehicles.

In order to fully unlock the vehicle dynamics potential of a steer-by-wire system, it is necessary to integrate the steering control system into a global chassis control (GCC) system (Semmler and Rieth, 2004; Krüger, Pruckner, and Knobel, 2010). With this holistic approach, all degrees of freedom of the integrated chassis control systems can be used to obtain maximum driving dynamics performance. Consequently, the steer-by-wire system can provide a change in yaw momentum in any driving situation in combination with other chassis systems, not only in critical driving situations, but also during normal driving, for example, in order to compensate crosswind or road disturbances. Installing a more complex steer-by-wire system, for example, with individual wheel steering actuation, it is possible to extend the limits even further, as the friction potential at every wheel can be used in an optimal manner (Eckstein, 2012).

4.1.3 Advanced driver assistance systems (ADAS)

Steer-by-wire systems provide the best possible prerequisites to integrate the steering system into advanced driver assistance system (ADAS). Possible applications include functions such as lane-keeping and lane-change assistance and reverse driving trailer assistance. Another

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto010
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

possible feature is (partly) autonomous parking, allowing to smoothly maneuvering the equipped vehicle hands-free into a parking space. Compared to conventional approaches to introduce these functions using an electromechanical steering or a superimposed steering system, steer-by-wire systems allow a realization without steering wheel movement or torques that need to be supported by the driver. Thus, also autonomous driving as demonstrated by Deutschle (2006) can be implemented. Steer-by-wire systems are able to completely fulfill any requirement of autonomous driving as the steering actuation is designed to perform any steering maneuver.

4.2 Package and production potentials

Two main package advantages result from the absence of a mechanical connection between steering wheel and the wheels. First of all, the absence of a steering column allows much better space utilization in the engine compartment as no specific packages have to be considered for right- or left-hand drive. In addition, during a frontal crash, there is less likelihood that the impact will force the steering wheel to intrude into the driver's survival space (Yih, 2005). In case of individually actuated steering of the wheels, the space usually occupied by the lateral connection, for example, by the rack and pinion steering gear is vacant as well.

Secondly, the entire steering mechanism can be designed and installed as a modular unit, thus leading to higher production volumes and easier assembly. Especially for commercial vehicles, the assembly process can be revolutionized with the introduction of steer-by-wire. Today, the chassis and the driver's cab are integrated at a very early stage because of the difficult assembly of the multipart steering column. Steer-by-wire would permit to assemble the chassis and the driver's cab independently, joining them at the very end of the production line. This would save significant space in the production plant and allow a more efficient task sharing.

Thirdly, steer-by-wire would allow an integrated cockpit concept including the steering device. Apart from advantages in production, this concept allows a significantly larger spread of vehicle derivatives especially with respect to the seating position and dashboard height. This is due to the fact that the mechanical steering column determines the angle of the steering wheel, which has a large effect on the driver's posture and is thus an important limiting factor.

4.3 HMI potentials

As, in a steer-by-wire system, operating forces are not directly transferred from the operating element to the wheel, the steering ratio between interface and wheel and the amplification of steering torque can be designed without any restrictions. In literature, this feature is sometimes referred to as *full steer-by-wire functionality*.

The benefit of freely designing the steering transmission ratio is the possibility to reduce the steering effort at low speeds and tight turns or while parking as well as to ensure a precise and stable control at high velocities. In contrast to a superimposed steering system, the spread in steering ratio is not limited by the fact that, in case of a failure, the ratio step must not exceed a value of about two points (e.g., from 17 to 19) in order to maintain sufficient controllability (Freitag *et al.*, 2001). In addition, without a direct mechanical connection between the steering wheel and the road wheels, noise, vibration, and harshness (NVH) from the road no longer have a direct path to the driver's hands and arms through the steering wheel (Yih, 2005), thus increasing driving comfort.

Owing to the lack of necessity to apply the complete steering forces manually in case of a disabled power steering system, it is possible to introduce new and innovative steering controls to steer the vehicle. Winner and Heuss (2005) conclude that the use of a steering wheel is caused by the historical development of motor vehicles and does not necessarily need to be continued when steer-by-wire systems are introduced. Among many options, Winner believes that the most likely successful option would be an active joystick, that is, a force actuated stick that is located at both sides of the driver and provides an appropriate steering feedback. As early as 2001, Eckstein shows that this operating concept is suitable for controlling a passenger car (Figure 2). His investigations in a motion-based driving simulator show that novice drivers are able to learn to operate a vehicle with sidesticks just as well as a vehicle with a conventional steering wheel and pedals.

Another option, which arises, is the possibility to allow vehicle control from several positions inside or even remote control from outside a vehicle. This is especially of interest in special-purpose vehicles and heavy-duty trucks and already state of the art.

Winner and Hakuli (2006) introduce a consistent advancement of the steer-by-wire concept. Their paradigm of conduct-by-wire removes the driver from the vehicle stability control loop leaving the responsibility to command the vehicle on the guidance level. The vehicle will be controlled by passing maneuver commands to the system. The actuation of the individual vehicle variables, that is, driving and braking torques as well as steering angles, is determined by a centralized controller and executed autonomously. The responsibility to monitor proper operation of the vehicle remains with the driver. To implement this innovative driving paradigm, a complete x-by-wire

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto010
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

architecture of the vehicle is required as well as a very complex sensor concept to capture the environment. The conduct-by-wire approach merges today's ADASs and vehicle stabilization systems into one complex vehicle conducting system.

5 CHALLENGES

Among the powerful potentials that can be realized by deployment of a steer-by-wire system, many challenges originate from it as well. Some of them are discussed in the following sections.

Two main aspects that have to be mentioned are reliability and safety. Besides these technical challenges, perception and acceptance by customers also play an outstanding role for possible success of this technology on the market. Acceptance also depends very much on costs.

In addition to technological and economic challenges, *legal aspects* also need to be addressed. While the relationship among the authorities, the manufacturers, and the driver is not affected in the first place, a clear definition of responsibilities between the vehicle manufacturer and the supplier of a steer-by-wire system is decisive and will also affect the development process and the system layout itself. The legal aspect is discussed first in the following section.

5.1 Legal requirements for steer-by-wire systems

Legal requirements such as the ECE reg. 79 (2005) define rules regarding the approval of steering equipment for vehicles. Revision 2 of the ECE reg. 79 (2005) from 2005 considers the advancements in steering technology and the advantages of steer-by-wire systems compared to steering systems having a mechanical link. Thus, it is nowadays possible to approve steer-by-wire systems having no mechanical connection between wheels and steering control.

According to the definition of ECE reg. 79 (2005), steer-by-wire systems belong to the steering equipment classification of full-power steering equipment. Solely one or more energy supplies provide, that is, the steering forces.

The ECE reg. 79 (2005) provides additional requirements that full-power steering systems need to fulfill. Regarding the system design, the regulation specifies different failure provisions:

- A failure in the transmission that is not purely mechanical has to be indicated to the vehicle driver via predefined warning signals. In this failure mode, a change in the average steering ratio is allowed only if the steering effort is not exceeding a predefined maximum effort value of 300 or 450 N over a period of time of 4 or 6 s, both values depending on the vehicle category.
- In the event of a failure in the energy source of the control transmission, the vehicle having an energy storage level at which the failure was signaled to the driver should be able to drive at least 24 "figure of eight" maneuvers with a loop diameter of 40 m at a velocity of 10 km/h with the same performance level given for an intact system.
- If a failure in the energy transmission occurs, with the exception of the parts not liable to breakage (e.g., steering column), no immediate change in the steering angle is permissible. A vehicle, still able to drive faster than 10 km/h, has to fulfill all test provisions after having finished at least 25 "figure of eight" maneuvers with a 40 m diameter at 10 km/h minimum speed. The energy storage level at the beginning of the test maneuver has to be the same as in the failure of the energy source of the control transmission.

The development process of steer-by-wire systems has to be in accordance with relevant standards, such as the ISO 26262, which address the functional safety of road vehicles. According to the ECE reg. 79 (2005), the manufacturer of complex electronic vehicle control systems has to accomplish specific requirements for documentation, fault strategy, and verification with respect to the safety aspects. Concerning the fault strategy, the design process has to guarantee the safe operation of the vehicle fail-safe procedures, required redundancies or necessary driver warning systems. ECE reg. 79 (2005) gives examples for design provisions for a system failure, which are for example

- fallback to operation using a partial system,
- change over to a separate back-up system, and
- removal of high level functions.

In summary, for approval of such a safety-critical system, the manufacturer has to provide a complete documentation of the transparent design process and on the system means to guarantee its safe operation.

5.2 Technical challenges

From legal requirements, customer demands, and OEM (Original Equipment Manufacturer) design goals, a complex list of technical challenges results. Accordingly, some of the most important challenges include the provision of functional safety, acceptable steering feel, and reducing costs and weight.

5.2.1 Safety

While mechanical systems are considered inherently safe, as a mechanical failure can be detected by inspection and is unlikely to fail in a sudden manner when properly designed and used within its specification boundaries, a mechatronic system can fail without prior signs of damage or wear. Thus, great care has to be taken designing a system that ensures a safe operation as well as acceptable reliability.

To achieve a safe state of a vehicle when a system failure occurs, it is obviously sufficient if the vehicle is stopped at a suitable location, for example, the emergency lane of a highway. To reach this safe state, it is important that any fault does not lead to an instable reaction of the vehicle and that the vehicle remains controllable by the driver during the emergency maneuver. This means that

1. the initial effect of a fault must be limited,
2. the cause of the fault is detected and addressed within a finite time (typically some milliseconds), and
3. the resulting vehicle behavior can be controlled safely by the driver.

Customer requirements by far exceed the demand for a safe system according to the earlier definition. System reliability plays an important role in terms of availability of all system and vehicle functions, as it greatly affects customer acceptance and warranty costs for the OEM. Depending on the likeliness of a fault occurrence and the presumed consequence, the developer needs to decide, which countermeasures need to be taken to reach a system reliability that guarantees sufficient availability.

A comparison to current solutions in the aeronautical industry shows that the general approach is to maintain control over the vehicle with no or only manageable interruptions. This can be achieved by either introducing redundancies that are able to fulfill the original functionality without limitations or time limited, thus providing a fail-operational behavior. Examples for redundancies are duplicated bus systems to ensure data transmission or additional batteries that allow further operation of the system for a limited time in case the main power supply should fail.

Besides the deployment of redundancies, a restricted functionality resulting from a failure of a subsystem or a combination of different faults is often commonly used in aeronautics. For example, it is possible to operate an airplane using only some of the available control surfaces. The plane is still controllable although some maneuvers might not be possible. This state of the system with reduced functionality is referred to as a *degraded state*.

Within the automobile industry, the concept of degraded states is used as well. ESC systems will be deactivated in case of a detected fault, whereas the basic hydraulic brake system is still in operation. Similarly, steering assistance by a power steering system is deactivated when a fault occurs. Both breakdown situations are accepted as a safe state although functionality and controllability are considerably reduced.

Proposals for steer-by-wire system architectures including suggestions for redundancies and degraded states can be found in literature (Binfet-Kull, 2001; Freitag *et al*., 2001; Heitzer, 2003; Wallentowitz and Reif, 2006; Hayama *et al*., 2008). To achieve a robust vehicle behavior, fault and event detection is a key factor. In this respect, the analogy with aviation may not be valid, as the required system reaction time in a vehicle driving on the road, for example, to prevent an unintended lane departure, is usually far shorter than those of an airplane.

5.2.2 Steering feel

As for any subjective assessment of a technical system when evaluating steering systems, different approaches and criteria are used depending on brand, vehicle class, or regional preferences. When new technologies are introduced, usually their impact and acceptance are discussed controversially. When, for example, EPS was first implemented in passenger cars, the fact that the steering feel differs from conventional hydraulic power steering systems led to criticism of the innovative system for its synthetic steering feel. As EPS[1] offers several additional innovative functions such as lane keeping, automatical[2] parking, side wind compensation, and even more, it was not surprising that EPS systems significantly penetrated the market. On the one hand, this was certainly due to an improved parameterization of the system functions and a reduction in fuel consumption; on the other hand, it was also successful due to a certain habituation effect by the drivers.

Regarding steer-by-wire systems, it is evident that steering feel needs to be provided completely on a synthetic basis, which may compose of an electromechanical steering feedback actuator as well as passive elements such as springs and dampers. The passive elements can assure the stability of the dynamic behavior of the steering wheel system itself in case of a fault of the feedback actuator. Using all degrees of freedom in designing steering feel dependent on, for example, vehicle speed, lateral acceleration, road friction, or lane keeping, a considerable amount of effort is necessary to achieve an adequate steering feel in all relevant driving states (Koch, 2010). On the other hand, the freedom in designing steering feel must be regarded as a big advantage of a steer-by-wire system, as a specific steering feel can easily be provided for different vehicle

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

models and markets including parameters for individualization and customization.

5.2.3 *Costs and weight*

From an OEM perspective, using the same steer-by-wire system across many vehicle models and markets yields cost savings because of economies of scale and reduction of variants. At least part of these cost savings need to be invested in compensating higher system costs. These can be expected to be higher even compared to a superimposed steering system, as additional components are needed to provide steering feel and redundancy of the steering actuator. The precise effect of this change in technology on costs, weight, and efficiency largely depends on the specific system layout and thus cannot be quantified in general. Aspects such as the number, location and performance of actuators, and the type of driver interface will be most influential. Barthenheier (2002) expects that it will be possible to reduce cost and weight because of the fact that many parts can be removed from the system. Other sources (Fleck, 2003; Grell, 2003) state that no positive effects are to be expected as the effort to achieve a safe system with redundancies will overcompensate the advantages. In the end, the success of *steer-by-wire systems* will largely depend on whether or not the customer has to expect additional costz for the system. This refers to purchase as well as to operating and maintenance costs.

Regarding the development cost for steer-by-wire systems, as for any complex technical innovation, the initial research investment is very high. If steer-by-wire systems are introduced in a small segment such as luxury vehicles, development costs are hardly acceptable (Winner *et al*., 2004). If, on the other hand, steer-by-wire would be widely introduced in mass production, the risk from an economic and marketing point of view is high if a large number of vehicles need to be recalled in case of quality problems.

5.3 Customer acceptance

When steer-by-wire systems are introduced to the automotive market, they will have to compete with current modern steering systems. As described earlier, steer-by-wire systems do have significant advantages regarding possible steering functions, although the advantages might not be immediately evident for the average driver. The main marketing challenge for the successful introduction of steer-by-wire systems will be to clearly communicate the advantages of the new and innovative system.

Whether this will be possible is not assessable from today's perspective, as customer acceptance is dependent on many influences and is hardly ascertainable in an early stage of the development process as Binfet-Kull (2001) states. Daniels (2003) expects that a major challenge will be skepticism toward the safety of a steering system lacking a mechanical connection between the steering wheel and wheels. The mechanical system has proved its reliability in recent decades and in general customer perception it is regarded as safe, whereas many drivers have already experienced failures of electrical systems—whether in their car or using consumer electronics.

The first steer-by-wire systems thus need to comprise a very convincing safety concept, which is highly effective and reliable. Communication should focus on evident benefits of such a system and ideally avoid the term *by-wire* in order to generate a positive perception of this promising innovation.

6 SUMMARY

While substantial research on steer-by-wire systems has been carried out over the past decades, this innovative approach has not made its way into volume production. Active steering systems superimposing an additional steering angle to the driver's command can be regarded as forerunner of steer-by-wire, as their performance would be sufficient to influence lateral vehicle dynamics under normal driving conditions while holding the steering wheel straight. In contrast to steer-by-wire, the torque provided by the steering actuator needs to be counterbalanced by the driver, and in case of a system malfunction, the mechanical steering column represents a well-known fallback.

While active steering and electric-powered steering systems already enable innovative functionality regarding vehicle stabilization and advanced driver assistance, full steer-by-wire systems offer three areas of potential: firstly, 100% freedom in designing the functional relationship between the operating device and the steered wheels, secondly more flexibility in package and production yielding time and cost savings, and finally maximum design freedom regarding the driver's working place.

On the other hand, the market introduction of steer-by-wire systems faces some major challenges: apart from legal requirements, the main challenge concerns the provision of functional safety while at the same time limiting the costs due to resulting requirements, for example, on redundancies of sensors, communication, and actuators. Finally, customer acceptance is the prerequisite for market success—the benefit of the introduction of steer-by-wire has to be understood immediately providing a unique driving experience.

Performance Target Conflicts in Normal Tires and Ultrahigh Performance Tires

Reinhard Mundl and Burkhard Wies
Technische Universität Wien, Vienna, Austria
Continental, Hannover, Germany

1 INTRODUCTION

Few people are aware of the fact that we are surrounded in our daily life almost everywhere by tires. Although they are often perceived as commodity, we all rely strongly on the high quality of their performance. Beside the very basic safety-related tire properties of durability and robustness, there is a bundle of the so-called additional tire performances such as grip on all surfaces, mechanical and acoustic comfort, safe handling properties, and, last but not least, a long lifetime. In recent times—also driven by legislation such as the new EU tire label—additionally, low rolling resistance has become important as a means to reduce fuel costs and climate change.

Unfortunately, these entire tire properties cannot be improved simultaneously. Each change in the tire's design that leads to an improvement in one specific tire property often leads to a trade-off in another one. It is now the demanding job of the tire engineer to come up with a well-balanced optimum for all the tire performances to satisfy the needs of the customers. Intensive research in tire technology and a deep know-how is needed to identify innovations to shift conflicting tire properties to a higher level. This chapter describes in the following these conflicts and provides the underlying rubber physics and tire mechanics.

2 PRODUCT DEVELOPMENT STRATEGY BY ENHANCING TARGET CONFLICTS

At the very beginning of the development of a new tire line stands the definition of a performance requirement book, which is based on competition analysis, marketing needs, and customer—more specifically, original equipment—requirements. This "book" covers tire performances, which are in most cases listed in relation to a reference tire. The differences are quantified by the relative deviation in percentage. More than a dozen of these tire performances define the strengths and weaknesses, which represent the individual character of a tire line on the market.

As an example, see the multidimensional presentation of tire competitors in a simplified, the so-called, spider graph in Figure 1. It shows on each ray the respective relative

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

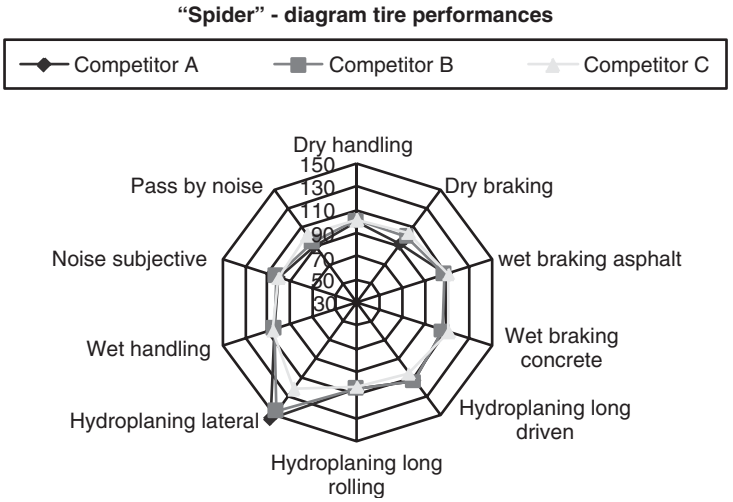

Figure 1. Multidimensional presentation of selected tire performances.

tire performance, thus delivering a specific picture of each competitor. The improvement of a single tire performance conflicts often with another one, making it very difficult for the tire developer to find a new optimum for all of them on a higher level. This sort of multitasking challenge can be easier overseen if one tries to achieve an improvement within a so-called performance conflict, neglecting the interactions to other performances. Owing to tire physics, conventional design changes of specific tire components cause only a shift along a so-called performance conflict line, thus improving only one performance but diminishing the conflicting one. This sort of adaption to changing targets is state of the art for an experienced tire designer, whereas innovative measures improve both performances at once and lead to a higher level perpendicular to the conflict line (Figure 2).

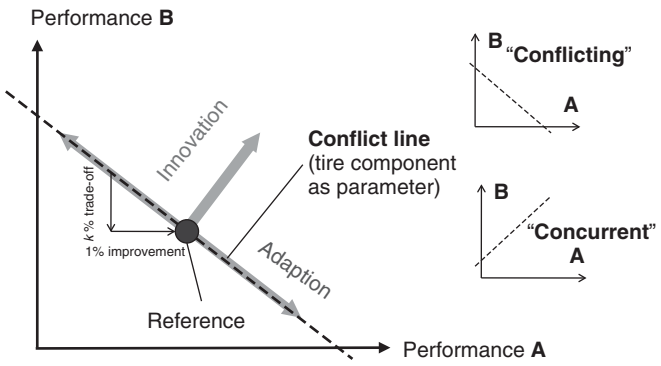

Figure 2. Schematic tire performance conflict diagram, distinguishing oriented measures of adaption and innovation and classification of dependencies.

3 SYSTEMATIC IDENTIFICATION OF TARGET CONFLICTS BY MULTIPLE PERFORMANCE ANALYSIS

From a mathematical viewpoint, if one has a number of n tire performances under investigation, a number of $n(n-1)/2$ target conflicts are possible. Regardless of the underlying physics, one can analyze the results of basic tire programs, where the influence of the change of a specific design parameter on a set of tire performances has been tested. This approach allows for rules of thumb to quantify the existing target conflicts. In particular, this leads to a ratio describing the decrease of performance B of $k\%$, when performance A is increased by 1%. In terms of mathematics, this ratio stands for the inclination k of the so-called conflict line to be seen in Figure 2. This conflict line can be extracted from the test results by applying linear regression analysis and is equivalent to the regression line.

Making these regressions, we can distinguish pairs of tire performances, which are *conflicting*, meaning that the inclination k is negative, and pairs of tire performances, which are *concurrent*, defined by a positive inclination, see again the visualization in Figure 2. It is noteworthy to mention that the described conflicting behavior has always an underlying change in a specific design parameter that can be positioned on the conflict line.

This sort of data mining has been done by Continental utilizing test results collected by the winter tire predevelopment department over almost one decade to get an overview on existing target conflicts for tread pattern variations (Figure 3). As mentioned at the beginning of this chapter, from the 13 tire performances investigated, 78 dependencies

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

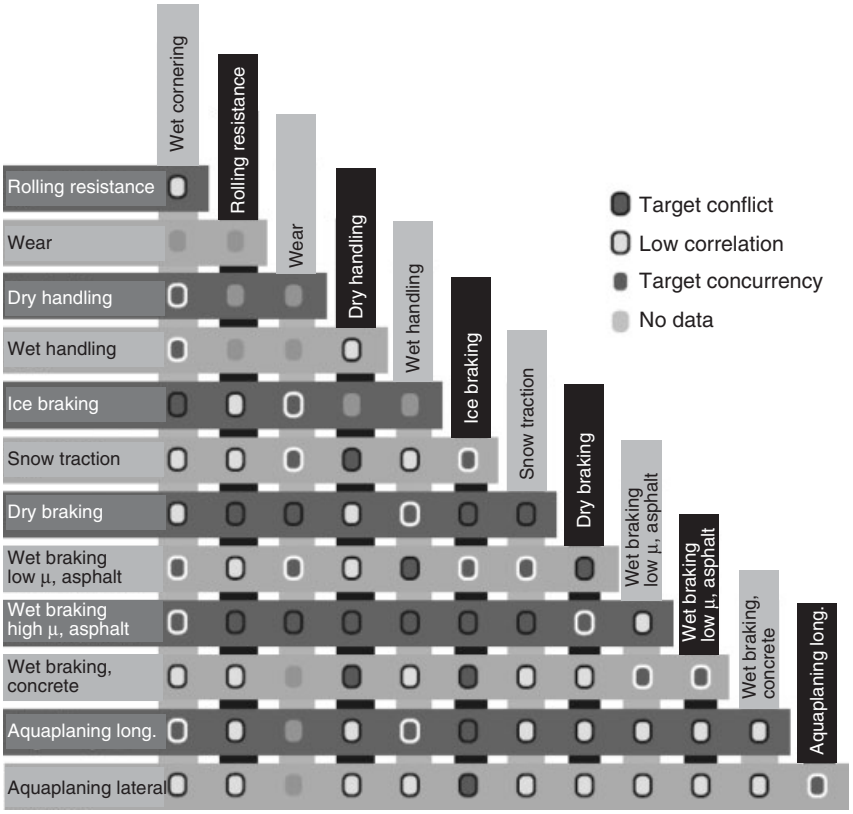

Figure 3. Overview of tire performance conflicts/concurrencies for winter tires.

were analyzed, out of which 18 are conflicting. An example for such a (pattern-inherent) performance target conflict, which can be explained by tread pattern mechanics, will be given in the following chapter.

4 DESIGN POTENTIAL OF MAIN TIRE DOMAINS AND RELATED TARGET CONFLICTS

Within a tire design, one can distinguish four main domains with significant influence on tire performances, the tread pattern, its compound, the outer shape of the cross section, named contour, and the tire carcass including the belts and cap plies (the latter domain herein summarized as construction). A qualitative estimation of the performance potential of design changes within these domains can be found in Heißing and Ersoy (2007) and is to be seen more detailed in Figure 4.

4.1 Tread pattern

From Figure 4, it can be seen that the tread pattern most influences grip on different surfaces and noise. Especially with media on the road, such as water, snow, or ice, the edges within a pattern, from blocks and tire sipes, contribute significantly to tire grip. In a large basic program, published in Doporto *et al*. (2003), a series of patterns ranging from ultrahigh performance (UHP) summer tires to highly siped Scandinavian tires have been tested in their interactions with a similar wide range of tread compounds.

From these results, we take as an example the dependency of wet and dry braking on the density of edges in the patterns structure (Figure 5). The rule of thumb for this *pattern-based conflict between wet and dry braking* consists in the same amount of trade-off for dry braking when one tries to improve wet braking by adding sipes to a pattern structure. This conflict can be explained by different frictional effects of the rubber edges: on a wet surface, the leading edges improve braking by wiping away the lubricating water film; on a dry surface, the trailing edges lift off because of higher frictional forces thus reducing the local contact area and in consequence dry braking.

For the tread *compound*, one sees a *concurrency between wet and dry braking*, where the improvements in dry braking are about only a third of the ones in wet braking. Both performances are concurrent because they are both

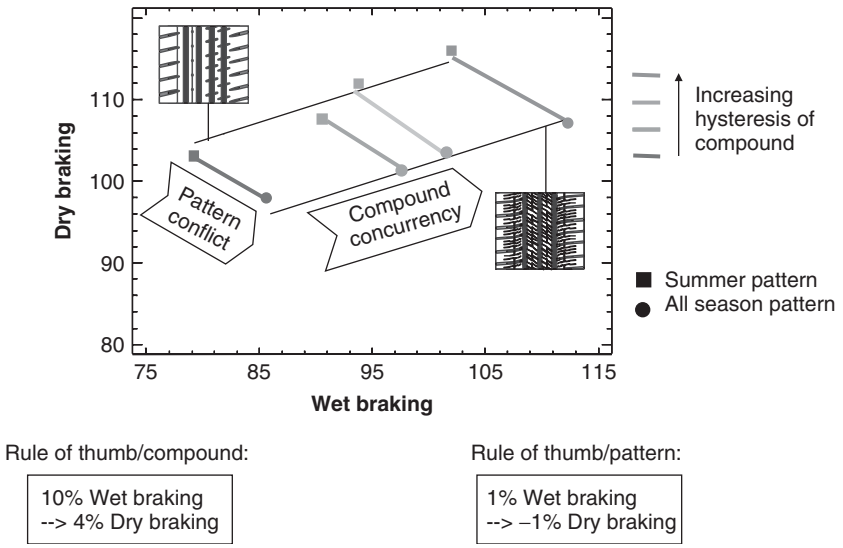

Figure 5. Example for tread induced performance conflict/concurrency and related rules of thumb.

caused by the traction physics of the compound's hysteresis. Its larger contribution to wet braking might be explained by a larger spread in hysteretic compound behavior at lower local contact temperatures because of the cooling effect of the intermediate water film.

Another extensive basic study, investigating the effect of pattern void on all relevant tire performances, was published in Mundl, Roeger, and Wies (2009). In Figure 6, one can see all major and minor conflicts/concurrencies visualized in a kind of balance: conflicting performances can be found on opposite sides of the balance and concurring performances on the same side. The lengths of the levers indicate the change in a specific property while increasing the void of the tire pattern by 1.5%. By void, one understands the empty space in a pattern realized dominantly by grooves in relation to the tread volume of the respective smooth tire. Opposing levers of a pair of properties signal a performance conflict and quantify the related rule of thumb by the levers' lengths.

The main conflict to be influenced by *void* is the one between *hydroplaning and tire noise*. Increasing of void delivers more space for water for drainage, thus increasing the critical speed at lift off of the tire's contact patch by a water wedge. By contrast, when larger grooves contact the road surface, more air volume is stimulated to vibrate and to emit noise. To a lesser extent, we encounter also the above-described conflict between braking on wet surfaces and dry ones. Less known is a conflict for winter

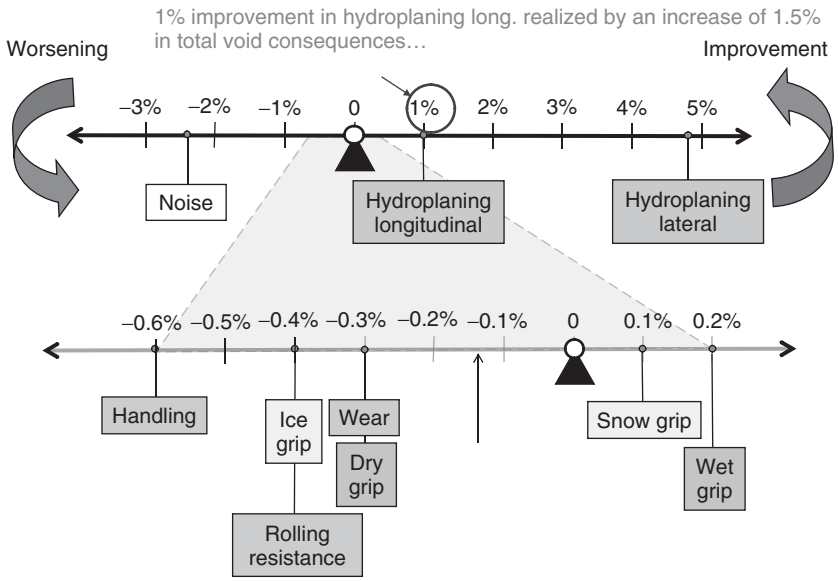

Figure 6. Pattern void based quantified conflicts/concurrencies. (Reproduced from Mundl, Roeger and Wies, 2009. © The Tire Society.)

tires, namely between traction on snow and ice. Owing to increased sinking into the snow, additional void is better for interlocking between the soft snow and the tread pattern, whereas on stiff ice, the contact area is relevant for braking. Finally, more void weakens the tread's structure and, in consequence, cornering stiffness, which is relevant for handling. Less void means also having more rubber available to wear thus increasing the rolling distance over lifetime. On the other side, the higher vertical deformations of the smaller rubber blocks under contact pressure induce higher hysteresis loss and increase rolling resistance.

It has to be mentioned that some of these results are inconsistent with those in Figure 3. The results, documented in Figure 3, are elder ones and mainly based on variations in sipe technology at constant void. Obviously, one has to be careful with general statements on performance conflicts and has to consider always in detail which influencing parameter is the dominant one in steering the conflict!

4.2 Tread compound

Figure 4 shows the dominant influence of the tread compound on braking, winter performance, rolling resistance, wear, and handling. Four of these capabilities can be found in the so-called "magic triangle," which visualizes the challenges for a rubber chemist (Figure 7). Centrally located is the wet braking behavior, being also most important from a driving safety viewpoint. It conflicts not only rolling resistance but also winter performance and wear.

Especially the conflict between *wet braking and rolling resistance*, which according to Societe de Technologie

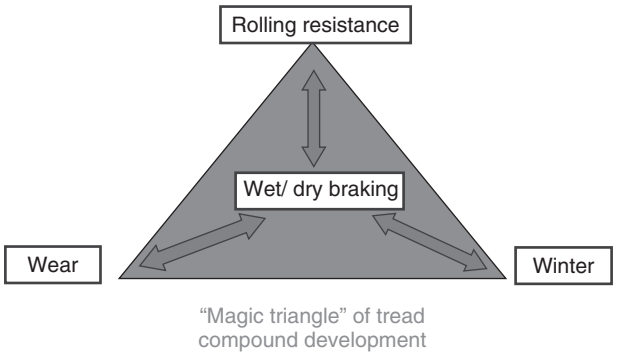

Figure 7. Schematic presentation of main tire performance conflicts influenced by tread compound.

Michelin (2005) causes about 20–30% of cars fuel consumption, must be dealt with in depth. For the reason of this conflict, both performances will be made transparent to the consumer by help of a future tire label classifying these performances by characters from A to G [see the related legislation from the European Union in des Europäischen Parlaments und des Europäischen Rates (2009)]. The material property causing this conflict is the hysteresis of rubber, measurable by the so-called loss angle δ. This loss angle significantly depends on the temperature, as shown in Figure 8. As rolling resistance is 50% because of the tread compound, we have to consider its operating temperature around 50°C and its operating frequency of deformation of about 10 Hz, which is also the excitation frequency of the measurement in Figure 8. Therefore, it can be concluded that the indicated dark gray

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto012
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

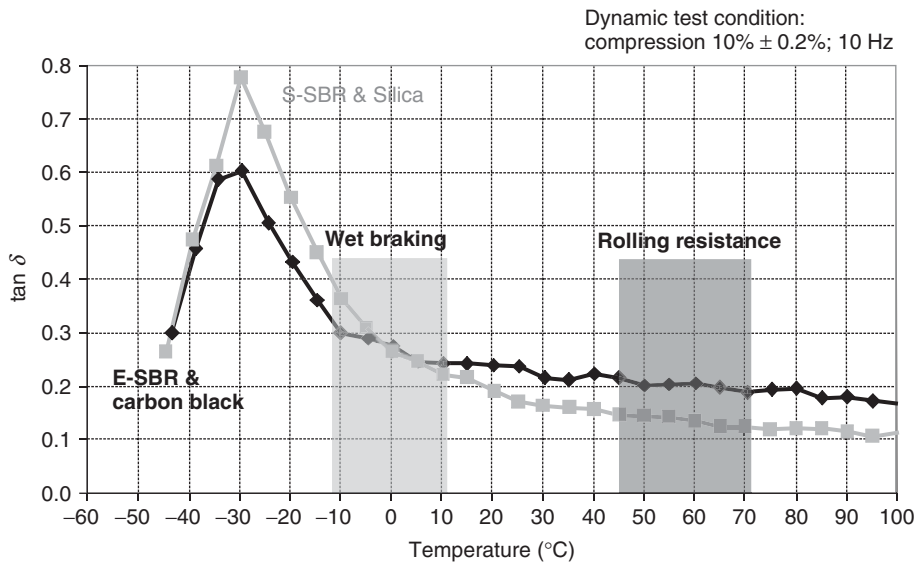

Figure 8. Loss angle as function of test temperature with correlating temperature ranges to rolling resistance and wet braking.

temperature range is the range of correlation in ranking between measured tan δ and measured rolling resistance. The light gray correlation range for wet braking is located around 0°C because of the underlying hysteresis friction mechanism, described in Kummer (1966), which operates around excitation frequencies of 10^4–10^7 Hz, depending on the roughness of the road and the sliding speed of the tread blocks. To make the conclusion complete, one has to consider the equivalence between temperature and dynamic excitation for rubber (Clark, 1982): qualitatively spoken, this stands for the phenomenon that rubber behaves equally when a colder operating temperature is compensated by a higher loading frequency and vice versa. This fact explains the shift of the correlation range for wet braking in regard to rolling resistance to lower temperatures.

One can now overcome the conflict between wet braking and rolling resistance only by changing rubber chemistry in a way that tan δ is increased at lower temperatures and decreased at higher temperatures. This happened with the introduction of silica as substitute for carbon black in the mid-1990s, shown by the light gray curves compared to the black curve in Figure 8. The tremendous progress in reducing this conflict since then, achieved by the rubber industry, is shown in Figure 9. It gives hope that, by use of new rubber materials, this most important conflict will be reduced significantly in future.

The conflict between *wet braking and winter capabilities* can be explained by a shift of the graph for the loss angle δ to negative temperatures. This shift is necessary to achieve winter capabilities by maintaining, under winter temperatures, the flexibility of rubber that is responsible for enhanced traction on snow and ice (Mundl, Wiese, and Wies, 2011). Doing so, one can deduce the lower ranking of those compounds in the temperature range for wet braking at 0°C. The conflict between *wet braking and wear* can be illustrated by the molecular model of the internal damping of rubber: it can be imagined as the energy consuming sliding of the molecular chains of polymers attached to the graphite crystal surfaces of the filler material, carbon black, by van der Waals forces. Hindering this internal sliding increases the internal cohesion and in consequence wear resistance but it lowers hysteresis necessary for wet braking as well.

4.3 Tire contour

A tire contour can be characterized by two main parameters: the radius of the tread and its width. These parameters span a two-dimensional plane qualitatively limited by the terms small/large and narrow/wide, wherein the optimal location of several tire properties are marked qualitatively (Figure 10). With round and narrow treads, the drainage of water is eased because of laterally shorter flowing distances for expressing water and a *hydrodynamic* better suited oval shape of the contact patch for plowing through the water layer. *Noise* is reduced because a narrower leading and trailing edge of the contact patch sees less impacting and snapping out of tread structures. The rounder shape of the contact patch has probably a more uniform and therefore less lateral noise radiation.

These tire performances *conflict* now with less *rolling resistance* and *wear* with a flatter curvature. This fact can

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

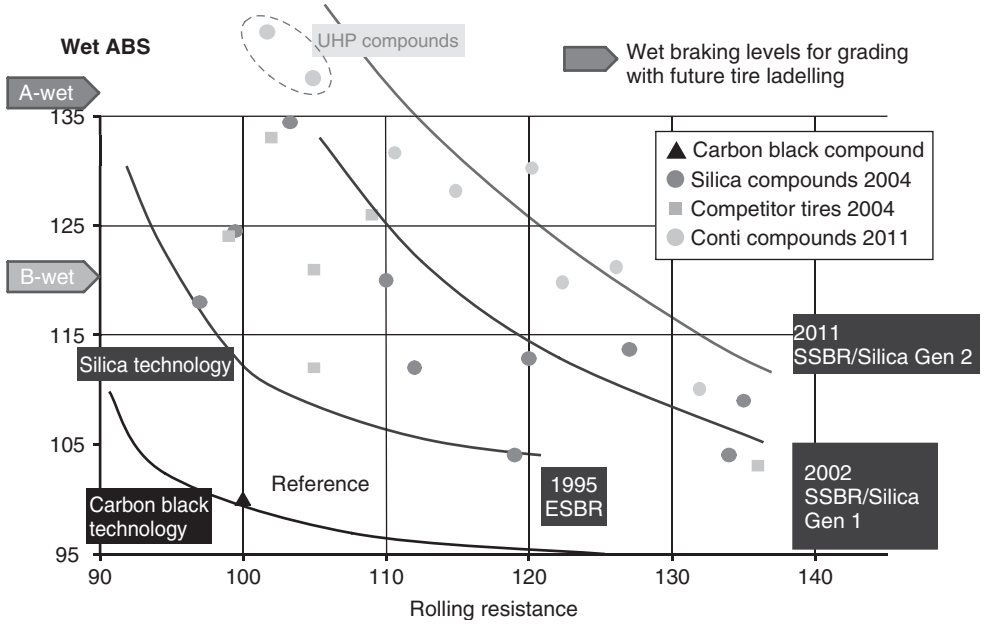

Figure 9. Evolution of the performance conflict between wet braking and rolling resistance from 1990 to 2008.

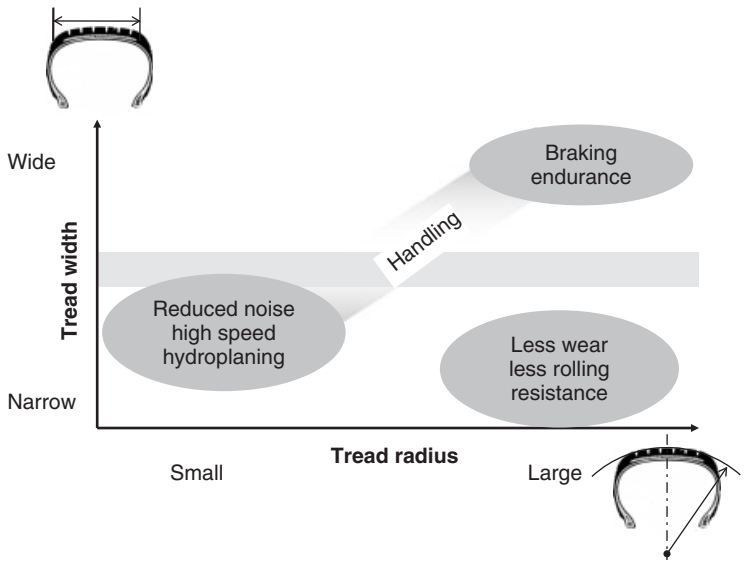

Figure 10. Target conflicts, resulting from tire contour variations.

again be explained with less energy input for flattening the tread structure resulting in a lower amount of internal damping and less frictional energy, which is responsible for abrasion.

They *conflict* also with *braking* capability, which improves with wider treads. This fact can be explained with a shorter contact length, which reduces opposed shear forces in the longitudinal direction, diminishing the overall friction potential.

4.4 Tire construction

Tire construction is first responsible for the endurance and durability of a tire. Secondly, it serves to optimize handling properties. It holds also for about 50% of rolling resistance. The dominant performance conflicts are therefore the ones between *durability/handling versus rolling resistance*. To make, for example, the tire sidewall more resistive against punctures under bad road conditions, a thicker rubber

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto012
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

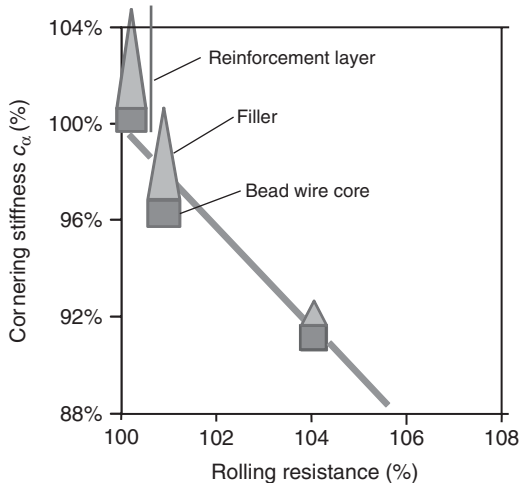

Figure 11. Conflict between handling and rolling resistance controlled by bead stiffness (various schematic bead designs).

coating and an additional ply are necessary to protect the reinforcing cords. This of course increases rolling resistance because more energy is needed to deform the thicker sidewall. For better handling, stiffening of the bead area by a higher apex often helps. Again more material is needed and increases rolling resistance, as can be seen in Figure 11. Therein the different bead constructions are indicated by symbols. The dark gray area stands for the bead wire layers, the light gray area for the apex rubber, and the gray line for the textile reinforcement layer. The textile reinforcement is only influencing the cornering stiffness, not the rolling resistance. Figure 11 shows that 2% increase in cornering stiffness leads to a change of about 1% in rolling resistance.

5 TARGET CONFLICTS OF UHP TIRES

5.1 Description of virtual development process

The development of UHP tires is dominated by the improvement of the three following performances: handling, high speed capability, and wear on race tracks. To shorten the development process and to save costly testing efforts, a major part of the development process has become virtual, which means to achieve handling requirements by simulation of virtual prototypes. Following Fischer *et al*. (2010) and visualized in Figure 12, the interface between tire evaluation and tire design is defined by tire target characteristics. In particular, a corridor in cornering stiffness for front axle (FA) and rear axle (RA) and increased lateral grip limits has to be achieved by the proposed tire variants under investigation. Both properties can be identified in the side force/sideslip angle dependency shown in Figure 13. The cornering stiffness is the inclination of above-mentioned dependency for slip angles up to 3°, whereas the grip limit is achieved at high slip angles. On the one hand, the cornering stiffness results only from stiffness properties of the tire, in particular the tread pattern stiffness and tire body stiffness connected in series. On the other hand, the grip limit is dominated

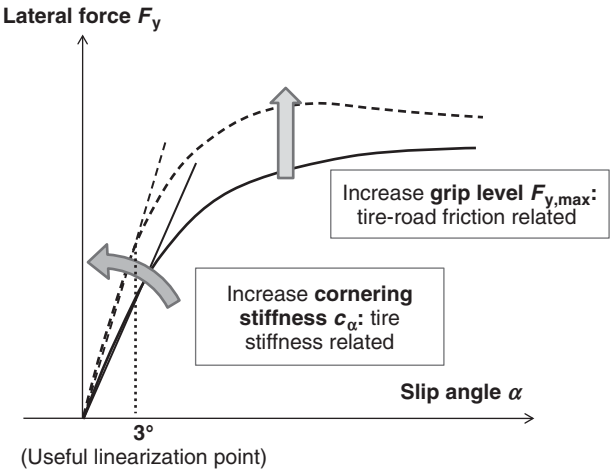

Figure 13. Main parameters of lateral force/slip angle behavior.

by the frictional properties of the sliding tread influenced by tread pattern structure and tread compound in reaction to the road surface. In a first loop of the virtual development process, the proposed tread pattern variants are simulated in their lateral stiffness; this shows the potential for improvement, the cornering stiffness being relevant for steering precision and driving stability. The related simulation tool is discussed in Mundl *et al*. (2008). The optimal tire pattern variant is realized in tire prototypes and checked against a base tire in its subjective handling performance on test tracks. These subjective evaluated results are associated with objective measurements of vehicle dynamics such as vehicle slip angle versus lateral acceleration (Figure 14).

In a second loop, proposed changes in tire body design are modeled and evaluated by finite element analysis in cornering stiffness and contact area. Optimization criteria are again maximal cornering stiffness and additionally maximum contact area under severe lateral forces with the consequence of an as low as possible contact pressure distribution for a maximum coefficient of friction. Again, a final vehicle handling evaluation is performed for the realized best variant to ensure the achieved targets in handling capability in serial production.

5.2 Main target conflict: grip limit versus cornering stiffness

As described earlier, it is essential for UHP tires to design them in a way that excellent handling on sports cars is achieved. This means that both cornering stiffness and lateral grip limit have to be increased and that in a way that the balance between FA and RA is maintained for the purpose of stable cornering. In general, driving at the limit may become also more challenging because of a smaller range of maximum grip (Figure 13). Inexperienced drivers may feel this as unpleasant. As grip is mostly affected by measures in the tread, a balance has to be found predominantly for the tread compound stiffness. The softer the tread compound is, the more the road asperities penetrate into the surface of the rubber blocks and interlock with them, thus producing enhanced grip. On the other hand, these softer blocks produce less lateral contact shear forces at a specific slip angle and therefore a lower cornering stiffness, as visualized qualitatively in

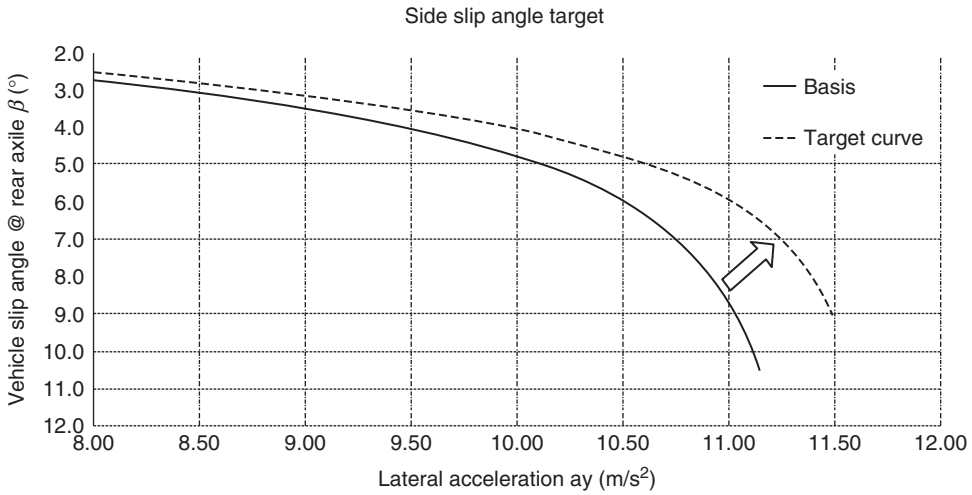

Figure 14. Slip angle at rear axle as indicator for improved grip at the limit. (Reproduced from Fischer *et al*., 2010. With permission from Aachen Colloquium Automobile and Engine Technology, 2010, M. Fischer, J. Ehlich, C. Schroeder, K. Peda and B. Wies, Continental.)

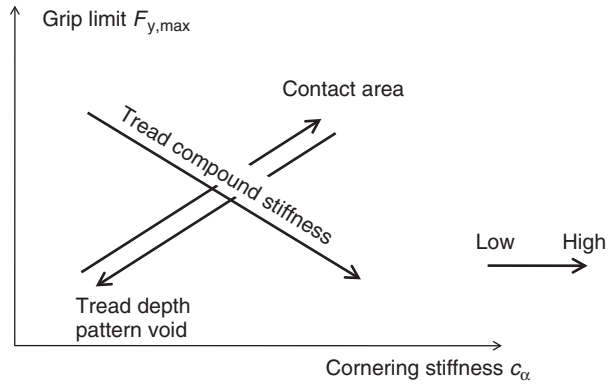

Figure 15. Qualitative influence of tire design parameters on grip/cornering stiffness conflict.

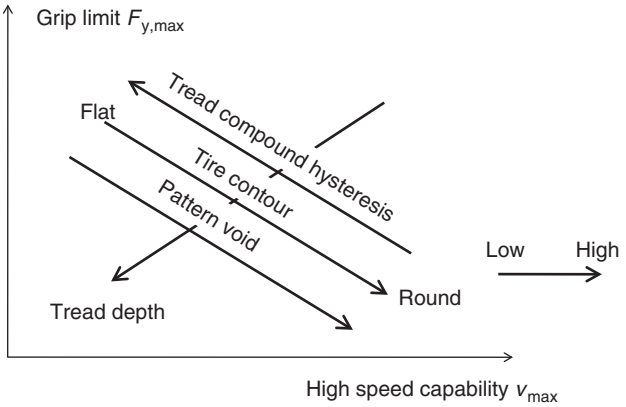

Figure 16. Qualitative influence of tire design parameters on grip/high speed capability conflict.

Figure 15. By chance, other design measures in the tread pattern, such as increased positive or a lower height of the pattern blocks, are positive for grip and cornering stiffness simultaneously (Figure 15). The same is true for a larger overall contact area of the contact patch, which can additionally be controlled by tire contour and tire body design.

5.3 Secondary target conflicts: grip limit versus high speed capability and wear

With their higher maximum speed, sports cars do need tires with a raised high speed capability. This can be in conflict to lateral grip as well (Figure 16). The hysteresis of the tread compound dominates this conflict. On the basis of the model of hysteresis rubber friction, see again the theory in Kummer (1966), a high internal material friction leads to increased grip, whereas hysteresis causes heat buildup in the rubber blocks, thus limiting maximum rolling velocity by depolymerization of the tread compound. Going back to Figure 10, we recognize therein that the contour is improving grip when it is flat but worsening high speed at the same time. The reason for this behavior is that a flat contour has a tendency to larger contact areas and better grip as mentioned earlier but causes higher pressure peaks in the shoulder area because of the dynamic growths induced by centrifugal forces and, in consequence, larger deformations and additional heat buildup. A high void in the pattern is a countermeasure for this, because it helps cooling but again negatively influences grip (Figure 16).

It has to be mentioned that resistance against wear of the tread compound conflicts also its grip capability. The explanation is that, again, higher hysteresis of the tread compound causes increased heat buildup, thus making the compound softer and less resistant to wear. The explanation is that under traction forces onto the driven axle, softer tread structures suffer from larger deformation energy in the contact area that is transformed into frictional energy at the trailing edge, resulting in increased wear.

6 OUTLOOK FOR FUTURE IMPROVEMENTS OF UHP TIRES

A conflict analysis of tire performances is helpful in giving hints where future innovations may take place. In the field of UHP tires, potential can be seen in two ways to improve the conflict between enhanced steering properties and increased grip level dominated by future compound aspects: an anisotropic compound behavior, such as higher shear stiffness and lower radial stiffness, may be achieved by oriented microfibers within the compound matrix, see also the physical reasoning in Chapter 4.2. Another vision is a deeper interaction with tire properties and advanced vehicle control systems using active steering, thus improving steering precision and handling stability even at lower cornering stiffness of the tires and leaving development space for ultrahigh grip levels.

Tire Pressure Monitoring Systems

Victor Underberg[1], Thomas Roscher[1], Frank Jenne[1], Predrag Pucar[2], and Jörg Sturmhoebel[2]

[1]*AUDI AG, Munich, Germany*

1 INTRODUCTION

The tire represents the link between vehicle and road surface. As such, the tire characteristics determine the transfer of forces between the vehicle and the road. One major factor influencing the actual tire properties with respect to vehicle handling, braking, fuel consumption, and tread wear is the tire pressure. Only with the vehicle-manufacturer-recommended tire pressures, the optimum of all the above-mentioned characteristics can be guaranteed. The recommended tire pressures do depend not only on the specific vehicle/tire combination only but also on anticipated driving conditions as vehicle load (partly or fully loaded) and travel speed (low or high).

Already in 1923, Bosch patented a mechanical device—the "Bosch-Glocke" (Bosch-Bell)—which was designed to warn the driver of under-inflated tires (Figure 1). The concept behind the "Bosch-Glocke" was that the deformation of an underinflated tire running through the contact patch activates a wheel-mounted lever, which, in turn, will ring a high frequency bell to alert the driver.

Today's tire pressure monitoring systems (TPMSs) are designed to monitor the current tire pressure in all four wheels in service—in some cases also the spare wheel—and to provide a warning to the driver if the tire pressure in at least one the wheels falls below a predefined threshold level. In general, there are three different pressure loss scenarios (Figure 2). First, there can be a tire blow out, where the tire loses all its air in just seconds because of sudden and severe tire damage, for example, by hitting a pot hole (TPMSs are not designed to warn drivers in the blow out scenario, as the driver will be alerted immediately by a sudden change in vehicle response). The second scenario is an air leakage or punctures with pressure loss rates of approximately 10 kPa (equiv. to 1.45 lb/in^2) per minute up to a week, usually caused by a puncture (nail, screw, etc.), a leaking valve, or improperly mounted tires. In most cases, a tire blow out or a leakage only affects one tire at a time. However, tires in service also naturally lose air through a process called *diffusion*, also known as *permeation*. In this case, air molecules pass through the tire, as the tire inner liner does not guarantee total impermeability. This scenario affects all four tires in the same way with an approximate pressure loss rate of about 10 kPa per month and will cause significant under inflation if tire maintenance is neglected by the driver, that is, tire pressure is not checked and adjusted over a long period of time.

At first, TPMSs were introduced as a comfort feature in the late 1980s. The model year 1987, Porsche 959

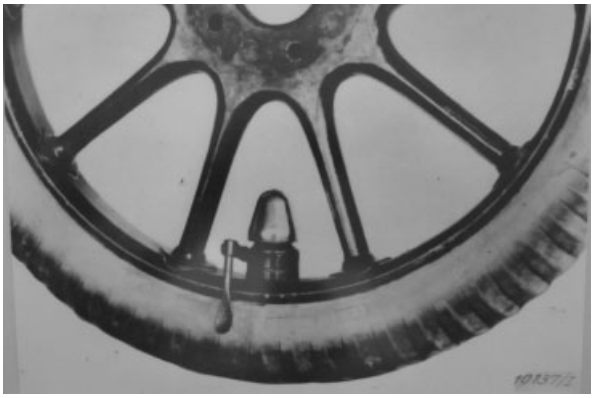

Figure 1. 1923 "Bosch-Glocke" (Bosch-Bell).

Figure 3. 1987 Porsche 959.

was the first series production car to feature a TPMS (Figure 3). The main components of the Porsche 959 TPMS, pressure switch and high frequency unit, are represented in Figure 4. After the turn of the century, having the correct tire pressure with the effect of maintaining low rolling resistance and by that increasing fuel economy shifted into focus. The first TPMSs were "direct" measuring systems, meaning tire pressures, and often temperatures, were measured within the wheel and the information was transmitted via radio frequency to a receiver inside the vehicle. The so-called indirect systems use the information embedded in the wheel speed signals of the antilock brake or electronic stability control system (ABS/ESC) to determine under inflation. Indirect measuring systems of the first generation were able to detect puncture scenarios only at one tire, whereas current state-of-the-art second-generation indirect systems are able to detect puncture and diffusion scenarios in up to all four tires. Indirect systems of the first generation became widely used in the early 2000s as a cost efficient alternative to complex and, back then, error prone direct TPMSs. The increasing market share of run-flat tires (others say "extended mobility" tires) around that time also caused the increasing market share of first generation iTPMS (indirect tire pressure monitoring system) as puncture detection systems. Especially when using run-flat tires, drivers have to be provided with underinflation information, as a flat tire will not be detected by visual inspection.

Figure 4. (a–c) 1987 Porsche 959 TPMS components.

In the year 2000, a series of fatal accidents related to tire tread separation on Firestone tires mounted on Ford Explorer sport utility vehicles triggered the US congress to pass the so-called TREAD Act (Transportation Recall Enhancement, Accountability and Documentation Act). Subsequently, in 2005, the new Federal Motor Vehicle Safety Standard No. 138 (FMVSS 138) was enacted, requiring all new passenger cars, multipurpose passenger vehicles, trucks, and buses with a gross vehicle weight rating (GVWR) of 4536 kg (10,000 pounds) to be equipped with a TPMS. Starting with a phase-in period in 2005, by September 2007, all new vehicles had to be fitted with a TPMS conforming to FMVSS 138 requirements. With that the United States was the first country to have a regulation specifying the installation and performance criteria for TPMSs. Targeting the fuel efficiency in addition to the safety aspect of correct tire pressure, in 2009, the EU parliament mandated ECE-R 64, a regulation requiring all new vehicle types to be equipped with a TPMS starting November 2012 and all new vehicles to be registered from November 2014.

2 DIRECT TIRE PRESSURE MONITORING SYSTEMS

Direct pressure monitoring systems are based on the principle of measuring tire internal pressure (and temperature) by wheel units fixed to the rim. The sensors send their data by radio frequency to vehicle body fixed antenna(s). The antenna(s) provides the data to an electronic control unit (ECU) for evaluation. The ECU communicates with the car's network and issues messages that warn the driver in case of a pressure loss via telltales and messages in displays in the instrument cluster and/or human–machine interface (HMI).

The functional principle introduces system complexity to the vehicle design. The parts required for the direct pressure monitoring functionality are the following:

1. wheel units
2. antenna(s)
3. ECU and wiring harnesses
4. optional parts and displays
5. development.

The following sections discuss the function of each system component.

2.1 Wheel unit

This component is mounted at least in each driving wheel. It measures at least tire pressure and temperature. In addition, data such as acceleration and rotational direction may be collected. The wheel unit sends the data wirelessly on standardized carrier frequencies of 433 or 315 MHz to a vehicle body fixed antenna.

Figure 5 shows a block diagram of an HUF Electronic sensor (formerly known as *BERU Electronics*). The low frequency (LF) module enables wake-up and data requests from outside the tire for diagnosis or functional purposes. The "over temperature protection circuit" allows survival for temperatures up to 150°C for several minutes. At 120°C, the wheel unit will fall into a protection mode to safeguard electronic parts at these temperatures. A lithium-based consumer battery, providing 3.0 V output, provides energy. In general, state-of-the-art sensors transmit data:

1. Continuously, when activated once (e.g., one transmission/minutes in regular intervals).
2. Roll switch activated at a certain threshold acceleration.
3. Outside requested, for example, by a diagnostic tool or TPMS trigger (initiated by an LF signal).

As the inner tire environment is hostile because of temperature variations (−40 to +140°C), humidity, and high acceleration (up to 2000 g), the plastic-housed electronics are protected by a potting compound. The opening for pressure measurements is either at the top of the housing or at membrane shielded and integrated into the potting.

For mounting the wheel unit to the rim, several different techniques are used. The most common solution is the attachment of the wheel unit to the valve as snap in or fixed by a screw to an alloy valve (Figure 6). In Figure 7, a valve-mounted wheel unit is shown in the wheel unit assembly and in a cross section. Besides that, metal bands around the rim are also in use.

Figure 6. HUF Electronic wheel units, generation 1 (a), 2 (b), and 3 (c).

2.2 Antenna

As to the antenna, receiving data from the wheel unit, several solutions are available:

1. passive external antenna
2. active external antenna
3. integrated antenna.

Passive antennas only receive the radio signals without processing the data. In this case, wire connections transmit the analog signals to a receiver, implemented, for example, into a TPMS ECU or a body computer. During the advent of TPMSs, receiver technology was unable to filter out disturbances effectively from the use-signal. For this reason, these systems were prone to electromagnetic compatibility (EMC) issues. An example of a passive antenna implementation is shown in Figure 8. As receiver technology progressed, and being less susceptible to EMC issues, this cost-effective solution was base for the so-called integrated solutions. Integrated in this sense means sharing receiver and antenna with other vehicle systems (e.g., keyless entry) and implementing the TPMS software into the body computer.

Active antennas represent the next step for improved receiver performance. In this setup, the receiver is integrated into this antenna module. An example of an active antenna component is shown in Figure 9. It decodes the received signals and transmits them in digital format via wire to the TPMS ECU where the analysis takes place. Figure 10 shows an example of an active antenna system implementation. This antenna generation is more sensitive to radio signals but more resistant against EMC issues. It assures easier application and modular system configuration. Another technology leap is represented by the so-called intelligent antenna, which means that TPMS ECU, receiver, and antenna are combined in one housing to reduce parts (Figures 11 and 12).

2.3 Electronic control unit (ECU) and wiring harness

The TPMS ECU processes and evaluates the data received by the antenna or additional data from other ECU; an

example of a TPMS standalone control unit is shown in Figure 13. It manages warnings, allocation of wheel units, and internal and external system diagnoses and provides data and messages for displays and menus. The ECU is connected to the car's wiring harness and communicates as part of this network with other ECU such as gateway, dashboard, and MMI. Wiring depends on TPMS structure and function. As minimum, there is connection to controller area network (CAN) bus, power supply, and ground. Additional components may be linked and organized by local internal network (LIN) or direct linked.

Figure 12. 2007 Audi Q7 modular low TPMS.

Figure 13. Stand-alone TPMS electronic control unit.

Learning and management of wheel units may be done via diagnostic tools at a car or tire dealer or by the TPMS software itself via auto learning and auto location. Auto learning and auto location is more or less static evaluation of information such as number of received tele messages, their signal strength, acceleration in combination with vehicle speed, and turning direction.

2.4 Optional parts and displays

Optional parts may be, for example, a 125 kHz transmitter, the so-called trigger, an example is shown in Figure 14. With this, the TPMS is able to build up a bidirectional communication. The transmitters, one placed in each wheelhouse behind the mudguard, are connected to the ECU. If the wheel unit receives the LF signal from this transmitter, it sends its data on 433/315 MHz to the TPMS antenna no

Figure 14. 125 kHz Transmitter unit, trigger.

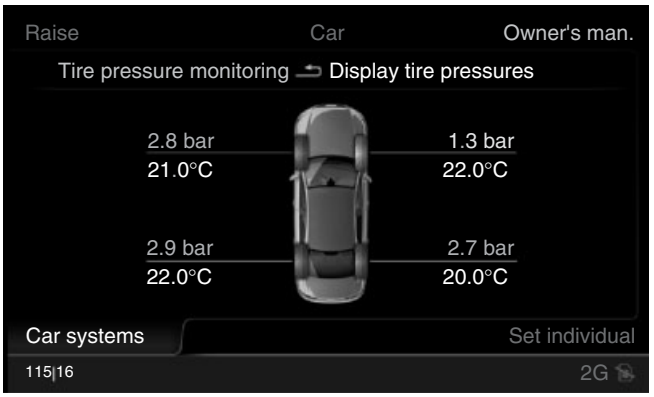

Figure 15. TPMS information in Audi MMI.

matter if the car moves or is stationary. The ECU is always able to request data, for example, when data are lost or for comfort purpose at door open as a status request. In addition, using this additional communication does allocation of sensors quickly and accurately.

Warning telltales and text messages in case of pressure loss or malfunction are displayed in a display in the dashboard. Additional information, such as pressure/temperature status, may be shown either on displays in the dashboard or suitable HMIs (Figure 15).

For operations such as resetting the system, start learning new wheel units, or storing tire pressures after adapting them, a push button connected directly to the ECU, or a menu either in the driver information system in the dashboard (DIS) or another HMI, provides this function

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to be executed by the driver. As the placard pressure may vary with mounted tire size, velocity to be driven, load and other characteristics TPMSs can provide various parameters to be chosen.

2.5 Development

Development of TPMS depends on OEM (original equipment manufacturer) functional, HMI, and legal requirements. In general, TPMS development can be grouped in the following categories:

1. hardware development
2. location/placement of hardware in the vehicle body (application)
3. software development.

2.5.1 *Hardware development*

All components of TPMS, except the wheel units, are subject to automotive industry standards depending on the location/placement of the different parts. For example, high temperature conditions can occur in the dashboard area. In addition, outside the passenger compartment, placed components need to be shielded against high humidity influences. In some circumstances, special protection against stone chipping is also needed. Electrical tests, for example, cover over/under voltage, voltage ramping conditions, EMC, or quiescent current topics.

As mentioned earlier, wheel units have to withstand the hostile environment inside a tire. In a joint effort, German car manufacturers (AUDI, BMW, Daimler, Porsche, and VW) and TPMS supplier DODUCO (later BERU, HUF Electronics) have developed detailed requirement specifications that describe the functional testing and validation of TPMS wheel units and attachments to the wheel by Alligator-developed alloy valves. Especially important were considerations about accuracy over component lifetime, minimal temperature dependency, resistance to high acceleration (up to 2000 g), temperatures higher than 120°C, and temperatures as low as −40°C. In addition, realizations of reliable functionality withstanding the high mechanical stresses were challenges mastered.

2.5.2 *Placement of hardware at car body (application)*

Positioning the receiver is crucial for TPMS functionality, as it strongly depends on the signal strength and reception rate of the wheel unit sensors at the location of the receiver. When placing LF transmitters in the wheelhouse, positioning of these components also requires that the wheel unit can be reached in all possible wheel positions (360° wheel rotation and all steering positions of wheel).

Investigations on digital mockup (DMU) adduce the first positions of components chosen based on available space and experiences from former vehicle projects. Subsequent tests on prototype vehicles give first impressions of the component functionality at the predefined position. To evaluate the receiver placement, the wheel unit sensor is set into a steady-state sending mode. The signal strength at the receiver is measured and evaluated for a full 360° rotation of each wheel. In addition, at the front axle wheels, this procedure needs to be carried out at full steering wheel angle, left and right turns. The objective is to have best possible reception and, if they cannot be avoided, only short "black spots," that is, positions where the signal strength falls below predefined threshold values during one revolution of the wheel. The same principle test needs to be performed for 125 kHz transmitter positions at each wheel position. The objective here is evaluating the flux density at the 125 kHz antenna of the wheel unit sensor during one full turn of a wheel. In addition, here, no or only minor black spots are to be accepted (Figures 16 and 17).

The reception rate of wheel unit sensor tele messages is measured while proving ground driving at different steady-state speeds, for example, 100, 150, and 200 km/h. Usually, two test conditions are analyzed and verified: confirmation of HF reception, when triggers are deactivated, and confirmation of the LF communication, when trigger mode is activated. Subsequent driving tests in all customer-relevant scenarios (high and low temperature, snow, rain, etc.) need to confirm proper functionality. As specific tire constructions may influence signal reception (signal damping effect), close cooperation with tire development is also necessary. EMC of the TPMS components/system within the vehicle environment needs to be verified as well, meaning that the TPMS is not influencing other electronic systems in the vehicle and vice versa.

2.5.3 *Software development*

TPMS software components can be grouped into base software, diagnostic and functional software. The base software ensures basic communication between the TPMS ECU and other car components via the vehicle network. Functional software contains warning algorithms and algorithms defining the appearance to the driver. To function within a vehicle network, data exchange via signals and protocols are standardized. Diagnostic behavior for defect and malfunction analysis in the technical service environment (e.g., workshop) also needs to be covered and defined to ensure fast and effective troubleshooting.

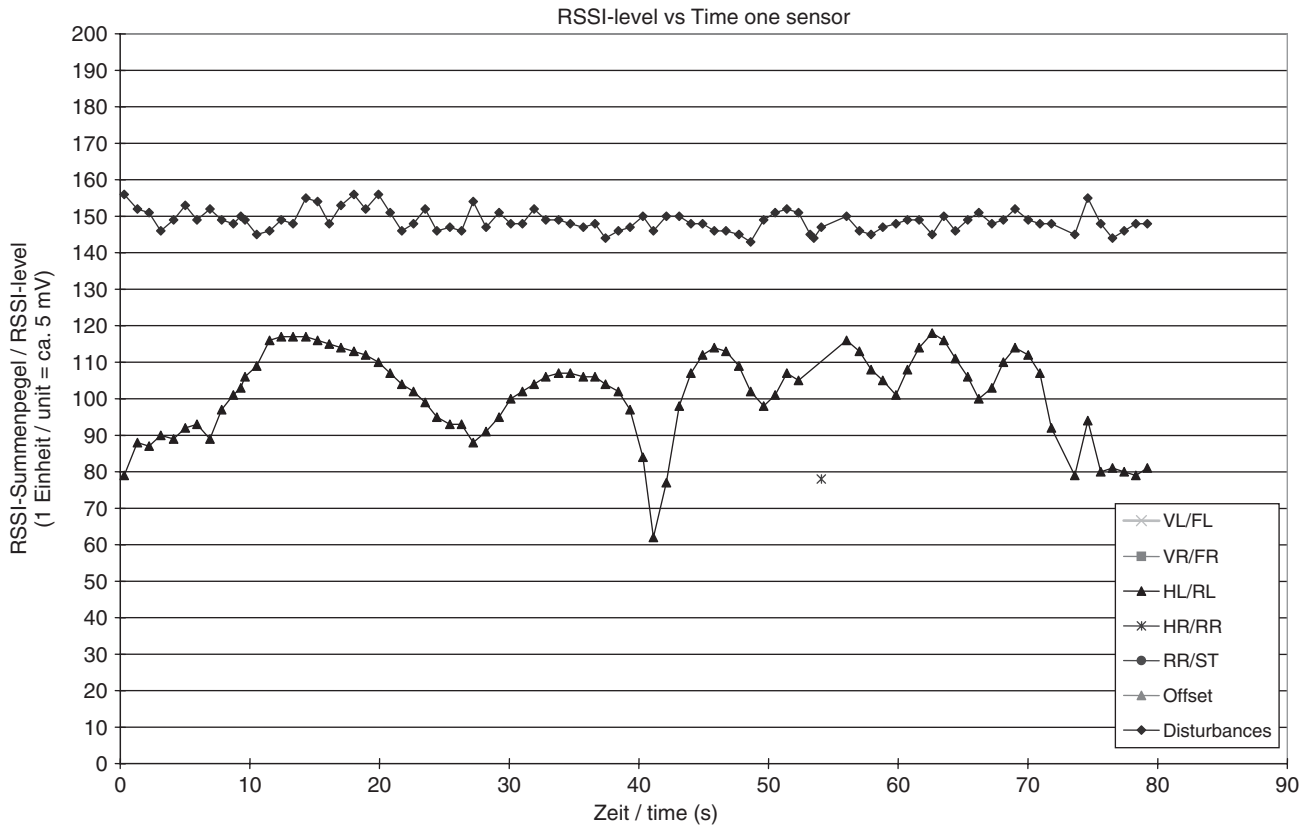

Figure 16. Signal strength diagram for a 360° rotation.

The functional software part defines warning strategies for different pressure loss scenarios, learning procedure of new sensors, learning of sensor positions, and the timing and sequence of telltale warnings and displays. Functional software setup depends on OEM requirements and philosophy as well as legal requirements for different markets. The warning strategy itself defines the pressure thresholds for signaling underinflation to the driver in case of a pressure loss because of puncture or diffusion pressure loss scenarios. As puncture usually means fast pressure loss (10–20 kPa/min), the warning needs to be displayed immediately when detected. Because of its long-term nature, detection of diffusion pressure loss need not necessarily be signaled immediately to the driver. This scenario is usually low pass filtered and often not displayed to the driver in the current ignition cycle but signaled at the next ignition on to assure cold tire pressure when the driver checks the pressures. In general—for customer acceptance purposes—it has been seen that warning thresholds too close to the recommended cold tire pressure have to be avoided. When signaling a warning at a pressures slightly below the cold recommended pressure, warning may be seen as nuisance by the customer and TPMS functionality is questioned.

Software verification is performed in hardware-in-the-loop (HIL), software-in-the-loop, and simulated network tests and in whole vehicle environment. Compliance to legal requirements and endurance is the main focus when doing approval vehicle tests.

3 INDIRECT TIRE PRESSURE MONITORING SYSTEMS

3.1 Tire as sensor

Directly measuring pressure sensors usually have components whose properties are dependent on the tire pressure and can therefore be used for measuring the pressure. Applying this basic principle in a generalized way leads to the approach of using the tire itself as a sensor. This is possible as various properties of a pneumatic tire are strongly pressure dependent and some of these properties are measurable using sensors being common and already installed for other purposes in most vehicles nowadays.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

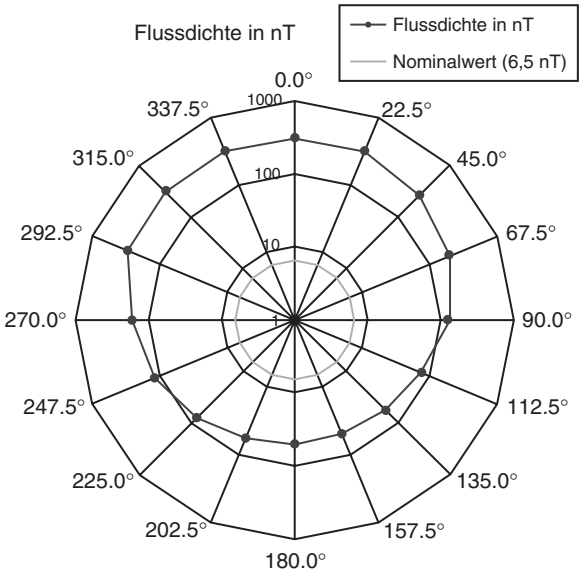

Figure 17. Flux density diagram.

The overall approach has various benefits as it avoids the installation of separate sensors and parts for the sake of monitoring tire inflation pressure. In this way, cost, weight, complexity, service, and logistics are efficiently avoided. In its most consequent application, it enables implementing a purely software-based tire pressure monitoring function into the ABS/ESC control unit as long an ABS or ESC system is fitted to the vehicle and can be utilized as a host for the TPMS software.

On the other hand, tires are complex products, which differ significantly in sizes, dimensions, materials, and technologies, as do their properties related to inflation pressure. The main challenge for iTPMS is to deliver consistent and reliable system behavior independent of the mounted tires. This variance in tire properties consequently is the main reason for iTPMS being relative by nature, meaning that they cannot monitor or display quantitative inflation pressure values but always need a reference state from which a deviation can be detected. The reference state can be viewed as an externally set reference point. The process where the user informs that a reference state is present is usually referred to as *reset* that is essential for the iTPMS. A reset is always required when inflation pressure has been adjusted, tires changed or rotated between different positions on the vehicle. In current applications, the reset is carried out actively by the driver (Figure 18). However, other options such as tire pressure gauges interacting with the vehicle could also enable other solutions in the future.

Subsequent to the reset, the iTPMS will analyze the pressure-dependent tire parameters and store the current parameters as reference data. This process is referred to as the *learning phase*. Once the learning phase is completed, the pressure-related tire parameters can be continuously monitored and compared to the stored reference data. If the current parameters deviate from the reference data in characteristics, according to predetermined patterns and/or exceeding certain thresholds, low tire inflation warnings are issued.

3.2 First-generation indirect TPMS

The first iTPMSs on the market, the so-called first generation iTPMSs, were only roll-radius or rolling-circumference-based systems. The basic principle is that the effective rolling radius of a tire is inflation pressure dependent and will decrease when the tire loses pressure. At a given vehicle speed, any inflation pressure loss can be detected by comparing and monitoring the individual rotational wheel speeds with each other (Figure 19).

The most important input signals are the individual wheel speeds. The wheel speed signals are obtained from measurements of number of teeth of the ABS rotor passing a certain point per time interval. The toothed rotors are fixed to each wheel and this way the rotational speeds used for ABS and ESC applications are calculated. This approach enables the effective and reliable monitoring of up to three out of four wheel positions but cannot detect same-rate

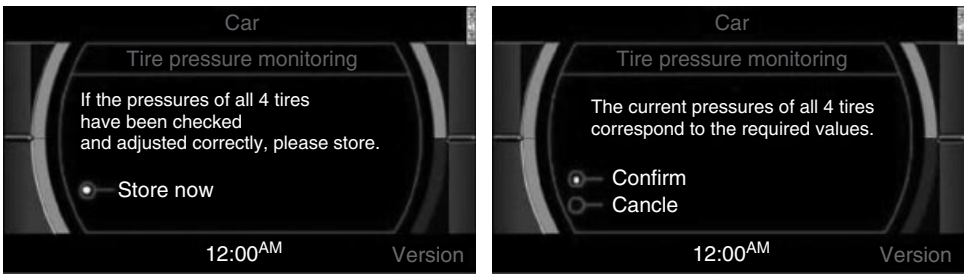

Figure 18. Guided reset procedure.

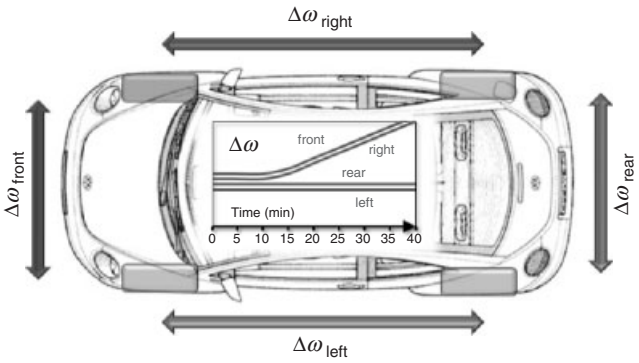

Figure 19. Four-wheel speed differences for rolling-radii-based indirect TPMS indicating a puncture front right.

inflation pressure losses on all four-wheel positions. The reason for not being able to detect the four-wheel deflation is that during the learning phase the relation between the wheel speeds is set. If all four wheels deflate in the same way, the relative difference will remain the same. Puncture detection is therefore possible with first-generation iTPMS but the diffusion/permeation detection due to slow natural air losses in all four wheels is not. Several approaches to overcome this limitation using wheel radius information only have been investigated, or are under investigation, but have not led to series applications yet.

Irrespective of the limitations, first-generation iTPMSs were mainly used and developed as the so-called run-flat-warning systems in combination with run-flat tires (see also ECE-R 64 requirements) as they are cost effective, reliable, and easy to integrate into ABS/ESC systems.

As the rolling radius is not only influenced by inflation pressure, other influencing parameters have to be considered of which the most influential one is the driving speed, which through radial forces influences the effective rolling radius and by that the wheel speed. It is common practice with iTPMS that they work in individual speed intervals for which reference values are stored. The current values are then continuously compared to the reference values stored for specific speed intervals. Other parameters that influence the rolling radius are cornering, braking and accelerating, load, and lateral or longitudinal road inclination. To eliminate the influence of these parameters, additional information such as engine torque, longitudinal and lateral acceleration, or the steering wheel angle are analyzed and used to compensate for the unwanted effects. On the basis of these auxiliary signals, the vehicle load can be estimated and compensated for. Advanced load compensation is possible using signals directly related to vehicle load, for example, air suspension pressures (when so equipped) or axle height signals commonly used with xenon front lighting systems.

3.3 Second-generation indirect TPMS

The wheel assembly is constantly excited by the road surface and oscillating in numerous vibration modes. In the course of trying to overcome the limitations of first-generation iTPMS, the oscillation properties of the wheel assembly have come into the focus of development.

Some of these vibration modes excited are highly inflation pressure dependent and some are possible to monitor with common sensor signals as the wheel speed sensors (Figure 20). The advantage of this approach is that the oscillation behavior of a wheel assembly can be monitored wheel individual and in absolute terms and not only relative to the other wheel positions as is the case for rolling radius. Realizing of monitoring the oscillation behavior therefore enabled the enhancement of iTPMS to a TPMS, comparable to direct systems, which are also capable of monitoring all four tire pressures individually. Indirect systems utilizing both the rolling radius and the oscillation behavior are called *second-generation iTPMS*. With this enhancement, the second-generation systems are able to comply with current and legal requirements that require both puncture and diffusion detections.

There are different options to utilize the vibration behavior but most common is to process the wheel speed signals and analyze them in a narrow frequency band of approximately 30–60 Hz as depicted in Figure 20 to reduce computational effort. Other approaches using vertical and/or translational oscillations have been investigated but not implemented, as additional sensors necessary are not as commonly used.

Figure 20. Spectrum behavior as function of tire pressure.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto014
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As with the rolling radius, the vibration behavior is influenced by other parameters than the inflation pressure alone. Vehicle driving speed is the most important and therefore the oscillation analysis is usually divided into different, consecutive speed intervals. The tire itself influences the oscillation behavior through their spring rates, effective mass, and inertia and so does the excitation by the road or effects of vehicle loading. One subset of these influences is compensated for through the reset procedure and learning phase, and the other subset can be actively compensated for by using additional signals such as ambient temperature or the signals also used for performing the rolling-radius analysis.

State-of-the-art second-generation iTPMSs use both rolling-radius and vibration informations and combine them by advanced signal processing to enhance the detection performance and increase robustness against disturbing factors.

3.4 Indirect tire pressure monitoring fundamentals

The so-called tire pressure indicator or TPI, an iTPMS and trademark of NIRA Dynamics, was the first iTPMS to be introduced to the US market in the 2009 model year Audi A6 to comply with regulation FMVSS 138 (Figure 21). In the following, some of its fundamentals will be discussed. Second-generation iTPMSs are also developed and marketed by Dunlop Tech (as deflation warning system or DWS) or Continental (as deflation detection system plus or DDS+).

TPI consists of two main modules; one monitoring the rolling radius called *wheel radius analysis* (*WRA*) and the other wheel spectrum analysis (WSA) is monitoring the oscillation or spectrum behavior.

The WRA and WSA modules calculate common properties or indicators, which describe the rolling-radius ratios of the wheels relative to each other as well as the wheel spectrum behavior. Having compensated for various disturbances, these properties can be used for a number of the so-called detectors, which have the purpose of monitoring certain deflation scenarios. For example, there are one-wheel-puncture detectors, two-wheel-puncture detectors, and several multi-wheel-diffusion-pressure-loss detectors. These indicators work independent from one another. Each of the indicators can, when triggered, issue a low pressure warning. Puncture detectors are typically characterized by their ability to react quickly due to the immediate safety relevance of the underlying pressure loss scenario. Diffusion detectors are typically low pass filtered to exclude influences of short-term disturbances. Detectors in TPI use both rolling-radius and spectrum informations simultaneously, such that the spectrum information is used as an attenuator or amplifier for base information obtained from the rolling-radius information. One exception is the four-wheel diffusion detector, which is purely based on spectrum information. Figure 22 shows the analyzed wheel speed differences and spectrum properties for a puncture scenario. As can be seen, the wheel radius difference and the spectrum are affected by the one-position-only pressure loss case. On the other hand, when all tires are affected at approximately the same pressure loss rate, no wheel speed

difference can be seen and only wheel spectrum behavior changes detect under inflation (Figure 23).

This system design is aimed to increase robustness toward short-term disturbances and make it independent to individual tire sensitivities. The use of wheel-individual detectors also enables the so-called isolation functionality that describes the ability of a TPMS to deliver position information about affected wheels, resulting in the possibility to display this information to the driver (Figure 24). Another advantage is the possibility to parameterize and adjust—or even deactivate—detectors individually and by that adapt the system specifically to the target vehicle and its operational/display concept as well as different functional requirement specifications. Additional subfunctions cover self-diagnosis capabilities, for example, in case of invalid or erroneous input signals.

3.5 Software integration versus standalone solution

Indirect tire pressure monitoring does not need additional hardware as it only consists of a software module, which is to be executed in the vehicle. Early applications of iTPMS required one additional stand-alone control unit. Examples for that setup are the current 2007 Audi TT or 2008 Audi A6. As this setup does not support one of the most important advantages of iTPMS—no additional physical parts—the integrated solution is preferred. The setup of an indirect system as software module integrated in the ESC software is shown in Figure 25.

Figure 25. System configuration for second-generation indirect TPMS in an 2012 Audi A6.

As the wheel speed signals are essential for any iTPMS, the selection of suitable host systems is limited to systems, which supply the wheel speed signals in sufficient quality

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto014
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and reliability. Wheel slip control systems therefore represent the natural choice to host iTPMS as they are also highly reliable and provide sufficient hardware resources, software structures, and interfaces. Adoption of standards such as AUTOSAR (automotive open system architecture) is becoming common for both iTPMS and slip control system and simplifies the software integration process. The iTPMS software module is normally embedded or wrapped into a so-called middleware with the main task to control iTPMS execution and transfer input and output signals to and from the iTPMS module. It also controls the use of shared resources such as RAM (random access memory), nonvolatile memory (EEPROM, and electrically erasable programmable read only memory), and diagnostic functions such as system state handling, malfunctions, and diagnostic trouble codes (DTCs).

The integration of an iTPMS is closely linked to the HMI, operational and display concepts, and requirements of the target vehicle. For example, the system integration needs to consider whether position information of underinflated tire is signaled to the driver via additional text messages or if the reset procedure is conducted via button or interactive interface.

3.6 Reset and learning phase

iTPMS as relative measuring systems require the external setting of a reference point, usually by the driver. As soon as relevant parameters such as tire pressure, mounting positions, balancing, or tire types have changed the indirect system needs to be reset to function properly. To prevent the reset function from being executed unintentionally, physical switches (buttons) are usually placed in locations where they cannot be activated without driver awareness (e.g., glove compartment). Additional measures such as a confirmation procedure via interactive menu guidance or plausibility checks, with a minimum vehicle standstill to allow resetting, are common practice.

Once the reset request is accepted by the iTPMS, the existing reference data are erased and the iTPMS starts collecting reference data in the speed intervals visited while the vehicle is driving. Collected reference data are stored in nonvolatile memory and continued learning takes place over several driving cycles if necessary until the learning phase is completed. Different strategies on when to issue full iTPMS functionality, depending on the learning phase completion, are common. Most iTPMS gradually become active depending on the amount of collected reference data and the current speed interval. Full warning sensitivity will be reached after approximately 20 min of driving. Complete learning, covering all speed ranges usually takes about 1 h driving, assuming all speed intervals have been covered. Learning progress also depends on driving style and external road conditions. Additional functionalities, for example, speed extra- and interpolation, allow detection capabilities in speed intervals not yet visited. The reset of the iTPMS is necessary for proper performance and also eliminates numerous disturbing influences such as tire wear, tire aging, seasonal temperature changes, and/or the use of different tire types.

3.7 Application of indirect TPMS

As iTPMS use the tire as a sensor and the fact that tires are not standardized regarding their sensitivity to underinflation, covering a wide range of different tire characteristics, one iTPMS setting is the major application task. Current research activities are under way to take tire sensitivity to under inflation into consideration already when designing tires. This will generate uniform responses over a certain tire program and thus considerably reduce application effort of iTPMS. In addition, chassis or driveline influences can have to be considered when doing iTPMS application. It is therefore important to adjust and adapt the iTPMS in the target vehicle toward the target tire program. As iTPMSs are following the open-loop concept, they can effectively be tested using vehicle test recorded data files covering all input signals. These data files can be replayed off-line using different iTPMS software versions and parameter settings without repeating the actual vehicle test (Figure 26). The application of an iTPMS normally consists of one or more structured data collection campaigns, where relevant target vehicle model variants and tires are tested under various conditions and the input data being collected (detection and robustness tests, winter- and high temperature testing, road surface screenings, etc.). The data files are then replayed off-line and complemented with further vehicle tests on demand. As soon the database status makes it possible, algorithms and parameter settings are iteratively optimized until the test results meet the OEM requirement specifications. Using automatic test environments drastically reduces optimization loop time.

4 LEGAL ENVIRONMENT

After a series of fatal accidents, which were related to tire tread separation on certain Firestone tires mounted to the Ford Explorer in 2000, the US Congress enacted the so-called TREAD act and subsequently a new FMVSS 138, requiring new light vehicles [passenger cars, multipurpose passenger vehicles, trucks, and buses with a maximum

DOI: 10.1002/9781118354179.auto014
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

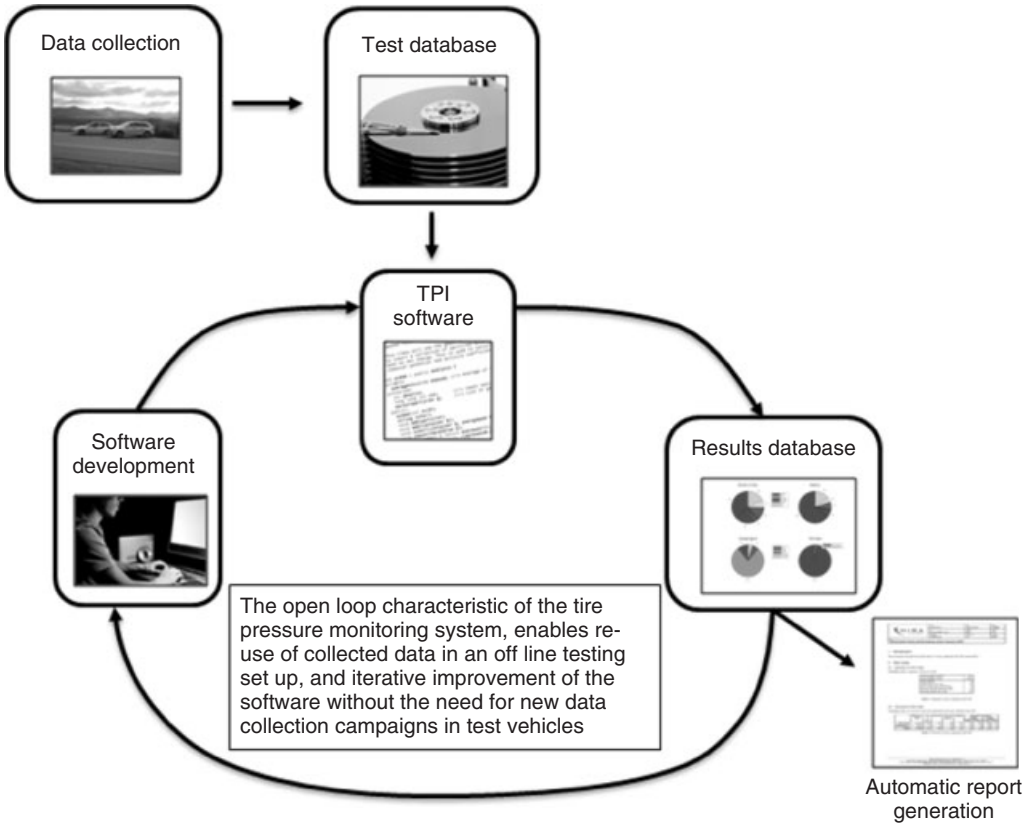

Figure 26. Representation of open-loop concept for iTPMS application.

gross vehicle mass rating of 4536 kg (10,000 pounds) to be equipped with a TPMS]. After a phase-in period starting in 2005, from September 2007, all new vehicles sold in the United States need to be equipped with TPMS conforming to FMVSS 138.

The safety goal of this regulation was to reduce accidents caused by tire failures that in turn were caused by significant underinflation. FMVSS 138 requires a warning to the driver, when the tire pressure falls below 25% of the cold recommended pressure level in one up to all four tires. In general, FMVSS 138 is a technologically neutral drafted performance standard, that is, it does not prescribe specific technology for fulfillment. Besides underinflation detection, FMVSS 138 also requires TPMS malfunctions to be signaled to the driver. A low tire pressure condition will be displayed by illumination of the standardized low tire pressure telltale (Figure 27). A number of OEMs chose to amend the minimum telltale requirements of FMVSS 138 with additional text messages to inform the driver about the situation and point him or her toward corrective actions.

In addition to the safety aspect of tire pressure monitoring covered in FMVSS 138, in 2009, the EU parliament decided mainly with focus on reducing CO_2 emissions to require

Figure 27. TPMS telltale in cluster.

TPMS for all new vehicles with the new regulation ECE-R 64. The regulation applies to M1 and N1 vehicles (passenger vehicles and vehicles designed to carry goods

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto014
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

with a maximum mass not >3.500 kg). From November 2012, all new types and, from November 2014, all newly registered vehicles need to comply with ECE-R 64. ECE-R 64 requires a low tire pressure warning at 20% pressure loss with respect to the "warm tire pressure." Depending on the pressure loss scenario, ECE-R 64 requires different warning times, 10 min for a puncture on one wheel and 60 min for simulating the diffusion on all four wheels. The telltale and display requirements are mainly carried over from FMVSS 138, and the malfunction detection time has been reduced to 10 min.

Compared to US regulation FMVSS 138, the European regulation ECE-R 64 represents a substantial reducing of warning thresholds, as not only the warning level has been decreased to 20% but also the pressure reference has changed from the recommended cold tire pressure to the in-service, operational or the so-called warm tire pressure. Actually, ECE-R 64 almost cuts the warning threshold in half compared to FMVSS 138. Figure 28 shows the pressure trace for FMVSS 138 and ECE-R 64 test procedures. Once the recommended tire pressure is adjusted, the vehicles need to be driven to allow the TPMS to learn current tire/pressure characteristics (calibration or learning phase). During driving the calibration phase, the tire will heat up and the pressure will be above the initially adjusted cold inflation pressure. Pressure build up is dependent on different influences such as driving style and axle load but usually reaches values of about 10–15% of the cold tire pressure. After the calibration phase, the pressure will be adjusted to the warning level (25% for FMVSS 138 and 20% for ECE-R 64), whereas the reference pressure for adjusting is the cold tire pressure (FMVSS 138) and the in-service pressure (ECE-R 64). Subsequently, the vehicle is driven in the detection phase, where the detection time requirements vary depending on the exact scenario tested. In FMVSS 138, the warning must be issued at the latest 20 min after deflation independent of the pressure loss scenario (deflation in one up to all four wheels), ECE-R 64 requires detection in 10 min for the one-wheel puncture and 60 min for the four-wheel diffusion scenario. Another important difference between US and ECE requirements is that the United States realizes a self-certifying regulation, whereas ECE-R 64 calls for a type approval/homologation process done by the OEM to allow for registration of vehicle.

All tire pressure-monitoring systems—except first generation indirect systems—have been shown to be able to fulfill current US and ECE regulations. A performance comparison between direct TPMS and iTPMS is shown in Figure 29.

5 FUTURE TRENDS AND DEVELOPMENT

Enacting legal requirements on tire pressure monitoring has and will further increase the market penetration of TPMS. After 100% mandating TPMS in the US market via FMVSS 138 since 2007, in 2014, the EU market will require 100% compliance with ECE-R 64.

On the side of direct systems, there is a clear trend toward reducing the number of components, complexity, and costs, most important for the sake of customer acceptance. US market experience has shown that, especially, the aftermarket has severe challenges to serve to the vast variety of direct systems currently available. Therefore, there is a clear trend toward standardization of hardware components and data transfer protocols, so systems from different OEMs/TPMS suppliers can interact in the future. It has also been understood that the issue of sensor replacement for direct systems over the lifetime of the vehicle poses a serious customer acceptance concern: market research has shown that only one-third of customers will replace sensors with empty batteries. Extensive research in the field of energy harvesting is on the way to eliminate the need for batteries in the pressure sensors of direct TPMS. Currently, the most promising approach for energy harvesting in the TPMS environment seems to be the deployment of the piezo-electric effect, but as of today, no energy harvesting system is in series production.

The topic of energy harvesting goes strongly connected to the implementation of the tire-integrated sensor (Figure 30). By attaching the sensor to the tire via gluing or curing, more functionality besides tire pressure monitoring could be realized. If permanently fixed to the tire, tire-specific data such as tire type (summer, winter, and run-flat) or speed and load index could be stored to the tire sensor, allowing for additional benefits: speed warnings could be issued when exceeding the speed index specified speed, or driver information could be provided if the tire type does not fit current weather conditions (summer tire running in winter conditions). In addition, the tire-integrated sensor could determine the size of the contact patch between road and tire, information that can be utilized when optimizing rolling resistance or determining wheel loads. Nevertheless, with regard to the tire-integrated sensors, not all issues are resolved yet. For example, the permanent sensor attachment necessary for realizing benefits beyond tire pressure monitoring has to address the issue of tire replacement when a tire is damaged or the tire life is reached because the tread has worn out. In this case, not only the tire but also the sensor will be disposed, which economically can only be done when sensor prices decrease substantially. On the other hand, making the tire-integrated sensor replaceable will not allow for realizing all possible benefits, because the stored tire information may not be correct because of tire changes. It is

Figure 30. Integrated tire sensor.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

expected that the tire-integrated sensor will start its market introduction in the high price sports car segment, where the tire program is usually limited and special customer needs justify the special effort and price. At the moment, no tire-integrated sensor solution is currently available in series production.

As it has been proved that indirect systems fulfill legal requirements FMVSS 138 and upcoming ECE-R 64 legislation, the market share of iTPMS is expected to grow substantially over the coming years. The benefits of providing a robust tire pressure monitoring functionality with reduced hardware and complexity in combination with no follow-up costs over the vehicle lifetime will appeal to mid-segment, cost-conscious, and premium-segment OEMs alike. For example, Audi has implemented the indirect system into almost all the vehicles in its model line up.

ACKNOWLEDGMENTS

We would like to thank Ralf Kessler and his team of HUF Electronics Bretten for significant contributions to the segment of direct systems. Another special thanks goes to Volker Rühr of Dr. Ing. h.c.Porsche AG and Dr. Andreas Köbe of Continental Engineering Services GmbH who supported on the topic of tire pressure monitoring system introduction and history.

The Harshness of Air Springs in Passenger Cars

Andreas Kind and Andreas Rohde
Continental Teves AG & Co. oHG, Hannover, Germany

1 INTRODUCTION

Air suspension systems have found widespread application in the luxury automobile segment in recent years. The advantages of air suspension systems in terms of load leveling, variable spring rates, and comfort have been greeted by a high degree of acceptance among consumers.

Customers in the luxury segment demand and expect constant refinements to driving comfort more than anything else and so the goal is to reduce vibration and noise to a level that is acceptable to passengers. This has resulted in permanent refinement and improvement of chassis components.

The comfort of air suspension can be determined mainly by the curve of the spring rate in relation to the frequency and amplitude of excitation. Harshness in this context refers to the undesirable stiffening of air suspensions in response to small, rapid vibration. This effect is primarily due to the characteristics of the bellows employed. Steps to improve comfort can flow into the development process as a function of the design of the air suspension system, the geometry of the components, and the materials that have been employed.

2 HARSHNESS OF AIR SPRINGS

2.1 Ride comfort

The demand for riding comfort in the passenger car segment is becoming ever more pronounced. While in the past, luxury cars were synonymous with excellent ride comfort, nowadays, middle-class automobiles, SUVs, and even sports cars come with expectations of comparable comfort. Most modern electronic chassis systems now offer the choice between comfort and sport modes. Changes in the suspension and dampers occur, depending on the input received by the wheels. These changes then influence the vibratory characteristics and, as a desired result, the impression of comfort. The result is an ideal balance between vehicle dynamics and ride comfort (Figure 1).

Undesired vibrations nevertheless do occur, depending on the type and severity of input to the wheels. The jolts travel from the pavement through the wheel and the chassis into the body. Vibrations and structure-borne noise are thus transmitted into the interior and to the occupants. Ride comfort is a reflection of the occupants' sense of well-being as a function of all vibratory influences. Depending on its frequency, vibration can be experienced as palpable vibration, noise, or a combination of both. The term *NVH* is used to refer to vibrations specific to automobiles. NVH stands for noise vibration and harshness and encompasses acoustical and mechanical vibration as well as people's subjective perception of it (Ersoy and Heißing, 2008).

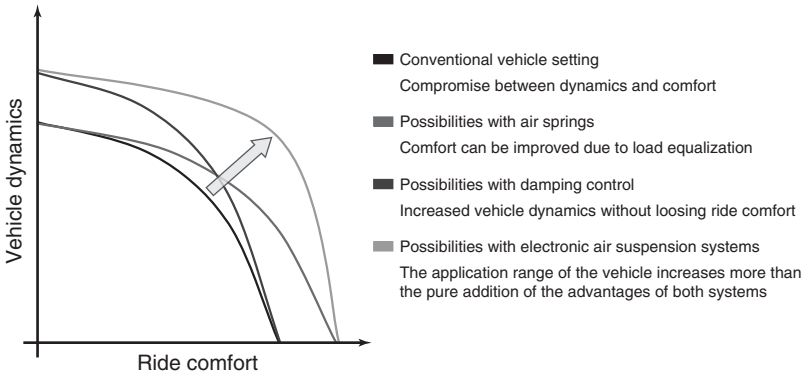

Figure 1. Increase of the chassis application range. (Reproduced by permission of Continental AG.)

2.2 A general definition of harshness

The term *harshness* refers to the intersection of vibrations and noise in a typical range of frequencies between 20 and 100 Hz. Harshness can also be interpreted as a kind of roughness. This roughness is elicited by an undesirable increase in the stiffness of the axle, which may lead to increased acceleration of the bodywork. The harshness effect is magnified at low amplitudes and high frequency excitation. Harshness is an unpleasant experience subjectively because the visual perception of the road often does not coincide with the rough ride the occupants are experiencing. For example, increased harshness can cause a ride over a road with an apparently smooth surface and not even the slightest unevenness visible to the human eye to become an uncomfortable experience because vibration and noise reign in the passenger compartment.

Axle components exert the main influence on harshness. The springs, the dampers, and all other components such as bushings and axle joints are responsible for transmitting vibration. The layout, and the resultant transmission characteristics of the components, thus exerts a direct influence on a vehicle's vibration. In addition, numerous elastomers are used because of the elastic-kinetic properties of the axle. These elastomers play a very important role because of their usually quasi-static and dynamic transmission characteristics and their nonlinear properties. Aside from the material properties, the design of the component is critical. Unevenness and abrupt transitions in the force–travel ratio lead to a marked deterioration of the impression of comfort.

Friction effects are still another leading cause of diminished comfort. On the one hand, there is material friction within the components themselves. On the other hand, friction also arises because of the relative movement of components in contact.

2.3 The basics of air suspension

The actual air suspension element is the air spring bellows. In passenger cars, it appears exclusively as a rolling sleeve-type. Figure 2 depicts a rolling sleeve-type. Metal rings clamp the bellows between the cap and the piston. Under pressure, the bellows roll over the rolling lobe on the outer piston geometry during axial motion.

Load capacity F of the air spring is a function of the pressure p_i inside the air spring and the effective area A_W (Equation 1).

$$F = p_i A_W \tag{1}$$

The effective area A_W is proportionate to the effective diameter (Equation 2):

$$F = \frac{\pi D_W^2}{4} \tag{2}$$

The spring rate c is derived from the load capacity F according to the distance s traveled by the air spring (Equation 3).

$$c = \frac{dF}{ds} \tag{3}$$

The rolling sleeve-type consists of thin layers of elastomer between which reinforcement materials in the form of individual threads or mats of fabric have been embedded. Depending on the application, reinforcement material can cross in two layers or can be arranged in one layer along an axis. One is known as a *cross-layered bellows* and the other is known as an *axial bellows*. The reinforcement material can generally only absorb the forces generated in the bellows in the direction of the threads. Cross-layered bellows can therefore also absorb circumferential forces as a function of the angle α between the strands and hence can assume a defined diameter on the application of

pressure. Figure 3 is a schematic diagram of a cross-layered bellows. The five-layer design consists of three elastomer layers—inner, intermediate, and outer rubber layers—and two fabric layers embedded in between. Cross layering results in an angle-dependent rhomboid pattern.

As opposed to axial bellows with a single fabric layer of 90°, the angle of the strands when manufacturing the blank for the cross-layered bellows generally lies somewhere between 45° and 70°, depending on the application. The original angle diminishes as manufacturing proceeds, first because of the bellows widening during vulcanization and shaping and then during pressurization in the static operating state. Here, an equilibrium angle and, as a function thereof, the exterior bellows diameter adjust themselves. The fabric strands stretch under pressure because of their elastic character. During operation, the outer diameter is subject to fluctuations depending on the type of the material used in the fabric. This is due to the magnitude of pressurization. These fluctuations must be considered when designing the component.

During spring motion, the bellows wall does not remain rigid; it fluctuates between the small piston diameter and the large exterior diameter. As the rolling lobe passes through, constant deformations of the bellows wall occur, as do modifications of the strand angle. The pressure inside the air spring causes the bellows wall to roll smoothly down the piston (Voss, 2002).

Alternatively, the air spring can be guided with a fixed external cylinder, which takes up the circumferential forces and diminishes stretching of the bellows wall. This is known as an *exterior-guided air spring*. Both cross-layered bellows and bellows with axial fabric layer find application in guided air springs. The advantages of guided air springs are that there is a lot less wear and tear on the bellows

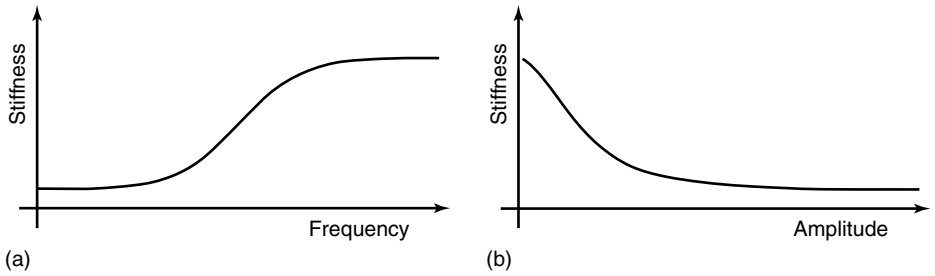

Figure 4. General stiffness curve on an air spring as a function of frequency (a) and amplitude (b).

and they guarantee a fixed diameter for design purposes. The bellows, primarily the reinforcement material and the rubber layers, can be designed much more thinly and delicately.

2.4 The harshness of air suspension

Harshness in connection with air suspension means that spring characteristics stiffen with specific axial movements. Increased stiffness is generally based on two main effects:

- *Frequency-dependent increase in stiffness*. In the direction of high frequencies due to thermodynamic changes in the air.
- *Amplitude-dependent increase in stiffness*. In the direction of low amplitudes due to the rolling resistance of the bellows.

Figure 4 illustrates the general stiffness curves of both effects.

The amplitude-dependent increase in stiffness plays the main part in the actual undesirable harshness of air suspensions. It is predominantly frequency independent and thus significant with every input from the road. The frequency-dependent increase in stiffness, on the other hand, occurs predominantly at frequencies that lie below (i.e., at frequencies below 0.1 Hz) those that are relevant for normal driving conditions (from 0.1 to 2 Hz). Therefore, the stiffness has already increased when the driving relevant frequencies are reached. What follows is a brief explanation of this behavior.

2.4.1 *Frequency-dependent increase in stiffness (due to thermodynamic changes)*

One can distinguish between static (isotherm) and dynamic (adiabatic) behaviors due to thermodynamic changes in the air. Depending on the rapidity of these changes, the following static equation applies (Equation 4),

$$pV = \text{constant} \tag{4}$$

The conditional equation (5) for the adiabatic case with $\kappa = 1.4$:

$$pV^{\kappa} = \text{constant} \tag{5}$$

The frequency-dependent increase in stiffness (Figure 4a) is marked by a transition from isotherm to adiabatic air behavior. It occurs at what is known as the *cutoff frequency* f' starting at approximately 0.1 Hz. The hysteresis of air suspension assumes a maximum value here. Force–travel curves as a function of different frequencies illustrate the marked degree of hysteresis in Figure 5.

For purposes of identifying the parameters of air suspension stiffness, test specifications thus call for sufficient distance from cutoff frequency f', mostly with test frequencies of 0.01 Hz (static) and 1 Hz (dynamic). These frequencies do not quite attain purely isotherm or adiabatic behavior but have nevertheless proved themselves to be of value for technical reasons.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

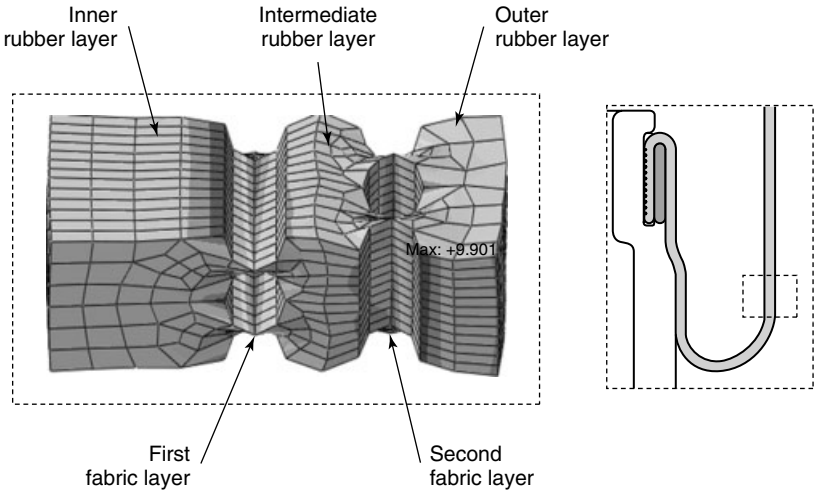

Figure 6. Extended bellows (submodel rolling lobe outside). (Reproduced by permission of Continental AG.)

Incorporating thermodynamic behavior, the value c_{spring} can be calculated as follows in Equation 6;

$$c_{\text{spring}} = p_{\text{i}} \frac{\mathrm{d}A_{\text{W}}}{\mathrm{d}s} + \frac{n(p_{\text{a}} + p_{\text{i}})(A_{\text{W}}^2)}{V} \tag{6}$$

The first term represents the spring value as a function of the change in the effective diameter. The second term in the equation reflects the thermodynamic portion of the spring value. For purely static spring action, $n = 1$ applies, whereas n to the isentropic coefficient $\kappa = 1.4$ results for purely adiabatic behavior. It is thus apparent that the consequence of dynamic spring action is increased spring rate as a function of the spring volume V.

Dynamic spring action is the main factor in a car body's natural frequency and hence in riding comfort. Static spring action, on the other hand, is responsible for pitch and roll. Static spring values are therefore also important for good handling because they have an influence on the car's stability in curves. It is thus worth trying to keep the difference between static and dynamic spring values as small as possible.

2.4.2 *Amplitude-dependent increase in stiffness (due to the rolling resistance of the bellows)*

The actual reduction in comfort that harshness causes results from low amplitude vibration. A classic example of this is rough, uneven asphalt on leaving the highway. However, driving over larger obstacles such as road joints, edges, or asphalt patches may result in an undesirable increase in stiffness. In addition to the harshness being affected by the bellows, often the harshness manifests itself on apparently smooth roads that have perturbations so small that the excitation cannot break through the suspension friction (including the rubber bushings of the suspension arms), resulting in the vehicle bouncing only on the tires in the frequency range of approximately 4–8 Hz and giving what Americans call "boulevard jerk." In the air spring system itself, the reason for the harshness is that the bellows pits a certain rolling resistance against axial motion once it leaves a static resting position. The flexible wall of the bellows must deform during expansion and contraction. As it passes through the rolling lobe, a complex deformation of the elastomer compound and the embedded reinforcement material occurs (Voss, 2002). Figure 6 shows how the rubber matrix stretches at the outer rolling lobe.

Added to the basic stiffness of the air suspension c_{spring} is consequently the portion of stiffness Δc_{harsh} from the rolling resistance of the rolling lobe. The result is the total amplitude-dependent stiffness of the air suspension c^*_{spring} (Equation 7):

$$c^*_{\text{spring}} = c_{\text{spring}} + \Delta c_{\text{harsh}} \tag{7}$$

2.5 Measuring harshness

Objective test methods do a good job of characterizing the harshness of air suspensions. To do this, they record the force–travel curves of an air spring at various amplitudes under harmonic sinusoidal stimulation at a frequency of mostly 1 Hz (Figure 7). The corresponding rates of stiffness are then derived from the observed data via the attendant slopes passing through zero (Figure 8). Amplitudes fall typically in the range 0.1–25 mm.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

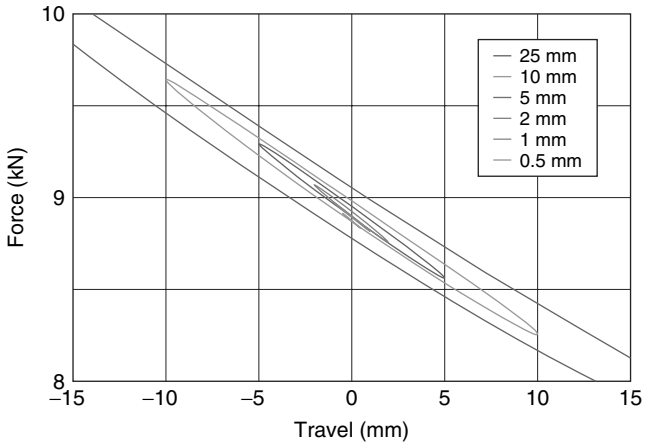

Figure 7. Force–travel curves as a function of amplitude at $f = 1$ Hz.

While the basic design stiffness of air springs regulates at high amplitudes of 25 mm, the spring rate increases in the direction of lower amplitudes. The hysteresis curves rise more steeply as they characterize the harshness effect along the stiffness curve. The harshness effect occurs largely frequency independent (Figure 8).

Measurement using actual air springs, as mentioned earlier, always includes thermodynamic changes. An alternative means of measurement is to attach the metering device to what is known as a *double rolling-lobe arrangement* in order to measure the pure resistance to rolling of the bellows during axial movement.

The device consists of two opposing, geometrically identical air springs with a cylindrical roll-off contour (Figure 9). The volumes of both are linked to each other. The double rolling-lobe arrangement is outwardly force free and allows direct measurement of the rolling resistance of both bellows. A direct, subjective impression "by hand" of harshness or the hysteresis forces is also possible. This arrangement thus permits unadulterated assessment of the components without intrusion by factors influencing the entire module.

Figure 10 illustrates the curve of forces and stiffness on the double rolling-lobe arrangement. While the hysteresis forces diminish as the amplitude declines, the force curve rises more steeply, and stiffness increases.

For the purpose of comparison and obtaining test results that can be reproduced, it is essential to precondition the components extensively and directly before recording any

signals. In the case of air springs, springs are usually preflexed to the maximum for a large number of cycles.

2.6 Assessment of harshness

2.6.1 Assessment using harshness coefficients

A coefficient is often used to assess harshness. On the basis of the amplitude response (see Chapter 2.5 "Measuring harshness"), the harshness coefficient $k_{\text{harshness}}$ in Equation 8 sets the relation of increase in the spring rate in relation to the basic spring rate $c_{25\text{mm}}$ of the air spring.

$$k_{\text{harshness}} = \frac{c_{0.1\text{mm}} - c_{25\text{mm}}}{c_{25\text{mm}}} \cdot 100\% \qquad (8)$$

Use of the coefficient, however, insufficiently reflects the actual typical behavior of the component. For example, an air suspension with a high degree of harshness associated with a high basic spring rate would presumably rate better under this equation than a highly comfortable air suspension with an associated very low basic spring rate that might be brought into play by a direct final axle ratio.

The harshness coefficient $k_{\text{harshness}}$ separated from the actual curve of extreme stiffness increase only makes sense in conjunction with the assessment of a specific vehicle or a specific axle.

2.6.2 Assessment in view of the stiffness curve

Simple observation of the curve of amplitude-dependent stiffness leads meanwhile to an optimized, independent assessment of harshness. Two criteria in particular merit our attention:

1. The increase in spring rate.
2. The deflection of the curve.

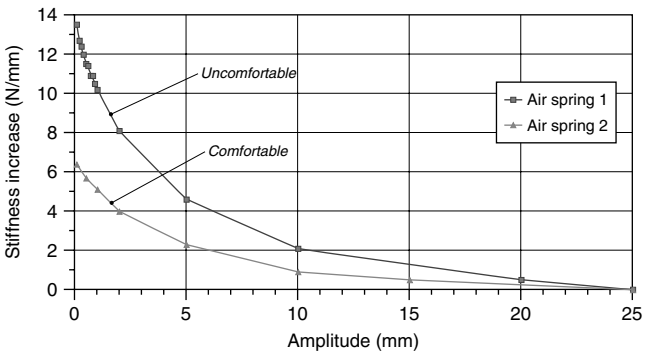

Figure 11. Illustration of amplitude-dependent increase in spring rate Δc_{harsh}.

The increase in spring rate and/or the leptokurtosis of stiffness Δc_{harsh} normalizes the amplitude-dependent spring rate by the value of maximum observed amplitude.

This sets the increase in spring rate at maximum amplitude to zero. This also considers the simple increase in spring rate. This depiction makes it easy to compare air suspensions with varying basic spring rates and facilitates discussion of their curves. Figure 11 illustrates the qualitative progression of a comfortable and an uncomfortable air suspension.

Another important assessment factor is the deflection of the curve in the form of a bulge. A slight increase in spring rate associated with a prominent bulge, that is, a rapid reaching of basic stiffness, is necessary for the comfort of air suspensions.

2.6.3 Correlation to subjective driving impressions

To what extent, there is a correlation to the increase in spring rate observed and its associated curve, in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

comparison to the subjective driving impression, depends greatly on the total automobile handling. There is thus no single specific answer to this question. Assessment of harshness on the test bench may reliably quantify the behavior of the component on the one hand. On the other hand, though, it can only provide a qualitative indication of how comfortable the vehicle is. The preconditioning performed on the components with large amplitudes (to ensure that the results can be reproduced and compared) does not correspond to the way the component actually behaves in the vehicle. What is missing is permanent high amplitude flexing. Uniform harmonic excitations also occur extremely rarely. It is therefore vital to constantly compare the observed, objective component characteristics with subjective driving impressions in order to accurately assess the comfort of air suspensions. Objective measurement on the vehicle can proceed in parallel with the aid of applied metrology and vibration profiles that can be reproduced. One example would be acceleration measurements on selected test tracks. This testing is expensive, however.

2.7 Causes and influencing factors

2.7.1 Causes of harshness

Characteristic of the increase in spring rate at low amplitudes is the *rolling resistance of the rolling lobe*.

This resistance to rolling that the bellows pits against axial motion results at the macroscopic level from the stiffness of the bellows wall at the rolling lobe. The bellows wall, acting as a stressed membrane under internal pressure, exerts a certain stiffness that influences the characteristic of the force–travel hysteresis. This portion of the bellows wall that stiffens the spring rate is the harshness effect. Among the causes is the mobility of the molecular chain, a characteristic of polymers (Voss, 2002).

To activate the spring, energy is necessary to deform the bellows wall in the rolling lobe. Various force components that occur while passing through the rolling lobe determine the amount of energy needed. Bending/flexing forces (as described by Thurow, 1995) that remain constant throughout the stroke are characteristic on the one hand. On the other hand, elastic and retracting forces occur that determine, as a function of amplitude, how much the material in the rolling lobe stretches. Viewed through a microscope, the rubber mainly deforms between and within the fabric layers during a rolling-lobe cycle. Figure 12 illustrates simulation of a bellows section of an unguided air spring transitioning from the interior to the exterior of the rolling lobe. The rubber stretches much more, particularly near the fabric layer.

Sufficiently large travel amplitudes cause a nearly constant resistance to rolling in the bellows while hysteresis remains constant. As amplitude diminishes, only a partial stroke of the rolling lobe occurs. The associated hysteresis force decreases. By contrast, the hysteresis curve rises more steeply, causing the spring rate to rise. The reason is that diminishing deformations within the elastomer matrix (due to its material properties) elicit

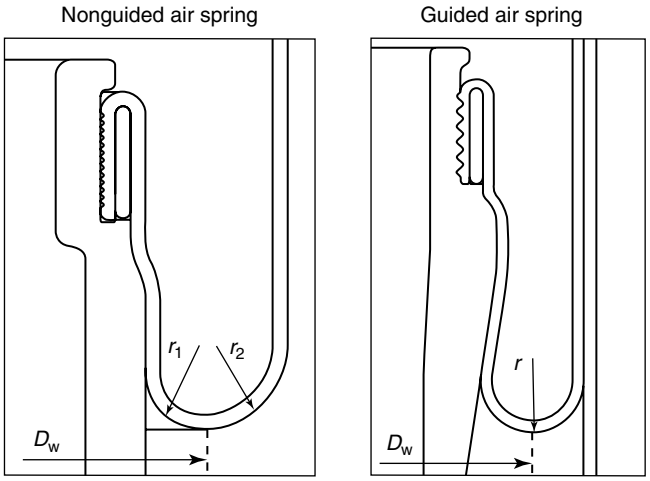

Figure 13. Geometry of the rolling lobe in an unguided and guided bellows.

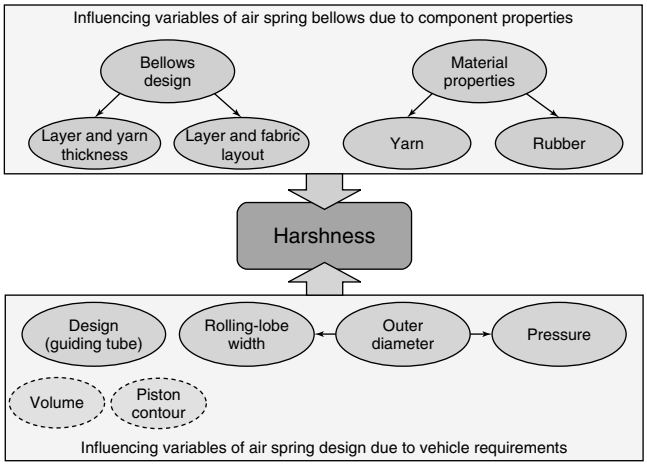

Figure 14. Factors influencing harshness.

the rising, nonlinear changes in force. Moreover, the resistance against the downward rolling motion results in deformation of the rolling lobe's geometry. A shift in the effective diameter may occur, independent of the piston geometry, depending on the stability of the rolling lobe. The result of this effect is an accompanying change in force, which plays a major part, primarily in unguided air springs. Figure 13 provides a detailed view of the rolling lobe's geometry with both a guided and an unguided air spring. The fold factor f_f describes the position of the lowest point of the rolling lobe and thus the effective diameter. With unguided air springs, the fold factor is subject to some variation because of the bellows design selected in conjunction with the material properties of the reinforcement material. The curvatures in the rolling lobe, simply described by the radii r_1 and r_2, do not act constant when rolling motions commence.

With guided air springs, the rigid outer guides largely prevent a change in the effective diameter. The rolling lobe remains more stable in its geometric form, and the characteristic geometry is more capable of retaining a constant curvature with a constant fold factor.

The bellows' resistance to rolling can be accompanied by a certain learning effect after it has stood still for a while. The persistence of the rolling lobe in one position when pressurized, as a function of time, increases resistance to any new motions. The elastomer's material memory "stores" a default position because of deformation in the matrix with the reinforcement material. Age can reinforce this effect. Added to this is the geometric formation of the bellows during vulcanization. A certain number of sufficiently large amplitudes are necessary to break down the resistance of the remembered default position.

Determining the effects of resistance to rolling demonstrated here are mainly the material properties of elastomer and yarn, plus the geometric relation of the whole assembly in conjunction with the kinematics of the rhomboid network in the rolling lobe. As a consequence, it is not impossible to cite a single specific factor for purposes of assessment. A multitude of interactive factors are responsible for the comfort of air suspensions. Figure 14 illustrates the main factors that influence comfort.

As Figure 14 demonstrates, influences from the specific properties of the bellows on the one hand, and influences from the air spring design due to the specific vehicle requirements are chiefly responsible for resultant harshness. The following discussion treats both influence groups in detail.

2.7.2 Influence of specific component properties of the bellows

2.7.2.1 Influence of the material properties of elastomer. Influencing the dynamic deformation behavior of an elastomer at low amplitudes are the fillers used in creating it. Fillers such as carbon black or silicic acid greatly improve physical properties of rubber compounds such as strength and durability.

Aside from the basic elastomer properties, the addition of fillers also leads to increased viscoelastic behavior on the part of the material. If sinusoidal deformation occurs, there will be a phase shift between stretching/shearing and tension. The complex shear module G^* can be subdivided into a memory module G' and a dissipation module G'' (Equation 9). The memory module G' is a measure of the stored elastic energy that is regained within a deformation cycle. The dissipation module G'' is the measure of energy

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

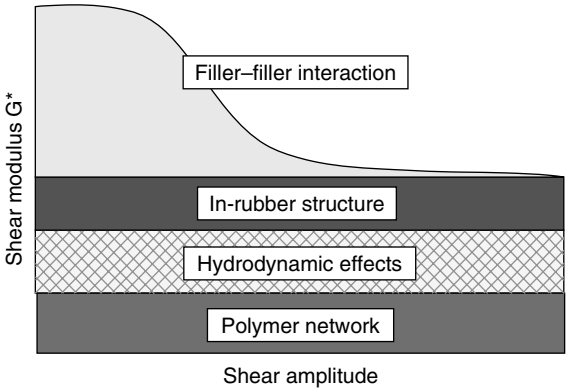

Figure 15. Payne effect. (Reproduced by permission of Joachim Fröhlich.)

dissipated as heat (Klüppel, 2007).

$$G^* = G' + iG'' \tag{9}$$

The ratio of both factors is known as the *dissipation factor* δ (Equation 10).

$$\tan\delta = \frac{G''}{G'} \tag{10}$$

The Payne effect describes the slope of the dynamic shear module G^* of a filled, vulcanized sample at an increasing amplitude of deformation (Figure 15).

The Payne effect adduces the breakup of the interactive filler compounds as the reason. According to Payne, other interactions between fillers and rubber, hydrodynamic effects of the filler particles or the properties of the pure polymer are largely amplitude independent. When the deformation retracts, these filler compounds rapidly reform. Figure 16 shows the breakdown of the interactive filler compounds using the example of a silica-filled elastomer.

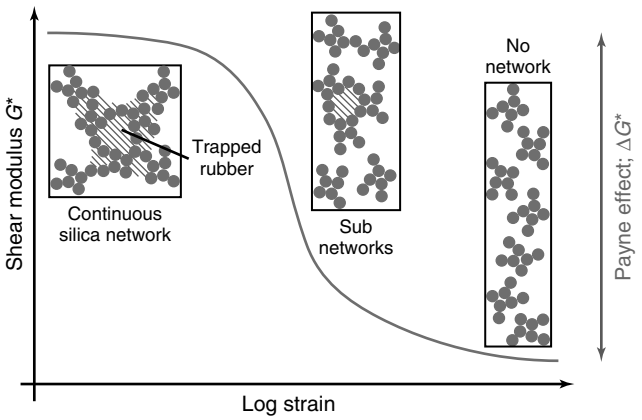

Figure 16. Payne effect regarding silica network. (Reproduced by permission of Joachim Fröhlich.)

The Payne effect and the characteristic viscoelastic properties become much more pronounced as the amount of filler increases. Figure 17 illustrates the decline of the memory module G' toward large deformations, plus the bulge of the dissipation module G'' as a function of the silica content.

There have been different interpretations of the Payne effect and its causes. The basic explanation of the material behavior of the elastomer ingredients nevertheless follows Payne's original core idea. Interactions occur not only within the filler material but also in the compound of the filler with the polymer matrix (Boehm, 2001). The literature generally speaks also of internal material friction based on a type of breakaway effect analogous to contact–friction phenomena.

Filled elastomers find application mainly in automobile air suspensions. The use of CR (chloroprene rubber), a chlorinated elastomer, is widespread. With the help of suitable ingredients, its properties render it capable of satisfying many of the requirements made on air suspension components in automobiles. Carbon black and silica are the main fillers used in various mixtures. The Payne effect is quite apparent here as well and explains the amplitude-dependent behavior of the increasing spring rate.

Alternative rubber compounds also come under consideration for improving comfort if one is willing to compromise regarding requirements for diverse automotive components. Natural rubber (NR), for example, offers great potential. A combination of various elastomer compounds for the bellows is also possible, depending on the function and the location in the bellows.

2.7.2.2 Influence of the material properties of the reinforcement material. Polyamide (PA) and, to a lesser extent, polyester (PES) and aramid find application as reinforcement materials in the form of individual strands of yarn or rolled fabric mats in automotive air suspensions. PA adheres very well to rubber and is inexpensive but exhibits rather low strength when highly stretched. The strength of PES is comparable to that of PA while its expansion properties are superior, especially with regard to temperature and durability. Aramid, on the other hand, is extremely strong and rather brittle, which somewhat limits its application because of its sensitivity to compression.

The material of the reinforcement plays a rather insignificant role in harshness. This is especially true as the configuration of the bellows leaves little freedom to choose materials because of the strength demands placed on the component. However, a strong fabric made of strong yarn

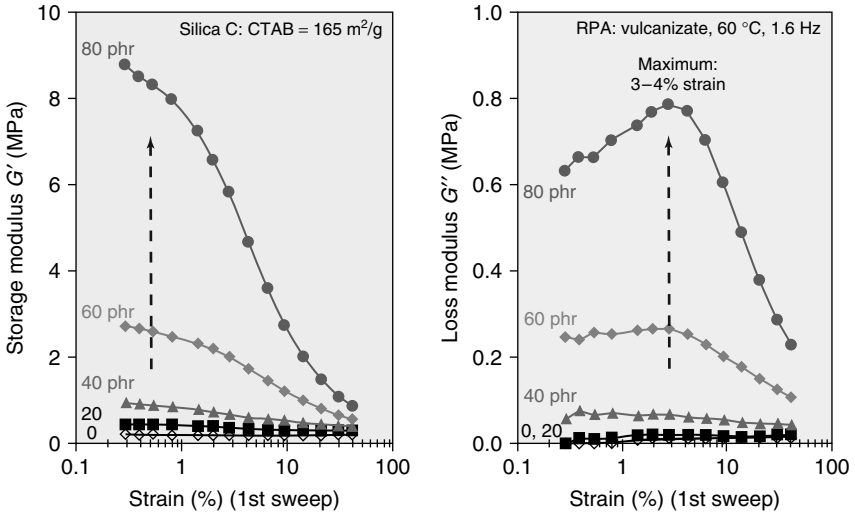

Figure 17. Memory- and dissipation-module curves. (Reproduced by permission of Joachim Fröhlich.)

and a high yarn density guarantee a stable rolling lobe with regard to less harshness. By contrast, however, the bellows wall may lack flexibility. Material properties may also have an influence on acoustical transmission.

2.7.2.3 Influence of the design of the bellows (wall thickness, yarn angle, yarn density, and thread count). The resistance to deformation of the bellows matrix not only depends on the materials used in the elastomer and the reinforcement but depends also on the design of the bellows. The main components here are the thickness of the elastomer layers, the diameter of the yarn, the yarn angle, and the thread count and/or the separation between strands. The combination of these parameters gives rise to a linked system that must undergo deformation. In the case of cross-layered bellows, a rhomboid pattern arises that determines the geometry and the deformation of the elastomer within the rhomboid. Figure 18 illustrates the stretch of the material within the rubber matrix as the rolling lobe passes through from the piston to the outer diameter. The example shows a bellows submodel of an unguided spring. The amount of material strain varies as a function of the bellows design.

To reduce harshness, material deformation must be kept low and the geometry of the rolling lobe must be kept stable. An advantageous design in this regard exhibits thin bellows with thin reinforcement material, little material, and slight deformations in the rhomboid pattern, thanks to optimized packing of yarn in conjunction with an optimized yarn angle. Such a high strength networked system, however, on the other hand, may slightly elevate the rigidity of the bellows wall during the rolling-lobe cycle.

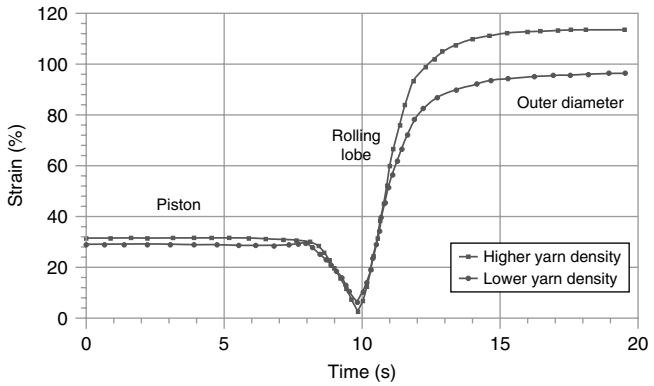

Figure 18. Depiction of the principal tensile strain in the rolling-lobe's cycle as a function of the bellows design.

Reducing the intermediate and outer rubber layer improves harshness markedly with regard to wall thickness. While yarn angle and amount in unguided springs depend essentially on the space available and requirements of engineering strength, the yarn parameters of an externally guided air spring can be put into effect for purposes of comfort under certain conditions. There is thus an ideal yarn angle for every bellows design.

Axial bellows do not exhibit any deformation with the rhomboid pattern because of the single layer of purely vertical yarn. This is the reason why axial bellows enjoyed the reputation until recently as being good for comfort. The entire arrangement, however, also provides less stability against deformation when the rolling lobe is in motion than the cross-layered arrangement. Moreover, thicker yarn must be combined with low rolling-lobe widths in an axial

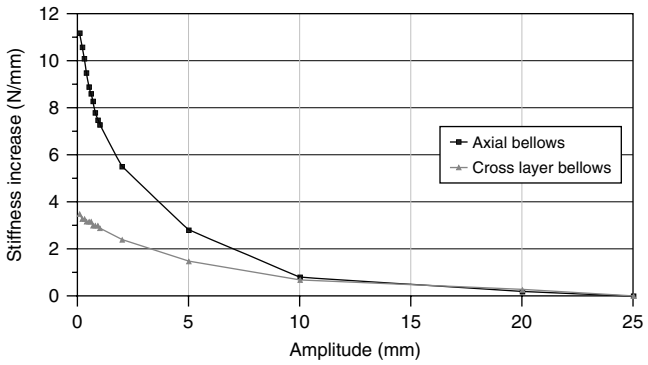

Figure 19. Harshness comparison between cross-layered bellows and axial bellows.

bellows for reasons of engineering strength. In addition, the operating pressure is capable of compressing the rubber material more strongly between the strands of yarn and deforming it even further. The rubber in the rolling lobe consequently experiences very severe deformation during movement. Bellows design is thus subject to severe limitations when it comes to the comfort of axial bellows.

By contrast, thin, guided cross-layered bellows offer the greatest possible leeway in shaping the parameters for improving harshness. Current developmental work has indicated that it is possible to greatly reduce harshness by employing very thin PA fibers and thin elastomer layers of CR in conjunction with the optimized air spring application. Figure 19 illustrates the great potential of a comfortable cross-layered bellows compared to an axial bellows used in the same air suspension of a luxury car. The excessive stiffness of the cross-layered bellows was reduced to approximately 30% of the level of the axial bellows. Its harshness of less than 4 N/mm has been reduced to a minimum.

2.7.3 Influence of the air spring design due to specific vehicle properties

The actual configuration of the air suspension exerts a major influence on harshness in conjunction with the properties of the bellows' components. Worthy of mention here are parameters such as air spring diameter with the accompanying pressure level, plus the opportunity to integrate exterior guidance, all the while considering such vehicle requirements as space for installation, load, and the intended spring rates.

2.7.3.1 Influence of air suspension diameter (pressure level and width of rolling lobe). Exploitation of the maximum air spring diameter is reflected in the reduction of the static pressure level. The internal pressure in the air spring stretches the bellows membrane and consequently puts an end to material expansion and the associated deformation (Voss, 2002). Reducing the pressure thus directly mitigates material deformation. The ideal amount for a minimum level of pressure, which would just guarantee the optimum forming of the rolling lobe in every situation, is generally not achievable in passenger car applications because of space limitations. In reality, the basic pressure $p_{\text{stat.rel.}}$ of approximately 8 bar is usual.

If there is sufficient space and clearance for the air springs, there is also a way to optimize the width of the rolling lobe r_b. Rolling lobes that are too small can quickly result in an increase of harshness because of a high rate of material deformation in the bellows wall. Moreover, they have a negative impact on engineering strength. By contrast, rolling lobes that are too wide necessitate large amplitudes for their initial pass-through, associated with a greater change of the yarn angle. The effective diameter (as a function of the rolling-lobe width) changes in parallel with the resultant operating pressure. The effect on harshness is, however, rather negligible.

Therefore, there will always be an ideal rolling lobe for each type of air suspension. Steps for reducing pressure and designing the ideal rolling-lobe width can make a major contribution toward reducing harshness. Figure 20 illustrates the influence of the rolling-lobe width using the example of a guided air spring.

2.7.3.2 The influence of exterior guidance. The expansion of the bellows reduces greatly when exterior guides are used. The rigid outside guide now absorbs the circumferential forces. This permits setting the yarn angle of the bellows generally between 60° and 90°, which then approximates the actual equilibrium angle during operation.

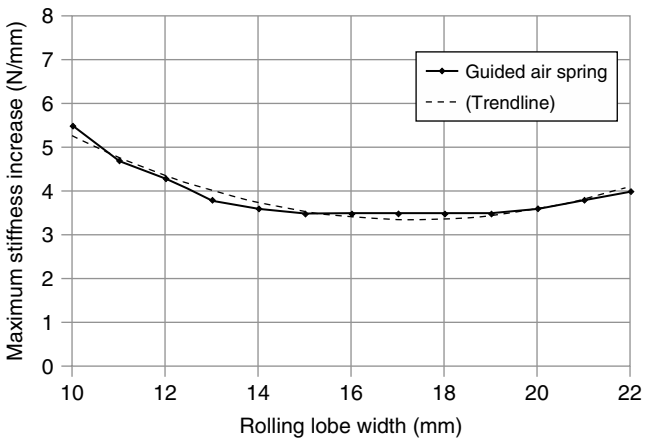

Figure 20. Influence of the rolling-lobe width on harshness.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Reinforcement material and elastomers are thus subject to much less load and deformation. This, in turn, allows for very thin-walled bellows. Above and beyond that, this protects the bellows from environmental influences. This makes it possible to keep the thickness of the outer cap to a minimum. Embedding thinner threads of yarn also contributes to a thinner bellows.

The rolling-lobe geometry remains stable because of the rigid outside guides and reduced deformation.

For purposes of comfort, air suspensions on passenger cars cannot do without exterior guidance. Most externally guided air springs are designed in the form of struts. It is somewhat more problematic to incorporate rigid guides in the case of freestanding air springs.

In contrast to the influences described earlier, the parameters such as air spring volumes and piston-roll geometry have only a negligible effect on harshness. Both generally affect only the basic spring rate.

2.7.3.3 The influence of air spring volume. The change in the air spring's nominal basic stiffness does not result in any increase in stiffness at low amplitudes. Studies of air springs with adjustable additional volume have confirmed this. While the basic spring rate increases as volume reduces, the resulting harshness only changes insignificantly (Figure 21).

On the other hand, the hysteresis forces of the air springs change as a function of the spring volume.

2.7.3.4 The influence of piston contour. The contour of the piston is an important parameter that influences spring characteristics, making it possible to adapt spring characteristics to the requirements of the car. When optimum rolling-lobe widths are considered and the angle of the piston is kept within certain limits, the effect on harshness is negligible. Of course, the piston contour exerts a strong influence on the geometry of the rolling lobe and its deformation, so that it is impossible to exclude an influence, especially for unguided air springs and very large changes in angle such as rises $>20^{\circ}$. As long as the rolling-lobe geometry can still "follow" the piston contour (i.e., the effective diameter is proportional to the piston diameter), its influence will be negligible.

Significant interactions among the influencing factors, depicted in Figure 14, will always occur. Each individual factor can change the harshness of air springs but it is necessary to find the optimum balance of all parameters for an individual application. Air spring manufacturers have specific configuration rules depending on the type of spring and bellows design employed. As a practical matter, it would be difficult to quantify values precisely with the aid of simulators and calculations because of the complex behavior of the material in the bellows structure. Values obtained empirically generally serve the development process. Table 1 summarizes the influencing factors and their importance.

It will be necessary to transfer all the influential factors shown here to the design and configuration of any air suspension system during the development process. The vehicle's axle design will determine the type of air spring. Consequently, certain limits already apply when attempting

Table 1. Factors influencing harshness.

Variable			Influence
Bellow design	Rubber	Material	Strong
		Thicknesss	Strong
	Yarn	Material	Neutral/medium
		Thicknesss	Medium
	Matrix layout		Strong
Air spring design	Guiding tube		Strong
	Pressure		Medium
	Rolling lobe width		Strong
	Volume		Neutral

to improve harshness due to the type of air suspension chosen.

3 HARSHNESS OF DIFFERENT TYPES OF AIR SUSPENSION

3.1 An overview

Air springs may be configured either as a strut or as a freestanding spring, depending on the type of axle employed. Struts see use in luxury cars predominantly on both front and rear axles while freestanding springs are found mostly on rear axles in middle-class and economy cars. Nevertheless, struts offer the greatest potential for diminishing the effects of harshness (Figure 22). The following spring–rate curves Δc_{harsh} are attainable in air suspensions being mass-produced currently:

- air strut, externally guided: $\Delta c_{harsh} = 3–6$ N/mm;
- air spring, freestanding, externally guided: $\Delta c_{harsh} = 6–10$ N/mm;
- air strut or air spring, unguided: $\Delta c_{harsh} = 10–15$ N/mm.

The differences make it quite apparent that the combination of an externally guided strut on the front axle with a freestanding, unguided air spring on the rear axle elicits a pronounced mismatch of the respective harshness. While the front axle probably provides good comfort, the rear axle may lag noticeably behind. Experience has shown that it is not possible to eliminate this discrepancy. The trend toward modular construction in the automobile industry is leading to uniformity in the axle concepts of middle-class and luxury cars. Consequently, there are efforts afoot to establish the freestanding spring for the rear axle also in the luxury segment.

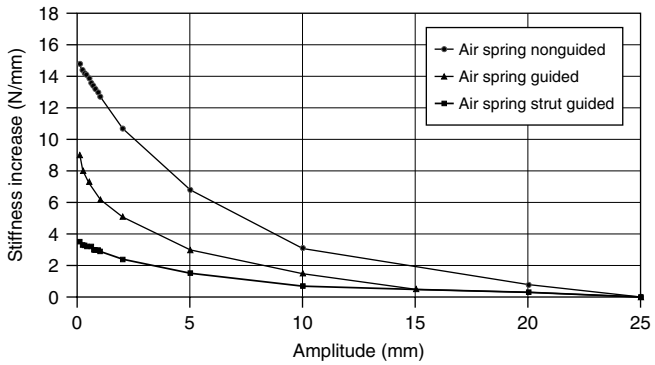

Figure 22. Harshness curves of different type of air suspensions.

3.2 Air struts

In strut architecture, the air spring is arranged concentrically around the damper, just as with a steel spring. The strut contains all the elasticity necessary to compensate for movements from the axle kinematics. Different configurations of air suspensions are possible, depending on the requirements of the vehicle and manufacturer. Figure 23 illustrates three possible configurations. Aside from simple, inexpensive unguided air springs, there are the more commonly used guided designs. The restricted motion of the bellows due to the rigid guide, however, necessitates integration of cardan compensation. Cardan means in this context that the air bellow needs to have certain flexibility into all directions. As will be shown soon, the strongly defined damper movement, defined by the suspension arm, makes the additional movement of the air spring itself necessary, as this is also connected to the top mount which is with the car body.

3.2.1 Externally guided struts

External guidance is indispensable if one is to diminish harshness appreciably. Assuming ideal parameters (see Section 2.7), it is possible to use cross-layered bellows with thin walls between 1.4 and 1.8 mm. Ultrathin PA yarn measuring 235 dtex × 1 serves as reinforcement. The yarn

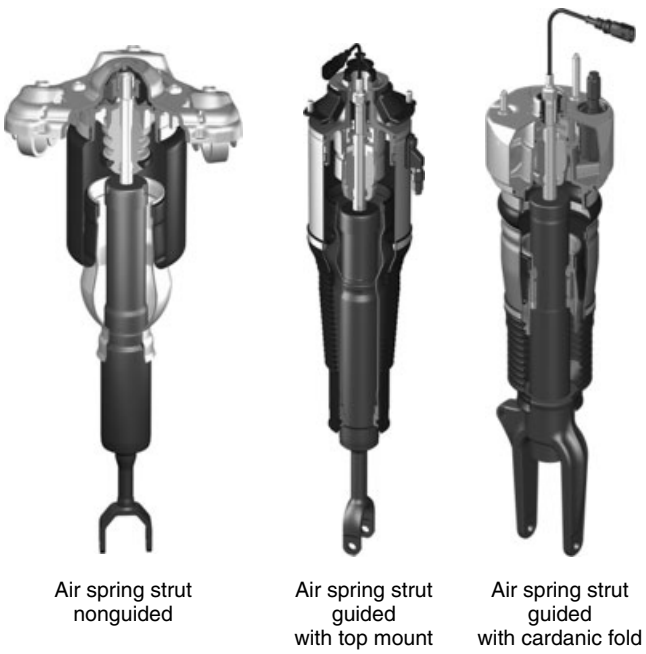

Figure 23. Selected strut configurations. (Reproduced by permission of Continental AG.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

has a diameter of just 0.19 mm. This makes it possible to achieve a minimal harshness Δc_{harsh} of up to 3 N/mm, which is hardly noticeable. The potential here has surely been largely exhausted. Any future improvements will require much effort in manufacturing the bellows when processing the fine yarn and the thin rubber layers. A major focus, moreover, will have to be on improving the material properties of the elastomer.

3.2.1.1 Cardan compensation. It appears much more important to focus on parallel effects that diminish comfort. The architecture of the air suspension can influence these two effects. Aside from the actual harshness of the air springs, the contact friction of the damper-piston rod plays a decisive part. Owing to the cardan motion of the strut in the axle, bending (flexural) moments are transmitted to the damper. They generate lateral forces on the piston rod, which increases friction as a direct consequence. As the strut compresses, it has to overcome a breakaway effect. This breakaway effect diminishes comfort appreciably (particularly at low amplitudes) and masks the harshness of the air springs noticeably (Ilias and Sorge, 2001).

The design of the struts determines the properties for taking up cardan movement within the axle's kinematics. The elasticity in the strut determines the quality of the cardan compensation and the transmission of bending (flexural) moments. Besides the elasticity of the air springs, this also includes the elasticity of the bearings used. A suitable air suspension design is thus capable of supporting optimum cardan compensation. Figure 24 illustrates that an additional elastomer bearing or a cardan fold could find application here. Elastomer bearings in the form of rubber and metal components can also have a decoupling effect because of their transmission behavior, and this also adds to the impression of higher comfort. Simply put, the cardan fold is an exposed, unguided bellows section that is reinforced and possesses a great deal of elasticity. It represents a simple, inexpensive solution.

3.2.2 Unguided air struts

Struts with unguided air springs play a somewhat subordinate role when it comes to comfort. The harshness effect is more marked because of their more robust structure and exceeds that of a guided spring many times over. The higher demands placed on the bellows make a thicker yarn necessary (at least PA 940 dtex × 1, yarn diameter approximately 0.33 mm) and a thicker outer cap. The total bellows wall thickness then lies in the range of around 2.0–2.4 mm. An optimum configuration of the remaining influential parameters can confine the spring rate to an acceptable range here. On the other hand, the good cardan compensation, mostly in the form of bellows elasticity, is advantageous.

3.2.2.1 Wheel-locating air struts. There is one promising way to improve comfort for unguided air springs with suspension struts such as the MacPherson strut. By locating the wheel, they transfer higher bending (flexural) movements to the strut, resulting in a greater lateral force with accompanying friction of the piston rod of the damper. An optimum air suspension design and configuration can nearly compensate for the transverse forces that occur. The reduced lateral forces consequently reduce friction of the piston rod and also provide a way

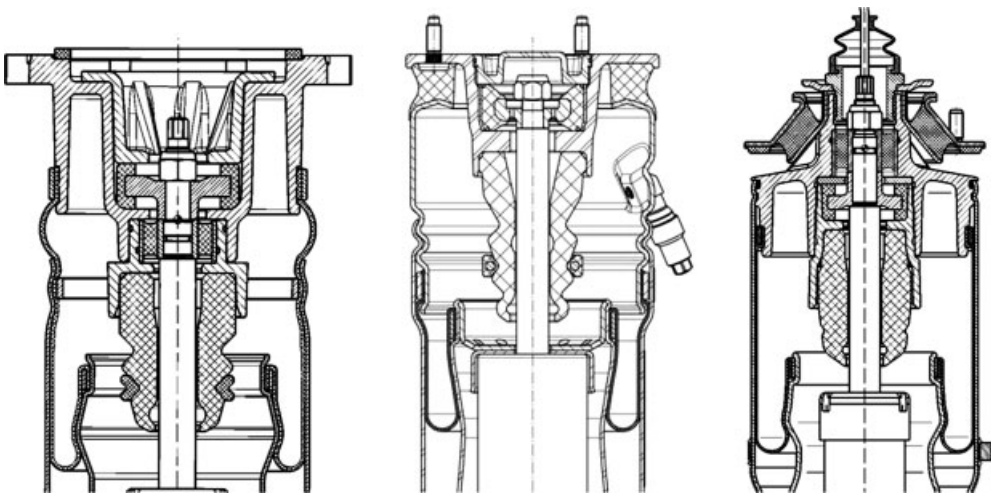

Figure 24. Cardan compensation of guided air struts. (Reproduced by permission of Continental AG.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to improve the design of the seals and the guides for the piston rod. However, these air suspension concepts are complicated and costly. What is more, the asymmetric arrangement of the bellows places greater demands on engineering strength.

3.3 Freestanding air springs

Rear-axle designs for automobiles call mostly for a spatial separation between dampers and springs. The freestanding springs are located more inboard. Their lower design height allows for a wider loading space in the cargo area. However, the springs' inboard position does result in limited space for installation. It also results in a relatively offset position for the air springs' pistons and cap because of spring motion. The rolling lobe may become more constrained as a consequence. Furthermore, the high spring ratio (up to $i = 0.5$) increases the load-carrying capacity and, consequently, the static pressure level. The high potential for additional load on the rear axle also adds to operating pressure. There is, therefore, a need for air suspension architecture that is capable of accepting cardan movements very well on the one hand and can offer the necessary space for spring travel with very little clearance on the other. The parameters mentioned earlier are counterproductive if one wants to optimize comfort. Using rigid, external guidance is problematic because of cardan motion and the permissible space. Parallel to this, the higher level of pressure requires robust bellows. Various types of freestanding air springs may offer a solution as illustrated in Figure 25. In addition, it is possible to make the lobe rolling upward. A guided version can also be seen in Figure 25.

The differences among the shown versions and the conventional model are the upside-down arrangement, the use of a double rolling lobe, and a flying external guide.

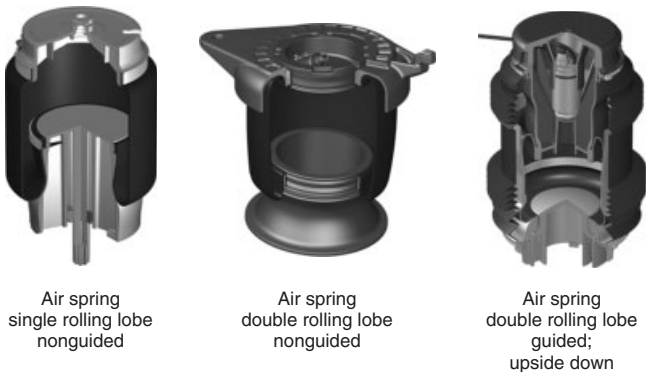

Figure 25. Selected versions of freestanding air springs and a guided one with a double rolling lobe. (Reproduced by permission of Continental AG.)

3.3.1 *Externally guided, freestanding air springs*

Compared to the front axle, acceptable values for harshness at the rear axle are achievable only with a guided design. To ensure cardan compensation and guarantee freedom of movement, experience has shown that it is necessary to have two rolling lobes and an upside-down arrangement. Inclusion of external guides requires a very compact flying design. This means that the external guide covers only a portion of the bellows and leaves the second rolling lobe largely exposed. All in all, the bellows wall can be made thinner although it must still be robust in the vicinity of the second rolling lobe. An extremely thin wall such as the strut is currently not possible for this reason. As a practical matter, though, it has already been possible to achieve a spring rate that is less than 10 N/mm in a luxury sports car.

There is potential for still more development. The second rolling lobe must be geometrically configured so that the stress sinks, on the one hand, and the harshness effect diminishes, on the other. In view of the above, it would be conceivable to achieve maximum stiffness rates of approximately 5 N/mm and thus to approximate the comfort level of the front axle.

3.3.2 *Unguided, freestanding air springs*

The use of freestanding unguided air springs in middle-class and light trucks is widespread due in part to cost and space limitations. Comfort is not the top priority in this segment, especially not in the case of rear-axle systems with load leveling. Combined with guided front air springs, the increased harshness occurs noticeably which means that it is necessary to pay attention to this area. As there is only limited freedom in configuring the bellows, any design must be functional and geometric.

An upside-down arrangement in conjunction with a second rolling lobe improves the kinematic movement of the springs and reduces the design height needed. It is then possible to design the geometry of the rolling lobe better and reduce the constriction of the rolling lobe.

What is more, a concept with a second rolling lobe permits placing it at the height of the effective diameter so that the spring rate of the rolling lobe activates in line and consequently sinks. This principle does entail limited freedom of configuration though. Optionally, an additional antiharshness layer in the form of an elastomer or polyurethane (PUR) layer can greatly improve transmission properties, particularly when it comes to acoustics. A simple elastomer layer is generally all that is necessary where the spring joins the bodywork.

The acceptable comfort range for unguided freestanding air springs is approximately 10–15 N/mm of spring rate.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto015
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

With proper measures, it should be possible to drop the rate to under 10 N/mm in the future.

These harshness numbers do not present a real alternative when it comes to comfort, however. Guided air springs are still indispensable here, ideally as a strut. Added to this is optimum cardan compensation to minimize any additional friction effects.

4 OUTLOOK

Air suspension's market penetration will continue. Air springs bestow a noticeable improvement in comfort, primarily in luxury and middle-class passenger cars. Small cars (which are coming to the market next time) need air springs most, but the cost is (up to now) the largest obstacle. The focus for future work is on improving the characteristics of air suspensions. The harshness effect is a fundamentally undesirable property of air spring bellows and is also an important, quantifiable gage of comfort for automotive components. Objective test results, however, must always be brought into line with subjective assessment.

In view of the various factors influencing harshness, it is possible to demonstrate extremely slight increases in spring rate at low amplitudes using targeted air suspension designs. Externally guided air springs with thin-walled cross-layered bellows and fine yarns of PA are capable of reducing the bellows' resistance to rolling to a minimum. These bellows find use predominantly in strut designs. More development work will be necessary to use thin bellows in freestanding spring designs in order to attain a comparable level of comfort. In addition to empirical experience with comfort-based air suspension, simulation processes will increasingly be used to predict harshness properties.

Beyond that, it will be necessary to analyze and reduce other factors that diminish automotive comfort. Besides the air springs themselves, it is worth mentioning the properties of elastomers where the suspension joins to the body and the response of hydraulic dampers as factors that can generate undesirable rubbing effects. However, the structural stiffness of the bodywork also plays an important part in transmitting undesirable vibrations and noises to the car and to the passengers.

5 SUMMARY

Air spring systems are introduced into the market, but for passenger cars, these systems suffer from harshness. This contribution gives a detailed explanation on the effects of harshness and the reasons for the existence. In addition, there are descriptions for the measurement, the simulation, and the reduction of the harshness effects to modern air spring systems. Detailed information will enable the automotive chassis designer to reduce the harshness effect in the future.

Air Supply for Advanced Applications

Hans Otto Becher
WABCO, Hannover, Germany

1 INTRODUCTION

The desired characteristic and performance of air suspensions in passenger cars can only be achieved in combination with an air supply unit (ASU). The ASU itself is necessary but undesired: it consumes space, increases weight, consumes energy, creates noise and vibration, and costs money. And exactly they are the key characteristics of an ASU, which are subject to continuous optimization.

However, the ASU is mandatory to generate compressed, dry, oil-free, and clean air to pressurize the air springs. The suspension elements have to be filled with a certain pressure for normal working operations. Natural leakage through bellows, pipes, connectors, and valves has to be considered to be compensated. In many cases, there are additional demands to increase the chassis level by inflating the air springs and decrease the chassis level by deflating the air springs.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016

The compressed air has to be distributed into the air springs, which is mostly done with multiple solenoid valve blocks. To lower the vehicle chassis height, the air springs have to be vented. The ASU provides solenoid valves for this function.

In addition to the above-mentioned criteria, key performance indicators for ASUs are airflow, maximum pressure, duty cycle, electrical current consumption, and peak current.

2 SYSTEM REQUIREMENTS FOR AIR SUPPLY UNITS

2.1 Two-corner applications for rear axles

There are two types of two-corner air suspension systems on the market:

- Leveling systems (combination of steel springs and air springs)
- Full air suspension systems (without steel springs).

Leveling systems are designed to carry the basic vehicle rear axle load (empty condition) with a steel spring and the additional load of passengers and cargo with an air spring. There is just one nominal level requested. Quick lifting/lowering is not needed.

Consequently, the airflow performance requirement is low, typically about 10 norm dm^3/min [where norm dm^3 is the amount of air which fills one dm^3 at 0°C and 1013 mbar at 6 bar. The pressure range however is between 1 (minimum pressure to avoid bellow damage) and 12 bar in the fully loaded condition. The pressure demand is quite high as the diameter of the air spring is limited because of

packaging reasons. These systems are popular in the North American market, but the market penetration is decreasing. The system layout is simple (only one common height sensor for right and left side) and the ASU design is very much cost driven.

Full air suspension systems for rear axles, carrying the whole rear axle load (empty vehicle load + passengers + cargo), are more demanding regarding the ASU (Figure 1). While the pressure levels are similar, the airflow requirement is higher (>20 norm dm^3/min at 6 bar). The end-user's requirement is a quick, visible compensation of chassis level drop after loading. Additional functionality is for instance a switch in the trunk area for manual lowering of the chassis for easy loading operation. This lowering procedure has to be quick as well to avoid waiting time. Consequently, the air passage through all system elements has to have a sufficient diameter. Usually, these ASUs have a double solenoid valve block to control left- and right-side air spring individually. This feature allows a right/left-balanced leveling even if the axle load is not centered. In addition, the roll stiffness is increased, as the airflow between right and left air bellows is blocked. Another feature is the load transfer away from one wheel in case of a damaged "run flat" tire. Unloading the damaged tire can increase the allowed driving distance.

Duty cycle demand for ASU's in two-corner systems is low (typically 10% on-time of a 10-min period, environmental temperature 23°C), as there is no normal operation mode, which requires a long continuous compressor run. The longest sequence is given by filling the empty air spring from buffer level to normal ride height and loaded condition. Typically, this operation does not take longer than 60 s.

In some cases [transporters and sports utility vehicle (SUV)], these systems have a reservoir for quick lifting and/or compressor running noise avoidance in certain conditions. Then, the ASU performance in terms of airflow and maximum pressure has to be even higher and on a level of typical four-corner reservoir systems (Section 2.2).

2.2 Four-corner applications

Most of the four-corner systems have a reservoir to enable quick lifting by a high airflow from the reservoir into the bellows. Performance demand for ASU's used in reservoir systems is typically >25 norm dm^3/min at 6 bar, maximum pressure up to 18 bars. Duty cycle requirement is higher (15%) than for ASU's in reservoirless systems, as the compressor run time to fill up a reservoir up to 18 bar is significantly longer than to inflate the bellows directly.

Another advantage of reservoir use is that the compressor must not be operated in the vehicle standstill condition, which is very noise critical (start–stop system, engine off). In closed systems, a reservoir is mandatory, as the air is moved between air spring and reservoir. Usually, a direct bellow filling by the compressor or exhausting of the bellows is not possible.

Some four-corner systems are working without a reservoir. These systems are designed to operate without attracting attention from the end user. Chassis-level changes are expected to be "invisible," thus the demand for the ASU airflow is low. Maximum pressure is similar to two-corner systems (12 bar). The compressor has to be operated also in standstill mode of the vehicle, and so the demand regarding very low compressor running noise is high.

Many four-corner systems are using not only the benefits of air springs in normal operation mode but also the possibility to lift or lower the chassis. Reasons for this include dynamic driving behavior and reduced fuel consumption

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

by low level at high speed, easy entry for passengers, and extended ground clearance for certain driving situations (e.g., off-road). These kinds of systems are demanding higher performance from the ASU: high airflow during lifting and lowering operations, high maximum pressure, and high duty cycle for frequent repeats of level changes. To monitor the duty cycle of a compressor and getting close to the thermal limits, the information about compressor temperature or at least environmental temperature in the area of the compressor is mandatory. Some systems have additional volumes that can be connected/disconnected to the air bellows to vary the spring stiffness. For the ASU, this means more air volume to be transported into and off the bellows. Figure 2 shows a typical example for a four-corner ASU.

2.3 Further demands for compressed air

Having an ASU installed in a passenger car increases the desire to use this energy also for other systems. As an example, a brake booster with compressed air could be packaged much more compactly than a typical vacuum brake booster. However, this concept was never realized. The only option, which was marketed so far, was a tire inflator. The compressor can be used to fill a flat tire or leisure equipment. For some special applications, there are systems on the market, which are able to control the tire pressure during driving. The main reason not using compressed air for other applications than air springs is that many features as the air suspension itself are just optional. One example is a dynamic seat contour, which uses inflatable cushions. An ASU for air suspension systems would be oversized for the seat operation alone. Therefore, these applications have own small compressors, directly installed in the seat.

2.4 General system requirements: future outlook

The load-bearing force of an air spring is as follows:

$$F = p_i \cdot A$$

The demand for smaller air bellow diameters and thus effective cross-sectional area of an air spring A because of packaging reasons in passenger cars leads to increasing bellow pressures p_i. Thus, the main future challenge for ASUs is a higher maximum pressure.

Furthermore, the vehicle manufacturers will specify size, weight, and inrush current limitation more strictly. Noise and vibration levels are also subject to improvement, because hybrid or electric drives in passenger cars allow a very low basic noise level, and the ASU must not stick out during those driving conditions.

3 GENERAL FUNCTION OF A COMPRESSOR FOR AIR SUSPENSION

3.1 Compressor

Following the system requirements in Section 2, the preferred solution for an ASU is a dry-running piston compressor driven by an electric motor. Other devices such as vane-type pumps or rotary screw compressors are not able to generate the requested pressure levels (10–18 bar) or are commercially not attractive.

3.1.1 One-stage open type

Open type means the compressor is sucking air directly from the atmosphere, compressing it to the requested level and feeding the air springs and/or reservoir. Exhausting the air from the bellows into the atmosphere lowers the chassis.

A typical 4-corner open system schematics is shown in Figure 3. By far, the most popular and common design is a one-stage piston compressor, open type (Figure 4). The air is taken in from the atmosphere through the air intake into the crankcase. If the piston is moving down,

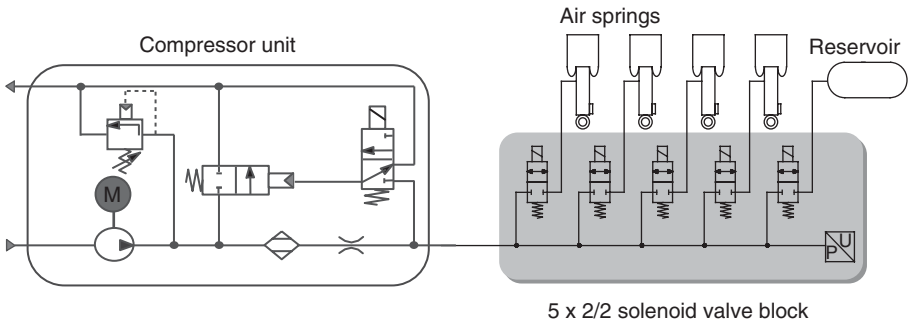

Figure 3. System schematics of a four-corner air suspension system (open system). (Reproduced with permission from WABCO Hitachi.)

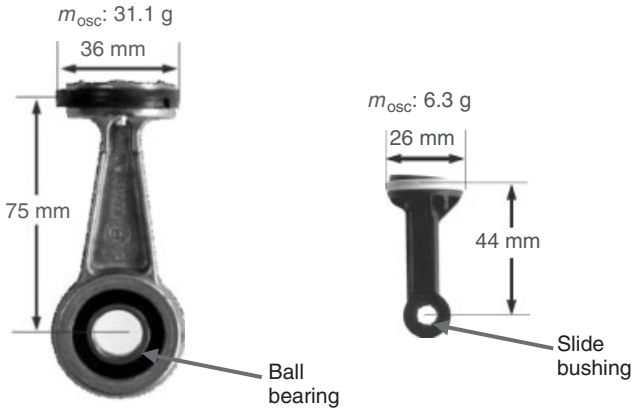

Figure 5. Wobbling pistons with ball bearing and slide bushing. (Reproduced with permission from WABCO.)

the air flows through the intake valve in the piston into the cylinder. If the piston is moving up, the air is compressed and guided through the pressure valve into the air dryer. The compressed air passes the desiccant and is then guided to the pressure port and entering the system.

All known one-stage piston compressors for air suspensions are directly driven by an electric motor. The crankshaft is fixed on the motor shaft and drives the connecting rod. The connecting rod bearing is—depending on the operation conditions and performance range—designed as a ball bearing or slide bushing (Figure 5).

In many cases, the piston and the connecting rod are designed in one piece without articulation between piston and connecting rod. This "wobbling piston" design requires special focus on the piston sealing elements, which have to tolerate an angular motion of the piston (Figure 6).

There are two possible solutions to piston sealing: piston ring or gasket (Figure 7). For both designs, the proved material is PTFE providing a sufficient heat and wear resistance without being lubricated. At the same time, the sealing has also to be able to work under low temperature down to -40°C.

The piston ring (Figure 8) is usually a machined part with a slot for assembly and for wear reasons. This design ensures a permanent defined axial contact pressure between the piston ring and the cylinder wall.

Although the piston sealing should be as tight as possible to achieve maximal volumetric efficiency, the piston ring has a natural leakage under static conditions. Thus, pressure balancing above and below the piston is given within the cylinder, which enables an easy compressor start. In comparison to the piston ring, a gasket is a more simple part, is fixed to the connection rod, and has always close contact to the cylinder. A piston ring has always a certain amount of clearance in axial direction (Figure 9) to allow

Figure 10. Articulated compressor piston. (Reproduced with permission from WABCO.)

the ring moving. However, this clearance has a negative impact on acoustics.

Another focus lies on lateral piston forces. These have to be minimized to achieve low friction, low wear, and thus a long lifetime. In some cases, an additional ring to carry the lateral forces and unload the sealing (Figures 9 and 10) accompanies the piston sealing.

There are also compressors in the market, which have an articulation between connecting rod and piston (Figure 10). The additional articulation with another bearing and a certain clearance might have a negative impact on acoustics.

Usually, the piston material is aluminum. In the case of lower pressure ranges (and thus lower temperature), the piston can be designed from plastic (comparison in Figure 5).

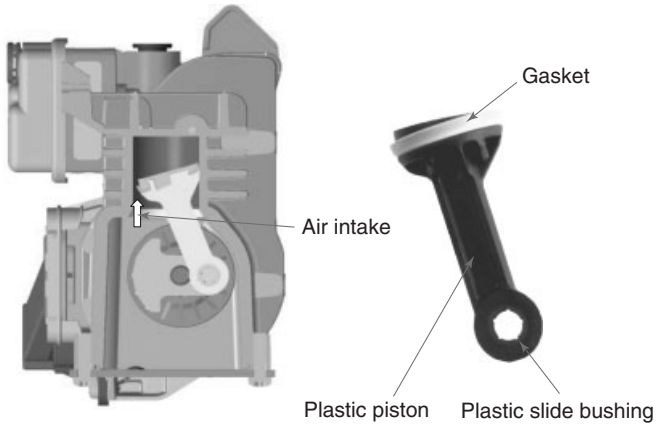

Figure 11. Low power compressor. (Reproduced with permission from WABCO.)

3.1.1.1 Air intake/suction valve. Air from the atmosphere has to be led into the cylinder. This can be done with an intake valve in the cylinder head or directly in the piston (Figure 4). The lower the stiffness of the intake valve, the higher is the volumetric efficiency. On the other hand, the design has to ensure low tension forces and sufficient strength of the part over lifetime.

In the compressor range of low pressures <10 bar, the intake valve can be omitted by opening a bypass in the lower position of the piston (Figure 11).

3.1.1.2 Pressure valve. The pressure valve is located in the hot area of the compressor, and consequently, it has to withstand high temperatures. In addition, it should have a low delta pressure (low stiffness) for efficiency and a low leakage level. Leakage would allow a flow back into the compression chamber, reducing efficiency and starting capability.

There is a trade-off between those demands: an elastomer pressure valve can achieve low leakage level, but high temperature could be an issue. Another design uses steel leaves as a check valve, which has good robustness against high temperature, but allows a certain amount of leakage. The steel leaf type has a very low mass and thus high dynamic capability. This gives advantages in terms of noise. In the market, both types of pressure valves are known (Figure 12).

3.1.1.3 Dead volume. To optimize the volumetric efficiency, the dead volume has to be minimized. This dead volume is also important for the stabilized pressure, which is achievable. Even at low environmental pressure (high geodetic heights) of about 0.6 bar, the compressor performance must not drop below the specified level. Test results are shown in Figure 13.

3.1.1.4 Compensation of oscillating and rotating masses. Figure 14 shows a typical configuration of a one-cylinder compressor. The target is a well-balanced share between rotating and oscillating masses. The force distribution in the *x*- and *y*-directions can be seen in the diagram. The overall compressor position in a car and the insulation between compressor and car chassis has to be considered as well for the layout of the balancing.

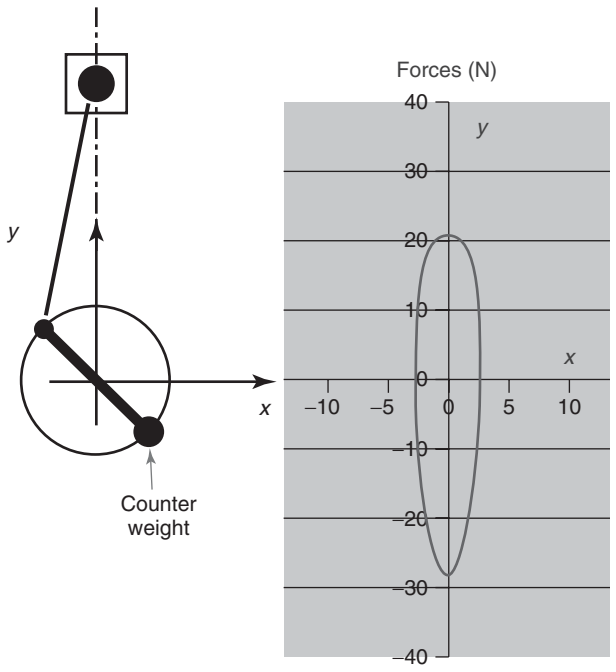

Figure 14. Trade-off between balancing of longitudinal and lateral forces. (Reproduced with permission from WABCO.)

3.1.2 Two-stage open system type

Two-stage compressors have an advantage in generating higher pressures; as a one-stage compressor is limited to maximum 18 bar, the two-stage compressor can provide much higher pressure and the efficiency in higher pressure ranges is better. Furthermore, the required

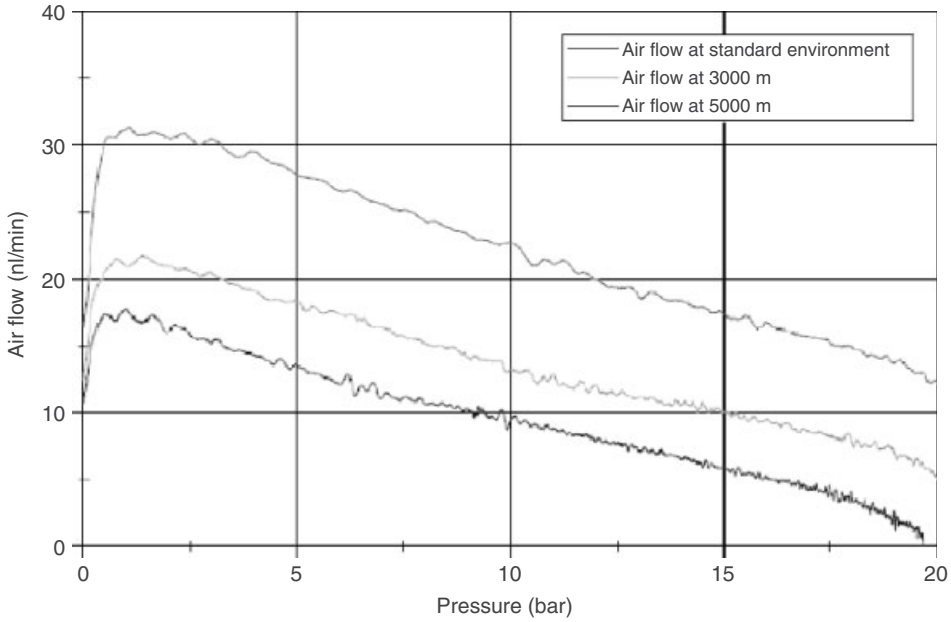

Figure 13. Compressor airflow at different geodetic heights simulated by different intake pressures. (Reproduced with permission from WABCO.)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

torque to drive the compressor does not show such high peaks as with a one-stage compressor. The torque is better distributed during one cycle. On the other hand, there are more mechanical parts needed to provide this function, friction is typically higher (two-piston sealing instead of one), and, owing to that fact, the efficiency in lower pressure ranges is worse than for a one-stage compressor.

The principle of a two-stage compressor is shown in Figure 15. Air is taken into the crankcase and then compressed in stage one (at the bottom, piston moves downward). This compressed air is guided through a channel within the double piston into the second stage for compression to the final pressure.

Figure 16 shows the comparison of two medium power compressors. The efficiency advantage of a one-stage compressor in lower pressure ranges is obvious.

However, at higher pressure ranges, the two-stage compressor is showing benefits compared to a one-stage compressor. Figure 17 compares the efficiency and the flow rate of one- and two-stage high power compressors.

3.1.3 Closed system type

Currently, there is one closed system type compressor on the market (Figure 18). The system configuration is more complex than with an open system (Figure 3). The reason is the airflow control valve unit. In a four-corner system,

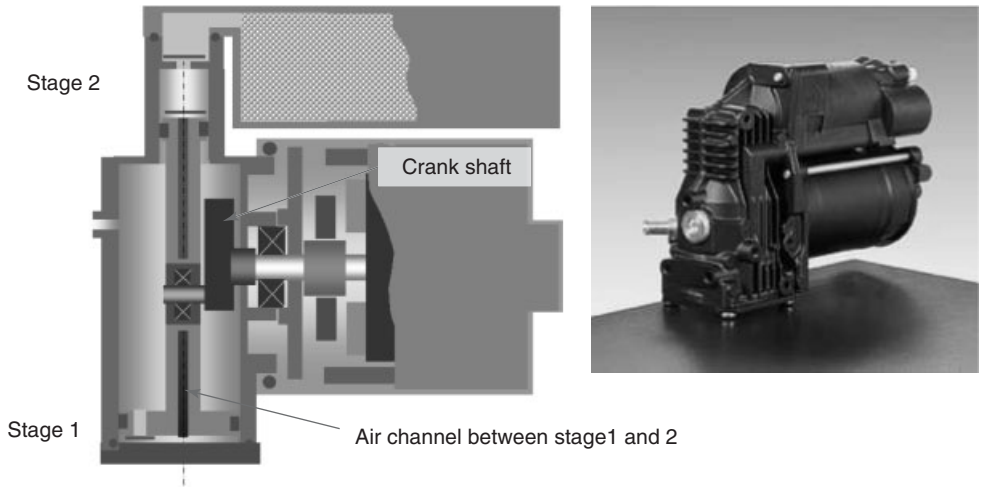

Figure 15. Two-stage compressor. (Reproduced with permission from AMK Automotive GmbH & Co. KG.)

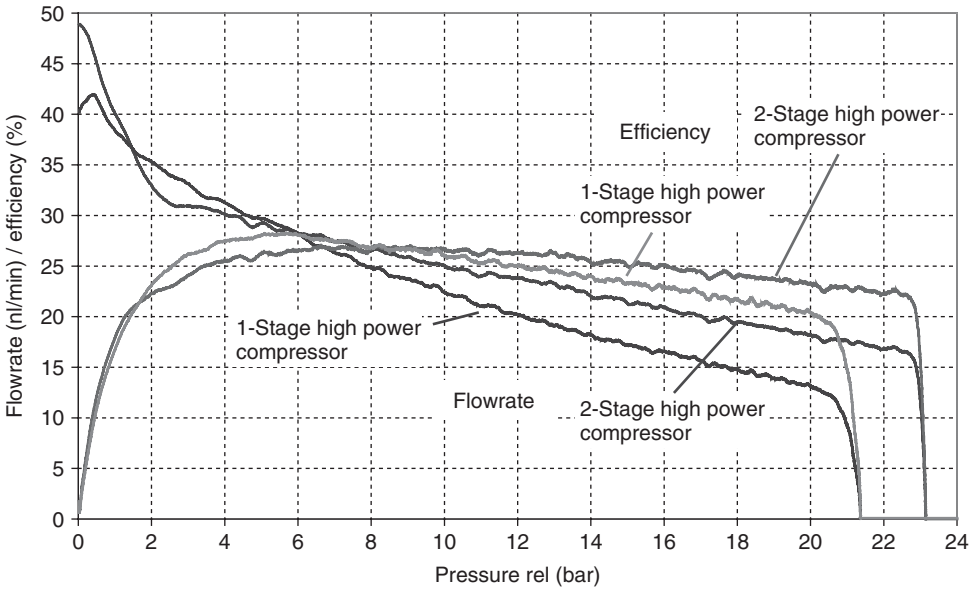

Figure 17. Comparison of a one- and a two-stage high power compressor. (Reproduced with permission from WABCO.)

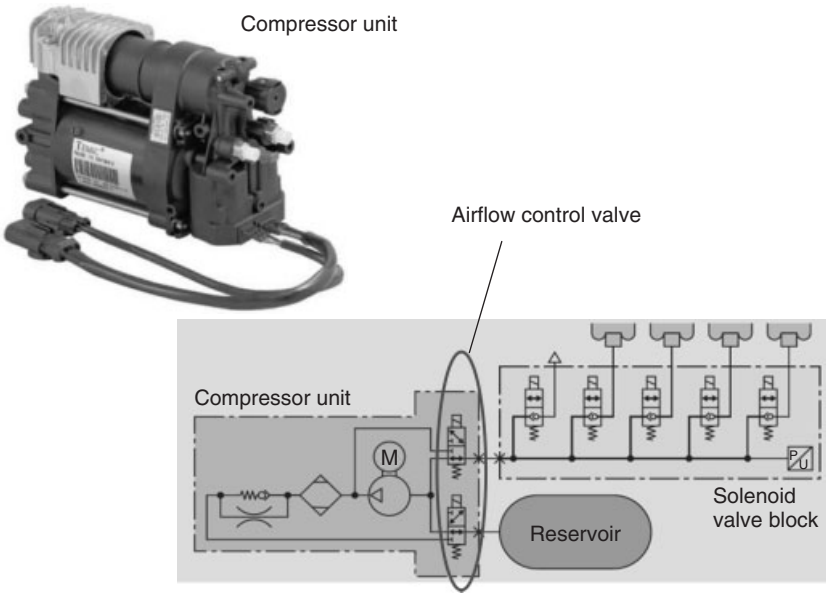

Figure 18. Closed system compressor and pneumatic layout. (Reproduced with permission from Continental AG)

a total of seven solenoid valves are necessary, whereas the open system only needs six solenoid valves.

Compared to an open system compressor, which gets always the atmospheric pressure at the air intake, the closed system type compressor can be precharged. Figure 19 compares the compression cycle of an open system type compressor and a closed system type compressor. The closed system type compressor is able to further compress a certain precharge pressure to the requested end pressure with a smaller stroke than an open type compressor. The area surrounded by the p-V line is equivalent to the work, which is needed to compress the air, or in other words, the requested energy for the compression cycle. In the shown example, the area (=work) is smaller in the closed system type compressor, and this is the reason for the energy-saving advantage of such systems.

The flow rate versus pressure of a closed system type compressor is shown in Figure 20. As a parameter, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

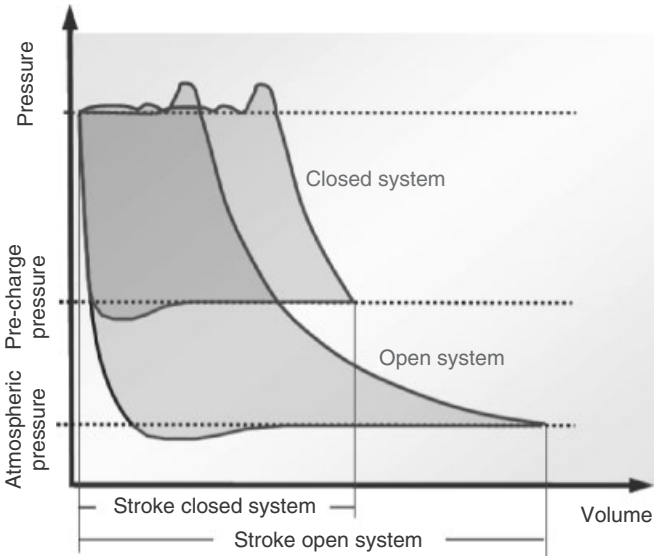

Figure 19. Compression cycle of an open system type compressor and a closed system type compressor. (Reproduced with permission from WABCO.)

precharge pressure is modified between 0 (atmospheric pressure) and 8 bar. This compressor has a smaller displacement than the open system type. Consequently, the airflow is very limited if it is operated in open system mode (e.g., system filling in workshop, see 0 bar line in Figure 20). The performance can be significantly increased if the compressor is charged with compressed air, either from the air springs or from the reservoir. The principle is to pump the air between the reservoir and the air springs or vice versa. The benefit is that the stored energy of the compressed air remains on a higher level and the compressor only has to increase the pressure by a low ratio (Figure 19). Lower energy consumption over vehicle lifetime is the positive consequence. The runtime of a closed system type compressor is roughly 30% of an open system type compressor in a four-corner application with reservoir, if just the pure lifting and lowering processes are considered. This will partly be compensated by necessary purge cycles to regenerate the air dryer: in a special operation mode, the dry air in the reservoir is used to dry the air dryer desiccant. This air loss has to be filled up from the atmosphere. Depending on environmental conditions, the share of compressor runtime for purging can be a significant amount on top of the normal compressor operation for lifting and lowering. Though, the overall compressor runtime in a closed system is about 50–60% compared to an open system.

3.2 Electric motor

Brushed direct current (DC) motors are used to drive compressors for ASU's in air suspension systems. Another option would be a compressor directly driven by the engine. This has been done in earlier times at Daimler Benz (1960s).

Advantages of electric motor for compressor drive:

- The compressor can be operated independently of engine type and vehicle.
- In the case of optional air suspension, the same vehicle engine can be used for both suspension variants.
- Compressor installation position can be anywhere in the vehicle.

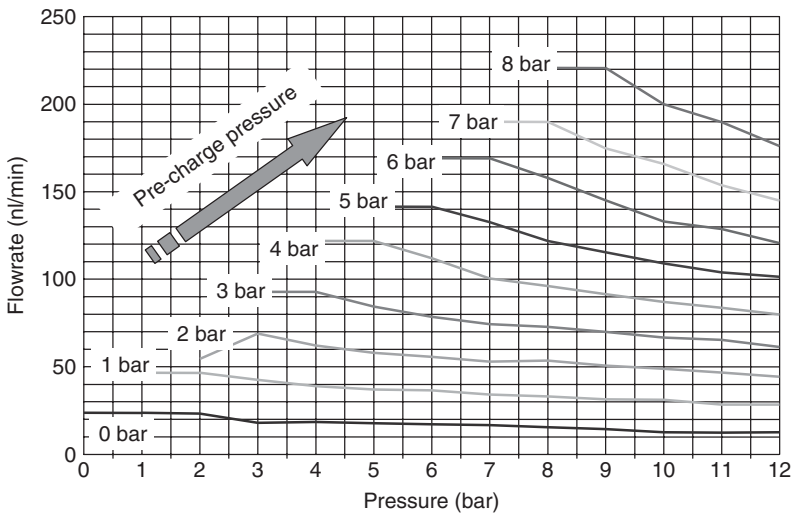

Figure 20. Flow rate versus pressure at various precharge pressures. (Reproduced with permission from WABCO.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- No issue with varying speed of the engine between idle and maximum speeds (ratio 10 : 1).
- No clutch would be required to couple/uncouple the compressor.
- In case of engine off (hybrid cars), the compressor can still be operated and thus lifting is possible even in "engine-off" condition.

Disadvantage of electric motor for compressor drive:

- Limited performance due to limited battery and generator capacity and electrical wiring dimension.
- Lower total efficiency due to double energy transformation.

In newer applications, for example hybrid cars, the inrush current of a relay-controlled DC motor is not accepted any more. To reduce the peak current and current gradient during the switch-on phase of the compressor, the relay can be replaced by a PWM (pulse-width modulation) control, which provides a soft start. The following picture (Figure 21) shows an example: the relay-controlled peak current of this compressor would be nearly 60 A. Thanks to a PWM control, the peak current can be reduced to 32 A.

In this context, there are also brushless motors considered for compressor drive. Motor life time is not the driver. Typically, the compressor run time is around 750 h in a vehicle life, which is easy to achieve with brushed motors. The main benefit of a brushless motor is the possibility for speed/current control.

The required torque at a certain speed mainly influences size and weight of the electric motor. To reduce the torque but keep the same performance, the speed has to be increased. However, the pneumatic efficiency of a compressor would decrease in case of higher speeds (valve dynamics, etc.) and thus such motors have to be transmitted to lower speeds at the compressor. Another factor, which influences weight and size, is the material of the magnets. Here is the classical trade-off between cost and weight.

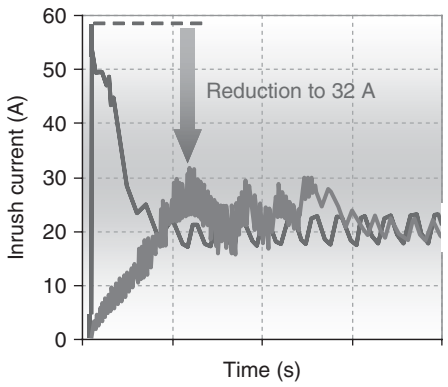

Figure 21. Comparison between relay controlled and PWM controlled compressor activation. (Reproduced with permission from WABCO.)

3.3 Compressor control

Compressors for passenger car air suspension systems are designed for intermittent operation, as a continuous run is not required and would increase weight and cost. Consequently, the compressor has to be protected against overheating. In simple applications, there is a thermal cut-off switch positioned in the electric motor. In systems with electronic control, at least the environmental temperature of the car is used to estimate the working condition. To be more accurate, a dedicated temperature sensor can be used to provide a signal to the controller. This sensor should be placed close to the hot spot of the compressor (e.g., cylinder head) to provide a realistic temperature information to the controller. In some cases, the sensor is placed somewhere in the environment of the compressor to provide at least an indication about the actual environmental condition. For economical reasons, the temperature information can be achieved using the solenoid of the exhaust valve as a temperature-dependent resistor (Bodet and Meier, 2007) (patent no. DE102005062571A1).

Another control feature is the starting and stopping of the compressor against low pressure: to avoid strong torque reactions, the gallery and the air dryer should be evacuated before the compressor is started or stopped.

3.4 Air dryer

By compressing the air taken in from the atmosphere, the natural humidity has to be considered: during compression, the water content remains constant; however, the relative humidity is increasing. This means that at a certain point water droplets are appearing as condensate.

Example: filling of a 5-L reservoir from 0 to 16 bar with air, $t = 30^{\circ}C$, and 75% relative humidity. Total mass of collected water is 1,767 g, which are about 35 droplets.

Car manufacturers expect a maintenance-free system, so a periodical manual drain of the condensate is not acceptable. Consequently, the air dryer is mandatory to avoid humidity/water ingress into the air suspension system. Without an air dryer, the amount of water transported into the air springs would be more than 5 L (considering average climate conditions in Stuttgart) and 20 L in Singapore over the vehicle lifetime with an open system. This calculation does not consider any leakage. In reality, there is always

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

leakage present. Considering a leakage rate of 5%, an open system would be able to provide dry air over the lifetime, as the air dryer regeneration does not need all air back during exhaust to achieve full regeneration.

In a closed system, the air dryer is only required in case of system filling in a workshop and in case of leakages. 5% leakage rate means 0.25 L water over the lifetime in Stuttgart or 1 L in Singapore. For this reason, even a closed system has to have an air dryer, and special purge cycles have to be fulfilled (Section 3.1.3).

As the air dryer itself has to be maintenance free, it has to provide a self-regenerating function. As desiccant in those applications, special beads of crystalline metal-aluminum silicates are used. These beads are produced synthetically and are highly porous, having a strong affinity to water. Depending on temperature, the desiccant is able to store water mass of 20% of its own weight. Figure 22 shows the principle.

Humid air flows through the desiccant cartridge (1). During this process, water is extracted from the air and stored temporarily in the desiccant beads (adsorption). The dry air leaves the cartridge via a check valve (2) into the pneumatic system.

During each lowering of the chassis level, the dry air that comes from the bellows flows through the air dryer back into the atmosphere. The 3/2 way solenoid valve (3) is activated and opens the relay valve (5). The air passes the solenoid valve and the throttle (4). In the throttle, the relative humidity of the air further decreases due to expansion. While passing the air dryer, the expanded air is regenerating the desiccant, meaning the air takes the water out of the desiccant beads and carries it through the relay valve (5) out into the atmosphere (desorption).

Key for efficient regeneration is the ratio between the nominal width at the entrance of the air dryer (dry air) and at the outlet (humid air). The orifice area at the outlet should be roughly four times bigger than at the inlet. This is to ensure a sufficient expansion of the compressed air. For further reference on this topic, see Section 3.5.

3.5 Exhaust circuits at open systems

The exhaust circuit of an ASU has to fulfill several demands:

- Controllable with electrical energy (solenoid valve).
- Providing sufficient airflow from the system into the atmosphere to achieve high chassis lowering speed.
- Expansion of the compressed air before it enters the air dryer for efficient regeneration.
- Robustness against water/ice in the "wet" area.
- Possible separation of the air dryer volume from the gallery. Advantage: air dryer volume does not need to be pressurized for a pressure measurement in the bellows or in the reservoir, thus the air loss during pressure measurement is minimized.
- Provide low noise level during exhausting.

Depending on the vehicle demands, there are several exhaust circuits on the market (see Figures 23 and 24).

3.5.1 Standard release circuit

The standard release exhaust circuit is also shown and explained in detail in Figure 22. To avoid too big and heavy solenoid valves, this circuit uses a small 3/2 solenoid as the pilot valve (3). Thus, the electrical current to operate the solenoid can be minimized. The 3/2 valve operates a relay valve (5) by air, which opens a big orifice to allow high airflow without velocity pressure out of the air dryer

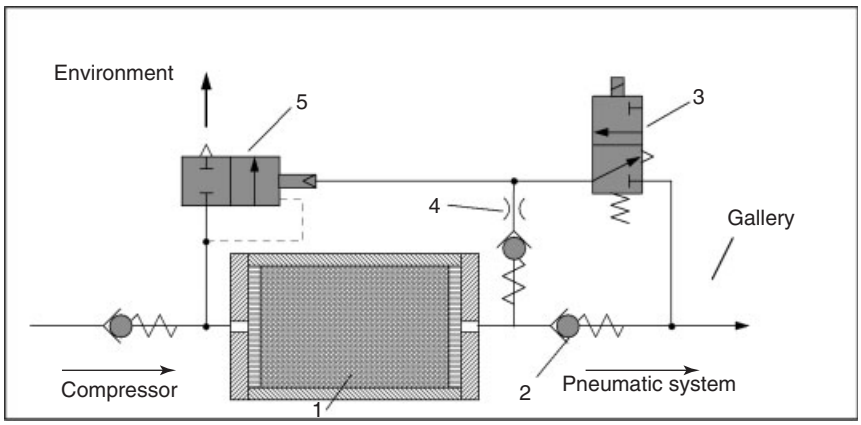

Figure 22. Standard release air dryer circuit. (Reproduced with permission from WABCO.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

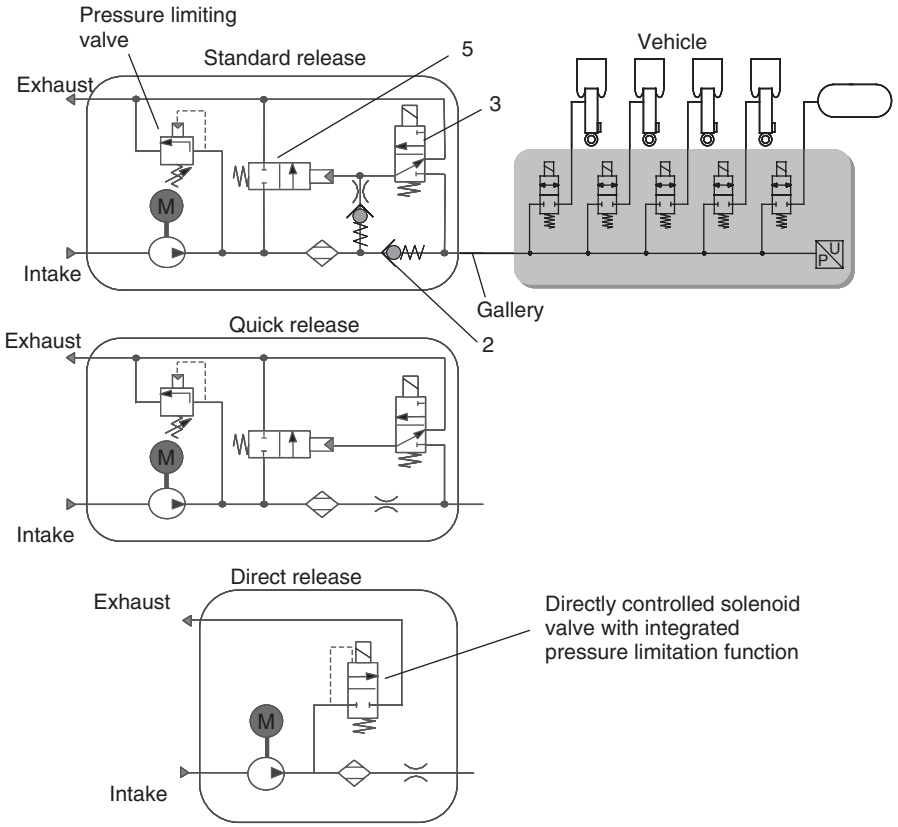

Figure 23. Different air dryer circuits in idle mode. (Reproduced with permission from WABCO.)

during exhausting. The relay valve itself, which operates in the wet area, is robust against water/ice. Separation of air dryer volume and gallery is achieved using a check valve (2). The only disadvantage of this circuit is a limited airflow, as the exhausting air has to pass the 3/2-solenoid valve (3).

3.5.2 Quick release circuit

The disadvantage of a limited orifice is not acceptable for vehicles that require quick lowering (SUV's). For this reason, the standard release circuit was modified and called a *quick release* circuit. Here, the exhausting air is not passing through the solenoid valve, and a bigger orifice is possible. To achieve this, the check valve (2) does not exist, which creates one disadvantage that the gallery and air dryer volume are always connected. In case of pressure measurements in the bellows or the reservoir, the air dryer volume has always to be inflated that consumes air and increases the chilling time for a pressure measurement.

3.5.3 Direct release circuit

For economical reasons, the relay valve/pilot solenoid valve is being replaced by one bigger solenoid valve. This circuit is called *direct release* (Figure 25). The solenoid valve is positioned behind the air dryer, and the exhausting air has to pass the solenoid valve. Special focus is on the robustness against water/ice, as the solenoid valve is located in the wet area. Pressure limiting function is integrated in the solenoid valve. Further advantages are achieved by integrating the filter/silencer into the air dryer body.

3.6 Pressure retention

In some cases, air suspension systems require a minimum pressure within the bellows, for example, if the car is lifted in a workshop. Without pressure retention, the bellows might be exhausted completely and would be damaged in case of lowering the car. The pressure retention function is provided either by dedicated valves in each bellow or by one central valve in the air dryer of the ASU. In case of standard and quick release circuit, the relay piston,

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

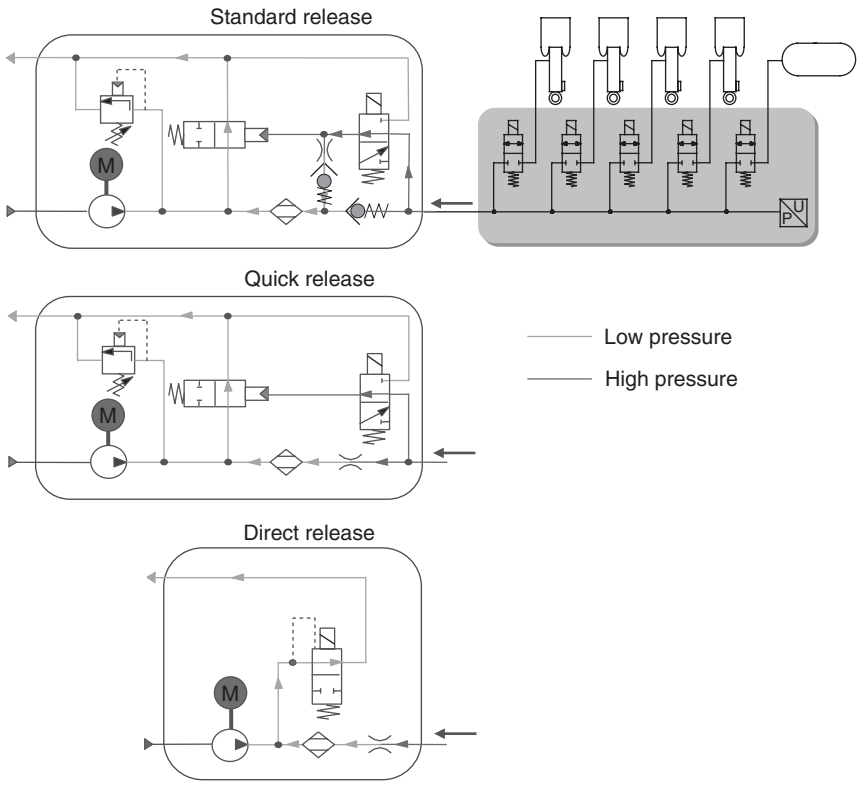

Figure 24. Different air dryer circuits in exhaust mode. (Reproduced with permission from WABCO.)

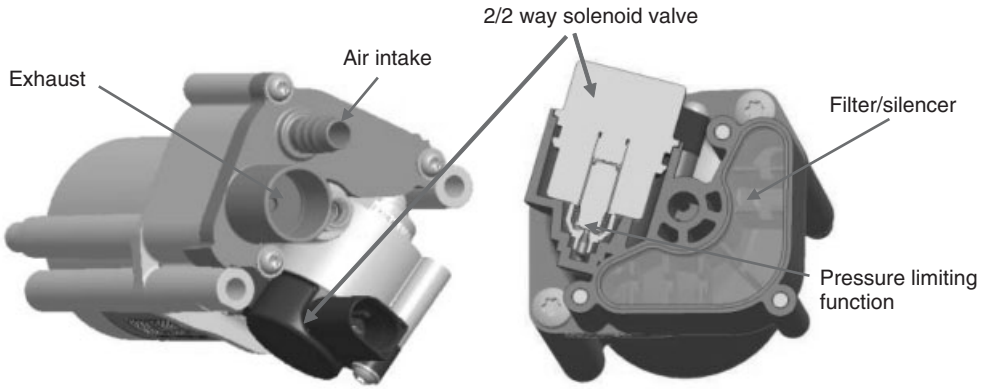

Figure 25. Direct release air dryer with integrated filter/silencer. (Reproduced with permission from WABCO.)

which closes by help of a spring, provides the pressure retention function if the system pressure drops below a specified level (Figure 4). Typically, this is between 3 and 1.5 bar.

If the air suspension system requires lower bellow pressures, this cannot be achieved with such a circuit. However, the direct release air dryer is able to exhaust the system down to atmospheric pressure.

3.7 Pressure limiting

To mitigate a risk that comes mainly from system FMEA (failure mode and effects analysis) considerations, a pressure-limiting function has to be integrated in the air suspension system. Typically, the ASU provides this function. This feature is only required if one other component has a failure. As an example, a sticking relay that

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

controls the electric motor/compressor might occur. As the compressor cannot be switched off anymore, the pressure in the compressor and the gallery would increase up to the natural stabilization pressure, depending on compressor performance and height above sea level. The desired cut-off pressure should be above the normal working pressure with sufficient margin. In reservoir systems, the maximum operating pressure is about 16–18 bar. Considering technical tolerances, the blow off valve should not open before 17.5–19.5 bar.

Pressure-limiting function is provided by a valve in the relay piston (Figure 4) or by the 2/2-way solenoid valve in the direct release air dryer (Figure 23). The bellow valves must be safe against this pressure level (ratio between gallery and bellow pressures); otherwise, the compressed air could pass through the solenoid valve and might lift the chassis unintentionally.

Although the pressure-limiting valve avoids damage in the system caused by too high pressure, the compressor might run until it overheats or empties the vehicle battery. Owing to this risk, some applications have electronic "relays" in both supply and ground line. A safe shut off of the compressor is always possible.

3.8 Air distribution

3.8.1 Air intake

The compressor has to get clean air from the atmosphere. For this reason, an air filter is installed in the air intake (Figures 2, 25, and 26). Particle sizes smaller than 10 μm are acceptable. The position where the air is ingested has to be in a dry environment (e.g., inside the car or at a place above the wade line) and where splash water has no access.

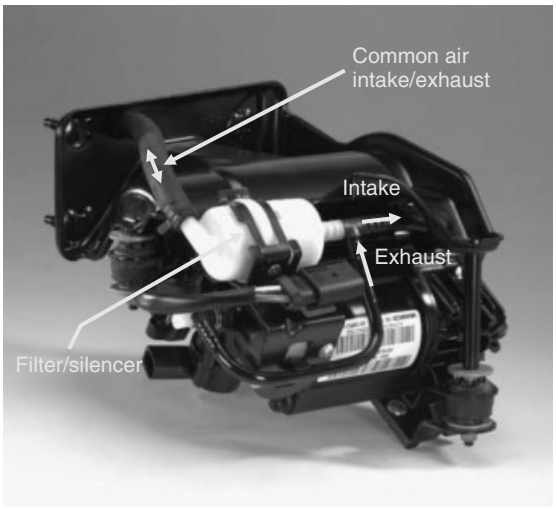

Figure 26. Air supply unit with common air intake/exhaust. (Reproduced with permission from WABCO.)

3.8.2 Exhaust

The exhaust port is noise critical. Therefore, a position outside the cab is favorable. A silencer is mandatory in many cases. Often, the air intake and exhaust of the compressor is combined into one port. Advantage is that the air filter can be used as silencer and ease of assembly. An example is shown in Figure 26.

A disadvantage of a combined air intake/exhaust is the trade-off between dry position and exhaust noise. In addition, the air-drying capability can be diminished. In the case of the exhaust process, humid air is guided through the comment pipe/filter. There might be condensation effects if the pipe temperature is lower than the exhausted air. During the next compressor run, the humid air—or even

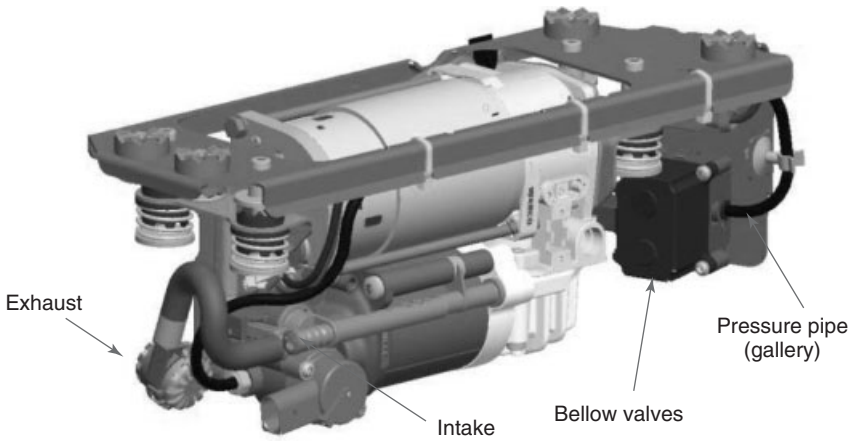

Figure 27. Air supply unit for rear axle air suspension, air intake, and exhaust separated. (Reproduced with permission from WABCO.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

water drops—in the pipe are ingested into the ASU. In case of longer air intake/exhaust pipes, a separation is recommended (Figure 27).

In many cases, the solenoid valves to control the air springs (bellow valves) and reservoir are assembled close to the compressor on one bracket (Figure 27). The connection between the multiple solenoid valve block and the compressor (gallery) should be as short as possible to reduce the volume inside this pipe. The diameter has to be selected depending on the nominal width of the bellow valves. Typically, it is a pipe 6 × 1.5 mm (outside diameter 6 mm, inside diameter 3 mm, and wall thickness 1.5 mm), in some cases, 4 × 1 mm is also used (inside diameter 2 mm).

A typical 5 by 2/2-solenoid valve block is shown in Figure 28.

A single pressure sensor is integrated. By connecting it to the bellows and the reservoir in a sequence one by one, the individual pressure can be measured. Here, the disadvantage of the quick release and direct release circuit becomes obvious, because in each case the air dryer volume has to be pressurized during a measurement. This takes a certain time and the pressure value can only be taken after a chilling time. After each measurement, the air dryer volume has to be exhausted.

Air distribution from the multiple solenoid valve block to the bellows is usually done with PA tubes 4 × 1 mm. This dimension avoids expensive preforming of the tubes, which would be required in case of bigger tubes (e.g., 6 × 1.5 mm).

Depending on the exhaust circuit, special attention is required on the pneumatic layout and dimensioning. In case of low bellow pressures and large pressure drops due to long pipes with small orifices, the relay piston in the air dryer might not receive sufficient pressure levels to stay fully open. In this case, the relay piston would swing within an intermediate position and would not be able to open the complete nominal width. This results in a bad regeneration of the air dryer, as the expansion of the compressed air cannot be provided as specified.

At rear axle systems, an integration of the bellow valves into the compressor can be advantageous. An example is shown in Figure 29.

4 COMPRESSOR PACKAGING/ACOUSTIC INSULATION

4.1 Inside mounting

Inside mounting is advantageous in terms of low demand for protection against water, corrosion, and so on. On the other hand, acoustic (air borne noise) and vibration (structure borne noise) of the ASU is very demanding. The

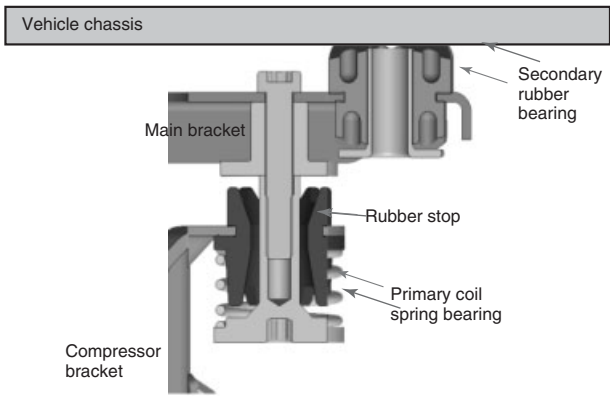

Figure 31. Typical insulation design between compressor and vehicle chassis. (Reproduced with permission from WABCO.)

compressor has to be suspended on flexible elements such as rubber bearings as shown in Figure 30.

Best insulation is achieved with coil springs (Figure 31). The tuning of the mass/spring system is typically subcritical, meaning that the eigenfrequency of the compressor/spring combination is below the first order of eigenfrequency of the compressor vibration if it is running. A well-balanced load distribution between the bearings (3 or 4) is key for NVH (noise, vibration, and harshness) reduction. As the coil springs have to be soft and damping is just done by a certain amount of friction, stroke limiters are required. To avoid the compressor structure hitting the bracket, rubber buffers are used. One reason for compressor movement is vibration caused by the vehicle on uneven roads. Another reason is the torque reaction if the compressor is switched on or off.

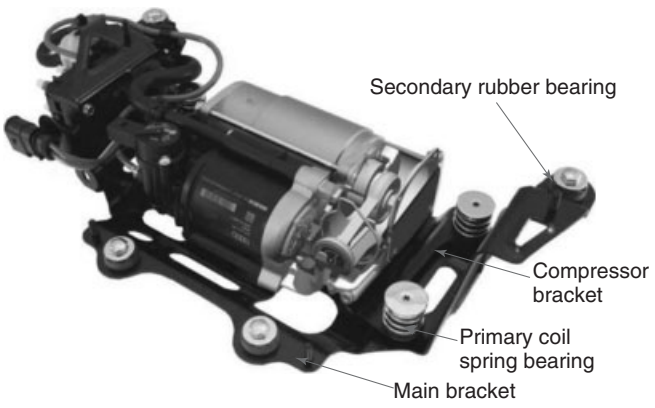

Figure 32. Air supply unit for four-corner air suspension. (Reproduced with permission from WABCO.)

4.2 Outside mounting

Corrosion resistance has to be provided following ISO 9277 NSS, typically 480 h. Protection class requirement is

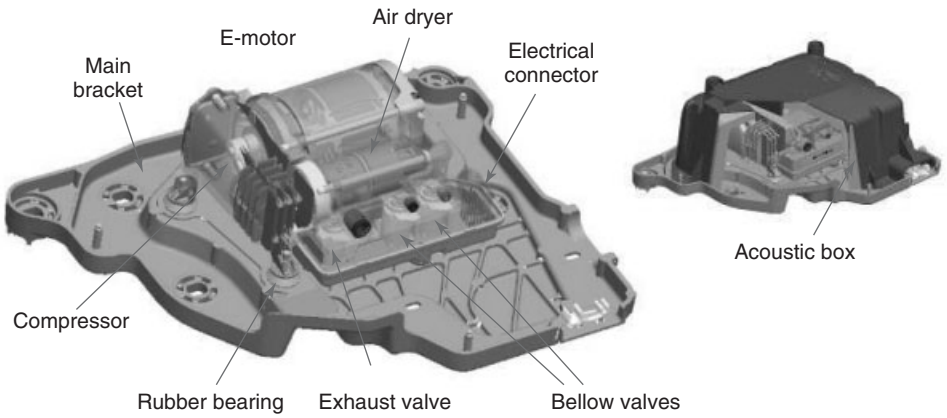

Figure 34. Details of a rear axle installation air supply unit with acoustic box. (Reproduced with permission from WABCO.)

typically IP6K6K, IP6K7, and IP6K9K according to ISO 20653.

Compared to the inside mounting, the air-borne noise is not that critical. In many cases, the ASU is not capsulated (Figure 32). A preferred installation space is the engine compartment. However, packaging and the neighborhood to hot elements might be critical. In many cases, the ASU is installed below the chassis in the rear area of the car. There might be hot elements (exhaust muffler) in the neighborhood as well.

In the following application, the ASU is covered by a case, which reduces airborne noise and protects the ASU against stone chipping and ground contact (Figure 33).

Details of the ASU for this rear axle solution are shown in Figure 34.

These examples show that—depending on the OEM (original equipment manufacturer) demand—there are various solutions how and where to place an ASU in a car. There is no standard solution, and the engineering effort to package a compressor into a car is significant both on OEM side and on supplier side.

5 SUMMARY

The purpose of ASUs in passenger cars is to feed the air springs with compressed dry air. Piston compressor technology is standard on the market, all driven by electric DC motors. System pressures vary between 7 and 20 bar, depending of the vehicle application. There are one-stage

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto016
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

compressors (for open and closed systems) and two-stage compressors (for open systems) used. Closed systems are pumping the air between the air springs and a reservoir back and forth, avoiding an exhaust of the pressurized air into the atmosphere. By keeping the pressurized air widely in the system, the overall energy balance has an advantage compared to open systems. In addition, the repeatability of lifting operations is better than with open systems. However, closed systems are more complex and a reservoir is mandatory. Furthermore, the maintenance-free air drying capability of an ASU requires purge cycles at closed systems, which worsens the energy balance. Open systems are less complex and are able to be operated without reservoirs, which also have a positive impact on overall system costs. One-stage compressors are simpler and have a better efficiency in low pressure ranges than two-stage compressor, whereas two-stage compressors have physical advantages in higher pressure ranges.

Besides those differentiators at the compressor, the major variation is packaging of compressors into the vehicle. As there is no "standard" installation space and environment, each new vehicle requires an individual design of bracket, insulation, piping, and wiring harness.

Future challenges for ASUs are weight and size limitations, acoustic performance, current consumption, peak current, and increasing pressure demand for smaller air springs.

Customer-Oriented Evaluation of Vehicle Handling Characteristics

Adrian Mihailescu, Stephan Poltersdorf, and Lutz Eckstein

RWTH Aachen University, Aachen, Germany

1 INTRODUCTION

This chapter gives an overview on methods that can be used to evaluate the handling quality of passenger cars with respect to the demands of real customers.

1.1 Motivation

The increasing handling quality and driving safety of modern passenger cars makes it difficult for car manufacturers to stand out in this area of vehicle quality. The available development resources must be strictly focused on technical changes that assure improved handling evaluations by customers (and journalists). The vehicle developers, therefore, need efficient methods to evaluate the perceived handling quality in all phases of product development.

1.2 Subjective versus objective evaluations

Classical evaluation approaches are subjective evaluations by customers or vehicle dynamics experts. Considering various rules regarding the execution (Section 2) and data analysis (Section 4), this method can generate valuable results.

The reproducibility and validity of subjective evaluations is limited because of several (human) factors, whereas the necessary effort remains high. Furthermore, the necessity for real vehicles conflicts with the increasingly virtual vehicle development process. These problems led to various approaches to support or even replace subjective evaluations by objective methods based on measurements or simulations (described in Section 3). The goal of these approaches is the identification of objective values that significantly correlate with subjective vehicle evaluations, and that can, therefore, be used to predict customer verdicts.

Successful methods for objective evaluations lead to well-defined and testable development targets. The product quality can be evaluated more often and more efficiently, thus reducing the dependence on varying or even biased subjective evaluations.

Over the last decades, a large number of useful objective measures have been identified. Section 5 gives an overview based on an extensive meta-study.

2 SUBJECTIVE VEHICLE HANDLING EVALUATION

In order to gather detailed and reliable handling evaluation based on the perception of individual drivers, several basic rules have to be considered. After a brief introduction of

the principles of subjective handling perception, these basic rules are presented in Sections 2.2 and 2.3.

2.1 Principles of subjective handling perception

Each driver stabilizes the vehicle on the chosen trajectory based on various methods of information perception and information processing. The driver's sensations and experiences in the scope of this stabilization determine the subjective evaluation of vehicle handling.

2.1.1 Information perception

The driver perceives information on the current driving situation mainly via three sensory channels: the visual, the vestibular (resulting from the organ of equilibrium), and the haptic (feeling sensors such as hands) channels (Mitschke and Niemann, 1972).

First of all, the high resolution of the visual channel enables the perception of deviations from the desired trajectory, the vehicle orientation, and the steering wheel angle. Velocities and accelerations can also be perceived based on the optical flow. Because of the widespread and precise visual information, this channel is the main information source for trajectory stabilization in the linear handling area (Schimmel, 2010). The equilibrium organs (vestibular system) enable the perception of linear and rotary accelerations. Compared to the visual channel, the vestibular sensation is less accurate but faster. The fastest information is provided by the haptic sense, which enables the indirect perception of vehicle accelerations and of the steering wheel torque across the contact surfaces between driver and vehicle.

2.1.2 Information processing

The processing of the perceived driving-state information can be described by a three-staged model (Rasmussen, 1983): skill-based driver actions constitute the first level and are very rapid and highly automated behavioral patterns not consciously modulated by the driver. On the second level, the driver makes unconscious decisions based on memorized experiences. The speed of information processing at this level is slower than on the first level. If the driver possesses no suitable skills or experiences for the current driving situation, he or she must consciously analyze the driving situation. This level of information processing is the third and the slowest stage of information processing.

With respect to subjective vehicle evaluations, one fact is crucial: because of different levels of skill and experience, different drivers handle identical driving situations using different levels of information processing and differently weighed sensory information. This results in a high variance of driver actions and vehicle evaluations among different drivers. For example, a skilled driver uses the haptic and the vestibular senses much more than an untrained driver, who mainly controls the vehicle based on visual information, which causes differences, for example, in the evaluation of steering feel.

2.2 Execution of subjective vehicle evaluations

Table 1 gives an overview on typical handling characteristics evaluated in subjective evaluation (Heißing and Brandl, 2002; Eckstein, 2011). The table shows the classes of characteristics that can be further detailed into subcharacteristics—especially in the scope of expert

Table 1. Criteria classes of subjective evaluation.

	On-center handling			Corner handling		
Steering feel	Center point feeling	Steering effort	Steering torque level and buildup	Steering torque evel and progress	Steering angle demand	Steering response
	Steering response	Self-centering	Steering friction	Stability feel	Steering precision	Feedback of road friction
		Post-pulse oscillation (hands off)		Torque and angle during parking	Steering clearance	Steering returnability
Vehicle behavior	Straight driving stability	Directional stability under braking	Response behavior	Self-steering behavior	Response behavior	Pitch and roll behavior
	Load-change behavior	General (straight) wind sensitivity	Cross wind sensitivity	Load-change behavior	Stability and lane change behavior	Corner exit behavior
	Lateral inclination sensitivity	Trailer stability	Aquaplaning behavior	Corner braking behavior	Aquaplaning behavior

evaluations. Subjective characteristics that are supported by significantly correlating objective measures (Section 5) are marked in gray.

2.2.1 Choice of drivers

Usually, professional test drivers are used for vehicle evaluations because of their more accurate, differentiated, and reproducible judgment (Schimmel and Heißing, 2009; Pfeffer and Scholz, 2010; Riedel and Arbinger, 1997). In contrast, untrained drivers offer realistic representation of the skill and experience of the real customers. The lower precision and reproducibility of their judgment is sometimes accepted, for example, if questions of driving safety or controllability are investigated (Bubb, 2003). A collective of normal drivers is best generated by random sampling among large heterogeneous groups of possible customers (Breuer, 2009). Bortz (2010) and Bubb (2003) describe how the appropriate size of the driver collective can be calculated based on the questions under investigation, the desired level of significance, the used evaluation scales, and the statistical distribution of data collected in pretests. This chapter can only give rough recommendations based on these sources: tests with professional drivers only need small numbers of drivers (2–5), especially when new vehicle variants are compared to reference variants that have been evaluated by a larger number of drivers. Tests with normal drivers that are used to compare two vehicle variants need more drivers (30–50). If tests with normal drivers shall be used to understand the relationship between subjective evaluations and certain driver characteristics (gender, age, and so on), a much higher number of drivers (e.g., >1000) are needed for highly significant results.

2.2.2 Choice of driving scenario

The vehicles must be evaluated in scenarios that provide realistic representations of real driving situations. The vehicles should be driven "closed loop" on a clearly defined course, so that the task of trajectory stabilization needs to be fulfilled (Kudritzki, 1989).

The shape and velocity profile of the used course should realistically depict the typical driving range with respect to velocity, lateral acceleration, and necessary steering frequencies. This is achieved by choosing a course with a wide range of cornering radiuses (20–500 m). Corners with special characteristics (lateral inclination, increasing curvature, and so on) should also be present with different radiuses (Heißing and Brandl, 2002). The necessary steering frequencies can be influenced by more or less immediate changes in corner direction and by the curvature gradients at the beginning and the end of corners (abrupt vs continuous changes in curvatures).

The maneuver definition must clearly describe in which handling area the vehicle has to be driven (linear area or nonlinear limit area). For limit maneuvers, Kudritzki (1989) and Neukum, Krüger, and Schuller (2001) suggest driver-dependent velocities, as the significance of subjective ratings increases as soon as the evaluating driver approaches his or her individual velocity limit.

2.2.3 Execution of driving tests

The test conditions (tire condition, vehicle load, track temperature, weather, daytime, and so on) must be kept as constant as possible. Evaluations should not last longer than 1 h (Barthenheier, 2004).

All vehicles should be "blind tested," that is, no driver should know which variant he or she is currently driving (Zong, Guo, and Hsin, 2000). Ideally, the vehicle variants should only vary with respect to the evaluated characteristics in order to prevent disturbances caused by the unintended evaluation of characteristics such as design or brand.

Variants should be evaluated together with a reference vehicle that has been evaluated by a large number of drivers before. Thus, relating the evaluation results to the highly significant evaluations of the reference variant can increase the significance of the results.

It is also recommended to repeat the evaluation of some variants, for example, the reference variant, in order to detect whether the scale of individual evaluations drifts off during a test-drive (Dettki, 2005). In order to prevent the so-called transfer effect (the judgment of one variant is influenced by the variants driven before), each driver should drive the variants in a different order (Bubb, 2003).

2.3 Design of subjective evaluation questionnaires

Commonly printed questionnaires with rating scales are used for the evaluation. Sometimes, an interviewer in the car personally asks for the evaluation. Käppler (1993) and Riedel and Arbinger (1997) point out that the low reliability of many subjective evaluations is caused by an inappropriate questionnaire design. Therefore, the evaluation scales and the kind, number, and formulation of the questions should be chosen thoughtfully.

2.3.1 Absolute versus relative evaluations

Absolute vehicle evaluations try to rate the vehicle handling on an absolute and universally valid scale. Different

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

vehicles can afterward be compared and ranked based on their absolute ratings. Relative evaluations do only try to evaluate a vehicle in comparison to a second vehicle. If all vehicle variants are compared to each other relatively, a ranking can be generated based on these relative evaluations.

Even for professional drivers, it is much easier to rate a vehicle in comparison to a reference vehicle than to rate a vehicle on an absolute scale (Mummendey, 2003). If preliminary tests show that reliable and reproducible absolute evaluations are not possible for a given investigation, it is still possible to switch to a more reliable relative evaluation.

2.3.2 *Content and formulation of evaluation questions*

The questions must be adapted to the vocabulary and experience of the drivers, as a prior "teaching" of expert language to normal drivers would not significantly improve the quality of the results (Kudritzki, 2000). The evaluation becomes easier for normal drivers when they are not asked for a technical vehicle rating but for their personal sensations and experiences in the vehicle (see scale example in Figure 2).

The total number of questions should be kept below 10 (Kudritzki, 2000; Heißing and Brandl, 2002).

2.3.3 *Evaluation scales*

Usually, drivers are asked to evaluate the handling with discrete scales. The steps of a scale must be "anchored" by verbal classifiers, that is, by descriptions of the individual scale steps, in order to minimize the room for (mis)interpretations.

Depending on the scope of the investigation, two basic scale types can be used. Open "unipolar" scales are used for absolute evaluations. On these scales, the magnitude of each rating is described on an absolute scale without a reference. Closed "bipolar" scales are used for relative vehicle evaluations. In this case, each vehicle is rated in comparison to a second (reference) vehicle.

When choosing the number of scale steps, a trade-off between reliability losses because of unperceivable scale differences and detail losses because of a too coarse scale has to be found. In general, the standard deviation for the repeated evaluations of identical vehicle variants by identical drivers should stay below 2 scale steps (Käppler, 1993; Bortz, 2010).

Käppler (1993) recommends an effective scale range of 7 steps for unipolar scales and professional drivers. Harrer, Pfeffer, and Johnston (2006) recommend an effective scale range of ± 6 steps for bipolar scales and professional drivers.

2.3.4 *Visual design of scales*

According to the western reading direction, the intensity of the scale anchors should increase horizontally from left to right. The full-scale range should be shown visually, continually, and undistorted (Käppler, 1993).

Figures 1 and 2 show two scale variants that have been derived from the explained principles. The first example (Figure 1) shows an absolute scale for professional evaluators and asks for a three-stage evaluation.

The second example (Figure 2) shows a relative, bipolar scale for untrained evaluators.

3 METHODS FOR OBJECTIVE EVALUATION

Various approaches try to identify objective characteristic values that strongly determine the customer rating of a vehicle. Figure 3 provides an overview on these methods.

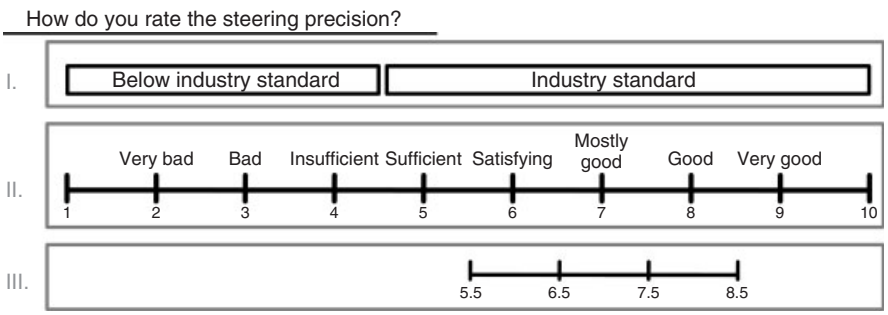

Figure 1. Unipolar scale for professional evaluators.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021

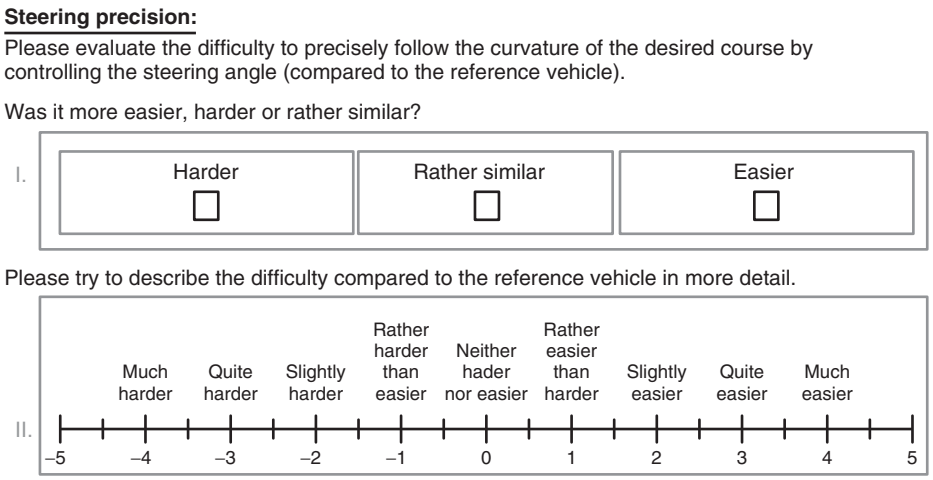

Figure 2. Bipolar scale for untrained evaluators.

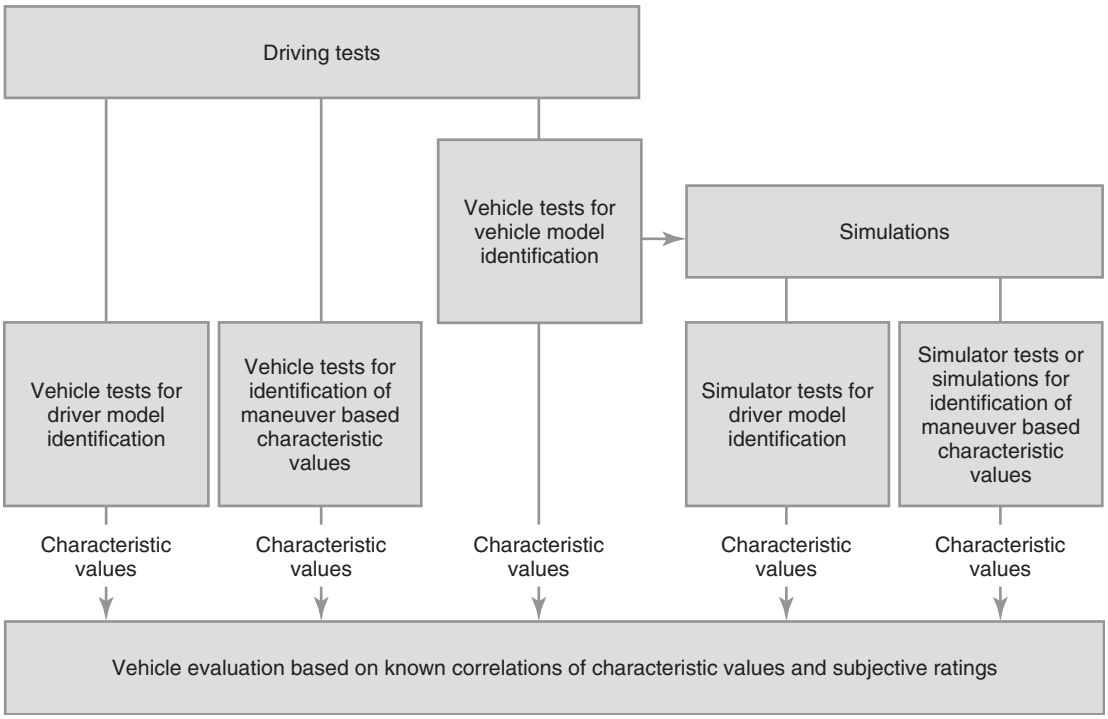

Figure 3. Objective handling evaluation methods.

3.1 Objective evaluation based on characteristic values from driving maneuvers

The classic method of objective vehicle evaluation collects characteristic values from vehicle measurements. Most of these values can also be collected efficiently in vehicle dynamic simulations. Usually, the characteristic values are collected in open-loop maneuvers, as, in this case, a high reproducibility can be achieved because of the reduced driver influence.

It is recommended that the catalog of characteristic values covers all information paths of human drivers. Visual characteristic values (e.g., lateral track offset) should be combined with haptic characteristic values (e.g., steering torque) and vestibular characteristic values (e.g., lateral acceleration) (Wagner, 2003).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Section 5 presents a large number of such characteristic values that correlate significantly with subjective evaluations. Most of these characteristic values are context-sensitive, that is, they only correlate with subjective evaluations from similar driving situations (Jürgensohn, Willumeit, and Irmscher, 1999; Pietsch, Schimmel, and Heißing, 2009a; Sagan, 2003). Therefore, a detailed evaluation of the complete handling behavior can only be achieved by a large variety of maneuvers and characteristic values.

3.2 Objective evaluation based on vehicle models

Vehicle models can be used for objective vehicle evaluations in two ways: one possibility is the determination of characteristic values from the vehicle model parameters themselves. For example, Barthenheier (2004) evaluates the steering behavior of a vehicle based on a simple steering model with the three parameters self-aligning torque, steering damping, and steering friction. So far, only a small number of significant correlations have been identified with this method.

The second and the more promising possibility is the determination of the classic characteristic values (Section 3.1) with the help of vehicle dynamic simulations. Thus, a large number of characteristic values can be gathered with high efficiency and reproducibility.

The models (e.g., extended single-track vehicle model, the dual-track vehicle model, or the steering-system models described by Zschocke, 2009, and Winner *et al*., 2003) can be parameterized automatically based on test-rig or test-drive measurements (Meyer-Tuve, 2009; Meljnikov, 2003; Pietsch, Schimmel, and Heißing, 2009a; Zschocke, 2009).

3.3 Driver-based characteristic values

A more direct way to predict subjective vehicle evaluations would be the determination of characteristic values based on the reactions of the driver in closed-loop maneuvers. A driver adapts his or her control behavior to the handling properties of a vehicle based on his or her skills and experiences (Wallentowitz, 1979). The easier this adaptation is, the higher his or her evaluation of the vehicle is going to be (Abe and Kano, 2008). This suggests that characteristic values based on the interaction of driver and vehicle highly correlate with subjective vehicle evaluations.

The central problem of all these driver-based objectivity approaches is the high variance among drivers. Using professional drivers and repeated measurements can reduce this problem.

3.3.1 Characteristic values based on driver–vehicle interaction

The results of closed-loop maneuvers can be used to determine characteristic values based on the positions of the control elements, especially the steering angle. For example, the steering angle measured in a double-lane change can be used to evaluate the vehicle stability and controllability in this maneuver. In the end, this approach is a closed-loop, driver-oriented variant of the classical maneuver-based approach.

3.3.2 Characteristic values based on driver models

This approach is based on the assumption that synthetic models can describe the control behavior of the driver. As the driver has to adapt to each vehicle, the parameters of the respective driver model must be vehicle dependent and can be utilized for objective vehicle evaluations (Abe and Kano, 2008; Henze, 2004; Decker, 2008; Dibbern, 1992). Common driver models are based on a combination of a feedforward part and a feedback part. The feedforward part estimates the steering angle necessary to follow the path ahead based on a linear single-track vehicle model. The feedback part compensates the path deviation caused by the inaccuracies of this model with a steering angle controller, for example, a PID controller. The vehicle-dependent parameters of these driver models (i.e., the feedforward and feedback amplification factors) can be automatically identified with the help of the test-drive data, either from a test track or from a driving simulator.

3.3.3 Characteristic values based on driver perception

Schimmel (2010) and Scharpe *et al*. (2012) suggest that the significance of characteristic values increases when the vehicle movement is transformed with respect to the paths of subjective handling perception. For example, characteristic values based on the lateral acceleration of vestibular organs (i.e., the driver head acceleration) or characteristic values based on the lateral pressure between driver and seat are more significant than characteristic values based on the lateral acceleration of the vehicle.

4 EVALUATION OF SUBJECTIVE AND OBJECTIVE DATA

The data gathered in subjective and objective evaluations must be correctly processed and analyzed in order to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

consider all relevant information and in order to prevent misjudgments. The description of the necessary mathematical methods lies beyond the scope of this chapter. Nevertheless, we would like to emphasize the necessity and the main goals of the data processing.

4.1 Processing of data from subjective evaluation

The subjective data must be tested for four central characteristics:

Objectivity: It must be mathematically proven that the results are independent from the persons conducting the experiments, for example, the interviewer in the car (Lienert and Raatz, 1969).

Reliability: It must be mathematically proven that the data are internally consistent and provide stable results in repeated evaluations (Magnusson, 1975; Riedel and Arbinger, 1997; Redlich, 1994; Bortz, 2010).

Validity: It has to be tested whether a scale/question is really measuring the attribute it is supposed to. It should be possible to distinguish vehicles differing in the analyzed characteristic by comparing the respective answers (Riedel and Arbinger, 1997).

Subjective–subjective correlation: It has to be tested whether there are redundancies in between questions/scales. In this case, removing these redundancies should shorten the questionnaire.

4.2 Processing of data from objective measurements

The objective data from measurements or simulations also have to be mathematically tested for reliability (internal consistency and repeatability) and validity (strong relationship to measured characteristic). An objective–objective correlation can be used to shorten the catalog of characteristic values by removing redundancies (Harrer, 2007). The data preprocessing must ensure the comparability of measurements from different vehicles with different sensor configurations, for example, by the removal of sensor delays and offsets and by the transformation of measurements to default reference points such as the center of gravity of the vehicle (Kobetz, 2004; Pfeffer and Harrer, 2011).

4.3 Correlation and regression analyses

As soon as the subjective and objective data have been processed as described earlier, the correlation and regression analyses are used to analyze the relationship between them. The correlation test determines the statistical significance (i.e., the probability of error) of relationships between objective characteristics and subjective evaluations. The absolute value of the correlation coefficient can be used as a measure for this significance (Bortz, 2010; Cohen and Cohen, 1983).

The regression analysis goes one step further by generating models that can be used to predict subjective ratings based on linear or nonlinear combinations of one or more objective values (Kudritzki, 1989; Dibbern, 1992; Harrer, 2007).

Only significantly correlating characteristics should be used for the vehicle evaluation. A certain amount of remaining probability of error (e.g., 5% for significant or 1% for highly significant correlations) is accepted.

5 OVERVIEW ON SIGNIFICANTLY CORRELATING VEHICLE HANDLING CHARACTERISTICS

Some of the characteristic values found in the literature are statistically proven, some are solely theories, and some are disapproved but often used nevertheless. In order to ensure the customer relevance, the characteristic value has to have been validated by real test-drives and regression analyses. In the further approach of this chapter, only the verified characteristic values of the 250 researched literature sources are considered.

Figure 4 shows the classification structure of the chosen vehicle handling characteristics and the section where it is elucidated.

Figure 4. Overview on the handling classification structure.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In the scope of this chapter, we first subdivide the handling into two areas: *on-center handling* refers to the steering behavior on and around straight ahead driving (Farrer, 1993); the handling at higher lateral acceleration is referred to as *corner handling*. In a second classification level, vehicle handling characteristics are categorized according to the vehicle response's effect on the driver: the *steering feel* and the *vehicle behavior* are being considered. The steering feel of the driver is a central handling characteristic and is, therefore, investigated separately for both handling areas. The vehicle behavior section sums up all the literature findings on verified correlations not related to steering feel—for example, yaw behavior or roll behavior.

The follwing sections show the verified correlations and their characteristic values. For each correlation, there is a sign describing the preferable value of the objective characteristic:

⇧ stands for high values;
⇩ stands for low values;
⊙ stands for an optimal value range.

These recommendations are based on investigations done by the referenced sources and not by the authors of this chapter. In some cases, there are further notes added to the correlation. This is marked by a code and is listed in the corresponding section.

5.1 On-center handling

5.1.1 Steering feel

Correlation notes sorted by code (Table 2):

OS1: The evaluation is done between the speeds of 160 and 200 km/h.

$$K_{\mathrm{L}} = \left| \frac{\delta}{\tau v_{\mathrm{res}}^2} \right|_{f_{\mathrm{R,opt}}} \cdot f_{\mathrm{R,opt}} \tag{1}$$

$\tau v^2{}_{\mathrm{res}}$ is a value describing the intensity of the stochastic crosswind disturbance. The value τ describes the angle between the longitudinal axis of the car and the direction of the resultant wind velocity $v^2{}_{\mathrm{res}}$, which is build by vector addition of the vehicle speed and the side wind velocity. The quotient is the resonant amplification factor between crosswind and steering reactions. $f_{\mathrm{R,opt}}$ is the resonant frequency of the driver's reaction to the wind disturbance.

OS2: The evaluation is done while driving between the speeds of 160 and 200 km/h.

$$K_{\mathrm{V}} = \frac{\left| \frac{\dot{\psi}}{\tau v_{\mathrm{res}}^2} \right|_{\max}}{\left| \frac{\dot{\psi}_{\tau v_{\mathrm{res}}^2}}{\tau v_{\mathrm{res}}^2} \right|_{\max}} \tag{2}$$

$\dot{\psi}_{\tau v_{\mathrm{res}}^2}$ is the yaw rate with and $\dot{\psi}$ the yaw rate without driver intervention. $\tau v^2{}_{\mathrm{res}}$ is a value describing the intensity of the stochastic crosswind disturbance.

OS3: The evaluation is done while driving at the speed of 100 km/h. $W_{\delta M_{\mathrm{H}}}$ is the steering work.

$$W_{\delta M_{\mathrm{H}}} = \delta \cdot M_{\mathrm{H}} \tag{3}$$

δ is the steering angle demand and M_{H} the steering torque demand. $W_{\delta M_{\mathrm{H}}}$ values below 5° Nm are preferable.

OS4: The evaluation is done while driving at the speed of 100 km/h.

$$\widetilde{\delta}_{\mathrm{H}} = \sqrt{\int_a^b \Phi_{\delta_{\mathrm{H}}}(f)\mathrm{d}f} \tag{4}$$

$\Phi_{\delta \mathrm{H}}(f)$ is the power spectral density of the steering angle. $\Phi_{\delta \mathrm{H}}(f)$ is integrated for frequencies between a and b. $\widetilde{\delta}_{\mathrm{H}}$ values below 0.09° for steering frequencies between 0.2 and 1.5 Hz and values below 0.011° for steering frequencies between 1.5 and 3.0 Hz are preferable.

OS5: A delay between 0 and 0.55 ms for a sporty car and between 0.55 and 0.8 ms for a comfortable car is preferable.

OS6: A gradient less than 0.05 Nm/(°)^2 is preferable.

OS7: A quotient between 0.22 and 0.3 Nm/° for a comfortable car and between 0.3 and 0.35 Nm/° for a sporty car is preferable. The evaluation is done at the speed of 100 km/h.

OS8: An amplification factor between 0.22 and 0.28 1/s for a sporty car and between 0.18 and 0.22 1/s for a comfortable car is preferable. The evaluation is done at the speed of 100 km/h.

OS9: This correlation is dependent on the vehicle segment. The evaluation is done at the speed of 120 km/h.

OS10: The evaluation is done at the speed of 80 km/h.

OS11: The evaluation is done at the steering frequencies between 0.4 and 1 Hz.

OS12–14: The evaluation is done at the speed of 120 km/h.

OS15–17: The evaluation is done at the speed of 80 km/h and the steering frequency of 0.5 Hz.

OS18: The evaluation is done at the speed of 120 km/h and the steering frequency of 0.5 Hz. The steering torque is measured during the reduction of the lateral acceleration.

OS19: A height between 0.5 and 1.5 Nm is preferable.

OS20: A width between 1.5 and 5.0° is preferable.
OS21–23: The evaluation is done at the speed of 120 km/h.
OS24: The evaluation is done at the speed of 120 km/h.

5.1.2 *Vehicle behavior*

Correlation notes sorted by code (Table 3):

OV1: Gradients under 1/90 (°)m^2/Ns are preferable. The evaluation is done while driving straight at the speeds of 100, 140, and 180 km/h.
OV2: The evaluation is done while driving straight between the speeds of 160 and 200 km/h.

$$K_G = \left| \frac{\dot{\psi}}{\tau v_{res}^2} \right|_{max} \quad (5)$$

τv^2_{res} is a value describing the intensity of the stochastic crosswind disturbance.

OV3:

$$RAT = 11.97 - 0.67 \cdot \dot{\Psi}_{max} - 7.37 \cdot T_{eq} \quad (6)$$

$\dot{\Psi}_{max}$ is the first maximum of the yaw rate. T_{eq} is the equivalent time delay (measured out of separate sine steer maneuver).
OV4: Values below 0.25 1/s are preferable. The maneuver is done at 100 km/h.
OV5: The evaluation is done at the speed of 190 km/h and a constant lateral inclination of 1.5%.

$$\tilde{\dot{\psi}} = \sqrt{\int_a^b \Phi_\psi(f)\mathrm{d}f} \quad (7)$$

$\Phi_\psi(f)$ is the power spectral density of the yaw rate. The root of the integral of $\Phi_\psi(f)$ between the steering frequencies 0.2 and 1.5 Hz shall have values below 0.1°/s.

Table 3. Objective criteria on-center handling (vehicle behavior).

On-center handling—Vehicle behavior					
Subjective characteristic	Objective characteristic	Code/note		Reference	Maneuver
Cross wind sensitivity	Gradient of ratio yaw rate deviation/crosswind pressure	*OV1*	⇩	Dettki, 2005	Crosswind
	Characteristic based on the maximum of the amplification factor between the wind disturbance and the resulting yaw rate	*OV2*	⇩	Wagner, 2003	
	Characteristic based on the first yaw rate maximum and the equivalent time delay (measured out of separate sine steer maneuver)	*OV3*	⇧	Zomotor, Braess, and Rönitz, 1997	
Lateral inclination sensitivity	First derivative of the yaw rate deviation with respect to the roll angle	*OV4*	⇩	Dettki, 2005	Straight driving
	Characteristic based on the frequency spectrum of the yaw rate	*OV5*	⇩	Dettki, 2005	Straight driving with lateral inclination
Straight driving stability	Characteristic based on the steering angle in combination with the time period between two steering corrections	*OV6*	⇧	Engels, 1993	Straight driving
	Characteristic based on the hysteresis between lateral acceleration and steering angle	*OV7*	⇩	Loth, 1997	Sine steer
	Lateral acceleration at zero steering torque	*OV8*	⇧	Zschocke, 2009	Weave test
	Difference between the lateral acceleration amplification factor at 0.2 and at 0.6 Hz		⇧		ISO frequency response test
Response behavior	Steering angle dead-band with respect to yaw rate		⇩	Farrer, 1993	Weave test, transition test
	Time lag between steering angle and yaw rate		⇩		

OV6:

$$\mathrm{SU} = 11.67 - 0.47\left(\frac{\overline{\delta}_{\mathrm{Leff}}}{0.3}\right) - 1.59\left(\frac{14.3}{\overline{t}_{\mathrm{Spur}}}\right) \qquad (8)$$

$\overline{\delta}_{\mathrm{Leff}}$ is the effective steering angle of a period. $\overline{t}_{\mathrm{Spur}}$ is the time period between two steering corrections. Maneuver is done at 90 and 150 km/h.

OV7:

$$\phi = \arcsin\left(\frac{\delta_{\mathrm{LP}}}{\widehat{\delta}_{\mathrm{L}}}\right) \qquad (9)$$

δ_{LP} is half the width of the lateral acceleration/steering angle hysteresis at 0 m/s^2 lateral acceleration. $\widehat{\delta}_{\mathrm{L}}$ is half the width of the hysteresis at maximum lateral acceleration.

OV8: The evaluation is done at the speeds of 100 and 150 km/h.

5.2 Corner handling

5.2.1 *Steering feel*

Correlation notes sorted by code (Table 4):

CS1–2: The evaluation is done at the speed of 80 km/h, the steering frequency of 0.4 Hz, and the lateral acceleration of 0.4*g*.

CS3–5: A progressive steering torque increase is preferable, that is, low torque at 1 m/s^2, medium torque at 4 m/s^2, and a high torque difference between 0.5 and 1 m/s^2. The evaluation is done at the speeds of 70 and 100 km/h.

CS6–7: The evaluation is done at the speed of 100 km/h and the lateral acceleration of 0.4*g*.

CS8–10: The evaluation is done at the speed of 120 km/h and the steering frequency of 0.5 Hz with a steering amplitude of 10°.

CS11: The evaluation is done up to a lateral acceleration of 0.4*g* with a step steer maneuver at the speed of

80 km/h or with a single sine maneuver at the speed of 80 km/h, the steering frequency of 0.2 Hz or with a weave test at the speed of 120 km/h, and the steering frequency of 0.5 Hz with an steering amplitude of 20° or with a frequency response test at the speed of 100 km/h.

CS12–13: The evaluation is done at the speed of 120 km/h.

CS14: The evaluation is done at the speed of 80 or 100 km/h and the lateral acceleration of 0.4*g*.

CS15–16: The evaluation is done at the speed of 80 km/h.

5.2.2 *Vehicle behavior*

Correlation notes sorted by code (Table 5):

CV1: Values around 0.2–0.3 s are optimal.

CV2: The TB2 value is the product between the peak response time $T_{\dot{\psi}_{\max}}$ of the yaw rate and the maximum vehicle sideslip angle $\beta_{\max}$.

$$\mathrm{TB2} = T_{\dot{\psi}_{\max}} \cdot \beta_{\max} \tag{10}$$

The TB2 value is not valid for vehicles fitted with rear-wheel steering.

CV3: $\ddot{\Psi}_{\mathrm{QuMW}}$ is the yaw acceleration mean square value.

$$\ddot{\Psi}_{\mathrm{QuMW}} = \frac{\left|\sum_{i=0}^{t_e} \frac{\ddot{\Psi}_i}{|\ddot{\Psi}_i|}(\ddot{\Psi}_i)^2\right|}{\sum_{i=0}^{t_e} \frac{\ddot{\Psi}_i}{|\ddot{\Psi}_i|}(\ddot{\Psi}_i)^2} \frac{\sqrt{\left|\sum_{i=0}^{t_e} \frac{\ddot{\Psi}_i}{|\ddot{\Psi}_i|}(\ddot{\Psi}_i)^2\right|}}{100 t_e} \tag{11}$$

t_0 is the point in time of brake application and t_e the point in time of the first driver interaction but has a maximum of 2 s.

CV4:

$$\ddot{\Psi}_{\mathrm{relAbsMaz}} = \frac{\left|\ddot{\Psi} - \ddot{\Psi}_0\right|}{\ddot{\Psi} - \ddot{\Psi}_0} \cdot \left(\left|\ddot{\Psi} - \ddot{\Psi}_0\right|\right)_{\max_{t_0 - t_e}} \tag{12}$$

$\ddot{\Psi}_0$ is the reference yaw rate acceleration, t_0 the point in time of brake application, and t_e the point in time of the first driver interaction but has a maximum of 2 s.

CV5:

$$\ddot{\Psi}_{\mathrm{Diff}} = \left|\left(\ddot{\Psi} - \ddot{\Psi}_0\right)_{\max_{(t_0 - t_e)}}\right| - \left|\left(\ddot{\Psi} - \ddot{\Psi}_0\right)_{\min_{(t_0 - t_e)}}\right| \tag{13}$$

$\ddot{\Psi}_0$ is the reference yaw acceleration and t_0 the point in time of brake application.

	Characteristic based on the yaw rate and reference yaw rate 1.5 s after an accelerator pedal kick	*CV11*	⊙	Schweers and Röth, 1995	Load-change acceleration

CV6:

$$\mathrm{RMI} = \frac{1}{2}[(z_{\mathrm{i,f}} + z_{\mathrm{o,f}}) - (z_{\mathrm{i,r}} + z_{\mathrm{o,r}})] \tag{14}$$

z is the vertical wheel travel with the suffixes i (inner), o (outer), f (front), and r (rear). A negative RMI value is preferable.

CV7:

$$\mathrm{WI} = \frac{\ddot{\varphi}}{a_y} \cdot h_{\mathrm{k}} \cdot \frac{1}{\pi} + \frac{\dot{\varphi}}{a_y} \cdot h_1 + \frac{\varphi}{a_y} \cdot h_1 \cdot \pi \tag{15}$$

h_{k} is the height distance between the driver's head and the roll axle, a_y is the lateral acceleration, φ is the roll rate, and h_1 equals the length of 1 m.

CV8:

$$\mathrm{AWP} = \frac{\ddot{\varphi}}{\delta_{\mathrm{H}}} \cdot h_{\mathrm{k}} \cdot \frac{1}{\pi} + \frac{\dot{\varphi}}{\delta_{\mathrm{H}}} \cdot h_1 + \frac{\varphi}{\delta_{\mathrm{H}}} \cdot h_1 \cdot \pi \tag{16}$$

h_{k} is the height distance between the driver's head and the roll axle, δ_{H} is the maximal steering angle, φ is the roll rate, and h_1 equals the length of 1 m.

CV9: The TB value is the product between the peak response time $T_{\dot{\psi}_{\max}}$ and the stationary vehicle sideslip angle β_{stat}.

$$\mathrm{TB} = T_{\dot{\psi}_{\max}} \cdot \beta_{\mathrm{stat}} \tag{17}$$

The TB value is not valid for vehicles fitted with rear-wheel steering.

CV10: $\Delta\delta_{\max,2}$ is the dissymmetry of the steering angle history of the second lane change and $T_{0,(\delta,a_y)}$ the time delay between steering angle and lateral acceleration.

$$\mathrm{KD} = \Delta\delta_{\max,2} + 2.5 \cdot T_{0,(\delta,a_y)} \tag{18}$$

CV11: $\dot{\Psi}$ is the yaw rate and $\dot{\Psi}_{\mathrm{ref}}$ the reference yaw rate.

$$\frac{\dot{\Psi}}{\dot{\Psi}_{\mathrm{ref}}}(t_0 + 1.5\,\mathrm{s}) \tag{19}$$

t_0 is the time of the accelerator pedal kick.

6 SUMMARY

This chapter describes how the handling quality of passenger cars can be measured by subjective and objective evaluations. Beginning with an introduction of the basic principles of the subjective vehicle handling perception, practical advice for the planning, conduct, and analysis of subjective evaluations with groups of selected customers or professional drivers was given.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto021
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The compliance with the presented rules can significantly increase the informative value of these evaluations. Objective evaluation methods based on characteristic values promise a more efficient way to assess vehicle handling and facilitate evaluations in virtual simulation environments. Therefore, this chapter has provided an overview on possible methods of objective evaluation. The necessary analysis of subjective or objective data and the identification of the relationship among both by means of correlation and regression analyses were described. The correlation coefficient has proven to be a reasonable measure for the statistical significance of the relationship. Finally, on the basis of an extensive meta-study, an overview on customer-relevant vehicle handling measures was given. In order to ensure customer relevance, only characteristic values that have been validated by real test-drives and regression analyses were considered. The identified measures have been summarized for practical use in the form of Tables 2–5.

The Potential for Handling Improvements by Global Chassis Control

Thomas Raste and Peter E. Rieth
Continental Corporation, Frankfurt, Germany

1 INTRODUCTION

From a driver's perspective, controlling of a vehicle means controlling the speed and the path curvature (Figure 1). In exceptional circumstances, for example, in emergency evading situations, also the orientation of the vehicle has to be controlled. In a narrower sense, vehicle handling refers to vehicle dynamics such as cornering and swerving and includes the vehicle stability.

In day-to-day use, speed control by braking or accelerating is largely decoupled from handling, because the steering wheel is turned slowly to steer the car. When driving on race tracks or in emergency evading situations, the steering rate reaches very high values. Skilled drivers are able to manage steering rates of 1000 deg/s or more. In those situations, the capability to follow a path is strongly depending on the speed. The most limiting factor is the tire–road friction, which restricts the lateral acceleration depending on the road conditions. Equation 1 shows how lateral (centripetal) acceleration a_y, vehicle speed v, radius R of the path, yaw rate ω, and sideslip ("spin") angle rate $\dot{\beta}$ are related

$$a_y = \frac{v_2}{R}, \quad R = \frac{v}{\omega + \dot{\beta}} \tag{1}$$

2 ACTIVE SYSTEMS

Active systems, which mean systems with auxiliary power and electronic control, are well suited to improve the handling of the vehicle. Especially, active braking has been established as the most effective active safety system. Electronic stability control (ESC) is now becoming mandatory in many countries all over the world. However, also active systems primarily designed for comfort are able to contribute to a better handling of the vehicle (Figure 2).

2.1 Requirements for active systems

Passive components affecting the handling of the vehicle need targets for the design in every stage of the development process (Figure 3). The feedback of extensive evaluations is used "offline" to tune the passive parts. Active systems lay a foundation for a new perspective in this development process. They offer the opportunity to determine their effectiveness "online" during driving based on the design targets. The active systems, therefore, need to be as generic as possible to minimize additional costs when setting up a new configuration (Andreasson, 2007).

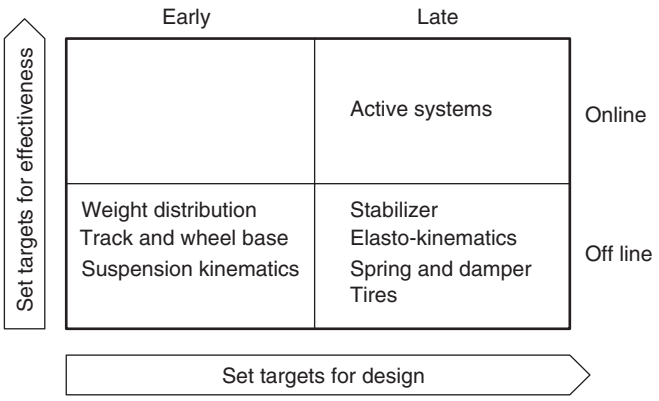

Figure 3. Target setting in the vehicle development process for passive components affecting vehicle handling in comparison to active systems. (Reproduced by permission of Continental.)

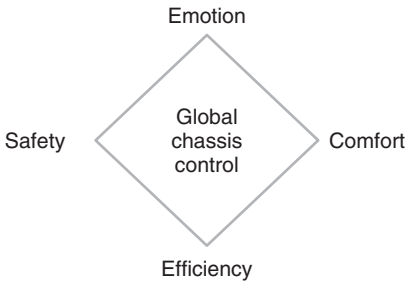

Figure 4. Trade-offs for global chassis control. (Reproduced by permission of Continental.)

The requirements for global chassis control are not unique. Figure 4 illustrates that there is usually a trade-off among emotion, safety, comfort, and efficiency. While safety will never be compromised, the remaining aspects are variable in positioning. There is a trend toward individualization and personalization of vehicle handling functions. The driver can select from different profiles with the push of a button. End consumers can thus buy just one vehicle and yet have the experience of driving different vehicle types. Above and beyond this, for example, for hybrid vehicles to come, a smooth blending of the friction brake and the generator brake for decelerating allows efficient driving with lower CO_2 emissions on a day-to-day basis (Bauer, Raste, and Rieth, 2007).

Active systems are safety-relevant components, which comprise the risk of malfunction. To minimize the risk, the development process has to be according to the safety standard ISO 26262 "Road vehicles—Functional safety." The criticality associated with a function of the system is the result of a hazard analysis and risk assessment and is classified by the Automotive Safety Integrity Level (ASIL). The classification reaches either from QM (quality management, not safety relevant) or from ASIL A (lowest level) to

ASIL D (highest level). The ASIL is then inherited by the software and hardware elements that realize the function and defines the safety requirements that must be fulfilled during concept phase, product development, and production and operation of the system. Typical safety requirements and ASIL classification can be found in Table 1.

2.2 Portfolio of active systems

In Figure 5, a portfolio of currently available active systems and their effectiveness in the regions of normal driving and at the friction limit is shown. The effectiveness of the individual standalone systems can be extended significantly by networking with other active systems or surrounding sensor systems (Raste, Bauer, and Rieth, 2008). Currently, the following topics are being further developed:

- specification of the areas in which the vehicle dynamics should be defined by global chassis control;
- composition of the best active system portfolio for a specific vehicle or a family of vehicles;
- partitioning of control functions on a certain electronics architecture with the need for managing complexity.

The path to a consistent, cross-vendor coordination approach for chassis control systems is still far away. However, there is consensus on the objectives: under normal operating range, the controller ensures maximum comfort and driving pleasure. In this case, the vehicle manufacturer determines all degrees of freedom for the individual setting of the vehicle character. In the friction limit range, all available actuators in the system are included in a coordinated manner to reach one target: to support the driver optimally for accident avoidance.

2.3 Potential of active systems

Figure 6 illustrates the contact patch tire forces and velocities of a single wheel during driving and how the wheel contributes to the total yaw moment of the vehicle. The wheel is steered by the angle δ and the actual direction of travel with velocity v_R defines the sideslip angle α. The resultant horizontal force F_R points toward the opposite direction of the contact patch sliding velocity v_G. The sliding velocity components v_{Gx}, v_{Gy}, each related to the longitudinal velocity v_{Rx} of the wheel center, define the tire

Effect plane	Active system	Normal driving range				Friction limit range		
		Ride comfort (z,θ,φ)	Agility (y,ψ)	Operational comfort	Ride safety (y,ψ)	Stability (x,y,ψ,φ)	Stopping distance	Traction
Horizontal	ESC electronic stability control		+	+	+	o	o	o
	ATV active torque vectoring		o	o	+	+		o
	ARK active rear axle kinematics		o	o	+	+	+	
	AFS active front steering		o	o	+	+	+

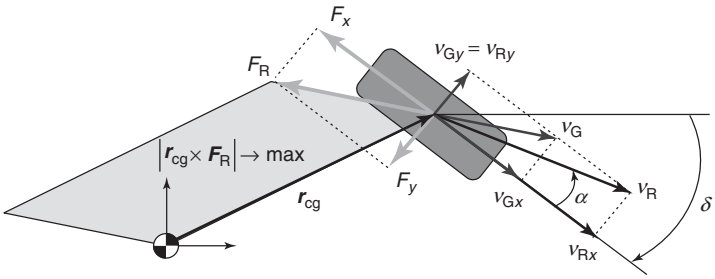

Figure 6. Tire forces, wheel and contact patch velocities, and contribution of the wheel to the yaw moment around the center of gravity of the vehicle. (Reproduced by permission of Continental.)

slip and sideslip angles, which, on the other hand, determine the magnitude of the forces F_x and F_y.

The magnitude of F_R is limited by the friction circle (Kamm's circle). The radius of the friction circle is determined by the product of the tire–road friction coefficient μ and the vertical tire force F_z. The portion of the yaw moment generated by each individual wheel is determined by the scalar product of the total tire force vector F_R and the position vector r_{cg}, denoting the distance between the vehicle center of gravity and the wheel center. The potential of an active system to maximize the scalar product is to increase the resulting area

- by aligning position and force vector orthogonally via steer angle (active rear axle kinematics (ARK), AFS, and electric power steering (EPS));
- by increasing the magnitude of the longitudinal force vector by wheel individual brake or propulsion intervention (ESC and active torque vectoring (ATV));
- by decreasing the magnitude of the lateral force vector by wheel load distribution (EAS, active rear wheel steering (ARS), EAD, and active body control (ABC)).

Figure 7 shows the potential of active brake, steering, and suspension systems selected from Figure 5 to generate additional yaw moments when activated during steady-state driving with constant radius (Schiebahn, Zegelaar, and Hofmann, 2007). It is evident that in the friction limit range, ESC has the highest potential to stabilize an oversteering vehicle. The active steering systems are highly effective to reduce lateral forces within the friction limit range. In case of AFS, this leads to a high turning-out yaw moment, whereas, in the case of ARK, this leads to considerable turning-in yaw moment. Both steering systems show high potential with opposite effectiveness within the normal driving range but only poor authority to increase lateral forces within the friction limit range. The potential of the active suspension system ARS depends as a first approximation on lateral acceleration.

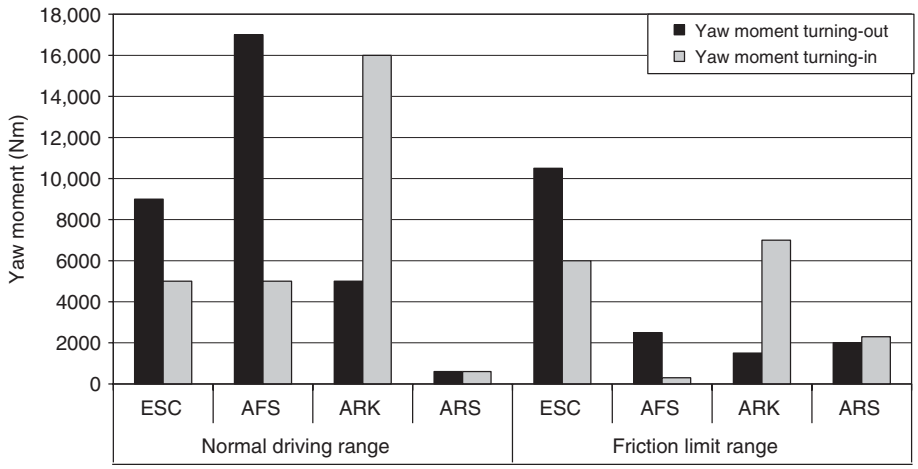

Figure 7. Potential of active brake, steering and suspension systems to generate additional yaw moment to force a vehicle in or out a curve, respectively, when driving in steady state with constant radius. (Reproduced by permission of Continental.)

3 VEHICLE DYNAMICS MODEL

In this section, a mathematical model describing the lateral motion of the vehicle is defined. The model is only valid for lateral accelerations below $0.4g$ and is illustrated in Figure 8.

3.1 Equations of motion

To derive the equations of motion, it is assumed that the center of gravity is on ground level and the steering angle δ_F on front axle and δ_R rear axle is small. The equations of motion of the lateral and yaw motions are given by

$$mv(\dot{\beta} + \omega) = F_{yF} + F_{yR} \tag{2}$$

$$J_z\dot{\omega} = l_F F_{yF} - l_R F_{yR} - \frac{b_F}{2}F_{xFL} + \frac{b_F}{2}F_{xFR} - \frac{b_R}{2}F_{xRL} + \frac{b_R}{2}F_{xRR} \tag{3}$$

where F_{yF} and F_{yR} are the combined front and rear lateral tire forces. The model parameters are the vehicle mass m, the moment of inertia around the z-axis J_z, the distances l_F and l_R from the front and rear axles to the center of gravity, and the front and rear track widths b_F and b_R. The lateral tire forces are assumed to be a linear function of the sideslip angles of the wheels with the effective cornering stiffness C_F and C_R

$$F_{yF} \approx -C_F\alpha_F, \quad \text{where } \alpha_F = -\left(\delta_F - \beta - \frac{l_F}{v}\omega\right) \tag{4}$$

$$F_{yR} \approx -C_R\alpha_R, \quad \text{where } \alpha_R = -\left(\delta_R - \beta + \frac{l_R}{v}\omega\right) \tag{5}$$

3.2 State-space equation

The state-space equation establishes a relationship between the system's current state and its input, and the future state of the system. The state-space form of the vehicle model is linear and time invariant if the vehicle speed v is considered to be a constant parameter. The system state vector x includes the sideslip angle β and the yaw rate ω. The input vector u contains the two steer angles and the four longitudinal forces illustrated in Figure 8. In addition to these six inputs, two more inputs are introduced, a (virtual) lateral force F_y and a (virtual) yaw moment M_z. These additional inputs are used as virtual control commands for controllability analysis in Section 5.2. The state-space equation of system (A and B) can be derived from Equations 2–5 and is written as

$$\dot{x} = Ax + Bu \tag{6}$$

$$Ax = \begin{bmatrix} -\frac{C_F + C_R}{mv} & -\frac{l_F C_F - l_R C_R}{mv^2} - 1 \\ -\frac{l_F C_F - l_R C_R}{J_z} & -\frac{l_F^2 C_F + l_R^2 C_R}{J_z v} \end{bmatrix} \begin{bmatrix} \beta \\ \omega \end{bmatrix} \tag{7}$$

$$Bu = \begin{bmatrix} \frac{C_F}{mv} & \frac{C_R}{mv} & 0 & 0 & 0 & 0 & \frac{1}{mv} & 0 \\ \frac{l_F C_F}{J_z} & -\frac{l_R C_R}{J_z} & -\frac{b_F}{2J_z} & \frac{b_F}{2J_z} & -\frac{b_R}{2J_z} & \frac{b_R}{2J_z} & 0 & \frac{1}{J_z} \end{bmatrix} \times \begin{bmatrix} \delta_F \\ \delta_R \\ F_{xFL} \\ F_{xFR} \\ F_{xRL} \\ F_{xRR} \\ F_y \\ M_z \end{bmatrix} \tag{8}$$

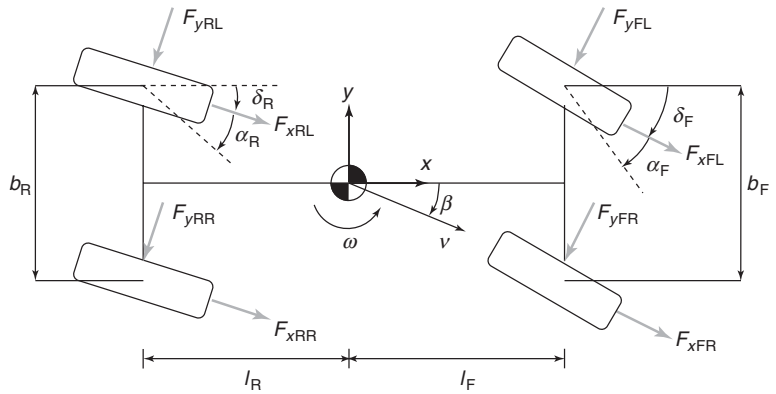

Figure 8. Vehicle model with the tire forces F_x and F_y, the vehicle speed v, the yaw rate ω, and the vehicle sideslip angle β. (Reproduced by permission of Continental.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto022
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The Equations 6–8 can be simplified for stationary operation with $\dot{x} = 0$ and the steer angle inputs only ($F_x = 0$, $F_y = 0$, $M_z = 0$). Under the assumption that the system matrix A is regular (a necessary condition is that $v > 0$), the stationary-state variables (β, ω) can be determined from Equation 6 by inverting A and introducing the parameters wheel base l and understeer gradient K_{us}:

$$x = -A^{-1}Bu \tag{9}$$

$$\beta = K_F\delta_F + K_R\delta_R, \quad \text{where} \quad K_F = \frac{l_R\left(1 - \frac{ml_Fv^2}{C_Rl_Rl}\right)}{l + K_{us}v^2}$$

$$\text{and} \quad K_R = \frac{l_F\left(1 + \frac{ml_Rv^2}{C_Fl_Fl}\right)}{l + K_{us}v^2} \tag{10}$$

$$\omega = K_\omega(\delta_F - \delta_R), \quad \text{where} \quad K_\omega = \frac{v}{l + K_{us}v^2}$$

$$\text{and} \quad K_{us} = \frac{m}{l}\left(\frac{l_R}{C_F} - \frac{l_F}{C_R}\right) \tag{11}$$

3.3 Vehicle parameter determination

The moment of inertia J_z can be approximated with the ease to measure total vehicle length L, the wheel base l, and the vehicle mass m. The distances l_F and l_R from the center of gravity to the axles are calculated using the weighted rear axle vehicle load m_R (Equation 12).

$$J_z = 0.1269 \cdot m \cdot l \cdot L, \quad l_F = \frac{m_R}{m} \cdot l, \quad l_R = l - l_F \tag{12}$$

The tire parameters are determined from a stationary circle vehicle driving test with constant radius R and zero steer angle at rear axle ($\delta_R = 0$). From these tests, two gradients with reference to the lateral acceleration a_y have to be derived from measurement plots. The required gradients are the sideslip angle gradient $d\beta/da_y$ and the steering angle gradient $d\delta_F/da_y$ ($=K_{us}$). The steering reduction ratio i_s between the front steer road wheel angle and the driver's steering wheel angle δ_H is assumed to be constant, that is, $\delta_H = \delta_F i_s$. The steering reduction ratio and the cornering stiffness can be calculated consecutively from

$$i_s = \frac{\delta_H.R}{l}, \quad C_R = -\frac{ml_F}{\frac{d\beta}{da_y}l}, \quad \text{and} \quad C_F = \frac{ml_RC_R}{K_{us}.lC_R + ml_F} \tag{13}$$

A set of vehicle parameters for a typical sedan car can be found in Table 2.

Table 2. Vehicle model parameters for a generic sedan car.

Symbol	Value	Unit	Description
m	1770	kg	Vehicle mass
J_z	3140	kg m^2	Vehicle yaw moment of inertia
L	4.841	m	Vehicle length
l_F	1.575	m	Distance from center of gravity to front axle
l_R	1.313	m	Distance from center of gravity to rear axle
b_F	1.562	m	Track width of front axle
b_R	1.590	m	Track width of rear axle
C_F	94672	N rad^{-1}	Effective cornering stiffness of front axle
C_R	160880	N rad^{-1}	Effective cornering stiffness of rear axle
i_s	17.6	—	Steering reduction ratio

4 HANDLING IMPROVEMENTS

The operational range for handling improvements is separated into two distinct areas, separated by the yaw rate at the friction limit range as illustrated in Figure 9. The "deep slip" range above the critical friction limit yaw rate is the application range of ESC.

Considering the basic idea that "the steering wheel is a yaw rate demand" (Blundell and Harty, 2004), improvements of handling mean that all the following are true:

- The path curvature can quickly and easily be altered with open-loop commands.
- The path curvature can be adjusted by the driver with only small closed-loop content.
- The vehicle response to steering input is predictable for the driver.

4.1 Handling improvements during normal driving

The alteration of the path curvature can easily be achieved by increasing the yaw gain, such that the driver steering input is small. This strategy is only applicable up to a medium speed. The yaw rate's normal driving range decreases significantly with vehicle speed, because the available tire–road friction is saturated at high speed quickly when the steering wheel angle input is too high (Figure 9). For normal tires on dry roads, this dangerous saturation level is reached at a lateral acceleration of 1g. The acceleration levels of 0.7, 0.3, and 0.1g correspond to wet, snowy, and icy roads. The strategy at high speed, therefore, must be to decrease the steady-state yaw gain at higher speed. From Equation 14, it can be seen that the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto022
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

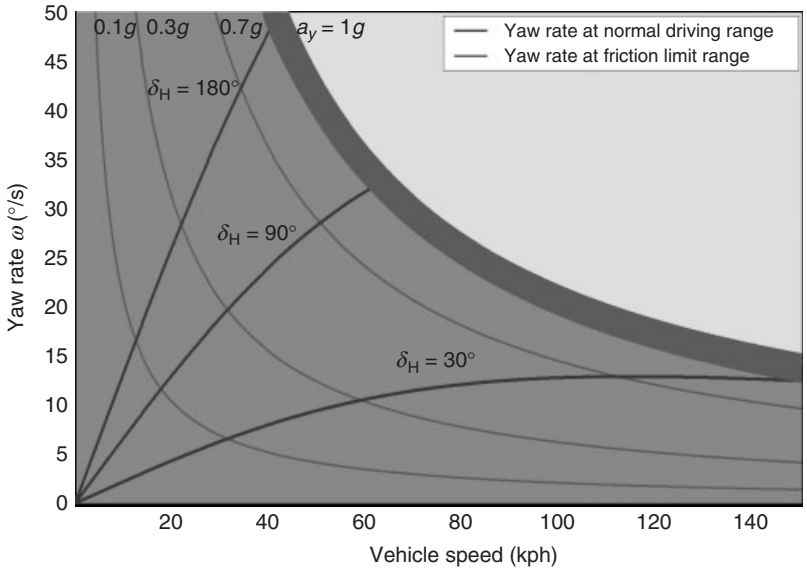

Figure 9. Operational range for handling improvements by global chassis control. (Reproduced by permission of Continental.)

yaw gain can be adjusted either by variation of the steering reduction ratio i_s or using a rear wheel steering. BMW uses both means together in their integral active steering (Herold *et al*., 2008).

$$\frac{\omega}{\delta_H} = K_\omega \left(\frac{1}{i_s} - \frac{\delta_R}{\delta_H} \right) \tag{14}$$

The potential for transient handling improvement is demonstrated with a simulated step-steer maneuver. This maneuver demonstrates that altering a path curvature quickly is not in conflict with a good damping behavior, when the controller is designed carefully. The handling controller used for the demonstration of the control potential is acting on the rear axle steer angle. A feedback of the vehicle's state $x = [\beta \ \omega]^T$ with gain matrix K_x improves the closed-loop dynamics of the vehicle, and a feedforward control part K_H is applied for a vanishing steady-state rear axle steer angle (Figure 10). The control law is given by the following equation, with parameters only valid for the given maneuver speed of 150 kph.

$$\delta_R = K_H \delta_H - K_x x, \text{ where } K_H = -0.0239$$
$$\text{and } K_x = (-0.0764 - 0.0896) \tag{15}$$

The controller increases the response of the vehicle by increasing the yaw moment of approximately 45%. This significant improvement can be seen from the yaw acceleration in Figure 10 and is due to the out-of-phase (= negative) steering of the rear axle at the beginning of the maneuver. This steering input leads to an initially negative lateral force on the rear axle and, therefore, a yaw moment contribution, which enhances the turning-in yaw moment compared to the vehicle with inactive controller. Further advantage of the controller is the reduction of overshoot in yaw rate, sideslip angle, and lateral acceleration. This considerably improved damping behavior provides for an increased safety margin toward the friction limit range. Furthermore, the decreased delay between the steering wheel and the vehicle sideslip angle rate leads to an improved perception of agility by the driver.

4.2 Handling improvements during friction limit driving

At the limit of friction, where safety becomes relevant, the handling controller determines how the vehicle remains stable. All available actuators, that is, those listed in Figure 5, are incorporated and coordinated to reach this goal. The active chassis gives the driver optimal support for avoiding accidents. In the region beyond the limit of friction, the main task of the control system is to prevent the car from heavily skidding such that the car remains on track.

During normal driving, car drivers usually expect a linear yaw response of the vehicle with small phase lag. Most drivers have no experience of loss of linearity caused by saturation of tire forces. If saturation happens at the rear axle, the sideslip angle will increase quickly and, therefore, causes a hazardous driving problem for many drivers. The primary task of the control system should be to keep the vehicle sideslip angle small. An average driver feels uncomfortable when the magnitude of the sideslip

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

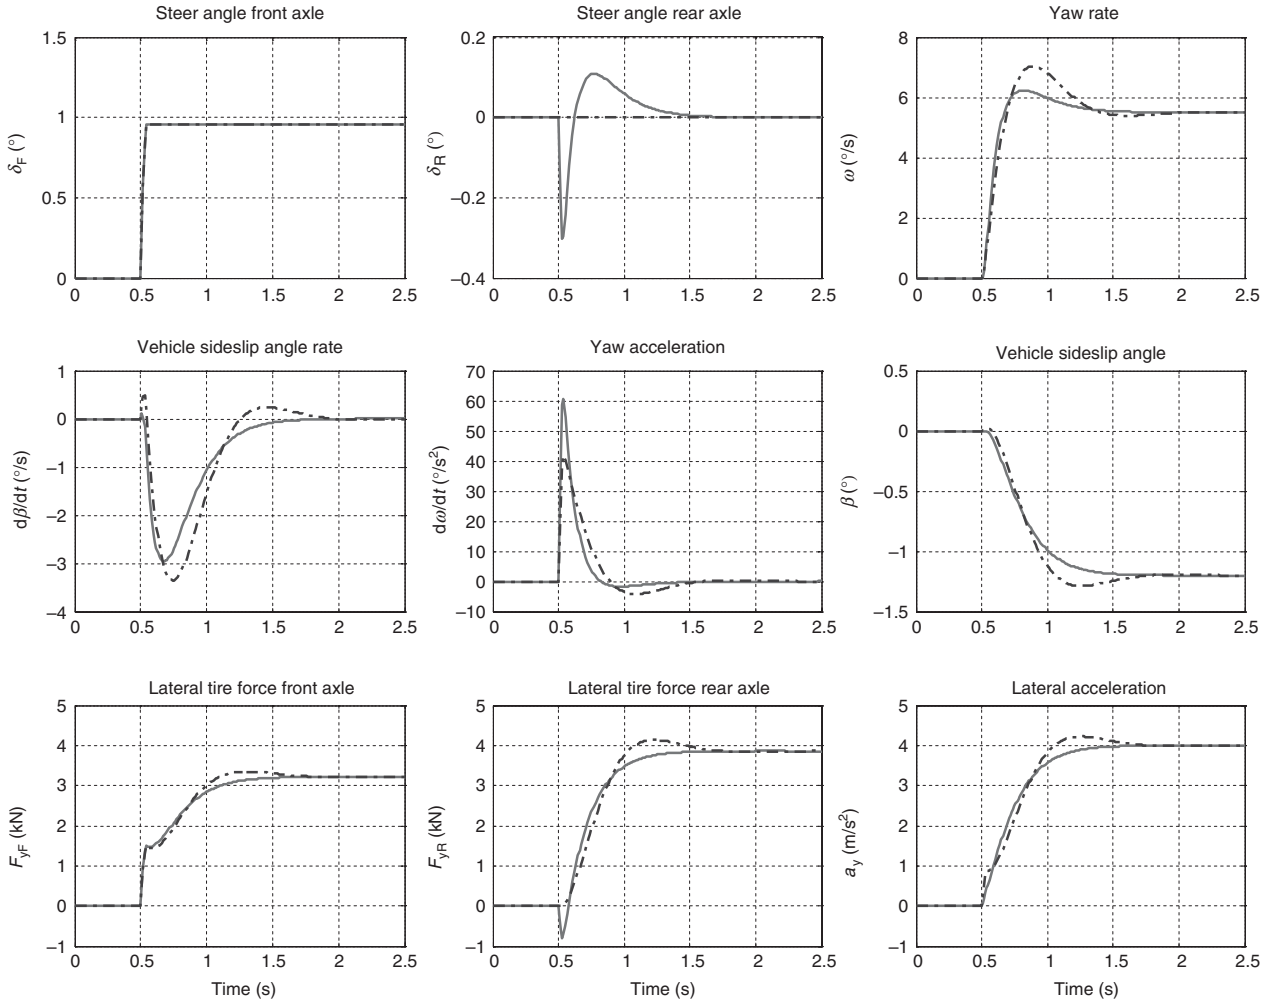

Figure 10. Vehicle states and inputs for a simulated step-steer maneuver with vehicle model Equations 6–8 reaching a steady-state lateral acceleration of $0.4g$ with a maximum steering wheel angle rate of $\delta_H = 500$ deg/s at a vehicle speed of $v = 150$ kph. The light gray solid line and the dashed dark gray line correspond to the controller active and the controller inactive, respectively. (Reproduced by permission of Continental.)

angle exceeds 3°. The state-of-the-art ESC systems limit the sideslip angle indirectly. ESC uses a reference yaw rate limited by the actual acceleration to account for the tire saturation. Additionally, the rate of change of sideslip angle is calculated and also limited. Figure 11 shows the results of a double-lane change vehicle test performed on a low friction surface. With the global chassis control (GCC), the vehicle response is stable and predictable to the driver at that particular speed level. ESC standalone will achieve a similar behavior, but at a much lower speed level. In the data plots of Figure 11, the scaling factor $k = 7$ is used for visualization purposes only. The scaling factor has been introduced to "normalize" the yaw rate for easy comparison of steering angle stimulus and yaw rate response. The unusual delay of the yaw rate response in the ESC standalone case becomes very obvious.

5 GENERIC MOTION CONTROL ARCHITECTURE

5.1 Overall control system

The fundamentals of the integration and coordination of the active systems into a hierarchically structured overall control system are shown in Figure 12. The first subtask in the overall control system is to determine the driver's intention. For that purpose, sensors on brake, steering, and accelerator pedal are interpreted to derive appropriate

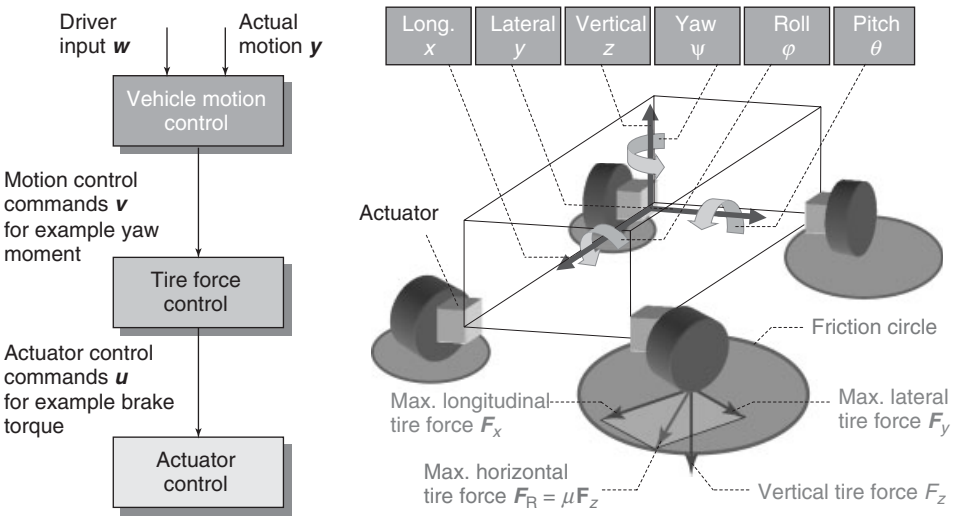

Figure 12. Overall control system. (Reproduced by permission of Continental.)

reference signals. In a second subtask, the driver's intention is compared to the actual vehicle motion, which is measured by inertial and speed sensors. If there are deviations, they are adjusted by calculating target forces and moments to change the actual vehicle's translational and rotational motions according to the driver's intention. The task of the tire force control is to distribute the motion control commands onto the individual wheels in order to change the tire forces in the contact patch area. The tire forces are adjusted by electromechanical or electrohydraulical actuators. A general limitation for the maximum achievable horizontal tire force is the friction circle (Kamm's circle),

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto022
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

which depends on the tire–road friction and the load at each wheel.

Tire force control is the task to distribute the motion control commands among the tire forces at each wheel. Mathematically, this is the task to solve an underdetermined, typically constraint system of equations. The ambiguity of the actuator effects is characteristic for vehicles with multiple active systems onboard. For tire force control, a control allocation approach is generally useful, when different combinations of actuator commands can produce the same motion result. When the number of actuators available exceeds the number of degrees of freedom being controlled, the vehicle is called *over-actuated*. A vehicle equipped with ESC falls under this category, because four individual brake actuators control three horizontal degrees of freedom. Control allocation of over-actuated vehicles involves generating an optimal set of actuator control commands while minimizing the control effort and complying with the position and rate constraints of the actuator.

5.2 Selection of actuator configurations

It is a challenging and complex question of how to select an optimal set of actuators. For handling control, a possible answer can be achieved by analyzing the lateral full state (β, ω) controllability property of the vehicle (Raste *et al.*, 2010). The analysis is based on the state-space Equations 6–8. To simplify the analysis, not all longitudinal forces but only the differential forces $\Delta F_{x\mathrm{F}} = F_{x\mathrm{FL}} - F_{x\mathrm{FR}}$ and $\Delta F_{x\mathrm{R}} = F_{x\mathrm{RL}} - F_{x\mathrm{RR}}$ are considered. The analysis requires the controllability Gramian matrix W_c, which can be found as the solution to the Lyapunov matrix Equation 16 (Kailath, 1980).

$$AW_\mathrm{c} + W_\mathrm{c}A^\mathrm{T} = -BB^\mathrm{T} \tag{16}$$

The system state (β, ω) is controllable if the matrix W_c has full rank. If the matrix W_c has at least one eigenvalue equal to 0, then it cannot have full rank and, therefore, the system state is not controllable. Figure 13 shows the normalized smallest eigenvalue $\lambda_{\min}$ of the controllability Gramian matrix W_c as a function of the vehicle speed. The results can be interpreted as follows:

- Controllability of the full state (β, ω) is given in the whole speed range if front and rear steer angle controls are used, which is approximately equivalent to a virtual control input (F_y, M_z) at low speeds.
- Controllability of the full state (β, ω) with longitudinal differential forces only, which is equivalent to a virtual yaw moment control M_z, is not given at low speeds.

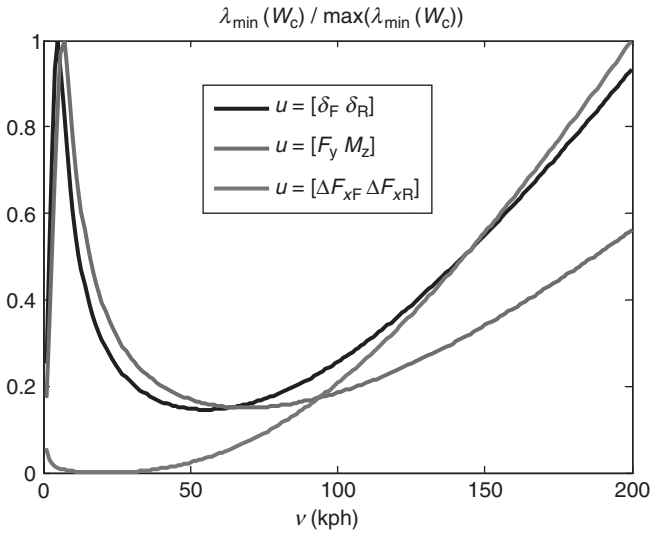

Figure 13. Controllability analysis based on the smallest eigenvalue $\lambda_{\min}$ of the controllability Gramian matrix W_c for different control input vectors. The black solid line corresponds to steer angle control input. The light gray solid line and the dark gray line correspond to virtual control input and longitudinal differential forces control input, respectively. (Reproduced by permission of Continental.)

- Simultaneous path and orientation controls, that is, full state (β, ω) control over the whole speed range, need both yaw moment actuators (e.g., ESC or ATV) and lateral force actuators (e.g., EPS, AFS, or ARK).

5.3 Compatibility of actuator configurations

The results from the controllability analysis are very useful to design the control system as generic as possible. A potential strategy to make the control compatible with various configurations of actuators is illustrated in Figure 14. The control feature A is originally designed for a rear wheel steering. It is assumed that δ_F is determined by the driver steering input. The task of the converter function is to transform the motion control commands into a target force and moment. These virtual motion control commands F_y and M_z might be used as a common basis for arbitration, for example, when requested by different control features. The control allocation procedure distributes the virtual motion control commands onto real commands for a given actuator configuration. The procedure is successful if the actuators generate a control effect as closely as possible to the virtual control demand.

To verify the feasibility of the strategy, a constraint control allocation library for MATLAB /Simulink has been

applied (Harkegard, 2003). Figure 15 illustrates the results with the same step-steer maneuver, which has been used in the previous section (Figure 10). It is worth to point out that the vehicle state variables β and ω show identical behavior for all three actuator sets. The feature is the transient control with the control law given by Equation 15. The steering signals are converted into the virtual motion control commands shown in Figure 15b. The constraint control allocation is able to consider the position and rate limits of each actuator. In the simulation, a constraint in the positive

direction of the force has been used to make the feature available for a brake-based active system. The resulting actuator commands are shown in Figure 15c. The driver input is now slightly modified. Further, simulations have to clarify if the deviation can be expected to be compensated by the driver or if the driver has to be supported by additional active systems, for example, EPS.

6 FUTURE TRENDS OF HANDLING CONTROL

In normal driving and also in hazard situations, the driver is supposed to be the master of control and, therefore, properly the source for reference signals. However, what happens if a driver does not react appropriately? In urban traffic situations, one of the main causes of accidents is driver distraction. The automotive industry has identified the great potential of active systems assisting the driver in such critical situations.

6.1 Emergency brake assist

The emergency brake assist (EBA) shown in Figure 16 intervenes if the driver is inattentive and shows no sign of having recognized the danger of an impending collision. The city version of EBA-City is active at speeds of up to 30 kph. It features an optical sensor that uses infrared beams to monitor the road space in front of the vehicle, up to a distance of about 10 m. Its electronics calculate the distance to the vehicle in front. If there is a risk of collision, EBA initially prepares the brakes, issues a warning to the driver, and then, if time starts to run out, automatically applies the brakes. If the maximum speed differential between the vehicles is no more than 15 kph, a rear-end collision with the vehicle in front can be avoided in most cases. If a collision is unavoidable, automatic emergency braking can significantly reduce the impact velocity and thus the severity of the accident.

6.2 Emergency steer assist

Automotive engineers currently develop systems assisting the driver in hazardous handling situations, when there is no time left for braking (Hartmann, Eckert, and Rieth, 2009). Figure 17 illustrates a typical use case for handling assistance. A driver quickly initiates an evading maneuver to avoid a collision with a suddenly appearing object in front. Although the conventional ESC mitigates the severity of the situation significantly, there is still potential for further improvement. The main benefit comes from surrounding sensors such as radar sensors, which are used to identify an imminent collision. In Figure 17, the object distance information is used to preset an ARK just in time for handling with optimal effectiveness.

The simulation data presented in Figure 18 provides a further insight into the potential of different active systems in combination with predictive handling control. While systems such as adaptive damper or active stabilizer have only limited handling potential, the rear-wheel steering considerably reduces vehicle spinning-out and increases yaw damping when applied early enough. This positive effect on vehicle safety is accompanied by a slightly increased driver-steering effort. The preferred choice of assistance in such a case is to stimulate the haptic channel of the driver via EPS.

6.3 Handling during highly automated driving

Advanced driver assistance systems can offer remedies. On the one hand, they can support the driver in demanding and difficult situations and, on the other hand, develop room for freedom during monotonous driving situations, which are often accompanied by the risk of decreasing attention. Especially, the latter is a potential field of application for highly automated driving.

In the case when the driver is distracted and inattentive, an option of handling assistance could be to carry out the maneuver autonomously. Figure 19 presents a solution based on the procedure shown in Figure 14. The steering maneuver is executed autonomously without the need of steering the front wheels (e.g., when EPS is not available). The control commands are allocated, in the present example, to both friction brakes on the left side and the rear steering. The vehicle behaves in exactly the same way as it would have with steering the front wheels and the controller given by Equation 15 acting at the rear wheels.

Where does the assistance in handling situations go from here? Will drivers understand the meaning of haptic steering feedback in critical situations? What happened if they do not react at all? Autonomous vehicle braking technology has been launched over the last few years with great success. However, a rapid introduction of autonomous vehicle steering is not very likely. The legal situation and the functional safety management raise many questions

at the moment. A first step toward a technically feasible solution has been presented by exploiting the opportunities given by the inherent redundancy of multiple active systems.

7 CONCLUSION

Global chassis control delivers significant benefits in normal driving and particularly, in emergency situations. The configuration and the coordinated interaction of the active systems are the key success factors for enhancing the vehicle performance. International standards such as ISO 26262 ensure quality and safety of the overall control system at the highest level. In the near future, the vehicle

Automated Driving

Adrian Zlocki
Institut für Kraftfahrzeuge (ika), Aachen, Germany

1 INTRODUCTION

First assistance functions for automobiles were introduced shortly after the automobile itself had been invented, for example, the introduction of the automatic engine starter in 1913. In addition, the idea of automated driving vehicles was already developed in the early twentieth century. One of the first steps toward this idea was the introduction of the first cruise control system in the Chrysler Imperial as the so-called auto pilot in 1958 (Rowsome, 1958). This mechanical system was able to keep a constant speed, set by the driver, and therefore was able to take over the longitudinal vehicle control on a motorway. With the development of microelectronics and the introduction of computer-controlled systems in the last quarter of the twentieth century, the possibilities to realize automated driving vehicles became available. On the basis of these possibilities, initiatives were started such as PROMETHEUS (PROgraMme for a European Traffic of Highest Efficiency and Unprecedented Safety), the American National Automated Highway System Consortium (NAHSC), the Intelligent Vehicle Initiative (IVI), and the Japanese Advanced Cruise-Assist Highway System Research Association (AHSRA) in the end of the 1980s. At present, automated driving basically can be divided into three main categories:

- Advanced driver assistance systems (ADAS): ADAS partly take over the driving task and support the driver in complex and monotonous situations.
- Infrastructure-based automated driving vehicles: These self-driving vehicles operate in a dedicated infrastructure such as dedicated lanes or closed areas automated.
- Fully automated driving vehicles: This type of vehicles are operated driverless.

2 REQUIREMENTS FOR AUTOMATED DRIVING VEHICLES

Automated driving vehicles need to fulfill technological and legal requirements. The necessary technology for automated driving vehicles needs to provide sophisticated information about the surrounding environment and the current vehicle status. This information is processed to determine the situation awareness and provide the correct action or even reaction by the actuators of the vehicle.

In contrast to conventional controlled vehicles, automated driving vehicles need to perceive the surrounding environment, process the information, and react to them fully automated (Figure 1). This reaction is targeted to the normal car operation and the supervision and avoidance of dangerous situations.

While the driver depends on his own recognition for information perception, for automated systems, vehicle and

ISBN: 978-0-470-97402-5

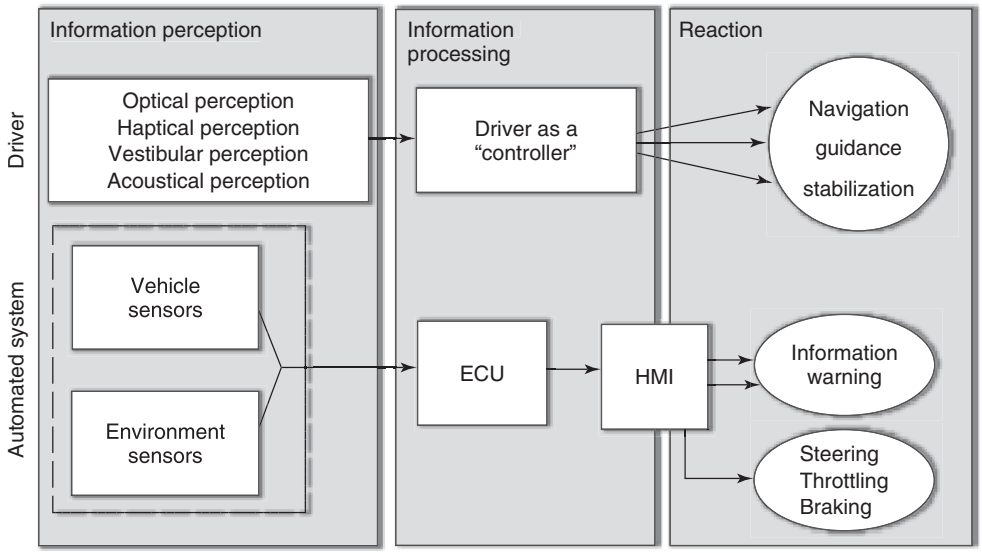

Figure 1. Vehicle control comparison between driver and automated system.

environment sensors are necessary for the perception. These sensors detect the driving condition (speed, acceleration, yaw rate, etc.) and the surrounding traffic situation (other traffic participants, objects in the driving path, current position, etc.). Information processing takes place in an electronic computer unit (ECU). The driver activates the system by means of an appropriate human–machine interface (HMI). Actuators such as the steering system, the accelerator, and the brake actuator or even the automatic gear shifter transfer the reaction of the system into changes of the vehicle's motion.

2.1 Sensor technology

Sensor technology is one of the keys for automated vehicles. The sensors need to be able to detect the vehicle's surroundings and to measure the dynamic status of the other vehicles in relation to the own vehicle. The frontal area of the vehicle is divided into a near field and a far field. The near field is the area up to 50 m around the vehicle. In this area, a wide observation angle is substantial. The far field goes up to 200 m around the vehicle. The range of the sensors and the evaluation of the relative velocities to others are important factors for the far field. Furthermore, position sensors and the communication with the infrastructure and with other traffic participants can provide additional information.

Different principles for environmental detection are available. The most important ones are radar (Radio Detection and Ranging), laser (Light Amplification by Stimulated Emission of Radiation), and image processing by camera picture analysis. Ultrasonic sensors are also necessary for very short ranges.

Radar sensors operate with electromagnetic waves, using frequencies in the centimeter or micrometer distance for object detection. Frequencies for automotive applications of radar sensor are in the 24 GHz and the 76–77 GHz bands.

The frequency-modulated continuous wave-radar (FMCW-radar) represents the most common used radar principle. The measurement of the distance to the relevant target of the FMCW-radar is based on the phase shift between the transmitted and the received signal with a periodic phase. In case the transmitter and the receiver are moved with a relative velocity, a frequency shift occurs between the transmitted and the received frequencies. This shift is due to the Doppler effect. The frequency increases in case the target is approached. The frequency difference depends on the relative velocity, which can be determined based on this effect.

Lidar sensors, which are based on laser technology, use the reflection of transmitted electromagnetic waves with lengths from 0.78 to 1 μm and thus in the infrared range, invisible to the human eye. In automotive technology, two methods are common, the transit time method and the laser-Doppler-shift method, which is based on short laser impulses being emitted by the laser. The Doppler-shift method is used to measure additionally the relative velocity. The frequency shift can be generated by the superposition of the reflected light impulse and a reference impulse of the same laser source. Another type of laser sensor is the laserscanner. Laserscanners use mechanically rotating mirrors. Owing to this, these sensors can scan a wide area

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and therefore they have high opening angles up to 270°. The own vehicle limits the complete 360° view, unless the sensor is mounted on the top of the vehicle.

Image processing is also used as a sensor. The environment is recorded by means of an optical device. Afterward the image data are converted into electrical signals by means of semiconductor image sensors (charge-coupled device or complementary metal oxide semiconductor). The digital image is analyzed by means of object detection algorithms. A very promising application for image processing systems is used by sensor fusion with other sensor systems, as it is used for collision mitigation and collision avoidance systems.

Vehicle-to-vehicle and vehicle-to-infrastructure communications provide additional information. This is done for short distance (e.g., intersection assistance) or even long distance (μ-factor information of the road surface or traffic sign information). Various communication technologies with different frequency bands are available today (e.g., Wireless LAN IEEE 802.11, HiperLAN, CALM etc.). A frequency range from 5.855 to 5.925 GHz is assigned for vehicle-to-vehicle communication in Europe.

Sensors for vehicle status detection, for example, position, friction coefficient of the road, and rain, have become of high importance for modern assistance systems. In particular, digital map data are used for many different ADAS as they contain attributes about the road infrastructure and legal information such as, that is, velocity limitations.

2.2 Actuator technology

In order to convert the signals of the ECU into the desired vehicle reaction, the vehicle needs to be equipped with actuators for steering, braking, and acceleration. Apart from these main groups of actuators, additional actuators (e.g., curve light and pre-crash) are available for ADAS.

At present, steering support is provided by means of hydraulic power steering (HPS). Additional support is provided by the adaptive HPS, the so-called Servotronic. The Servotronic steering system is able to reduce the steering support with rising vehicle velocity and therefore can offer an easy moving steering wheel for parking in the low velocity range as well as a comfortable steering behavior at high velocity.

Compared to the HPS, the electrohydraulic power steering (EHPS) consists of an electronic powered hydraulic pump, which provides the steering force. The control is managed demand controlled.

The electric power steering (EPS), also called *Servoelectric*, provides the steering force to the servo hydraulic power assistance with the help of an electric actuator. The electric motor and the related transmission exemplarily are fixed with the steering column, with the steering gear pinion or with the gear rack. The EPS provides the possibility of a steering boost by any dimension.

Additional steering angle can be applied by the active front steering. The additional angle is applied by means of a planetary gearbox, integrated into the steering system. This superposes the driver's steering intention with any desired angle. The mechanical connection between the steering wheel and the wheels leads to a direct response in lateral dynamic driving conditions.

By-wire steering systems decouple the steering-wheel input from the front wheels. The concept is based on performing steering maneuvers without mechanical transfer of steering torque. There is no mechanical connection between the steering wheel and the front wheels existent. In order to achieve necessary safety requirements, complete system redundancy is necessary. The vehicle has to remain steerable, even in the case of a system error.

The necessary brake interference for ADAS and automated driving vehicles can be realized on the basis of

- Brake booster:
  The brake booster is able to regulate a desired target brake pressure hydraulically and can therefore brake the vehicle without usage of the brake pedal by the driver.
- Electrohydraulic brake (EHB) system:
  The EHB system can divide the brake force up to each single wheel. The advantage of EHB system is the improved operating time because the control unit recognizes the demand for more braking by observing the pedals or their operating rate and acts before a fully hydraulic brake could build up pressure.
- Electromechanical brake (EMB) system:
  The EMB system is a rearrangement of the brake system to a completely electronically operated brake with dry function for the brake disks. This brake system offers subfunctions for automatic driving (e.g., automatic parking or automatic emergency braking).
- Hybrid brake system:
  The hybrid brake system represents a combination of a hydraulic and an EHB at the front axle and a dry electrical brake at the rear axle of the vehicle. An advantage of the hybrid brake system is the simplified package at the rear axle by the omission of hydraulic components.
- Brake-by-wire system:
  In brake-by-wire systems, the desired deceleration by the driver is electronically passed on from the pedal to the brake system. The by-wire-brake system works electrically without a hydraulic medium. This allows a simple electronic interface for driver assistance systems

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as well as the realization of additional comfort functions and package advantages. Redundancies are absolutely necessary. A high quality battery and energy management is necessary because the brake system does not work on hydraulic basis.

Automated acceleration can be provided by means of electronic acceleration pedals (e-gas). These pedals are equipped with electric motors, pedal sensors, and electronic throttle-position controllers. The pedal sensor transforms the accelerator pedal position into an electronic signal, which is transferred into an appropriate position of the throttle. Modern ADAS pedals provide force feedback functionality, for example, for giving drivers feedback in critical driving situations or urging them to reduce driving velocity.

2.3 Legal aspects

From the today's point of view, automated vehicles are facing different legal issues. In a very first but important step, it must be understood that legal issues will usually strongly depend on the nature of access rights to the roads: as far as automation is to be used on roads with unrestricted access, the legal issues mentioned in the following are strongly relevant. In case, however, that the testing of the automation is done on test grounds with only restricted access by the public (e.g., enclosed working areas or test tracks), the risks for life, health, and property of employees as well as visitors and even trespassers will need consideration. It potentially raises the issue of liability in case of an accident. Apart from this, the limiting issues in case of higher automation levels generally are the national regulatory law on the conduct of the driver, product liability, road traffic liabilities, and vehicle type approval (Gasser, 2010a, b).

The most important starting point to identify those legal issues, which are relevant in case of automation on publicly accessible roads, is to clearly describe the level of automation provided. The ADAS, which are already available today, show quite easy how high the level of legally permissible automation already is today. In terms of regulatory law of conduct of the driver, this automation level is possible, as the driver always remains in the position to take over control immediately and at any point. The driver therefore necessarily observes the surrounding traffic, which belongs to his tasks from the legal situation, found in the terms of regulatory law on driver's conduct. As far as systems actively intervene into the task of driving, it is their overrideability that ensures compatibility with regulatory law (such as the Vienna Convention on international level). This will usually be an issue in case of systems, addressing near accident situations (Gasser, 2010a).

Apart from this, product liability takes an important role in the implementation of the automation for road transport. As far as automation is meant in the way that the vehicle remains under control of the driver and does not reach the level of autonomy, the risks, combined with the estimation of foreseeable use, in terms of product liability remain fundamental. In technical terms, any higher level of automation will require precautional technical measures in terms of reliability, in order to avoid running into product liability. Currently, a nationally focused project group has investigated the legal issues combined with the increasing amount of automation in road traffic, lead by BASt (Federal Highway Research Institute) in Germany. The report is expected in 2011 and it will cover the issues of automation in traffic in general. The report will not be restricted to interventions into the task of driving. These are rather well researched already and discussed with respect to the international law (Vienna Convention on Road Traffic) (Gasser, 2010a).

For near-accident situations, the most important aspects discussed so far are again regulatory law, highlighted in the discussion on the meaning of the Vienna Convention on Road Traffic for intervening systems as well as—most important again—product liability.

Art. 8 (1) of the Vienna Convention from 1968 on Road Traffic postulates that

> "*Every moving vehicle or combination of vehicles shall have a driver.*"

Consequently, Art. 8 (5) VC constitutes the driver's obligation to be able to control his vehicle permanently:

> "*Every driver shall at all times be able to control his vehicle or to guide his animals.*"

Art. 13 (1) VC substantiates this obligation with regard to speed and distance between vehicles; Art. 13 (1) VC says (in extracts):

> "*Every driver of a vehicle shall in all circumstances have his vehicle under control so as to be able to exercise due and proper care and to be at all times in a position to perform all manoeuvres required of him [. . .].*"

National road traffic regulations such as the German Road Traffic Regulations reflect this basic idea of permanent controllability.

Interventions of automated systems in the vehicle guidance, which do not comply with the driver's will and which cannot be corrected and overridden are therefore considered as incompatible with controllability in terms of the Vienna Convention (Seiniger *et al*., 2011).

79	Uniform provisions concerning the approval of vehicles with regard to steering equipment

Figure 2. Relevant regulations concerning the type approval of added functionality. (Reproduced from Seiniger *et al*., 2011. © The interactIVe Consortium.)

The second crucial aspect concerning near-accident interventions into driving is product liability. Liability claims arising from damages caused by a defective product may be based on three distinct liability systems: product liability (based on the Product Liability Directive 85/374/EEC), contract (contractual liability), and/or tort (extracontractual liability) in EU Member States (Seiniger *et al*., 2011).

With regard to the liability deriving from the above-mentioned sources of law, a product should comply with the state of the art in science and technology—in order to be able to prove that this state of the art was adhered to during the design, the construction, and the production processes and with that in order to reduce product liability risks, relevant systems of rules such as the RESPONSE 3 Code of Practice (Knapp *et al*., 2009), and technical standards such as the FDIS/ISO 26262 (Sauler and Kriso, 2009) should be observed. From a product liability point of view, it is recommendable to design near-accident interventions in a way allowing the driver to override automated braking and/or steering interventions any time the driver wishes to do so.

On EU-level, Product Safety Law is based on the General Product Safety Directive (GPSD) 2001/95/EC. Owing to its character as a directive, the GPSD had to be transposed into national law by the individual EU Member States. Art. 2 GPSD defines terms such as "product," "safe product," "dangerous product," "recall," and "withdrawal" for the purposes of the GPSD (Seiniger *et al*., 2011).

A very technically oriented legal aspect to be assessed in detail is that of type approval. The mandate to approve vehicles for traffic belongs to the government of each country. However, European countries accept requirements defined by the United Nations Economic Commission for Europe's World Forum for the Harmonization of Vehicle Regulations (UN ECE WP.29) because of the transposition of the EU directives 2007/46/EC, 2002/24/EC, and 2003/37/EC.

There are two different types of vehicle regulations: the 1958 agreement system, which requires vehicles to be certified by an independent technical service (Europe, Japan, rest of the world), and the 1998 agreement (the United States, China, most of the 1958 states), which requires the vehicle manufacturers to certify their vehicles themselves.

The 1958 agreement with its ECE regulations covers most of the world with the exception of the United States and China. It is considered as the most important set of vehicle regulations.

Intervening systems and automated systems act on the vehicle brakes, throttle, and steering systems. The following regulations are of relevance, concerning the type approval of the added functionality (Figure 2).

3 ADVANCED DRIVER ASSISTANCE SYSTEMS

ADAS compensate the known weaknesses of human drivers and support them in their driving tasks. The motivation for the introduction of ADAS and the research of automated and automated vehicles are manifold. The four most important objectives are as follows:

- Increase of driving comfort: Comfort systems relieve the driver from annoying and monotonous tasks in order to ease the drive. Those systems already have a positive effect on traffic safety, as they are for instance keeping the distance to other cars and they avoid quick changes in speed.
- Increase of vehicle safety: ADAS support the driver by increasing the active safety of a vehicle. Active safety can be separated into perception safety (driver support in order to perceive relevant traffic information of the vehicle to other traffic participants), control and interaction safety (driver support to interact with vehicle control elements and perception of vehicle status information), driving safety (support the driver in critical driving situations), and condition safety of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the vehicle (support the driver during the drive, that is, by comfortable climate conditions).

- Improvement of traffic efficiency: ADAS support the improvement of street capacity. Thus, traffic jams can be prevented or are dissolved faster. In addition, the vehicles, which are approaching the traffic jam, can be redirected automatically.
- Reduction of environmental impact: ADAS support the reduction of fuel consumption and noise emissions, for example, assistance systems can give suggestions for gear changes, acceleration maneuvers, or early reduction of vehicle velocity depending on the situation and traffic. In addition, for the optimization for complex drive train structures (hybrid engines), the operating strategy can be implemented.

Support systems or automated systems require the interaction with the environment and an action of the driver, for at least the activation of the system. ADAS, which take over part of the driving task, are part of the closed control loop.

The driver support is divided into one of the three levels of the driving task (Donges, 1982). ADAS are classified, based on their functions and their type of driver support, into the levels navigation, guidance, and stabilization (Figure 3).

On the navigation level, the driver decides on his route inside an existing road network. While driving, the navigation includes the perception of necessary information to maintain the route. If needed, an adjustment of the route due to changed boundary conditions can be pursued. The time demand for the driver on the navigation level is not critical and amounts to over 10 s.

On the guidance level, the driver adapts his driving style to the perceived course of the road and the surrounding traffic. The guidance level comprises subtasks such as lane keeping, following, overtaking, and reaction to road signs. The tasks of this level can be divided into lateral and longitudinal guidance and are realized between 1 and 10 s.

The stabilization level is characterized by changes of the chosen driving strategy in vehicle-related control variables by the driver (steering movement, accelerator, brake, and gear choice). There is a permanent comparison between set and current value of speed and lane position. "Stabilization" for the driver means the avoidance of unsupervised momentum of the vehicle. The stabilization level is highly time critical with a time demand below 1 s. On the basis of this, time criticality automatic intervening systems are used for the stabilization level. The driver does not carry out the necessary action for the vehicle stabilization on his own. Systems on the stabilization level are mostly equipped with a possibility to activate or deactivate the HMI. In some cases, there is no visible HMI during driving (e.g., ABS and ESP).

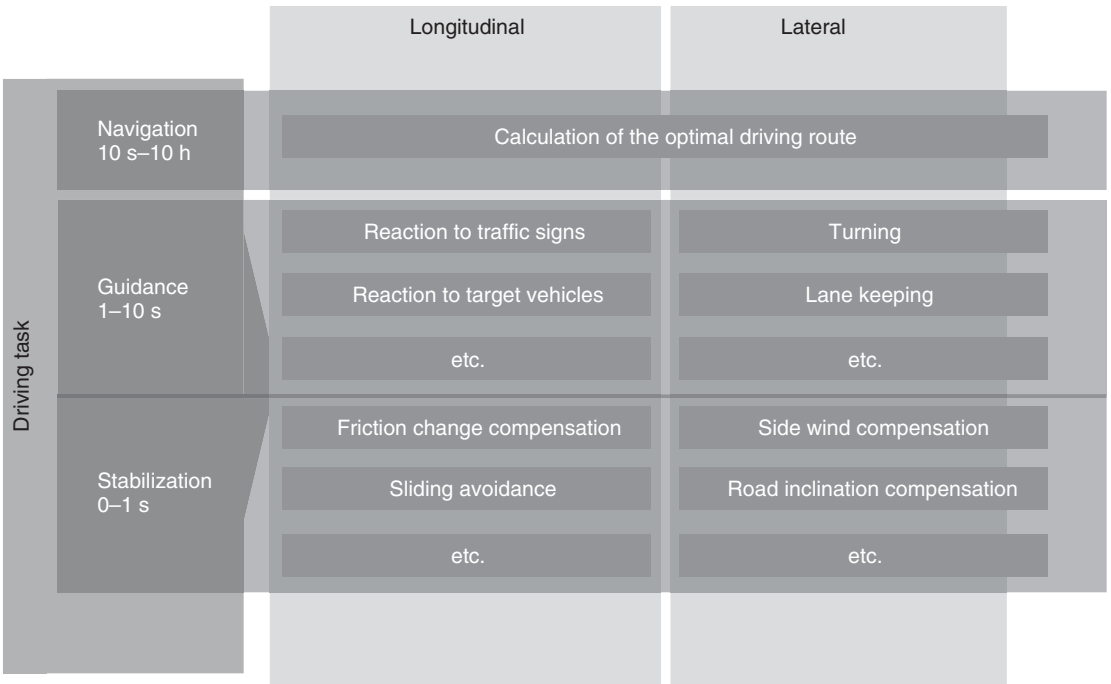

Figure 3. Classification of ADAS in three levels of the driving task.

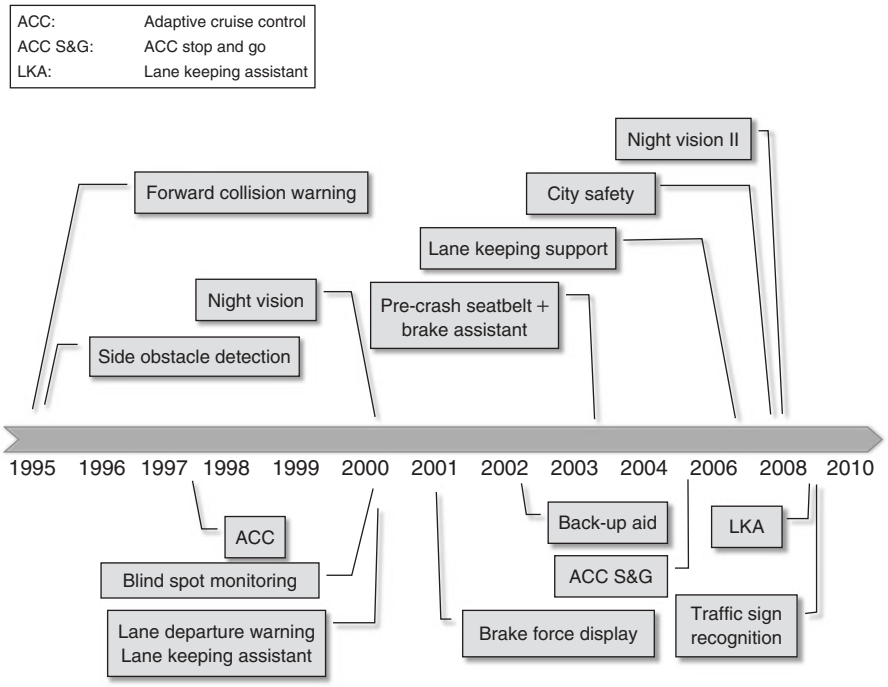

Figure 4. Market introduction of ADAS.

3.1 Overview of ADAS

One of the first ADAS introduced in the market was a collision warning system for heavy goods vehicles in 1995, which was based on a 24 GHz radar sensor for object detection and forward collision warning system. Figure 4 shows the market introduction of different ADAS on guidance and navigation level.

Currently, various different ADAS are available in premium vehicles. They are also being introduced in middle class vehicles. Examples are systems for parking support, driving at nighttime, longitudinal, and lateral vehicle control.

One of the first systems introduced to provide continuous support was adaptive cruise control (ACC). ACC is an enhancement of the cruise control, which was one of the focus research fields of the PROMETHEUS project. The system particularly supports drivers on motorways and country roads by keeping a safe distance and controlling the velocity with respect to vehicles in front. In case the vehicle approaches a slower vehicle, the system intervenes by means of reducing the throttle first and then operates the brake system in order to keep a safe distance to the preceding vehicle. Therefore, the ACC uses its distance sensor in order to detect the range and range rate of the vehicle in front. The desired values regarding the distance are mostly dependent on the velocity and the drivers can adjust the distance by defining a time gap to the vehicle in front. The acceleration and the deceleration behaviors of the vehicle are controlled depending on the driving status by an ECU. The driver is able to turn the function off or override it at any time by pushing the accelerator or the brake pedal. In case no target vehicle is present, the ACC is used as a conventional cruise control.

The market introduction of ACC for different vehicle manufacturers in Europe is given in Figure 5 as an example.

3.2 Research on ADAS

In addition to available ADAS, research on future systems is ongoing in different research areas. The most important ones are as follows:

- Safety (e.g., collision mitigation and avoidance)
- Environmental protection (decarbonization and noise reduction)
- Integrated HMIs and integrated interaction strategies
- New mobility concepts
- Automation

With regard to automated driving vehicles, research on platooning provides the next step to automation. A platoon is described by at least two vehicles, which are electronically connected without any mechanical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

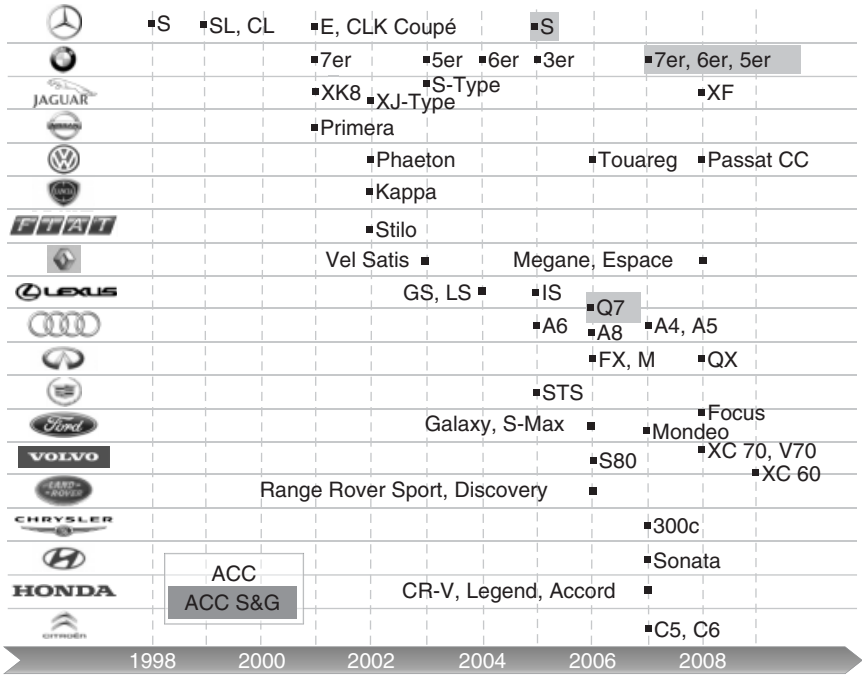

Figure 5. Market introduction of ACC in Europe.

connection between the vehicles. Work in this area was undertaken by VW called *CONVOY Driving* in the PROMETHEUS project (Ioannou 1997), by the PATH (Partners for Advanced Transit and Highways) project of the Institute of Transportation Studies (ITSs) of the University of California in Berkeley together with the California Department of Transportation (Caltrans) in the Unites States in 1996 and the ARTS project (Advanced Road Transportation System), which was funded by the Japanese Ministry of Construction. The ARTS project was merged to the ITS (Transportation System) project in 1995.

The lateral vehicle control of the automated vehicles in these projects is based on magnetic studs, which are integrated into the infrastructure in the form of a dedicated guide way every approximately 3 m. The nails provide the trajectory of the vehicles. Longitudinal vehicle guidance in the platoon is provided by distance and velocity detection in each single vehicle. This information is transmitted via vehicle-to-vehicle communication or vehicle-to-infrastructure communication.

The aim of PATH was to develop long-term strategies in order to cope with the immense traffic in California. Between 7 and 10 of August 1997, a vehicle platoon consisting of eight Buick LeSabres vehicles was demonstrated. The distance between each longitudinal and lateral controlled vehicle was 6.5 m at a velocity of up to 96 km/h. The distance accuracy was measured in the range 10 cm at constant driving and 20 cm at acceleration and deceleration maneuvers (PATH Program, 1997). However, even today, there is no impact on the road traffic in the United States.

In contrast to the PATH approach (only lateral control by means of magnetic nails, longitudinal control provided only to following vehicles based on vehicle sensors), the point-follower approach (infrastructure/vehicle sensors, no target vehicle necessary) demands additional communication between the road infrastructure and the vehicles. This

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

communication can be provided by LCX (Leakage CoaXial Cable) cables at the surface of the road. The LCX cable provides data transmission and acts as an antenna. Field tests were conducted on a test tracks in Germany and Japan (Gehring, 2000). Figure 6 shows field tests with a MAN bus demonstrator using a guide wire in the ground of the driving way in 1977 (Zeit, 1980).

In Europe, truck platooning was performed for the first time in the European research projects PROMOTE CHAUFFEUR 1 and 2 of the fifth European framework program. The following distance between the three used demonstrator trucks was between 6 and 16 m at a velocity of 80 km/h. On the basis of the reduced air resistance, fuel in the range between 15% and 20% was reduced compared to conventional driving.

The control approach was called *tow-bar* principle, which was realized by means of vehicle-to-vehicle communication in the 5.8 GHz band and an infrared camera system. The distance to the target vehicle as well as the velocity and the acceleration of each vehicle was transmitted to all following vehicles in the platoon. The infrared camera determined the relative lateral position between the vehicles.

Next to the "tow-bar" principle, the so-called CHAUFFEUR assistant was introduced in PROMOTE CHAUFFEUR 2. The assistant was a combination of an ACC system and the lateral control in order to support the driver of the first vehicle in the platoon.

The final demonstration of all functions was done on the IVECO test track in Balocco, Italy, on 7 May 2003 (Bonnet *et al*., 2003).

Similar to the PROMOTE CHAUFFEUR project, the national funded German research initiative KONVOI performed research on truck platooning. Next to technical research questions, covering the steering hardware and the function development for automated longitudinal and lateral control impacts on surrounding traffic, the strategies to build the platoon, acceptance studies, and impacts on truck drivers were investigated in detail. In addition, legal aspects for an introduction of truck platoons were analyzed. The demonstration of a truck platoon with four tractor–semitrailer combinations took place on the German motorway in 2009 (Figure 7) (Deutschle, 2008).

SARTRE is a European project, cofunded by the seventh framework program of the European Commission, that targets to develop strategies and technologies to allow vehicle platoons to operate on normal public highways with significant environmental, safety, and comfort benefits.

In the SARTRE platooning system, a human driver like in KONVOI drives the lead vehicle manually. The other vehicles follow the trajectory of the lead vehicle. Thus, the lead vehicle driver has a huge responsibility. In order to improve the safety in a platoon, different ADAS systems are installed in the lead truck to support the driver.

In order to improve the comfort and support the drivers to find suitable platoons, a back office unit calculates the meeting point for the potential following of the platoon and provides navigation instructions to the drivers (Deutschle, 2008; SATRE project, 2011).

4 INFRASTRUCTURE-BASED AUTOMATED DRIVING VEHICLES

Operation of automated vehicles in dedicated infrastructure provides several advantages compared to fully automated driving vehicles. Dedicated infrastructure can separate automated vehicles from ordinary traffic participants, which solves integration issues. Furthermore, dedicated infrastructure can be equipped with sensors, for example, LCX cables for platooning. Basically two different scenarios are possible for automated vehicles in dedicated infrastructures:

- Guide ways to separate automated vehicles from other traffic participants
- Guide ways to support automated vehicles or ADAS

Different vehicle types are possible to be operated in these scenarios:

- Personal rapit transit (PRT)
- High tech busses
- Vehicle platoons
- Automated vehicles

Infrastructure-based automated driving vehicles provide new mobility concepts especially in the field of public transport, that is, PRT and high tech busses.

PRT is a fully automated transport system using small driverless vehicles (Figure 8). The vehicles navigate automatically along a network of dedicated guide ways. PRT

offers a driverless taxi, providing on-demand. By this, a nonstop transport from the origin station to any other destination station selected by the passenger on the whole dedicated guide way network will be possible. Therefore, PRT can be described as a horizontal lift or elevator. All PRT systems under current development are electric powered and thus (locally) emissions free. PRT systems aim to have empty vehicles waiting at stations for arriving passengers, so that there is little or no waiting time. Because the electric vehicles are quiet and emit no exhaust pollutants, they can be routed through buildings.

One system installed at the airport in Heathrow is "ULTra," developed by Advanced Transport Systems of Thornbury, the United Kingdom. The four-seater vehicles have four rubber-tired wheels and the size of a small car. They are powered by electric motors, running from lead-acid batteries. ULTra vehicles are driving on a 2 m wide concrete or metal track. Batteries are recharged in the stations. The maximum driving velocity is 40 km/h, and the vehicles can climb a 10% gradient and negotiate 5 m radii. They can go reverse and steer backward, offering great flexibility in maneuvering (Bly and Lowson, 2009). Another PRT system in operation is located in Masdar, Abu Dhabi (2getthere, 2011).

High tech buses in separated lanes are also already in operation. An example for such a BRT (bus rapid transit) system is the Phileas program in Eindhoven/Veldhoven. Phileas is a new concept for comfortable passenger transport on high frequency dedicated bus lanes (Figure 9). The guide way is fitted with magnetic markers for electronic lane assistance and precision docking. Phileas has hybrid electric propulsion, a large transport capacity, and precision docking, which makes it possible for passengers to quickly enter and exit the vehicle. Thus, the stop times are short and the average speed can be kept as high as possible. In comparison with tram or metro systems, the investment and maintenance costs for the infrastructure are low. Overhead wires and rails are not needed. Phileas combines the advantages of tram and metro systems with the flexibility and low costs of a bus system (Phileas, 2011).

Figure 9. Phileas high tech bus on a dedicated guide way (Phileas, 2011). (Reproduced by permission of VDL Bus & Coach bv.)

In industrial applications, different types of automated and driverless vehicles are already utilized since many years. These are vehicles, which transport goods on dedicated driving routes in factories or work yards.

In 2001, the FOX GmbH in Germany to transport large amounts of euro pallets on a factory yard has modified two commercial vehicles. The vehicles were equipped with additional sensors for automated driving. The driving route of 190 m is marked by transponders in the floor. These

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

transponders are detected by the vehicles with an accuracy of about 5 mm. Therefore, the lateral control of the vehicles on the driving route is possible within a 2 cm range at a velocity range of about 5 km/h. A laser scanner detects obstacles in front of the vehicles. In addition, the vehicles have sensors integrated in the front bumpers. The bumpers are made of soft foam. In case of contact between an obstacle and the bumpers, the sensors activate the braking system and the vehicles are able to halt within a range of 0.4 m after contact. The vehicle position and movement is transferred to a control room by means of communication technology. The vehicles are driving automatically, but a driver can override the overall system at any time (Götting KG, Abt. FOX, 2008).

5 FULLY AUTOMATED DRIVING VEHICLES

Automated driving vehicles are under research since the 1970s. Different research activities demonstrated automated driving according to the latest state-of-the-art technology available at the time of the activity. In recent years, sensor technology for environment detection and electronically controlled actuators became available in production vehicles. Vehicle manufacturers use their knowledge on the necessary technology and provide demonstrator vehicles for automated driving in order to underline the public perception of the company image.

As legal issues still do not allow automated vehicles to be driven on public roads, first systems in low velocity ranges are available at dedicated infrastructures such as company depots, work yards, or for demonstration purpose within inner city limits, separated from conventional traffic.

In order to stimulate recent research on automated vehicles and automated driving by universities and research institutions, different challenges have been initiated by different stakeholders (e.g., military and governments). On the basis of the experience of the research work and the availability of sensor systems for path planning and obstacle detection, automated driving vehicles demonstrators have been set up to fulfill manifold purposes, such as creating development platforms, organizing driver training, or defining new markets. Furthermore, new mobility concepts are being investigated by means of automated driving vehicles.

5.1 Research activities

In the last decade of the past century, different research activities on automated vehicle guidance were conducted with the results of automated driving demonstrations. Within these activities, prototype vehicles were built up and tested. Some tests of the prototypes were carried out as journeys on public roads in real traffic:

- VAMP: test on a journey of approximately 1600 km from Munich (Germany) to Odense (Denmark) in 1995 (Maurer *et al*., 1996);
- NavLab 5: test on a journey of approximately 4587 km from Pittsburgh (USA) to San Diego (USA) in 1995 (Bertozze, Broggi, Fascioli, 2000);
- ARGO: test on a journey of approximately 2000 km in the MilleMiglia tour (Italy) in 1998 (Bertozze, Broggi, Fascioli, 2000);
- Google Cars: test drives of approximately 1600 km without human intervention and more than 230,000 km in total (Markoff, 2010).

In the recent past, challenges were announced by different stakeholders. The American DARPA (Defense Advanced Research Projects Agency) initiated the DARPA Grand Challenges and the DARPA URBAN Challenge in order to demonstrate the state of the art for automated driven vehicles. In Europe, the Grand Cooperative Driving Challenge (GCDC) was initiated to combine different European research activities in cooperative and automated driving.

5.1.1 VaMoRs/VAMP

One of the first automated driving vehicles was called *VaMoRs* (Versuchsfahrzeug für autonome Mobilität und Rechnersehen) of the German Bundeswehr University of Munich. The second vehicle from Daimler was called *VITA*.

Between 1985 and 2004, a transporter of the type Mercedes DB 508 was converted in order to control electronically the lateral and longitudinal dynamics of the vehicle. The core of the research activity was machine vision, which was performed by means of camera systems. The vision system detected objects and lane markings in a distance of up to 120 m in front of the vehicle. By means of this collision avoidance, automated distance control, lateral control, and lane change maneuvers were implemented. Next to machine vision, additional sensors of a digital map and satellite position system were used in order to detect intersections and turnings.

The achieved know-how of the VaMoRs project was used to build up the vehicles VAMP (VaMoRs Passenger Car) and VITS-II. These Mercedes Benz 500 SEL vehicles were equipped with a radar distance sensor additionally to the machine vision system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

After thousands of test kilometers automated driving for testing purpose, a demonstration was conducted from Munich (Germany) to Odense (Denmark) in 1995. The test route had a length of approximately 1600 km. A total of 95% of the test track was driven in automated mode at velocities of up to 180 km/h. In total, approximately 400 lane changes were performed during the test drive (Maurer *et al.*, 1996).

5.1.2 *No hands across America*

In 2005, the "No Hands Across America" tour was performed by the Robotics Institute of the Carnegie Mellon University, Delco Electronics, and AssistWare Technology. The prototyped vehicle called *NavLab 5* drove approximately 4587 km from Pittsburgh to San Diego (USA).

The vehicle was equipped a windshield mounted camera, a GPS receiver, and a radar sensor for obstacle detection, which were used for lateral control of the vehicle. Longitudinal vehicle control was performed manually by the driver.

NavLab 5 was able to drive 98.2% of the journey (4503 km of a total of 4587 km) with automated lateral control. The system proved to be robust with respect to real road and traffic conditions. The major problems encountered were due to rain, low sun reflection, shadows of overpasses, construction zones, road, and road markings deterioration (Bertozze, Broggi, Fascioli, 2000).

5.1.3 *The ARGO project and the VisLab intercontinental autonomous challenge*

From 1996–2001, the University of Parma worked on the ARGO project, which had the goal to enable automatic lane following on motorways for a modified Lancia Thema. In 1998, a demonstration of a 2000 km long journey on the motorways of northern Italy with an average speed of 90 km/h took place. A total of 94% of the time the car was in fully automated mode, with a longest automatic stretch of 54 km. The vehicle was equipped with only two black-and-white cameras and used stereoscopic vision algorithms to perceive its environment.

On the basis of the results of the ARGO project, the idea for the intercontinental autonomous challenge was born. In total, 13,000 km was driven from Parma (Italy) to Shanghai (China) with four automated controller electric vehicles (two vehicles traveling and two vehicles as backups). The challenge was performed from 26 July 2010 to 28 October 2010 including two different continents with changing geographical morphology, traffic conditions, weather, infrastructures, and so on.

Figure 10. Vehicles of the VisLab Intercontinental Autonomous Challenge. (Reproduced by permission of Vislab.)

Each test vehicle was equipped with seven cameras, four laserscanners, GPS receivers, and vehicle-to-vehicle communication. The vehicles are shown in Figure 10.

During the journey, all vehicle data and all perception data were logged. The amount of data added up to about 50 TB and provided a data set for a variety of different driving situations, weather conditions, and infrastructure conditions.

In difficult situations, for example, bad weather or heavy and chaotic traffic conditions, driver had to take over control and switch to manual mode because not sufficient information from the perception system had been available (Broggi, 2011).

5.1.4 *DARPA grand challenges*

The DARPA Grand Challenge took place in the years 2004 and 2005. The task of the Grand Challenges was to cover a track of about 150 and 132 miles through the desert in fully automated mode with no human intervention. The route was announced shortly before the start of the challenges so that the competing teams could not tune their automated vehicles according to the track.

In the first challenge of 2004, no vehicle was able to cover the route. The best team was only able to cover around 5% of the track. In 2005, four vehicles reached the destination within the given time limit of 10 h.

The winner of the Grand Challenge 2005 was a VW Touareg called *Stanley* of the Stanford University. The vehicle was equipped with four laser scanners, 24 GHz radar sensors, mono- and stereo image processing systems, and a GPS system. The vehicle movement was measured by means of an internal measurement unit. The sensor

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

data and the control algorithms were processed by seven Pentium M processors with 1.6 GHz calculation speed each (Thrun, 2006).

5.1.5 DARPA urban challenge

The DARPA Urban Challenge was conducted in 2007 on an old military area close to Victorville in the state of California in the United States. The main differences to the Grand Challenges were the involvement of other traffic participants and the urban scenario with road regulations and urban infrastructure. Especially, the behavior of the other traffic participants, which were vehicles driven by stuntmen, needed to be considered. Pedestrians and bicycles were not part of the Urban Challenge. The route was shortened to 60 miles, which needed to be covered in <6 h.

The winner of the DARPA Urban Challenge was the team Tartan Racing of the Carnegie Mellon University with the vehicle called *Boss* (Urmson *et al*., 2008).

5.1.6 GCDC in Europe

In contrast to the DARPA Grand Challenges and the Urban Challenge, the European GCDC has no military background. It was initiated by TNO, a governmental research organization of the Netherlands and High Tech Automotive Systems (HTASs). The goal was to create a liaison between research groups on the topic of cooperative and automated driving. The first GCDC was held at Helmond in the Netherlands in 2011. It took place on the highway A270, which was closed for public traffic while the challenge was performed.

The focus of the first GCDC was on longitudinal vehicle control for platooning by means of vehicle-to-vehicle communication for cooperation. Different communication and sensor hardware and different types of vehicles needed to be part of the control strategy. In order to provide boundary conditions, the communication protocol, the signals to be communicated, safety measures, the wireless communication, and a mandatory message set needed to be used by all participants. Each participant could choose the vehicle, in-car architecture, the environmental sensors, the control strategy, and the usage of the communicated information freely.

In total, 11 teams competed in the four given scenarios (platoon stability, joining a platoon, joining a platoon at a traffic light, and merge on intersections). The teams were grouped into 2×2 platoons on parallel lanes. The organizers provided the lead vehicles, which were defining the driving velocity of the platoon. Points were provided for different criteria such as string stability and smoothness. The first GCDC was won by team AnnieWay of the Karlsruhe Institute of Technology in Germany (Grand Cooperative Driving Challenge, 2011).

5.1.7 Google cars

The Internet Company Google also works on automated vehicle in terms of using artificial intelligence software for driverless vehicle control. The vehicle combines information from the company's Google Street View service with sensor signals from video cameras inside the vehicle, a LIDAR sensor on top of the vehicle, radar sensors on the front of the vehicle, and a position sensor attached to one of the rear wheels. The system drives at the speed limit, which is stored on its digital map and maintains its distance from other vehicles using the environmental sensors. The driver can override the automated driving function at anytime (Markoff, 2010). In 2010, seven test vehicles have driven 1600 km without human intervention and more than 230,000 km with only occasional human intervention. Next to the technical feasibility demonstration, Google lobbied for two changes of state laws that made the state of Nevada (USA) the first state, where driverless vehicles can be legally operated on public roads. The first bill is an amendment to an electric vehicle bill that provides for the licensing and testing of automated vehicles. The second bill will provide an exemption from the ban on distracted driving to permit occupants to send text messages while sitting behind the wheel (Markoff, 2011).

5.2 Examples for automated vehicle demonstrators and research platforms

In recent years, car manufactures, computer companies, and universities established a variety of different research platforms. On the basis of the experience of the DAPRA challenges, research on automated driving is proceeding in manifold ways.

At the University of Braunschweig, Germany, automated driving in the city's inner ring road of Braunschweig is demonstrated in the so-called *Stadtpilot* project. The goal is to drive fully automated in the traffic flow and to behave according to traffic rules (Saust *et al*., 2011).

The Volkswagen Group Electronics Research Laboratory and Stanford University are working on the Audi TTS Pikes Peak automated vehicle. The vehicle is a modified Audi TTS Coupé Quattro called *Shelly*. The goal is to improve vehicle automation and explore capabilities of current and future driver assistance systems by automated drive up the legendary 12.42 miles Pikes Peak Hill Climb route in Colorado, the United States. The focus of the research

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto023
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

work is on path planning and vehicle stability. The route to Pikes Peak consists of paved and graveled roads and can contain weather changes at all time. Therefore, vehicle guidance of the Audi TTS Pikes Peak is working entirely on differential GPS and vehicle state information such as speed and acceleration measured by wheel-speed sensors, an accelerometer, and gyroscopes, but without additional sensors for environmental detection. The control algorithm for path planning and vehicle stability compares the sensor data to a digital map of the route to determine possible deviations and necessary maneuvers. The resulting action for longitudinal and lateral vehicle control is performed by the vehicles production hardware, which already exists in Audi production vehicles (Blackman, 2010).

The VW Golf 53 + 1 is an automated driving robot, which was developed to perform reproducible driving maneuvers in the high dynamic range on test tracks (Kompaß, 2008). Reproducible driving maneuvers allow vehicle development by means of a driver-independent analysis of vehicle dynamics (function or system), driver behavior (impact of the system), and boundary conditions (environment). The driving robot is able to take over the function of the driver with sufficient accuracy and reproducibility. Longitudinal and lateral vehicle dynamics are controlled by the robot and therefore provide automated driving on a predefined course. The driving trajectory is determined by means of a differential GPS. The transmission of the additional correction signal allows a positioning in the centimeter range. Traffic cones mark the driving track, which are detected by a laser scanner in the front of the VW Golf. The vehicle ECU fuses the GPS and the laser scanner data and calculates the driving trajectory on the track. Within the driving path, the ideal racing line is calculated for lateral vehicle dynamic control. These calculations result in desired values for the maximum driving velocity and the vehicle acceleration. The vehicle is equipped with a brake booster, which allows high dynamic braking maneuvers (Kompaß, 2008).

The BMW "Track Trainer" was designed by BMW for race driver training (Kompaß, 2008). The ideal racing line of the racetrack is calculated off-line. The calculation considers position data from GPS as well as vehicle parameters from test runs of professional drivers. An inertial measurement unit compensates the GPS position in order to detect inaccuracies of the positioning. The vehicle ECU controls longitudinal and lateral vehicle dynamics and keeps the vehicle automated on the ideal racing line of the course. The driver experiences the vehicle behavior for some test rounds on the racing course and therefore learns how to stay on the ideal racing line. In a second phase, the driver takes over vehicle control and is supported by the vehicle (haptic and acoustic advises) in case he leaves the ideal racing line. All vehicle data are logged during the test drive. Afterward the driving style can be analyzed in detail and recommendations can be given by the system (Kompaß, 2008).

5.3 Cybercars

Owing to the usage of vehicles in highly populated urban environment, severe problems with respect to pollution, noise, and safety arise. A new mobility concept in terms of Cybercars uses the advantages of automobiles combined with automation technology. The idea of Cybercars was developed in the European funded research project "Cybermove" (Cybermove project, 2004). Cybercars are slow-moving automated driving vehicles for existing road infrastructure. The design of the vehicles allows easy and clean transportation within inner cities. Different persons, depending on the vehicle size, can share the electric vehicles. With existing technology, the velocity is limited to 30 km/h and therefore sufficient for inner urban usage. Some of these vehicles can also allow traditional manual driving in order to run among normal traffic. In these cases, the vehicles are called *dual-mode vehicles* and their automated capabilities allow them to be used in platoons, for example, in order to collect the cars.

Several companies and research organizations have been involved in recent years in the development of Cybercars. The first systems have been put in operation in the Netherlands at the end of 1997 and have been running successfully 24 h a day. Several other systems have been implemented in European research projects on this topic, see Cybermove project (2004), Cybercars project (2006), and CityMobil project (2011). The focus of the research is on the development of tools and systems to enable the driverless vehicles to perform the necessary driving maneuvers in a cooperative manner, that is, in cooperation with each other and also in cooperation with conventional driven vehicles (Vlacic and Parent, 2009).

6 SUMMARY

A first step toward automated driving is the introduction of ADAS into the market. Currently, the development of new assistance functions and the improvement of existing functions are ongoing. Especially, progress in sensor and actuator technology allows a shift from pure comfort function toward active safety and continuous driver support. In the recent past for longitudinal and lateral support in all velocity ranges from parking to city driving up to high speed driving became available.

Research activities in the field of automated driving demonstrate technical solutions for fully automated

systems. At present, these are being utilized in niche markets. However, in the evolution of today's ADAS toward automated driving systems, the legal aspects and the assessment of the systems need to be considered. High market penetration of ADAS in the future will be the foundation toward the fully automated driving vehicle.

Brake Systems, an Overview

Christoph Drexler and Ralf Leiter

TRW Automotive, Koblenz, Germany

1 INTRODUCTION

Today, some highly powered vehicles are on the road, often without it being clear what the required capacity of the brake system of these vehicles is. Thus, for example, when braking a modern vehicle of the upper middle class with an engine output of 130 kW (178 HP) to a complete stop from a speed of 220 km/h, the brake force must be more than three times the engine output. In addition to reliability and safety of the brake system, it is also required that this process takes place with absolutely no noise, is easy for the driver to apply and especially easy to control, as well as being comfortable for all passengers.

Even though the vehicle brakes have reached a very high level of development, more than 50% of all technical defects in motor vehicles are caused by the brake system.

The first vehicles (including the means of transportation of antiquity) were already equipped with devices to stop the vehicle from rolling while stationary. This was the start of parking brakes. Thus, the vehicle brake is surely as old as the wheel itself. As these vehicles increased speed (Roman chariot races), an operating brake was developed that was required to stop the vehicle from rolling when stationary, as well as for decelerations, when driving downhill or when stopping.

2 TYPES OF BRAKES

Generally, the brake is a device to slow down the vehicle:

- until it stops
- to secure the parking vehicle
- to control (reduce) the speed of the vehicle.

During the brake application, kinetic energy is converted to heat. The parking brake prevents rolling of the vehicle. When operating during standstill, this brake works without wear or heating. It can be executed as a friction brake or also as a locking device like in an automatic transmission gear box.

According to the physical work principle, vehicle brakes can be subdivided into three main groups:

- mechanical friction brake
  by solid state friction (wear) of two rigid bodies.
- hydrodynamic brake
  - by inner friction of a medium: water, oil, and fluid friction.
- electrodynamic brake
  - by magnetic effect of the electrical field: generator and eddy brake.

2.1 Friction Brake

In this contribution, only friction brakes are considered, which are working on the principle of mechanical solid friction. They can be used as a parking brake as well as a dynamic brake (stop the car, control the speed). In the case of dynamic braking, it works strictly as a wearing brake. Disk, drum, belt, or cable brakes can be used. Here, only disk and drum brakes will be dealt with.

2.2 Disk brakes

The disk brakes usually consist of a disk (gray iron, cast aluminum, carbon fiber pellets, and ceramic reinforced with carbon fibers), which is mounted to the shaft. The disk brake is predominantly made as a partial disk brake. The friction lining only covers a sector of the disk ring, and not the entire perimeter. The brake calliper encloses the disk such as a gripper. Assisted by one or several hydraulically operated pistons, steel or aluminum segments with applied friction material that are axially movable are pressed against the disk. Very high surface press forces are possible due to the opposing tensioning force (Figure 1).

With increasing wear of the friction linings, the pistons extend further and readjust the wear path. The brake clearance, which must be guaranteed after each operation, remains constant. Additional fluid volume required for this flows from a reservoir. Protective caps on pistons and guide bolts prevent the brake from seizing due to dirt and corrosion. Despite high local temperatures, few fluctuations in adhesion factor occur, compared to drum brakes. This will be shown later.

Disk brakes have good cooling from air flow, as long as the installation space in the vehicle permits air access. With high thermal load, inner ventilated and/or perforated disks are used. The heat expansion is not critical, as it works toward the tension forces. Cracks in the brake disk are considered as production or design faults.

Figure 1. Disk brake. (Reproduced with permission from TRW.)

The disk brake provides a simple and easy accessible device for maintenance and checking for wear. The design of the disk brake is further explained in the example of the brake Colette, a frequently used floating calliper brake. The brake (Figure 2) consists of a housing part, which can be adjusted using two guidance bolts, and a stationary support. The brake linings are hold on the support (4) in this type of brake, and they are held in position with springs (1). These springs mainly prevent noisy rattles and clicks (2 and 3). The lining material that is glued to the back plate is between 10 and 15 mm thick and should be replaced when there is residual thickness of 2 mm. Between the lining back plate and the piston, most disk brakes have a noise damping panel.

The floating calliper brake has proved to be well-suited for small installation spaces in vehicles with negative king pin offset. The housing only contains (one up to three) pistons on the disk side. When operating, the hydraulic pressure works on the pistons and the housing evenly. The piston moves out and presses the neighboring lining against the disk. At the same time, the floating housing, perpendicularly arranged to the disk, is moved in the other direction, so that the second lining is pulled against the other disk side. The holding of the brake must be rigid, which limits the realizable disk diameter, as the rim determines the maximum available space. The movement of the floating calliper is arranged by the guide bolts. The bolt on the disk inlet side positions the housing to the support, whereas the second provides a fixed seat with its rubber coating and prevents rattling in the bore while driving. The relationship of lining size to design size is very high compared to other disk brake designs.

To change the lining (example component, Figure 3), merely release the hex screw. Afterward, the housing can be folded away and the linings can be pulled out away from the disk (upward). In addition, the support also carries the linings in circumferential direction, so that no circumferential forces must be transferred via the guide bolts.

New types of designs have a lining without retainer springs on the upper lining edge. One Nirosta spring sheet on each side position the lining in nonbraking condition and increases its lateral mobility to the disk. The response time of the brake improves, and the residual friction torque of the linings are reduced when the brakes are not in operation.

The movements of the lining parallel to the disk are highly limited. A groove together with the spring sheet on both ends prevents unscrewing while braking. This also minimizes the lining travel to the disk for braking and clicks (as well as squeaking) no longer occur when changing

direction of rotation. On uneven roads there is no rattle as well.

To improve lining wear, the latest brakes (Figure 4) no longer have symmetrical designs. The piston is offset opposite the lining back plate, which also identifies the milling groove necessary on the wheel side for processing the housing. The brake plate is only reinforced on the outlet side, which is also where most of the forces are to be transferred. This leads to additional weight reduction.

The brake lining is eccentrically placed on the back plate corresponding to the piston axle. Opposite the back plate, the piston is also radially offset, using a partial sheet that is simultaneously a damping plate, or the piston is displaced opposite the lining's center of gravity. This sheet, in bare or rubberized execution, can be placed or glued to the back plate. This dampens lining vibrations that result during the braking process in the friction path. Minimizing sounds is becoming more and more significant in modern brakes. For this reason, special design measures are even being introduced for damping noise (dynamic vibration absorber). The friction process is the trigger for all brake noises. Each wear optimization that affects the friction process also leads to noise reduction, as the origins of specific noises are prevented.

The frame brake (Figure 5) is a significantly more rigid execution of a floating calliper brake. Design and function are similar to a floating calliper brake. In the RC 5424/13 design with a high performance spectrum, the housing was shifted to the outside and the carrier with linings to the inside. This makes the housing bridge especially

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

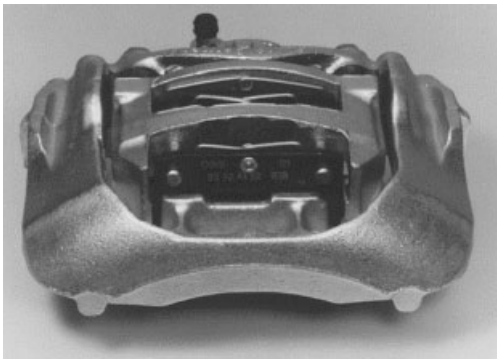

Figure 5. Frame brake. (Reproduced with permission from TRW.)

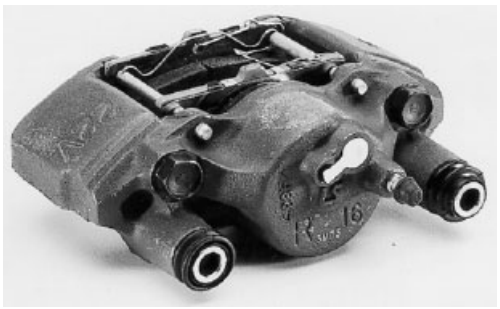

Figure 6. Semi-integrated disk brake. (Reproduced with permission from TRW.)

rigid. The tension forces on the disk are transferred in the plane of force (piston axle), so that there is no radial bending up. However, the benefit of a thinner bridge is offset by width, and the disk diameter can be designed to be larger. The cross member must be very rigid (solid), which increases the weight. The linings are carried by the support in circumferential direction and they are positioned with central springs in the center of the lining. The stable lining pressure is radially and tangentially well supported. Despite the large size, the lining size is somewhat small. This brake is installed on the front axle in larger vehicles like, for example, the VW Transporter with permitted total weight up to 2.8 t.

The FIS16 brake (Figure 6) is a semi-integrated floating frame calliper brake of the middle performance spectrum (semiabutment). Semi-integrated means that only the outer lining is supported in the housing and the housing guide bolts must transfer these circumferential forces. In contrast, the inner lining is directly supported by an integrated steering knuckle carrier. Fully integrated brakes with support of both linings in the housing are also in series.

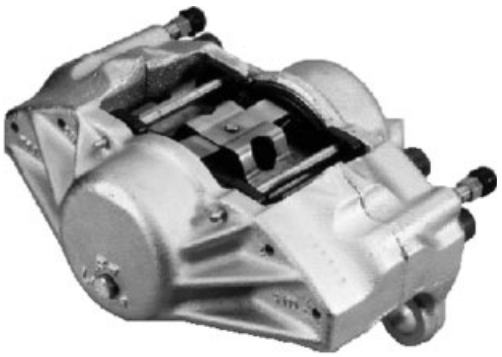

Figure 7. Two-piston-fixed caliper brake. (Reproduced with permission from TRW.)

Today, all brakes are provided with surface protection against corrosion. This can consist of galvanizing followed by yellow chromate conversion coating, of special paint coats or similar.

Another design is the fixed calliper brake (Figure 7). Instead of a sliding housing, a stationary housing is used. There is no support. The tension forces are applied by the opposite pistons. Fixed calliper brakes are built with up to eight pistons per side. All pistons are hydraulically connected with each other. For this, it is necessary to bring brake fluid through the bridge over the disk to the other side of the calliper. If there is longer braking (e.g., in the mountains), or with many successive hard stops, the hot brake disk can heat up the brake fluid in the bridge up to steam formation. As steam is compressible, the brake system loses effect heavily (fluid fading).

The design, which is extremely solid because of the fixed connection between housing halves, allows very large tension forces with minimal housing deformation (high performance spectrum). The response behavior is especially good due to this. The two or three hydraulically connected pistons per lining are individually optimally pressed. The lining wear is thus very even, (no diagonal, tangential, or difference wear). The noise production is also decreased. The clearance when releasing the brake is the same for both linings (inner and outer) and is also quickly deployed. The difference wear is also less when the brakes are not applied. Application noises do not occur.

It is not possible to install fixed calliper brakes for vehicles with negative kin pin offset because of lack of space. The ball joints of the wheel suspension and the brake disk slide too closely together or work on the same spot in the wheel disk.

A completely different version of the disk brake is the wrap-around brake. It has the great advantage of moving the friction process to the largest possible radius, and thus

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to achieve a higher brake torque than outer disk brakes. It is a high performance brake. However, as there are disadvantages from difficulties in manufacturing and also in assembly and maintenance (due to poor accessibility), this brake may not be considered in this context. As a summary, this type of disk brake is very expensive and technically too complex for use in series production.

2.3 Drum brakes

The drum brake (Figures 8–10) is predominantly designed as an inner shoe brake. By spreading apart radially, the brake shoes are pressed against the inner side of the rotating brake drum. The shoes can be housed on the carrier in different ways: we differentiate between brake shoes with single or double pivot, members or friction pads. The drum brake shown here contains friction pads with glued-on linings. Earlier drum brakes exclusively had riveted linings.

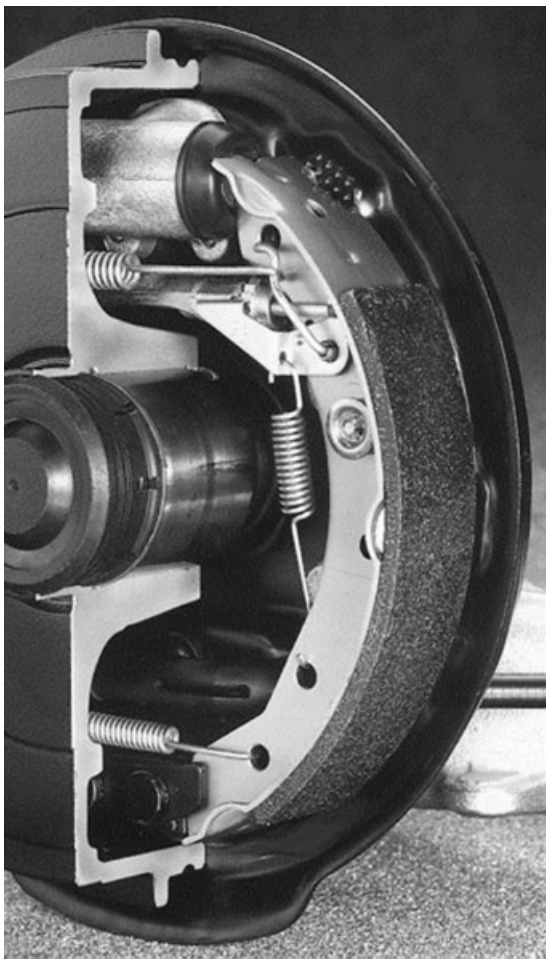

Figure 8. Drum brake. (Reproduced with permission from TRW.)

Figure 9. Simplex drum brake. (Reproduced with permission from TRW.)

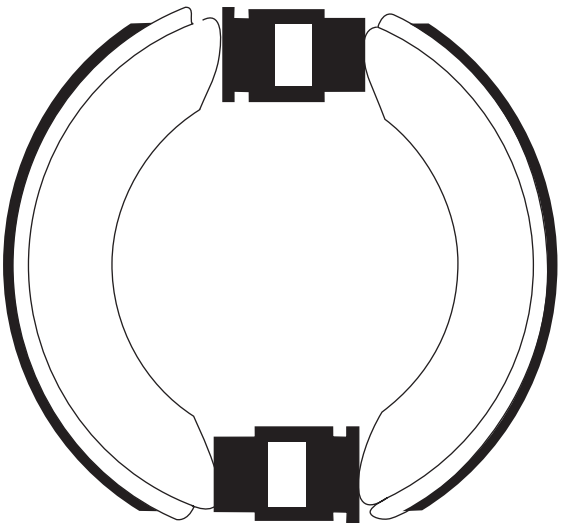

Figure 10. Duo duplex brake. (Reproduced with permission from TRW.)

The linings generally have a very long service life; despite this, a resetting device is required for wear, because of the longer application path. Drum wear is also minimal. Different designs are dependent on the mounting and operation of the brake shoes. The parking brake function is easily realized with an additional mechanical operation. The brake factor is high due to self-reinforcing effect; however, it can vary significantly because of the adhesion factor fluctuations during operation. Altogether, the drum brake is a cost-effective design.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Today, the simplex brake is the most commonly used drum brake. Figure 9 shows the light-weight version, with the anchor plate, the support and the brake wheel cylinder made of aluminum. When the drum turns counterclockwise, the left brake shoe becomes the leading shoe with self-reinforcing effect (accumulating) and the right becomes the trailing shoe with reduction (self-attenuation). By a hand brake lever and a pressure rod, that simultaneously contain the automatic resetting device, the drum brake can be operated mechanically using a cable pull (parking brake). The upper and lower return springs pull the linings away from the drum after releasing the brake and provide clearance again. The retaining spring provides the correct position of the brake shoes along with the lower support.

During operation, high adhesion factor fluctuations can occur, which effects the brake characteristic C*.

The longer application path of the shoes due to lining wear is automatically reset. With the aid of an adjusting lever, a pinion is operated over the application path, which steadily spreads the brake shoes apart. The necessary clearance is always maintained.

If there is a longer application process, the drum expands as a result of the heat. If there is an automatic clearance reset now, the brake would jam after cooling off. To prevent this, a thermal-bimetal (thermoclip) compensates for the longer application path because of temperatures, and the resetting is suspended.

The cooling application of the drum brake, especially those of the brake shoes, are not as good as with a disk brake. The thermal expanding of the drum negatively effects the braking behavior. This results in an extension of the application path of the brake shoes, which is compensated with increased piston travel in the wheel cylinder. This causes a greater volume intake of brake fluid and with it a longer pedal travel. (If the drum is already heated, the driver first steps into emptiness at the start of operation.) The incorrect application of the shoes in the drum decreases the actual lining application length and decreases the brake lining parameter. This results in uneven brake behavior (temperature fading). For this reason, a maximum temperature of of 400°C is permitted at the drum brake during application. Depending on the manufacturer, the disk brakes are between 750 and 1000°C.

Different designs of the drum brake are dependent on the mounting and operation of the brake shoes. Here, the five most important types of drum brakes are more closely described.

The simplex brake (Figure 9) was already described. Both rotation directions have the same total brake force.

Duplex brakes have two single wheel cylinders and two leading shoes; however, they only provide a double reinforced brake force when driving forward. When driving in reverse, the brake force is significantly less (decreasing two times).

The duo duplex (Figure 10) brake is similarly built as the duplex brake. However, it is equipped with two double wheel cylinders and two leading shoes for both rotating directions. This ensures the same strong brake force each time. When changing rotation direction, usually application noises occur.

The power brake consists of a double wheel cylinder and the floating housing of two accumulating sliding shoes when driving forward due to the support force of the primary against the secondary shoe. This leads to a very high self-reinforcement, however only when driving forward. When driving in reverse, it corresponds to a simplex brake. Here, application noises also occur when changing rotation direction.

The duo servo brake is designed similar to the power brake. Dependent on the rotation direction, the two shoes are supported by a support bearing. With this, there are two leading brake shoes for both rotation directions with very high self-reinforcement. Application noises occur when changing rotation direction. This type of brake is frequently used with a mechanical expander lock as a parking brake.

2.4 C* value of brakes

The brake torque is the product of the average friction radius r_{Bm}, the piston surface A_K, of the hydraulic pressure p_{hydr} and the brake lining parameter C*. This parameter describes the relationship between the circumferential force and the tension force, which is dependent on the design and the adhesion factor (Figure 11). As the braking torque should, if possible, remain the same during the brake process, a constant lining-friction parameter (linig adhesion factor) is required.

This requirement is best fulfilled by disk brakes. Here, the C* value is equal to twice the adhesion factor. The brake lining parameter depends on the self-reinforcing factor of the drum brake (geometry). It reacts very sensitively against adhesion factor fluctuations. Figure 11 shows the dependence of the brake lining parameter C* on the lining adhesion factor with different brake designs. As adhesion factor fluctuations are unavoidable, and always occur, but the torque created by the brake should be as even as possible, only the simplex brake is still considered for practical application in modern cars, except for the disk brake. With correct design and moderate self-reinforcement, the simplex brake only differs from the disk brake a little bit. The remaining drum brakes with high self-reinforcements are unsuitable because of the difficult dosing, but were used in the past. The advantage has been that no brake booster

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

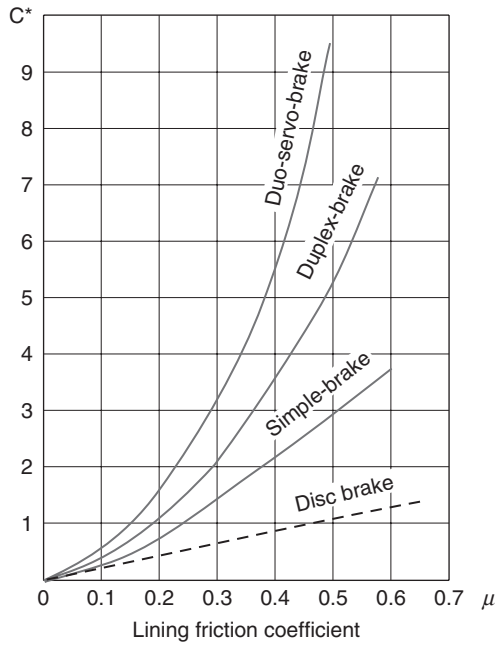

Figure 11. C* values of different brakes. (Reproduced with permission from TRW.)

have been necessary. Today, the brakes with the minimal C* values require additional reinforcement of the driver's foot force through a separate brake booster.

2.5 Leightweight design

In addition to the main task of light-weight design, to reduce the vehicle weight in total and to decrease the fuel consumption, there is especially the requirement to reduce the unsuspended masses on the axles of a vehicle. This includes the brakes and the brake disks as significant parts. Assuming a proved design, the parts containing iron with high density (e.g., steel and cast parts) are replaced with other materials. As a 1 : 1 substitution is usually not possible because of strength, wear, or thermal reasons, the components must be modified in design, corresponding to the requirements of the new material. This often leads to compromises, and the maximum possible weight reductions (with Al 62%) are not reached, as the modified components have more volume.

The following materials are used or under development as light-weight materials:

- Aluminum in various combinations, predominantly as ALMMC (aluminum metal matrix composite), a composite that is reinforced with 20–50 vol% silicon-carbide. This improves the mechanical characteristics, and the melting point increases.
- Ceramics as porcelain from silicate, exclusively used for pistons. Heat-resistant technical ceramics made of silicon-nitride is too expensive by 10-fold.
- Plastic, made of venyl and epoxy resin with good mechanical and thermal characteristics.
- In addition, pistons made of Nirosta sheet metal or anodized aluminum and magnesium are under development.

The modifications due to the new materials are, for example, as follows:

- The brake disk, previously manufactured from gray iron, has a larger thickness in the friction circle so it does not fail thermally. However, in many applications, this material cannot be used, as the thermal stresses overall are too high. Application area is the rear axle.
- On the floating calliper housing, previously made of spherical graphite iron, the bridge strength was increased by ribs when made of aluminum, to keep the expansion during operation to a minimum.
- The wall of the piston made of plastic, ceramics, or aluminum is also thicker than in the previous steel piston, to keep the pressures at 160 bar.
- The weight of the lining rear plate is additionally reduced by bulges. In the former steel plate, there were still reserves here. In addition, the connection with the lining material is improved and the form closure is improved.

The high thermal stress of the brake with the aluminum brake disk is opposite the low melting point and less strength of the material. Therefore, only the use of fiber or particle-reinforced alloying such as ALMMC is possible. The maximum operating temperature of 450°C must be absolutely maintained; above that, the material loses its strength and already reaches its melting point at 550°C. Owing to the lower density, with the same volume, ALMMC only has a very low absolute heat storage ability compared to gray iron, despite the higher specific heat capacity.

The time history of the temperature during a stop, calculated using the finite element method, indicates the distribution of energy within the disk (Figure 12). The temperature in the friction path center increases as the first and quickest; in the disk head, it does not increase until the end or after the stop. The heat released through convection during the stop (radiation or heat conduction into the disk head) can be ignored, independent of material, as during the highest case it only amounts to 5% of the energy conducted in only a few seconds during braking. Therefore, the brake

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

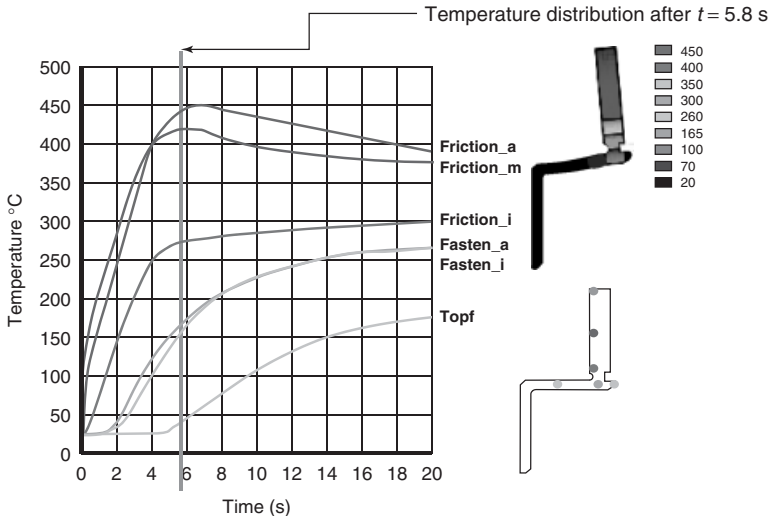

Figure 12. Heating of the disk during a brake process. (Reproduced with permission from TRW.)

disk during a stop is to be considered purely as a heat accumulator, which gets filled.

After braking, in the cooling phase, a material with good heat conduction brings advantages. The temperature profile within the disk circle is better balanced, which causes a quick convective heat release and more convenient heat conduction into the head. The heat conduction into the head must be limited to prevent excessive heating of the wheel bearing; the grease would leak out in fluid form.

Owing to the temperature distribution, different expansions occur, which leads to deformations and tensions of the disk. Figure 12 shows the deformations in a high performance test with successive stops, a vehicle is braked several times in a row with a high deceleration of 70% of gravity and is then accelerated as fast as possible. The first five stops are performed from 90% of the maximum speed to 80 km/h and the last stop to 0 km/h.

Comparing gray iron to an iso-volumetric ALMMC disk, it becomes obvious that the aluminum disk is quickly heat saturated. The temperature in the gray iron disk continues to increase. Owing to the lower storage capacity of the ALMMC, the temperature difference at the same stops is larger. Owing to the higher heat conductivity of the ALMMC, the cooling between stops occurs better than with gray iron.

The temperature of the disk head near the wheel always increases after a stop, an indication that the heat conductivity during a stop can be ignored. The maximum temperature of 180°C clearly shows that the neighboring parts, such as wheel bearing or rim also experience heating, which also occurs more quickly especially with longer braking, and therefore prevails longer than with the gray iron disk.

Test bench tests with ALMMC disks have shown that the thermal loads together with the mechanical loads can be managed with aluminum. The strength of such disks, especially against abrasion, is ensured by silicon carbide particles. A black lining layer forms on the disk surface, so that the lining material rubs against itself. The brake wear is also heavily reduced by this. There is also less wear on the brake linings that are specially developed for aluminum disks.

The tests performed for rear wheel brakes (high performance and fading successive stop brakes as well as the simulation of a slow alpine descent: long-term braking for 45 min) were successful. When exceeding the performance (in this case with double vehicle mass), the disk does not completely fail. On the surface, the melting temperature is reached and deep ridges result. The protective coating is destroyed. An iso-volumetric exchange ALMMC for gray iron will not be possible in most cases. This material can only be used when still additional installation space will be available. Highly loaded brake disks, as are necessary for high powered heavy vehicles on a front axle, cannot be made of ALMMC with the same dimensions.

Brake disks in sandwich construction are under development for use in highly loaded front axle brakes. To decrease the high thermal and wear-inflicted loads of the disk surface, an aluminum brake is protected at the corresponding spots with resistant layers. This principle is already used in brake drums, in which the friction surface is embedded in the inside drum with a gray iron ring. Thus, known friction pairs can be used. Aluminum is then usable without particle reinforcement and is also easier to recycle. The achievable weight reduction, however, is less.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

By half-empirical iterative layer calculation, a thermotechnical pre-design was performed, and the transient temperature profiles for all applications were determined. Such a sandwich disk is only safe for operation, if the maximum temperature in the contact surfaces of both materials is under the maximum allowable temperature of the aluminum, and if between both materials there is no thermal contact resistance. The gray iron layer must not overheat. During cooling, a part of the heat can flow in the groove; however, for convection, the protective layers are insulating. Owing to thermal tensions and aging effects, chipping of the protective layers can occur. For most of the planned application areas, the thermal load is at a critical range. However, the sandwich disk is not yet finished in development. The long-time effects through time, temperature, and corrosion aging have not yet been researched. For this, to evaluate the multiparametric operating load collectives, the correlations, and the specific test procedures, tests must still be developed for.

Increasing engine power and increasing cost pressure have led to a decline in light-weight construction in recent decade. The tire diameters grew as fast as the brake disk diameters. More lining volume for higher operating life required broader partial disk segments and thus broader and heavier brakes. The CO_2 laws and increased efforts to reduce fuel consumption will turn this trend back. Light-weight construction is gaining significance again, and people are willing to pay for it.

2.6 Brake circuit design

To prevent the loss of brake power by leaks in the brake system, the system is divided into two separate circuits for safety reasons. From all the possibilities, only the best-known five brake circuit divisions are presented here:

TT. Simple two-wheel brake system (front, rear axle division or also named: black, white division). Each circuit supplies the brakes on one axle. This is a simple system design, there are no special requirements for the axle design—the typical division for upper middle class and upper class cars. In case of a failure in the rear axle circuit: only small brake performance derease, in case of a failure in the front axle: large decrease in deceleration, as the rear brakes are not very powerful. There will not be a moment around the vertical car axis.

X. Diagonal two-wheel brake system (diagonal distribution) per circuit. One front wheel and one opposing rear wheel are braked by one circuit. This is also a simple design. If there is a failure in one circuit, this results in a moment around the vertical axis of the vehicle. In case of a cicuit failure, the brake power is always cut in half. The moment around the vertical car axis can be independently compensated by designing the axle with a negative king pin offset, otherwise the driver must countersteer. This is the usual division of small vehicles up to middle class.

HT. Two-wheel brake system. The front axle requires a four-piston fixed calliper or a two-piston floating calliper or a piston of the floating calliper is connected to a different brake circuit. If there is a circuit failure, only the half brake force can be applied to the front axle with constant brake pressure and the same piston surface.

LL. Three-wheel brake system. Each circuit effects half of the front axle and one rear wheel. In case of failure, the front axle brakes half and on the rear axle there is always one nonbraked wheel that can take the side forces.

HH. Four-wheel brake system. Here, as with the front axle, four-piston fixed callipers or two-piston floating callipers must be installed on the rear axle. Each circuit works on the half front and the half rear axle brakes. The effect on both individual circuits is identical.

The design of the brake circuits depends on, which cause of failure is significant and whether an antilock braking system (ABS) is to be installed. As the standard-production application of ABS and ESP (electronic stability program), the HH division is considered too complicated, the LL division is inconvenient. The HT division has poor emergency brake characteristics (over braking of the rear axle) if there is a failure at the half front axle. All systems with two circuits on the front axle are only convenient with good thermal design, the brake fluid must be connected over the disk to the other pistons if there are fixed callipers, which makes these easy to overheat by the hot disk (evaporation). This leads to failure of both circuits.

Heavy and power vehicles of the upper class with rear wheel drive and motor in front have at least a TT division. For front wheel drive with front motor, a vehicle is equipped with floating callipers because of the (necessary) negative king pin offset and the diagonal division (X) is used.

2.7 Parking brake

The parking brake must work independent of the hydraulic service brake. By adding a mechanical actuation, the parking brake is integrated into the service brake. The primary task of the parking brake is to hold the parked car on a slope. By law, it is required that this is still possible with a slope of 18% in front or rear position of the fully loaded vehicle (ECE in Australia 30% slope).

Parking brakes are predominantly installed on the rear axle of the vehicle, as these brakes are less heavily stressed due to the brake force distribution (which is why they

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are also smaller) and an installation is simplified by the wheels that are not steered, in contrast to the front axle. The integration of a parking brake into a drum brake was already explained earlier. Operated by a bowden cable, the brake shoes are pressed against the drume with the aid of a lever. Integration is more difficult in disk brakes because of the smaller free space ratio. The installation of a separate smaller duo servo drum brake in the head of the brake disk (drum in disk) provides one possible solution that is exclusively used as a parking brake. Figure 13a shows an example for such a small servo drum brake. Figure 13b shows the arrangement of the drum brake in the disk brake.

Another solution is the integration of a mechanical device into the housing and the piston of a floating calliper brake. From the outside, this parking brake can only be identified because of the hand brake lever and the loop of the cable support (Figure 14a). In Figure 14b, there is the floating calliper housing with the hand brake lever and the cable support. The piston, which brings up the tension forces to the friction linings and the disk, is operated either hydraulically by the pressure of the brake fluid or mechanically by the hand brake lever using the integrated mechanism.

For hydraulic operation by the service brake, the piston is moved and pressed against the lining. The reaction force moves the housing away from the disk and presses the outer lining against the disk. The hydraulic pressure generates the tensioning forces. For mechanical operation, the main shaft is rotated, which is activated by the hand brake lever. Instead of the hydraulic pressure, a ball rolls up a ramp and spreads the piston shaft away from the housing with the piston. Both linings are pressed against the disk. In contrast to hydraulic operation, now the ball generates the tension forces within the ramp-shaped groove. The mechanical operation is independent of the hydraulic operation. However, both effect the same operation of the brake, exactly as with the drum brake.

In the inner part of the piston, there are resettings necessary for the mechanical operation. It is activated during one of each brake procedures by both operating types

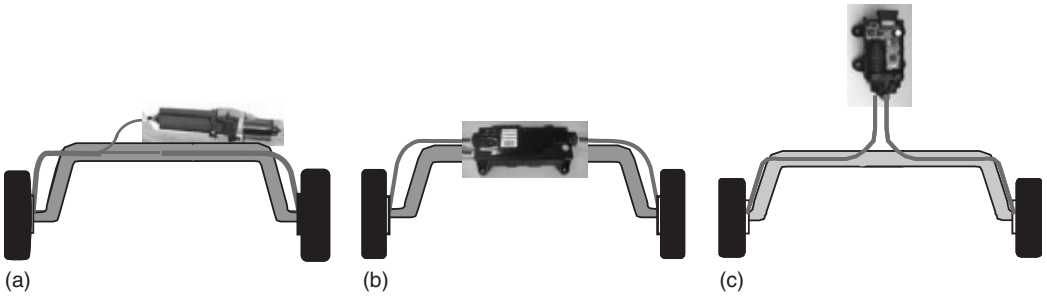

Figure 15. (a–c) Various cable systems for operating parking brakes. (Reproduced with permission from TRW.)

(hydraulic and mechanical) and extends the piston out of the housing mechanically with decreasing lining thickness (due to wear). Owing to the adjustment, there is a constant base clearance at any time between the piston and the mechanical operation when the brake is released. As the mechanically generated base clearance of the piston is larger than the hydraulically created clearance from roll back, the clearance between disk and linings is the same as with a disk brake without parking brake.

The parking brake devices work when operating the cable using hand lever, foot lever, and an electromechanical actuator. The cable puller operation is available for reaction force cable systems (a: also called *conduit systems*), transverse force cable systems (b: also called *cross-pull*), and parallel pull cable systems with force balance bars (c: also called *forward pull*) (Figure 15).

The integrated electric parking brake (EPB) replaces the cable operation using a small electric motor with transmission at the brake and the adjustment device via software. This brake is an additional step to decrease operating forces and to obtain design space in the vehicle interior. The electric operation allows the use of minimal forces, which not only physically weak and disabled people appreciate.

Instead of ball ramp and the automatic adjustment device, a spindle is inserted in the EPB, on which there is a compression nut, which—secured from rotating—is pressed against the piston head or is pulled back from there again. The motion thread is self-locking. A maximum tension force of 23 ± 2 kN can be generated with the device. With this tensioning force, a "slip stick" effect begins in the thread of the spindle. These high tension forces must be considered when developing brake disks (Figures 16 and 17).

The spindle is supported with the flange against the axial bearing on the bottom of the brake housing. The flange has an end stop that prevents the pressure nut from tensioning against the flange. This is important for manual and electric lining change and for the end of the line—calibration (calibration on assembly line).

For emergency release, the actuator can be unscrewed and the brake is opened using a Torx wrench—that is a factory solution. Generally, before an emergency release, it must be considered, how and where the vehicle will next be securely parked even if no power is available.

The variant produced by TRW is operated using dual buttons with neutral setting, mounted in vehicle longitudinal direction. The front position (press) closes, and the rear position (pull) opens. If it is not operated, the switch stays in neutral position. The contacts are redundant, each with a normal open (NO) and a normal closed (NC) contact per switch position. Using the NO contact, a capacitor is placed so that the NO connections can also be constantly monitored with a pulsed test voltage. Thus, a single fault can be securely and immediately detected.

The processor is a Star12 from Motorola with on-chip flash memory that is widely used. The motors are each switched to one FET (field effect transistor). Changing rotation direction is realized using two relays. The real flowing currents are measured with each one shunt, likewise the voltage level and polarity. The control unit (Figure 18) can have up to four end levels for direct control of pilot lights.

For ignition "on," the control unit is in active mode and continuously performs self-tests. After ignition "off" and a shut-off delay, the control falls into a power-saving sleep mode (maximum 200 μA), from which it awakens operating either by a switch or by ignition. A second processor that simultaneously executes the monitoring function controls this and independent of the main processor can lock the end levels. The "end of line" configuration and the diagnostics occur using the CAN (controller area network) bus.

For vehicles with integrated starting assistance, an additional inclination sensor can optionally be provided in the control unit. If this is installed, it can differentiate between the static and dynamic mode by evaluating the vehicle movements during the drive even with failure of the CAN velocity signals.

The software runs in a 20 ms main loop, from which all function modules are continuously addressed.

This is strictly a status machine, whereby the different modes can only be exited using predetermined events (mode control). Subroutines, such as the composition of switch commands with other system signals (demand calculator/clamp force controller) or the motor control (motor controller), are set up as status machines.

The main function is the static closing of the brake with ignition on. The switch must be operated for that. The software checks whether the ignition is switched on and whether the wheel speeds are zero. After 100 ms (5 cycles), the command is accepted and transferred to the motor control. This enables all functional motors in tension direction and monitors the tension flow. This measures the voltages. While driving over the clearance, the motor current is determined and considering the voltage, the motor temperature is estimated. Both voltage and temperature are used for the formation of a correction value for the cut-off current that is then added to the no-load current. A fully loaded vehicle on a 30% incline

is assumed to define the cut-off current. Figure 19 shows the time history of a tensioning and a release process.

During the drive, a temperature model runs for the rear brake disks to detect excessively hot disks. By repeated tensioning, the system provides the opportunity after approximately 3 min to realize a one-time (cycle-related) force super elevation beyond the nominal tension force. Rollaway detection can also trigger multiple tensions, which lead to high tension forces, especially, if there is not enough energy available because of undervoltage.

To open the parking brake, the relays are switched in release direction and the FETs are energized. As soon as the current curve has fallen to the no-load current while opening, this point is retained as the new relative zero point, and after clearance adjustment time, the motor is switched off. This time is determined by declamp-voltage and declamp-current (to estimate motor speed).

If the ignition is off, and the switch is operated, only tensioning the parking brake is possible, but not opening (child safety lock) It becomes difficult for drivers that switch off the ignition while driving downhill; wheel speed signals are no longer available from the CAN bus. A CAN follow-up function ended by the EPB ensures that the electric brake does not close until the vehicle is standing. Even if wheel speeds fail, the brake is not closed until the ignition is off and vehicle standstill has been detected.

The total software overview is shown in Figure 20.

If the service mode is activated with ignition on via the diagnostic function of the service mode, both pressure nuts move back to their end stop. Then the linings can be replaced.

The dynamic deceleration is passed to the operating brake system by the EPB using CAN message, which then executes the braking using the ESP system and takes over again with a speed <7 km/h.

Probably, the most convenient function of the EPB is the automatic release when starting. Using the integrated incline sensor, the required engine torque is determined and when reaching this threshold, the brake is opened. For manual transmission, a clutch position sensor is engaged. From the gradients of the clutch position (so the release speed), the grip of the clutch is calculated and the brake is released when there is sufficiently high torque.

The starting assistance is also important for automatic vehicles. Today, less and less creep torques already allow automatic vehicles to roll back on smaller inclines (12%) If the parking brake is not used, semiautomatic vehicles generally roll back when moving the foot from the brake pedal to the accelerator. Using the starting assistance, the rolling-back can reliably be prevented. Undesired starting is prevented by additional signals, for example, starting with the starting assistance is only permitted for a driver whose seatbelt is buckled. Manually releasing EPB is only possible

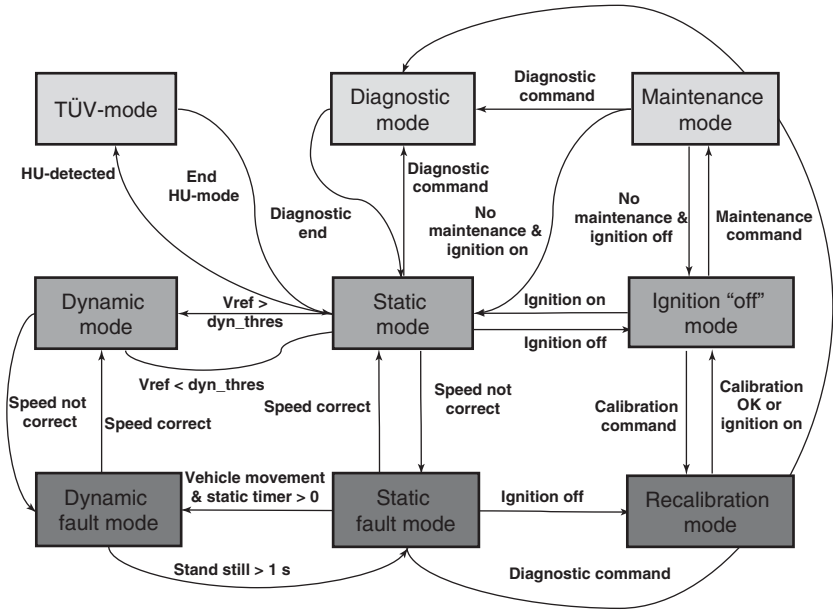

Figure 20. Software condition diagram. (Reproduced with permission from TRW.)

by pressing a button if either the brake or the accelerator is pressed down.

With the typical techniques such as continuous ROM test, RAM test, external watchdog, and second processor, the security of the control unit is ensured up to ASIL D corresponding to ISO 26262. In addition to voltage supply, the redundant operating element, the fault lamp, and the actuators are also monitored for proper function. Using a constant current source (approximately 2 A), the performance output stages are tested for switching on and off. The relays for pole change can only be tested one time when the ignition is switched on, owing to their service life.

All signals are subject to a plausibility test as much as possible before processing. If the ignition is switched on, the CAN must also be there, if the EPB motors are switched on, shortly thereafter the voltages must fit with correct polarity. If the brake opens, the current must decrease; if the brake closes, the current must increase; if the driving speed decreases heavily, there is either an incline or the brake light switch is on. Changes to the drive speed must synchronously go with the signals.

If there are missing signals, if possible, replacement parameters are used. If the vehicle speed is missing via the CAN, the corresponding filtered incline sensor signal is used to detect standstill. If terminal 15 (voltage in the system) is missing, CAN is present and notifies the switched-on ignition, this is used.

The faults are classified as follows:

1. casual faults (e.g., CAN loss): the EPB system continues to work and indicates the faults;
2. interfering faults (e.g., communication with the motor control unit interrupted): the function (here, drive away) is switched off, and the EPB system continues to work and indicates errors;
3. channel fault (e.g., channel to motor defective): the EBP system tries to open the brake with the next release command and switches the affected channel off, the other channel continues to work, and the fault is indicated;
4. system fault (e.g., processor fault): the EPB system switches off, and the fault is indicated.

With this system, the parking brake function is also electrified now. In the coming years, an integration of the electronic steering in the ESP control unit will happen—many functions and signals are "related," the safety requirements are similar.

3 THE BRAKE PROCESS

The stopping distance required during the brake process is composed of

- rolling distance: the vehicle continues to roll without braking; only air and rolling resistance are working—no motor brake torque. The amount of the rolling distance depends on

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

  - time to turn toward view
  - reaction base time
  - time to implementation
  - response time.
- threshold path: braking begins, the brake torque increases
  - threshold time.
- braking distance: the vehicle is decelerated
  - time of braking (complete or partial braking).

All distances together cover the stopping distance.

The introduction and the execution of a braking process in traffic occurs due to visual perceptions. This process is composed of three phases:

- Objective reaction summons: start of visibility of the object
- perception of the object: in general peripheral, on the edge of the field of vision of the driver, only rarely in central field of vision of the driver (time to turn toward view)
- Object fixation: Recognizing the risk that originates from the object, start of muscular reaction

The fact that conscious decisions and appropriate reactions are never made based on peripheral perceptions has fundamental significance. Conspicuous objects in the peripheral field of vision always first trigger a glance. The foveal area generally only has an opening angle of 1°. If there is more than a 0.5° deviation from the driver's field of vision, a view adjustment is made. Object fixation and a conscious reaction are only possible after the *time to turn toward view* (Figure 21).

The *reaction time* begins after turning toward the view. The reaction base time lies between the object fixation and the start of muscular reaction. It is a process with the same behavioral patterns for all individuals. The time span is independent of outer boundary conditions (e.g., brightness and weather conditions) and independent of the situation.

Afterward, with the start of muscular reaction, the *implementation time* begins. The accelerator is released; thus, the first appropriate movement of the foot happens.

The first contact with the brake pedal is the start of the application or *response time*. The brake shoes/lining are applied. The implementation and application times are short compared to the reaction time.

As the brake pressure increases, the *threshold time* begins, where the increase of the hydraulic pressure is significant for the gradients of the deceleration. Normally, the wheels of the vehicle lock before reaching the maximum pressure. In modern passenger cars, the ABS activates beforehand and prevents locking, keeps the wheels in optimal slip range and secure the maneuverability of the vehicle during the brake application.

The following is the *brake time*, which lasts as long until the entire emergency brake process ends with the vehicle at standstill. It is dependent on the output speed, the degree of deceleration, and the achievable friction values at the tires (at 250 km/h and highest possible vehicle deceleration, the process takes approximately 12 s). This time span is solely determined by the capacity of the brake system and the vehicle, assuming that the driver does not reduce the brake pressure.

In contrast, the *reaction time* depends on human movement sequences, physical–technical laws, and the abilities and conditioning of the driver. Additional factors affecting the driver are of special significance: road and weather conditions, traffic volume, distraction, high degree of information, and stress.

The brake process starts as soon as the driver identifies the reason that requires braking. From this time up to the rise of brake pressure, the vehicle practically continues to roll without brakes. At this point, the modern driver assistance systems start—a shortening in reaction time by 0.5 s reduces the probability of an accident up to 80%. The brake effect from air, rolling, or motor resistance can be ignored here, as their effect is very minimal compared to the power of full braking.

In emergency or sudden braking, the driver applies a pedal force of 250 N and moves the brake pedal for approximately 80 mm. The brake master cylinder, connected to the brake pedal, generates a hydraulic-volume shift in the direction of the brake system because of this pedal movement. Owing to the compressibility of the brake linings and the deformation of the brake callipers, the entire brake system absorbs a volume of approximately 8 ml. At the same time, a brake pressure of 80 bar occurs. This leads to a deceleration of approximately 0.9 g (90% of gravity). In panic situations, more than 500 N pedal force and more than 160 bar hydraulic pressure were measured—however, the deceleration did not increase further from this.

The deceleration, with which an average driver brakes, lies in the range 0.01–0.4 g. Only in absolute emergency or exceptional situations are up to 0.8 g achieved. During their entire driving practice, most drivers never brake above 0.5 g. However, the brake system is designed for up to 1.2 g.

4 BRAKE DYNAMICS

The control of the braking process is decisive for the availability of a vehicle in practice, to be able to ensure safety in traffic. A vehicle must be designed in a way that it does not produce unforeseen reactions even during panic

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

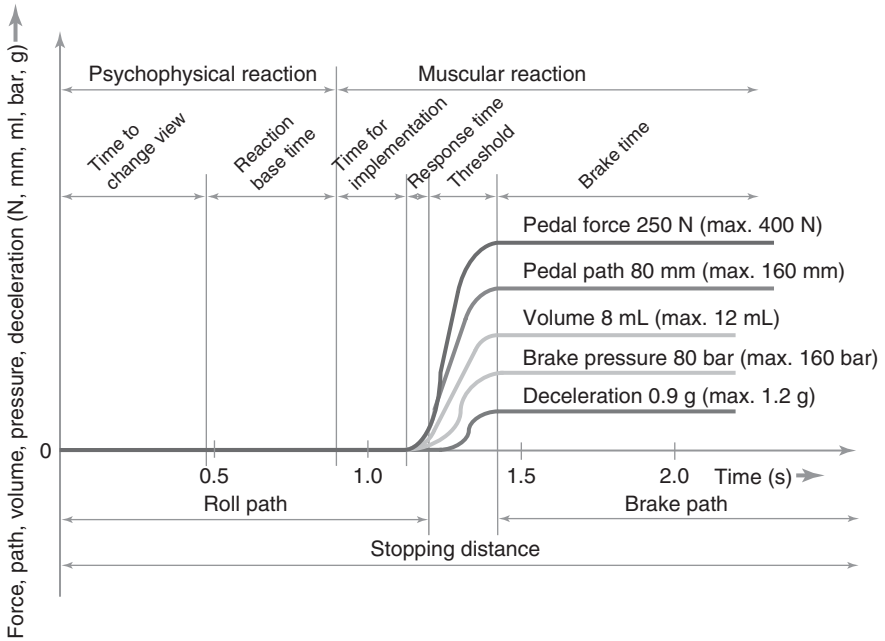

Figure 21. The brake process. (Reproduced with permission from TRW.)

braking and always behaves like the driver expects from his or her experience. Only then the vehicle is safe.

The knowledge of the outer brake dynamics of the vehicle is of special significance for designing a brake system. This is dependent on the brake force distribution that follows from the design parameters of the vehicle. For installation or for the demand-oriented change of the brake force distribution, corresponding control devices are installed in the brake system.

The brake system must be able to brake the vehicle with maximum deceleration. The driver must be able to do this with an application of average forces. The existing limits are the contact area between the wheels and the road, which are only the size of a palm of the hand, and the adhesion coefficient of the tires of $\mu_B = 1.1$ at most. With an assumed friction coefficient of $\mu_B = 1.0$, a maximum vehicle deceleration of $1\,g$ ($=9.81\,m/s^2$) can be reached. In theory, with specific rubber, the μ-factor may even be higher (race cars).

The brake application must be stable, the vehicle must not become unstable or even worse, that the rear axle swerves. A short braking distance naturally occurs with the highest possible deceleration. The processes during braking will not have any reactions on the driver or the behavior of the vehicle (no noises, no rubbing, no steering wheel torsional vibrations, and no pulsing of the pedal). The response of the system improves with only minor volume absorption in the callipers, which also decreases the brake pedal travel (operation, roll back, and widening the brake calipers). Pedal travel going against zero is not appropriate because of ergonomic reasons.

The brake force will be well dosable, so that with light pedal operation, no strong deceleration occurs. A slight decrease in the liner friction coefficient while braking, which forces the driver to step on the pedal again, is preferred. The support by brake boosters should allow every driver to perform locked braking with average use of force in emergencies. On the other hand, the increase must not lead to poor dosing with minimal deceleration. The booster devices are realized with progressive, degressive, or linear characteristics, depending on the manufacturer. In addition, all brake actions will never generate noise (inside and outside of the vehicle) from the liner and the disk wear. Traffic light systems with signals for blind people had to be changed from beeping to clicking because there was confusion with brake noises.

This especially includes the following:

- rubbing: vibrations due to speed fluctuations from differences in thickness of the brake disk;
- squeaking, chirping, and muh: average to high frequency noise or friction fluctuations;
- rattling and clicking: from the moveability of the linings, with pot holes, when applying the linings.

For the quality of a vehicle in practice, the stability is decisive in case of emergency braking. Only with sufficient

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

brake stability, the vehicle is prevented from skidding, and the steerability is ensured with good cornering forces. Regardless of size, type of motor, or design of any vehicle, the rear wheels may not lock before the front wheels lock (legal requirements are setting a limit with minimum 8 m/s^2 deceleration). When the front wheels lock, the vehicle can no longer be steered; however, it stays in its track. Because modern, electronically controled brake balance no longer has these mechanically secure fallbacks, only partial brakes are allowed for (displayed) failure.

The brakes (brake linings) may not lead to strong friction coefficient changes (high temperature fading), as in addition to the loss in brake power, especially a change in the brake balance by fading of front to rear axle occurs, which can endanger the stability of the vehicle. The same can happen because of evaporation of brake fluid (fluid fading).

The tire characteristics must also be adapted to the vehicle. A vehicle that stably brakes with approved tires (first the front axle locks) can become unstable during emergency braking by installing tires with higher maximum adhesion coefficient on the front axle. Then the rear locks first. If the rear axle skids due to premature locking of the wheels, it is impossible to react to this using steering movements. The vehicle immediately goes out of control (Figure 22).

To calculate the vehicle behavior, a rigid two-wheel model is used, and the method with minor disturbance is applied. In doing so, the vehicle is to be considered a rigid body, deformation of the axles or the wheel suspensions are ignored. Owing to a disturbance, the vehicle has the sideslip angle ß between the longitudinal axis of the vehicle and the driving direction. This driving condition generates sideslip angles at the front and the rear wheels (same amount like ß) and then side forces are acting between the road and the tires. The masses and the lateral force affect the vehicle's center of gravity. These counteract the deceleration forces and the side forces on front and rear axles.

The yaw angle or the yaw acceleration can be determined from the balance of forces in x- and y-directions and the moment balance. A positive value means an increase in the sideslip angle. This can become unstable, finally a skidding of the vehicle may happen. A reduction of the sideslip angle points toward stability. The vehicle body will returned to the driving direction. The smaller the moment of inertia J_z, the faster the vehicle turns (e.g., when the engine is in the center of the vehicle).

By relating the brake forces to the vehicle mass, the yaw acceleration in dependence of the deceleration can be determined. The simulation results show immediately under what conditions the vehicle becomes unstable (for instance in Figure 23: 70% g). The additional load of the vehicle is also of great influence, as not only the overall weight, but also the brake balance changes. The behavior of the rigid two-wheel model with ideal tires is a straight line (neutral steering behavior).

For the evaluation of a vehicle, the deviation from the straight line is decisive.

At a deceleration of more than 80% of g, the empty vehicle begins to skid (in the example of Figure 23). The yaw acceleration is positive and increases extremely

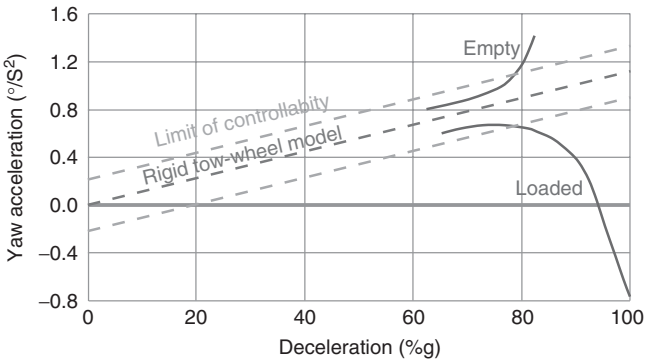

Figure 23. Vehicle stability model.

quickly. A yaw acceleration of $1^\circ/s^2$ corresponds to a yaw angle of approximately $57^\circ/s$ after 1 s and an increase of the angle by 30°. A normal driver cannot handle this. An acceptable value for yaw acceleration is $0.25^\circ/s^2$. Then, the braked vehicle can still be stabilzed by countersteering.

In real vehicles, the elasto-kinematic design of suspensions and stabilizers delivers inherently stable behavior. For the control of the vehicle by a normal driver, the brake behavior in case of circuit failure or with differing low adhesion surfaces (right/left, μ—split) is decisive. At standstill, the weight force in the center of gravity and the wheel loads at the front and the rear axles are acting on the car. The center of gravity has the distance l_1 to the front axle. The wheel base is indicated as I, and the hight of the center of gravity above the road is named h.

During the brake process, the mass forces zG_g (equivalent to vehicle mass multiplied with the deceleration) and the brake forces are added to the front and rear axles. This assumes that neither the position of the vehicle to the road nor its center of gravity change.

The dynamic balance in driving direction leads to the deceleration factor z ($z = a_x/g$ with a_x as longitudinal deceleration) . As a result of the height h of the center of gravity and the inertial force in the center, a dynamic axle load distribution $\pm\Delta G$ results from the rear axle to the front axle. The equations for dynamic axle load arise from the equilibrium of moments around the wheel contact points of the front or rear axles. These equations can be found in Kane (2008).

Assuming the same utilization of traction (that means the same μ) on the front and the rear axles, the equations can be used to generate a diagram that shows the ideal distribution of the brake forces (means: the same friction coefficient at the front and the rear axles during deceleration). This is a diagram (Figure 24) with the brake force related to the total weight, at the front axle as abscissa and at the rear axle as ordinate.

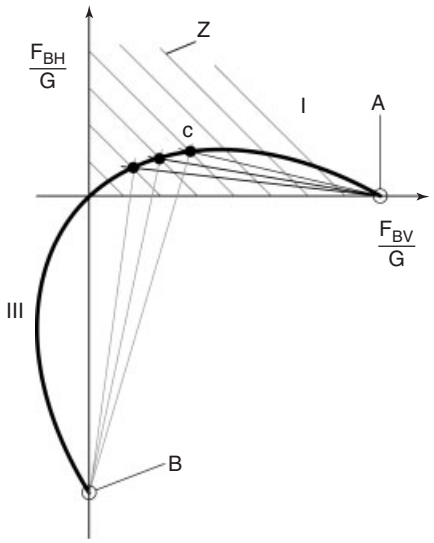

Figure 24. The brake force distribution diagram.

On this parabolic curve, the ideal case of the same adhesion utilization on front and back axles is always realized. It is solely described by the data: center of gravity height, center of gravity position between the axles, total vehicle mass, and wheel base, and it is existing in the first (braking) and third (acceleration) quadrants of the coordinate system.

The deceleration factor z can be drawn in as lines of constant braking at an angle of 45°. On the parabola of the ideal axle force distribution, $\mu = z$ always applies. The lines of same coefficients of adhesion of the tires are also straight lines that go through the "point of ideal operation" (point C).

There are two useful physical explanations for no brake forces at the rear axle:

1. $z = 0$, there is no braking that means no deceleration (coordinate origin).
2. $F_{BH}/G = 0$, the rear axle is completely released (point A).

No brake forces at the front axle can also be explained: The same applies to acceleration, here z is negative

1. $z = 0$, there is no braking that means no deceleration (coordinate origin).
2. $F_{BV}/G = 0$, the front axle is completely released (point B). This means that the car is accelerated (not braked) and therefore the related deceleration z is negative.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The deceleration factor z must be drawn in Figure 24 to be able to plot the green lines (starting in B) and the red lines (starting in A) of constant friction adhesion between tires and road surface. All red straight lines of constant friction adhesion between rear axle and road must cross point A (lifting the rear axle). There is no more friction at the rear axle in this point. Point B is crossed accordingly by straight lines of constant friction at the front axle. During acceleration, the front axle will be lifted under the conditions in Point B.

In point C, the straight lines of friction utilization meet each other. The parabola defines the ideal brake distribution that means for instance the full utilization of friction at the rear axle (may be 0.4) and at the front axle (may also be 0.4). The parabola is valid for $z = \mu$.

Practical statement: The installed brake force distribution in the first quadrant counts as stable, in case the installed distribution line is below the ideal distribution until $z = 1$ (by legal requirements $z = 0.8$). If a friction coefficient of 0.4 is assumed (the same value at front and rear axles), then the brake force P can increase along the line of the installed brake force distribution until the line crosses the green line of the friction utilization of the front axle (P_1 in Figure 25). The front axle locks at this point and the deceleration can be seen (Figure 25).

In case the brake pressure is still increased, the brake force at the front axle is no longer increasing. The braking point is going upward along the green line of the constant friction utilization of the front axle until the red line for the friction utilization of the rear axle (same value like at the front) is crossed. In Figure 25, this is shown as point P_4. Now the rear wheels are also locked. The gradient from P_1 to P_4 is not vertical, as the lines for the constant friction coefficient at the front axle are crossing in point B (comp. Figure 24).

For the evaluation of the brake behavior of a vehicle, the ideal distribution in the first quadrant is used. The installed brake force distribution is considered with respect to the ideal distribution.

As an example for a vehicle, the ideal brake force distribution is shown in Figure 26. This is like the characteristic in the first quadrand of Figure 24. This ideal distribution is also named as outer dynamics of a vehicle. The brake force distribution installed in the car can be regarded as information about the inner dynamics of the vehicle.

The brake force distribution installed provides information about the inner dynamics of the vehicle. The distribution is evaluated from the parameters of the brakes on front and rear axles and it normally represents a straight line. The intersection point of the straight line with the line of the ideal distribution indicates the deceleration (z-value) at which both axles look at the same time. As long as the line for the installed brake distribution is below the ideal one, the front axle will lock first if the road friction will not be sufficient. If the brake operates above the ideal distribution line, the rear axle will lock first and the vehicle will be immediately unstable. The intersection point of the installed distribution with the ideal brake force distribution indicates the so-called critical braking z_{kr} by which the two axles lock simultaneously.

For safety reasons, most vehicles are designed so that the critical braking (locking of all four wheels) is at $z = 0.9–1.0$. As the drivers normally avoid these high deceleration values, the vehicle normally will not become unstable by braking.

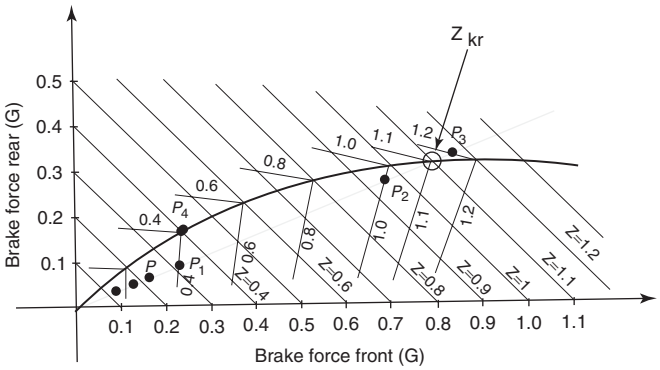

Figure 25. Brake pressure increase and locked wheels at $\mu = 0.4$.

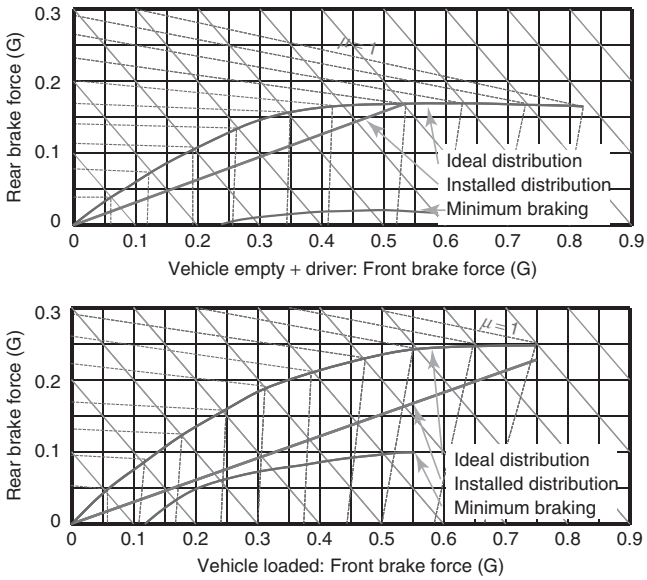

Figure 26. Brake force distribution diagram with vehicle empty + driver and vehicle loaded.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In addition, the minimum brake force distribution given by law is drawn in this diagram. With these minimal values, the requested deceleration will be reached. However, they are far too much low for practical driving.

To prevent the rear axle wheels from locking, which means to keep the installed brake force distribution below the ideal distribution, valves to reduce the brake pressure at the rear axle have already been installed for many years. These components respond to specific brake or vehicle data.

If an increasing pressure is given to the brake system via the master cylinder, the pressure-dependent valve only allows no or only a small increase in pressure to the brakes of the rear axle if a specific brake pressure has been exceeded.

The load-dependent valve works like the pressure-dependent valve. It is mainly used in vehicles with front wheel drive with front motor and low rear axle load, as the brake force distribution can significantly change there because of the vehicle payload. The spring deflection of the body is used to adjust the valve, thus the pressure switching point changes according to axle load (dynamic). In reality, the load dependence is a travel dependence (spring path dependence).

For valves with an acceleration-dependent switching point, the brake force reduction is dependent on the vehicle deceleration. High operating speeds of the brake pedal distort the mode of the valve's action. For diagonal brake circuit distribution, it is necessary to control both circuits in parallel, which is very inconvenient. These valves can also be installed between the wheels of an axle to react to lateral accelerations. For driving in extreme curves, this can prevent locking of the inner wheel.

For a vehicle without brake force control devices or ABS, the limit of brake stability is therefore achieved shortly before the locking limit of the rear wheels at the highest possible deceleration. Figure 26 shows a fixed distribution that enables such a design; it already cuts the ideal distribution with braking of 0.7.

The development is clearly moving from brake pressure control devices and going to real control systems. The antilock system that today predominantly works on all four wheels separately or on both wheels of an rear axle (select low) provides reliable brake stability with almost optimal vehicle deceleration and gives still steerability of a car, even during severe braking.

Together with an electronic brake force distribution, the braking power can ideal be used in every emergency situation, independent of load condition and adhesion coefficient of the tires, as long as the driver only demands the brake system sufficiently, generates corresponding high pressure, and also keeps the pressure while braking.

If the engine power increases with a constant vehicle weight, then generally more powerful brakes are required. If the vehicle weight increases with the same engine power, then the brakes can usually be retained from the point of view of brake force distribution and subsequent braking behavior.

5 THE FRICTION PROCESS

The friction process results from the resistance of the relative movements of two bodies. With relative movements without lubricant, dry friction or solid friction results. The amount of the resistance depends on the size, the texture, and characteristics of the contact surfaces. This includes

- the material combination (strength and deformation behavior, heat conduction, and chemical characteristics);
- the design combination (shape, surface profile, and roughness);
- the operating conditions (kind of stressing: duration, time history, pressure, temperature, and relative speed);
- the environmental medium (chemical affinity between friction partners and environmental medium in connection with the mechanical–thermal energy in friction contact);
- the type of manufacturing process;
- the degree of deformation;
- the formation of reaction layers; and
- the degree of movement (the relative speed and static and dynamic adhesion factor).

Owing to the roughness of technical surfaces, the contact of fixed bodies is always only "discrete." Compared to the nominal, in reality, there is a much smaller contact surface, as the contact only occurs on the roughness peaks. The true contact surface is formed from the sums of these partial surfaces (percentage: contact area). The result is a much higher surface load than the surface pressure formed by the nominal contact surface. This results in elastic and plastic deformations of the roughness and the surface profile, which increase with normal force. In contrast to the nominal specific surface pressure, however, the real surface pressure does not increase proportionally with the normal force. Deformations and wear lead to hardening of the surface layer, a increase of the contact ratio and cause a change in the friction characteristics (embedding).

The friction force is composed of a deformation and a shearing part: the elastic part of deformation causes vibrations of the roughness peaks affected by the friction process. These vibrations are irreversibly converted into

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto024
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

inner energy (heat). The softer body, whose roughness peaks have a lower spring stiffness, receives the largest portion of the energy. Whether it also retains and depends on the heat conductivity and the heat capacity of both bodies (heating- up).

The shear force portion of the friction force is due to adhesive force from cold welding and adhesion forces between the oxide layers. The adhesive forces are dependent on the mixture of the oxide layers that in turn are dependent on the mechanical and chemical characteristics of both surfaces, as well friction energy density. The friction energy density can locally lead to very high flash temperatures of several thousand degrees centigrade in the friction path. This stimulates the formation of oxide layers with lower hardness and lower shear resistance that results in a decrease of the adhesion factor (lining fading). This process is a great disadvantage for the vehicle brake, as the brake performance is directly dependent on the adhesion factor. However, a certain continuous renewed oxide layer by wear, also called *friction carbon layer*, is necessary for a constant, stable adhesion factor (Figure 27).

Brake linings consist of a formula of varying materials that are bound with phenolic resin. During manufacturing, the mixture substance is pressed onto the lining back plate either cold or warm. After the installation into the vehicle, the linings do not yet deliver the target adhesion factor. Not enough friction contact surfaces lead to high local friction temperatures with low adhesion factors. After a little while, the linings are ground in and optimal adapted to the disk and to the movements of the brake housing (embedded). In addition, the disk surface did also run in. In general, the adhesion factor also improves after the lining has experienced higher temperatures once during the braking processes and has hardened due to outgassing. However, during the entire lifetime of a lining (approximately 50,000 km), the adhesion factor does not in anyway remain constant.

The adhesion factor depends on the contact pressure, the temperature, and the speed of the vehicle and the disk (with constant vehicle weight). After violent braking, which affects most of the decrease in adhesion factor, the brake linings have the ability to regenerate in the course of the stops following. They are stable against extreme adhesion factor fluctuations (fading) and are not sensitive to wet conditions and salt. The wear of a brake lining should be as low as possible to realize a high lifetime and a narrow design. The friction process, however, leads to oxidation processes that accelerate the mechanical abrasion as well as wear. Often, a specific wear is necessary to ensure comfort characteristics.

The temperature sensivity of the wear from the lining material should be small. Tears or edge breakage due to thermal stress can be ignored in today's series linings. In this context, the coordination of friction partners is important, so the brake disk or the brake drum on the lining. Structural conditions and hardness can shift the wearing process from "lining *eats* the disk" to "disk *eats* the lining." In general, the disk or drum lifetime is twice that of the lining lifetime. The characteristics of the lining materials are as follows:

- high breaking strength against chipping
- high shear strength against loosening from the back plate
- low natural frequency with good damping characteristics
- an average compressibility for good comfort, which, however, keeps the brake from becoming too soft
- low heat conduction to isolate against the brake fluid
- small heat expansions to prevent rolling away while using the parking brake
- no formation of residue on lining or disk/drum
- corrosion resistance.

Today, comfort behavior is more and more important. Thus, a buildup of friction vibrations is critical, if it leads to rattles and steering wheel vibrations. The response and threshold behavior of the brake depends significantly on the friction and compressibility. Compressibility leads to increased pedal travel, and adhesion factor changes effect pedal force changes. A modern lining must not make any noises out of the friction combination and the entire brake system during the whole lifetime; the lining must rathehave damping effects on the vibration system.

6 SUMMARY

Modern vehicles have disk brakes for performance reasons and drum brakes for cost reasons.

Large energy storage devices are made out of gray iron for performance reasons and energy storage devices are made out of alternative materials for weight reasons

(aluminum, fiber reinforced ceramics, and carbon fibers). The latter can only store a clearly lower amount of energy with the same design space. Friction brakes ensure safe braking up to standstill, and these brakes can securely hold the vehicle mechanically and without energy conduction.

The secure design of the brake systems is optimized by electronic control systems (ABS, ESP, EVB—electronic brake force distribution, BA—brake assistant). Comfort and safety functions (EPB, ACC—adaptive cruise control—speed and distance contol unit) reduce operation force and support the driver while driving and braking.

The man–machine interfaces are more and more understood (response behavior, pedal feel, and indicator lights).

Everything that the driver experiences in brake technology in the vehicle is a compromise decided by the manufacturer between costs, lifetime, and a performance, which usually goes far beyond the legally required levels.

The Development of Alternative Brake Systems

Bernd D.M. Gombert, Martin Schautt, and Richard P. Roberts

RG Mechatronics GmbH, Seefeld, Germany

1 INTRODUCTION

Brake system development has always been characterized by the search for and development of new technologies. Although this initially concentrated on the optimization of systems driven by pure muscle power, over the past 150 years, there has been a steady increase in the importance of powered brakes, as a response to both heavier vehicle weights and higher speeds. There has also been repeated interest in self-reinforcement as a means of lowering brake forces, either for the driver or for the actuation system. Critical to the success of such developments has been the provision of good controllability, repeatability, and comfort for the driver. Economic viability and a well-considered safety strategy are of course also essential to any such system. Such hurdles have resulted in many promising systems not being brought to the mass market, but either being restricted to niche applications or disappearing altogether. Some ideas have then reappeared as the technological boundaries have expanded, for example, due to the introduction of powerful but inexpensive microprocessors.

The future of the automobile will be significantly shaped by networked sensors and electronics and increasingly powerful driver assistance systems. These will exert even more influence on the major vehicle controls than is currently the case, intervening in the drive train, brakes, and steering. Starting with ABS (anti-lock braking system) and ESC (electronic stability control), it has been possible to control the vehicle in ways, which are simply not possible for the driver, who has neither the information available (e.g., individual wheel speed sensors), nor the ability to intervene appropriately (e.g., braking of individual wheels for ESC), nor the necessary speed of reaction. This trend will continue in the foreseeable future, with the continued improvement of existing systems, more requirements from more electric vehicles (e.g., blending of regenerative and friction braking), and the introduction of new lower bandwidth systems that exploit the possibilities offered by affordable new sensors.

For existing vehicle systems, such as ABS, TCS (traction control system), and ESC, the braking system must be able to control the force at each wheel individually and autonomously from the driver input, which can be zero. This will continue to be the minimum requirement for future braking systems. A simple electronic interface will increasingly be required between the many vehicle level systems and the high performance brake system. At the same time, the overall use of energy should be reduced to minimize the fuel consumption and production of CO_2. A significant step in this direction can be made using components that only use energy when they are actually required, which typically means a move toward more electric systems. At the same time, the desire to increase vehicle safety will ensure that the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

performance requirements will tend to increase rather than reduce.

As a response to these requirements, the automobile industry has already introduced a variety of systems that can be signaled electrically and include some form of power supply, which is independent of the driver's mechanical energy. The simplest form of such a system is the pump in an ESC system, which permits braking pressure to be produced without intervention from the driver. In order to proportion the braking forces between friction and regenerative braking, a smart booster may be used, allowing a relatively straightforward modification to existing braking systems. At the high performance end of the spectrum is the electrohydraulic brake (EHB), where, in normal operation, the pedal only functions as a simulator, which generates an electronic demand for the system. The hydraulic pressure is supplied from an accumulator and the pressure in the individual brake cylinders is controlled by means of proportional servovalves. These examples illustrate one of the key features of "by-wire" systems that the control and energy paths are separate, in contrast to a standard mechanical brake. The signaling is electronic, but the power supply can be hydraulic (EHB), pneumatic (smart booster), or electric. Electric-powered solutions can be either "wet" or "dry." An example of the former is using an electric-driven pump to provide hydraulic pressure, either

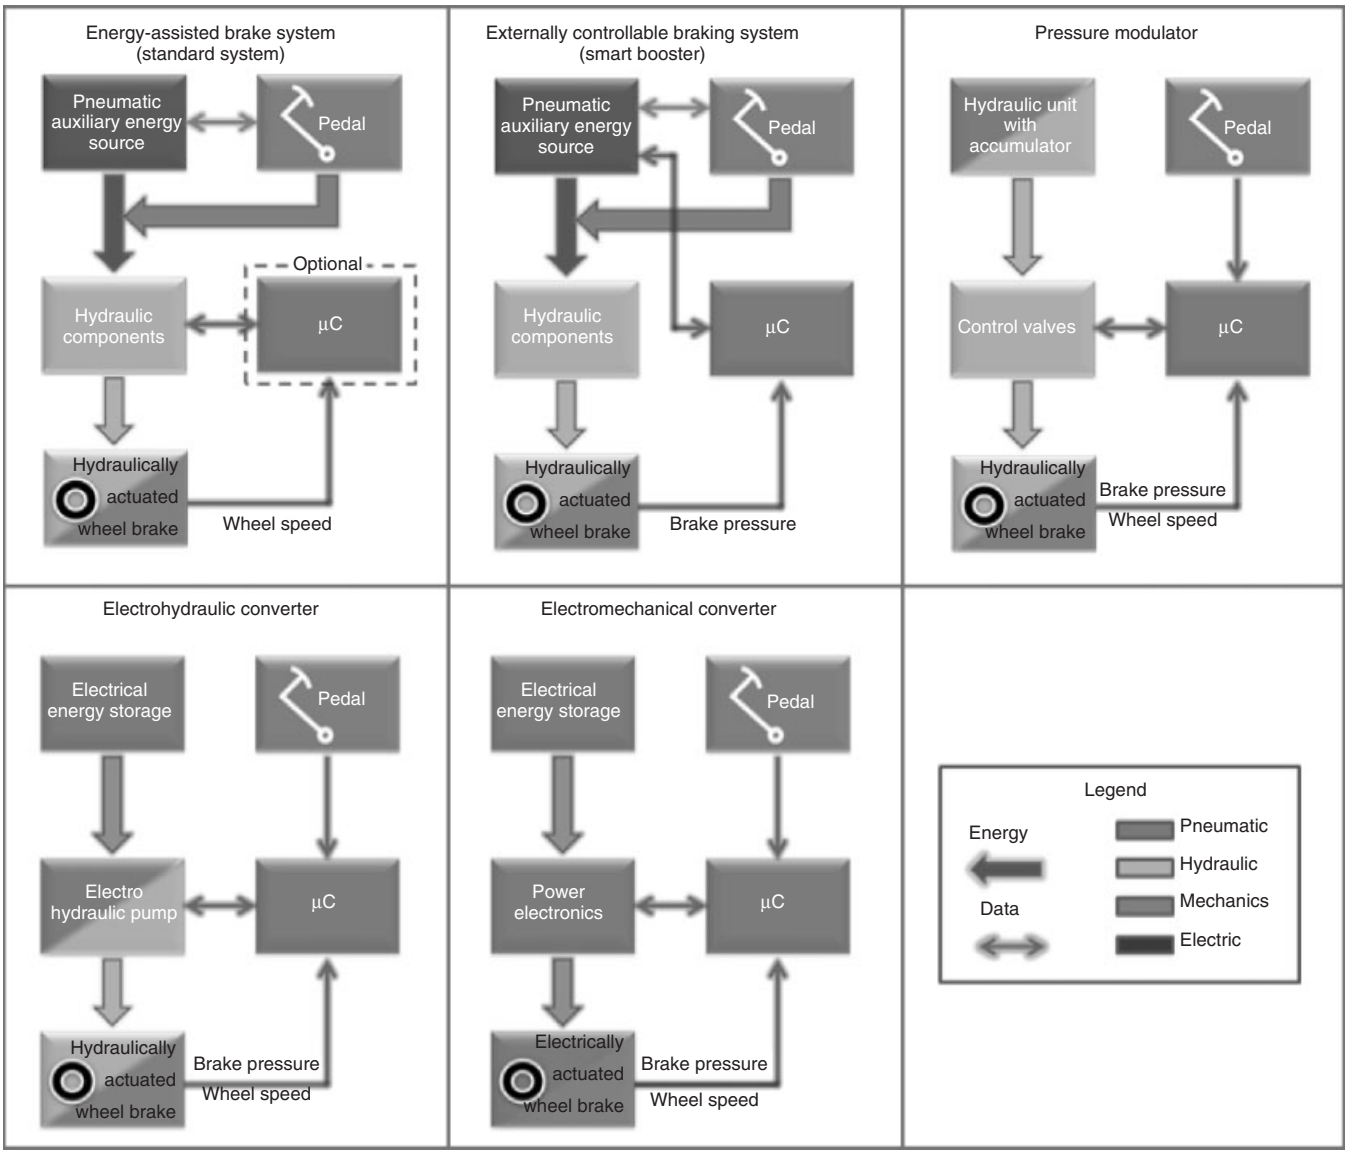

Figure 1. Signaling and power options for brake systems.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on demand or for storing in an accumulator. In "dry" systems, the power is transmitted by purely mechanical means, obviating the need for hydraulics.

An overview of typical possibilities for powering an automobile brake system is provided in Figure 1. Of these five architectures, three can be considered by-wire systems: the pressure modulator, the electrohydraulic converter, and the electromechanical converter. The first two of these use hydraulic wheel brakes, whereas the last one is the only "dry" system illustrated.

Hydraulic systems have the great advantage of being able to store energy at a high energy density over long periods of time without significant losses. This is both an advantage for the system energy supply (a hydraulic accumulator can store much more energy in a smaller volume than a battery) and for the actuation itself. Thus, a constant wheel force can be held simply by closing a valve, without requiring a constant input of new energy, except for that, needed to overcome leakage. This is clearly true of the EHB solution (pressure modulator). Other solutions (electrohydraulic converter), where the hydraulic system can be thought of as a form of gearbox, do not share this advantage, as they have to actively hold the brake pressure. For booster systems, this requires maintenance of a certain amount of suction from the engine, in order to support the driver.

Practical electromechanical systems do not share this advantage and also have to actively hold the brakes closed. This requires current and hence electric power. For a classic electromechanical brake (EMB), this static requirement can be minimized using higher gear ratios, but this conflicts with the actuator dynamics required for ABS systems. Both the achievable rate of change of brake force and the actuator acceleration can be an issue here. This sets an upper bound to the possible gear ratio. The lower bound is effectively set by volume and weight constraints for the brake actuators. Even motors with modern rare earth magnets have a limited torque density and a direct drive system is simply not feasible. Hence, some form of gearing will always be required.

The designer of a classic EMB is therefore faced with a dilemma: if the gear ratio is too low, the long-term power requirements will be higher, which will have an impact on the long-term fuel consumption of the vehicle (not to mention higher requirements on the power electronics, etc.); should it be too high, then achieving the necessary dynamics for effective ABS control will demand high power peaks. These will have very little impact on the fuel consumption directly but will significantly affect the dimensioning of the vehicle power supply. Confronted with this problem, a general consensus has developed within the automobile industry that conventional EMBs are a possible solution for the rear axle but that a 42 V power supply is required, if they are to be used for the front brakes. Consequently, conventional EMBs are still under consideration within the industry. However, alternative approaches have been sought in order to meet all requirements with 14 V power supplies.

Within this chapter, we consider various approaches to the problem of dry brake-by-wire (BBW) actuators. In nearly all cases, an attempt has been made to reduce the required static actuator force. This means that a lower gear ratio is required between motor and brake pad and that the dynamic requirements can consequently be met more easily. The additional benefit is that many components can be reduced in size, providing actuator cost and weight savings.

2 POTENTIAL BENEFITS

The first question that arises is why such developments could be of interest. After all, the performance of existing brake systems is already quite impressive. Some points have been touched on in the introduction but we will expand on them here. It needs to be stated in advance that there is no single overriding reason why such systems have to be introduced. As a result, it will be a judgment on the part of OEMs and suppliers as to when/whether a switch is made. However, when this point is reached, none of the major players can afford to be left behind.

Firstly, it is clear that the coming years will see increasing electrification of vehicles. A wide variety of systems is possible, with mild hybrid systems at one end of the spectrum and electric or fuel cell vehicles at the other. The former will become common in the mass market, whereas the latter will probably be restricted to small production runs in the near future. For all vehicles, there will be a trend to lower fuel usage and reducing CO_2 output, as a response to rising fuel prices and as part of a political solution to achieving climate goals. Within the European Union, this has resulted in the regulatory requirement to reduce fleet average CO_2 production to 95 g/km by 2020. The significant savings offered by hybrids and electric vehicles in city traffic, where a significant proportion of drivers live and commute, will mean that more electric vehicles have an important role to play in meeting such goals. Such developments are also being pushed politically.

As a result of this increasing electrification, more electric energy (and power) will be available in vehicles. Minimizing its use is important both for reducing CO_2 output for more conventional vehicles and for ensuring

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

maximum range for minimum battery size in electric vehicles. Efficient use of the available energy and power requires the following:

- *Minimizing* quiescent power losses (power on demand)
- *Maximizing* the efficiency of the individual components
- *Controlling* power consumption via
  - Intelligent power/battery management
  - Intelligent consumers.

The consumers themselves have to be prioritized so that essential systems (e.g., steering and braking) are always provided with sufficient power, whereas comfort systems, especially those with a large power draw (e.g., seat heating), can be either controlled or disabled, should the need arise. This requires significant information flow around the power management system and demands that the critical systems can signal their needs before the power situation becomes critical.

Thus, we can see that

- the primary signaling interfaces are *already* electronic;
- the primary power interface is *becoming* electric;
- energy-efficient solutions are required, both in operation and when "off";
- more central intelligence will be required for power management;
- more local intelligence will be required to enable the power management to function properly;
- more communication will be required between "better integrated" vehicle systems, to permit optimum use of the available power and energy.

All of these factors point to more automotive by-wire solutions in the future. The main advantages of electrically powered systems are that, if correctly implemented, they only need to draw power when it is actually needed (e.g., electric power-assisted steering) and packaging, installation, and maintenance can be simplified. They are also clearly compatible with situations such as a hybrid vehicle driving in electric mode.

The issues discussed earlier are valid for any vehicle system. However, what would be the advantages of a dry BBW system? The first obvious issue is removing the hydraulic fluid itself. This saves time and hence costs during the production process and in servicing, particularly as there is no longer a need to bleed the brake system. It is no longer necessary to replace and dispose of the fluid several times during the vehicle lifetime. The brake booster and vacuum pump can be removed from the engine compartment, saving considerable volume. The lack of hydraulic architecture permits more flexibility in the system design and contributes to a more modular system, which is easier to assemble.

Perhaps the most important gains can be obtained in the pedal region. The pedal is reduced to a feel simulator system with sensors. This removes any sort of direct connection with the brakes themselves. This has significant benefits for the passive safety and for reduced noise transmission into the passenger compartment. Pedal force and travel is no longer constrained by the requirements of the hydraulic brakes themselves, so the travel can be reduced without any significant effect on the system. The feel can then be made exactly the same for a range of vehicles and can be potentially be tuned via software to individual requirements (e.g., 5% female vs 95% male). Mounting the pedal unit should be simpler and the location of the supporting structure is less constrained by other components. Finally, there will be no pulsing of the pedal during ABS interventions—some see this as an advantage and some as a disadvantage.

As regards performance, electric systems are by nature more linear than hydraulic systems and less sensitive to temperature (viscosity of hydraulic fluid). Individual wheel braking is of course implemented as standard. Experience suggests that it is possible to make an all-electric braking system perform as well as a very "highly tuned" hydraulic system and significantly better than most conventional systems. Traction control interventions in particular can be made smoother than existing systems. Tuning can be performed by means of software, which makes the process quicker and more flexible. Thus, the same hardware can be "branded" differently by adapting the software. The additional electronics provide new possibilities for system diagnosis and fit well with the concepts of intelligent power management.

3 BRIEF REVIEW OF ALTERNATIVE SYSTEMS

Two separate issues are addressed in this section:

- The various proposed brake systems
- Proposed vehicle configurations.

Different developers have taken different routes to realizing the goal of a dry BBW system, all probably with slightly different motivations. As yet, none of these systems has been applied to a mass production vehicle, although some have come close. Our review here is based on published information, which means that some developments are probably excluded, either for lack of such information or because it has not come to the attention of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the authors. Many suppliers and OEMs choose to be very discrete about their developments.

3.1 Brake actuators

We will split the brake actuators into two groups: those, which do not use self-reinforcement and those, which do. While self-reinforcement offers significant benefits, the brake response can easily be influenced by varying friction—coefficient between pad and disk, requiring higher gain controllers to ensure repeatable performance. There are also other risks, which we will address later. As a result, much development has focused on more conventional actuators, which were seen as lower risk solutions.

3.1.1 Actuators without self-reinforcement

3.1.1.1 Conventional electromechanical brake. Conventional EMBs consist of a motor, gearbox, and a ball- or roller screw, which replaces the hydraulic piston. They have been investigated by a large number of organizations, and one sample of collaboration between industry and academia is given in the article by Schwarz *et al*. (1998). As discussed earlier, a consensus has developed that a 42 V supply is required to power such actuators for the front axle of a passenger vehicle. Development of such systems has stalled; therefore, the prospect of a vehicle using pure EMB has receded.

Nevertheless, there is still interest in these actuators. The main reason is that it is relatively straightforward to include a latch mechanism in the gear train and so to produce an integrated parking brake. The actuator can be sized for the maximum parking brake force and used on the rear axle of the vehicle with a conventional 14 V supply. As braking forces when driving are generally relatively low on the rear axle because of stability considerations, the actuator dynamics are adequate for existing ABS/TCS applications.

3.1.1.2 Maximum torque brake (Delphi). The maximum torque brake (MTB) was an attempt to solve the problem of using an EMB on the front axle of the vehicle. The idea is relatively simple—instead of one brake disk, the MTB uses two. This doubles the number of friction interfaces and hence approximately halves the actuator force required compared to the EMB. Assuming the same motor, sized on long-term torque requirements, the gear ratio can therefore be halved. As nearly all the inertia is in the motor itself, this change results in approximately double the rate of change of brake force and four times the acceleration of the conventional solution. This provided sufficient dynamics to allow the MTB to be installed on the front axle with a conventional 14 V power supply (Smith and Hudson, 2003).

The most difficult engineering challenge here is in ensuring that all the sliding components move correctly relative to one another under all conditions and throughout the vehicle lifetime.

While development effort on the MTB seems to have ceased, this approach is clearly one way of overcoming the limitations of the conventional EMB. The concept can also still be powered by hydraulics if required, perhaps offering some economies of scale. In addition, it is certainly possible to make such concepts work: aircraft brakes have long relied on stacks of rotors and stators to provide the necessary energy absorption. These systems are also now moving in the direction of electric actuation.

3.1.2 Actuators with self-reinforcement

A second path to reducing the actuator forces and improving the dynamics is to use self-reinforcement. This can ideally result in the condition that no actuator force is required to produce any given braking force. While this was seen as a hard boundary for hydraulic actuators (which were only designed to push), for electromechanical actuators, this is actually the point of neutral stability. When the self-reinforcement goes beyond this point, the actuator is unstable and requires a controller to stabilize it. This means that, in the event of a failure, some independent means is required to ensure that the brake fails open.

A second issue arises with self-reinforcement, namely what happens when it disappears, typically due to the vehicle stopping. This is particularly critical on a slope. For example, if a car is braked to a halt going up a hill, then, once it has stopped, it will try to roll backward. Thus, the force, which should normally be assisting the brake, acts against it and tries to open it. Some strategy is required to deal with this problem smoothly and safely.

3.1.2.1 Electronic wedge brake. Considerable development work was conducted on the EWB by Siemens VDO in the period between 2004 and 2007. It was designed to use self-reinforcement in both the stable and unstable regimes, so as to obtain the maximum benefit from the technology (Hartmann *et al*., 2002). Adjustment for wear, a parking brake function and a fail open function were implemented in an additional mechanism to the main brake actuator. It was possible to demonstrate vehicles containing all the main modern brake control functions (ABS, TCS, and ESC), which could operate using a 14 V supply.

At this point, it is worth considering why this can be the case. It has been noted by other authors that the energy

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

required to expand the caliper is not that high, with the implication that self-reinforcement is redundant. We will examine the benefits by means of calculations based on simple assumptions.

Firstly, for a conventional EMB, we will assume a linear caliper stiffness of 20 kN/mm and a maximum clamping force of 35 kN. The energy required to achieve the maximum clamping force is therefore

$$E = 0.5 \times F_{\text{Max}} \times \Delta x_{\text{Cal}} = 0.5 \times 35{,}000 \times \frac{35{,}000}{20 \times 10^6} = 30.6\,\text{J} \quad (1)$$

Assuming the maximum force is for a fading case and that this needs to be achieved in 0.2 s, then the power required per brake to reach this force is an average of approximately 150 W over this 0.2 s, ignoring the mechanical losses.

For a wedge brake with actuation in the plane of the disk, the actuator requires lower forces to achieve the same clamping force but has to move further. Hence, if α is the wedge angle and μ is the coefficient of friction between pad and disk, then

$$E = 0.5 \times F_{\text{Max}} (\tan\alpha - \mu) \times \frac{\Delta x_{\text{Cal}}}{\tan\alpha} = \left(1 - \frac{\mu}{\tan\alpha}\right) \times 30.6\,\text{J} \quad (2)$$

Thus, excluding the mechanical losses, the wedge brake will always require less energy than the conventional solution as long as $\mu < 2\tan\alpha$. For high friction coefficients, the energy works the opposite way round to a conventional brake: the EWB requires energy to open the brake rather than to close it.

To consider the dynamic case, we have to make some more assumptions. We will assume that the wedge brake is constructed with $\tan\alpha = 0.35$ and that it is designed to operate normally for $0.15 \le \mu \le 0.55$. This means that the actuator force is reduced to 20% of that required by an EMB. Assuming we use the same motor, dimensioned so that it can hold the maximum steady torque indefinitely for both applications, then the EWB requires a gearing factor 5 less than the EMB for the same application. If the EWB must rotate at 250 r/s to meet the requirements for rate of change of force, then the EMB must rotate at

$$\omega_{\text{EMB}} = 5\tan\alpha \times 250 = 437.5\ \text{r/s} \quad (3)$$

We will assume that the motor has an inertia of 25 kg mm^2 and that this dominates the inertia of both systems. Hence, the kinetic energy required to achieve the same dynamics for the two brakes is

$$\text{KE}_{\text{EMB}} = 0.5 \times 25 \times 10^{-6} \times 437.5^2 = 2.39\,\text{J} \quad (4)$$

$$\text{KE}_{\text{EWB}} = 0.5 \times 25 \times 10^{-6} \times 250^2 = 0.78\,\text{J} \quad (5)$$

If we now consider that the maximum speed must be reached in the order of 10 ms to produce good ABS control, then the average mechanical power required for the EMB is 239 W whereas that for the EWB is 78 W. The peak power will of course be considerably higher than this.

Thus, the main advantage of the wedge brake is in providing superior dynamics for the same power. This has been demonstrated in dynamometer and vehicle tests. The penalties are as follows:

- More complicated mechanics (forward/backward braking, adjustment, and emergency release functions)
- More complicated control.

3.1.2.2 Cross-wedge brake (Mando). Mando has also been developing a wedge brake to allow braking with a 14 V supply (Kim, Kim, and Kim, 2009). The so-called cross-wedge mechanism has been used, with the aim of producing even pad wear and avoiding the use of rollers, which were felt to be vulnerable to contamination. High force amplification was not a goal, and a subjective view of the wedge design based on the publications seen suggests that the brake should normally operate in the stable regime ($\tan\alpha \approx 0.75$). This would obviate the need for an emergency release mechanism (assuming the friction coefficient can be guaranteed). However, the use of a worm gear to change the direction of the drive through 90° raises the question of whether the system can be back-driven open. An electric parking brake (EPB) function has been integrated into the brake (Kim *et al*., 2010), which is thought to be implemented by disabling the motor and allowing the worm gear to hold the force. If so, this would cause problems with the system safety requirements, which should demand that a faulty brake is opened if the vehicle is moving.

Results have been presented, which show that the brake can be used for ABS and ESC control, although the authors admit that the performance is not yet equivalent to a conventional brake system (Kim *et al*., 2010).

3.1.2.3 VE brake. The Vienna Engineering group has proposed a solution, which relies on a nonlinear lever mechanism to provide a limited degree of self-reinforcement (Putz, 2010). Because of the mechanism, both the overall mechanical advantage and the effective wedge angle vary with position. It is designed to produce a higher force ratio at higher forces but should not become unstable. Thus, no

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

additional release mechanism is required, as long as this can be guaranteed. A parking brake function can be integrated in the brake, although its precise implementation has not been specified in the published literature. At the moment, only dynamometer results have been published, but it is clear that vehicle tests will follow (Vienna Engineering, 2011).

In the view of the authors, the main challenge here is that the bearings in the lever mechanism must be able to support the forces acting on the active pad and rotate freely for the lifetime of the brake.

3.2 Vehicle concepts

A second aspect of the development of advanced brake systems is the configuration to be applied in the vehicle. As mentioned earlier, none of the systems has yet reached series production, so all of the solutions mentioned here must be regarded as provisional.

3.2.1 Rear EMBs only

In this configuration, the front axle of the vehicle retains an existing hydraulic brake system, whereas the rear axle uses EMBs, ideally with integrated parking brakes. As a means of introducing the BBW systems to the market, this approach has several advantages:

- The design requirements for the hydraulic system are simplified.
- The rear axle suits the strong points of the EMB and permits a 14 V power supply.
  - No additional parking brake required.
  - Simple integration of hill-holder type functions within the brake system.
  - Fail-silent and adjustment functions without any additional mechanisms.
- The safety concept can build on that for conventional systems.
- Service experience with such a hybrid concept will help generate reliability data for later systems.

Continental has, for some years, been developing an electrohydraulic combi (EHC) brake based on this approach (Neunzig and Linhoff, 2009).

3.2.2 Front and rear EMBs

At the start of interest in dry BBW systems, this was naturally the favored configuration. As discussed earlier though, it was determined that such an approach is only practical when a 42 V supply is used. Consequently, at the time of writing, such configurations do not appear to be being seriously investigated.

3.2.3 Rear EWBs only

Mando is investigating a vehicle with their cross-wedge EWBs on the rear axle (Kim *et al.*, 2010). It is not known whether this is intended to be representative of a production configuration or it is only intended for prototype testing. In the opinion of the authors, it must be the latter, because this configuration gains the minimum advantage from self-reinforcement while being most susceptible to its disadvantages (see, e.g., the following section).

3.2.4 Front and rear EWBs

This configuration was successfully investigated by Siemens VDO. The performance of the system was extremely good and more than lived up to expectations.

The main challenges, which arose, were mainly the result of changes in direction of, or loss of, self-reinforcement. As discussed earlier, on coming to a halt forward on an up slope, the direction of the self-reinforcement changes. If nothing is done, the EWBs will draw a high current and may not be able to hold the vehicle stationary. The solution adopted was to split the braking directions of the EWBs just before the vehicle stopped: the front axle remained in the forward direction whereas the rear axle was set to brake backward. Should the direction of the self-reinforcement change, then there is always one set of brakes, which will hold the vehicle. The overall braking force was held approximately constant while this occurred. On stopping, a brake current limit was introduced to prevent the system using too much power. Because of the high degree of self-reinforcement, the brakes, which were acting in the "correct" direction, could always hold the vehicle using this reduced current.

This works well in most circumstances, but it is more tricky in the case of rear-wheel drive cars, particularly automatics. Here, the driven axle can continue pushing against the closed brakes, increasing the current required to hold them closed. Should traction control be required at low speed, then there is also the danger that the rear brakes will continually be changing direction to allow for the (potentially) different directions of self-reinforcement. Switching round the directions of the braking on the front and rear axles is not attractive because the system is then always trying to brake with the "wrong" axle at low speed.

An additional motor was required for the EPB function. To avoid producing a conventional EMB for this case, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

EPB force was reduced and distributed between all four wheels. This is not ideal for the critical case of holding the vehicle on a slope with a loaded unbraked trailer attached.

Such issues will be relevant to all the proposed systems that use self-reinforcement. Clearly, the lower the level of the self-reinforcement is, the less critical the problem becomes.

3.2.5 Front EWB and rear EMB

MOBIS has prepared a prototype vehicle in which the axles each have a different dry by wire brake (Cheon *et al*., 2010). It appears to be a well-thought-out solution, because it uses the actuators where they show most potential:

- The EWBs on the front axle require only a 14 V supply, as with the Siemens vehicles.
- The EMBs on the rear axle implement the parking brake function and are not sensitive to changes in direction.

Using this type of concept, it would be possible to increase the braking force on the rear axle once the vehicle has stopped, so that there is no danger of the vehicle moving.

While for production systems, the two different types of actuators might be regarded as a cost disadvantage, in terms of the system safety, the possibility of common mode failures is significantly reduced.

4 CHALLENGES

It is clear from what has already been written that there are benefits to be had from introducing new BBW systems and that there are solutions, which are technically feasible. However, while there has been done considerable research on this topic during the past decade and a half, there is no such system on the mass market yet. This alone demonstrates that there must be significant hurdles to overcome. So, what are they? We will list some of the major issues.

4.1 Somebody has to be first

This category contains a range of issues, for which we could think of no better title. Because no such system exists, there is no single set of requirements, which can be applied to it, so there is no well-defined set of rules to work by. Within ECE-R13H, it can be seen that there are passages, which have been added to accommodate the EHB. For any developers of future EHBs, it is therefore possible to follow these guidelines and it should be possible to obtain certification for a large number of markets. While the first one to market a dry BBW system may have the advantage of being able to help write these regulations, this requires considerable extra effort and liaison with a number of safety authorities. There is also the possibility that competitors may not only offer constructive criticism in such cases!

Any such system will now be subject to ISO/DIS 26262. This also represents a challenge, because the standard is still new and not all the associated documentation is yet available (mid-2011). In some cases, it may still be necessary to fall back on the IEC 61508, because not all the processes are completely clear, especially for such a complex system as this. This will again require additional effort and specialized personnel.

The fact that there is no internationally agreed path to certification is a major obstacle. Until such a process is agreed, there will remain a residual risk of having to repeat tests and certification work, even if the development is almost complete.

Assuming these issues are overcome, there is then the issue that the OEMs may require two independent suppliers for such systems. This is obviously not likely to be the case, and this means that at least one supplier will have to have an OEM firmly "on-board" before deciding to go ahead with production.

4.2 Costs

Costs will always be a challenge, especially now that even relatively high technology brake systems are more-or-less sold "by the kilogram." A supplier has to be willing to invest a lot of money up front to produce a system and must be very sure that there will be sufficient return on it. Quantifying exactly the scale of investment is also not easy, because of the issues mentioned earlier.

In uncertain economic times, this requires some courage, not least because existing brake systems will not stand still, neither in capability nor in price. Moreover, it will be more difficult to leverage low labor costs for a new, high technology system than for well-understood, conventional systems. Finally, competitors will be certain to make life more difficult when the new product is ready to be launched.

Thus, as always in the automobile industry, cost control will be a key factor in a successful development process.

4.3 Reliability/availability

A system containing many electronic components will have to be very well designed and tested to achieve reliability

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

rates comparable with a "dumb" hydraulic system. There is simply more that can go wrong. In addition, some of the electronic components are likely to be located in harsh environments (wheel well, with shock and vibration, and large temperature changes), which will not make this any easier.

4.4 Conclusion

In general, it is clear why there is a marked reluctance to be first in the field, despite the potential of dry BBW systems. It is perhaps not surprising that an "outsider," such as Siemens VDO, has to date been the most willing to push their development: they have the most to gain and the least to loose. Existing suppliers are often satisfied with the status quo, which is more predictable and which (still) produces reasonable margins, especially for "higher level" brake functions. In Germany, in particular, there is also the memory of the introduction of the EHB, which has made suppliers and OEMs alike more risk averse. At the same time, nobody wants to be left too far behind should the market take off.

Both these factors perhaps explain Continental's development of the EHC brake, which represents a stepping stone in this process. There is an understandable desire to minimize risk and also to ensure that the hardware is really ready for production before introducing it.

5 EXAMPLE: ELECTRONIC WEDGE BRAKE

Here, we discuss some of the experiences gathered by the authors during the development of the EWB. We split the section into subsections devoted to a particular topic.

5.1 Mechanical design

A good mechanical design is clearly the basis for any successful product. In the case of the wedge brake, there were several difficult problems to be solved in a relatively confined space.

The first obvious issue is that the brake must be actuated in two directions. This demands motion perpendicular to the direction of travel of the roller screw. The solution chosen was to attach the roller screw to the wedge with reinforced leaf springs (to prevent buckling). The forward actuation was designed to be in the plane of the wedge angle, so that normally no perpendicular motion was required. In the reverse direction, the motion was proportionally quite large, but the travel was reduced because smaller braking forces were needed. A view of this design is provided in Baier-Welt and Schmitt (2007).

The next major issue was the force sensor. Here, a new development was undertaken to produce a sensor integrated in the caliper using cheap Hall sensors to measure the relative deflection of a loaded and unloaded part. The noise level from this sensor was noticeably lower than that of the load cells used in the early prototypes, but it was more sensitive to drift. Some detail about this development is provided in Baier-Welt (2007).

The most complicated single development was that of a mechanism to implement the following three functions:

- Emergency release (fail silent)
- Pad wear adjustment
- Parking brake.

This was built around a second motor, a solenoid, and a cam. During normal operation, a roller sat on the cam slope, supporting the brake clamping force. The cam was actively locked by means of the solenoid. In the event of a loss of power, a spring opened the solenoid and the cam released the brake force. The pad wear adjustment relied on interaction between the solenoid and the secondary motor and could not be conducted under load. Finally, the parking brake used a stable depression in the cam surface to hold load without power. Illustrations of these functions are provided in Baier-Welt (2007).

5.2 Actuator control

Control was obviously a major issue in the development of the EWB, simply because the wedge can be unstable. Any controller has to be able to address this fact. The taken approach was to design a controller, which could stabilize the brake, even if the friction coefficient between pads and disks was 1. This also required an estimate of this friction coefficient, so that the motor could not be overpowered and pulled in.

Two different approaches were taken, which were to some extent dictated by the mechanical design. The early Beta prototypes were designed with two motors so that drive-train backlash could be actively removed (Roberts *et al*., 2003, 2004). They were also stiff in the axial direction. The latter property allowed the controller to be based on a conventional cascaded design, with an inner current loop, followed by a rate loop, and an outer force control. The motors were controlled either to remove backlash if the friction was close to the ideal value or to cooperate if more axial force was required. Brief details are provided in Ho *et al*. (2006) and Lang *et al*. (2006).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto025
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The preproduction prototypes were all based around a single motor. On the one hand, this simplified some of the control, but on the other hand, the mechanism required for forward and backward brakings was much more flexible in the axial direction than in the earlier hardware. For this reason, it was necessary to use a state "feedback" controller. The system was stabilized for a μ of 1.0 and a conventional PID controller was then used to achieve the desired performance. This process is discussed in Fox *et al*. (2007).

5.3 Vehicle control

Vehicle level systems were designed and optimized with considerable use of simulation tools. This, together with the well thought out structure, enabled a comprehensive system to be produced in a relatively short time. It also simplified the process of adapting the control to different vehicles.

A hierarchical structure was built up, with slip controllers at the lowest level to manage ABS and traction control interventions, and a vehicle dynamics controller at the level above this. This implemented the brake force distribution, ESC, and some wedge-specific functions (e.g., direction control). This structure helps produce relatively smooth interventions, which were not only of benefit to passenger noise and comfort but also suit electromechanical actuators in general, where the motor inertia is an important influence on performance. More details are provided in Semsey and Roberts (2006).

5.4 Functional safety

A description of the approach to functional safety is provided in Schaffner *et al*. (2006). The brake system requirements were taken as far as possible from ECE-R13H, whereas IEC 61508 was used to cover the electrical and electronic components. At this stage, ISO 26262 was still a working draft and it was mainly used for categorizing risks into ASILs (automotive safety integrity levels). Three major categories of failures were found to lead to ASIL-D (most severe):

- Unintended braking
- Insufficient braking
- Braking (or lack of it) leading to vehicle stability problems.

After consideration of a number of potential architectures, a solution was proposed based on.

- three pedal sensors (fail-operational)
- two EPB button sensors (fail-silent)
- a central electronic control unit with three microcontrollers (fail-operational)
- two energy management systems, each with an associated backup battery, attached to the main vehicle power supply. Each power channel feeds one brake diagonal, the central electronic control unit, and the pedal unit.

In the case of a single fault, the objective was to achieve either fail-operational or fail-degraded behavior (reduced performance). For a second fault, it had to be possible to bring the vehicle to a controlled stop. For a failure where the next failure could lead to a critical loss of performance, an Auto-Stop function was proposed. This would have led to additional hazards of its own.

5.5 Electronics

The design of the electronics followed the functional safety requirements. A fail-operational central control unit was designed and produced. The wheel unit electronics featured an independent "safing control" processor and were developed in two phases: firstly an external version to check the circuitry and then an integrated version. Considerable thermal modeling and testing was done to support the latter development. It was found that, in order to meet the EMC targets, integration within the actuator was a "must." More information can be found in Zelger (2007).

6 CONCLUSIONS

In this contribution, we have tried to lay out some of the background to the development of dry BBW systems. The technical motivation for such systems belongs to an increasing development over the past few years: more and more manufacturers look seriously at hybrid vehicles and electromobility. Although the level of research being conducted is not currently as high it perhaps has been, there are still a number of organizations working on the problem. There are a variety of different solutions under investigation, both in terms of actuator technology and vehicle architecture. There has even been some new actuator concepts been developed in recent years, relying on limited self-reinforcement.

It is nevertheless easy to see why such systems have not yet been brought to market. There is nothing simple about introducing a revolutionary new product into an established market for a safety-critical application. However, the authors are still in the firm opinion that it is only a question of when this breakthrough occurs, not if. The "fit" between this technology and the trends in automobile development

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is simply too good. Once this occurs, the very obstacles, which have discouraged many from taking this step, will act to secure a competitive advantage for the successful organizations.

GLOSSARY

ABS	Anti-lock braking system
BBW	Brake-by-wire
EHB	Electrohydraulic brake
EHC	Electrohydraulic combi brake
EMB	Electromechanical brake
EPB	Electric parking brake
ESC	Electronic stability control
EWB	Electronic wedge brake
OEM	Original equipment manufacturer
MTB	Maximum torque brake
TCS	Traction control system

Carbon-Fiber-Reinforced Silicon Carbide: a New Brake Disk Material

Andreas Kienzle and Hubert Jäger

SGL Carbon GmbH, Meitingen, Germany

1 INTRODUCTION

Brake disks in cars are safety relevant parts, which require high reliability and a high lifetime. The task of a brake disk is to transform the kinetic energy during braking by friction into heat, which is absorbed by the brake disk and the brake pads. The absorbed heat must be dissipated in the surrounding area by thermal conduction, heat radiation, and convective flow of heat. A brake system of this kind is accordingly limited by the friction characteristics of the brake materials and its ability to store and remove the heat. In general, brake materials must have very good thermomechanical properties, high and constant friction characteristics, and good resistance against abrasion. With the development of the first cars in the late *nineteenth* century, the kinetic energies are still very low but never the less, the cars must be stopped safely. Therefore, there was an increasing demand in equipment, which allows their safe stopping. The first cars used the running surface of the wheels directly for braking. Brake linings out of wood or leather were pressed mechanically by a lever on this running wheel surface. This brake was substituted by the brake drum made out of metal. Brake disks for braking need around another 50 years before they were used in cars. Nevertheless, the first patent regarding to brake disks was granted in 1902 to Lanchester (1902): This patent describes the first time the idea to use a brake disk, which is mounted on the wheel hub. The brake linings were pressed mechanically on the disk surface during braking. The first brake disks out of gray cast iron were used for race applications (Jaguar winning the 24-h race of Le Mans in 1953). Alfa Romeo introduced the first brake disks in road vehicles. The BMW 502 3.2l was the first German car equipped with disk brakes on front wheels, which can be ordered as an option followed by Mercedes 1961 in the 300 SL.

In addition, the development in the material optimization of gray cast iron and in the production process technologies for the production of ventilated disks allowed reducing cost and improved the quality constancy of the material. Nevertheless, the main disadvantages of the gray cast iron disks, that is, like high weight due to the high material density of 7.2 gcm^{-3}, corrosion sensitivity by oxygen and water, limited high temperature stability, and high wear rates, could not be solved. In addition, the speeds, which are attained nowadays by such vehicles, are constantly increasing. Since 1950, the top speed of upper class

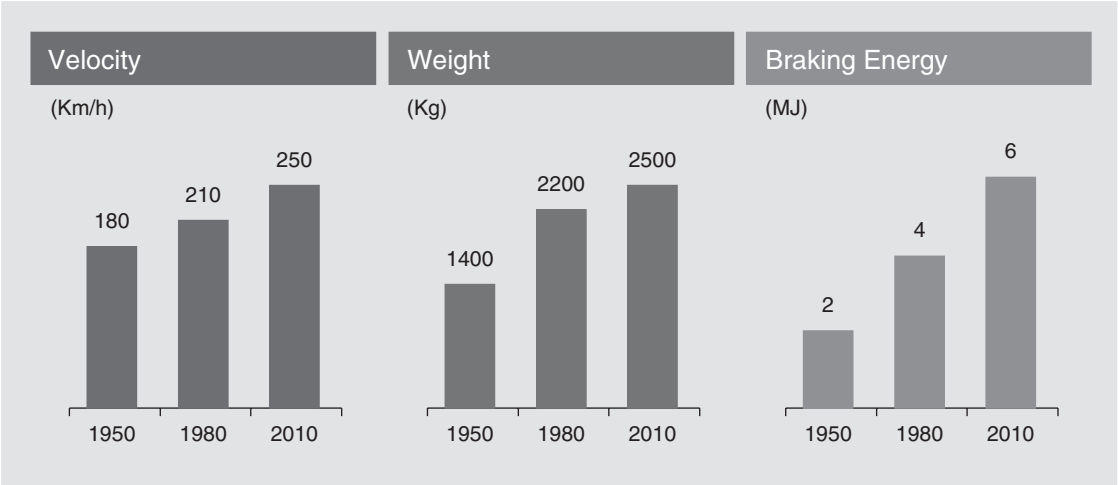

Figure 1. Increase of kinetic energy of upper class limousine shown here since 1950 up to the year 2010 leads to a demand of the automotive industry to look for new brake disk materials. (Reproduced by permission of SGL Carbon GmbH.)

limousine increased from around 180 to 250 km/h in the year 2010. The 250 km/h was a limit decided by the car manufacturer (OEM) for tire reasons. In the same time, also the car weight increases from around 1400 to 2500 kg. This leads to higher kinetic energy from 2.38 MJ in the year 1950 to 6.0 MJ in the year 2010 (Figure 1). This high energy results in a lower lifetime of the metal disks because of the increasing thermal loads during braking. This heat can also negatively result in a reduction of the friction coefficient during braking, called *fading*, with the result of longer stopping distances.

This leads to an increasing demand of the automotive industry to look for new brake disk materials and systems, which are stable under these rising braking conditions.

2 CARBON FIBER AND C/C BRAKES

With the development of the carbon fibers in the early 1960s, a new type of composite material, the carbon-fiber-reinforced carbon (CFC) material, which is made out of these fibers, leads to a new high temperature stable material class. These materials show very low weight because of their low density and found fast interest for high energy braking systems such as race cars or aircraft brakes and railway applications. The used carbon fibers are produced out of polyacrylnitrile polymer (PAN) or pitch-based fibers by carbonization at temperatures up to 1800°C under inert atmosphere. They show very high mechanical strength and high stiffness and additionally they show a very high temperature stability >2000°C in inert atmosphere without losing their mechanical performance. The disadvantages of these fibers are their behavior against oxygen. Owing to the oxidation reaction of carbon with oxygen under the formation of CO and CO_2, they are only stable up to 500–600°C under air. Nevertheless, the C/C brake disks and CFC pad materials developed for race car applications show excellent high friction coefficients that are stable even under extreme loads. The disadvantages of these disks are the low friction coefficient on cold disks surface and also in the wet state of the disk. In addition, the high wear rates especially in the cold disks combined with the high production costs limit this disk material mainly for race or aircraft applications. These disadvantages avoid a broad entrance of this CFC material class in the area of the normal road vehicles.

3 C/SIC BRAKES

The problems of the C/C brake disks could be solved by the development of a new type of brake material: the fiber-reinforced SiC-based ceramic brake disks (CF/SiC). Here, the carbon fibers are embedded in a ceramic matrix made out of SiC. Normally, ceramic materials suffer from their brittle behavior under mechanically and thermally induced stresses, which limit their applications. Different ways to improve fracture toughness of ceramics were developed in the past decades. The toughening of SiC ceramic by C-fibers or ceramic fibers such as SiC-fibers is the most effective way to reduce such brittle behavior (Bader, 1993; Evans, Zok and Davis, 1991) and opens the wide field for the use of this material. First trials to use these types of CF/SiC materials started in the past decade of the last century, based on public-funded projects in Germany for the development of ceramic brake disks for high speed trains.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

First patents for CF/SiC brakes were granted for Krenkel and Kochendörfer (1994). They used woven fabrics for the C/C performs production. After the infiltration of this preforms with liquid silicon, they get the C/SiC material, which could be used as brake disk. The commercialization of CF/SiC brake disks started with the development of the short fiber-reinforced CF/SiC materials. This type of material was first developed at SGL and closely parallel at Daimler Chrysler and described by Gruber and Heine (1997) (SGL) and Haug *et al*. (1997) (Daimler Chrysler) in the patents. This material shows good friction coefficients in cold and wet disk states. Owing to the high hardness and low porosity of the material, it shows additional low wear rates in cold and hot disks. Their low weight (more than 50% reduction of unsprung mass compared to cast iron), high hardness and high stability of resulting friction coefficients, high corrosion resistance, and long lifetime are the main advantages for using CF/SiC ceramics as brake disk material or clutch material for automotive applications and their increasing demands. At the Frankfurt Motor Show in 1999, the carbon-ceramic brake disk was shown the first time to the public. In 2001, Porsche AG was the first car producer who installed the carbon-ceramic brake disk as series equipment into the 911 GT2. Since that time, also other premium cars use the advantages of CF/SiC brake disks. At present, for nearly all high end sport cars and luxury limousines for instance from Ferrari, Porsche, Audi, Bentley, Bugatti, and Lamborghini, CF/SiC brake disks are available (Figure 2). Ferrari equips today all new cars by series with the CF/SiC brake systems. In the year 2011, in total around 80,000 CF/SiC brake disks were produced.

4 PRODUCTION WAYS TO CF/SIC MATERIALS

There are different ways available for the production of carbon-fiber-reinforced silicon carbide, which are summarized in Figure 3. These technologies show different ways to bring in the ceramic matrix in a porous carbon fiber preform under the formation of C/SiC. The technologies used are chemical vapor infiltration (CVI), liquid silicon infiltration (LSI), and the polymer infiltration and pyrolysis (PIP), which bring the ceramic SiC matrix in a carbon fiber preform. These technologies can be used alone or in combination and are explained in the following sections.

4.1 Chemical vapor infiltration

Starting from a porous carbon fiber preform, the ceramic matrix can be impregnated by a gas-phase deposition reactions chemical vapor infiltration (CVI) at temperatures $>1000^{\circ}$C. To control the interface of the fiber to the ceramic matrix, a special interface layer must be deposited on the fiber surface. In most cases, this is a thin carbon layer (several micrometer thickness) deposited by CVI. Subsequently, the types of gases are changed and the ceramic matrix is deposited. Very slow infiltration rates are necessary for this reaction to keep the infiltrating channels open. After several days of infiltration, the surface must be brushed to open closed porosity on the surface. These together with the slow infiltration rates lead to long production cycle times of several weeks and to the high

Figure 3. Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

costs of this technology. The resulting parts produced by this technology show excellent mechanical behavior and a matrix porosity up to 15 vol%.

4.2 Polymer infiltration and pyrolysis

The impregnation of the porous carbon fiber preform with inorganic silicon-based polymers such as polysilans or polycarbosilanes used in the polymer infiltration and pyrolysis (PIP) technology is another way to build up the SiC ceramic matrix around the coated carbon fiber preform. The ceramic composition after the pyrolysis depends on the used inorganic polymer. These polymers are infiltrated under vacuum followed by a pressure cycle in the preform. After the pyrolysis of such impregnated preforms at temperatures up to 1000°C under inert atmosphere, the polymer decomposes and is transformed into a porous amorphous ceramic SiC material. To get a mechanical stable material, these impregnation and pyrolysis cycles must be done several times. Each cycle increases the density and closes the residual open porosity and raising the mechanical stability of the resulting CF/SiC material. Normally up to 5–6 cycles are necessary to get enough density, stability, and porosity lower than 10%. Production times for the PIP route are therefore 1–2 weeks. High process and polymer costs and the polymer availability limit currently this production way. To reduce the infiltration cycles, additional fillers in the preform can be introduced. Use of inorganic polymers such as polysiloxanes or polysilazanes lead to other ceramic matrix materials such as ceramics in the ternary systems Si-C-O and Si-C-N, which are currently not used for brake disk applications. This can be an option for the future.

4.3 Liquid silicon infiltration

The fastest way to produce CF/SiC brake disks is the reaction way via the LSI process. Here, the liquid silicon is infiltrated at temperatures higher than the melting point of pure silicon (>1420°C), in the porous C/C preform. To increase the infiltration speed, the infiltration is done under vacuum. The liquid silicon is infiltrated by capillary forces in several minutes into the porosity of the preform and reacts with the carbon matrix in a strong exothermic reaction under the formation of β-silicon carbide (Figure 4).

The residual porosity of the material is filled with the unreacted excess silicon. This LSI production way allows a fast production of C/SiC parts. The resulting material shows a low porosity of <1%. A small dimensional change only during the transfer from the CFC part to the ceramic part is a great advantage of this advanced technology.

For the CF/SiC brake disk, the LSI process is currently the mainly used process for production.

5 ELEMENTS OF A CERAMIC BRAKE DISK

The ceramic C/SiC brake disk of today is normally built up out of the following elements (Figure 5):

- The CF/SiC carrier body is the main element of the brake disk. It has the task to transfer the forces and to store and transport the heat, produced during braking. Therefore, the material of the carrier body must have a high mechanical stability and ductility and a good

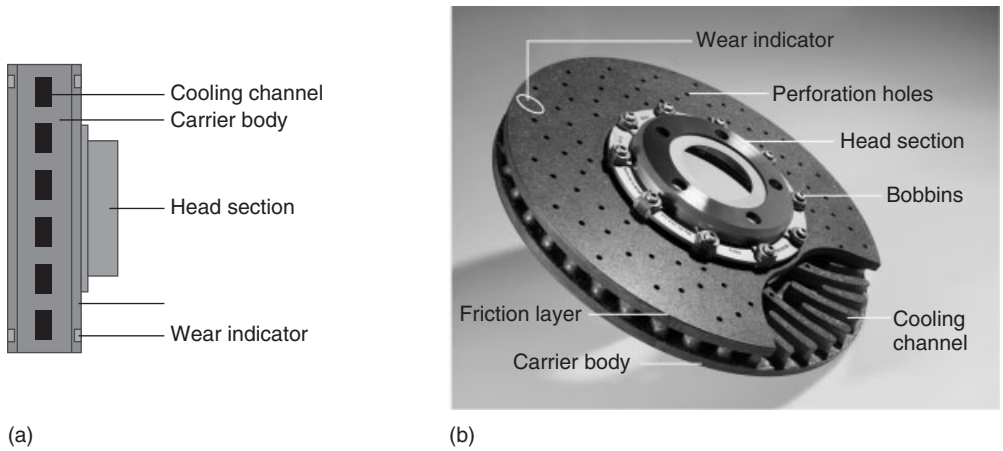

Figure 5. (a,b) Assembly up of a typical C/SiC brake disk. (Reproduced by permission of SGL Carbon GmbH.)

heat conductivity to transport the heat from the friction layer to the cooling channels. C/SiC material of the carrier body has typically higher carbon fiber content than the separate produced friction layer. Moreover, longer carbon fiber bundles are used than in the other disk parts because of the higher strength needs.

- The cooling channels in the carrier body have the task to allow a fast cooling of the brake disk. Therefore, the heat has to be transported as fast as possible out of the disk by the air passing through the cooling channels. The design of the cooling channel can be optimized to the demands coming from the car such as top speed and weight of the car.
- The friction layer is the contact area of the brake disk to the brake linings. Friction coefficient, wear, and lifetime of the disk are depending on the interaction of the friction partners. The friction layer material has a higher hardness than the carrier body material and typically a low carbon fiber content. If carbon fiber bundles are used, they are smaller and shorter than in the carrier body. As the C/SiC material has already low wear rates, brake disks can also be applied without a special friction layer.
- The head section today is typical out of metal. It is mounted on the brake disk by special bobbins, which allow compensating the different thermal expansion of the metal head section and the ceramic disk during braking. The head section is the contact area of the disk to the hub. The materials used for the head section are stainless steel or aluminum.

The dimensions of the produced C/SiC brake disks today start with outer dimensions of 350 mm up to above 420 mm and a thickness of above 32 mm, depending on the car weight and maximum speed.

6 PRODUCTION OF C/SIC BRAKE DISKS

6.1 Protection of carbon fiber bundles against reaction with liquid silicon

To reduce the direct reaction of the carbon fiber with the liquid silicon during the infiltration step, the carbon fibers must be protected. Therefore, the production of short fiber-reinforced CF/SiC brake disks starts with the preparation of the short fiber bundle with a special protection against liquid silicon. During the past decades, different technologies were developed to protect the fiber bundles against the reaction of liquid silicon (Gruber and Heine, 1997; Haug *et al*., 1997; Krätschmer *et al*., 2004). One promising way to prevent the carbon fiber bundles siliconization is the filling of the porosity in the bundles with various types of carbon. One example is the infiltration of the fiber bundles with phenolic resin or pitch followed by a pyrolysis step (Figure 6).

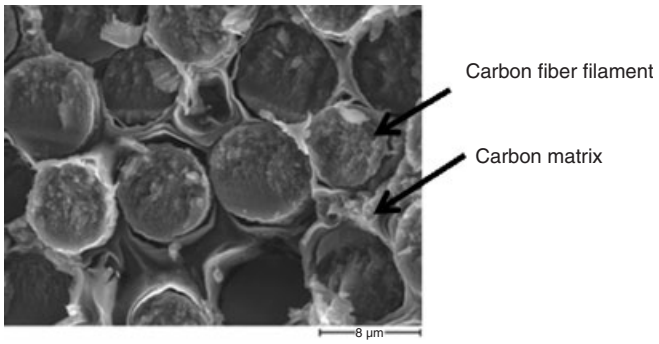

Figure 7. Cutting surface of a densified carbon fiber bundle by impregnation with pitch followed by a carbonization step. (Reproduced by permission of SGL Carbon GmbH.)

The carbon fiber bundles are used in the form of fiber rovings, woven fabrics, or pressed short fiber plates. The bundles are filled with phenolic resin or pitch and then carbonized up to temperature of 1200°C. Additional impregnation and carbonization cycles lead to a decrease in porosity in the bundles and an increase in fiber bundle stability and integrity. Figure 7 shows the SEM image of the cutting surface of an impregnated and compacted C-fiber bundle. The space between the single C-fiber filaments of the fiber bundle is filled with a dense carbon layer of pitch-based carbon. These dense carbon structures in the bundle give a good protection of the carbon fiber filaments against the reaction with liquid silicon during the siliconization process. The schematic production way to a ventilated C/SiC disk with friction layer is shown in Figure 8.

6.2 Mixing and molding step

For the carrier body of the disks, these stabilized fibers are mixed with phenolic resins as binder and further carbon-containing fillers such as graphite powder or coke powders.

After the mixing step is finished, the press masses are ready for the filling step. In the case of a production of solid disks without cooling channels, the press mass is filled directly in the mold and densified under pressure to the necessary green density. The plates therefore are heated up to 200°C where the phenolic resin starts to cross-link. After the cross-linking of the resin, the final CFRP disk is removed out of the mold and ready for further processing.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For the preparation of ventilated disks, more effort is necessary. Here, different technologies were developed. For cooling channels with an easy and radial geometry, the solid disks could be machined after the molding step. The disadvantages of these machining of the cooling channels are the high material loss and the high machining effort. To avoid these machining steps and also to allow more complex cooling channel geometries, three different production technologies are used today:

(a) The disk could be produced out of two parts with ribs on each part (Martin, 1999). The cooling channels of the ventilated disk are formed after gluing the two disks together in the contact areas of the ribs.
(b) For basic geometrical radial cooling channel, geometries drawable cores out of metal are used (Pacchiana and Goller, 2001). After the pressing step, the cores are removed mechanically out of the CFRP disk.
(c) For complex formed cooling channels, the lost core technology is used (Bauer *et al*., 2002). Therefore, a core is produced with the geometry of the designed cooling channels. This core material is decomposed during the heat treatment of the disks completely. A disk with near-net-shaped cooling channels remains for further processing.

6.3 Carbonization

The pressed CFRP disks are removed out of the molds and are machined with conventional machining tools in the outer and inner diameter and thickness. After this premachining step, the disks are carbonized at temperature up to 1200°C under inert gas atmosphere. During the heating up to 1200°C, the organic binder material is thermally decomposed and transformed in porous glassy carbon such as carbon material under evolution of organic species with lower molecular weight. The weight loss of the used phenolic binder systems is typically in the range 40–60 wt%. The main weight loss of the binder is thereby in the temperature area between 400 and 600°C. These temperatures must be carefully crossed to avoid damages of the ceramic fiber-reinforced ceramic (CFRC) disks.

6.4 Friction layer

For disks with friction layer, the friction layer is glued on the porous CFRC carrier body. The friction layer itself is produced in a separate way and a special recipe is used. Therefore, a mixture of carbon fiber bundles, fillers, and phenolic resin as binder is mixed to form a press mass analogous to the carrier body press mass. In difference to the carrier body typically lower, carbon fiber bundle content is used. In addition, the used fiber bundles are smaller in their dimensions than in the carrier body material (Gruber, Heine and Kienzle, 2001). The friction layer is molded equal to the carrier body, on a press at temperatures up to 200°C. The produced CFRP parts were carbonized in the next step under inert atmosphere and then glued on the porous carrier body by a separate pressing and heating step. After the fixation of the friction layer, the final green machining step starts (perforation holes, etc.) and the disks get their finished design. After an additional carbonization step to transform the glue to carbon, the disks are then ready for the siliconization step.

6.5 Siliconization

The siliconization process of the CFC disks is performed in graphite crucible on wicks out of porous carbon material. The crucibles are filled with the calculated amount of solid silicon and are heated up to temperatures of 1700°C. The heating is done under a vacuum atmosphere in special siliconization furnaces. At a temperature of 1420°C, the silicon starts to melt and the molten silicon is absorbed by the wicks and transported by capillary forces into the porous CFRC disk. The infiltration into the body starts immediately and, in a highly exothermic reaction, the CFC disk is infiltrated completely and the matrix carbon and also some fiber filaments on the surface of the fiber bundles react with liquid silicon under the formation of SiC. The formed layer around the fiber bundles protects the fibers in the inner part of the bundle against further reaction with the liquid silicon. After the infiltration is completed, the furnace is cooled down to room temperature. Owing to the lower density of liquid silicon compared to solid density, some of the excess silicon is pressed out of the disks and forms some bigger Si drops, which must be removed after cooling. The density of the resulting C/SiC disk after siliconization is in the range 2.2–2.4 gcm^{-3} and depends on the used recipe and the CFC density of the disks.

In the next production step, the C/SiC disks are machined in inner and outer diameters and on the friction layer using diamond tools. The holes for the fastener elements are drilled in the C/SiC state to guarantee the necessary high precision. To protect the carbon fiber bundles in the disk against oxidation at temperatures >500°C during braking, the disks are further impregnated with an anti-oxidation solution. The C/SiC disks are then assembled with the metal head section using connecting elements made out of stainless steel and the disk is finally machined to the defined tolerances of parallelism between the head section/hub area and the friction area. The assembly is balanced by a groove, machined in the coverage of the brake disk. Every finished

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

disk is quality controlled via sound test to detect internal defects. The dimensions of the disks are measured and additionally the thickness of the friction layer is controlled by measurement. The disks are then ready for shipping.

7 MATERIAL BEHAVIOR

7.1 Microstructure

An overview of the microstructure of a typical short fiber CF/SiC material from the carrier body of a brake disk is shown in the micrograph of Figure 9. The fibers are oriented perpendicular to the press axis *z*. In the *xy*-plane, the fibers are distributed with a random orientation or depending on the filling step. The fiber bundles are embedded in a SiC matrix (gray color). The porosity of the porous CFRC structure is filled with silicon (white areas).

Owing to the fiber protection of the bundles, the reaction with the silicon takes place only on the surface of the fiber bundle under the formation of a dense silicon carbide layer. This dense silicon carbide layer protects the fiber against further reaction during the infiltration. The different thermal expansion coefficients of the carbon fiber bundles, the silicon, and silicon carbide matrix lead to the formation of microcracks formed during the cooling of the material from 1420°C to room temperature. The microcracks are stopped in the neighboring fiber bundles. In addition, there are some areas of unreacted amorphous carbon matrix in the microstructure, which are also embedded in a formed SiC layer.

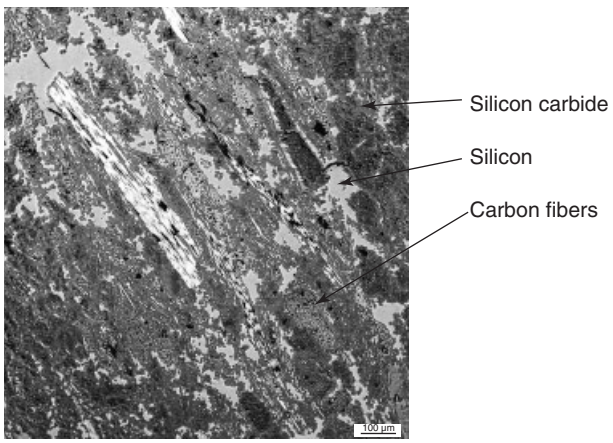

Figure 9. Micrograph of carbon-fiber-reinforced SiC. Sample of carrier body from a brake disk material. (Reproduced by permission of SGL Carbon GmbH.)

7.2 Material properties

In Table 1, the material data of typical short fiber CF/SiC materials in comparison to gray cast iron are summarized. In addition, the typical values of 2D reinforced CF/SiC material are mentioned. This material is produced by the siliconization of 2D CFC material out of woven C-fiber phenolic prepregs by lamination and carbonization. Short fiber-reinforced material shows a lower mechanical stability (strength, modulus, and elongation at maximum stress) than the long fiber-reinforced CF/SiC material. The higher density of the short fiber-reinforced material and the higher content of silicon and silicon carbide lead to increases in heat conductivity through the material. The density of the CF/SiC materials with values of 2.3 gcm^{-3} is significantly lower than the metal with densities of >7.2 gcm^{-3}. This lower density gives a significant weight advantage. If, on the front and rear axles, the CF/SiC brake disk is used instead of metal disks, weight reductions of up to 20 kg by car can be achieved for disks with 400 mm diameter. The differences in physical properties of the two types of CF/SiC materials are summarized in Table 1 together with gray cast iron GG-20.

The specific heat capacity of CF/SiC material is around 40% higher than cast iron. The combination of the high heat capacity, low Young's modulus, and high heat conductivity results in a high thermal shock resistance of the CF/SiC material, compared to the GG 20.

Table 1. Summary of the material data of short fiber- and long fiber-reinforced CF/SiC.

	I C/SiC *Short Fiber*	II C/SiC *Long Fiber*	GG-20
Density (g/cm^3)	2.3	1.9	7.2
Four point bending (MPa)	70–80	200	220
Strength modulus (GPa)	30	70	110
Elongation at break (%)	0.3	0.45	0.3–0.8
Heat conductivity *z*-axis (W/(mK))	35	10	54
Thermoshock resistance (W/m)	$>27,000$	$>27,000$	<5400
Maximum operating temperature (°C)	1400	1400	700

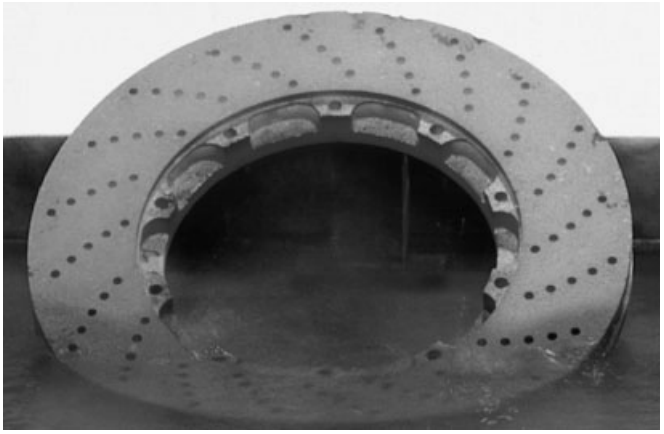

Figure 10. Thermal shock test of C/SiC brake disk. (Reproduced by permission of SGL Carbon GmbH.)

Figure 10 shows a disk, which is heated up to 1000°C and then dipped into water with one-half. While the side in the water is cooled down below 100°C, the non-dipped part is still red hot. Silicon carbide ceramic without fiber reinforcement would not survive such extreme thermal shock conditions. Another big advantage of the CF/SiC materials is the increase in mechanical stability with increasing temperatures (Figure 11). During the heating up to temperatures of 1200°C, the mechanical strength of CF/SiC increases up to 80% higher values, compared to respective room temperature values. In addition, the stiffness of the material is also increasing. In comparison to CF/SiC, the gray cast iron loses at temperature of 700°C around 40% of the mechanical room temperature strength and also stiffness.

Under dynamic load tests, CF/SiC materials show a reduction in stiffness in the range 20% but without reduction in the mechanical strength of the material (Thielicke, 2005). Owing to the heterogeneous material structure of the CF/SiC and the formed microcracks resulting from the different thermal expansions of the materials during the cooling step, critical stresses are reduced. In addition, newly formed cracks from an applied load are bridged or bypassed by carbon fiber bundles and the cracks are stopped. These effects also result in a low notch sensitivity of the CF/SiC materials. The high hardness compared with the good mechanical behavior and the increasing mechanical behavior with increasing temperature makes the short fiber material an ideal candidate for the use as brake disk material. The CF/SiC ceramic material combines the beneficial behavior of a hard ceramic material, which is responsible for the low wear, good tribological behavior, and long lifetime of the brake disk with the advantages of fiber-reinforced material that shows high fracture toughness and damage tolerance. The resulting quasi-ductile properties of the ceramic composite material ensure the resistance to high thermal and mechanical stability. Limitations are coming from the oxidation of the carbon fibers at temperature over 500°C under air. This oxidation can result in a decrease of the mechanical strength of the CF/SiC and may have a negative impact in the lifetime of the

disks. Anti-oxidation agents such as aluminum hydrogen phosphates are preventing long time any negative oxidation effect during application.

8 C/SIC AS BRAKE DISK MATERIAL

8.1 Dimensioning and design of the disk

For the design of a CF/SiC disk for a new car, identical tests must be performed as for gray cast iron disk. Main control parameters are the maximum speed and the maximum load and their distribution on front and rear axles and the time to stop the car from maximum speed. The brake disk layout is largely determined by the response during full braking at v_{max} when the tensile stresses hit their peak because of the superimposition of the maximum braking and centrifugal forces.

The resistance of the brake disk mainly depends on their design of the chamber interface and interior disk rim as well as on the shape of the webs and cooling ducts. In addition, the cooling conditions of the disks are important factors. In usage, the brake disks are mainly strained by centrifugal loads and braking forces. Therefore, they must withstand lateral forces as well and further consideration must be given to thermal loads and stresses occurring at the interface between the brake disk and the brake disk chamber. Calculations for assembled carbon-ceramic brake disks include the design of the head section connection. The necessary dimensions of the disks are further calculated to ensure all possible mechanical load situations during the brake use over the lifetime of the car. This prevents that neither the disk itself nor any other component in its direct neighborhood is exposed to excessive thermal loads. To remove the heat as fast as possible out of the disks, the cooling channel geometry must be optimized using numerical methods for each car model. First prototypes are produced from the optimized disks and cooling channel dimensions and tested on a test bench also under extreme load conditions (Figure 12). The mechanical stability, braking performance, and heat dissipating behavior of the tested brake disks are the main results from these tests.

These results are used to optimize the simulated and calculated behavior of the disks and consequently modifications in the construction are transferred. The loads over the lifetime of the car are simulated on the disks and their mechanical stability is tested. These tests are done with disks directly after the production and also after surviving the simulated lifetime, for example, by bursting tests. Finally, right after perform dynamometer tests and analyzing the results, the tests on the car are done. They cover not only high speed runs on a test circuit but also mountain passes, descents, and road tests in normal traffic under winter and summer conditions. During these test runs, the test driver evaluates the brake behavior, the braking performance, and the braking comfort.

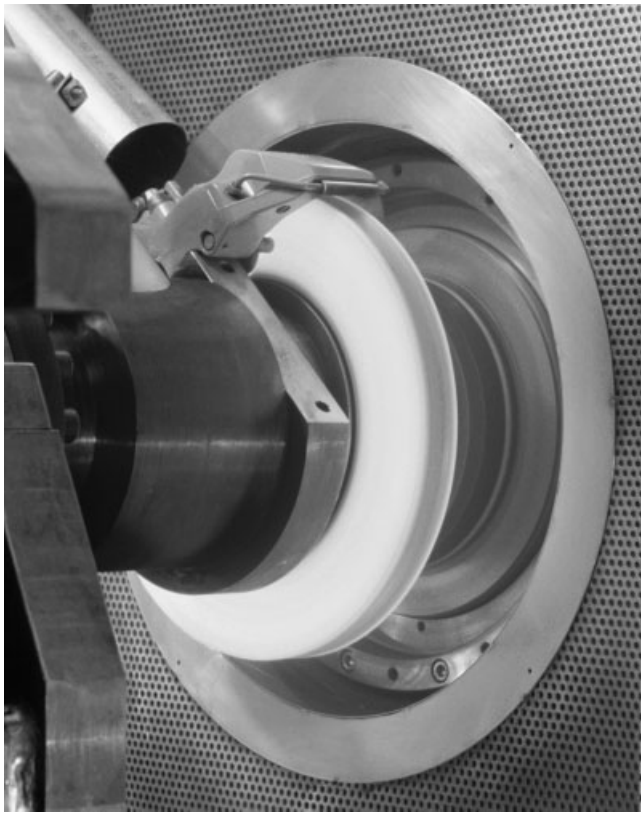

Figure 12. Overload friction test of a C/SiC disk on a test bench. (Reproduced by permission of SGL Carbon GmbH.)

8.2 Brake caliper and brake pad

For the CF/SiC brake disks today mainly fixed caliper with up to four opposing piston pairs are used. The pistons clamp the CF/SiC disk during braking between the pad materials. To avoid overheating of the hydraulic fluid of the caliper, the pistons are equipped with a layer with low heat conductivity between the brake pad and the piston. At present, mainly organic bounded pads are used as brake pad. The material is matched to the friction behavior of the ceramic surface of the disks. Metal bounded pads and ceramic bounded material pads were tested for the C/SiC brake disks and show good friction performance. Owing to comfort problems, such as noise evaluation during braking, various improved pad materials are still under development and testing.

8.3 Advantages C/SiC brakes

In comparison to the standard metal brake disk, this ceramic brake disk has several advantages:

Low Density. The low density of around 2.3 gcm^{-3} leads to a significant reduction in weight of the brake disks compared to gray cast iron (−30% to 70%).

High Abrasion and Corrosion Resistance. Gray cast iron disks show a reduction of the disk thickness during lifetime by wear and corrosion, which can be measured easily. In comparison to this, the CF/SiC brake disk shows only low wear rates because of the high hardness of the SiC ceramic and consequently only a low reduction of disk thickness during lifetime of the car is measurable. The significantly lowered wear of disk and pad material offers as additional advantage the reduction of break dust. This is a very positive contribution for the environment.

Noise during Braking. High thermal loads during cooling after high energy breakings at temperatures over 700°C form cracks and deformations of the metal disks. These deformations result in noise during braking and lead to disk changes. Owing to the low thermal expansion and the high temperature stability of the C/SiC disk, there is no significant change in dimensions or geometries of the disks measurable during braking, which could reduce the performance of the disks.

Friction Behavior and Fading Stability. With increasing temperatures, the CF/SiC disks show additionally a slight increase of the friction coefficient during braking in comparison to the gray cast iron disks. This friction behavior results in an improved fading stability of the CF/SiC disks compared to a metal disk. The fast build up of the friction coefficient and the higher possible values of the friction coefficients of >0.45 compared to gray cast iron (from $\mu = 0.3$ up to 0.45) lead to an excellent positive pedal feeling for the driver and results in significantly shorter stopping distances especially from high road speeds.

8.4 Other automotive friction applications of CF/SiC materials

Owing to the high strength and ductility of the long fiber CF/SiC material and the high hardness of this material, it can be applied as material for clutch disk systems. This type of disk was for the first time used in the high end sports car Porsche Carrera GT. The main advantages for CF/SiC in clutch applications are the low wear rate under extreme load, the low weight, and the high and stable friction coefficient. The disks can be designed in smaller dimensions and allow lowering down the drive train and the center of gravity of the vehicle with the better performance of the driving characteristics. Currently, this ceramic clutch material is mainly used in high end race cars.

9 OUTLOOK

The current CF/SiC disks are mainly used in high end sports and luxury road vehicles because of high costs of the disks. To enter the market of normal cars, the price of the disks must come down. This will happen with the development of new brake systems allowing easier disk geometries and resulting in a less complex production. Of ongoing importance is the increase of the automation of the production processes. Therefore, new production technologies must be developed, implemented, and qualified. With their high lightweight potential, the C/SiC brake disk in combination with their discussed braking performance, the CF/SiC material is the right brake disk material for cars in future.

10 SUMMARY

Since 1950, the top speed of upper class limousine increases from around 180 to 250 km/h in the year 2000. In the same time, the car weight also increases from around 1400 to 2500 kg. This leads to higher kinetic energy, which results in a lower lifetime of the metal disks and fading problems, with the result of longer stopping distances.

In the past decade, the carbon-fiber-reinforced silicon carbide brake disk material is developed. The material is produced by liquid siliconization of porous CFC perform with liquid silicon under vacuum. The resulting material shows a low weight because of the low densities of around 2.3 gcm^{-3} and high hardness. At the Frankfurt Motor Show in 1999, the carbon-ceramic brake disk was shown the first time to the public. At present, for nearly all high end sports and luxury cars, CF/SiC brake disks are available. In this contribution, the production processes of the CF/SiC disks are described and an overview of the CF/SiC material and brake disk behavior is given.

The Cooperation of Regenerative Braking and Friction Braking in Fuel Cell, Hybrid, and Electric Vehicles

Zhuoping Yu and Lu Xiong

Tongji University, Shanghai, China

1 INTRODUCTION

It is well known that when the brakes are applied in a car to slow it down, some energy is wasted. The kinetic energy converts into heat and becomes useless. However, the energy crisis is becoming more and more serious at the moment and carbon emission is reaching a peak. Therefore, energy must be used as efficient as possible.

The beginning of the twenty-first century could very well mark the final period in which internal combustion engines are commonly used in cars. Now, automakers are trying to apply new energy technologies, such as pure electric, hybrid, plug-in hybrid, hydrogen fuel cell, and other alternative fuel energies such as biofuel. At the same time, automotive engineers have beaten their brain out to wring the maximum efficiency out of aerodynamic streamlining of the bodies and use of lightweight materials. Among them, regenerative braking is one of the most important technologies.

When driving a car, you have to hit the brakes occasionally to stop the car or adjust the speed. For a conventional car, about 80% of its energy converts into heat through friction. However, with a system that can recapture much of the car's kinetic energy and convert it into some other restorable and reusable energy, regenerative braking is able to capture as much as half of that wasted energy and put it back to work. Therefore, the fuel consumption can be reduced by 10–25%.

Figure 1 shows the energy conversion by braking system. The conventional braking systems convert the kinetic energy into friction heat and acoustic energy, for example, braking squeal, which cannot be reused. To convert the kinetic energy into some storable and useable energy, a lot of various schemes of regenerative braking have appeared. For instance, the kinetic energy of the vehicle can be converted into electrical energy by the electric motor and stored in the battery or supercapacitor or mechanically converted to the kinetic energy of a flywheel (e.g., KERS in some F1 racing car), etc.

The regenerative brake with electric motors is the well-developed one than other variants of regenerative braking systems. It is used in electric vehicles, primarily pure

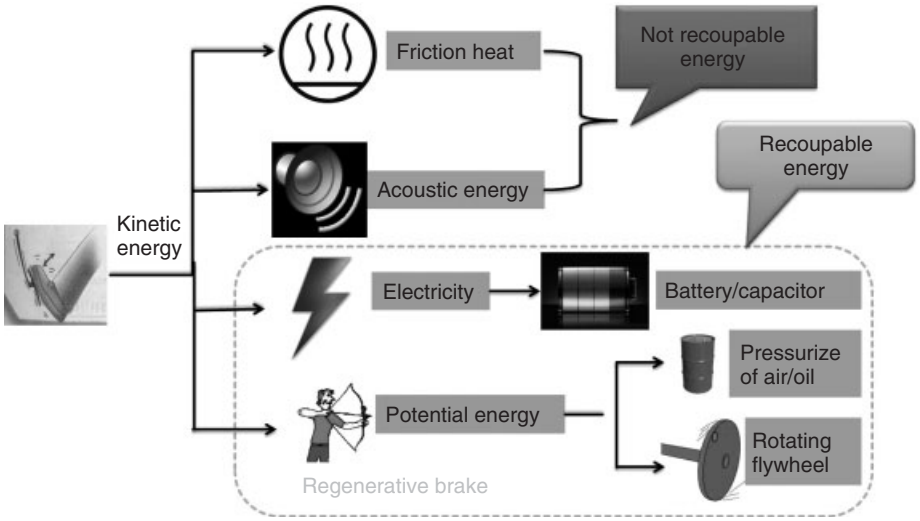

Figure 1. Energy conversion by braking systems.

electric vehicles and hybrid electric vehicles, whose battery can be used for longer periods of time without the need to be recharged by external charger or get gas service. The traction motor or the electric machine would work as a generator when using the regenerative braking, it could produce a brake torque, meanwhile producing electrical energy and stored it into energy storage components, namely, battery or supercapacitor.

2 HISTORY OF THE REGENERATIVE BRAKING SYSTEM

The origin idea of regenerative braking dates from the nineteenth century. In the most common form, there is an electric motor working as an electric generator. In electric railways, the generated electricity is put back to the supply system, whereas in battery electric and hybrid electric vehicles, the energy is stored in a battery or bank of capacitors for later use.

2.1 The Krieger electric landaulet

Louis Antoine Krieger (1868–1951)'s horse-drawn cabs were incipient examples of regenerative braking system. There is a drive motor with a second set of parallel windings in each front wheel. The motors are free to revolve a short distance either way around the large spur wheel and drive the wheels through spur gearing. Under the driver's seat is the main battery and under the passenger seat is an additional one. While descending a hill, there is certain provision for charging the battery (Figure 2).

Figure 2. Krieger electric landaulet. (Reproduced from Harris & Ewing, 1906. Library of Congress, Prints & Photographs Division, photograph by Harris & Ewing.)

2.2 "Regenerative control" in tramway

In order to reduce electricity consumption, tramway operators brought the Raworth system of "regenerative control" into use in the early 1900s in British cities such as Devonport (1903), Rawtenstall, Birmingham, Crystal Palace-Croydon (1906), and many others. While slowing down the car or keeping its speed in the downhill, the motors worked as generators, braking the car and capturing the kinetic energy at the same time. There were also wheel brakes and track slipper brakes in the tramcars in case of failure

of electric braking systems. The tramcar motors were shunt wound in several situations, and the systems on the Crystal Palace line utilized series-parallel controllers. However, an embargo was promulgated on this form of traction in 1911, because of a serious accident at Rawtenstall. Fortunately, the regenerative braking system was reintroduced 20 years later.

2.3 Application of regenerative braking in railways

Regenerative braking has been widely used on railways for many decades. The advantages of the regenerative system are the reduction of energy consumption, the reduction of wearing of brake shoes and wheel tires, and the consequent lowering of maintenance costs. The disadvantage is that the motors are larger and more costly. There are many examples of remunerative regenerative braking abroad in mountain railways and on lines where the gradients are heavy. From Riksgränsen on the national border to the Port of Narvik, the trains use only 20% of the regenerated energy. This regenerated energy is sufficient to power the empty trains back up to the national border. Any excess energy from the railway is pumped into the power grid to supply families and businesses in the region, and the railway is a net generator of electricity (Figure 3).

3 COOPERATIVE WORKING OF REGENERATIVE AND FRICTION BRAKING SYSTEMS

In a traditional braking system, brake pads produce friction with the brake rotors to slow or stop the vehicle. Additional friction is produced between the slowed wheels and the surface of the road. This friction is what turns the car's kinetic energy into heat. With regenerative brakes, on the other hand, the system that drives the vehicle does the majority of the braking. When the driver steps on the brake pedal of an electric or hybrid vehicle, these types of brakes put the vehicle's electric motor into reverse mode, causing it to run with reverse torque, thus slowing the car's wheels. While running with reverse torque, the motor also acts as an electric generator, producing electricity that is then fed into the vehicle's batteries. These types of brakes work better at certain speeds. In fact, they are most effective in stop-and-go driving situations. However, in a cooperative regenerative braking system, there still exist two sub-braking systems, that is, traditional friction braking system (usually hydraulic braking system) and regenerative braking system based on electric motors. Generally, the reasons are as follows:

1. The regenerative braking torque is not large enough to cover the required braking torque; furthermore, when the motor speed rises, regenerative braking torque will decrease because of the flux-weakening control.
2. The regenerative braking cannot be used for many reasons such as high state of charge (SOC) or high temperature of the battery to increase the battery life.
3. Regenerative brake cannot brake to stop (because of its work principal).

The relationship between regenerative and friction brake system is shown in Figure 4.

At the beginning of braking, the motor (light gray line) could meet the driver's rapidly rising demand for the total braking torque (black line), when the motor reaches its full potential, the hydraulic braking (dark gray line) begins to intervene. Continue with the braking, vehicle speed decreases, and the motor torque raises a little (light gray line). The motor torque declines rapidly (light gray line) when the vehicle slows down, and the braking torque is fully provided by the hydraulic brake (dark gray line) when close to stopping.

3.1 Three ways to cooperate the two sub-braking systems

There are three ways to realize the cooperative working of friction and regenerative braking systems (Zheng, 2010; Zhang and Ning, 2009).

The first way is to add the regenerative braking system directly onto the original hydraulic braking system without changing the arrangement of the original hydraulic braking system (Figure 5). The advantage of this way is simplicity.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto028
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

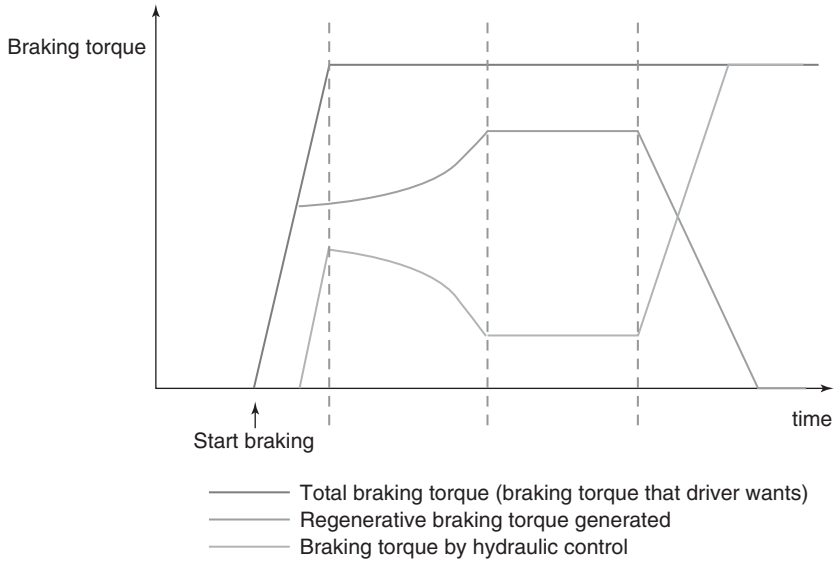

Figure 4. The relationship between regenerative and friction brake system.

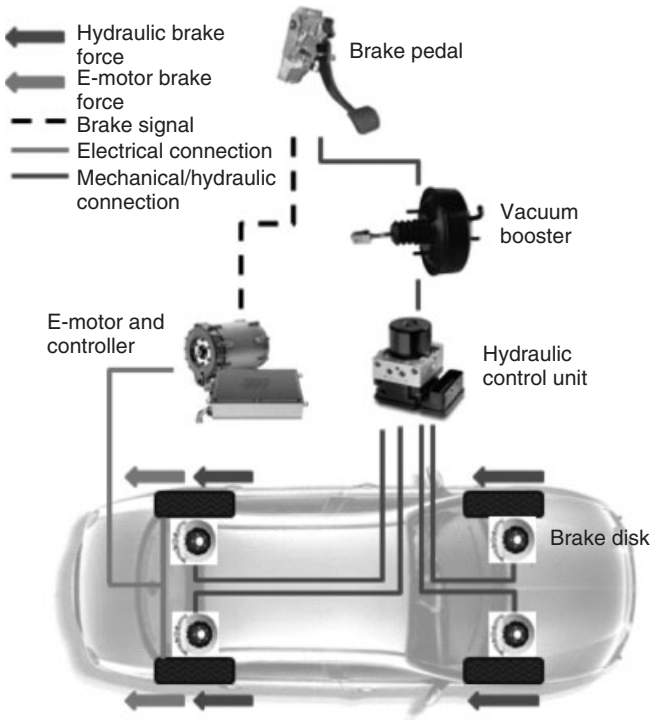

Figure 5. Add the regenerative braking system directly.

It is not necessary to rebuild a braking system. In this way, the structure is simple and what need to be changed can be minimized. However, the disadvantage is the low energy recovery efficiency because of the current braking force distribution design (Zhang and Ning, 2009).

The second way is brake-by-wire technology, where many of the functions of brakes that have traditionally been performed mechanically will be performed electronically (Zhang and Ning, 2009) (Figure 6). Here, electronic braking pedal and integrated sensors are used. When drivers step down the brake pedal, the sensor records the force, displacement, velocity, and other necessary signals to identify drivers' brake intention. The controller would give command to the pedal displacement simulator in order to supply the designed friction brake force. In this way, the friction brake force can be controlled actively to maximize the energy recovery efficiency. At present, different automakers have come up with different circuit designs to handle the complexities of regenerative braking. However, in all cases, the most important part of the braking circuitry is the braking controller.

The third way is redesigning the current hydraulic braking system by a large margin (Zhang and Ning, 2009). By adding and controlling the valves on the hydraulic braking pipelines, the hydraulic braking pressure can be controlled in time to generate the designed friction brake force. In terms of theory, this design of cooperative regenerative braking system can achieve the highest energy recovery efficiency.

3.2 The structure of the cooperative regenerative braking system

Regenerative braking system is used in the vehicles driven fully or partly by electric motors. Electric motor supplies the regenerative brake force. One of the most interesting

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto028
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

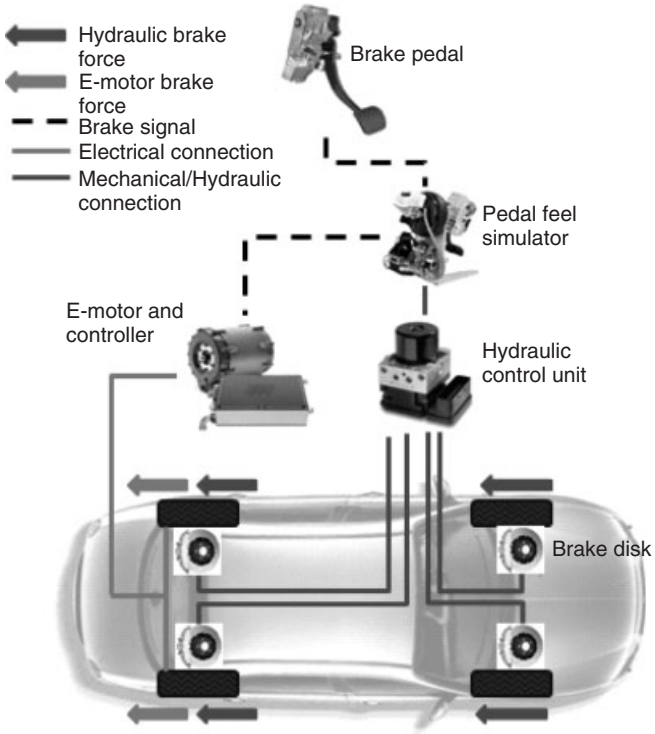

Figure 6. Brake-by-wire technology.

properties of an electric motor is, when it is running in one direction, it converts electrical energy into mechanical energy that can be used to perform work (such as turning the wheels of a car), but when the motor is running in reverse mode, a properly designed motor becomes an electric generator, converting mechanical energy into electrical energy. This electrical energy can then be fed into a charging system for the car's batteries, shown in Figure 7.

A cooperative regenerative braking system includes a frictional braking device for applying a friction brake torque to the wheels, and a regenerative braking device for applying a regenerative brake torque to drive wheels of the vehicle. Here, frictional braking device means a system which operates on the principle of friction mechanism to generate brake force regardless of using disk brake structure or drum brake structure, hydraulic or pneumatic actuating device (usually it is hydraulic braking system). The regenerative braking device means the system which operates to transform the vehicle kinetic energy to electricity energy, usually it is electric motor. A cooperative regenerative braking system is usually used in the following three kinds of new energy vehicles, such as pure electric, hybrid electric, and fuel cell vehicles.

3.2.1 *Regenerative braking in battery electric vehicle*

Battery electric vehicles use the motor as a generator when using regenerative braking: it is operated as a generator during braking and its output is supplied to electrical loads and it provides the braking effect. This energy can be saved in a storage battery or a supercapacitor and can be used to propel the motor (Figure 8).

3.2.2 *Regenerative braking in hybrid electric vehicle*

A hybrid vehicle is a vehicle that uses two or more distinct power sources to propel the vehicle. The term most commonly refers to hybrid electric vehicles (HEVs), which combine an internal combustion engine and one or more electric motors. Hybrid system is divided into series hybrid, parallel hybrid, and series–parallel hybrid.

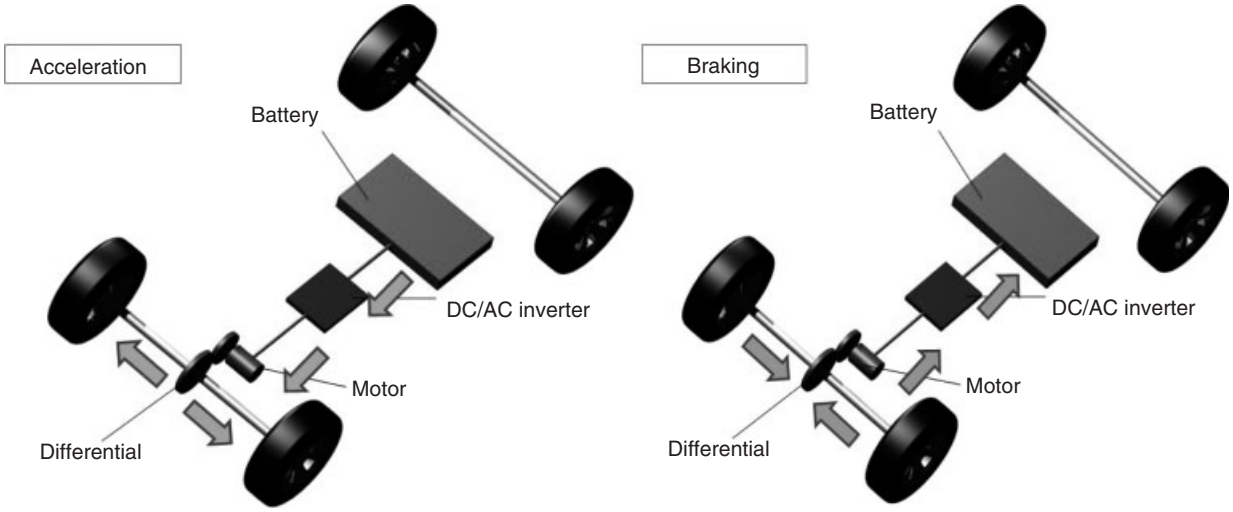

Figure 8. Cooperative regenerative braking system of the pure electric vehicle.

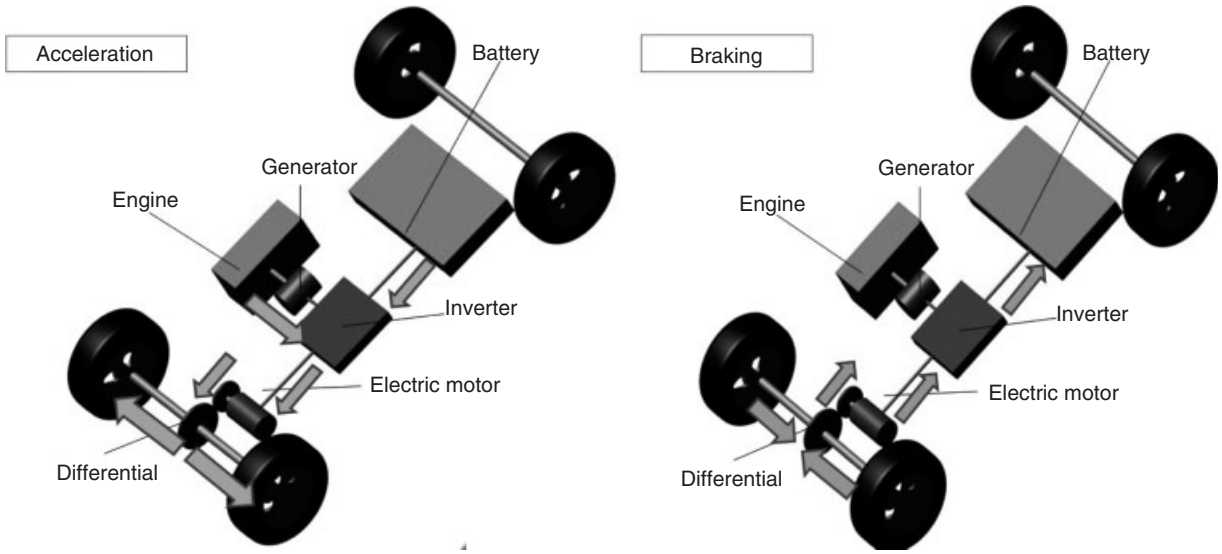

Figure 9. Cooperative regenerative braking system of the series-hybrid vehicles.

Series-hybrid vehicles are driven by the electric motor with no mechanical connection to the engine. Instead, there is an engine tuned for running a generator when the battery pack energy supply is not sufficient for demands (Figure 9).

In a parallel hybrid, the single electric motor and the internal combustion engine are installed so that they can power the vehicle either individually or simultaneously. In contrast to the power split configuration, typically, only one electric motor is installed. Most commonly, the internal combustion engine, the electric motor, and the gearbox are coupled by automatically controlled clutches. For electric driving, the clutch to the internal combustion engine is open, whereas the clutch to the gearbox is engaged. While in combustion mode, the engine and motor run at the same speed (Figure 10).

In a series-parallel hybrid electric drive train, there are two motors: an electric motor and an internal combustion engine. The power from these two motors can be shared to drive the wheels via a power splitter, which is a simple planetary gear. The ratio can be from 0% to 100% for the combustion engine, 0% to 100% for the electric motor, or an anything in between, such as 40% for the electric motor

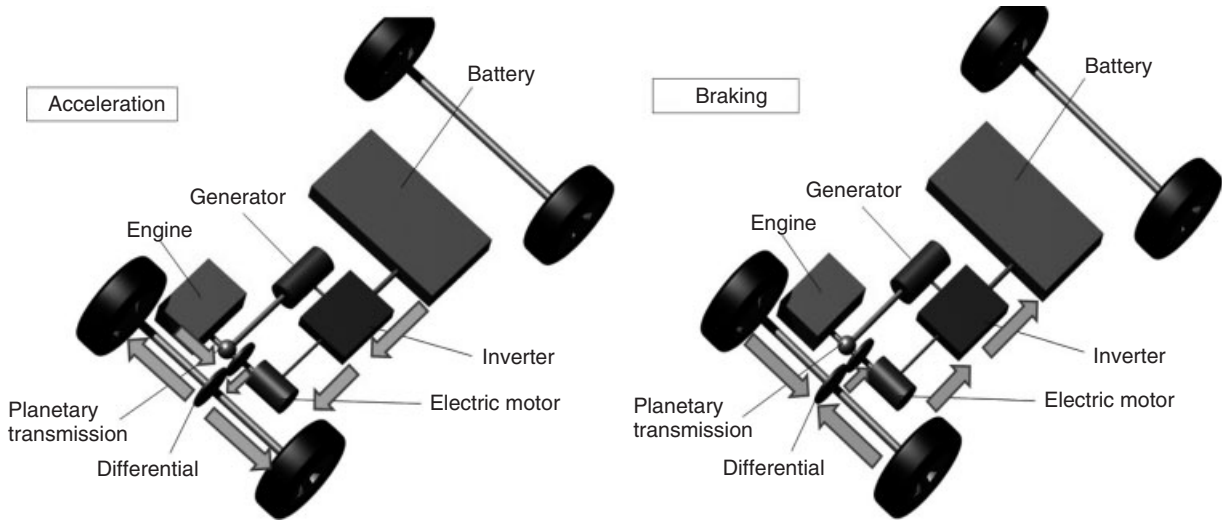

Figure 11. Cooperative regenerative braking system of the series–parallel hybrid vehicles.

and 60% for the combustion engine. The electric motor can act as a generator charging the batteries (Figure 11).

3.2.3 Regenerative braking in fuel cell vehicle

A fuel cell vehicle is a type of hydrogen vehicle that uses a fuel cell to produce electricity to power its electric motor. Fuel cells in vehicles create electricity to power an electric motor using hydrogen and oxygen from the air. The electricity produced by the fuel cell is delivered to the electric drive system in the vehicle, which converts electric power into the mechanical energy and drives the wheels of the car (Figure 12).

4 THREE PARTS OF THE COOPERATIVE REGENERATIVE BRAKING SYSTEM

From the point of view of control system theory, the cooperative regenerative braking system is made of three parts: signal part, control part, and actuator part (Zhang and Ning, 2009), shown in Figure 13.

1. *Signal Part.* The signals include the brake pedal position, vehicle speed, energy storage (e.g., battery) status, hydraulic pressure in the pipeline, pneumatic pressure in braking valves, etc., shown in Figure 14.

Figure 13. Three parts based on control system.

The most important task in this part is to identify the driver's right intention in time.

2. *Control Part*. Electronic devices that control the regenerative braking function remotely by transmission parts and electronic control unit (ECU).
3. *Actuator Part*. Considering that there are two sub-braking systems, hydraulic or pneumatic braking system parts belongs to the friction braking system. Electric motor belongs to the regenerative braking system.

4.1 Signal part

The vehicle can be regarded as a closed control circuit consisting of driver, vehicle, and traffic condition. The driver gives the command based on the current traffic condition and personal intension. By steering, shifting gears or stepping down gas pedal or brake pedal, the driver can speed up or slow down the vehicle to adapt to the current outside environment and meet personal demands. Braking intention can be shown as how the driver controls the brake pedal.

4.1.1 The categories of braking intention

The braking intention can be divided into three categories: mild braking, moderate braking, and emergency braking (Zhang *et al*., 2009), shown in Figure 15.

Mild braking means the driver brakes, slows down, or stops the vehicle actively. It is common to see this kind of braking intention on the cross road when the driver is turning around the corner. In this case, the pedal angular velocity is small and the hydraulic pressure in the pipeline increases slowly (Yu *et al*., 2005).

Moderate braking means driver brakes passively. In this situation, the pedal angular velocity is big and the hydraulic pressure changes sharply. It is common to see this kind of braking intention on the highway when the front vehicle suddenly brakes or in case the vehicle needs to be stopped within a short brake distance. Sometimes, this kind of braking would be withdrawn very soon.

Emergency braking means the driver has stopped the car rapidly till the car completely stopped.

4.1.2 The ways to identify braking intention

In the cooperative regenerative braking system, by collecting signals such as brake pedal step force, pedal displacement and velocity, or hydraulic pressure change

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto028

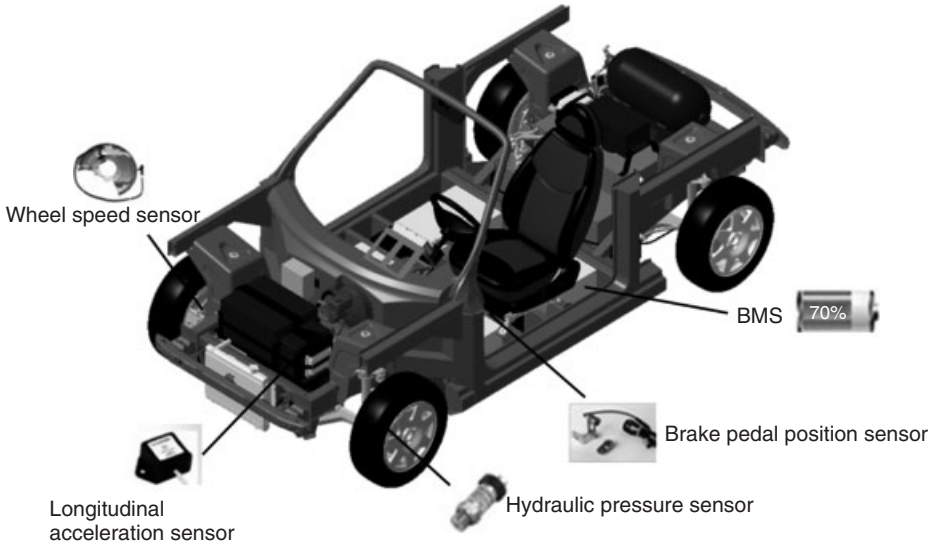

Figure 14. Signal parts.

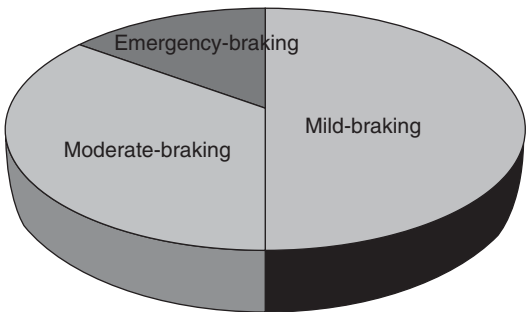

Figure 15. The categories of braking intention.

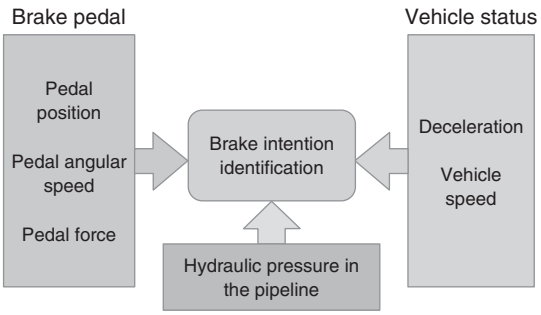

Figure 16. The signals that are used to identify the driver's braking intention.

rate in pipeline, shown in Figure 16, the driver's braking intention can be identified (Zhang *et al.*, 2009). At the same time, the rotation velocity of each wheel should also be monitored, to assure the vehicle is under safe condition.

4.2 Control part

4.2.1 Requirements for the braking system

Because there are two sub-braking systems in the cooperative regenerative braking system, its complexity is higher than the traditional braking system. The requirements for the cooperative regenerative braking system are as follows (Xiao, 2009):

1. sufficient brake force according to the driver's intention supplied;
2. the recovery efficiency of braking energy maximized;
3. the road adhesion coefficient best exploited to achieve the highest braking efficiency;
4. the driver's requirement about braking comfort met.

4.2.2 The role of the controller

The regenerative braking controller monitors the rotational speed of the wheels and the difference in that speed from one wheel to another. In vehicles that use these kinds of brakes, the brake controller not only monitors the speed of the wheels but also can calculate how much torque (rotational force) is available to generate electricity to be fed back into the batteries. During the braking operation, the brake controller directs the electricity produced by the motor into the batteries or capacitors. It not only makes sure that an optimal amount of power is received by the batteries but also ensures that the inflow of electricity is not more than the batteries can handle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto028
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The most important function of the brake controller, however, may be deciding whether the motor is currently capable of handling the force necessary for stopping the car (Lampton, n.d). If it is not, the brake controller turns the job over to the friction brakes, averting possible catastrophe. In vehicles that use these types of brakes, as much as any other piece of electronics on board a hybrid or electric car, the brake controller makes the entire regenerative braking process possible.

4.2.3 Influence of the position of the electric motor

As mentioned in Section 3, there are three types of cooperative regenerative braking system according to where the regenerative brake force acts. So obviously the position of electric motor has effect on the braking efficiency and vehicle stability. When the regenerative brake force acts on the front wheels, it can achieve better vehicle stability and braking efficiency because it can make better use of the road adhesion coefficient (Yu *et al*., 2008). When the regenerative brake force acts on the rear wheels, vehicle's stability is worse and it is not good for energy recovery. Therefore, Section 4.2.4 control strategy is based on the principle that electric motors supply regenerative brake force on the front wheels at first. When brake force is not enough, regenerative brake force would act on the rear wheels. In the case of emergency, electric motor and hydraulic braking system would work together to supply brake force.

4.2.4 Control strategy

For the vehicles, on which electric motors are just added to the original friction braking system, the control strategy is to control the electric motor to generate the designed brake torque that equals to the insufficient value between the realistic braking force distribution curve and ideal curve.

For the vehicles, on which the cooperative regenerative braking system is realized by "brake-by-wire" technology, the control strategy is more complicated. With the clutch connecting, the backward drag force from combustion motor should be considered. The following control strategy is under the circumstance without considering the backward drag force from combustion motor. In the case of mild or moderate braking, recovering kinetic energy is regarded as the priority goal. Therefore, in the case of mild braking, all the brake force would be supplied by electric motor. In the case of moderate braking, electric motor would supply brake force at first. The hydraulic braking system serves as a "backup" in case that the brake force is not enough. In the case of emergency braking, braking efficiency would be regarded as priority goal. In such circumstance, electric motor and hydraulic braking system would work together to supply the maximum brake torque within the shortest time (Zhang and Ning, 2009). The interconnectedness and mutual influence of electric motor braking and hydraulic braking should be considered. In this case, it needs help from ABS to keep the wheels unlocked. Considering system control simplification and motor protection, the motor's regenerative braking function of composite brake systems is usually turned off when ABS works (Figures 17 and 18).

4.3 Actuator part

Usually, for the friction braking system, hydraulic braking system is the actuator part whereas for the regenerative braking system, it is electric motor.

4.3.1 Electric motor

According to the PWM control theory, by switching the arm of the inverter conduction power tube, the armature current can be changed in opposite direction under the same magnet poles to drag the electric motor reversely. In this way, the power battery can be charged while part of the electricity is consumed by motor internal resistance in forms of heat. The energy stored in the battery can be used in idling, start, acceleration condition to achieve the purpose of energy saving and pollution reducing.

4.3.1.1 The limitations of electric motor regenerative braking.

1. Regenerative braking relies on the electric motors. Therefore, this kind of braking system cannot apply on the wheels that are not driven by electric motors (Zhang and Ning, 2009);
2. Because brake torque supplied by electric motors cannot exceed the maximum electric motor torque at current rotational speed, if pure regenerative brake torque cannot meet the current braking requirement, friction braking system should supply the rest brake torque (Zhang and Ning, 2009);
3. The energy regenerative efficiency relies on the battery SOC. The upper and lower limits of SOC depend on the internal resistance of battery. When SOC is too high, the power battery should not be charged in order to keep its normal operational life cycle. The recovery power of braking energy should not exceed the charge power of the battery (Zhang and Ning, 2009).
4. In the case of regenerative braking, when the rotational speed of electric motor is lower than the rated speed, the electric motor works with the rated brake

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto028
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

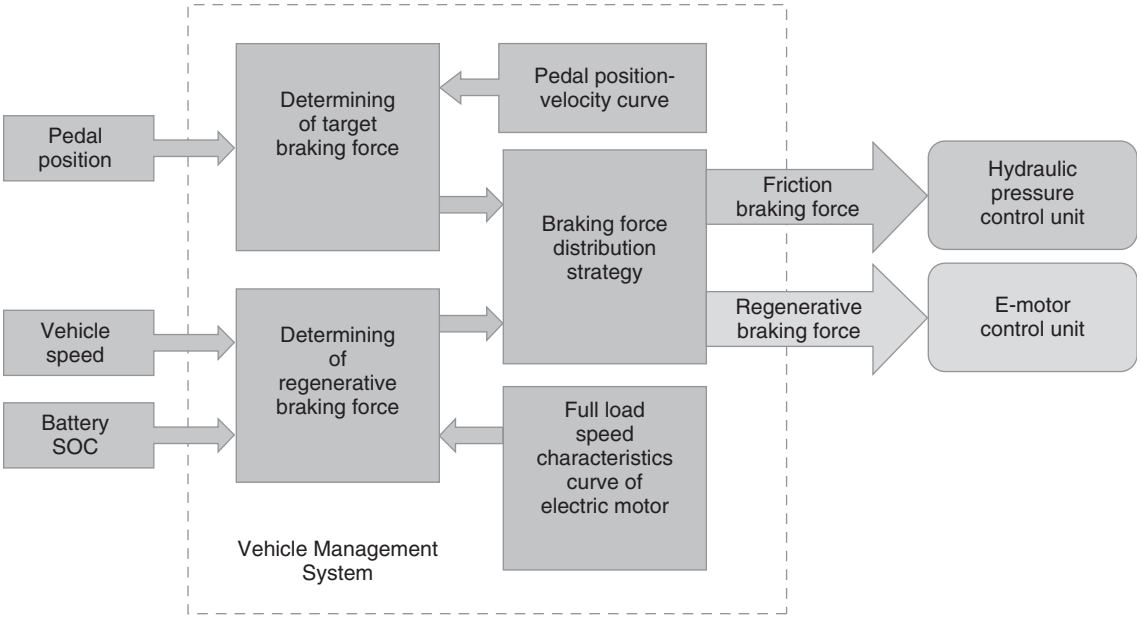

Figure 17. Control strategy.

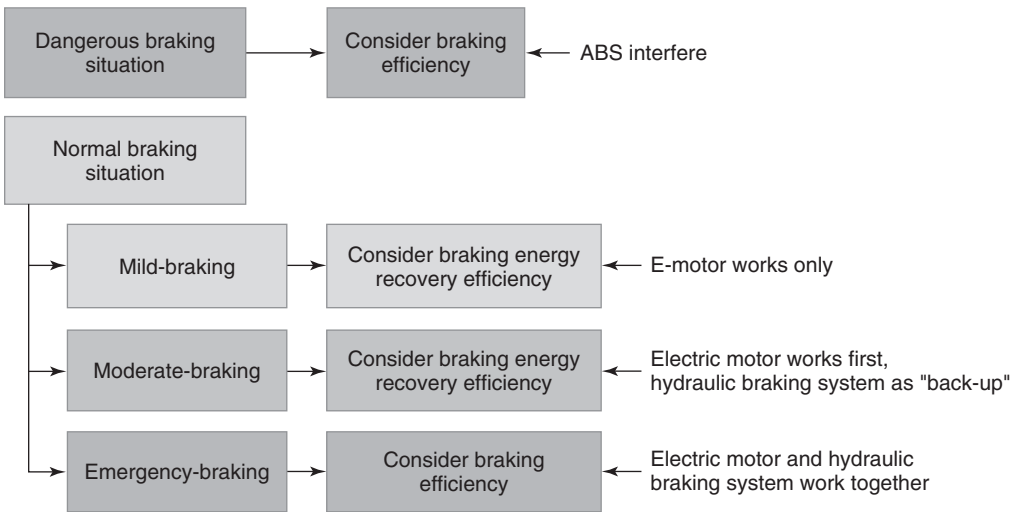

Figure 18. The control strategy under different braking intentions. (Modified from Zhang and Ning, 2009.)

torque. When the rotational speed of the electric motor is higher than the rated speed, the electric motor works under the rated power. When the rotational speed of the electric motor is too low, the regenerative braking fails to work because of the too low electromotive force. In this case, the regenerative braking force decreases to zero immediately (Zhang and Ning, 2009).

5. By emergency braking, the required braking torque may be many times higher than which the traction motor can supply. In this case, the conventional braking system is indispensable for a compensation of the braking torque to achieve the desired deceleration.

4.3.1.2 Different kinds of the electric motors. Most commonly used electric machines in electric vehicles are permanent magnet synchronous motors (PMSM), AC induction motors (IM), and switched reluctance motor (SRM). IM is simple-structured, rugged, low cost, and relatively mature in speed vector control technology. However, compared to the permanent magnet motor, it has a lower efficiency and power density.

PMSM uses permanent magnet to replace its excitation system, and it has a higher power density, a higher efficiency, and a wider speed range. Vector control is often used when the drive system works in a low speed range, whereas the flux-weakening control is used in a high speed range.

SRM system features a compact and solid motor, suitable for high speed operation, with a simple and low cost drive circuit, performance reliable in a wide speed range with relatively high efficiency, and it can easily realize four-quadrant control. The disadvantage is the torque ripple and noise. In addition, by contrast to PMSM, the power density and efficiency is lower.

4.3.2 Hydraulic braking system

The traditional hydraulic braking system can be divided into two categories, with variable β and with fixed β (Zhang and Ning, 2009). Here, β is the braking force distribution coefficient. With variable β, the realistic brake force distribution curve is much closer to the ideal distribution curve. The technique of variable β is called *electric braking distribution* (*EBD*, shown in Figure 19). At present, with the application of ABS, wheel lock cases can be avoided. However, the biggest disadvantage is that ABS cannot realize regenerative braking. All braking energy is wasted.

In the cooperative regenerative braking system, if the hydraulic braking force can be controlled, the realistic brake force distribution curve can be much nearer to the ideal curve by adjusting the hydraulic brake force. Yet, currently in many cases, the cooperative regenerative braking system is realized by adding electric motors directly onto the original hydraulic braking system, the frictional brake force cannot be adjusted. In this case, the electric motor regenerative brake force can be adjusted in order to get near to the ideal distribution curve.

5 RELATED RESEARCH FIELDS IN THIS REGARDS

The cooperative regenerative braking system brings us more energy efficient vehicles, but at the same time, it brings more challenges for automotive engineers to ensure the vehicle safety, control stability, and riding comfort.

5.1 Brake feel

Brake feel (Zhang and Ning, 2009) can help the driver make the judgment, which includes the brake pedal displacement, the resistance force of brake pedal, and the vehicle braking performance which the driver can feel (Figure 20).

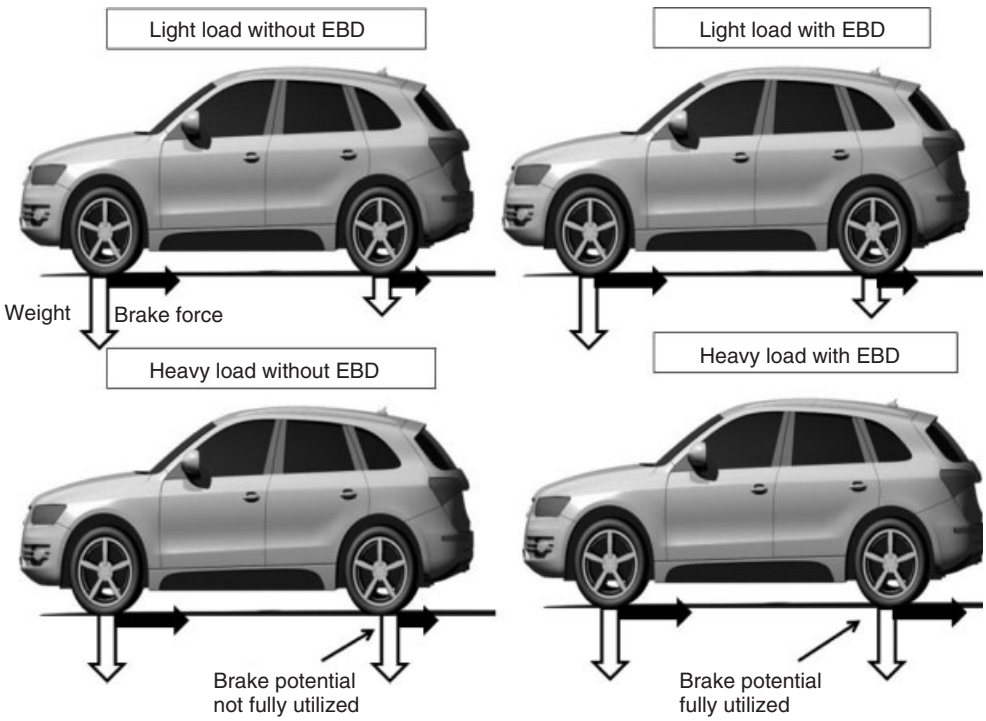

Figure 19. The influence of using EBD.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.
This article is © 2014 John Wiley & Sons, Ltd.
DOI: 10.1002/9781118354179.auto028
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

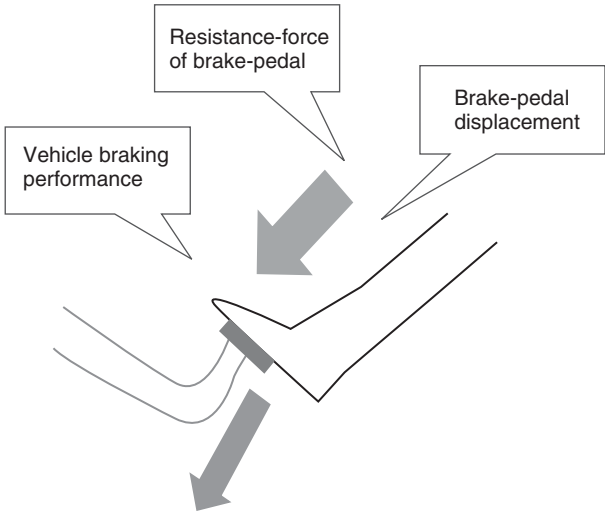

Figure 20. Brake feel.

Currently, some cooperative regenerative braking systems are realized by adding the electric motor systems directly onto the traditional friction braking system. Compared with hydraulic braking system, the electric motors respond faster. However, it brings a new problem, different brake feel. Therefore, if it needs to make sure of the same brake feel, automotive engineers have to postpone the active time point of the electric motor. Another problem is how much brake force should electric motor supply. The uncertainty increased with the change of the brake deceleration. To solve those problems, it is common to install an electric motor under the brake pedal to simulate the feedback of brake pedal force and displacement for the driver.

In addition, in the case of regenerative braking, brake fluid cannot flow to the wheel brake cylinder because of valve resistance. It results in a smaller brake pedal displacement. As the regenerative braking changed to friction braking because electric motor cannot supply torque when the rotational speed is too low, the valve switched from closed to open, it brings a sudden change in brake pedal displacement. At this point of time, definitely, it brings a sudden and significant bake feel change.

5.2 The influence of the cooperative regenerative braking system on ABS

To maximize the braking efficiency, hopefully the wheels would be in a lock/unlock state. ABS is a system that adjusts the wheel slip rate to make sure that the wheels in the right state. Because electric motor has advantages in fast response and easy control, usually the electric motors would act at first to supply the regenerative brake force (Zhang and Ning, 2009). If it is not enough, the traditional friction brake system would work as a "backup."

The motor's regenerative braking function is usually turned off when ABS works in order to simplify motor control and protect motor. For four-wheel-driven vehicles, in-wheel electric motors can work together with hydraulic system to realize the function of ABS to adjust each wheel's slip rate by controlling motor current and the wheel's brake torque in order to keep the wheel's ideal status.

For central electric-motor-driven vehicles, electric motor can only take the job of EBD. The function of ABS can only be realized by the hydraulic brake system. In the vehicles on which the electric motors are just directly added onto the traditional friction braking system, controlling the pressure of the brake fluid can adjust the wheel's slip rate.

5.3 The energy recovery sufficiency

Electric motor plays the role of energy transform in the cooperative regenerative braking system. There should be some parts to store the retrieved energy such as battery. Basically, there are three energy storage devices: battery, supercapacitor, and flywheel. At present, battery and supercapacitor would be the prior choices. Either one or some different kinds of devices can be used together in vehicles (Figure 21).

Energy recovery efficiency depends on the battery property, electric motor working property, the charging speed, etc. In the cooperative regenerative braking system, over charging and fast charging happen quite often. It makes the working environment of electric motor and battery very bad. In this case, the key point to get higher energy recovery efficiency lies in the electric motor control strategy as well as the battery energy storing technology.

6 CASES ABOUT THE COOPERATIVE REGENERATIVE BRAKING SYSTEM

Although the regenerative braking technology was first used in trolley cars, it has subsequently found its way into such unlikely places as electric bicycles and even Formula One racing cars. At present, these kinds of brakes are primarily found in hybrid vehicles, such as the Toyota Prius, and in fully electric cars, such as the Tesla Roadster. Followings are some cases showing how the cooperative regenerative braking system works in the hand of different automakers.

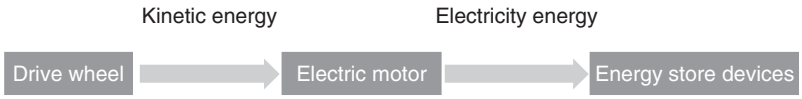

Figure 21. The theory of regenerative braking system.

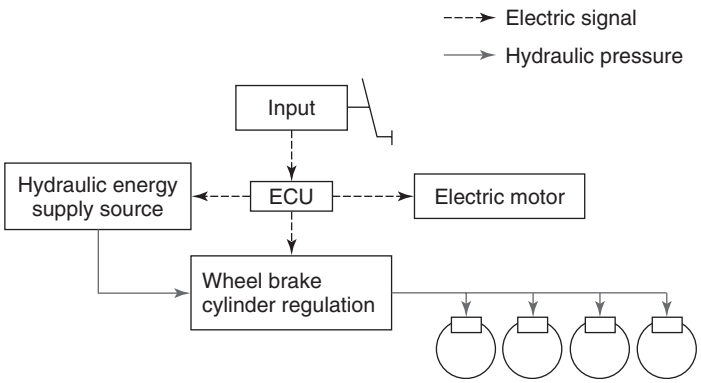

Figure 22. The regenerative braking system of Prius.

6.1 Toyota Prius

It is well known that Toyota Prius is the most popular hybrid electric vehicle in the world with the highest degree of industrialization and largest market share. The cooperative regenerative braking system in Prius is working based on the linear electromagnetic valve developed by Toyota, shown in Figure 22 (Lampton, n.d).

The design is based on the concept "brake by wire" (Zhang and Ning, 2009). Because the input from brake pedal controlled directly by the driver is separated from the brake fluid pressure, the pressure in the wheel brake cylinder can be controlled completely without the influence from the movement of brake pedal. When the driver steps down the brake pedal, the pedal displacement simulator transmits the information to the ECU instead that the pedal pushed the piston in brake main cylinder directly. The ECU decides how much brake force should the hydraulic braking system supply. With this feedback, the piston in the brake main cylinder would be pushed forward to generate the designed pressure.

6.2 Continental

Engineers in Continental developed a regenerative braking system for electric and hybrid vehicles (http://www.conti-online.com/generator/www/de/de/continental/engineering_services/themes/brakes_chassis/download/one_pager_regenerative_braking_pdf_uv.pdf). The design is also based on the concept "brake by wire." The components in this brake system include ESC with eGap (generator), electric vacuum pump, simulated brake actuation, and electromechanical brakes (Figure 23).

Cooperation between brake and power train system include

1. monitoring of driver brake request;
2. decouple driver demand from friction braking;
3. recuperation interface between brake and power train.

Different solutions for regenerative braking is as follows:

1. brake actuation with pedal force simulator (full by-wire braking);
2. Use of electrical brake caliper (by-wire braking at one axle);
3. eGap (the generator) realized by electronic brake system (conventional hydraulic brake system).

7 SUMMARY

Although there is still a long way to go for the cooperative regenerative braking system to achieve the same degree of the success and popularity as ABS, one thing seems certain: the application of regenerative braking is an irreversible trend. As hybrids with electric motors and regenerative brakes can travel considerably farther on a gallon of gas, some has achieved more than 50 miles per gallon at

Torque Vectoring for Drivetrain Systems

Claus Granzow and Matthias Arzner
ZF Friedrichshafen AG, Friedrichshafen, Germany

1 TORQUE VECTORING

The term *torque vectoring* describes the active generation of a vehicle yaw moment by a directed distribution of input torques over the left and right sides of the vehicle. Torque vectoring can be used to influence the degree of yaw of the vehicle and in this way to actively control the driving dynamics (active yaw control).

2 TORQUE DISTRIBUTION IN THE DRIVELINE

To avoid stress on the driveline and tire wear during cornering, a transmission is needed that provides free speed compensation. These compensating or differential transmissions create a fixed torque distribution over the two outputs, while making different rotational speeds possible.

Relating to one axle, that is, in the transverse vehicle direction, the differential distributes the torque 50%/50% on the two wheel sides. In the longitudinal vehicle direction of a multi-axle-driven vehicle, differentials are also used for the necessary speed compensation. Not only equal distribution, but also asymmetric torque distributions are possible here (e.g., 33%/67%, 38%/62%). They are selected depending on the traction potential of the axles and the desired handling behavior.

Although differentials are unavoidable for passenger cars, a permanently fixed torque distribution has disadvantages in many driving situations. Widely different road-tire friction coefficients of the wheels on one or different axles can cause individual wheels to build up high slip that limits the torque transfer capability. The wheel with the lowest friction coefficient determines the total transferable torque of the driveline. This means that free speed compensation impairs the traction behavior on different road surfaces. For instance, if one wheel is on ice, it builds up a high level of tire slip, whereas all the other wheels on asphalt cannot transfer any more torque than the wheel rotating on the ice. This gives the vehicle a poor start-up performance.

This can be remedied by limited slip differentials (LSDs) that can prevent the compensating effect in critical driving situations. Principally, a distinction can be made between three types of LSDs:

- Shiftable black–white differential locks that can lock the speed compensation by 100% (automatically or manually).
- Self-locking differentials either in torque-sensing or in speed-sensing design. The first type locks the speed compensation as a function of the torque to be transmitted, whereas the locking rate of the second type represents a function of the differential speed.
- LSD that can be activated externally. These systems are usually electronically controlled and feature a hydraulic or electromechanical actuator. Usually, the locking rate is continuously variable between 0% and 100% and is determined by a strategy depending on the driving situation.

2.1 Definition of locking value

The locking value S is a characteristic value that defines the degree to which the compensating effect of the differential is prevented. The definition is as follows:

$$S = \frac{\text{Locking torque } T_B}{\text{Input torque } T} = \frac{T_{right} - T_{left}}{T_{right} + T_{left}} \quad (1)$$

The possible value range is between 0% and 100%. An ideal open differential has a locking value of $S = 0\%$, whereas a fully blocked differential has a locking value of $S = 100\%$. Normal open differentials have locking values of approximately $S = 5–10\%$. Torque-sensing limited slip differentials have a constant locking value.

Limited slip differentials can be used mainly to increase traction by compensating any slippage that occurs. The drive torque is largely transmitted to the vehicle side or vehicle axle that still has potential for transmission. The originally fixed torque distribution between the differential outputs (e.g., 50%/50%) is superimposed by the differential locking torque. As a basic principle, a limited slip differential only enables torque transmission from the side that is rotating faster to the side that is rotating more slowly. When a vehicle drives round a curve with an even friction coefficient, actuating the limited slip differential tends to lead to understeering. The limited slip differential can be used to stabilize the driving dynamics.

Torque-vectoring systems expand the function of controllable limited slip differentials. The directed asymmetric torque distribution over one axle can be used to apply a yaw moment around the vehicle vertical axis. Beside the differential locking effect, a torque-vectoring system must also be capable of transmitting torques to the shaft that is rotating faster and therefore increasing the difference in speed of rotation between the left and right vehicle sides. During cornering, it is possible to affect an inward turning; this means a more agile vehicle handling.

2.2 Definition of vectoring torque

The difference between the two-wheel torques (in the direction of travel) is called the *vectoring torque of an axle*:

$$T_{TV} = T_{right} - T_{left} \quad (2)$$

Positive vectoring torques lead to a counterclockwise yaw moment of the vehicle around the vertical axis. The maximum vectoring torque depends on the vehicle moment of inertia around the vehicle vertical axis as well as the required operating range of the torque-vectoring system. Typically, affecting traction at low speeds requires higher values of vectoring torques than affecting driving dynamics.

2.3 Hang-on clutches and torque splitters

As an alternative to differentials with superimposition units (limited slip differentials or torque-vectoring units), there is also the option of achieving speed compensation using a slipping multidisk clutch. Here, there is no differential, because the required torque is completely transmitted via a multidisk clutch operated during slipping. A basic distinction is made between clutches for torque distribution in longitudinal and transverse configurations.

Clutches that distribute the torque between different axles replace an interaxle differential and are called *hang-on clutches*. A permanent all-wheel-drive system with hang-on clutch requires a specially designed clutch as well as a suitable actuating system and operating strategy. The torque flow to the hang-on or secondary axle can be freely selected within the range of the speed conditions according to aspects of traction and driving dynamics. The strategy must also achieve the speed compensation in case of cornering.

The differential relating to one axle as speed compensation in the transverse direction can be functionally replaced by a twin clutch system. Here, the two wheel drive torques are set by the respective clutches and used individually for influencing the traction and driving dynamics. Twin clutch systems are also known as *torque splitters* because they are only able to individually distribute the input torque to the two drives. In contrast, torque-vectoring systems with the above-mentioned superimposition units can generate wheel differential torques and therefore yaw moments independently of loads.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

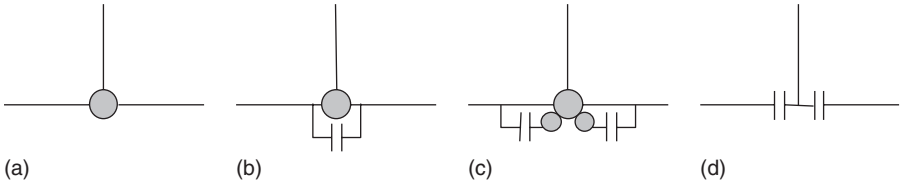

Figure 1. Diagram of the basic elements of transverse torque splitting. (a) Open differential with fixed torque distribution (50%:50%), full speed compensation. (b) Differential with lock and basic distribution (50%:50%), active compensation of differential speeds, torque transfer from faster to slower sides, mainly used to increase traction. (c) Differential with superimposition unit and basic distribution (50%:50%), additional torque can be superimposed, torque transfer to faster side also possible, active yaw rate control possible. (d) Twin clutch system without basic distribution, individual distribution of the input torque possible, no generation of differential torques in coast situation, also covers active longitudinal distribution (hang-on system).

2.4 Speed error

Another essential design criterion apart from the maximum vectoring torque is the speed error. The speed error is the maximum speed difference of the two output shafts in percentage until which torque transmission to the faster rotating output shaft is possible. At the vehicle level, this is the minimum curve radius at which agility-increasing vectoring activities are still possible. While stabilizing or traction-increasing interventions are possible under any speed conditions, agility-increasing interventions are not possible below a minimum curve radius.

Very large speed errors collectively cause increased friction power on the clutches. That is why, it is important when determining the speed error to weigh up the smallest curve radius that is still relevant for torque-vectoring interventions and what collective friction power can be collectively covered by the clutches.

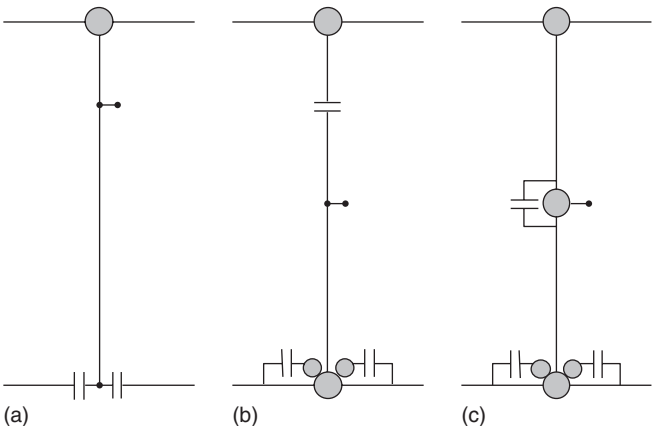

Figure 2. Diagram of driveline examples with active transverse torque distribution. (a) Twin clutch on rear axle, front axle as primary axle (e.g., Honda SH-AWC). (b) Rear axle torque vectoring and hang-on front axle (e.g., BMW X6). (c) Rear axle torque vectoring and Torsen center differential (e.g., Audi Sportdifferential).

2.5 Torque distribution strategies/designs

Figure 1 shows the basic elements of transverse torque distribution. Together with the various options for longitudinal torque distribution, this can be used to arrange various drivelines. Figure 2 shows some driveline configurations available on the market.

3 INFLUENCING VEHICLE HANDLING WITH TORQUE VECTORING

The free distribution of torques between the four vehicle wheels can be used to actively influence the vehicle handling. The way this works is comparable to the steering principle of a tracked vehicle. When the driver of a tracked vehicle wishes to change the travel direction, different track speeds are applied to the inner and outer tracks. The different speeds cause the vehicle to turn around its vertical axis.

Torque-vectoring systems in a passenger car driveline influence the direction of travel in a similar way. Depending on the system characteristics, this can occur depending on or independently of the current input torque of the vehicle. Simple torque splitters can only influence the ride direction when there is input torque. To utilize the effect, the driver must consciously select trailing throttle or acceleration mode.

Torque-vectoring systems with superimposition function can generate the required differential torque without limitation by the input torque. They offer a much wider scope for influencing the driving dynamics. As they work independently of the input torque, they can also be seen as components purely for influencing vehicle dynamics, comparable with steering systems.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto029
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.1 Yaw moment by torque vectoring

The vectoring torque, also called *wheel difference torque*, occurs due to different longitudinal forces on the two wheels of a vehicle axle. In the simplest case, these are two longitudinal wheel forces with identical magnitude and preceding plus or minus signs. However, in most cases, the differential torque is superimposed by symmetrical drive or braking forces.

According to the track width of the vehicle, the wheel difference force leads to a free torque around the vehicle's vertical axis. This torque influences the yawing motion of the vehicle and can be used to change the direction of travel.

The complex friction conditions on the vehicle tires can influence the effect of torque vectoring especially during cornering. In respect to the traction limit given by the circle of forces, the lateral wheel force can be weakened by superimposed longitudinal wheel force. Superimposed vectoring torque reduces the amount of lateral wheel force in the same way as additional drive or braking torque. In any case, the additional longitudinal force causes the amount of lateral wheel force and generates an additional influence on the vehicles yaw behavior.

Depending on the place of installation of the torque-vectoring device at front or rear axle and the sign of the vectoring torque, this effect can reinforce or weaken the effect on the vehicle yaw moment.

3.2 Inward- and outward-turning differential torque

The yawing motion of the vehicle around its vertical axis can have a stabilizing effect or can increase the dynamics. In principle, a difference is made between an inward-turning and an outward-turning torque.

Inward-turning torque supports vehicle cornering by reinforcing the yawing motion around the vertical axis. The inward-turning torque reduces the curve radius. The outward-turning torque slows the vehicle yawing motion and increases the curve radius. This is why the outward-turning torque is used to stabilize the vehicle. Figure 3 describes the relation between direction of yaw torque and vehicle behavior during cornering.

3.3 Influencing self-steering using torque vectoring

For reasons of safety and controllability, modern vehicles built to today's standards are designed to have a general understeering behavior at the driving limits. This means that with increasing lateral acceleration, the steering angle

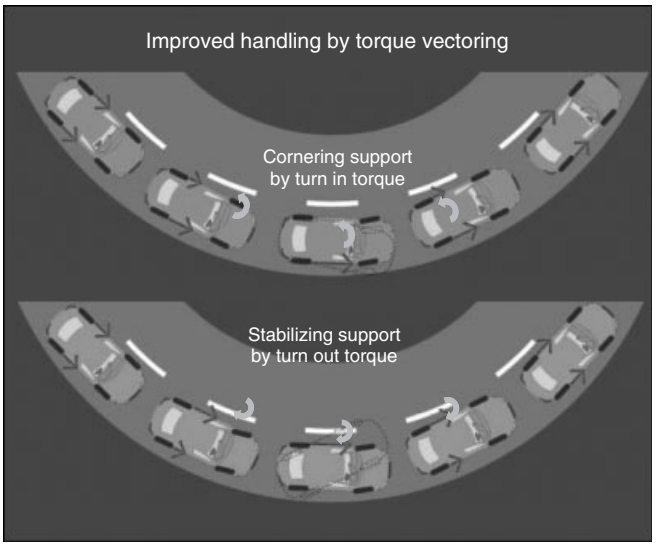

Figure 3. Influencing the driving dynamics with the torque-vectoring function. Agility-increasing and stabilizing yaw moment.

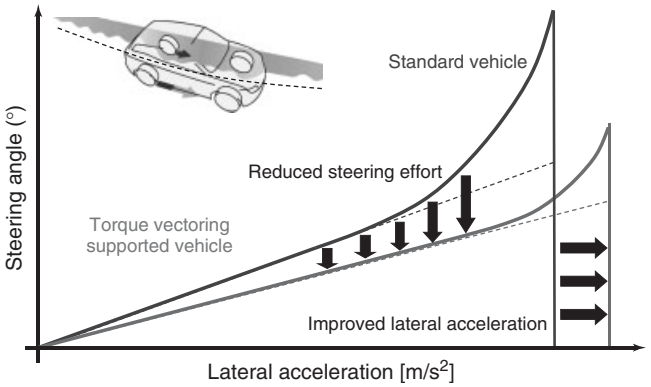

Figure 4. Altering the self-steering response by superimposing the torque-vectoring function.

needed to further reduce the curve radius increases disproportionately. The maximum possible cornering forces of the front tires limit the minimum curve radius. The vehicle stability limit is indicated to the driver by a stable vehicle with slipping front tires. The relation in terms of driving dynamics between the steering angle and lateral acceleration is also called the *vehicle self-steering effect* (Figure 4).

This understeering tendency of the vehicle is intensified when a braking or input torque is additionally applied to the steered axle. Especially in the case of front-wheel or all-wheel-drive vehicles, this is called *load understeering*.

In combination with a suitable, dynamic steering system, a torque-vectoring system offers the option of freely influencing the self-steering effect. In most cases, it is used

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto029
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to reduce or compensate for the understeering tendency described. If, due to overloading or high cornering speed, the front axle reaches the limits of its cornering force, the yawing motion of the vehicle can be increased by the application of a free yaw moment around the vertical axis. The vehicle continues to follow the driver's steering command and behaves in a sporty and neutral way.

In particular, drivers often find the responsive reaction of the vehicle to their steering commands and the very late or even complete absence of understeering a very positive characteristic.

In general, the torque-vectoring unit is actuated by means of a driving dynamics control. In a similar way to a brake-based stability system (ESC), this monitors the driving condition of the vehicle by comparing a measured vehicle yawing rate with an ideal yawing rate calculated from the steering angle and the vehicle speed. The great advantage of torque-vectoring-based regulation of driving dynamics is the system's continuous mode of operation. It corrects the direction of travel gently and smoothly without any speed-reducing braking interventions.

3.4 Driving dynamics limits of torque-vectoring systems

As with any driven wheel, the torque transmission capability is limited by the friction coefficient and the vertical tire force. The vertical tire force is particularly important because it can change dramatically during cornering.

Constant cornering produces a positive wheel load distribution on the two wheels on the outside of the curve. The force potential gained here can be used to supply the outer wheels with additional input torque. In this way, the wheel load distribution toward the outside of the curve supports the generation of an inward-turning yaw moment.

In the opposite case, the load is reduced on the two inner wheels of the vehicle during high lateral acceleration. The accompanying reduction in wheel force potential limits the force buildup of a stabilizing yaw moment. Therefore, a torque-vectoring system is particularly suited to creating an inward-turning yaw moment.

4 MECHANICAL CONCEPTS OF MODERN TORQUE-VECTORING AXLE DRIVES

Generally, a torque-vectoring system is understood as an axle drive that can generate a positive or negative wheel differential torque irrespective of the drive situation.

The basic power distribution is always provided by a differential compensating transmission. The differential decouples the two wheel speeds and distributes the input torque between both wheels, ideally 50% per wheel. The function can be performed by a conventional bevel gear differential. For reasons of space saving and effectiveness, a spur gear differential is used in some applications.

The torque-vectoring function itself is achieved with the help of so-called *superimposition units*. They make it possible to apply alternative power flows inside the transmission and enable controlled power distribution between the two wheels.

In general, torque shifting is required bidirectionally between both wheels of an axle (inward- and outward-turning redistribution), so two separate superimposition units are installed in a transmission. Here, each unit takes care of one redistribution direction. Depending on the transmission concept, the units can be installed symmetrically on the left and right of the basic axle transmission (see ZF and Magna concept as described in Sections 5 and 7), or arranged nested on one side of the axle drive (Mitsubishi).

A single superimposition unit always consists of a friction clutch and a transmission stage. While the friction clutch provides the actuation moment necessary for torque distribution, the transmission stage ensures the speed error required for initiating and intensifying the torque-vectoring effect.

5 ZF VECTOR DRIVE© CONCEPT

The ZF Vector Drive© axle drive consists of a conventional bevel gear differential and two symmetrically arranged superimposition units. The superimposition unit consists of a planetary gearset, which itself consists of two sun gears, one planet carrier, and three planetary gears. The inner sun gear is connected to the differential cage, whereas the outer sun gear is connected to the relevant side shaft. A multidisk brake acting between the planet carrier and the transmission housing acts as a torque modulation element (Figures 5 and 6).

With the help of a roughly 11% speed error in the planetary gearset, the application of a braking torque achieves a power flow from the axle drive via the planetary gearset to the individual wheel.

The ZF Vector Drive© transmission was used for the first time in volume production in 2008 in the BMW X6.

6 THE MITSUBISHI CONCEPT

The classic, asymmetric torque-vectoring transmission design is called the *Mitsubishi concept*. In the current version, it features a planetary-designed axle drive. The

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto029
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

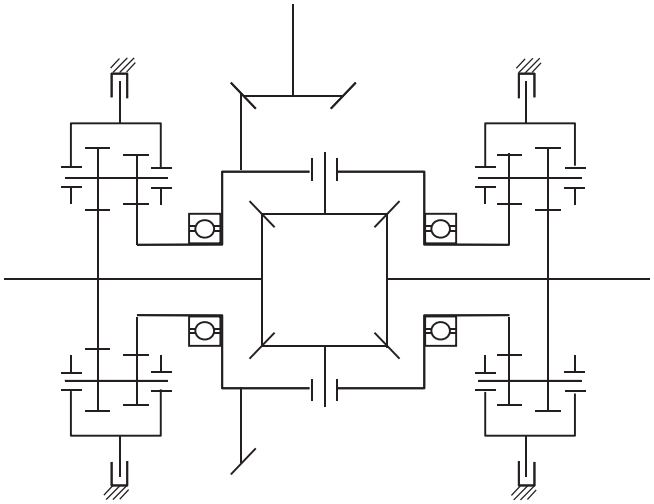

Figure 5. Schematic diagram of the ZF Vector Drive© system.

Figure 6. Sectional drawing of the ZF Vector Drive© system.

advantages of this design are the low self-locking value, the narrow construction shape, and the direct action on the opposite output shaft.

Added to the axle drive is a nested superimposition unit installed on the right side. The input and output of the superimposition unit are each connected to the two side shafts of the axle drive. The superimposition unit itself consists of two multidisk clutches and two transmission stages allocated to the individual clutches (Figures 7 and 8).

The difference is that the transmission stage on the inner clutch generates increased slippage compared to the wheel differential speed, and the transmission stage on the outer clutch provides a reduced clutch slippage compared to the wheel differential speed. Depending on which clutch is

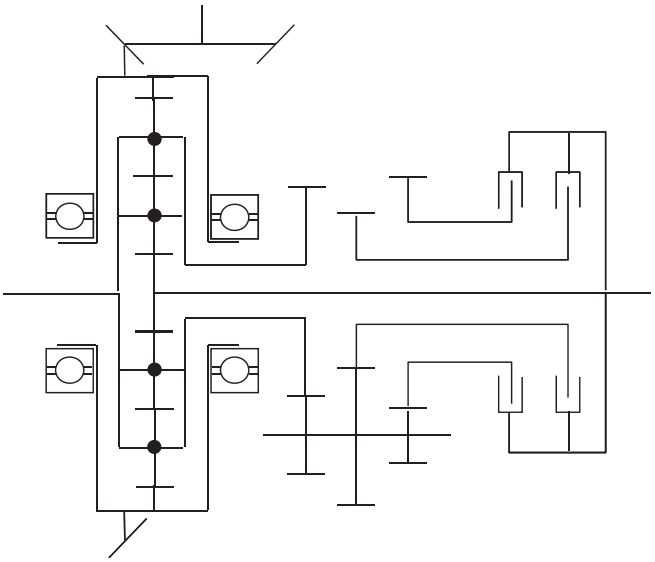

Figure 7. Schematic diagram of the Mitsubishi torque-vectoring system.

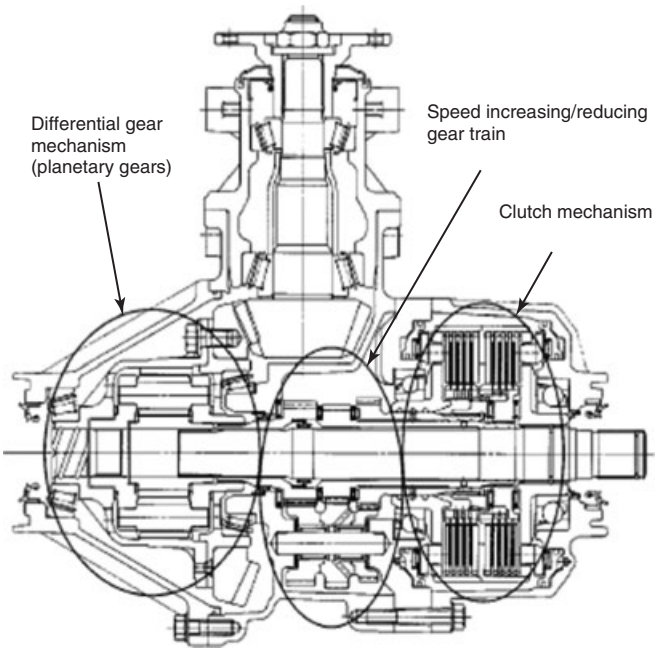

Figure 8. Sectional drawing of the Mitsubishi torque-vectoring system. (Photo: Mitsubishi.)

actuated, the different differential speeds of the two clutches can create a specific power flow directly between the two rear wheels.

The first time a torque-vectoring transmission was used in volume production was by Mitsubishi in 1996 in its Lancer Evolution 4 model. That makes Mitsubishi along

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto029
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

with Honda one of the pioneers in the application of this technology. The planetary basic differential design presented here has been in use in the Lancer model since the Lancer Evolution 8 generation.

7 THE MAGNA CONCEPT

The Magna concept also has a symmetrical design, consisting of a bevel-gear-based drive unit and two individual superimposition units attached outboard. The superimposition units each feature two individual, single-stage transmissions connected by a multiplate clutch. Each of these transmission stages consists of a sun gear and a ring gear, which has a radial displacement in respect to the sun gear. The sun gear of the inner transmission stage is connected to the differential cage, and the sun gear of the outer transmission stage is connected to the output shaft. To generate the required speed error within the superimposition unit, the ratios of the two stages differ slightly by about 10%.

Friction clutches are used to control the torque distribution. The two wet-running clutches are each installed between the two ring gears of each superimposition unit and also run with a radial offset to the drive units' output axis (Figures 9 and 10).

When the clutch is actuated, the positive speed error creates a power flow from the axle drive to the wheel via the first transmission stage, the clutch package, and the second transmission stage.

The Magna torque-vectoring transmission was introduced for the first time in 2009 in the Audi S4 under the name "Sportdifferential", and then made available as an optional extra in further Audi models.

8 TORQUE SPLITTER AND LIMITED SLIP DIFFERENTIALS

The two types torque splitter and limited slip differential are special forms of torque-vectoring axle drives. They also enable splitting of the input torque between the wheels, although with the above-described limitations (Figure 11).

The torque splitter does not use a conventional differential-based axle drive. The power or torque splitting is achieved directly by two control elements that control individual wheels. The control elements usually consist of friction clutches that are connected either directly or with the help of planetary gearsets. In both cases, a sophisticated ratio selection must ensure that both clutches have a differential speed in order to generate a positive power flow to the individual wheel.

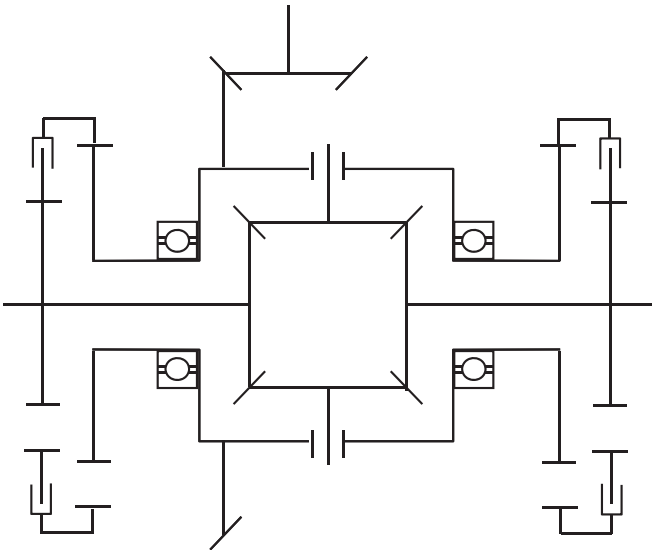

Figure 9. Schematic diagram of the Magna torque-vectoring system.

Usually, an electronically controlled limited slip differential consists of a bevel gear differential and an additional multidisk clutch. The clutch is installed between the differential cage and one of the side shafts. It enables a direct flow of power between the differential cage and the side shaft.

9 ACTUATING SYSTEMS

A further distinction between different torque-vectoring transmissions is the selected concept of actuating system. The whole range of mechatronic designs can be used to actuate the multidisk clutches installed. Apart from classic hydraulic actuation, electromechanical and electromagnetic actuations are also used for products in volume production.

Each of these technologies comes with advantages and disadvantages. Electrohydraulic actuation features a high power density and enables central energy generation for both clutches. Compared to separate actuators for each clutch hydraulic actuation can have favorable effects in terms of installation space and weight, but have to be weighed up against disadvantages in efficiency and dynamics at low temperatures.

Electromechanical actuation is attractive due to its integrated position sensing with very precise controllability and high actuating dynamics. Another advantage is the temperature resistance especially under cold conditions. Viscosity

effects only have minor influence on the actuation function. Compromises must be made in the package and weight because the actuator mechanics cannot be installed freely on the drive unit.

Both electrohydraulic and electromechanical actuation use electric motors to generate the control power. When high dynamic handling is required, the motors provide for short-term higher energy takeoff from the vehicle main power system.

The advantage of electromagnetic systems is their better package and high dynamics. The concentric arrangement of the actuator coils around the side output shafts allows for compact, space-saving installation. The disadvantages of direct magnet actuation are higher weight and lower energy density. To generate high clutch torques, large and heavy coils must be supplied with high currents. These disadvantages can be avoided by using electromagnets to actuate only a pre-control clutch. The pre-control clutch turns a ball-ramp mechanism, using the rotary motion from the driveline. Clutches based on this principle are a common and very cost-effective solution for many all-wheel applications.

10 FURTHER DETAILS OF A TORQUE-VECTORING SYSTEM USING THE EXAMPLE OF ZF-VECTOR DRIVE©

10.1 Torque Bias Effect

The direct influence of the self-locking coefficient on the control accuracy of a modern torque-vectoring drive unit is called *torque bias effect*. This effect occurs when the drive unit is included in the power flow for generating the differential torque (see ZF and Magna concept as described in Sections 5 and 7).

Depending on the type of load (trailing throttle, acceleration, or coast) and the required vectoring torque, a residual torque occurs within the drive unit. This residual torque relates to the differential itself and is not transferred by the superimposition unit.

Owing to the locking value S of an open bevel gear differential, the drive unit generates an outward-turning differential torque. The sum of the outward-turning differential torque and the vectoring torque by the superimposition unit determines the overall torque split between the two output shafts.

Depending on the value of the self-locking coefficient, the differential torque in the (very important) case of inward turning is weakened, and in the (less important) case of outward turning, it is strengthened. A self-locking coefficient that is as low as possible and remains constant over the entire lifetime is key to the constant and efficient functioning of a torque-vectoring system.

Figure 12 shows the torque flow of the ZF Vector Drive© system during accelerated cornering in connection with an inward-turning differential torque.

10.2 Actuation

Active control of self-steering properties and of the driving-dynamics-related vehicle response through highly dynamic transversal distribution of wheel torques requires an actuator that can perform very quick and precise actuations. Electromechanical actuating systems are compact and very efficient, with low power consumption. The torque of the E-motor is boosted by a spur gearset before it is transformed into an axial force via a ball ramp. The axial force is used to pressurize the multiplate disc and thus for the transfer of the specifically desired torque (Figure 13). The geometry of the ball ramp can be designed in such a manner that ensures the fastest-possible free travel with optimal resolution and controllability of the operating range. The adjustment time from 0% to 90% of the maximum possible differential torque of 1800 Nm is just 80–100 ms. Figure 14 gives an example of control accuracy measurement with a step-type vectoring- torque request.

10.2.1 Electric motor

In addition to the requirements in terms of dynamics and precision, the E-motor must fulfill the requirements relating to safety and the environmental impact. The safety concept for a de-energized (failure) condition requires that the torque-vectoring moment is immediately reduced and that the transmission behaves like an ordinary rear drive unit

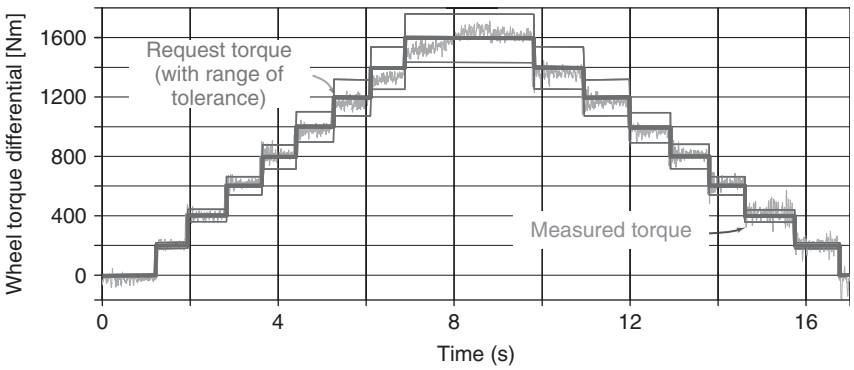

Figure 14. Control accuracy sequence of the ZF Vector Drive © system.

with open differential (fail-safe). As regards the E-motor, this means that the automatic opening of the multiplate disc must not be hindered by a locking moment. Use of the E-motor in the area of the differential implies extraordinary strains in terms of leak tightness, vibration, and temperature.

All these requirements are optimally fulfilled by asynchronous E-motors. These E-motors do not need a brush, nor do they need permanent magnets. They are thus free from any locking moment and ideally support de-energized opening in the event of a failure. Moreover, they are wear-free and provide a high level of ruggedness. Operation is possible with the E-motor open toward the drive unit, which permits free oil flow between motor and space of drive unit. The oil of the drive unit thus also lubricates the bearings of the rotor shaft, and separate venting of the E-motor is not necessary any more.

10.3 Electronics and safety concept

A dual-controller unit with integrated power electronics controls the drive. The vectoring torque calculated by the driving dynamics function is processed further in respect to present operating conditions. This means the controlled electric motors apply the multidisk brakes to generate an accurate vectoring torque.

Angle-of-rotation sensors sense the motor position and permit precise and prompt actuation of the multidisk brake. The software includes compensation functions for temperature, speed, and aging effects.

Owing to the intervention in the driving dynamics and stability of the vehicle, the safety concept was classified according to SIL 3, which corresponds with an error response equivalent to that of an active steering angle intervention. The safety concept implemented in the control

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto029
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

unit constantly monitors all units and ensures an immediate reaction to any sudden faults, so that the vehicle response is never compromised.

A dual-controller control unit implements the safety concept on the basis of mutual monitoring through redundancy functions. If the results from the two controllers differ, the vectoring torque will immediately be reduced to establish a safe condition of the system. This ensures that an error will not result in a safety-critical driving condition, which might endanger the driver and which he might not be able to handle. To meet the high system requirements, a precise tuning of the safety functions especially in respect to the units' mechanical characteristics is necessary.

10.4 Performance

Modern driving dynamics functions are based on vehicle models, and use sensor information such as steering angle, lateral acceleration, yaw rate, and vehicle speed to calculate the necessary vectoring torque highly accurately. In general, the overall control consists of two main control elements. The pre-control element sets the optimal and reproducible wheel differential torque for any driving situation. At the same time, the yaw rate control element corrects any deviations between the target and actual yaw rates, ensuring the required driving dynamics are maintained. This ensures a high degree of agility, controllability, and safety even at the stability limits of the vehicle. High setting accuracy and dynamics of the torque-vectoring system is essential to provide these benefits (Figures 14 and 15).

10.5 Efficiency factor and drag torques

As part of current efforts to reduce energy consumption and carbon dioxide emissions, efficiency, including reducing losses that occur within the axle drive, plays an increasingly important role. Every torque-vectoring system creates additional losses due to its components, gearing, and bearings. However, the levels of loss are different depending on the torque-vectoring design and the driving situation. The goal is to keep the extra consumption as low as possible in the driving cycle that is relevant to the driver.

Figure 16 shows the proportion of drag power caused by the two TV units of the ZF Vector Drive© system examined. The driving situation this is based on is straight-ahead driving at constant speed without actuation, such as occurs on freeways. Compared to the total losses from axle drives, the losses here are relatively low. The reason for this is that in this driving situation, the planetary gearset rotates as a block so that there is no gearing roll-off. Furthermore, a careful choice of oil and lining material means the fast-running multidisk clutches have a very low drag torque.

10.6 System networking with other driving dynamics control systems

Modern vehicles can feature a large number of other control systems apart from torque-vectoring systems, which make it possible to actively influence the driving dynamics. Active steering systems offer an additional superimposition steering angle that can be used to influence driving dynamics. Active rear axle steering systems can be used for active sideslip-angle control. Active roll stabilization impacts the self-steering response. Furthermore, braking interventions on selected wheels can also be used in addition to ESC to influence driving dynamics. What all these systems have in common is that they can electronically control the movement of the vehicle around the vertical

axis. Super ordinate strategies link up the individual driving dynamics systems and help optimally coordinate interventions. This not only increases functionality by using interventions that supplement or support each other but also ensures maximum availability and increased driving safety.

11 DISCUSSION AND CONCLUSION

Torque vectoring for drivetrain systems represents a powerful vehicle technology to improve vehicle performance. The systems allow the intelligent distribution of propulsion torque to influence traction and vehicle dynamics. Different concepts, approaches, and designs have been developed and are nowadays available on the customer market. Several car manufactures use the technology of torque-vectoring to further improve the precision and agility of their modern and sporty vehicles.

The microcontroller-based control strategy of modern torque-vectoring systems allows a defined tuning of the vehicle behavior. The possibility of asymmetric torque distribution generates a yaw moment on the vertical axis and provides a strategy-based input for the intended vehicle behavior. Depending on the application and the intention of the manufacturer, different priorities in performance gain can be chosen during the development of the vehicle.

Beside the dynamic improvement, the optimization of the traction behavior still plays a crucial role, as this is one of the most important motivations for all-wheel-drive vehicles. Torque vectoring can also support the demand for increased traction and off-road performance by the lateral distribution of propulsion torque.

The technical effort to implement a torque-vectoring system at a modern vehicle unfortunately increases the weight and cost of the car. Additional gearsets, clutches, and actuators incorporate losses, which have negative effects on the efficiency and emissions. The losses are quite different, depending on the realized concept but nevertheless, they can restrain the technology from a wide spreading on the present car market.

1 INTRODUCTION

Full-scale global chassis control systems are being developed by various companies for use in passenger cars. This development started in Europe in 1983 with the Daimler-Benz 4Matic four-wheel drive (4WD) system, which used online calculation of vehicle states. Calculation results from a bicycle model and yaw rate measurement results from the wheel speeds were compared to determine whether to engage the front axle to the drive train using electronically controlled clutches. This system used longitudinal slip and lateral vehicle dynamics for control for the first time (German patent DE 35 05 455 CS, 1985). Other early examples include the integrated active suspension, active rear steer (ARS) system, traction control system (TCS), and antilock brake system (ABS) in the Toyota Soarer in 1991 (Tanaka *et al*., 1992) and the introduction of an in-vehicle local area network (LAN) with the 4WDi-Four and ARS system in the Toyota Crown Majesta in 1992. In addition, in 1992, BMW offered dynamic stability control (DSC), the first electronic stability control (ESC) in its 850i sports car. This system controlled the throttle and the ignition timing after comparing the vehicle behavior to a bicycle model. Mercedes and Toyota as ESC released additional brake intervention controls in 1995. These were followed in 1997 by the release of the Toyota Hybrid System (THS) in the Prius, which featured the first example of technology that combined braking performance with the recovery of regenerative energy. Subsequently, various companies are now developing global control systems that integrate powertrain, steering, and active braking systems. These include the integrated chassis management (ICM) system developed by BMW, the vehicle dynamics management (VDM) system developed by Bosch, the vehicle dynamics integrated management (VDIM) system developed by Toyota, and so on. Such systems are beginning to be considered as fundamental technology for enhancing safety and environmental performance as well as driving enjoyment. In addition, advances in vehicle environment recognition technology have led to the development of driver assistance systems such as precrash safety (PCS) and the like. This chapter describes an outline of integrated vehicle systems, focusing on global chassis control. It also

presents an overview of the integration of driver assistance systems and global vehicle dynamics controls to enhance safety technology and discusses the value of the regenerative energy recovery and integrated vehicle dynamics control functions of hybrid electric vehicle (HEV) systems in enhancing environmental technology.

2 HIERARCHY OF INTEGRATED VEHICLE SYSTEMS

The process of driving a vehicle consists of three related factors: the driver, the vehicle, and the traffic environment. The component technologies that make up integrated vehicle control must be structured simply and rationally while considering the requirements to enhance the overall value of the vehicle in terms of safety, driving enjoyment, and environmental performance. Figure 1 shows the hierarchical structure of an integrated vehicle system. The system consists of the following five parts.

1. VDM
2. driver assistance management
3. energy management
4. human–machine interface (HMI) management
5. occupant protection management.

Currently, the most important of these parts are VDM and driver assistance management. It is likely that further advances will occur in the field of sensing, such as cooperative communication among vehicle environment recognition systems using autonomous sensors such as radar and camera, navigation systems, and roadside infrastructure. Such advances are particularly likely for integrated safety systems and VDM is a key technology supporting this progress.

2.1 Integrated safety

This section briefly discusses the concept of integrated safety. Figure 2 shows the trends in active and passive safety technology. Advances in the field of passive safety technology include optimized body structures, enhanced restraint systems such as airbags, and measures for various different types of accident formats (i.e., compatibility in crashes with different vehicle types, pedestrian safety, and the like). However, active safety has grown in importance in recent years. The aim of active safety systems such as ESC, VDIM, and PCS is to help reduce the number of accidents that occur. Systems that coordinate with roadside infrastructure using communication technology may also be developed in the future. On the basis of these trends, it is likely that active and passive safety systems will be introduced together as integrated packages rather than as separate technologies. The aim of integrated safety management is to create a simpler overall system that helps to seamlessly operate each function together (Figure 3). For

this reason, VDM will play a fundamental role acting as the muscles and nerve system of the vehicle.

3 EVOLUTION OF CHASSIS CONTROL DEVICES

The development of more advanced chassis control devices that act as the muscles of the car to control the tires is an essential part of enhancing vehicle dynamic performance. This requires expanding the degree of freedom of control over the forces generated at each tire contact point from the longitudinal direction to the lateral and vertical directions. This can only be achieved by smooth and highly responsive control in all directions. The following sections describe recent development trends in chassis control devices and examples of their application.

3.1 Brake control

The development of brake control systems has accelerated because of the adoption of ABS and electronic brake distribution (EBD) systems as standard equipment. In combination with advances in ESC technology, the major effect of integrated brake control systems in helping to reduce accidents has been confirmed in the real world. As a result, the United States and other countries have begun to mandate their usage and such systems are likely to become standard equipment in the future.

The popularization of HEVs in recent years has also contributed to the development of electronically controlled brake (ECB) systems (Figure 4) with the aims of achieving linear hydraulic brake control and improving response (Nakamura, 2002). This is a brake-by-wire system in which the hydraulic brake pressure at each wheel is isolated from the brake pedal and braking control is performed by a high pressure source through linear solenoids. This system facilitates braking force coordination during regenerative braking in an HEV. As its smooth and highly responsive controllability can also be utilized as part of ESC systems, ECB systems are also spreading to other vehicle types in addition to HEVs.

3.2 Drive system control

This field has seen progress in active controls such as systems that transfer torque to the front and rear wheels in a 4WD vehicle, as well as limited slip mechanisms in center, front, and rear differentials. In recent years, systems for distributing driving force to the left and right wheels using a speed-increasing mechanisms installed inside the differential have been developed. The characteristics of these systems are being actively used to improve cornering performance.

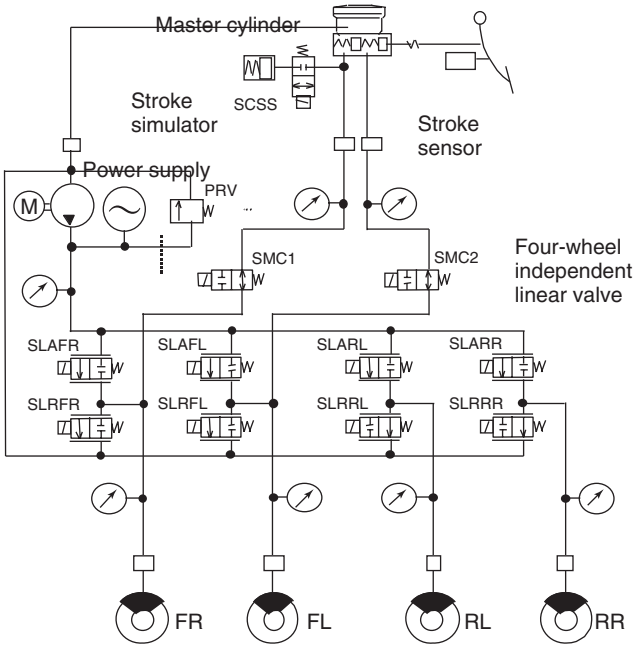

Figure 4. ECB structure.

In contrast, the electrification of driving forces has started in HEVs and electronically controlled 4WD vehicles to enable smother and more responsive driving force control. The practical application of motors capable of driving each wheel independently in the future may also help to further enhance dynamic performance.

3.3 Steering control

Electric power steering (EPS) systems are being rapidly adopted to improve fuel efficiency, as well as for use in HEVs and the like. In addition to simply replacing hydraulic power steering, the role of EPS is spreading to new functions that make active use of its capability to freely vary the assistance force.

For example, it has already been introduced in some vehicles to perform the following functions in coordination with ESC. EPS can assist the driver's steering effort to facilitate countersteering when the rear wheels slip or to prevent understeering when the front wheels slip. It can also be used as an actuator in functions that help the driver keep the vehicle in its lane by assisting the driver's steering effort. Alternatively, EPS can also function as an actuator in automatic driving systems such as Intelligent Parking Assist.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto030
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

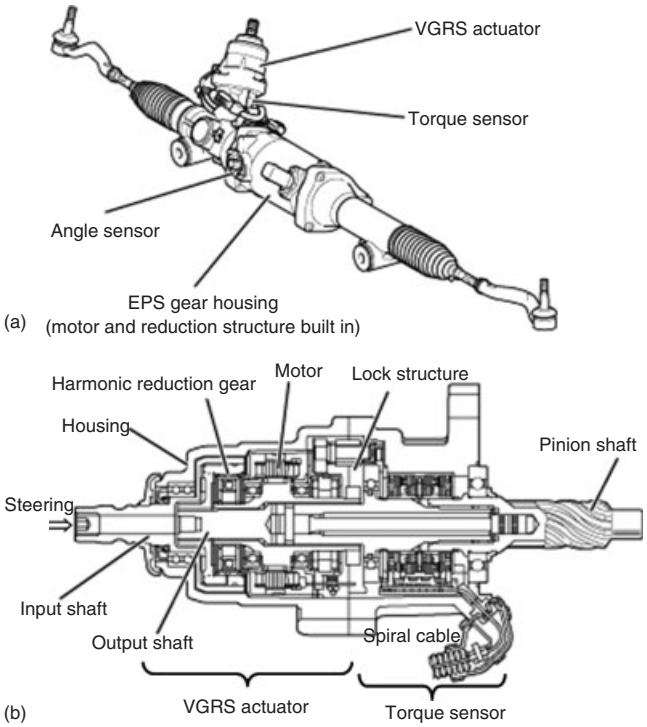

Figure 5. (a,b) VGRS actuator.

In addition, variable gear ratio steering (VGRS) systems have been developed that vary the steering response characteristics of the vehicle yaw angular velocity (Figure 5). Conventionally, the steering characteristics of the yaw angular velocity were determined by the specifications of the suspension. VGRS is capable of varying these characteristics to a constant optimum level in accordance with the driving environment. Furthermore, ESC devices are starting to be used, which utilize the capability of VGRS to control the turn angle of the front wheels independently of the steering wheel angle.

ARS has also been adopted on some vehicles, and its enhancement of dynamic performance has been verified. In recent years, vehicles have been released that combine ARS with front-wheel active steering systems to further improve dynamic performance (Katayama, 2007; Kojo, 2002; Ono, 2007).

3.4 Suspension control

The suspension of a vehicle consists of springs, shock absorbers, and link mechanisms. However, there is a long history of control technology applied to suspensions to improve both ride comfort and vehicle stability. Examples include the semiactive suspensions introduced in the 1980s for controlling shock absorber damping force. Improvements have continued since then. Recent years have seen the development of electronically controlled active stabilizer suspension systems that actively reduce vehicle roll (Figure 6). Progress is also being made toward the development of electronically controlled fully active suspensions. As a result, the use of actuators in suspension control is spreading, and these are expected to help improve vehicle performance through the active variation of vehicle attitude and vertical load.

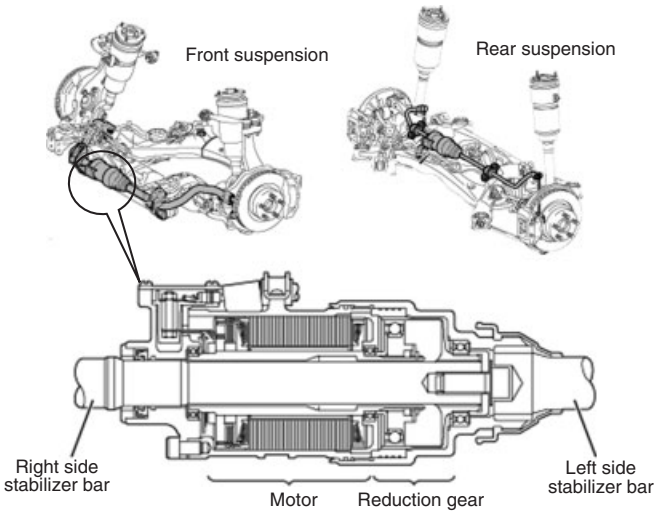

Figure 6. Active stabilizer actuator.

3.5 Evolution of vehicle environment recognition technology

One current trend is vehicle environment recognition technology that supports the cognitive processes of the driver. The development of environment recognition sensors such as radar and cameras is advancing rapidly.

Forward recognition technology using radar is already used by cruise control systems. PCS systems have been developed that help the driver to avoid accidents through coordinated control with the brakes (Tsuchida, 2007). A more accurate system that combines information from radar with camera images (Figure 7) and a system that coordinates information with a camera that detects the orientation of the driver's face have also been developed.

Lane Keeping Assist, Intelligent Parking Assist, and other driving assistance systems that use image-recognition technology have already been commercialized. However, the number of systems in this field is likely to grow further as researchers study ways of utilizing information provided by roadside infrastructure.

4 EVOLUTION OF CONTROL USING VDIM

4.1 Concept of VDIM

Since the 1980s, various attempts have been made to enhance vehicle dynamic performance using active chassis control. In 1986, the Daimler-Benz 4Matic system was the first to use lateral dynamics for control purposes. Direct yaw moment control systems with active braking such as ESC enable good performance in the critical limit region (Shibahata *et al*., 1993; Koibuchi *et al*., 1996; Van Zanten, 1996). The aim of the next generation of vehicle dynamic control systems is to provide seamless vehicle maneuverability and stability at all times through the integrated control of driving forces to all four wheels. Figure 8 shows the concept of Toyota's VDIM system. This illustration is called the *ball in a bowl* concept (Hattori *et al*., 2002). The ball corresponds to the state of the vehicle, which is maintained within a bowl constructed by the control. The inside of the bowl is the stable region, and the outside is the unstable region. In conventional systems, the walls of the bowl are constructed from independent functions such as ABS, ESC, and TCS, which form sheer boundaries before an emergency occurs. As a result, although these functions are capable of stabilizing vehicle motion, the motion may be discontinuous in some cases. In contrast, VDIM realizes smoother behavior because the conventional control systems are restructured to form a continuous and smooth wall.

As vehicle control systems are becoming more diversified, the algorithm is required to perform cooperative control of many systems, such as the drive train, braking, and steering, easily. Accordingly, the compatibility of the algorithm with various system configurations is important. The hierarchical control system structure shown in Figure 9 has been adopted for VDIM (Hattori, 2002; Fukatani, 2005).

The first layer (vehicle dynamics control) calculates the target forces and moments of the vehicle to achieve the desirable vehicle motion corresponding to the driver's pedal input and steering wheel angle. There are several examples of research for the first layer. In the critical limit region, the determined target resultant force and moment also satisfy robust stability conditions to avoid vehicle spin (Ono *et al*., 1998). However, in the moderate region, Yamakado *et al*. (2010) have proposed a target longitudinal acceleration/deceleration model determined by predicted lateral jerk to improve driving enjoyment. The target resultant force and moment of the vehicle motion are distributed to the target tire forces of each wheel based on the friction circle of each wheel in the second layer (force and moment

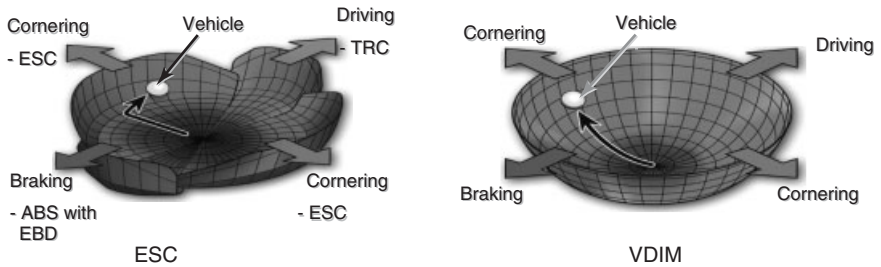

Figure 8. Evolution of control using VDIM.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto030
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

distribution). The third layer (wheel dynamics control) controls each wheel motion to achieve the target tire force. There are redundant degrees of freedom in the second layer. The vehicle dynamics performance in the critical limit region depends on the force and moment distribution algorithm, which uses these redundant degrees of freedom.

The motion of a vehicle in the three degrees of freedom (longitudinal, lateral, and yaw) is controlled by the steering and traction or braking forces from the four tires. If each tire can be individually steered and operated for traction or braking, the control system has redundancy. Vehicles move using the friction between the tires and the ground. The frictional forces at the tires have limits dependent on the conditions of the road surface. These limits are called the *friction circle*, and a tire cannot exert force on the road surface in excess of the friction circle. To extend the limits of the performance of vehicle dynamics, it is necessary to ensure that the forces exerted by all tires work efficiently in cooperation with each other. The problem of integrated control of vehicle motion then becomes how to best use the redundant degrees of freedom. As the friction circle has nonlinear constraints because of the limitations on the frictional forces at each wheel, the distribution of the longitudinal and lateral forces and the yaw moment (vehicle forces and moments) to each tire force becomes a nonlinear problem.

Ono *et al*. (2009) proposed a vehicle dynamics integrated control algorithm using an online nonlinear optimization method for four-wheel-distributed steering and four-wheel-distributed traction and braking systems. The proposed distribution algorithm calculates the magnitude and direction of the tire forces to satisfy constraints corresponding to the target resultant forces and moments of vehicle motion and also to minimize the maximum μ rate (=tire force/friction circle) of each tire. This research demonstrated the convexity of this problem and guaranteed the global optimality of the convergent solution of the recursive algorithm. This implies that the theoretical limitation performance of vehicle dynamics integrated control can be reached.

Comparing it with general quadratic programming can show the efficiency of the proposed algorithm, which calculates the theoretical limitations of vehicle forces and moments. The following minimization problem of the sum of squares of the μ rate may be considered as a benchmark. This is an extension of the problem described by Mokhimar and Abe (2003). In this simulation, the generated vehicle longitudinal forces are compared for straight-line braking on a split road with different coefficients of friction μ (μ =1.0, 0.2).

Figure 10 shows the tire forces of a vehicle controlled by the proposed method and a vehicle controlled by quadratic programming. Both of the controls achieve the reference braking force within a moderate area when the reference braking force is 7000 N. However, unlike the vehicle controlled by quadratic programming, the vehicle controlled by the proposed method can also achieve the reference braking force in the critical region when the reference braking force is 10,000 N.

4.2 Configuration of VDIM

Figure 11 shows the overall configuration of the VDIM system. Using in-vehicle sensors to detect the yaw rate and steering angle, VDIM collects together various items of data for optimally controlling the brakes and front steering to stabilize the vehicle attitude. It achieves a steer-by-wire function using an active front steering (AFS) system with two actuators (VGRS and EPS) to control the steering angle of the front wheels and the reaction torque of steering. It also acts as a wide-ranging safety control function in coordination with the ECB system.

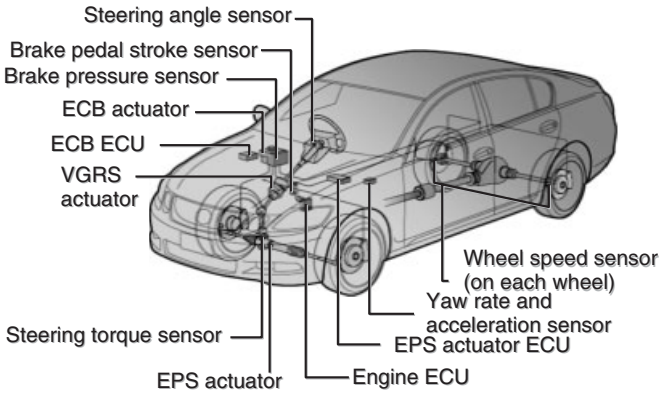

Figure 11. Configuration of VDIM system.

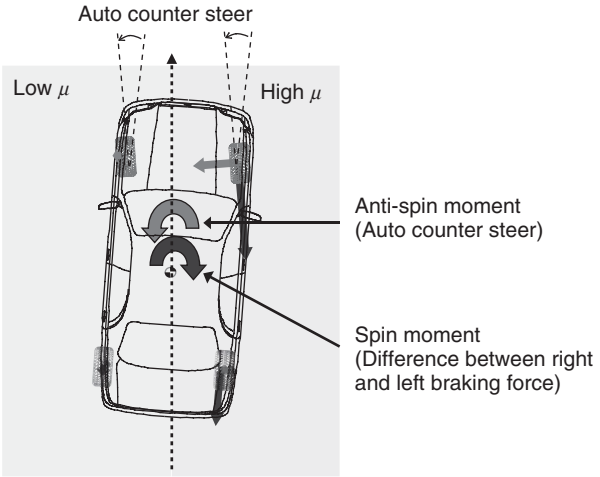

Figure 13. Corrective steering control during braking on split μ road.

Figure 12 shows the layout of functions for controlling vehicle dynamics and behavior using VDIM. Creating this layout diagram clarifies the role of each function individually and in combination with other functions. VDIM enables true integration of vehicle control by emphasizing the development of each function and its actions.

4.3 Performance of VDIM

Figure 13 shows the outline of control when driving on a road with different coefficients of friction (μ) under the left and right wheels. As shown in the figure, when the driver brakes, spin moment is generated in accordance with the difference between the left and right braking forces, resulting in deflection of the vehicle. On this type of road surface, a vehicle dynamics control system that uses just longitudinal forces cannot achieve a high degree of stability and braking simultaneously with driving performance. In contrast, this can be achieved by an AFS system that is capable of controlling the vehicle in the lateral direction.

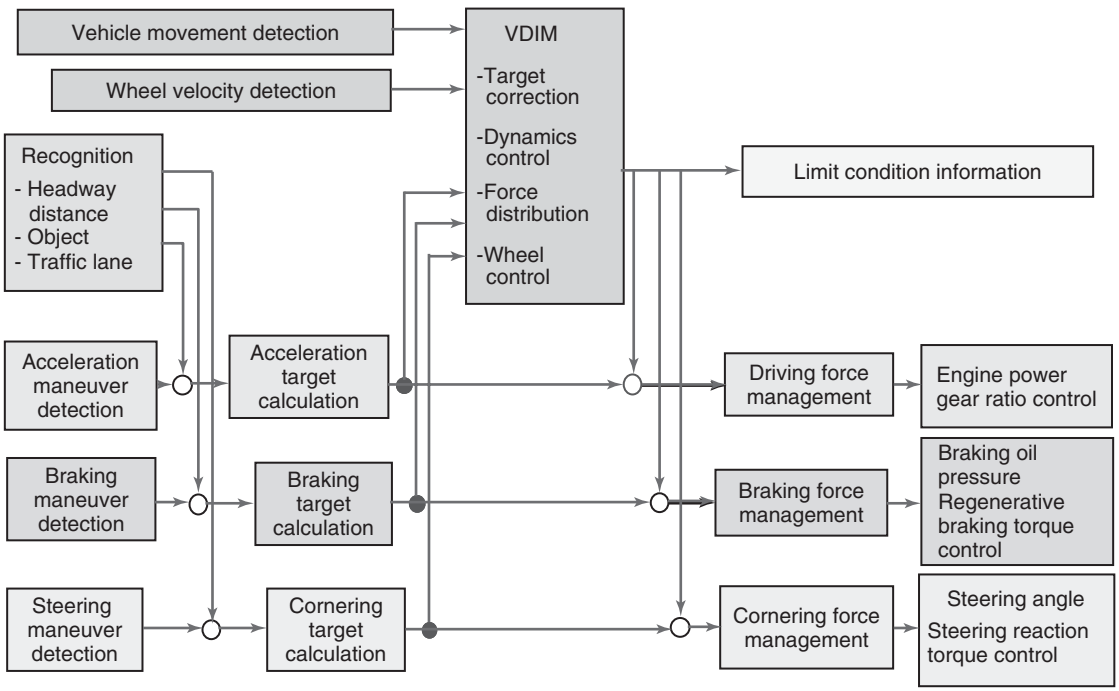

Figure 12. Layout of VDIM software functions.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto030
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 14 shows the test results of straight-line braking on a split μ road. It shows the normalized steering angle and peak yaw rate after braking (state without control = 1). With the active steering control, the peak yaw rate was reduced by approximately 50% compared to the rate without the control. In addition, the AFS control requires less corrective steering effort from the driver and generates a lower peak yaw rate on the vehicle than conventional ABS.

AFS has a large effect on side slipping of the front wheels. In particular, for a vehicle braking on a road with different coefficients of friction under the left and right wheels, AFS is capable of maintaining both vehicle stability and driving force. It also helps to suppress vehicle spin behavior when the driver performs an evasive maneuver (Figure 15). AFS is more effective at suppressing spin as it can generate moment by controlling the slip angle of the front wheels in addition to the conventional control that generates moment to reduce spin using braking force.

Figure 16 shows the results of a test comparing the effects of VDIM and ESC. In the test, the vehicle was steered mechanically through a slalom using constant steering operations while accelerating on an artificial low friction surface ($\mu = \sim 0.3$) simulating a snowy road. At the limit regions, the slip angle with VDIM was half that of ESC (+TCD), which shows that VDIM is capable of greatly improving the vehicle stability.

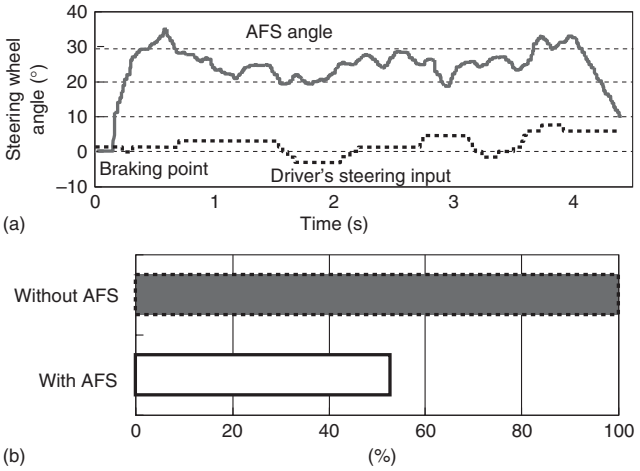

Figure 14. Effect of AFS on braking on split μ road. (a) Time domain data example and (b) normalized peak yaw rate.

4.4 Further evolution in control using VDIM

4.4.1 Enhancement of collision-avoidance performance using environment recognition technology

Toyota developed a collision-avoidance support system in 2006 that aimed to help reduce accidents by assisting evasive maneuvers by the driver. This system uses a forward monitoring function consisting of a millimeter wave radar and stereo camera to judge the risk of a collision with an object and assists the driver to avoid the collision by varying the steering gear ratio and braking. This system consists of a block that detects objects and judges the collision risk, a block that determines the evasive maneuver by the driver, and a block that controls vehicle behavior (Figure 17). The system operates as follows (Figure 18).

1. If a high collision risk is judged, the system warns the driver to take evasive action.
2. The system reduces the VGRS steering gear ratio to assist the driver's evasive steering maneuver.
3. If a high collision risk is judged, the system begins automatic braking. When the driver performs an evasive steering maneuver, deceleration during the maneuver is achieved by reducing braking force with a gradual gradient. In this event, VDIM controls the steering and brakes appropriately in accordance with the vehicle state.

Figure 19 shows the results of a double lane change test with and without system operation. The system reduces the driver's steering wheel angle and steering velocity to enhance the object evasion capability of the vehicle.

4.4.2 G-vectoring

VDIM is basically a feedback control that aims to restore the ball to the bottom of the bowl in the ball in a bowl concept. In contrast, G-vectoring control (GVC) is a feed-forward control mechanism that enables the ball to start rolling toward the edge of the bowl in coordination with driver's maneuvers. In 2008, Yamakado and Abe identified an original trade-off strategy between longitudinal traction and cornering force using jerk information to observe an expert driver's voluntary braking and turning actions (Yamakado and Abe, 2008). This strategy was used to develop GVC, which is basically a mechanism for achieving automatic longitudinal acceleration control in accordance with vehicle lateral jerk caused by the driver's steering maneuvers (Yamakado *et al*., 2010). With GVC, the direction of the resultant acceleration (G) changes seamlessly (i.e., by vectoring) in the same way as it does when an expert driver is behind the steering wheel. In this way, ideal vehicle motion can be achieved. The following

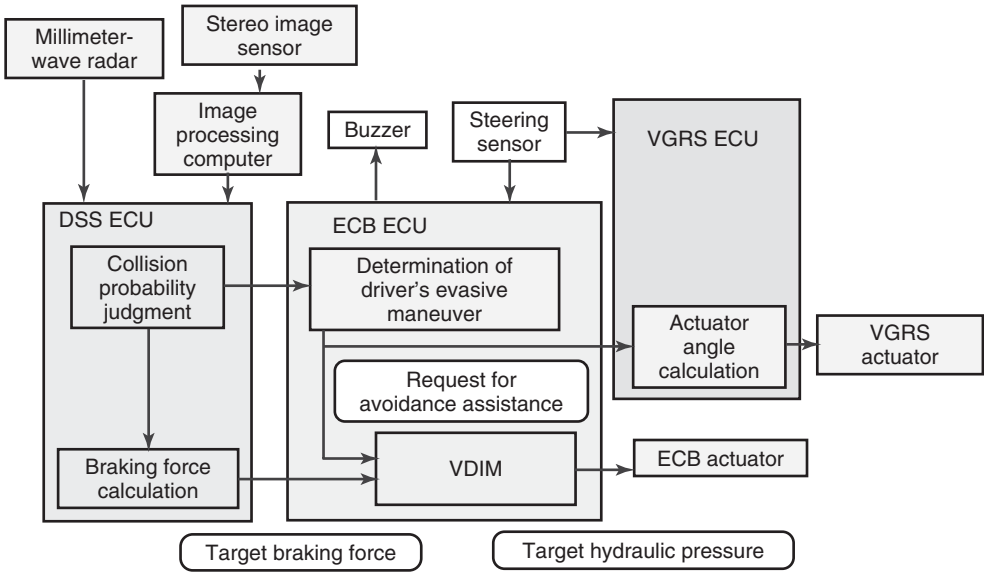

Figure 17. Functional configuration of object avoidance assist system.

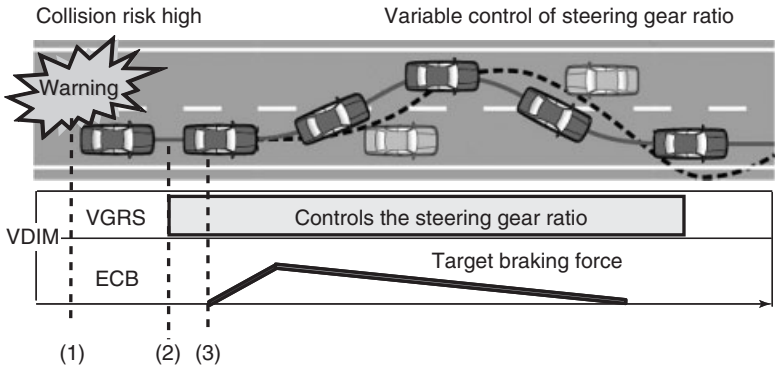

Figure 18. Control procedure of object avoidance assist.

equation was proposed as the fundamental equation for GVC.

$$G_{xt} = -sgn(G_y \cdot \dot{G}_y)\frac{C_{xy}}{1+Ts}|\dot{G}_y| \quad (1)$$

where G_{xt} is the longitudinal acceleration command, C_{xy} the gain, and G_y the lateral jerk.

Figure 20 illustrates the GVC concept. When the vehicle starts turning a corner, it starts braking simultaneously as lateral jerk increases (vehicle positions 1–3). After that, the braking stops during steady-state cornering (vehicle positions 4 and 5) because the lateral jerk becomes zero. The vehicle begins to accelerate when it begins to return to straight-ahead driving (vehicle positions 6 and 7). If a bowl were fixed to the vehicle, a ball in the bowl would move smoothly along the level curve as shown at the top of the figure (ball positions 3–5) because of the change in inertial force caused by the acceleration of the vehicle. Considering the shift in wheel vertical load between the front and rear wheels (which is caused by the acceleration and deceleration of the vehicle), the handling of the vehicle when entering a corner and its stability when leaving a corner will be improved.

Figures 21–23 show the measurement results obtained for cases with and without GVC. These results show that applying GVC makes it quite possible to emulate expert driving.

5 METHODS OF DESIGNING INTEGRATED CONTROLS

The previous sections have described how integrated controls have a large potential to enhance vehicle dynamic performance. However, the integration of controls increases the complexity of the systems, substantially increases the scale of development and the work hours required, and makes it more difficult to secure reliability. Consequently, the original goal of improving performance also becomes more difficult to achieve. For this reason, the key concepts for designing integrated control are to create a hierarchy and to mask and abstract information.

5.1 Creating a hierarchy of function and application levels

When constructing a control, it is important to consider the failsafe conditions and other operations in the event of an abnormality, in addition to approaching the control from the standpoint of the normal targeted performance and operation. This is particularly important for integrated controls. The control has to be constructed on a layered hierarchical basis, categorizing the functions to be integrated and the functions that operate independently and autonomously. In creating the hierarchy, it is convenient to envision the relationship between the actions of a person's hands and feet and the reflexes of the brain and spinal column. Actions that require fast reactions and actions with a fixed pattern are achieved by spinal column reflex and the situation is reported to the brain. The brain directs overall actions by sending commands to the hands and feet. VDIM was created based on this concept (Figure 24). The roles are determined in sequence from the control devices equivalent to the lower order muscles, and the configuration is

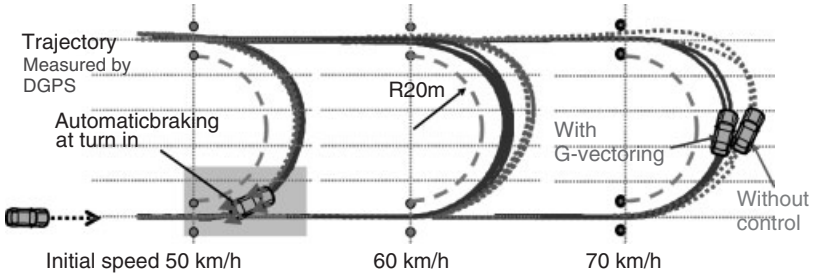

Figure 21. Trajectory evaluation.

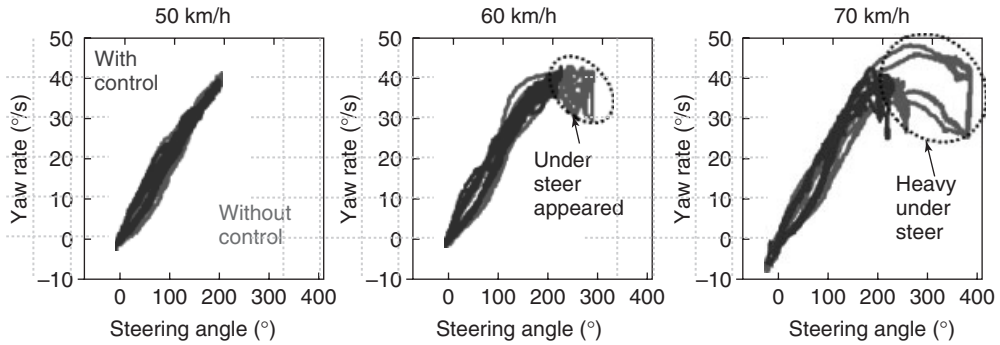

Figure 22. Steering angle versus yaw rate.

designed as much as possible to allow independent action and the selection of functional operation.

5.2 Masking and abstracting information

When constructing various functions in a hierarchical structure, another key point is the masking and abstracting of information when collecting information and transmitting commands. From this standpoint, it is simple to envision the relationship between a team manager and the team members in a corporate organization. Normally, the team members perform work based on instructions from the manager. However, the manager does not have a detailed grasp of each specific aspect of the work of the team members and the manager does not give specific detailed instructions about that work. Therefore, if the manager is ill or in another abnormal situation, the team members can operate autonomously to a certain level. In addition, the manager above the team manager is capable of running the organization without knowing the last detail of the work of the team members. Therefore, this manager can produce results that would not be possible individually. A simple and highly reliable system can be constructed by making use of this type of information collection and command transmission system.

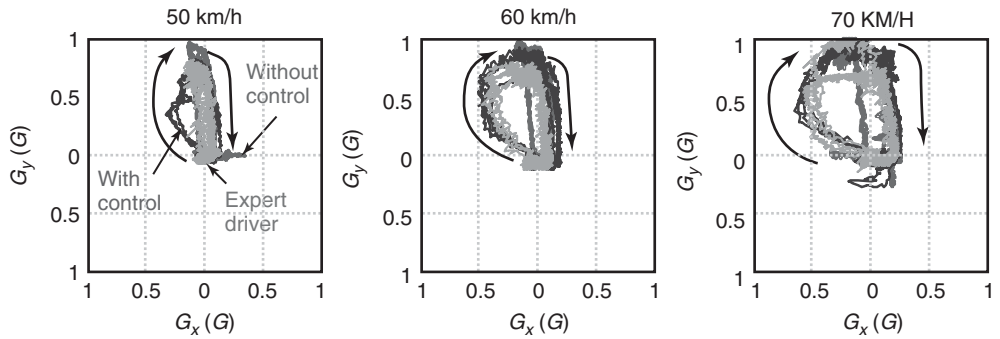

Figure 23. "g–g" diagram.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto030
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

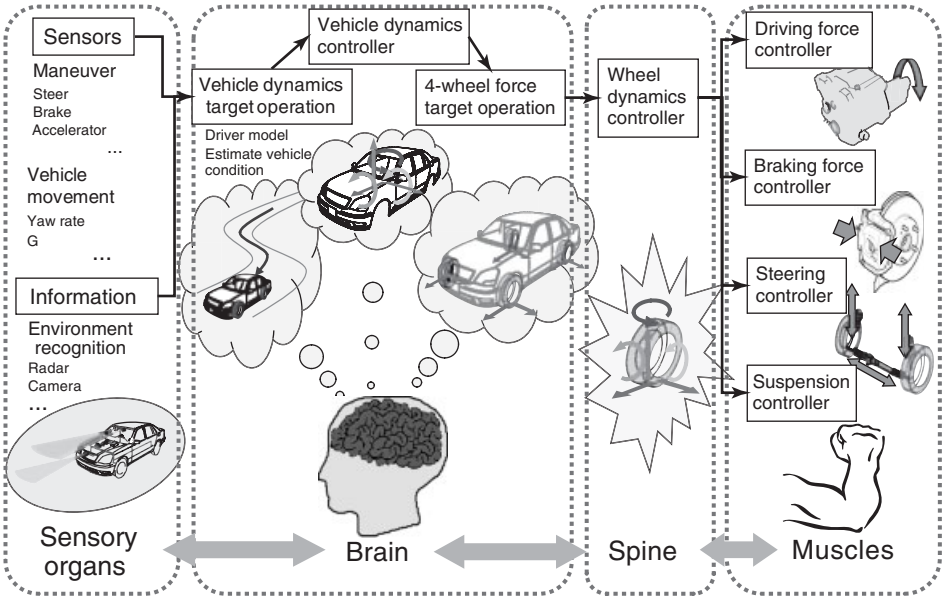

Figure 24. Hierarchy of VDIM and outline of components.

If the upper level system relies on detailed information from the lower level system, it becomes difficult to change the system configuration or add new functions. For example, in the case of brake control, the upper level system can simply control the total braking force even when in combination with a motor or another device. This is carried out by masking internal operations based on an abstraction and normalization concept. This concept positions braking force and braking *G* above hydraulic pressure and hydraulic pressure above the solenoid current of the actuator. Furthermore, if a theoretically different brake actuator is added into the system, there is only very little impact on the upper level system.

5.3 Creating packaging level hierarchies

The adoption of software platforms and operating systems (OS) is advancing to absorb differences in inputs and outputs, as well as in the communication between hardware and software, and to create freedom in application package locations for integration into ECUs. Conventional software structures are constructed differently based on the approach of each automaker and software supplier. However, standardization efforts are under way to achieve integration. Future development will also have to consider these trends.

5.4 AUTOSAR activities

AUTOSAR (automotive open system architecture) is an enabling technology for integrating systems in a vehicle. As mentioned in Section 5.3, AUTOSAR defines the basic software architecture, which consists of a hardware abstraction layer (HAL), system/communication services, and a runtime environment (RTE). RTE is an embodiment of a virtual functional bus (VFB) that enables the integration of application software and the physical allocation of applications into each ECU (Figure 25).

The system/communication services provide standard functions such as communication and OS. HAL absorbs the differences between microcontrollers, sensors, and the like. Figure 26 shows the basic AUTOSAR architecture.

AUTOSAR is being advanced by a development partnership, in which many global automotive companies are participating in AUTOSAR activities to develop AUTOSAR specifications as a worldwide de-facto standard (Figure 27).

6 FUTURE TRENDS OF INTEGRATED SYSTEMS

6.1 Expansion of active safety and driver assistance

The previous sections have highlighted the significant contribution of integrated control technology in active safety systems. The systems are likely to grow even more important in the future. Normally, the driving process consists of cognition, judgment, and action phases. An error in even one of these driving processes may result in an

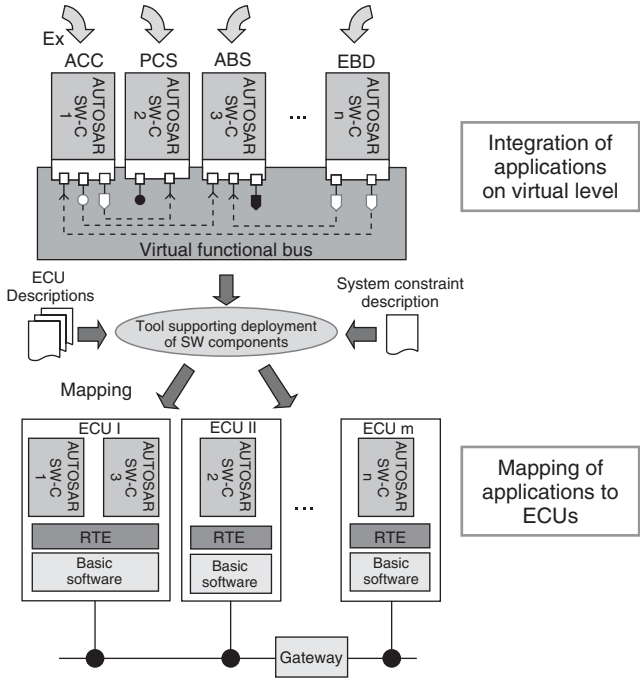

Figure 25. Integration of applications.

accident. Consequently, active safety technology is being developed to support each phase (Figure 28).

Figure 29 shows the technological areas of the various control systems that have already been commercialized. The direction of brake technology has already changed from brake assist (BA) type systems to PCS and other automatic braking systems. However, there are still many undeveloped areas on the horizontal axis, which is likely to be the direction of development in the future.

Although the physical limits are determined by the performance of the tires, brakes, and the like, technologies such as ESC have been developed that support driver operations at these limits. These technologies are now also being integrated with steering controls. In the future, it is likely that development will continue toward the commercialization of vehicle dynamic control that can stretch the possibilities at the physical limits. This development will be based on research such as the verification of theoretical limits when four-wheel independent steering and four-wheel independent braking and traction systems are combined with force control technology through suspension control.

In addition, technology to assist the cognition and judgment phases is likely to become more sophisticated as recognition technology advances. Coordination between dynamics control to enable automatic evasive maneuvering in the lateral direction will probably progress. In preparation for these developments, vehicle dynamics control must have the capability to freely control vehicle behavior. Integrated control technology will play a major role in accomplishing this aim.

6.2 Future trends

Figure 31 shows a matrix depicting the concept for total vehicle system integration. In addition to the integration of energy within the vehicle, further integrated controls are being considered that incorporate the vehicle, driver, and the traffic environment in the same way as active safety. Possible methods of helping to improve the environment

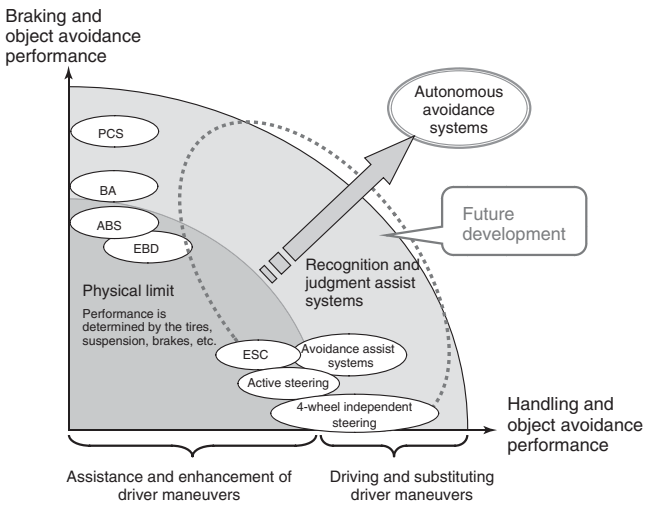

Figure 29. Current control systems and future development areas.

include the shift lever indictor and CO_2 reduction control using ACC. Integrated functions based on traffic signal controls and ITS (information technology services) that also factor in the traffic environment may be developed that help to alleviate congestion.

From the standpoint of active safety, the evolution from integrated vehicle dynamics controls to integrated active safety controls will focus on the development of driver monitoring functions in PCS systems. In the future, these technologies will develop into systems that provide assistance to individual drivers as appropriate in coordination with the driver and integrated safety systems that are coordinated with the traffic environment and infrastructure. The matrix in Figure 30 is also related to the achievement of sustainable mobility in terms of vehicle safety, the environment, and comfort. In addition to the autonomous and infrastructure-coordinated driving environment detection technologies shown in Figure 31, an area of growing importance will be individual applications designed in accordance with navigation system and traffic control ITS information and the state and personal characteristics of the driver. Therefore, an integrated HMI that incorporates individual information, instructions, alerts, and warnings will be the key for creating an integrated control that helps to enhance safety, the environment, and comfort.

7 CONCLUSION

Dynamic control technology for controls related to the suspension, steering, braking, driving forces, and the like is advancing relentlessly. At the same time, cognition and judgment functions equivalent to the eyes and brain are also being rapidly developed. However, the number of people hurt or killed in traffic accidents remains at a high level.

Therefore, this technology has to be consolidated and applied properly to fulfill the responsibility of automakers to develop vehicles that do not cause accidents. Control systems are required that are highly reliable, flexible, and

have the potential for widespread use. This chapter has described the trends and configurations of these systems. Comfort and driving enjoyment are essential parts of a vehicle and these must not be sacrificed. For this reason, the development of these systems will continue while enhancing basic vehicle performance.

Chassis Control Systems

Gerhard Klapper and Ralf Leiter

TRW Automotive, Koblenz, Germany

1 INTRODUCTION

The appreciation of vehicles and the differentiation between the manufacturers and models is mainly gained from the increased use of more and more complicated control systems, including their electronic components. This trend will rapidly accelerate in the near future, as indicated by the top models from various manufacturers already on the market. In some companies, there is still the "world car" idea; but in the meantime, nearly everybody has also learned that different regions require different coordination of the chassis. Moreover, the greatest dream is still to achieve this using software coding.

In general, the target of the chassis development can be described as monitoring the vertical wheel forces in a way that the necessary longitudinal and lateral forces can be transferred to the road with simultaneous maximum comfort and safety for passengers and minimal fuel consumption. The classic chassis presents many compromises in design and performance; the use of electronics permits design shifts to improve the performance even further.

Legal requirements and environmental protection can be achieved by bringing microprocessors into the vehicle. The exhaust laws of today can only be met by regulating ignition timing and injection quantity in dependence of the catalyst sensor. This was followed by safety systems such as antilock braking system (ABS) and the airbag, which brought additional microprocessors into the vehicle. Over time, components became so reliable that now complex control strategies can be implemented with simple control systems.

This chapter defines the classic components as the chassis system:

steering,
suspension and damping, and
chassis and brake control.

These components cover the controls for longitudinal and lateral guidance of the vehicle, while simultaneously controlling the vertical movement.

2 STEERING

The steering of a vehicle presents the most sensitive components in the control loop of driver-vehicle. The driver has decisive influence over the behavior of the machine to be operated. A vehicle is moving dependent on the feel and the individual capability of the vehicle's driver. Next to the general vehicle design, steering is the most important feedback to the impressions and control information reported to the driver.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

The driver receives feedback about the street, the environment, and the vehicle behavior from the respective steering design that he can immediately incorporate into his behavior to operate the vehicle safely. This is a variety of visual (e.g., deviations from the wanted position on the lane), acoustic (e.g., warning strip noises from the tires), and dynamic information (e.g., the torque on the steering wheel, the yaw angle velocity, or also the lateral acceleration) that the driver must simultaneously receive and process. The driver can derive and implement the necessary control interventions with regard to steering the vehicle, releasing the acceleration pedal or even pushing the brake pedal. Since the drivers themselves function as dynamic controllers, it is important that they do not make the entire system unstable. Their basic dynamic behavior is a second order system, which can become unstable.

Today's steering systems do not only ensure the sensors and feedback of important information for driving a vehicle, but depending on execution, they also provide much additional assistance for the driver. This applies to the typical simple servo-support (auxiliary power units to relieve the steering forces the driver must use) until the steering movement support that is mainly dependent on the speed (additional steering angle), in some situations even from the yaw rate sensor.

The latest step forward in steering has been realized by electrical power steering systems. Even those systems can be developed further. The different types of electrical power steering are making this obvious.

2.1 Electrically powered steering

Especially for smaller vehicles with less axle loads, electric drives for power steering are becoming reality. With regard to positioning and space required, the electric drive is superior to the hydraulic drive. This is also true with respect to fuel consumption.

Electric drives reduce the range of their components to:

- cable harness,
- drive motor,
- clutch,
- transmission, transmission housing,
- steering wheel torque sensor,
- control unit or partial integration in present control unit, and
- mechanically functioning steering gear.

In addition, advantages of the electric assistant steering systems are:

- reduction in the number of parts (no pump, pump drive, oil container, and hydraulic lines),
- less weight,
- less space required,
- independent of vehicle motor, operation as possible with combustion engine shut off,
- less loss in driving power,
- better adaptation to the power requirements, reducing gasoline consumption,
- steering force regulation as needed: speed or load dependence is possible, and
- no need for inconvenient hydraulic maintenance.

There are also disadvantages that limit the complete introduction of the electric power steering in the automotive industry. They are evidenced by:

- limited performance, dependent on available energy sources (12-V electrical system);
- considerable protection needed from system failure due to use of electronic components;
- increased development expenses due to software and hardware adaptation work; and
- ever-increasing manufacturing costs (compared to hydraulic power steering systems).

Potential installation positions for the electric steering assist are more numerous than with hydraulic systems. Figure 1 gives an impression of the different possibilities. Electric motors can also be arranged:

- directly under the steering wheel on the steering column;
- like all hydraulic systems on the steering gear and on the rack-and-pinion; or
- for example, using a belt on the recirculation ball gear.
- in parallel to thes steering rack.

Electric power steering systems can also be preassembled modularly, as they are independent of hydraulic lines, which enable verifiability during production and can significantly reduce the production costs again.

The various manufacturers of such systems on the market use a variety of different drive and sensor concepts. Unlike with hydraulic systems, the steering angle and also torque applied are recorded by sensors and converted to electric signals. The control unit evaluates these signals and converts them into corresponding commands for the drive motor. This now works on the mechanical steering gear with the torque associated with the command.

2.1.1 Column drive (drive arranged on the steering column)

In this application (Figure 2), the electric motor is directly fastened to the steering column. The unit can be pre-manufactured separately from the vehicle assembly and delivered as a module to the assembly line.

The additionally required electronic control unit can either be integrated into the module or be positioned separately from the servo unit in the vehicle. Depending on the vehicle concept, the control unit can also be integrated in other control units. Synergies with this procedure are evident in the reduction of electronic components. Reductions in costs are the result.

Figure 2. Steering tube drive. (Reproduced by permission of TRW.)

The steering tube or the steering spindle between the steering wheel and the steering gear are powered.

To record the necessary input sizes, a torque sensor, or in individual cases, a rotary sensor and possibly according to requirements also speed sensors are integrated into the system.

2.1.2 Rack-and-pinion drive (with concentrically arranged motor)

The application in this case requires a rack-and-pinion steering with side pickup. Accordingly, other potential rack-and-pinion variants are conceivable, however, with more effort for the realization. Placing a coaxially working motor requires corresponding installation space in the middle region of the rack-and-pinion mechanics. Figure 3 shows one possibility. Often, the engine/gearbox unit requires this space.

2.1.3 Belt drive

In order to save space and still be able to directly grasp the rack, this variant (Figure 4) is available for electrical application of the assistance. The overall design of the unit provides significantly more clearance. In individual cases, the correct variant of those possible must be determined by an installation study, due to difficult installation dimensions in the front of the vehicle. The corresponding suggestion is therefore to evaluate cost/effort.

As is typical for the introduction of electronic components in safety-relevant vehicle systems, the demand for quality controls and safety tests increases considerably.

This is supposed to prevent critical driving conditions and drive situations, caused by malfunctions in the electronic components.

Such malfunctions can occur with:

- Too high current load at the motor
- Motor blockade due to seizing components such as bearing or rotor body

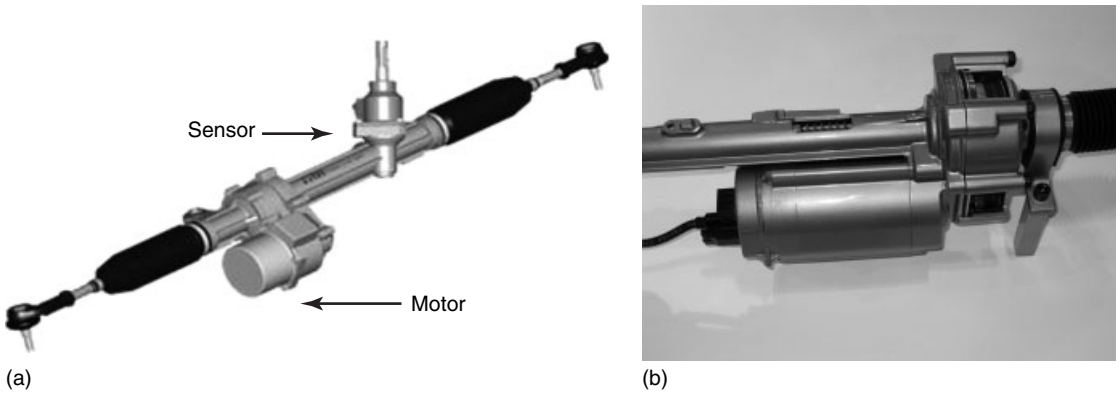

Figure 4. (a, b) Belt drive. (a: Reproduced by permission of TRW, b: Reproduced by permission of H. Wallentowitz.)

- Manipulation of electronics or the electrical system
- Sensors that give incorrect signals

To avoid all these fault possibilities, vehicle manufacturers exclusively use high quality materials and components. In addition, in production, up to 100% checks can be used (production of safety components).

In addition, redundant systems are required and introduced, which can balance the failure of parallel working systems on one hand, and on the other hand find use for control purposes of main systems and switch off the system if there are deviations in the signals.

Furthermore:

- The current values are technically limited;
- Voltages and sensors are permanently checked; and
- Torques are monitored.
- As further safety equipment, plug connectors that cannot be manipulated and so-called *electric couplers* are used.

Self-diagnostic programs constantly monitor all-important functions. This occurs by comparing the actual announced values with the specified target values or target value windows.

Fault detection shuts down the auxiliary systems and simultaneously notifies about faults using the system lights in the dashboard. The driver also recognizes the fault function by the increased steering forces. These behave exactly like with a strictly mechanical steering system without power steering.

Since the 1980/1990s, there have been cars with rear wheel steering in the market (mechanically powered (Abe, Ogura, and Sato, 1988), or different hydraulically powered systems (Donges, 1989; Kuroki and Irie, 1991). Now, there are systems coming to the market with electrically powered rear wheel steering systems. They may be considered in the next paragraph.

2.2 Active rear steering

Four-wheel steering is a known method to improve the maneuverability at low speeds (opposite impact to reduce the curve radius) and to enable better vehicle stabilization at high speeds. The simplest algorithms adjust the steering angle of the rear axle linear to the steering wheel angle. Advanced algorithms support the development of the yaw moment, dependent on speed, first with opposite turning, but then control back to the same direction, releasing the yaw angle and increasing driving stability (Abe, Ogura, and Sato, 1988).

The active control of slip angles at the rear wheels allows a targeted increase of the cornering forces. This can influence the steering of a vehicle (e.g., development of sideslip angle in the vehicle's center of gravity). Side wind influences can also be automatically compensated, without the driver needing to intervene.

Four-wheel steering can make the vehicle significantly more agile, but it can also change lanes without (in reality with reduced) a yaw movement occurring. That opens new possibilities to the algorithms of automatic accident prevention. The first electronically operated system has been introduced by BMW in the beginning of the 1990s (Donges, 1989; Wallentowitz, Donges, and Wimberger, 1994).

2.3 Superimposed active steering

Another modern steering system, which is in the market since 2003 (Köhn *et al*., 2003), is the superimposed steering system. AUDI followed with an own solution in 2007. This

Figure 5. Electric superimposed steering. (Reproduced by permission of EBM-Papst.)

is the first step to combine steering commands generated by the driver with steering movements coming from an electronic.

The superimposed steering makes it possible to realize a steering intervention on the front axle independent of the driver, without separating the mechanical coupling between steering wheel and front axle. An additional gear, an electric motor, sensors, and a control unit, expands the normal steering system. Figure 5 shows the additional gearbox in such a system. This system now enables the continuous change of the steering gear ratio—dependent on the driving situation detected. The effective steering angle at the wheels can be larger or smaller than the driver adjusted with the steering wheel. This just depends on whether the auxiliary system is steering in the same direction as the driver, or whether it is steering in the opposite direction. Thus, in city traffic, there is less steering required by the driver; at higher speeds, the vehicle can be better stabilized, thanks to an automatic and limited "counter-steering" of the system.

If the electric motor is not actuated, there is a direct mechanical connection between the steering wheel and the front wheels, as with conventional steering. Thus, such "intelligent" steering fulfills the existing legal requirements.

2.4 Steer by wire

In the last level of the current development, the driver is mechanically and hydraulically completely separated from the power units of the steering systems (like with the control of engines and automated transmission gear boxes). Steering angles are accepted as input parameters by the driver using the steering wheel or in the future, the so-called *joystick*, but are converted into electronic control commands for the actuators, moving the wheels.

Currently, law still requires permanent connection either mechanically or hydraulically (then limitation) vehicle speed to be able to react as needed if the electronics fail. This is called *fully redundant safety measures*. However, the entire vehicle industry is working on other "clever" systems to avoid this expense in the future and to be able to change the laws accordingly.

A complete separation of the input interfaces of the power aggregates would lead to:

- Enormous savings in materials,
- Reduction of parts, and
- Crash behavior improvement

The environment can also profit from this, as no poisonous hydraulic fluids would have to be disposed of. Rubber seals are not used in the large circumference; expensive manufactured tubes and hose lines are no longer needed; as well as a part of the mechanics, using a lot of energy during manufacturing, will not be necessary any longer.

The steering reaction can from this time forward be coordinated to all potential input parameters of the variety of sensors already present in today's vehicles (steering angle and steering torque sensors, yaw rates information, or camera images). Even safety-promoting interventions of the electronics into the handling (already realized in partial areas) are conceivable.

The potential configurations with redundant mechanical backup systems could look as shown in Figure 6.

In the basic idea, the "steer by wire" will not have any mechanical connection between the driver and the front wheel. Obviously, it is extremely important that in this case several redundant electronic systems must efficiently, and above all, safely prevent the steering from failing.

Figure 7 gives an impression of such an idea. Nissan is just now suggesting a similar system, but in addition to the electronic backup, there will be still a mechanical backup with a clutch, which is normally open (Kubota).

Ultimately, the vehicle manufacturers and their development partners have not yet reached series introduction of

Figure 6. Fully electronic steering with mechanical backup. (Reproduced by permission of TRW.)

these systems. The cheaper and always mechanically redundant hydraulic power steering used in series today is still the main percentage of power steering systems used on the market. Electric/electronic steering systems suffer the enormous price pressure under which the vehicles must be built today. An additional hurdle is coming from the numerous electronic components, which are installed mainly for comfort reasons. This stresses to the limit of the currently used 12-V electrical systems of the vehicles. Fundamental changes of the electrical infrastructure of today's vehicles are currently being controversially discussed from this viewpoint (Amsel, 2003; Wallentowitz and Amsel, 2003).

3 SUSPENSION AND DAMPING

Advanced suspension systems are realized by air springs and by hydraulically actuated conventional steel springs. This chapter describes some of the systems and the possibilities for advancements.

3.1 Air spring

The trend for more comfort in the passenger compartment and less vibration in the vehicle's suspension, independent of load, for continuous control of the height level as well as level adaptations to entry and loading assists, air suspensions in passenger cars, after a first application in the 1960s, became common equipment in passenger cars of the upper class in the 1990s. The suspensions of the 1960s are not comparable to the modern systems.

In semitrucks, where, thanks to the pneumatic brake system, the air energy is already available, air suspension for street transportation vehicles has become routine. As the air compressor and the air dryer are consuming a lot of energy, even here changes are wanted.

Today, the compressors still mostly work in open systems. The air is taken from the environment, compressed and either pressed directly into the air spring or is kept available in a reservoir. Excess air (when lowering the vehicle structure) is returned to the environment. The vehicle structure can only be raised relatively slowly and with limited frequency (load of battery and compressor). Closed systems found a solution where the air is pumped

Figure 8. Air spring with variable effective area. (Reproduced by permission of Meritor.)

back and forth between the spring and reservoir at high pressure. This clearly permits faster-level changes with less needed energy. This technology now also allows lowering the chassis while driving (lower air resistance) or raising the vehicles body (more clearance with poor street surface or driving out in the country).

An interesting variant is changing the effective area of the air springs with an additional interior air bellow. This allows the spring stiffness to increase threefold in a few milliseconds or to decrease without needing much air volume. Figure 8 shows this spring in soft condition (a) and in stiff position (b). There is only compressed air necessary to blow up the small air spring, which changes the rolling piston diameter (Lloyd, 2010).

This "active air spring" enables various operating modes, adapted to the vehicle driving conditions. The main advantage can be created during cornering. The wheel on the outer side of the curve not compress as much with a stiff air spring; the car body remains more horizontal. During acceleration or braking, the anti-dive and anti-pitch can be organized by these air springs. Unfortunately, these types of air springs are not commonly used in the market. For keeping the car horizontal, today active stabilizers are used. Their functionality is described in the next paragraph.

3.2 Active stabilizer

Conventional mechanical chassis are always a compromise between comfort and driving safety. When driving in curves, the vehicles roll around the rolling axle. The roll angle depends on the lateral acceleration. The softer the stiffness of the body springs and the larger the distance between center of gravity and rolling axle, the more roll angle can be built up. This soft roll stiffness can even cause roll over (elk test) if there are quick directional changes and simultaneous minimal roll damping. To decrease the tilt angle, the stabilizer bar rigidity must be increased.

The stabilizer is an additional connection between chassis and structure. The roll moment when driving in curves leads to the wheel load differences becoming larger with increased lateral acceleration (but the sum of wheel load of an axle remains the same). The wheel on the outside driving around a curve compresses and the wheel at the inner side rebounds. Its coupling rod rotates the stabilizer, and the forces at the bearing point create a torque, which counteracts the roll movement of the car's body.

The rigidity of the stabilizer has considerable influence on the roll stiffness of the vehicle. With the coordination of front and rear stabilizers, the vehicle behavior is changed between understeering and oversteering. Additional influential parameters for the driving behavior are the stiffness of the springs between chassis and body (as already mentioned above) and the position of the roll centers on the front and the rear axle. The specific roll center height results from the design of the used axle. The roll centers may be above the road, on the road, or even below. They are (mostly) virtual points.

As the stabilizer represents an additional spring, which is also active for one-sided deflection, named copying, active stabilizers have been invented. They reduce copying and they can in addition reduce the roll angle of the vehicle during cornering. Active stabilizers are realized with electric or hydraulic actuators in two or more stages. Yaw rate, lateral acceleration, steering angle, and speed are

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

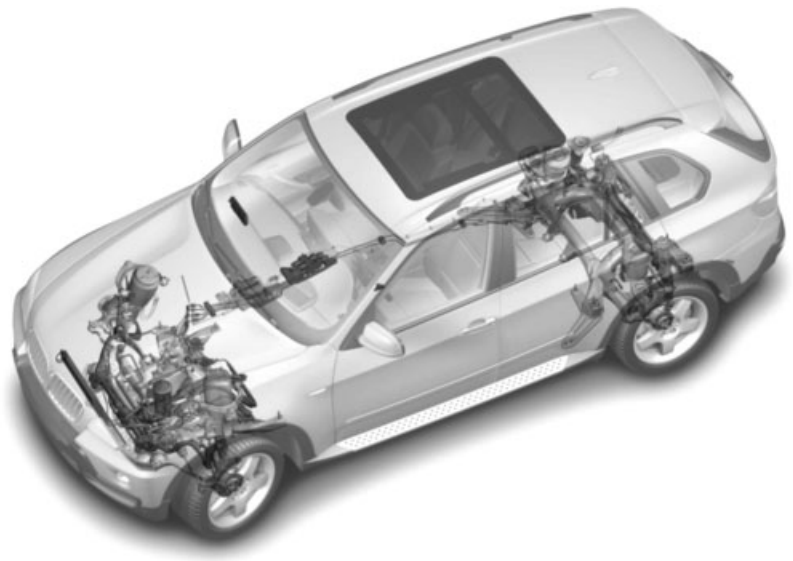

Figure 9. BMW with active chassis control (Dynamic Drive) (Jurr *et al*., 2001; Konik *et al*., 2000). (Reproduced by permission of BMW AG.)

considered as incoming parameters. Two pressure sensors, six valves, and one electronic controller provide the "right" driving behavior, which is adjusted using hydraulic pressure from a motor-powered tandem pump. Figure 9 gives an impression about the installation of the system in a car.

Hydraulic motors can even actively intervene in the chassis regulation with a very quick electric tandem pump unit. However, the pump power must be approximately as great as that of the electric hydraulic power steering. This leads to short-term electrical system load >100 A.

After switching on, the control units run a self-test and perform a functional self-test on the connected valves and sensors. Body control does not occur with standing vehicle. At approximately 20 km/h, the systems are active. Cornering is detected by the lateral acceleration signal, steering wheel angle, and speed. With up to 180-bar hydraulic pressure, counter-torque of 600 Nm (front axle) and until 800 Nm (rear axle) is generated on the stabilizer. At higher speeds, understeering drive behavior is preferred; thus, a higher roll torque amount is required on the front axle. To increase agility, a higher roll torque is temporarily set on the rear axle.

Simpler active stabilizers, especially with all-terrain vehicles, can only decouple the two stabilizer ends on driver command and permit an increased linking of the axles, which significantly improves the traction out in the country. Logically, this occurs at speeds below 50 km/h. When driving straight-ahead, the comfort is improved by decoupling (minimizing the copying tendency), but for normal cornering, these stabilizers work like rigid coupled ones.

3.3 Hydraulic chassis

The hydro-pneumatic suspension (a gas suspension with interconnected oil column) was already used in 1953 in passenger cars from the Citroen Company. Every wheel is equipped with a suspension/damping element, which contains nitrogen in the upper half of the hydro-pneumatic accumulator. The gas (constant mass of the gas) compresses and releases during the wheel movements and takes care of the reaction forces with respect to the wheel loads. A rubber membrane separates the gas from the hydraulic oil in the lower half of the strut.

During compression, the piston presses the oil through the pressure valve, arranged in the cylinder. During rebound, the gas presses the oil down through the harder adjusted rebound valve. In principle, the strut is an upside-down one-tube damper. The design level position in the vehicle is set using a lever-operated valve by adding or releasing oil, independent of load.

In the mid 1990s, Citroen added an active hydraulic stabilization system to its hydraulic suspension. This system was able to improve the driving comfort, but all in all, hydro-pneumatic suspension was replaced by air spring suspension. Only special solutions are still on the market, such as the system mentioned in the following paragraph.

3.4 ABC chassis

The active body control of Daimler AG is an electric-hydraulic chassis to meet the goal to always keep the

Figure 10. ABC chassis components (Wiesinger). (Reproduced by permission of Daimler.)

vehicle structure at the same height (Wiesinger). In addition to steering angle, wheel speed, yaw moment, and longitudinal and lateral acceleration, the height of the vehicle body is sensed against the wheels. The control unit "observes" the body behavior, and it can almost completely compensate the vertical body movement, the roll, and pitch with assistance of hydraulic cylinders on the support of the coil springs. The base points of the steel springs are hydraulically controlled with frequencies until 5 Hz—the shock absorbers are responsible for the wheel damping.

Electric-magnetic stop and control valves permit the individual control of each strut. With this system, individual wheel loads can be specifically increased or decreased, depending on what the drive situation requires. It is also easily possible to use wheel load control to optimize the brake and side forces in the tire contact area. Acceleration sensors on the vehicle body support the control strategy. Roll torque can be distributed to front and rear axle. A car with ABC suspension does not have a stabilizer bar.

Figure 10 shows the chassis components of such a suspension.

Right before opening the driver's door, the vehicle is lifted to entry height. When driving in curves, the outer springs are pressed together. To reduce roll, the spring base point is lifted until the compression stroke of the spring has been compensated. While braking, this base point tracking occurs on the front springs that are compressed. On the rear axle, the steel spring releases and the base point shifts downward. During acceleration, the base points are shifted just opposite. This compensates pitch and bounce movements.

Level sensors record bumps and correct for these. In a speed range between 65 and 140 km/h, the vehicle body is continuously lowered to 15 mm. Another 40-mm clearance is available with the push of a button. At 80 km/h, the crosswind stabilization is available, which can, however, be canceled again by quick and strong steering movements.

The advantages of such a system are: the car body remains horizontal, even during cornering, accelerating, or braking; mechanical stabilizers are no longer required; a radial piston pump provides the system with up to 210-bar oil pressure; and individual pressure sensors monitor the control movements. One disadvantage is the additional energy consumption to operate the system.

Pre-scan system is just now in series, which allows the ABC system to work with foresight by laser scanning the lane in front of the vehicle, but such systems are still under development.

3.5 Adaptive damping

In 1987, BMW was the first manufacturer in Europe to introduce adaptive damping. The previous systems could only select between several fixed damping characteristics (sport, normal, and comfort), but the BMW EDC has already worked with continuous adjustment. Today's systems also do this. Control programs that use the various areas of the shock absorber parameters are used in every case. In addition to automatic control, the driver can tune the system toward sportier or more comfortable operation as desired using a switch. However, in any way, the system reacts continuously. The damper characteristics are adapted to the driving situation as much as possible.

The former situation with the fixed settings of the damper can be explained by the so-called *conflict diagram* (Figure 11). Every combination of body spring stiffness and damper characteristic delivers driving comfort and driving safety results above the limiting curve. There is no simultaneous optimization of driving comfort and driving safety possible. To overcome this limiting curve was only possible with adaptive dampers.

Three acceleration sensors (two on the front axle, one on the rear axle), the steering wheel angle sensor, and the wheel speeds are the input parameters for the system, which then can adapt the chassis to the driving situation using the four adjustable dampers.

Usually, forces are calculated from the signals. Different simultaneous active control loops try to determine the optimum damping for the respective driving situation. There are vertical, lateral, and longitudinal control algorithms installed. The algorithm with the hardest setting determines the damping characteristics to be set on the shock absorbers. If possible, the soft setting is used until another setting is required.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

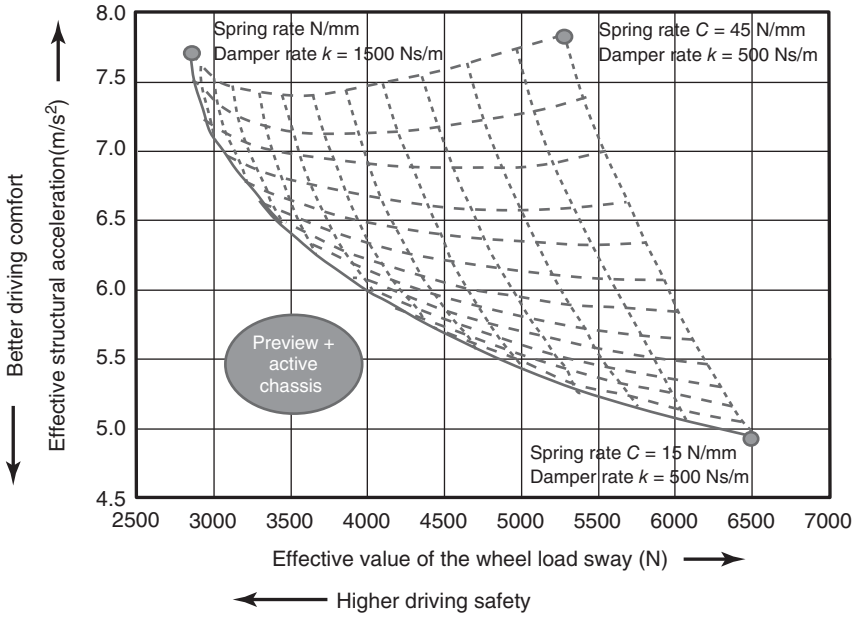

Figure 11. Conflict diagram passive wheel suspension.

The vertical dynamics controller (also called *hub controller*) reacts to the movements of the vehicle in vertical direction. Input parameters are wheel and body accelerations and their time integrals, that means wheel and body speeds. The wheel vibrations are between 10 and 16 Hz. When driving on uneven roads, irregularities occur in the wheel speeds, which can be used to estimate the quality of the street surface. The vertical body speed (the body vibrates approximately with 1 Hz) is determined with consideration of the driving speed, the frequency range of the street surface, the load, and the size of the excitation. Every axle is first individually controlled; a downstream parallel controller then provides for parallel movements.

The longitudinal controller reacts to accelerations and brake processes. The wheel signals (two per cable directly from electronic stability program (ESP), two additional ones via controller area network (CAN), and the vehicle speed) are the input parameters to calculate the static and the dynamic portion of the longitudinal acceleration.

On the basis of this, most of the dampers for both axles are adjusted the same to better support the vehicle.

The lateral dynamic controller detects yaw moments very early on using driving speed and steering angle. The dampers, which are adjusted harder (separate regulation of front and rear axle), already permit better vehicle support during cornering.

The vehicle roll with one-sided compression and rebound of the wheels while driving straight is called *copying*. It is reinforced by the axle stabilizer, which transfers the compression of one wheel (as a result of unevenness, the vehicle structure is lifted on this side) to the other wheel on the axle and also allows this wheel to compress. This increases the roll angle of the body. This is uncomfortable. The vehicle body reacts to this one-sided ground unevenness when in the comfort setting. The right and left body accelerations that are measured above the front axle detect this copying. All dampers are set to be harder and work against this unwanted body movement.

The diminishing mechanical damping characteristics are compensated by a tolerance adaptation. Thus, even defect dampers can be identified. If there are systems faults, an average damping is set that would correspond with a passive chassis, or if there is a total failure, the dampers automatically go to the hard settings.

For comfort reasons, the goal is to drive as long as possible with "soft" dampers and only switch to "hard" for safety reasons. This takes energy from the body and the wheel movements. In Figure 12, a cross section of a damper piston with an adaptive control mechanism can be seen.

Whether the damper rate is set using magnetically influenced rheological fluid or by a proportional valve is only a secondary issue as seen from a technical view.

The recuperation of the energy, now converted into heat in the dampers and radiated into the ambient air, is currently discussed as source for electricity generation. Whether it will be used in series is yet to be seen.

3.6 Tire pressure monitoring

Air is a structural component of today's tires. It provides both lateral rigidity (cornering stiffness) and vertical stiffness (spring affect) of the contact surfaces between tire and road. If there is air loss, the tires lose a substantial part of this rigidity and they deform more than the design allows.

If there is not enough air in the tires, they deform more while rolling. This causes friction between the reinforcement materials (textures) in the tire and the rubber. Heat is generated in the tires. This heat leads to degeneration of the tire materials until pyrolysis—finally leading to total failure of the tire.

The sidewall reinforcements of modern tires are so large that visual monitoring cannot detect a pressure loss of 20%. Even daily pressure monitoring has its limits with strong temperature fluctuations between day and night. The pressure difference can easily amount to 0.4 bar (from 21 to 0°C). While the majority of drivers (82%) claim to check tire pressure at least every 3 months, tests have shown that only 13% actually do. The Ford-Firestone case made this clear. Even today, many accidents caused by tire damage can be led back to tire pressure that is too low. This was found out by checking the other tires of a car after an accident. In addition to lack of maintenance, more than 30% of the pressure gauges at the gas stations indicate the pressure too high. After the cost for fuel, tires are in position two on the maintenance cost of a car.

The longitudinal and the lateral dynamic behavior of the car depends on an intact interface between the tires and the road. If this is disturbed, these vehicle dynamics cannot reach their full capacity. Therefore, the demand is made more and more to combine the tire pressure monitoring (already legally required in the United States of America and Europe) with the brake regulating system, to adapt the controller of longitudinal and lateral dynamics to the pressure loss. This adaptation already starts with the simple determination of the real vehicle speed, which like wheel speed measurement is dependent on the wheel circumference. An additional potential function would be the reduction in the maximum speed due to pressure loss.

3.7 Tire pressure adjustment

With the availability of compressors fed by the electrical system (for instance, for air suspension) and the minimal probability of perception of indicator lamps, it is logical that an active tire pressure control will be useful in chassis control. These technologies are already available for military vehicles and for fire engines today.

The road condition identification of the ESP supply the input parameters for air pressure selection in the stages mud, sand, snow, country road, expressway, and escape. Obviously, the driver can also preselect the pressure. By entering a tire model and the automatic wheel pressure detection (e.g., using the air suspension pressure), the correct pressure is automatically selected. The controlling occurs per axle until permanent refilling for acute loss of pressure. This requires a permanent monitoring. The normal cycle of the pressure measurement every 15 min is reduced to 15 s in case of pressure loss detection. The maximum compressor power is used to stabilize the tires and thus the vehicle. If the system cannot balance the pressure, the driver is warned after 2 min.

4 CHASSIS CONTROL BY USING VEHICLE DYNAMICS THEORY

A wide field of chassis control was opened, when the microcomputers became more powerful at the beginning of the 1980s. Until that time, the ABS (antilock devices for brakes) electronics used specific hardware, which limited the flexibility of the control tasks.

With the expanded electronics, it was possible to use the bicycle model and to evaluate the car behavior as a result of speed, vehicle mass, wheelbase, center of gravity position, and above all the cornering stiffness of the front and the rear axle. Figure 13 shows the yaw amplification factor as function of vehicle speed (Wallentowitz, 2007).

Understeering vehicles have a declining characteristic and are defined with the so-called *characteristic velocity*. With the equation in Figure 13, it is possible to evaluate the vehicle characteristic by using the data. In case the yaw rate, the vehicle speed, and the steering wheel angle are measured, the real relationship between these data can be compared to the theoretical ones (evaluated by online simulation of the equation). In case the real relationship is below the characteristic line, the car is more understeering, in case this point is above, the car tends toward oversteering.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

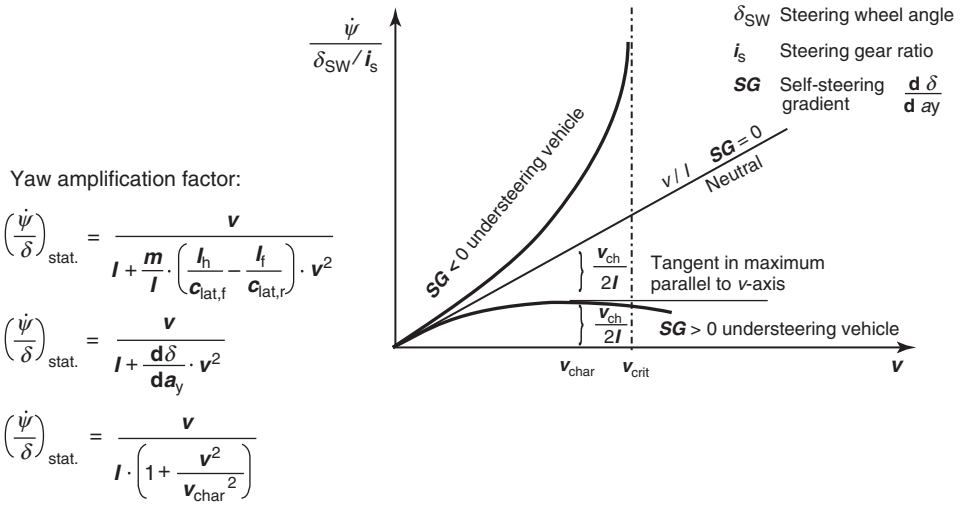

Figure 13. Yaw amplification factor as a function of vehicle speed. (Reproduced by permission of Henning Wallentowitz (2007).)

These theoretical background was used first in the Daimler-Benz All-Wheel-Drive 4Matic—starting in 1986 and in BMW dynamic stability control (DSC) system (dynamic stability program) in 1992 (Debes *et al*., 1997). The next step was the introduction of ESP in the market, which has been done by BOSCH in 1996 (van Zanten, 2000). Other companies followed. There is also the name TRC used.

The comparison of these data derived measures for switching on the all-wheel-drive or controlling the engine. The other systems used at that time only monitored the longitudinal dynamics. Thus, the ASR (traction control system while starting to drive) was realized over a motor interface, to quickly decrease the excessive motor torque at the source. In addition, braking was used to control the spinning wheels, to reach traction with the wheel that is not spinning. The drag torque control was possible due to the active throttle in modern cars.

4.1 Electronic stability program

Since 1996, the ESP is in the market. In addition to the DSC function (Debes *et al*., 1997), it uses brake applications to steer the car in the direction the driver intents to steer to. Under oversteering identification (comp. Figure 13), one front wheel is applied, under understeer, one of the rear wheels is braking, to keep the right driving direction. The values of yaw rate and sideslip angle in the center of gravity are the decisive information. To identify the actual sideslip angle, the measurement of vehicle speed and yaw rate is necessary. The sideslip angle itself is computed during driving.

In addition to the basic functions, electronic brake variator (EBV) (electronic brake force distribution), brake assist system (BAS) (electronic brake assistant), ABS (antilock system), dynamic traction control (DTC) (traction control while driving), ASC (automatic stability control), and DSC,

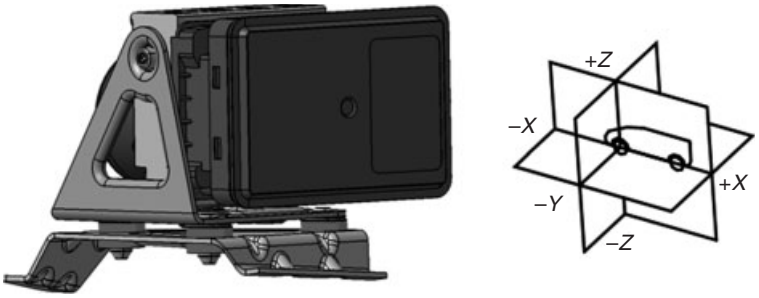

Figure 14. ESP with integrated sensors for yaw rate and longitudinal and lateral acceleration. (Reproduced by permission of TRW.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

modern ESP systems also have CBC functions (curve brake control—with consideration of the varying wheel loads in the curves and active braking of inner curve wheels), electronically controlled deceleration (ECD) (electronic braking due to other systems such as wheel sensors or electrical parking brake), HDC (driving down mountains), AAS (automatic trailer stabilization), and FLR (the control of driving performance—reduction for brakes that are already overloaded).

Even the brake lining-wear sensors are now evaluated by the ESP, in passenger cars still with one or two steps, in semitrucks already continuously. The originally separate electric parking brake is integrated into the ESP—the control unit must now execute the complete dynamic management (including the brake and warning light control) and the standstill management (including auto-hold) for the vehicle (Figure 14).

Internal temperature models of the brake disks are required for the fading brake support (FBS) (brake fading support) as well as for HTR (tension algorithms of the parking brake at high temperatures).

4.1.1 Networking of ESP and electrical steering

One function of ESP is steering of the vehicle by using the brakes. The driver enters the steering wheel and defines the direction. Single brakes are applied to follow this direction. Now, an automatically generated steering angle of the front wheels can be as effective as the brake intervention, but much more comfortable. And the combination of both actions can be even more effective.

If the vehicle oversteers, the combined system with an earlier steering intervention can possibly avoid the brake intervention. If the vehicle understeers, the steering wheel torque drops and the ESP begins with engine and brake interventions at the rear axle. An active feedback by steering already before interventions from ESP can help the driver avoid the situation.

If the combined system detects braking with different friction coefficients on the right and left lane side, it can automatically take on the necessary steering angle correction, without waiting for the driver. Driving and braking of a vehicle with a flat tire requires more skill to brake than the normal driver has. At the same time, a steering wheel turn is required. If the tire pressure monitor signals which tire is affected, the steering can compensate for the difference torque. By this additional steering input, the stopping procedure remains balanced. This allows quick stopping with high driving stability. This performance will be further improved with an additional networking with the lane assistant (usually realized optical via video cameras). This can realize an automated stabilization of the vehicle in the lane—when networked with the radar system even in the foresighted safe free lane. Fully automatic rescue support will thus be possible in the future.

4.1.2 Networking of ESP and transmission

The introduction of gears, for which not only the distribution of the drive torque between front and rear axle is possible but also the distribution between right and left drive wheel (torque vectoring), opens completely new possibilities for vehicle stabilization. In addition to steering and braking interventions, one-sided drive forces can now also influence the yaw moment of the vehicle. The necessary information signals (torque distribution between front and rear, friction utilization of the different wheels and the wheel speeds) are available from the ESP electronics. Thus, torque vectoring can be a subroutine of ESP.

4.2 EV (electric vehicle) and HEV (hybrid-electric vehicle) and electric brakes

The next level of complexity is achieved with hybrid and electric vehicles (EVs) and electric brakes. At commercial semitrucks, it is typical that in case of drive stability control, all disturbing systems (such as retarders, automatic transmissions, and exhaust brakes in engines) are switched inactive to have only strict brake control of the friction brakes. Now, from the development of the (not yet introduced) electric brakes, it is common knowledge that differences in torque caused by tolerances in spindles, gears, and electric motors are already noticeable with light braking. The car is slightly pulled sideward. Different cable lengths and two different energy reservoirs (X-split of the batteries) reinforce these symptoms as well as different temperature left/right.

If the manufacturing tolerances could be caught up with a final calibration, then there are also influences during driving such as temperatures (one-sided sun, batteries, cable, and motors) and uneven chassis and tire wear. The necessary corrections of offset and tolerances are done by long-term corrections (per ignition run and per brake procedure).

If two drive motors are installed on one axle, the same correction principle can and must also be used for drive torque and generator torque. The necessary prepared signals (wheel speed, yaw rate, lateral acceleration, longitudinal acceleration, steering wheel angle, and steering torque)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are already available in the ESP as control unit for the longitudinal and lateral coordination, as well as for the necessary compensation algorithms. It is to be expected that the complete compensation of tolerances in drive and brake systems must be performed in the ESP.

4.3 Wheel hub electric motors

Ferdinand Porsche already used wheel hub motors more than 100 years ago in his Lohner vehicles. However, afterward, the drive concepts were characterized by a centralization of the torque generation. The idea of wheel hub motors did not return until EV and hybrid-electric vehicle (HEV). The unsuspended masses are significantly larger by adding the electric motors to the wheels. This is the same problem as with the increasing combustion engine power: larger wheels were the consequence. The 20-inch wheels mainly serve to accommodate larger and heavier brakes. This decreases the axle natural frequency and the vehicle body structure is more excited, which leads to decrease in comfort. At the same time, the wheel load fluctuations increase—which finally leads to semi-active or active chassis due to the better controllability.

The use of decentralized motors now allows a vehicle stabilization even using the drive. In doing so, targeted one-sided drive torques are created to move the vehicle in the direction the steering wheel angle sensor is indicating.

All technology steps listed above can each only improve individual compromises of the conventional chassis design. Their combination, however, cannot be used functionally independently of each other. Using the steering wheel, drivers specify the driving direction and with the accelerator pedal the vehicle speed is determined via the drive train. The necessary forces in the vehicle center of gravity (the mass is estimated first or derived from the air suspension pressures or wheel deflection suspension) deliver the measured lateral and longitudinal accelerations. From there, the necessary forces are calculated at the four-wheel contact points (all three force vectors). These can now (depending on vehicle equipment) be influenced by various systems. The used one is determined by the energy requirement of each individual function. The system with the least energy requirements is selected (potentially, the vehicle can be steered more simply with the wheel individual motors than with a steering intervention). In addition, those systems with the best efficiency are advantageous. A comfort calculation is superimposed to keep roll, yawing, and vertical movements within limits. As superior hierarchy element, the safety functions control the system behavior. This determines whether the maneuver can be driven this way, or whether a different focal point must be set, such as relations to other traffic participants (avoiding accidents).

5 CENTRAL COMPUTER COMPARED TO DISTRIBUTED INTELLIGENCE

First, electronics for single systems have been installed in the vehicles. The next step was to combine functions. A motor control unit can simply be expanded to the function of a speed control system by reading in additional sensors. The typical "butter soft" shifting of the automatic transmission today already requires a more complex interaction of the control algorithms of the engine and the automatic transmission.

In the start of the 1990s, some engineers tried to put a large central computer into the vehicle. That was also supposed to take on further control tasks, such as transmission control or the ABS.

The main arguments for suggesting this were that distributed intelligences waste a large part of the performance for communication. In addition, it was intended to reduce costs. A large processor is cheaper than two smaller ones. In addition, redundancies are necessary inevitably the central unit only needs one (e.g., hardware: housing, power supply, EEPROM and sensor inputs; and in the software: operating system and diagnostics). While in distributed systems. Theoretically, synergies take effect with the summary of several functionalities.

It was also already tried to implement the idea of the central control unit by summarizing comfort control units from several suppliers. Inconsistencies regarding the resource administration, the product responsibility, the protection of each supplier's knowledge, the cost and coordinate of change management during series production, and the allocation of errors in the warrantee processing brought the specially founded company to a quick end.

The reality went a different direction. In any case, increased functionality means more sensors and actuators, thus, more cables and a higher complexity. If the *one*, central control unit is in a central site, all cables must be routed there. The electric mirror adjustment might be an example: the button is in the left door and the motors are in the left and in the right door. With one central computer, this positioning resulted in many meters of cable to the central control unit and back again. Cables are weight, space, fault sources, and not least costs.

An additional argument against the centralization is the complexity. Every control task demands that the associated sensors are scanned in a fixed pattern and/or processed at very specific times. The sensor requirements of an ABS or an engine controller are significantly different. If sporadic tasks are added, such as controlling an exterior mirror, this places considerable demands on the processor; the corresponding processor performance must be available for the potential concurrency. The controllability of so

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

many layers of requirements is much more complex in one program. The standard PC operating system is certainly an example for such complex programs. The complexity is not controlled so well, that everything is always available at critical moments.

Like with any software, in the chassis systems, there remains a residual error probability of approximately 2500 ppm at the start of series production (aviation is at approximately 250 ppm). This means in a million rows of C-Code, there are 2500 errors that are equally distributed to light, average and critical errors. Half of the errors are caused by incorrect specification, thus, surprising nonfunctionality or failures that were not planned. The probability of errors is approximately 10 times higher than the probability of hardware failures.

To be able to control the entire complexity, to not have to route all cables to one site, to switch off systems in case of error, to compensate for malfunctions of individual systems, every task requires its own control unit. The knowledge of the supplier and its protection lies multiplied in the software. The allocation of legal and financial responsibility is easily possible with single systems.

Finally, it should be noted that the current specifications of the automobile manufacturer already now exceed the capabilities of the microprocessors coming on the market in 2 years. This is true with regard to the memory capacity as well as the loop-time. All demanded algorithms can no longer be processed by the time slot specified by the driving dynamics. The electronic engineers like to compare software to the ideal gas: the software immediately fills all available storage and consumes every available calculation time, without generating noticeable advantages to the end customer.

This makes all safety consideration unanswerable when central computer systems will be in the vehicle. In the future, there will not be any "computer center" in the car.

6 COMMUNICATION OF DISTRIBUTED INTELLIGENCES

To avoid the disadvantage of multiple sensors or actuators with distributed intelligences, data must be exchanged. Let us take the example of cruise control: The engine control unit has obtained the speed signal from the speedometer. The ABS constantly determines the wheel speeds. What could be easier than for the cruise control to use the ABS speed signal? Logically, the speedometer signal should also be generated from the ABS speeds. Doing this generates the advantages for the automotive manufacturer that the transmission pickup can be omitted and the costs could be reduced.

To use data multiple times, a means for transport is required. There should be a communication system that is inexpensive and secure. The vehicle manufacturers and the large suppliers had already recognized the necessity of such a system at an early stage and began doing research in the 1970s.

6.1 CAN bus

In the early 1980s, Bosch began testing the bus systems on hand to see whether they were suitable for vehicles. After none of the existing systems satisfied the requirements of Bosch, they began specifying their own system in 1983. Daimler soon joined and Intel was gained as a hardware supplier. In early 1986, CAN was born.

CAN is a serial multi-master system. Every device connected to the bus determines itself when and how many messages are placed on the bus. The Ethernet network in the office networking is also one such serial multi-master system. However, only one message can be transferred to the bus at a time using the serial system. With the Ethernet, everything is regulated by "trial and error". If two messages collide with each other, both senders must try again using a specified schematic. With a higher busload—many participants try to transmit something at the same time—it can happen that no messages can be transmitted.

CAN is avoiding this with a nondestructive prioritized arbitration. In addition, a series of fault-detection mechanisms are integrated that ensure that transmission faults can be detected securely and generally can be avoided because of repetition of the message.

To simplify the handling, large parts of this standard were realized in hardware. Today, the processors used in the automotive industry are available with up to three integrated CAN interfaces. Every bus participant must be able to transmit its messages at the right time, complete and error-free.

At the start of networking, this was still simple: if the automatic transmission and the engine control unit communicate in 20-ms rhythm, there is never any danger that a message would be lost.

Later, the ABS was added to enable starting assistance together with the engine control unit and to be able to realize ESP functions with additional control units. However, these safety functions are only a small part of the control units in the modern vehicle. Mirror adjustment, window lifter, and electric seat adjuster are raising the need for communication exceedingly. The amount of information is limited by the bus width and the cycle speed of the bus. With a serial bus, the calculation is simple. For 500-kBit/s

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

bus frequency (the standard frequency for high speed CAN) and 20-ms cycle time for the critical signals, the following results:

$$500\ \text{kBit/s} \times 0.02\ \text{s} = 10,000\ \text{Bit}$$

This information rate could be transferred. Those are approximately 76 messages with each 130 bit message length (8 byte user data + overhead)

6.1.1 *Structuring*

The messages that must be transferred to the bus can be subdivided into important, less important, urgent, and less urgent messages. The messages of safety relevant systems are naturally extremely important, most also urgent. However, non-safety relevant controls can also require a high data transfer speed. The critical systems have an uninterrupted need to communicate—there are closed control loops that expect and send data in fixed time intervals—whose information environment is deterministic. Lost messages are not acceptable.

The vehicle manufacturers first routed two busses in the vehicle, so that critical messages are separated from the less critical messages:

- A high speed bus for the critical messages that are characterized by all messages are routed in cycles on the bus and their busload never exceeds 60% (e.g., drive train bus).
- A low speed bus (comfort bus) that must handle the rest of the communication needs.

To administer the comfort bus, generally, a network management is used to ensure that every participant receives its messages in acceptable times on the bus. Here, the bandwidth of the busses in critical conditions (all simultaneous messages are to be released) is not enough.

The bandwidth is a cost factor. By executing the comfort bus as a low speed bus, the system costs are reduced. Today, in Europe, the CAN is the most widely used bus system in vehicles. However, there were also alternatives, as, for example, VAN in France or in the USA Standard J1850 for Class B Network.

The CAN has a constant cost share with its safety, realized in hardware. If the requirements for cost and safety are lower, the local interconnect network (LIN) bus will be in favor, which halves the costs for a bus node.

6.1.2 *Wireless*

For networking the vehicle with the environment, for example, for cell phone, personal digital assistant (PDA) connection, and so on, bluetooth (e.g.) is already being used. This type of data transfer is unsuitable for safety systems, because of how it is influenced by electric and magnetic fields.

6.1.3 *New requirements*

In applications that are currently still covered by CAN, there are new requirements coming up. Driving stability systems that connect active suspension systems with electric steering and with ESP, engine control and adaptive cruise control, to be able to perform active corrective maneuvers, require closed control circuits that cannot be managed by an event-controlled CAN.

The main problem is that the time allocation of the messages cannot be guaranteed due to an accumulation of events or faults. (Highly prioritized messages receive priority and defective messages are repeated.) The variety of participating control units bursts the bandwidth that is available. High transmission rates from up to 10 Mbit/s are required.

The CAN is no longer able to cover the safety requirements set by the X-by-Wire functions (brake-by-wire, steer-by-wire). In some systems, there will be no mechanical fallbacks any more. In the currently used EHB systems (electric-hydraulic brake, the brand name at Daimler is SBC), some brake pressure can still be generated in emergencies, using the pedal. However, it is obvious that the development has reached a limit, which now requires new solutions to expand the technology.

6.2 Flexray

The bus system that is step by step being implemented in the automobile is called *Flexray*. It is a communication system as it has a fixed communication protocol and fixed hardware. It permits a deterministic, collision-free data transfer with guaranteed latency and jitter period with a scalable synchronous and asynchronous data transfer. The latency is the time between an event and the (delayed) reaction following. Jitter is the first derivative of the delay; the back and forth and the cycle frequencies during transfer of digital signals are designated by it (Figure 15).

Minimal latency and jitter times save signal filter times at the recipient. The support of redundant transfer channels, as well as the error tolerance and time-controlled actions implemented in the hardware, permit a quick fault detection and short reaction times.

Instead of arbitration such as with CAN, the Flexray has a fault tolerant synchronous time basis as global time basis of all systems in the vehicle. Owing to the support of Star Technology, partial switch-offs can be realized.

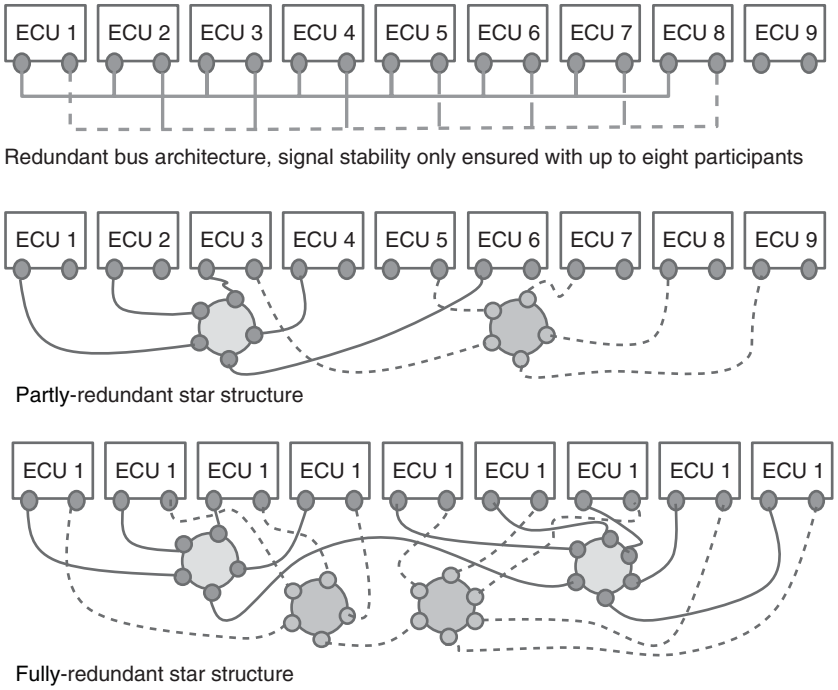

Figure 15. Flexray networking structures. (Reproduced by permission of R. Leiter.)

The Flexray can offer approximately 20 times the bandwidth of the CAN (until 10 Mbit/s) and it permits short cycle times (starting with approximately 1 ms). The consequences are doubling the costs for the bus nodes and the necessity that these bus systems must already be designed during design of the E/E architecture of the vehicle, including all signals and transfer time points. The automobile manufacturer is the only one who can do this. He must rebuild the necessary expertise (including the detailed knowledge of the individual system). Subsequent changes (e.g., adding new bus participants) are extraordinarily costly and time-consuming.

6.3 Gateway

The accumulation of control units forces structuring. As described above, as no bus fulfills all requirements, the bus systems are fit into the vehicle corresponding to the tasks. This means that a vehicle today can easily have five different busses installed; thus, the vehicle has an IT—infrastructure that is not inferior to that of the average production operation.

To make information that is required by many control units available to all systems, for example, the setting of the ignition key or the vehicle speed, that, for example, switches away the television receiver during driving, the information must be transferred to the various bus systems. Gateways take on this task.

6.4 Networking

Without the network, many of the currently available functions, such as vehicle stability control or adaptive cruise control, would not be possible. The new developments build on progressing networking in the vehicle. The comfort for the driver is increased; active safety and driver support systems can be realized with it.

6.5 Hierarchies in the control systems

The limited options of individual control units require cooperation that must be regulated. This will lead to a grouping in function areas—exactly like the supplier and automotive manufacturer are set up in their departments.

Thus, in the lower level of the driver's domain, there are the longitudinal and lateral dynamics, the vertical dynamics, and the drive and energy recovery. In the comfort domain, we have the air-conditioning/heating and the operating forces; and in the communication domain, the geophysical position, the site-related information, the information from other vehicles and local hosts, the driver's intention detection, driver feedback, and information for or about the driver (e.g., recording health status) (Figure 16).

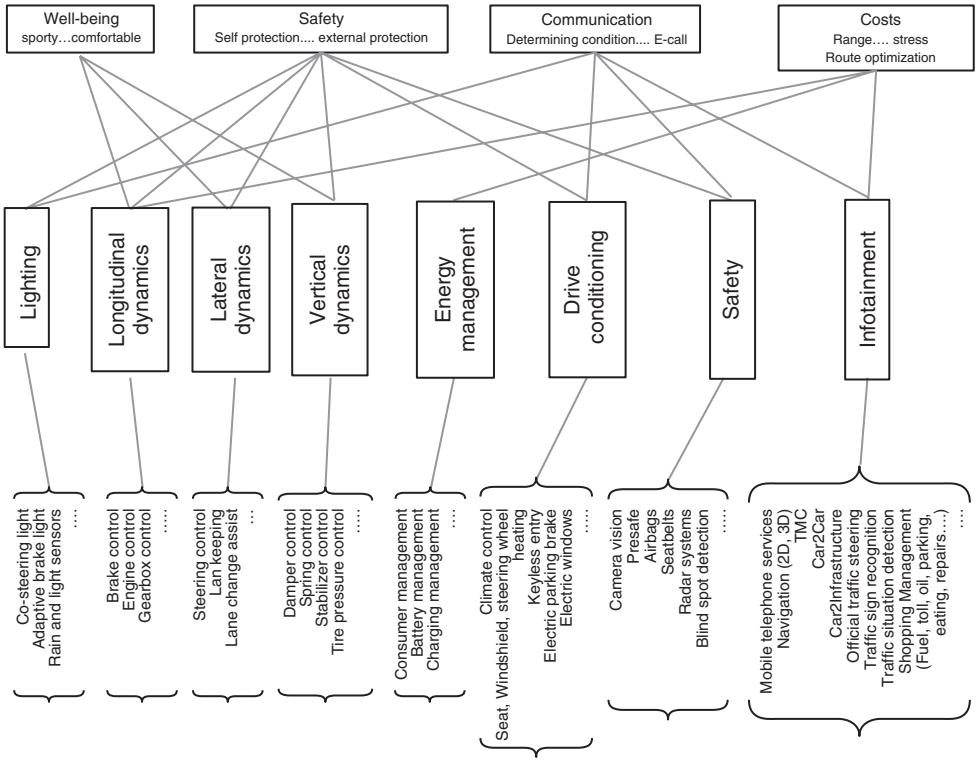

Figure 16. Domain structure. (Reproduced by permission of R. Leiter.)

Each domain has its own controller in which the tasks are joined. In addition, the vehicle manufacturer can place the characterizing master computer that sets the standard specialties specific to the vehicle, and in the case of fault, provides alternative strategies.

6.6 Shortened development times, tight resources

The new technology cannot be introduced without secondary effects. The classic development systems were tested in the vehicles long before the start of series production. Then, high quality and safety standards of the automotive manufacturer were brought into series.

Currently, the manufacturers' desire to innovate is keen and fast. Not just *one* new system is integrated in a new vehicle.

The shortened times to market introduction now mercilessly show their negative sides. All these new systems are specified early on, but naturally due to overall short resources, are only finished at the time when the final integration tests are supposed to be performed. Problems that no one thought of do not appear until then.

An example: the electric parking brake contains a logic that does not operate the brake in dynamic condition when the accelerator pedal is pressed while driving (preventing the driving against the brake). On the CAN, the electric parking brake algorithm only shows the respective brake condition once it has been reached. The cruise control should be abandoned by operating the parking brake (dynamic delay). As the cruise control pays attention to a brake-information, that was not visible at the start of the action, it tries to counteract this force at the start of braking and increases the engine power. The parking brake sees the gas pedal information that the cruise control uses to increase the motor power and it does not execute the command to decelerate. Consequence: the networking function does not work.

The reasons for this problem have been small misunderstandings of the specifications. Since such things do not show up until a time when the actual finished system should run endurance tests, the test times cannot be adhered to, with known and unknown consequences.

6.7 Integration and simulation

The way out from the dilemma is simulation and integration tests on simulation basis. To do this, HIL (hardware in the loop) and SIL (software in the loop) systems are combined. Available control units are connected to vehicle simulation (HIL). In these vehicle simulations, the high

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto032
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

level algorithms of the new systems are incorporated as software simulations, so that the overall vehicle can be tested long before the first prototype.

These techniques are available, yet not developed so widely that they could also detect the last problems. Unfortunately, the work never reflects the current development status of the communication participants, but rather the specification that always left interpretation gaps. The human language is not able to sufficiently define the IT: there are communication difficulties between the vehicle dynamics specialists and the "software workers" that are to implement the ideas of the vehicle dynamics specialists.

6.8 Black box and the operating system

With the high degree of networking, it is no longer possible that the automotive manufacturers purchase black boxes from their system suppliers and also shift the responsibility on them.

To be able to successfully integrate all systems, the vehicle manufacturer must have intimate knowledge of the subsystems and provide sufficient engineering resources. The vehicle manufacturer becomes the system-integrator, even if several functions are calculated in one control until. He can only accept the responsibilities connected with this, if he knows the processes in the control unit sufficiently well. The "game rules" must be followed. Accepting the prescriptions of operating systems such as AUTOSAR can do this. Industry started with OSEK, to define software standards. Currently, AUTOSAR 4.0 is used. If the suppliers used to have their own operating systems (and the responsibility for them), today they have to follow the strategy of the automotive manufacturers. The search for errors is very difficult in such complex systems, where due to networking, an overlapping of influence fields happens. Thus, there is also a possibility for faults.

6.9 Risk factor driver

The variety of system functions is supposed to support the driver and increase both his comfort and his safety. However, every automotive manufacturer has its own operating philosophy, also to keep its brand identity.

Most drivers do not take the time to study the operating instructions, and they expect self-explanatory system functions. The same system can function differently with a different manufacturer; even within a fleet of a manufacturer, there could be function differences due to different generations of systems (e.g., autonomous cruise control systems of generation 1 functioned between 30 and 180 km/h, the same technology in generation 2 now works until standstill).

There are many opportunities for faults by the driver, when a foreign vehicle must be controlled.

Once the driver is accustomed to the design of a safety function, he must be able to count on it. If, in a critical driving situation, partial systems fail, that can be critical. The system may overextend most drivers.

7 SUMMARY

The complexity of chassis control in cars is exploding.

Networking is one of the basic technologies of the innovation explosion.

The diagnostic systems and the diagnostics are not keeping up.

1 INTRODUCTION

The rising demands on technical systems in automotive and general applications in mechanical engineering result in products with an elevated degree of complexity and a wide range of integrated functionalities. To fulfill the requirements regarding system performance and reliability, modern technical systems must combine subsystems of different technical disciplines such as pneumatics, hydraulics, electronics, and mechanics as well as informatics and control techniques.

These very different technical subsystems must interact precisely in order to realize the required functionality of the entire system. In contrast to developments in the past, the engineers involved in the development process of such systems can no longer rely on estimated formulas or simple static design techniques. The use of simulation techniques is therefore indispensable in today's development processes. Furthermore, the used system simulation tools are required to provide functionalities for the coupling between different technical disciplines to coordinate the interactions between the implemented subsystems.

To meet the requirements, several software tools such as DSH*plus*, AMEsim, and SimulationX are available to aid the engineer during the whole development process.

2 SYSTEM SIMULATION

2.1 Simulation procedure

In the following, the general modeling procedure and the basic calculation methods of one-dimensional simulation tools will be illustrated, using the example of DSH*plus*. System simulation tools provide a detailed description of the real system, which is to be investigated, using sophisticated models of the component and transfer properties in the form of mathematical equations.

To ease the creation and compilation of those equations, most simulation suites provide a graphical user interface, which allows the synthesis of the system from single functional component units. These are available in libraries that contain hydraulic and pneumatic as well as electrical, control engineering, and mechanical elements. The functional units usually constitute a technical component such as a valve or a cylinder, but can as well be used to synthesize complex technical systems. Behind every functional unit,

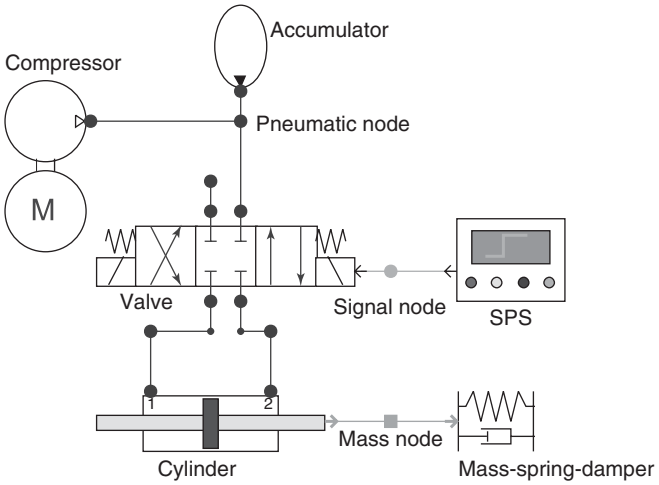

Figure 1. Simple pneumatic system.

such as a high pressure injection pump or a piston pump, for example, lies a mathematical description of the component. The components are thereby available with different levels of detail according to the needs of the simulation focus. To remain on the example of pumps, a pump, for example, can be modeled by just providing a constant volume flow to the system or in very detailed way considering all geometric circumstances and physical effects. In the second case, the volume flow of the pump will show all volume flow pulsations resulting from the number of pistons, for example. This is not necessarily needful for the simulation of entire systems but it might be of great importance for the investigation of noise problems.

If the provided libraries are not adequate to model the desired component functionalities, most simulation environment offer the possibility to create user-specific function units in a common computer language. In case of DSH*plus*, the programming language *C++* is utilized to create components from scratch. This enables the user to implement even the most complex physical models, as long as they are mathematically conveyable and the computation time is economically acceptable. The downside to the use of *C++* is the requirement for the user to be familiar with at least basic programming techniques.

In the further modeling process, different functional units can be connected by the user via nodes in the graphical user interface depending on their physical interaction with other functional units. A simple simulation model of a pneumatic cylinder drive consisting of different functional units and component connections is shown in Figure 1.

On the basis of the connections of the functional units, the mathematical equations of the physical system are automatically generated by the simulation tool. The dynamic behavior of the technical system is represented in a differential equation of the *n*th order or *n* differential equations of first order. The notation in *n*-differential equations of first order is far more suitable for the numerical integration because numerical solution methods utilize the same form of equation.

With a given set of parameters for the system components and starting values for the state variables, the system of equations can be treated as an initial value problem of common differential equations (FLUIDON, 2007):

$$\dot{\underline{y}} = \underline{f}(t, \underline{y})$$
$$\underline{y}(t_0) = \underline{y_0} \tag{1}$$

with

$$\underline{y} = \begin{pmatrix} y_t\,(t) \\ y_2(t) \\ \dots \\ y_n(t) \end{pmatrix} \tag{2}$$

and

$$\underline{f} = \begin{pmatrix} f_t\,(t, y_1, y_2, \dots, y_n) \\ f_2(t, y_1, y_2, \dots, y_n) \\ \dots \\ f_n(t, y_1, y_2, \dots, y_n) \end{pmatrix} \tag{3}$$

Solving the set of differential equations and integrating the state variables over time provides values to the state variables at a later time step.

2.2 Calculation of pneumatic and hydraulic values

The node-oriented model structure and a concentrated calculation of the state variables within the connecting nodes are the basic principles of all system simulation tools, which therefore are also called *lumped parameters simulation tools*. Figure 2 visualizes the calculation core of such lumped parameter approaches for the example of a pneumatic system. Within the nodes, the pressure derivatives are calculated from the balances of the entering and leaving mass flows. These pressure derivatives are then integrated to pressures, which are transferred to the components. Mass flows, however, are calculated in the components from the difference of the pressures applied to their connections. To define the characteristics of the pressure buildup, for example, in a pneumatic connection node, the starting values for the volume, temperature, and pressure must be specified by the user. In case of volume changing components, as for example cylinders, the volume and its derivative are transferred to the nodes to allow their consideration in the pressure buildup equation.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

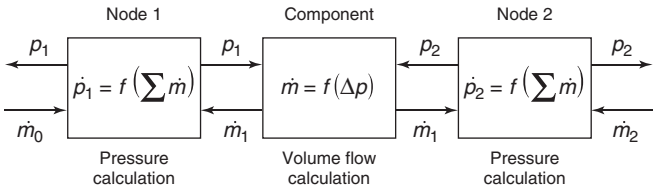

Figure 2. Calculation method of simulations with lumped parameters.

The correlation of volume flow and mass flow is described by the density ρ, which can be calculated by ideal gas equation (Equation 4) using the temperature T, the pressure p, and the gas constant R.

$$\rho = \frac{p}{T \cdot R} \tag{4}$$

The change in pressure of a pneumatic system is caused by mass flows, heat transfer, and volume change. The pressure change is described by the first law of thermodynamics for open systems and results in Equation 5:

$$\dot{p} = \dot{p}_{\dot{m}} + \dot{p}_{\text{th}} + \dot{p}_{\dot{V}} \tag{5}$$

The energy exchange resulting from the mass flows in between the components and the nodes is considered in Equation 6 by the variable $\dot{p}_{\dot{m}}$:

$$\dot{p}_{\dot{m}} = \frac{\kappa}{V} \cdot R \cdot \left(\sum \left(\dot{m}_{\text{in}} \cdot T_{\text{in}}\right) + \sum \left(\dot{m}_{\text{out}} \cdot T_{\text{out}}\right)\right) \tag{6}$$

Furthermore, the heat flow from and to the environment is represented by $\dot{p}_{\text{th}}$ in Equation 7. κ is the polytropic exponent. For air, this can be an adiabatic process and then κ would be near 1.4. In an isothermic process, the κ is 1.0. The heat transmission coefficient α describes the ratio of heat flux per unit area to the temperature difference from component wall with the contact area A to the air inside the balanced system

$$\dot{p}_{\text{th}} = \frac{\kappa - 1}{V} \cdot [\alpha \cdot (T_W - T) \cdot A] \tag{7}$$

The performed work due to the volume change at the balanced system is considered by $\dot{p}_{\dot{V}}$ in Equation 8:

$$\dot{p}_{\dot{V}} = -\frac{\kappa}{V} \cdot p \cdot \dot{V} \tag{8}$$

The temperature is acquired by means of the ideal gas equation as shown in Equation 9:

$$T = \frac{p \cdot V}{m \cdot R} \tag{9}$$

The time derivative of the ideal gas equation delivers the change in temperature over time:

$$\dot{T} = \frac{\dot{p}}{p} \cdot T + \frac{\dot{V}}{V} \cdot T - \dot{m} \cdot \frac{RT^2}{pV} \tag{10}$$

To minimize the computation time of the simulation, the pressure change $\dot{p}$ is calculated first. In a second step, the preceding results are used to determine the temperature change $\dot{T}$.

2.3 Numerical integration

The system of differential equations representing the modeled system describes the derivative of all state variables in all operating points. To solve the system of differential equations of the entire simulation model, DSH*plus* provides different numeric integrators, which allow an explicit as well as an implicit solving on a time-discrete basis.

The explicit solver only uses values, which are already calculated and therefore available from former time steps. The implicit solver in contrast uses the solution of the current time step as well.

The integral interval $[t_0, t_n]$ is divided into time increments.

$$t_0 < t_1 < t_2 < \cdots < t_n$$

with the local time increment of $h_i = t_{i+1} - t_i$ for $i = 0 \ldots (n-1)$. An approximation for $y(t_i)$ is obtained by Equation 11 with $i = 0 \ldots (n-1)$.

$$\underline{y}(t_{i+1}) = \underline{y}(t_i) + \int_{t_i}^{t_{i+1}} f(t, y(t))\mathrm{d}t \tag{11}$$

Furthermore, modern system simulation tools offer solvers, which work with an automatic step size control instead of a constant step size integration. The advantage of this multistep methods is a small time increment in high dynamic operation modes and a bigger time step, when no or only small changes in the model behavior are present. Multistep methods therefore reduce the computation time. As a consequence of the numerical integration, a discretization error has to be encountered for. To reduce this error, DHS*plus* offers an automatic step size control in order to achieve optimal results for highly nonlinear very stiff systems. The step size control adapts the step size in such manner that a specific error tolerance is met.

2.4 Typical applications

Typical applications of system simulation tools such as DSH*plus* within the automotive engineering are all fluid-containing systems, such as functional systems, safety systems, or comfort systems. As an example, comfort systems such as air springs or semiactive dampers are virtually analyzed and optimized with the help of system simulation tools. Further, common simulation applications are power steering or braking units as well as safety systems such as ABS (antilock brake system), ESP (electronic stability program), or active roll systems with their related control strategies.

Beneath simulation applications on the entire system level, it is also common practice to look at the single component as a system. Applications on the component level are fuel injection pumps, hydraulic or pneumatic lines, fuel injectors, hydro bearings, or torque converters, for example.

3 SIMULATION EXAMPLES

To illustrate the wide range of possible applications for DSH*plus*, a rather unusual example of a modeling approach for pneumatic seat components is described. The example shows the whole process including data acquisition for component parameterization, the buildup of the simulation model in DSH*plus*, and the comparison of the simulation results with measurements. The example not only reveals the advantages of simulation tools in the design process but also displays the flexibility of modern system simulation tools.

3.1 Example 1: pneumatic seat adjustment

Pneumatically actuated comfort systems for the dynamic adjustment of the shape of automotive seats are characterized by their compactness and consist of miniature pneumatic components. These components are a compressor, a number of valves—depending on the application—inflatable plastic cushions, as well as the necessary connectors and hoses. Figure 3 depicts the functions and the pneumatic components built into an automotive seat.

Commonly, the components mentioned earlier will be delivered to the seat manufacturer by different suppliers. Therefore, a fast, exact, and energy-efficient method is necessary to compare components of different producers or to characterize or assess single components regarding their usability for the automotive seat. The pneumatic elements are low priced components according to their usage in the automotive sector, which is well known as a *mass market*. Their functionality and fabrication result in a large variation of their pneumatic characteristics. This variation of the components' characteristics leads to a strong variation of the system behavior. Therefore, an integral approach for the characterization and simulation to determine the system behavior is of great importance. DSH*plus* is utilized to evaluate the applicability of the components regarding the specified behavior of the complete system. As pneumatic cushions are quite rare system components in typical pneumatic applications, there is no library containing similar components available in DSH*plus*. Furthermore, because of the early development stage of the components, there are no specific datasheets available to parameterize the components. Hence, the parameterization of such a model by estimates would result in an inaccurate description of the system behavior. To ensure accuracy of the model,

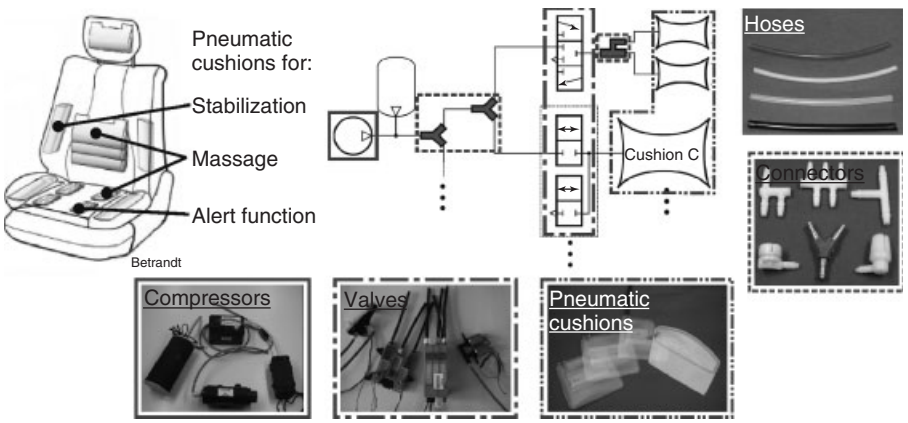

Figure 3. Pneumatically actuated comfort system of an automotive seat with its functions and its builtin components.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

components are calibrated and the results are used to reproduce the exact component behavior in the system simulation in DSH*plus*.

3.1.1 Valves

Figures 4 and 5 depict the mass flow characteristics derived from measurements and the mentioned parameters of an exemplary valve for the flow path $1 \rightarrow 2$ and $2 \rightarrow 3$, respectively.

The result of one gauging procedure is the mass flow characteristic over pressure p_1. Regarding the flow through the valve, p_1 represents the static pressure in front of the valve (input pressure). A set of characteristics results from the variation of the pressure p_2 downstream of the valve. According to the interesting pressure range from p_{Amb} to $1.5\,\mathrm{bar_{Abs}}$, p_2 was varied in 0.1 bar steps. The set is completed by changing the flow direction from "normal" flow to "reverse" flow.

In a second step, the outlet metering edge was measured (Figure 5). In addition, the switching delay t_{SD} was determined (Siebertz *et al.*, 2010). This is an important parameter, which characterizes the valve's opening dynamics. A second parameter, the pressure loss coefficient $K_{\mathrm{V},\Delta p}$, describes the valve's leakage behavior. Both parameters are implemented in the simulation model described in the following sections.

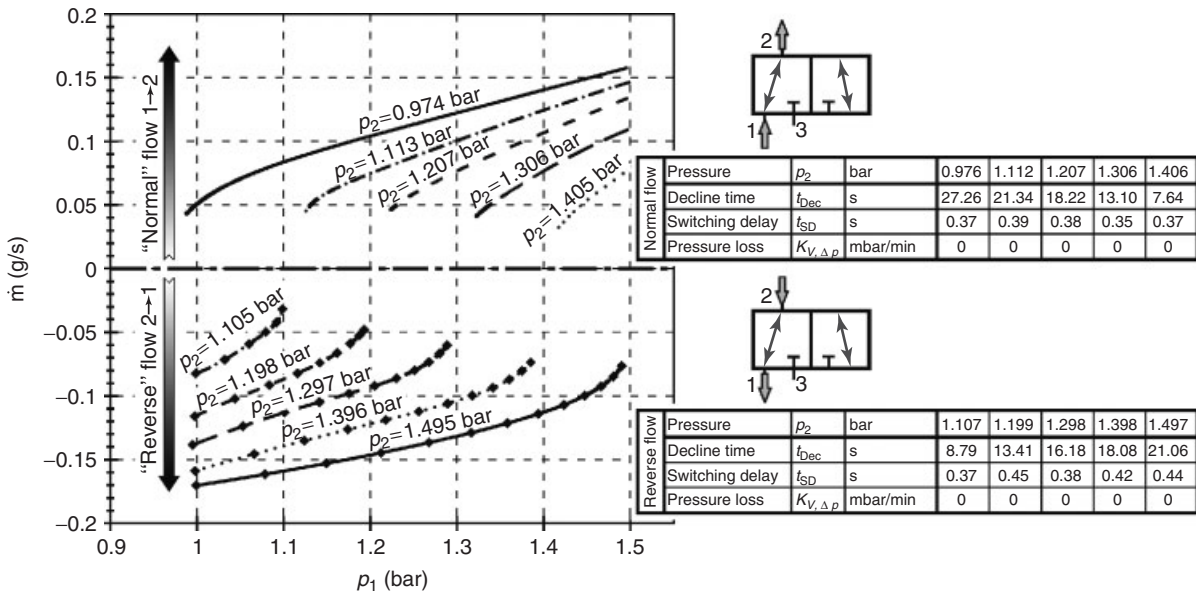

Figure 4. Characteristics and parameters of the flow path $1 \rightarrow 2$ of an exemplary valve.

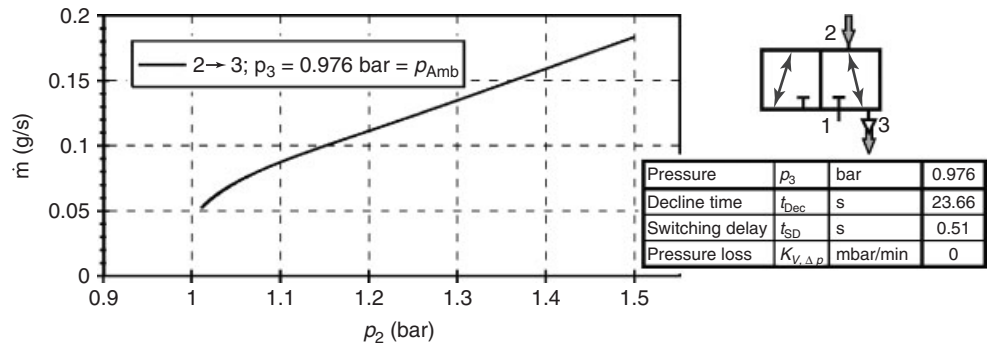

Figure 5. Characteristics and parameters of the flow path $2 \rightarrow 3$ of an exemplary valve.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.1.2 Compressor

The result of the compressor gauging is its conveying characteristics and a few other parameters, as depicted in Figure 6. The characteristics over the relative pressure difference of two exemplary compressors are shown. According to the compressor's performance, the pressurization of the measurement volume is only possible up to the compressor's maximum pressure $\Delta p_{\mathrm{Max}} = p_{\mathrm{Max}} - p_{\mathrm{Amb}}$. The leakage rate $K_{\mathrm{C},\Delta p}$ is determined in order to specify the compressor's quality. Driving the compressor's motor with 12 V, the power consumption of the compressor is quantified by the averaged current value I_{Avg}. While the compressor's characteristic is used for simulation, the other parameters can be used as quality attributes of the compressor, too.

3.1.3 Cushions

The volume as a function of the internal pressure characterizes the seat cushions' pneumatic behavior. It is determined by scaling the cushion while filling it with water, as water can be deemed to be incompressible in the investigated pressure range and its specific weight is well known. To allow the measurement of pressure-dependent characteristics, the water reservoir, connected to the cushion, is pressurized by an entering airflow, whereas the internal pressure of the seat cushion is determined by a pressure sensor at its inlet. Figure 7 shows the behavior of three different cushions, measured without applying a load. It becomes obvious that—after a filling period with minimal pressure rise—a linear relationship of pressure and volume exists. The results show steady-state volumes, whereas the strain of the cushions' plastics leads to a time dependence, comparable to a first-order lag element. The knowledge of the system behavior is necessary to enable a correct implementation of the cushions in DSH*plus*.

3.1.4 Measured data processing

The behavior of the measured compressors and valves has to be transferred into characteristic fields for their use in the one-dimensional simulation. These characteristic fields have—in the case of valves—two input parameters (the inlet and outlet pressures p_1 and p_2) and one output (the mass flow $\dot{m}$). The simulation software DSH*plus* requires tables, providing an output value for each possible combination of input sampling points (FLUIDON, 2007). This

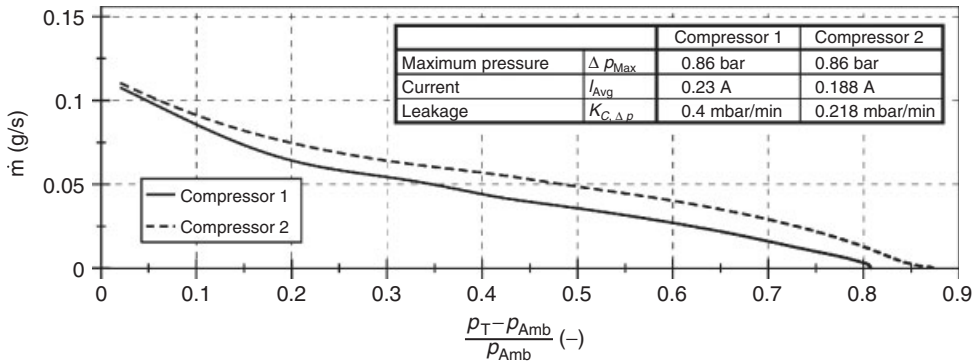

Figure 6. Characteristics and parameters of two exemplary compressors.

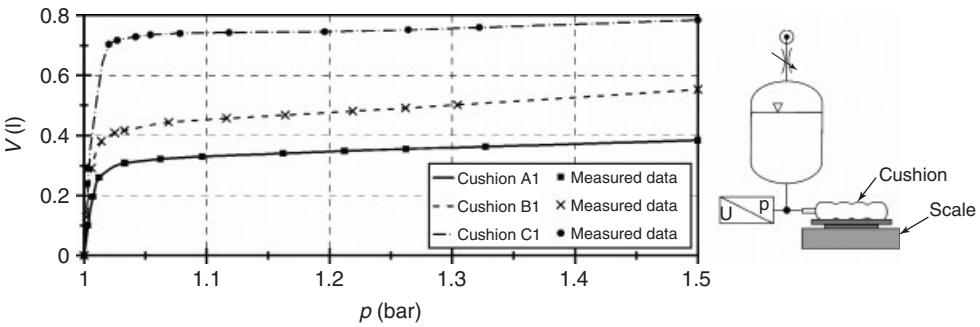

Figure 7. Cushion volume as a function of its internal pressure.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

means, in case of the above-mentioned gauging method, that the sampling points of the inlet pressure have to be identical for each measurement, whereas the outlet pressure is varied. The measured inlet pressure is influenced by the mass flow across the measured object. Thus, at different points, the measurements will vary. Common sampling points have to be generated by a spline interpolation algorithm, interpolating from the measured points at defined pressure levels. Here, the "radar-spline" method can be applied to generate additional curves between the measured ones and thus can be used to avoid the above-stated problems, occurring during linear and common spline interpolations. This method considers zero mass flow in case of pressure equality, represented by an additional diagonal in the characteristic diagram. Its endpoints serve as center points for the radar-splines, defined by one center point and crossing points with the present curves. Finally, additional curves between the measured ones can be achieved by interpolation of sampling points generated by radar-splines. In this way, a characteristic diagram with a more continuous behavior (Figure 8) is generated. The level of discontinuity and the difference from the above-described physical law decrease with a higher number of data points in the characteristic map. As the number of data points to be generated with the radar-spline method is unlimited, the model behavior can be optimized by a compromise between model quality and data volume. The data import into DSH*plus* is realized either by a provided characteristic map creator for two-dimensional characteristic maps (one input parameter results in one output parameter) or by an ASCII-text file. The wide compatibility of almost any data acquisition software to ASCII-text files allows the import of measured data from almost any source to DSH*plus*. Furthermore, this method allows the import of three-dimensional characteristic maps by simply appending a two-dimensional characteristic map for every coordinate in the third dimension to the text file.

The deflating valve can be described by a one-dimensional characteristic (Figure 5), as the ambient pressure is considered to be constant ($p_3 = p_{\mathrm{Amb}} =$ constant). The measured compressor mass flow as a function of its outlet pressure can also be imported as a one-dimensional characteristic without further calculations (Figure 6). The inflatable seat cushions are described by their pressure-dependent volume. The dynamical strain behavior is considered by summation of a proportional and a first-order lag element.

3.1.5 Simulation model

The validation of the component models in DSH*plus* can be achieved by simulating and measuring the time variant pressure in a system, consisting of elements measured beforehand. The system includes a compressor, a triple valve (three single 3/2-way valves in one housing), three cushions of two different types, and several hoses. In the DSH*plus* model, each component is represented by a corresponding component model, parameterized by measured characteristics, whereas the volume of the hoses is contained in the depicted volume nodes. Compressor and valves of the simulation model are driven by the measured control signals of the test bench to achieve identical conditions for simulation and measurement. Figure 9 shows the test bench and the corresponding simulation model.

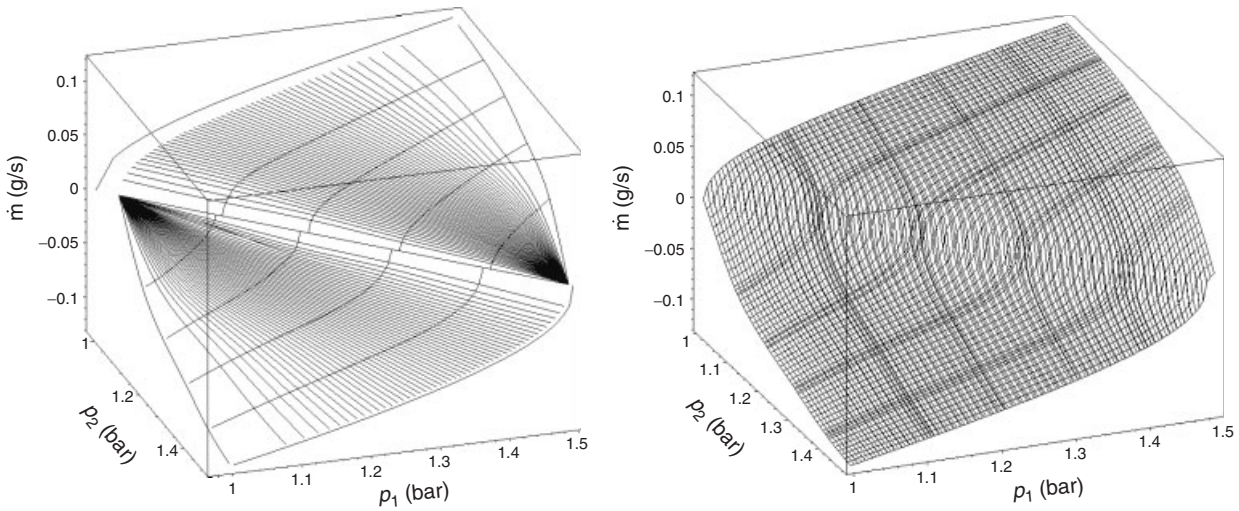

Figure 8. Characteristics map of the valve using the radar-splines method.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

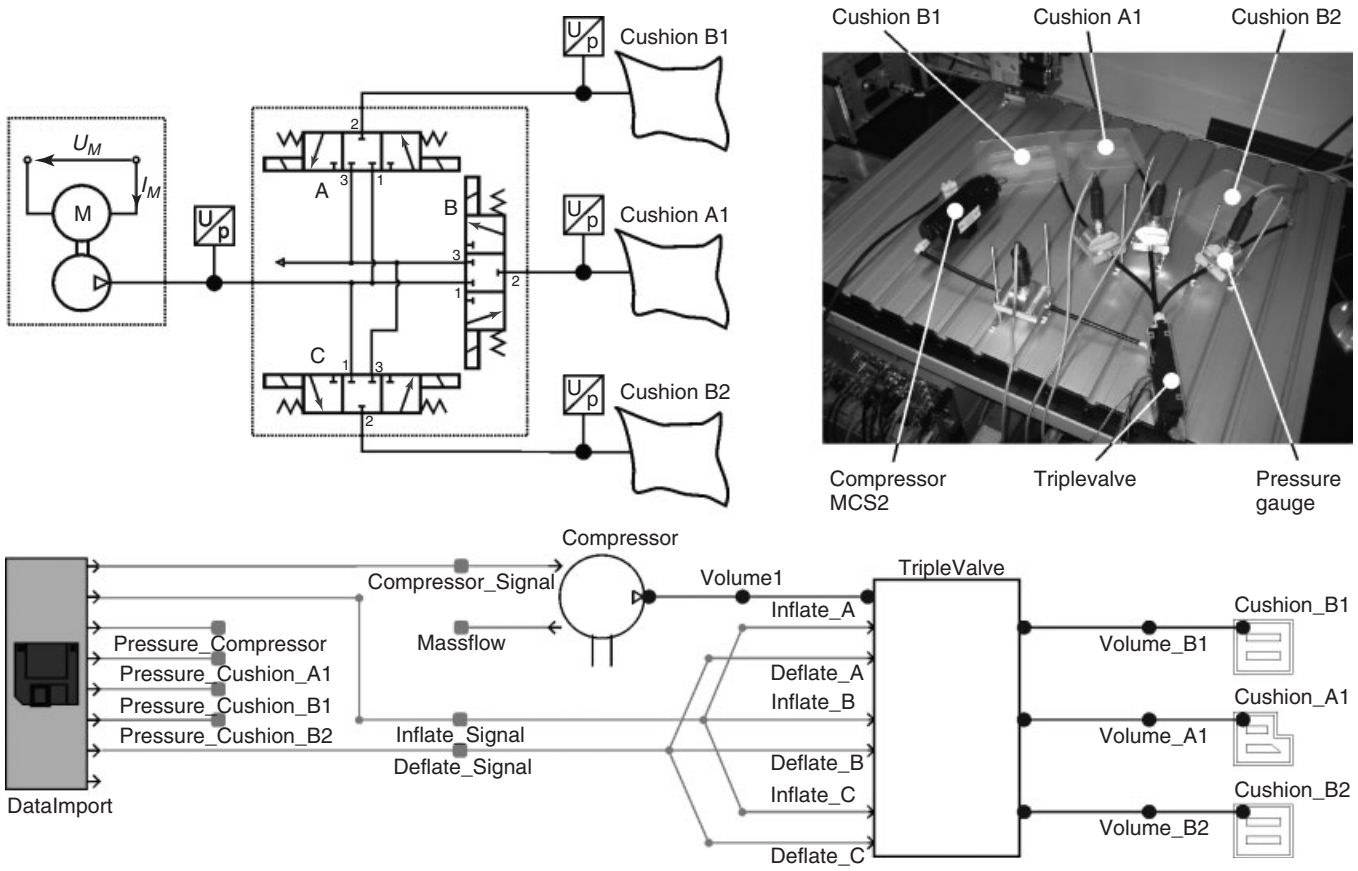

Figure 9. Test bench and corresponding simulation model.

The very good correlation between simulation results and measurements shown in Figure 10 emphasizes the high quality of the gauging method and the modeling. In combination with the fast gauging method for all system components, the simulation model enables the user to optimize the contour adjustment of automotive seats in a very short time. This is a big improvement compared to the state of the art method consisting of trial and error bench testing of hardware components.

The one-dimensional simulation enables the user to conduct parameter studies in a very fast and comfortable way, because no additional pneumatic components are required.

3.1.6 Summary of example 1

As an example of a complex pneumatic system, a pneumatically actuated comfort system for the contour adjustment of automotive seats was presented. A measurement method for the characterization of the system's elements can be used for quality inspection tasks, fault detection, and quantification, as well as the extraction of element-specific maps and parameters. These maps and parameters can be used for parameterization of a simulation model. Pneumatic valves, compressors, and cushions were investigated in order to determine their theoretical model behavior. The measurement method is not limited to pneumatic miniature elements and can be used for common elements of industrial pneumatics, likewise. The good correlation between measured pressure characteristics and its simulated values during the validation phase emphasizes the high quality of the simulation model and the need for highly accurate data to parameterize the components. Therefore, the simulation model can be used for a preestimation of the system's behavior or an investigation of the parameters' sensitivity.

3.2 Example 2: simulation of tubes and hoses

In automotive engineering, tubes and hoses are used most of the time to connect different pneumatic and hydraulic subsystems and components, such as the fuel system, the air conditioning, brake systems, exhaust systems, and power steering unit. These components typically consist of highly

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034

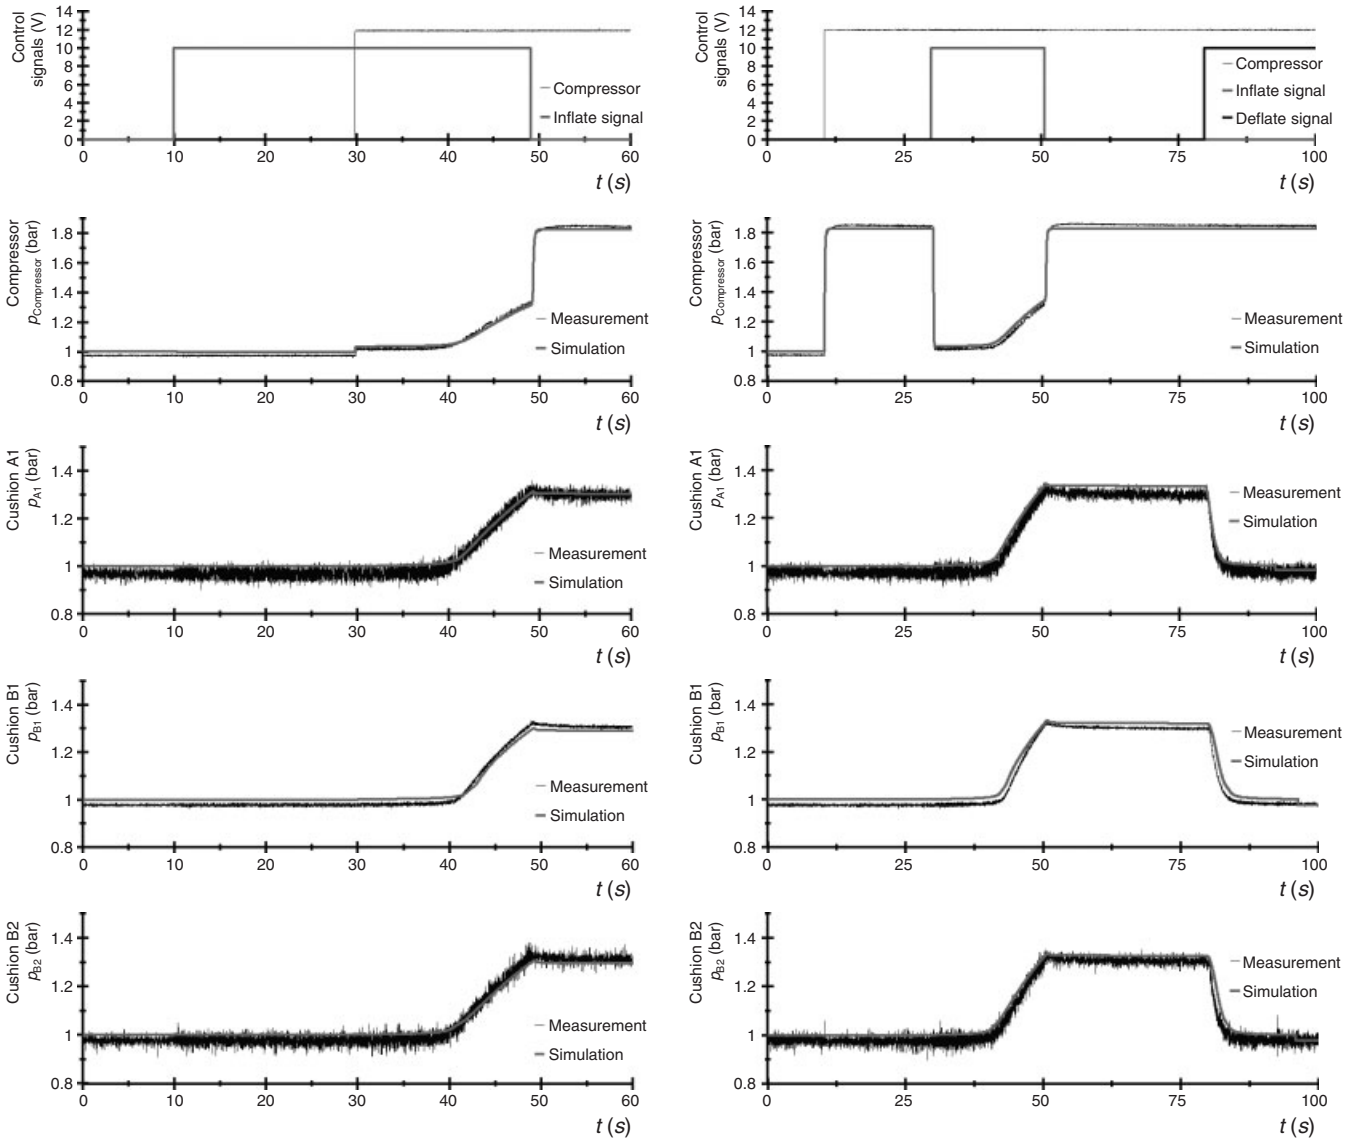

Figure 10. Validation of the simulation model.

integrated components, which must be are arranged on a very limited installation space. These limited installation conditions require flexible pathways and good mechanical features. Tube and hose connections fulfill those requirements and represent very flexible connection elements.

Figure 11 shows a typical expandable automotive line of average complexity, used in power steering units.

Owing to excitation from different sources, such as pumps, valves, and vibrations caused by the engine or other ancillary units, unwanted pulsations in the tubes or hoses can arise. These pulsations can lead to mechanical vibrations, which could cause unwanted noise emission in the form of structure-borne sound. The vibrations can cause a disturbance in the passenger cabin, which deteriorates the comfort of the vehicle. Furthermore, pressure peaks caused by resonance can result in high component strains especially in high pressure connections. These effects are summarized within the term *NVH* (*noise, vibration, and harshness*), which is also used to describe the study and modification of noise and vibration characteristics of vehicles.

Well known as a source of noise within the interior of a vehicle is the hydraulically assisted power steering system. The hydraulic pump of the steering system initiates a pressure ripple into the hydraulic circuit in which the pressure ripples propagate throughout the system as fluid-borne noise. To minimize the noise emitted by the power steering system, different noise reduction techniques are used. The most convenient way to reduce the noise emission

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 11. Typical expandable automotive line with average complexity (Johanning, Baum, and Wurmann, 2009). (Reproduced by permission of Heiko Baum.)

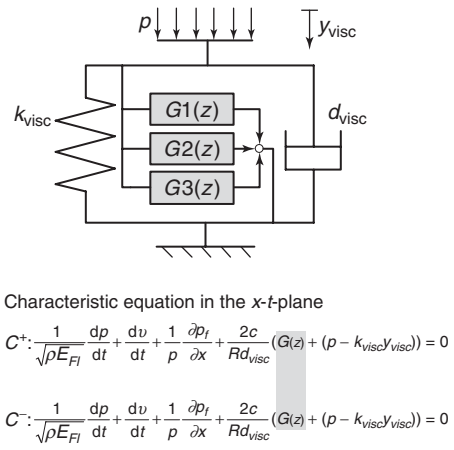

Figure 12. Implementation of parametric resonance into the characteristic equation (Baum and Johanning, 2009). (Reproduced by permission of Heiko Baum.)

is the installation of a tuning cable with a certain length to induce a destructive interference and therefore attenuate the amplitude of the pressure ripple (Visteon, 2005).

In addition to the destructive interference, structural damping can be used for noise reduction. The length of elastic hose elements in the hose assembly is increased, so that the energy from the pressure ripples is absorbed by the expansion of the hose wall. Furthermore, the hose reduces the wave speed in the fluid (Visteon, 2005).

If excessive noise emission and vibrations occur in the final product, the reinstatement work usually takes a lot of effort and time. To compensate or suppress the propagation of these pulsations throughout the connections and components, the mechanical features of the connections must be considered in an early stage of the development process.

In the past, a combination of different methodologies using analytical (Beater, 1999) and experimental approaches were used. However, all of these methodologies show significant disadvantages. The experimental methodology using a trial-and-error approach on a physical model is very time consuming and therefore costly. The analytical methodology uses a set of equations in a closed form and is therefore often restricted to simplified geometry and material properties. Furthermore, the increasing complexity of, for example, the power steering system and the typically nonlinear system behavior complicate the analytical description. The use of a finite element approach allows an accurate description of the isolated tubes and hoses but struggles with the simulation of the whole system because of the complexity of component interactions, which must be regarded.

A methodology without the above-mentioned disadvantages facilitates a time-based modeling approach provided by modern system simulation tools, such as DSH*plus*. In contrast to finite element method, the time-based approach allows the accurate and fast evaluation of the NVH characteristics of the system, including system vibration, airborne noise, and fluid-flow characteristics because the parameters at the boundaries are calculated by physically modeled system components such as the pump and valve of a power steering unit. This even enables the simulation of time-dependent operating conditions such as driving maneuvers.

This makes the system simulation the first choice to perceive and circumvent problems regarding NVH. Furthermore, changes can be applied and tested in an early development stage, which leads to a significant cost saving and reduction of time to market. In addition, system simulation tools can be used to troubleshoot systems in which NVH problems occur. The system simulation allows to clearly identify the source of vibration in a depicted and parameterized system. Furthermore, the system simulation enables the user to develop and test adequate countermeasures in a short period of time.

To obtain accurate results, all relevant physical aspects of the connection element must be implemented and properly parameterized. In the modeling process, this poses the greatest challenge. For example, steel tubing allows a simple phenomenological approach to describe the viscoelastic properties of the tube walls by a simple spring damper model (Müller, 2002), whereas the damping of hoses is essentially influenced by the temperature- and pressure-dependent viscoelastic properties of the material

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

used for the hoses. Furthermore, measurements showed that typical hoses used in power steering units allow volumetric expansion rates of 15–35 ccm/m at 23°C, which is substantially higher than steel tubes.

The viscoelastic properties have a significant influence on the damping and are adjustable by the hose material and the winding characteristics. In a simple spring damper model of the hose wall, the interaction of the characteristic frequency of the connection element and the damping of the connection wall is neglected. The representation of these specific characteristics requires a more complex model. Therefore, a parametric resonance is implemented into the model Figure 12.

The parameterization of the phenomenological models is done by measurements on a test bench, which allows the characterization of a specific material property of a hose.

On the basis of the characterization of different hoses, the characterization for frequently used fittings and hose elements, as shown in Figure 13, is available in the DSH*plus* component library.

By combining these basic elements, almost any desired elastic hose configuration can be modeled. Furthermore, the combination of basic elements allows the integration of resonators such as volume, Helmholtz, and cavity resonator, as well as throttles or orifices. Furthermore, a combination with a tuner cable is configurable and allows the optimization of a whole hose assembly.

3.2.1 Measured data processing

The foundation of realistic simulation results is the correct parameterization of the system components in the system

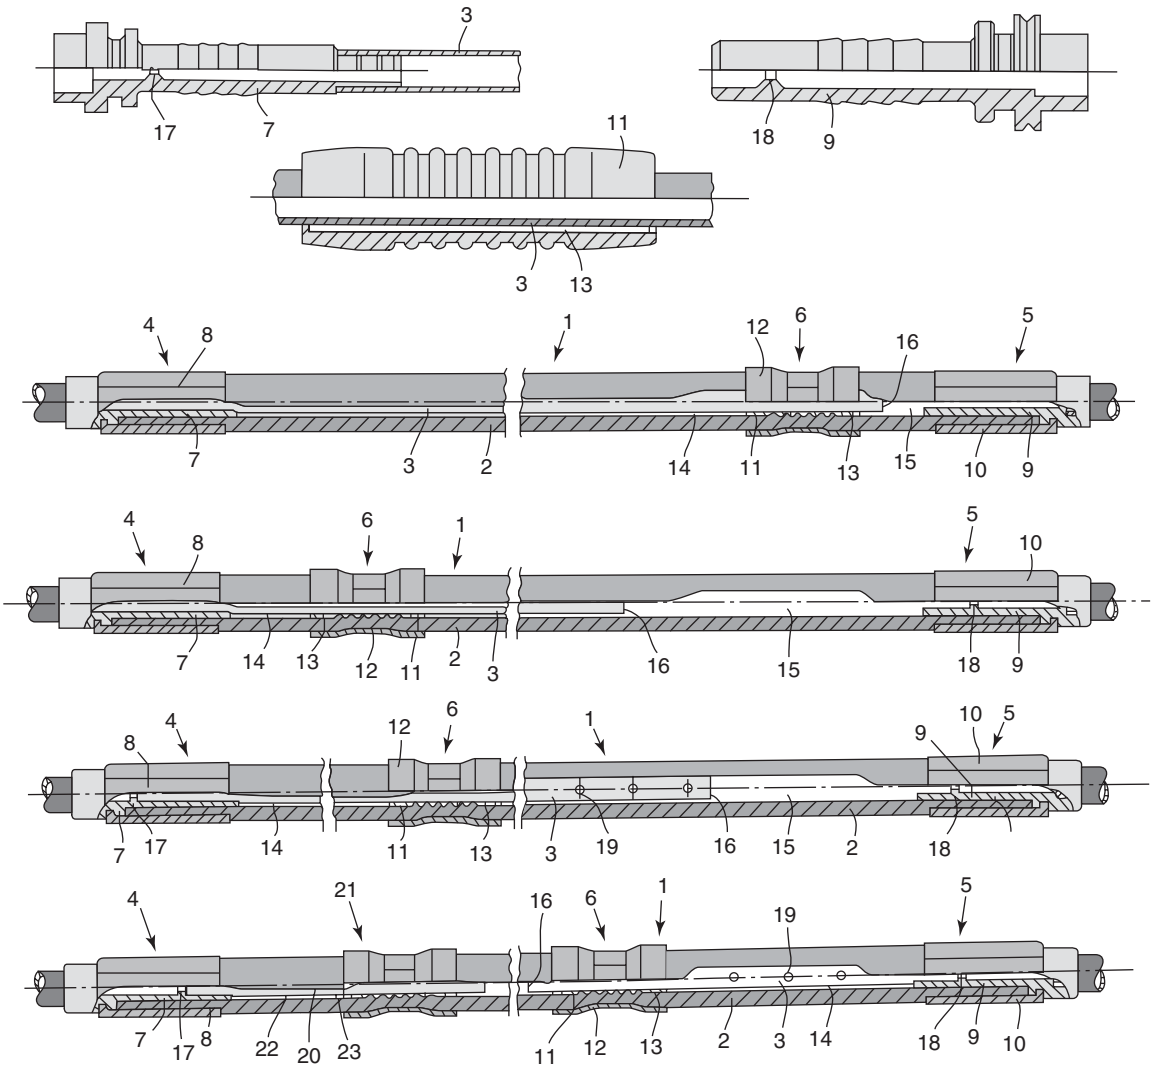

Figure 13. Examples for fittings and flexible hose elements. (Eaton, 1992. Reproduced by permission of Eaton Aeroquip GmbH.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

simulation. To correctly parameterize connections in the simulation, their dynamic properties are required. A well-established approach to determine the dynamic properties from experimental data is the quadrupole analysis, which allows the determination of the wave propagation in tubes and hoses in a wide frequency spectrum. On the basis of the measured data, the transmission behavior of the connection can reliably be reproduced in the simulation tool.

The quadrupole analysis is based on a process, originated in the field of electrical engineering, and is used to characterize an electrical network with two pairs of terminals connected together internally by the electrical network, which is to be investigated. This allows the mathematical description of any linear circuit detached from the physical buildup, provided that the circuit does not contain an independent source and satisfies the port condition. The port condition requires that the same current must leave and enter each pair of the terminals.

By the transferability of electrical effects to fluid power effects, the current corresponds to the volume flow and the potential corresponds to the pressure.

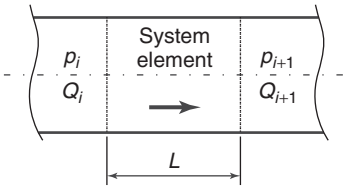

Figure 14. Line segment.

Therefore, a linear fluid technical system element can be described similarly to an electrical system element by four parameters. The transfer matrix consists of the elements T_{ij}, which correlate the pressure p_i and volume flow Q_i of the input side with the pressure p_{i+1} and volume flow Q_{i+1} of the output side of a line segment (Figure 14).

$$\begin{pmatrix} p_i \\ Q_i \end{pmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{pmatrix} p_{i+1} \\ Q_{i+1} \end{pmatrix} \tag{12}$$

The vector of state variables in the frequency domain of $\hat{p}_1$ and $\hat{Q}_1$ on the input side results from the multiplication

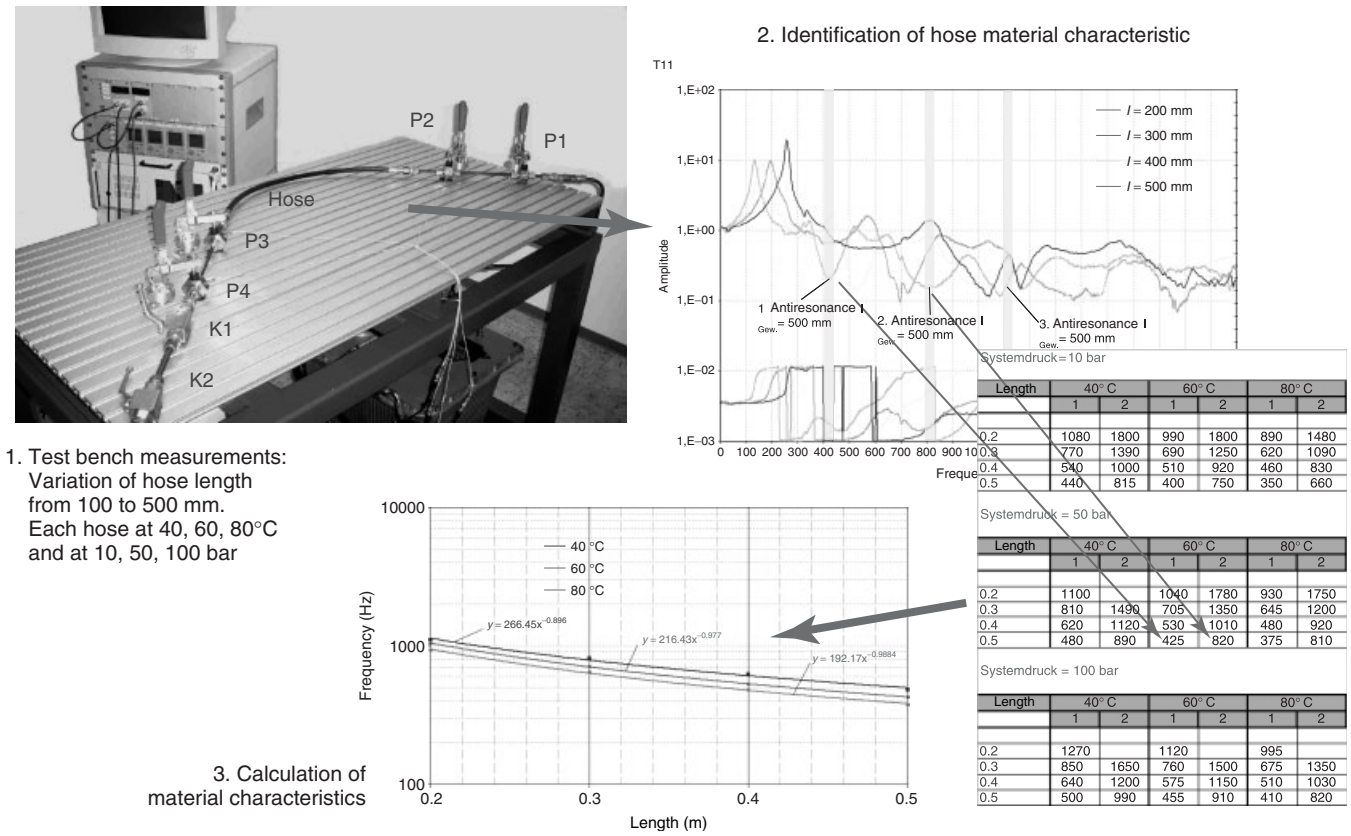

Figure 15. Test bench for identification of hose material characteristics (Baum and Johanning, 2009). (Reproduced by permission of Heiko Baum.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the transfer matrix T and the state variables $\hat{p}_2$ and $\hat{Q}_2$ on the output side.

To determine the transfer matrix T, the pressure pulsations can be measured directly with high resolution using pressure sensors. An indirect measurement method is necessary to determine the volume flow because volume flow rate sensors either have an influence on the pressure propagation or lack the required dynamic properties. Therefore, the volume flow rate is usually determined in a reference tube, whose characteristics are well known, so that the flow rate can be determined indirectly from the measured pressure signal.

3.2.2 Test bench

The transfer matrix can be determined from the Fourier transformation of the measured pressure signals of any given tube or hose. Figure 15 shows the test bench with a mounted hose segment.

The measured tube characteristics allow the system simulation to consider the connection properties. Hence, any combination of these elements can be simulated. The model validation of a line assembly is conducted on the real test bench, which is also available as fully parameterized component in DSH*plus*, depicted in Figure 16. Therefore, the validation process of newly implemented components is narrowed down to comparing the simulated line characteristics to the measured line characteristics.

The following example shows the optimization process of pulsation propagation in DSH*plus*.

At the beginning of every development, process stands the customer specifications regarding the dynamic system behavior of the assembly of expandable hoses and tubes. The goal of the simulation process is to find an adequate assembly of hoses and tubes, which fulfill the targeted pressure losses, frequency response, or amplitude damping.

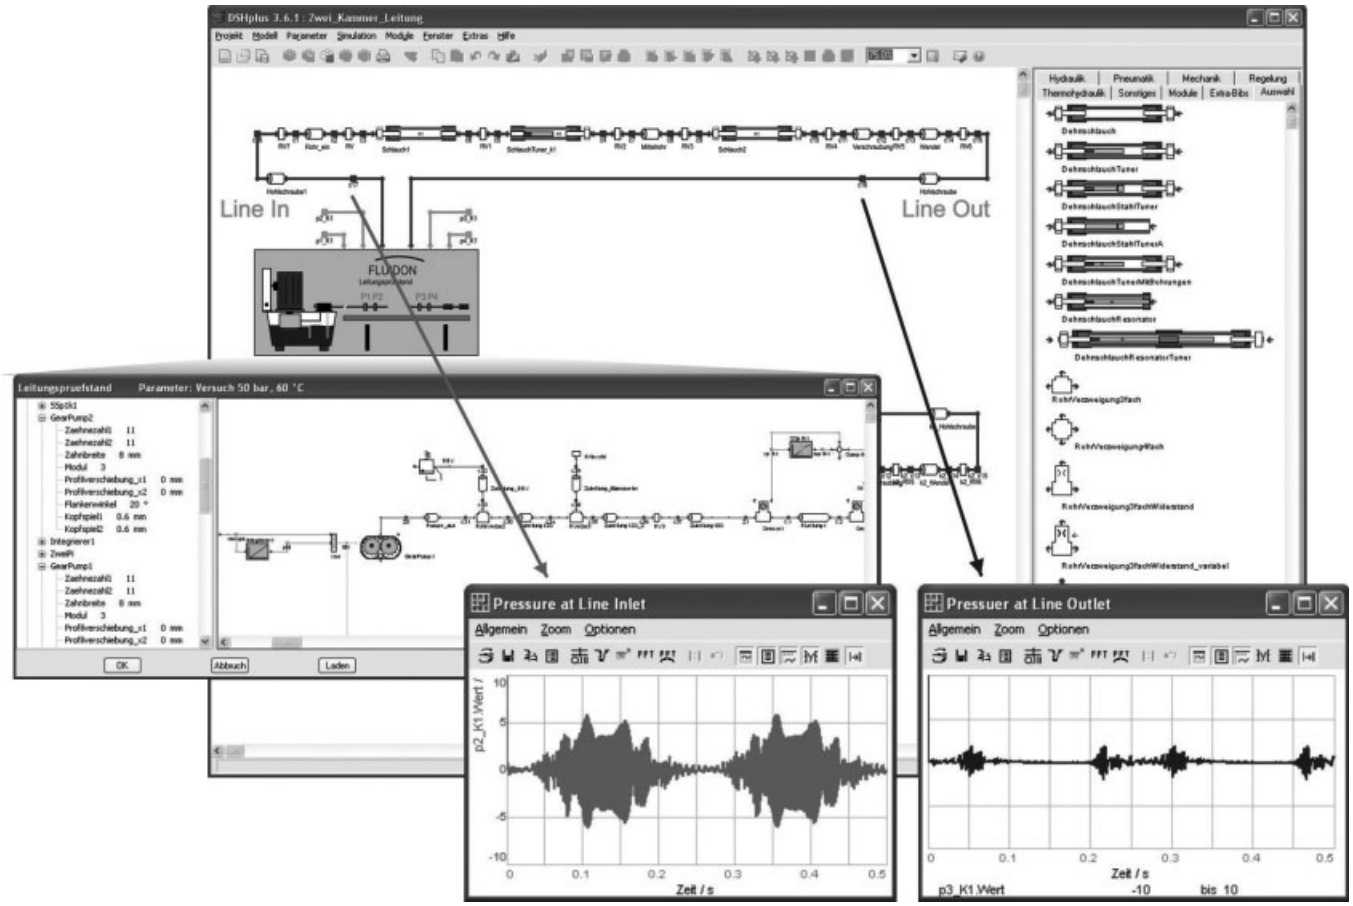

Figure 16. Flexible hose element library and simulation model of test bench with installed line (Baum and Johanning, 2009). (Reproduced by permission of Heiko Baum.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

For the final design, only little tuning on the test bench or the vehicle is required. This allows a significant time saving compared to a typical trial and error procedure.

Figure 17 depicts the procedure of the optimization process. Beginning with the CAD data of the packaging space and connection alignment, a first connection design is created, outgoing from developments in former projects.

On the basis of the geometrical data of the CAD model, the assembly is recreated in DSH*plus* from the component library and parameterized by the geometric dimensions of the design. Only the expandable hose sections are parameterized by a data set that describes the elastic properties of the hose material. If the data set of the specific material is not available in the material database, the material properties must be measured once before the design process and are then available for future projects from the material database.

Integrating the design into the virtual hose test bench, which is equilibrated with the real test bench, offers a simple way to validate the simulation model.

Furthermore, the flow conditions of the desired application on the ends of the hose assembly must be set.

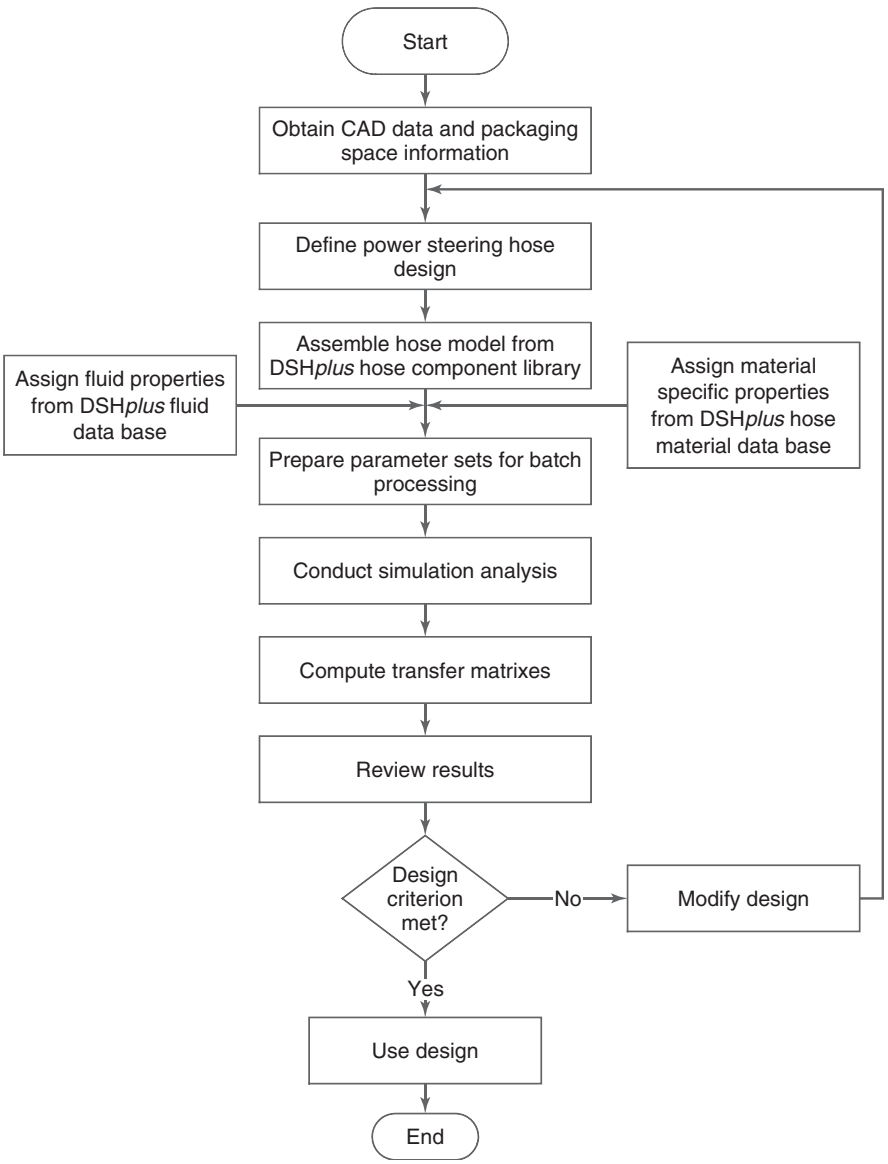

Figure 17. Development methodology to optimize automotive hose assemblies (Baum and Johanning, 2009). (Reproduced by permission of Heiko Baum.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

This can be achieved either by modeling the necessary system components such as valves or pumps or by a characteristics diagram of the connected components. If the parameterization of the hose assembly is finalized, an automated design variation under consideration of the prescribed packaging space and design requirements can be initiated. The quadrupole analysis of DSH*plus* allows the graphical representation of the findings.

Furthermore, DSH*plus* allows a parameter-driven design optimization. The user specifies quality criteria over a certain frequency spectrum, which is then used to drive the parameter variation. Furthermore, the influence of different geometric design parameters can be investigated by a design of experiment (DOE) analysis.

If the developed geometry satisfies the design requirements, a prototype can be build up; otherwise, the user should return to the beginning of the design process and start again with a new starting design.

3.2.3 Application of the tube and hose model

Using the example of a two-chamber automotive line with PTFE tuner and a single-chamber automotive line with steel-flex-tuner, the suitability of DSH*plus* as simulation tool is presented. The two connections are existing stock parts and have been modeled in DSH*plus* to use in a design parameter study. The design parameter study allows the automated variation of geometric lengths and diameters of the tuners, hoses, and tube segments as well as the position of the tuner elements.

To validate the simulation results, the flow characteristics of the connections have been measured on the test bench.

Figure 18 shows the transmission behavior of the two-chamber automotive line. The transmission behavior of the initial configuration A shows a distinct rise in the amplitude ratio in the frequency range 500–700 Hz. The optimization process of configuration B results in an improved damping

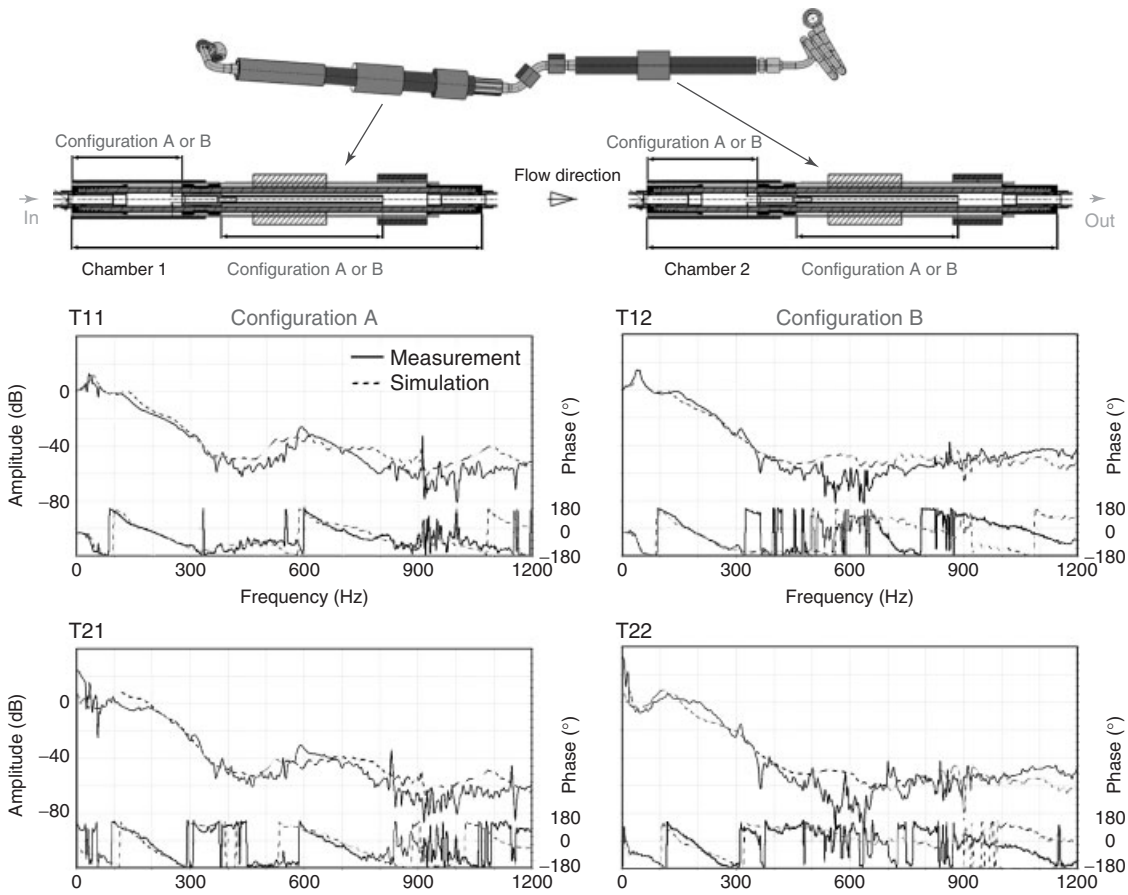

Figure 18. Measuring and simulation of two-chamber automotive line (Baum and Johanning, 2009). (Reproduced by permission of Heiko Baum.)

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

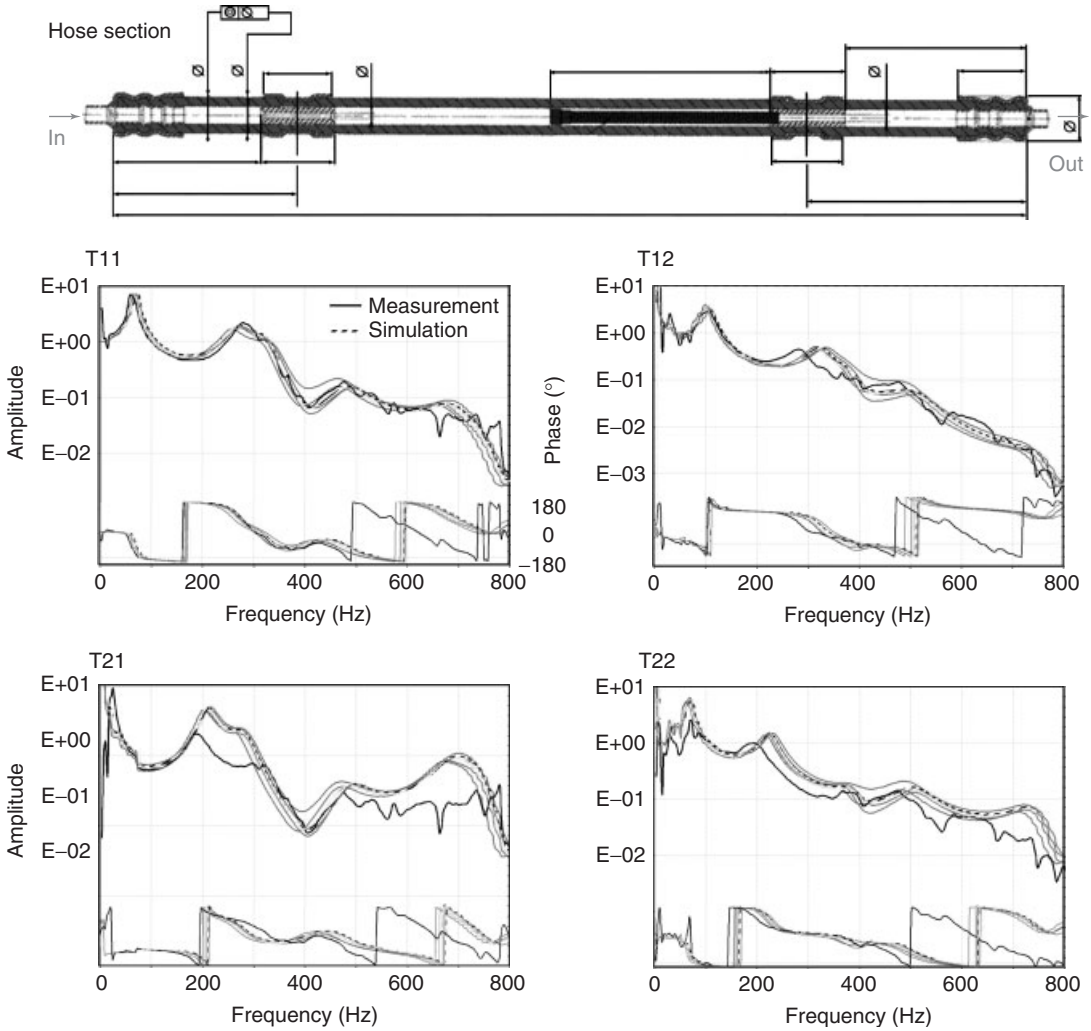

Figure 19. Robustness analysis of a one-chamber line with steel tuner (Baum and Johanning, 2009).

in the frequency range, owing to a variation of the throttle position and length of the tuner cable.

Figure 19 depicts the measurement and simulation of a flexible one-chamber-line with steel tuner.

In the first simulation of the one-chamber line, the exact geometric dimension of the existing line was modeled. On the basis of the performed simulation, a parameter variation of the relevant geometric dimensions, as depicted in Figure 19, is conducted. The limits for the parameter variation of the geometric dimensions were deduced from the tolerance specification of the line. This analysis shows the variation in the dynamic properties of the line within the accepted tolerance span of manufacturing. The simulated variations envelope the curve of the simulation using the exact geometric dimensions. The parameter variation enables the identification of sensitive geometric dimensions. On the basis of the simulation results in an early development stage, appropriate countermeasurements can be considered.

3.2.4 Summary of example 2

The use of system simulation tools accompanying the development process of expandable automotive lines in the early stages allows a significant cost and time saving because protracted trial-and-error studies can be circumvented.

DSH*plus*, among others, has all necessary software modules to aid the designer during the whole design process. The component library for automotive lines allows the user to start with a virtual prototype for a variety of different application fields not only limited to the automotive sector. On the basis of the virtual prototype, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto034
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

design and optimization process regarding the specified design requirements can be performed. In order to do this, DSH*plus* offers a comfortable way to perform optimization and robustness – as well as sensitivity studies for the line design. Furthermore, DSH*plus* allows the evaluation of different parameters utilizing methods of DOE. This accelerates the overall design process and significantly reduces the number of time-consuming field tests.

4 SUMMARY

Modern system simulation tools are an indispensible utility in the modern design process, applicable to a wide variety of fields in engineering. System simulation tools such as DSH*plus* provide the user with a certain level of planning security in an early design stage. Furthermore, modern simulation tools provide a possibility to test different design concepts with relatively little effort in time and money. Later in the design process, system simulation tools offer valuable optimization tools to optimize an initial design under consideration of the specified design requirements. The resulting design is optimally attuned to the specifications in a short time span compared to conventional methods of trial and error. In addition, the provided tools allow an elaborate comparison and assessment of different designs.

Furthermore, system simulation can be used to illustrate and evaluate the system behavior of interconnected components. Early system evaluation significantly reduces failure during first startup. Furthermore, the depiction of whole systems allows optimal choice of components before realization. Hence, a cost optimal solution can be found for the manufacturer and for the customer.

RWTH Aachen University, Aachen, Germany

1 INTRODUCTION

Progress in simulation technology leads to a wider application of simulation software for the reduction of testing costs in many engineering disciplines. This trend is also true for vehicle design at all development levels. The level of detail of the models is sufficient for simulation of entire vehicles as well as for detailed simulations of separate mechanical or electrical components. Each engineering discipline applies its own software tools, developed specifically for the purposes of application. An updated and complete overview of single programs is thus not easy to provide and lies beyond the scope of this chapter.

In order to meet the increasing requirements to safety and comfort in a vehicle, pure mechanical systems are complemented or replaced by mechatronic systems. This tendency can be also observed in chassis systems. Typical examples of such systems are antilock braking system (ABS) and electronic stability control (ESC), which are currently part of a standard equipment of each modern vehicle. Moreover, there is an increase in the development and marketing of comfort features, such as adaptive damping or electric power steering. Such systems can be strongly connected with safety critical systems, such as ESC. To exemplify this statement, electric power steering can be named, which receives steering directions from the ESC and thus also implements a safety critical task.

In addition to the pure mechanical construction of the chassis components, the development of mechatronic systems receives a steadily growing attention of the automobile manufacturers, as mechatronic systems can help to meet both safety and comfort requirements. However, interconnection of mechanical and electrical components and integration of the control software make the development even more complex. In this area too, there are a number of modeling technologies for simulating a vehicle. Modern functional developments are based on the methods of Rapid Control Prototyping (RCP). With these methods, it is possible to test the developed control functions during early stages of the development cycle. In addition to established signal-oriented modeling methods, new physically based, object-oriented modeling languages, such as Modelica, are applied.

The purpose of this chapter is to provide an overview of various modeling approaches in the area of vehicle simulation for the application in the functional design and to show how these models can be used in the development

ISBN: 978-0-470-97402-5

process of RCP. In addition to the explanation of the different modeling approaches, two different ways to model these differential equations on a digital computer will be introduced: (1) the established signal-oriented methods, as they are implemented in Simulink and (2) an object-oriented method using the modeling language Modelica.

The chapter is organized as follows: in Section 2, the principles of RCP as a method of modern functional development are elucidated, and the resulting necessity of having various model types is demonstrated. Section 3 gives an overview of popular modeling approaches for the dynamical description of the longitudinal, lateral, and vertical dynamics of a vehicle. An attempt is made to provide the reader with the instructions on various applications to facilitate the choice of an appropriate model. This chapter provides only a general overview and description of the methods and refers the interested reader to the related literature for details. Section 4 presents a comparison between signal-oriented and object-oriented methods for differential equations. On the basis of these methods, the widely used software Simulink by the Mathworks and Dymola are described. This chapter concludes with a summary.

2 RAPID CONTROL PROTOTYPING

Examination of the developments in the automobile industry during the past decade shows that the number of mechatronic systems in a vehicle grows steadily and will continue to grow in the future. The same is also true for chassis control. This trend is particularly encouraged by the increase in safety and comfort that is possible with the use of mechatronic systems. ABS and ESC are the most typical examples of such systems. To a great extent, these functions are realized by software that is integrated as an embedded system into a vehicle. A further trend is a stronger interconnection of separate functions in the vehicle, which makes the functional development of new systems even more difficult and time-consuming.

To guarantee goal-oriented and efficient development of the control software in these complex systems, the concept of RCP has been established for controller development. It combines the advantages of the classic method of V-modeling with the possibility of early testing at separate development stages in a standardized development environment. This testing helps to eliminate the disadvantages of the classic modeling in which certain design errors are only detected rather late in the development cycle. The basic prerequisite here is the use of a continuous tool chain to allow the designer to concentrate on the core competencies. Figure 1 depicts the V-model of a controller design for the graphical visualization of the single steps and their succession in the development.

According to the V-model, the design comprises the following steps: requirement analysis, specification, rough and detailed design, simulation, component test, and system test. In the classic development cycle, these steps are performed one after another, and the tests are performed at the end. In the RCP concept, the tests can be performed much earlier in the development cycle using the corresponding software tools. The development steps need not occur in the above-mentioned succession and can be performed repeatedly, rather quickly, with the assistance

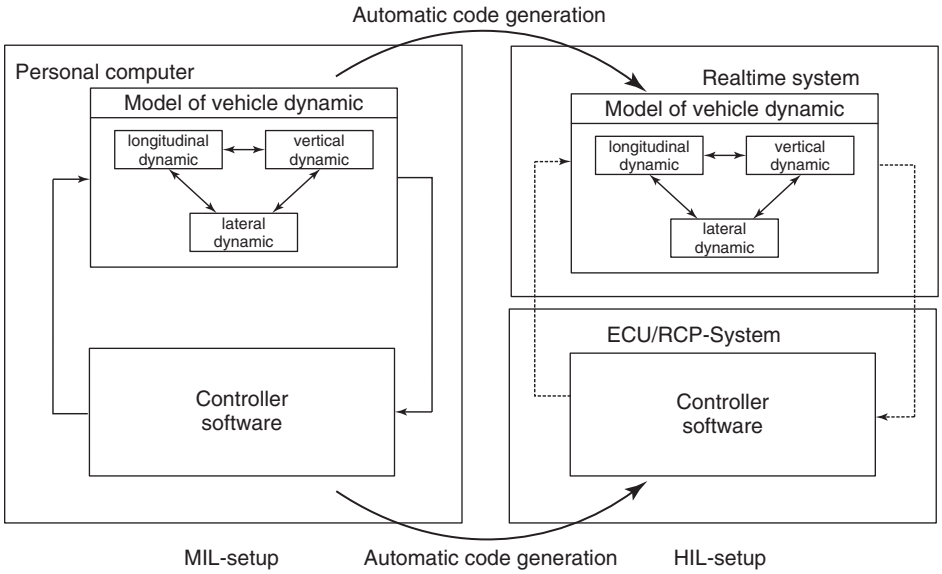

Figure 2. MIL-test.

of the software tools, in order to even more quickly detect and eliminate design and implementation errors.

Essential features of the methods of RCP development are Model-in-the-loop (MIL) and Hardware-in-the-loop (HIL) tests. They help perform tests during various stages of the development cycle, for example, for the purpose of also implementing horizontal iteration loops. Thus, it allows an early creation of controller software in the process of development by using automatic code generation, as well as testing with the available real components or with models of yet unavailable real components.

In Figure 2, two scenarios are compared: the MIL and the HIL tests. The MIL test can be performed during early stages of the development cycle, as the development environment can be, for example, Matlab/Simulink by The Mathworks, in which the controller development also often takes place. The primary goal of a MIL test is the development of the controller's concept and validation of control quality. Therefore, it is important that the MIL models describe the real vehicle behavior as good as possible.

In contrast, in a HIL test, both components (system model and controller model) must be executed in real time. Using automatic code generation, it is possible to transfer the models to a real-time simulation platform. This step is one of the central elements of RCP because the complex manual software design can be automated. It allows making quick changes and tests directly in a real-time system by the press of a button. The primary goal of HIL tests is performing system tests in which the designed controller structure runs on the target platform and is tested there in combination with all other components.

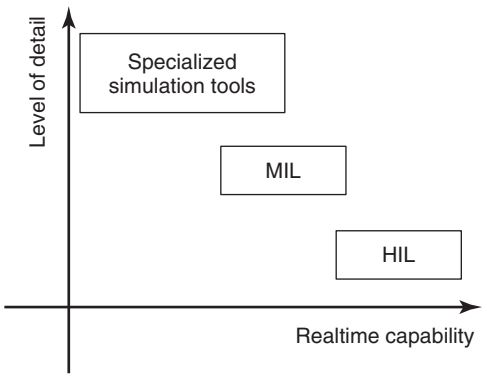

Figure 3. Comparison between different types of models.

Simulation models of the controlled system play a crucial role in all these testing strategies. On the basis of their application, the MIL and HIL models differ in their level of detail and in real-time capability.

Figure 3 shows the relation between real-time capability and level of detail for various model types. Special simulation tools such as ADAMS by MSC Software or Simpack by SIMPACK AG, that can be used to design the mechanical components of a chassis, possess the highest level of detail and also require the highest amount of computation time. Generally, these models are not suitable for simulation of an entire vehicle because of their computation time, and thus are seldom used for controller development.

Concerning MIL models, they can simulate an entire vehicle with all its essential components at a high level of detail. Examples of these models are CarMaker by IPG or CarSim by Mechanical Simulation Corporation. Depending

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on the selected level of detail, these models are capable of providing real-time performance on very powerful computers. Because the simulation of an entire vehicle they provide is of a high quality, these models are used for MIL tests, which are primarily intended for validation of the control functions. The MIL test need not be run in a real-time environment and can be performed directly on a personal computer. As the controller development is implemented mostly in Matlab/Simulink, the MIL test is also often performed as a co-simulation in Simulink. Most software producers offer corresponding interfaces for Simulink.

Another model type is a HIL model. The main function of the HIL models is real-time performance that, however, reduces the level of detail and thus the accuracy of the models. The model accuracy must be sufficient for the interaction of all designed features and the corresponding diagnosis functions. The control quality does not have the primary importance here, as it has already been tested during the MIL tests. The real benchmark is always to be found in a real vehicle where the quality of the target results of the described process can be judged on the basis of real tests.

Thus, both detailed and real-time capable system models are equally important for modern controller development. In addition to the application of the models for validation of the controller software, these models can also be used in the development of the control concept. A model-based controller design usually requires a linear control model that can be applied either for control design or even as a component of the control concept itself. Thus, the application of simulation models gains further importance, simultaneously making it more difficult to choose a suitable model for a certain purpose. Section 3 deals with various models with different levels of detail for a number of applications. Each model is illustrated with an example of its application to facilitate the reader's choice of a right model.

3 OVERVIEW OF MODELING TECHNIQUES FOR DIFFERENT CHASSIS APPLICATIONS

3.1 Aim of modeling

Developing a chassis application requires a mathematical model that describes the vehicle's dynamic behavior in an adequate manner with respect to the considered application. In particular, the relevant system inputs (e.g., the steering angle) and outputs (e.g., the yaw rate) have to be identified. Subsequently, the dynamic system behavior has to be described in terms of differential equations. The level of detail, that is, the number of differential equations and the number of employed inputs and outputs, inherently depends on the chassis application. From the perspective of control engineering, a process model is required for the purposes of *analysis*, *controller synthesis*, and *validation*, as subsequently explained. As far as process *analysis* is concerned, a plant model is used to analyze the open-loop, that is, the uncontrolled, process behavior. In the linear case, the process' eigenvalues are crucial for the plant's stability, its dynamic time constants, and the damping ratio. For the purpose of *controller synthesis*, a simplified plant model is commonly employed to design the controller in such a way that the closed-loop system fulfills the desired requirements such as stability, offset-free tracking of reference values, the ability to suppress external disturbances, or further performance requirements. Before the controller is applied to the real plant, it is *validated* in numerical simulations. Simplified (linear) plant models are used for controller synthesis, whereas plant models with much higher complexity are employed for validation purposes.

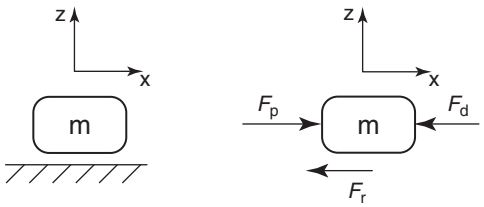

Figure 4. Free body diagram.

In order to illustrate the above-mentioned issues, the process of modeling is subsequently illustrated for several chassis applications having different requirements as far as model complexity is concerned. In this context, applications of longitudinal, lateral, and vertical vehicle dynamics are taken into account.

3.2 Longitudinal vehicle dynamics

In this section, model approximations for applications in which primarily the longitudinal dynamics are of interest will be presented. In particular, linear model approximations, that are often used for the application of adaptive cruise control (ACC), and nonlinear effects, that are needed, for example, to model problems addressed by ABS, will be discussed. In the following sections, the chassis will be modeled as point mass that is subject to the forces applied from the surrounding environment. A free body diagram is given in Figure 4.

F_p, F_d, and F_r represent the propulsion force, the drag force, and the rolling resistance. According to (Mitschke and Wallentowitz, 2004), the main influencing forces and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

consequently the longitudinal vehicle dynamics on flat terrain can be described by:

$$m\dot{v}_x = \underbrace{\frac{T_e\left(n_e, \alpha_{th}\right) \bullet \eta \bullet i_g}{R}}_{F_p} - \underbrace{c_w A \frac{\rho}{2} v_x^2}_{F_d} - F_r \qquad (1)$$

Thereby T_e, n_e, and α_{th} denote the engine torque, the engine rotational speed, and the throttle input, respectively. The gear ratio, efficiency, and static tire radius are given by i_g, η, and R while the drag coefficient, the reference area, and the air density are given by c_d, A, and ρ. The above equation holds for engine operation; for brake operation, the term F_p changes sign and has to be replaced by an actuator dynamics that is controlled by a brake pedal position α_{br}.

3.2.1 Linear approximations

To differentiate between absolute values and differences with respect to the operating point, we introduce the perturbation $\tilde{v}_x = (v_x - v_{x,0})$, and $\tilde{\alpha}_{th} = (\alpha_{th} - \alpha_{th,0})$. If we neglect the velocity dependence of the rolling resistance and assume that the engine rotational speed can be related to the velocity as $n_e = v_x \bullet i_g/(2\pi r)$ with an effective tire radius r, the Taylor-series expansion of Equation 1 results in the following approximation of the velocity dynamics:

$$m\dot{\tilde{v}}_x + \left(c_d A \rho \bullet v_{x,0} - \frac{\eta \bullet i_g^2}{R \bullet 2\pi r} \bullet \left.\frac{\partial T_e}{\partial n_e}\right|_0\right)\tilde{v}_x = \frac{\eta i_g}{R} \bullet \left.\frac{\partial T_e}{\partial \alpha_{th}}\right|_0 \tilde{\alpha}_{th} \qquad (2)$$

Equation 2 exhibits a first-order lag behavior that can be summarized by

$$\tau \bullet \dot{\tilde{v}}_x + \tilde{v}_x = K_v \bullet \tilde{\alpha}_{th} \qquad (3)$$

where the time constant τ and the static gain K_v depend on the above-mentioned vehicle parameters and the operating point. Likewise, the dynamics during braking can be approximated by a linear model. Therefore, the partial derivative of the braking force with respect to the brake pedal position α_{br} has to be included instead of the derivatives of the engine torque.

The above model assumes that the engine torque or a braking pressure (or force) are used as system input that can directly be controlled. However, this is often not the case, and further dynamics have to be included. As a result, another model that is frequently used in literature describes the longitudinal acceleration denoted by a_x. Very often, lower level controls are applied to linearize the resulting dynamics such that this can be approximated again by a first-order lag element as

$$\tau \bullet \dot{a}_x + a_x = a_{x,ref} \qquad (4)$$

where τ denotes the resulting time constant. Concerning the approximation of drivetrain dynamics and underlying linearizing controls further reference is given to (Lu and Hedrick, 2004; Rajamani, 2006) and (Ha, Tugcu, and Boustany, 1989) respectively.

3.2.2 Nonlinear effects

The linear models introduced by Equations 2 and 4 stem from a Taylor-series expansion that is only valid for small deviations from the operating point. Typical driving conditions do normally involve a wide interval of operating points (e.g., different throttle or braking commands at different velocities) and hence cannot be expressed by only one of the models mentioned above. Often, this problem can be dealt with by switching between several different linear models that best describe the current operating point. It should be noted that this is only possible as long as operating conditions change slowly; otherwise, it might be better to use true nonlinear models to describe the drivetrain dynamics.

Besides different operating conditions, another source of nonlinearity arises from the force transmitted between tire and road. For the above-mentioned models, we were basically assuming that any torque applied to the wheels (through engine or brake commands) is transmitted to the road and results in a net force accelerating the mass m. But, the angular speed of the wheels ω and the longitudinal vehicle speed v_x are coupled by a nonlinear friction-slip characteristic that limits the transmittable force between tire and road. If the rolling resistance is neglected, the transmittable force can be expressed by

$$F_x = \mu \bullet F_z \qquad (5)$$

where μ and the tire slip λ are related by a (generally) nonlinear static mapping (friction-slip characteristic). The longitudinal tire slip is defined by

$$\lambda = \frac{\omega \bullet r - v_x}{v_x} \text{ (braking)}, \quad \lambda = \frac{\omega \bullet r - v_x}{\omega \bullet r} \text{ (acceleration)} \qquad (6)$$

For low slip values, a (quasi-linear) ascent of friction (or force) goes along with an increasing tire slip. If the slip exceeds a critical value, friction and hence the transmittable force do not further increase but decrease. Effective force-slip characteristics of a Pacejka tire model are shown in Figure 6a for the longitudinal direction discussed here and in Figure 6b for the lateral direction. A more detailed view of (nonlinear) tire models is given in Section 3.3.2 focusing on the lateral direction. Owing to the decreasing force (beyond the critical slip value), the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

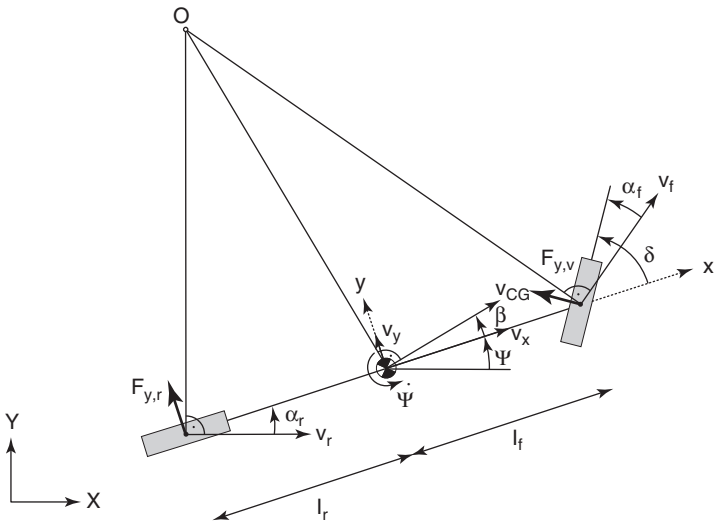

Figure 5. Free body diagram of single track vehicle model.

slip further increases until the wheel spins (during acceleration) or skids (during braking). Using ABS, this problem can be reduced and the maximum force can be achieved during the braking maneuver. As a result, the transmittable force and hence the longitudinal acceleration are limited by a maximum value. For critical maneuvers with high acceleration values, this effect has to be taken into account. As an example, a simplified extension of the linear model in Equation 4 would be an additional saturation of the effective acceleration to account for the related effects.

3.3 Lateral vehicle dynamics

3.3.1 Single-track model

Applications that aim at guiding the vehicle in the lateral direction require a plant model that is basically different from those that have been illustrated in the previous section. When considering advanced driver assistance systems (ADAS) such as lane keeping systems or even autonomous driving systems that are only capable of changing the vehicle's steering angle, a single-track model (see Figure 5) according to (Mitschke and Wallentowitz, 2004) is commonly employed to describe horizontal vehicle dynamics.

The single-track model combines the two wheels of an axle to a single one, while the center of gravity (CG) is placed on the road surface, that is, $h_{\mathrm{CG}} = 0\mathrm{m}$. In Equations 7–9 all rolling resistances as well as aerodynamic drag are neglected. Furthermore, it is assumed that no longitudinal forces are applied at the wheel. In particular, Equations 7 and 8 describe the translational degrees of freedom in the longitudinal and lateral directions with respect to the vehicle reference frame. Furthermore, yaw dynamics are modeled by Equation 9.

$$m\dot{v}_{\mathrm{x}} = m\dot{\psi}v_{\mathrm{y}} - F_{\mathrm{y,f}}\sin(\delta) \tag{7}$$

$$m\dot{v}_{\mathrm{y}} = -m\dot{\psi}v_{\mathrm{x}} + F_{\mathrm{y,f}}\cos(\delta) + F_{\mathrm{y,r}} \tag{8}$$

$$J_{\mathrm{z}}\ddot{\psi} = F_{\mathrm{y,f}}\cos(\delta)l_{\mathrm{f}} - F_{\mathrm{y,r}}l_{\mathrm{r}} \tag{9}$$

In this context, v_{x} and v_{y} denote the longitudinal and lateral velocities at CG with respect to the vehicle reference frame, $\dot{\psi}$ the yaw rate, δ the wheel steering angle at the front axle, m the vehicle mass, J_{z} the mass moment of inertia with respect to the vertical axis, and l_{f} and l_{r} the front and the rear wheel bases. When considering a lane keeping or path following system, additional differential equations are required to model the relative motion between the vehicle and the desired path, see (Keßler et al., 2007). As this section primarily focuses on the issue of modeling lateral vehicle dynamics, these equations are omitted for reasons of clarity. In order to determine the tire force $F_{\mathrm{y,f}}$ at the front and $F_{\mathrm{y,r}}$ at the rear axle, a tire model is required. In the following section, a modeling approach for these tire forces is discussed depending on the magnitude of the considered lateral accelerations.

3.3.2 Tire models

If small lateral accelerations are considered, that is, $|a_{\mathrm{y}}| \leq 0.4g$ on a dry surface, a linear tire model is sufficient to model the resulting tire forces, see (Mitschke and Wallentowitz, 2004). In detail, the side force $F_{y,i}$ at each wheel

$$F_{\mathrm{y},i} = c_{\alpha,i} \bullet \alpha_{\mathrm{i}}, i \in \{f, r\} \tag{10}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is assumed to depend linearly on the tire sideslip angles α_i where $c_{\alpha,i}$ describes the nominal tire cornering stiffness for pure cornering. In this context, the vertical tire load is assumed to be constant. The tire sideslip angles define the difference angle between the velocity vector at the wheel and the longitudinal wheel axis, that is,

$$\alpha_\mathrm{f} = \delta - \arctan\left(\frac{v_\mathrm{y} + l_\mathrm{f}\dot{\psi}}{v_\mathrm{x}}\right) \tag{11}$$

$$\alpha_r = -\arctan\left(\frac{v_\mathrm{y} - l_r\dot{\psi}}{v_\mathrm{x}}\right) \tag{12}$$

When considering larger lateral accelerations, nonlinear tire behavior has to be taken into account, see (Katriniok and Abel, 2011). In literature, the Pacejka Magic Formula tire model (Pacejka and Bakker, 1992) is frequently employed to model the steady-state lateral tire force at pure cornering, i.e. only lateral forces are transmitted at the wheel, as a nonlinear function of the tire sideslip angle

$$F_{\mathrm{y},i} = D_\mathrm{i}\sin\left[C_\mathrm{i}\arctan\left\{B_\mathrm{i}\alpha_\mathrm{i} - E_\mathrm{i}\left(B_\mathrm{i}\alpha_\mathrm{i} - \arctan\left(B_\mathrm{i}\alpha_\mathrm{i}\right)\right)\right\}\right], \quad i \in \{f, r\} \tag{13}$$

In general, this model can also be used to determine the longitudinal tire force as well as the aligning torque. An example of the Pacejka tire model for modeling the side force is shown in Figure 6b.

It can be seen that there are basically three regions in the tire model: one "stable" region of static friction (i.e., region II) and two "unstable" regions of sliding friction (i.e., regions I and III). In particular, the maximum absolute tire force that is physically feasible is limited to $F_{\mathrm{y,i,PMF,max}}$ for a tire sideslip angle of $\alpha_{\mathrm{i,PMF,max}}$ respectively $\alpha_{i,PMF,\mathrm{min}}$. If the absolute sideslip angle increases even more, the tire begins to slide over the road surface such that the resulting absolute tire force is decreased. When comparing both tire models, it can be noticed that the cornering stiffness

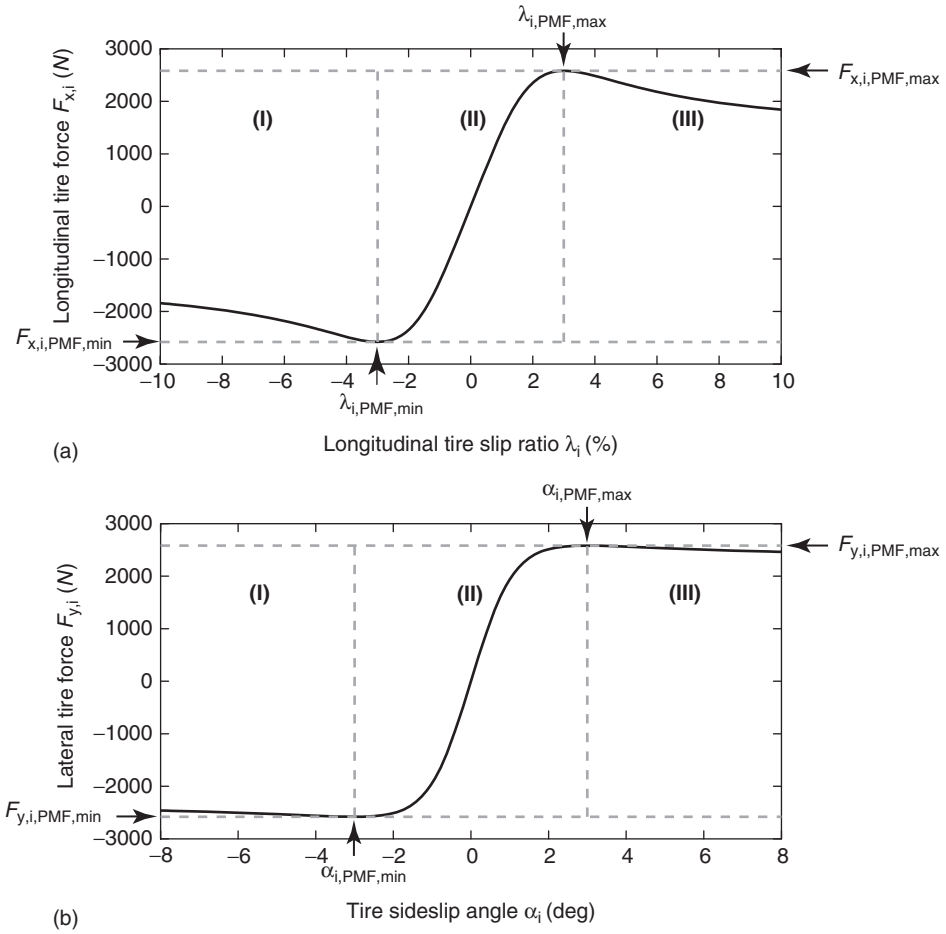

Figure 6. Pacejka Magic Formula tire model.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

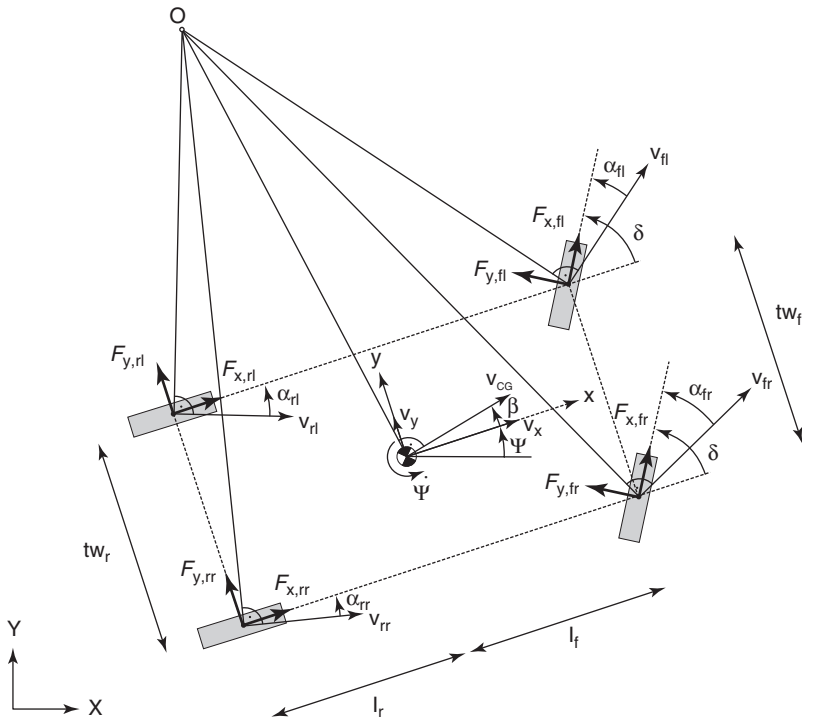

Figure 7. Free body diagram of the two-track vehicle model.

$c_{\alpha,i}$ of the linear tire model corresponds to $dF_{y,i}/d\alpha_i$ for $\alpha_i = 0rad$ with respect to the Pacejka Magic Formula tire model. The same principle, which is illustrated in Figure 6a, holds for the transmission of longitudinal tire forces that basically depend on the longitudinal tire slip λ_i. If the considered application requires that combined slip, that is, transmission of longitudinal and lateral forces at the same time has to be taken into account, there are several approaches to include this issue into the Pacejka tire model, see (Johansson and Gäfvert, 2004). Furthermore, load transfer can also be incorporated into the tire model. Especially, if the chassis application operates at the vehicle handling limits, the application has to be aware of the maximum feasible tire forces that inherently change with the vertical tire load.

3.3.3 *Two-track model*

So far, this section has mainly focused on chassis applications that are only able to change the vehicle's steering angle. If the simultaneous transmission of longitudinal and lateral tire forces at each wheel has to be considered, for example, for an ESC or torque vectoring, the single-track model is not sufficient to describe horizontal vehicle dynamics in the required level of detail. Therefore, the two-track model that is illustrated in Figure 7 is commonly employed.

In contrast to the single-track model, all the four wheels are considered such that Equations 14–16 contain the forces $F_{x,i}$ (longitudinal) and $F_{y,i}$ (lateral) at each wheel $i \in \{fl, fr, rl, rr\}$. These forces can again be determined by employing one of the tire models described in the previous section. Furthermore, tw_f and tw_r denote, respectively, the front and the rear track widths.

$$m(\dot{v}_x - v_y\dot{\psi}) = \left(F_{x,fl} + F_{x,fr}\right)\cos(\delta) - \left(F_{y,fl} + F_{y,fr}\right)\sin(\delta) + F_{x,fl} + F_{x,rr} \tag{14}$$

$$m(\dot{v}_y + v_x\dot{\psi}) = (F_{y,fl} + F_{y,fr})\cos(\delta) + (F_{x,rl} + F_{x,fr})\sin(\delta) + F_{y,fl} + F_{y,rr} \tag{15}$$

$$J_z\ddot{\psi} = l_f[(F_{y,fl} + F_{y,fr})\cos(\delta) + (F_{x,fl} + F_{x,fr})\sin(\delta)] - l_r(F_{y,rl} + F_{y,rr}) + \frac{tw_f}{2}[(F_{x,fr} - F_{x,fl})\cos(\delta) + (F_{y,fl} - F_{y,fr})\sin(\delta)] + \frac{tw_r}{2}\left(F_{x,rr} - F_{x,rl}\right) \tag{16}$$

3.4 Vertical vehicle dynamics

Finally, this section illustrates the issue of determining a sufficient dynamic plant model considering vertical vehicle

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

dynamics. In particular, this section focuses on the application of an active suspension, that is, the vertical movement of the vehicle body (the sprung mass) that results from an uneven pavement should be suppressed. For this purpose, the vehicle and its suspension can be reduced to a quarter car that consists of an unsprung mass m_u—the tire—connected to the road through a spring (i.e., the stiffness of the tire) and a sprung mass m_s—the vehicle body—connected to the unsprung mass through a spring c_s and a damper d_s (i.e., the suspension), see Figure 8. In order to model an active suspension, a force actuator is added between the sprung and the unsprung mass that is able to apply a force F_a to suppress external disturbances of the road.

In this context, z_s denotes the vertical position of the sprung mass, z_u the position of the unsprung mass and z_r the road elevation. According to (Mitschke and Wallentowitz, 2004), the dynamic behavior of the plant can be described with respect to the equilibrium point by the following differential equations

$$m_s\ddot{z}_s = c_s \bullet \left(z_u - z_s\right) + d_s \bullet \left(\dot{z}_u - \dot{z}_s\right) + F_a \qquad (17)$$

$$m_u\ddot{z}_u = c_s \bullet \left(z_s - z_u\right) + d_s \bullet \left(\dot{z}_s - \dot{z}_u\right) - F_a + c_u \bullet \left(z_r - z_u\right) \qquad (18)$$

In Equations 17 and 18, the springs and dampers are modeled as linear elements. If nonlinear effects have to be taken into account, the spring stiffnesses c_u and c_s and the damping ratio d_s have to be modeled as nonlinear functions of the vertical deflection and the vertical velocity. If the consideration of linear elements is sufficient, it inherently depends on the considered chassis application and has to be determined during the development process. If, for example, a controller for suppressing external disturbances of the road by applying the force F_a has been developed using a linear model and tested with satisfying performance on the real plant, nonlinear effects need not be taken into account for controller synthesis. Nevertheless, it might be useful to consider nonlinear effects in the validation model that is used to validate the controller. Finally, it has to be stated that the presented suspension model is well suited for a general analysis of its dynamic behavior, that is, its damping or eigenfrequency. Furthermore, vertical vehicle dynamics can be combined with longitudinal and lateral vehicle dynamics when the presented plant model is combined with single- and two-track models, see (Mitschke and Wallentowitz, 2004).

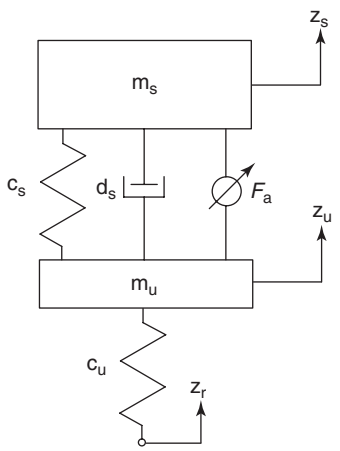

Figure 8. Free body diagram of a quarter car model.

4 USAGE OF DIFFERENT MODELING TECHNIQUES IN COMMON SOFTWARE TOOLS

4.1 Signal-oriented versus object-oriented modeling

Two main modeling concepts are common in many modern simulation tools for simulating dynamic systems: block-oriented (or signal-oriented) and object-oriented modeling. The main differences are found in the way the equations governing the behavior of the system are described and implemented.

A very easy-to-understand method is the block- or signal-oriented approach. For signal-oriented models, cause–effect relationships are modeled directly. A signal-oriented model consists of blocks that are interconnected by signals. The direction of the signals defines causality. Blocks have fixed inputs and outputs, signals only "flow" from block outputs to block inputs; therefore, there will be no feedback from a downstream block to an upstream block if no explicit feedback path is established. In order to be able to create a signal-oriented model, knowledge of the basic governing equations is needed. If an equation contains derivatives, it should be solved for the highest derivative before implemented in order to generate a well-defined block-oriented model. Thus, the lower derivatives can be established by integration of the higher derivatives, preserving causality. For example, if a moving mass is to be considered, its equations of motion should be solved for the acceleration. The velocity is then calculated by integration of the acceleration and the position is calculated by the integration of the velocity.

In Figure 9, an oscillator consisting of two point-shaped masses interconnected by a spring shall serve as an example.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto035
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

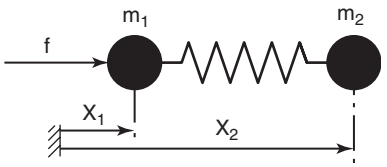

Figure 9. Example: Simple two-mass oscillator.

In order to generate a block model, first the equations of motion of the individual masses are derived:

$$m_1 \bullet \ddot{x}_1 = f_{\text{Spring}} + f$$
$$m_2 \bullet \ddot{x}_2 = -f_{\text{Spring}} \tag{19}$$

Using the equation for the force created by the spring $f = C \bullet (x_2 - x_1)$ and solving for the highest derivates of each state, two differential equations are found:

$$\ddot{x}_1 = \frac{1}{m_1} \bullet \left[f + C \bullet \left(x_2 - x_1 \right) \right]$$
$$\ddot{x}_2 = \frac{1}{m_2} \bullet \left[-C \bullet \left(x_2 - x_1 \right) \right] \tag{20}$$

On this basis, the equations can be implemented using standard blocks, for example, using Simulink. The resulting block diagram can be seen in Figure 10.

As one can see, the structure of block models does not necessarily correspond to the equivalent physical system (Fritzson, 2003); therefore, modeling of complex physical systems can become quite difficult. One main reason for this is the above-mentioned absence of implicit feedback due to the use of unidirectional signals. As of Newton's third law, according to which every action is accompanied by an equal and opposite reaction, almost all real physical systems incorporate a feedback loop that has to be accounted for, which in block-oriented modeling language leads to additional signal paths. Hence, although there is only one physical connection between the two bodies, there are two signal paths - one into and one out of the blocks representing the body. Still, a signal-oriented approach can be a good choice for a physical model. Especially for relatively simple systems, signal-oriented models are easy to understand. Most importantly, however, solving the underlying equations is very straightforward and can be done using a relatively simple ordinary differential equation (ODE) solver. This can especially be useful if a real-time capable model is needed, that is, if the computational effort for simulation needs to be predictable. This is the case here because ODE solvers do not necessarily need to use iterations. Apart from the use as a modeling formulation for physical systems, block models are widely used in control engineering. They are very useful for the description of digital control algorithms, which essentially are calculation instructions and therefore have built-in causality. Especially, as solving the equations is straightforward and well defined, it is possible—under certain restrictions—to automatically generate code from a block diagram that can be implemented on a microcontroller. Therefore, the block-oriented description approach can also be seen as an intermediate step between control engineering theory and controller programming.

Another modeling approach is object-oriented modeling. Here, the very universal object-oriented modeling language "Modelica" shall serve for illustration. A thorough introduction to object-oriented modeling with Modelica can be found in (Tummescheit, 2002). In Modelica,

Figure 11. Implementation of two-mass oscillator in Dymola.

physical systems are described using so-called objects that can be interconnected. For example, the two-mass oscillator mentioned earlier can be described as a connection between two objects of type "mass" and one object of type "spring." Figure 11 displays the resulting model as implemented in Dymola, a commercial simulation environment for simulation of Modelica models. All objects can have states, parameters, and equations that contribute to the overall model. They also have connectors that define interfaces to other objects. For example, in this case, each mass object has a parameter containing its mass as well as state variables containing its speed and location. The spring is described by an equation that relates its deflection to the force it exerts on its connected objects.

Unlike signals, which have a fixed direction, interconnectors establish additional relationships between connected elements, but do not yet determine the direction of causality. The connector equations account for both cause and effect, so it is not necessary to explicitly incorporate the resulting opposite reaction. Also, conservation of energy is automatically accounted for, greatly simplifying the task of creating models that are physically correct.

An important aspect of object-oriented programming is the concept of classes and inheritance. A class is a description of a certain type of object. For example, the two masses in the example are both of the class "point mass," both having the same structure. So the actual objects are instances of that class which only has to be defined once, leading to high reusability. In addition, class properties can also be inherited by other classes. For example, going back to the case of the quarter-car model, a "tire" class could be created. A tire would contain an unsprung mass of the type mass as well as a spring. Therefore, the class "tire" automatically inherits the states of the tire (velocity, position) and the equation for the spring, but for the end user can be displayed as a tire. It is also possible to incorporate interchangeable components. For example, it would be possible to give the user a choice of springs to simulate the behavior of different types of tires.

Especially when the system to be modeled becomes more complex, high level languages such as Modelica can be advantageous. However, it should be noted that a Modelica model describes physical systems but not the simulation process. Therefore, additional software is required to simulate the model using the equations specified in Modelica. Modelica models can incorporate differential, algebraic, and discrete equations (Tummescheit, 2002). Their solution can require high computational effort and iterative solution methods. Thus, the models may not always be suitable for real-time computation.

4.2 Modeling example in Matlab/Simulink, and Dymola

4.2.1 Implementation in Simulink

In this section, the implementation of a plant model to be used for numerical simulations will be illustrated using Matlab/Simulink. For this purpose, the application of an active suspension, introduced in Section 3.4, is considered again. According to Section 3.4, the dynamic behavior of the plant is described by the following differential equations

$$m_s\ddot{z}_s = c_s \bullet (z_u - z_s) + d_s \bullet (\dot{z}_u - \dot{z}_s) + F_a \tag{21}$$

$$m_u\ddot{z}_u = c_s \bullet (z_s - z_u) + d_s \bullet (\dot{z}_s - \dot{z}_u) - F_a + c_u \bullet (z_r - z_u) \tag{22}$$

One possibility to implement the plant model (Equations 21 and 22) in Matlab/Simulink is to use integrator, gain, and sum blocks that are part of the Simulink library. Figure 12 shows a possible realization in Matlab/Simulink.

Equation 21, describing the vertical movement of the sprung mass, is modeled in the upper part of the Simulink model; the coupling of the two masses through the spring and the damper in the middle and the vertical movement of the unsprung mass, defined by (22), is modeled at the bottom. Considering the sprung mass, the acceleration $\ddot{z}_s$ is computed by dividing the sum of all forces acting on m_s by the sprung mass m_s. Subsequently, the velocity $\dot{z}_s$ and the position z_s of the sprung mass are determined using two integrators. As the spring and damper forces are proportional to the relative distance and velocity of the two masses and the road, these forces are modeled using the sum as well as gain blocks. The system inputs, that is, the road's elevation z_r as well as the actuator force F_a, and the considered system outputs, that is, the vertical velocity and position of both masses, can be recognized as sources and sinks.

In order to obtain a clearly arranged implementation, Simulink allows for creating subsystems. Thus, the plant can be reduced to its inputs and outputs as illustrated in Figure 13.

Another possibility to implement the quartercar in Matlab/Simulink in a clearly arranged way is to use the *state space*-block, which belongs to the Simulink block

library and supports linear time-invariant systems having the structure

$$\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u} \tag{23}$$

$$\boldsymbol{y} = \mathbf{C}\boldsymbol{x} + \mathbf{D}\boldsymbol{u} \tag{24}$$

Using $\mathbf{x} = [\dot{z}_\mathrm{s}\ z_\mathrm{s}\ \dot{z}_\mathrm{u}\ z_\mathrm{u}]^\mathrm{T}$ as state vector, the actuator force $u = F_\mathrm{a}$ as control input, the road elevation $z = z_\mathrm{r}$ as system disturbance, and $\mathbf{y} = [\dot{z}_\mathrm{s}\ z_\mathrm{s}\ \dot{z}_\mathrm{u}\ z_\mathrm{u}]^\mathrm{T}$ as system output, Equations 21 and 22 can be rewritten as

$$\begin{bmatrix} \ddot{z}_\mathrm{s} \\ \dot{z}_\mathrm{s} \\ \ddot{z}_\mathrm{u} \\ \dot{z}_\mathrm{u} \end{bmatrix} = \begin{bmatrix} -\frac{d_\mathrm{s}}{m_\mathrm{s}} & -\frac{c_\mathrm{s}}{m_\mathrm{s}} & \frac{d_\mathrm{s}}{m_\mathrm{s}} & \frac{c_\mathrm{s}}{m_\mathrm{s}} \\ 1 & 0 & 0 & 0 \\ \frac{d_\mathrm{s}}{m_\mathrm{u}} & \frac{c_\mathrm{s}}{m_\mathrm{u}} & -\frac{d_\mathrm{s}}{m_\mathrm{u}} & -\frac{c_\mathrm{s}+c_\mathrm{u}}{m_\mathrm{u}} \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \dot{z}_\mathrm{s} \\ z_\mathrm{s} \\ \dot{z}_\mathrm{u} \\ z_\mathrm{u} \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \\ -1 \\ 0 \end{bmatrix} F_\mathrm{a} + \begin{bmatrix} 0 \\ 0 \\ \frac{c_\mathrm{u}}{m_\mathrm{u}} \\ 0 \end{bmatrix} z_\mathrm{r} \tag{25}$$

$$\mathbf{y} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \dot{z}_\mathrm{s} \\ z_\mathrm{s} \\ \dot{z}_\mathrm{u} \\ z_\mathrm{u} \end{bmatrix} \tag{26}$$

As described earlier, only linear dynamic systems having the structure as in (Equation 23) can be modeled using the state space block. Thus, z_r has to be defined as an input such that Equation 25 can be written as

$$\begin{bmatrix} \ddot{z}_\mathrm{s} \\ \dot{z}_\mathrm{s} \\ \ddot{z}_\mathrm{u} \\ \dot{z}_\mathrm{u} \end{bmatrix} = \begin{bmatrix} -\frac{d_\mathrm{s}}{m_\mathrm{s}} & -\frac{c_\mathrm{s}}{m_\mathrm{s}} & \frac{d_\mathrm{s}}{m_\mathrm{s}} & \frac{c_\mathrm{s}}{m_\mathrm{s}} \\ 1 & 0 & 0 & 0 \\ \frac{d_\mathrm{s}}{m_\mathrm{u}} & \frac{c_\mathrm{s}}{m_\mathrm{u}} & -\frac{d_\mathrm{s}}{m_\mathrm{u}} & -\frac{c_\mathrm{s}+c_\mathrm{u}}{m_\mathrm{u}} \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \dot{z}_\mathrm{s} \\ z_\mathrm{s} \\ \dot{z}_\mathrm{u} \\ z_\mathrm{u} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ -1 & \frac{c_\mathrm{u}}{m_\mathrm{u}} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} F_\mathrm{a} \\ z_\mathrm{r} \end{bmatrix} \tag{27}$$

With this modification, Equations 25 and 26 can be implemented in Simulink as illustrated in Figure 14.

The overview that has been given earlier is just a compendium of the possible modeling techniques that can be employed in Simulink. The particular implementation depends on the complexity of the considered plant. If, for example, a model of an entire car is implemented, it is reasonable to implement, for example, the vehicle

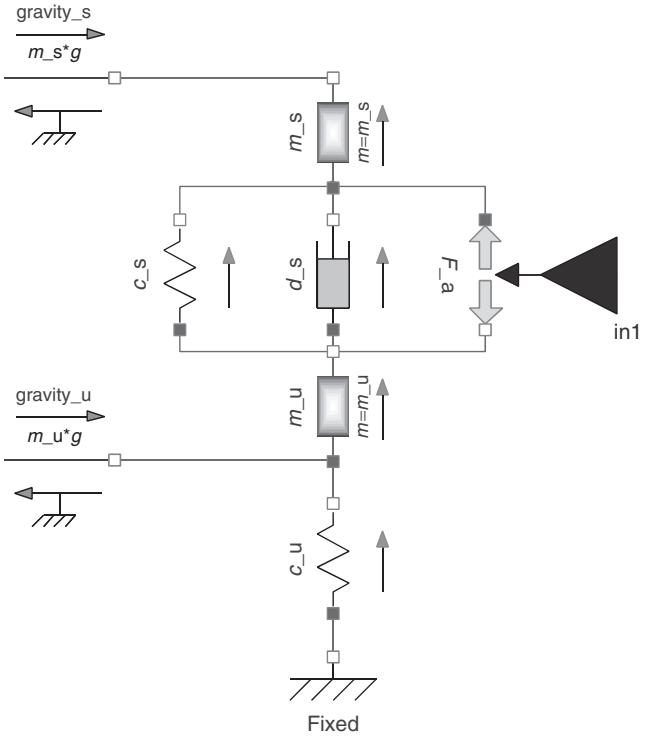

Figure 15. Dymola implementation of the quartercar example.

body, the suspension, and the power train as interconnected subsystems.

As mentioned in Section 3.1, plant models are required and employed for different purposes. For controller design, the model that has been described earlier has an appropriate complexity to be used for a first analysis of the dynamic plant behavior as well as controller design. For the purpose of controller validation, plant models of higher complexity that consider nonlinear effects are commonly employed. In this regard, it is reasonable to run co-simulations of Simulink and third-party software tools. As far as vehicle dynamic control applications are concerned, IPG CarMaker and CarSim^{TM}are two powerful tools that provide several vehicle models as well as validated tire datasets to be used for validation purposes. In this context, both software packages allow for MIL as well as HIL testing procedures.

4.2.2 Implementation in Dymola

The chapter concludes with an implementation of the quartercar model in Dymola (Figure 15). Using blocks that are part of the free Modelica Standard Library Modelica Association (1998–2008), the model can be assembled using the predefined components for the masses, springs, and the damper as well as the interface elements "force" and "force2." The interface element "force"—used here to account for gravity—applies an additional force to its connected element, whereas "force2" creates a generic force between two elements and is used here to introduce the actuator force acting between sprung and unsprung mass. As one can see, the structure of the model is very close to the structure of the physical system it describes, making it more accessible. This is mainly due to the above-mentioned use of connectors as opposed to unidirectional signals. Still, it is also possible to incorporate model parts that have fixed causality. For example, a control algorithm calculating the desired actuator force can be implemented using the signal input "in1."

Chassis Modeling and Optimization by the Advanced Method ABE

Ingo Albers

ZF Friedrichshafen AG, Dielingen, Germany

1 INTRODUCTION

Wheel suspensions have the important task to serve as a connection between the road surface and the chassis, guiding the wheel while driving. The suspension has to fulfill many tasks: cushioning, damping, steering, force transmission, powering, and braking.

The way in which a wheel is guided significantly determines the kinematics of the system and hence which type of movement the wheel is capable of doing. One differentiates between inflexible (or rigid) and elastic kinematics. With the inflexible kinematics, it is given that all connecting components such as suspension arms and joints are ideally stiff and the joints only show one or more pure rotation degrees of freedom toward the desired directions. In reality, the elements of wheel suspensions are seldom considered to be ideally stiff. Especially, elastomer bushings have a considerable effect on the kinematics of the wheel suspensions. In addition, structural elasticity of the involved elements is to be considered to precisely analyze the kinematics. The kinematics of a wheel under the influence of a real element rigidity and the so-called soft elements such as rubber bushings, overload springs, or bump stops is usually called *elasto-kinematics*. The elasto-kinematics can be differentiated drastically from the idealized stiff-kinematics, still it is highly suggested that a clear analysis and synthesis of the stiff-kinematics is performed before looking at the real elasto-kinematics.

To make the kinematics of wheel suspensions tangible and especially comparable, numerous values on axle kinematics have been developed in the past, which have established themselves in the daily life of chassis engineers. This applies to both single values, valid for the so-called design position, and complete characteristic data. These trends are identified and evaluated for compression and rebound and steering or action of forces – or torque conditions (braking, powering, cornering, and vertical loads).

Nowadays, within the automotive industry, usually a first model in 3D-CAD and a model in the multibody system (MBS) are defined when designing the layout of an axle. For a fast prelayout without MBS knowledge, for university purposes, for Formula Student suspensions, or in all other cases in which an MBS model is not feasible (e.g., due to high fees), a simple program can be self-created to calculate the stiff-kinematics. To do so, the mathematical approach by Matschinsky (1992) is used, which is complementary to a program family called *ABE* (axle calculation in Excel) (Albers, 2003, 2009).

2 THEORETICAL BASICS ON INDEPENDENT WHEEL SUSPENSIONS

2.1 Necessary degrees of freedom of a wheel suspension

Fundamentally, a stiff body has six degrees of freedom in space and can perform a translational movement in *X*-, *Y*-, or *Z*-direction or a rotational movement around every axis of a Cartesian *X*-*Y*-*Z* coordinate system.

As road roughness has to be compensated and high accelerations of the vehicle body have to be avoided, an independent suspension basically has to have a vertical movement option. The degree of freedom is, thus, $F = 1$. This degree of freedom does not necessarily have to be a parallel movement, but can generally also be a combined stroke, cross, and tilt movement. With such a combination of translational and rotational moving parameters, all parameters are in direct relation to each other, the so-called kinematic constrained motion. A body suspension spring is responsible for saving and releasing the energy. Simultaneously, a damper is dissipating energy and reducing vibrations. The suspension system adjusts to the statically defined weight balance of the vehicle. The spring element represents a highly elastic suspension arm; the degree of freedom $F = 1$ is, thus, appropriate only if a force is applied (Albers, 2003).

If a body is stiffly hung to six suspension arms in a room, which illustrates a wheel with a wheel bearing solidly attached to the vehicle. To maintain the degree of freedom of $F = 1$, one of the six suspension arms has to be removed and one gets the basic type of an independent suspension, the so-called common space 5 rod wheel guidance. The calculation program described here is, thus, only applicable to independent suspension systems, which can be illustrated or be derived from the "common 5 rod suspension." This, for example, also includes the double wishbone axle as well as the common McPherson axle at the front (Albers, 2003).

The guidance of the suspension and definition of the degrees of freedom takes place with the components shown in the following.

2.2 Components of wheel suspensions

A wheel suspension can be considered as a kinematic chain. The wheel hub is the connecting rod. Suspension arms serve as intermediate components of the chain. Joints are the smallest elements of such a chain. The total degree of freedom results from the degrees of freedom of the bodies to be guided, all joints as well as the confining degrees of freedom of the suspension arms. In the following, the different types of joints are shown in Figure 1. How many degrees of freedom is required by the respective joint constrain will be explained. A small "f" identifies the joint degrees of freedom (Albers, 2003).

2.3 Characteristic values of axle kinematics

In the automotive literature, there are numerous different vehicle suspension characteristic values. Matschinsky (1992) describes them in great detail in his PhD thesis, thus only a small overview is given in Tables 1 and 2.

2.4 Velocity status of the wheel carrier

Looking at the respective definitions of the kinematic values shown (Matschinsky, 1992; Albers, 2003), it becomes evident that they can be calculated through either geometrical positions or translational as well as rotational velocity conditions of either the tire contact point or the wheel carrier. The complete velocity status consists of the translational velocity vector $\vec{v}_M$ and the angular velocity vector $\vec{\omega}_K$. The translational velocity is only valid in the reference

point, which, reasonably, is the center of the wheel (M). Within a solid body, the angular velocity vector is identical, thus it is defined for the wheel carrier body (K) (Albers, 2009).

The wheel carrier including the tire contact point, which is rigidly coupled with the wheel carrier over the wheel, is abstracted by a wheel carrier level, which, at the beginning, is defined by the tire contact point (A), the wheel center (M), as well as a once defined auxiliary point (H) (Figure 2). The auxiliary point is conveniently defined as being part of the wheel axle; in addition, the lines MA and MH are perpendicular to each other. The distance between H and M is simply the wheel radius, hence points A, M, and H construct an orthogonal, equally sided triangle in space (Albers, 2009).

This plane is being incrementally moved in spring and steering activity. In doing so, the kinematic velocity is being analyzed. Through summation by integration of the incremental speeds, the position is also always known.

As an example for a position-orientated calculation, the toe and camber calculation is shown. The track width is a value, which is trivially determined from the positions of the tire contact points. For the identification of the geometrical constraints of points A, M, and H, it is advisable to show a wheel in a random position and then examine it in two layers. It is very important to determine the respective distances correctly in their respective depiction in the layer. Shown in Figure 2 is a wheel with a positive camber and a positive wheel steer angle. A positive wheel steer angle at the left wheel means negative toe-in (Albers, 2009).

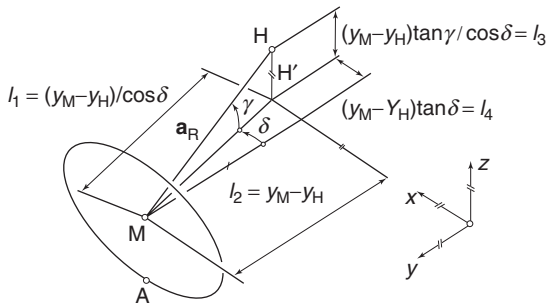

Figure 2. Wheel and wheel carrier in optional, steering situation. (Reproduced from Matschinsky, 1998. With kind permission from Springer Science+Business Media.)

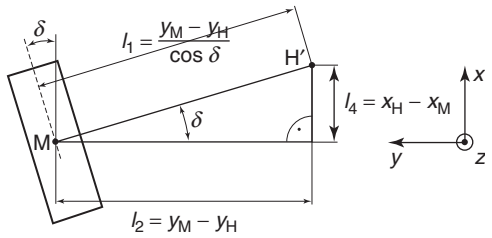

Figure 3. View from above in *X*-*Y*-level.

Viewed from above, the picture is shown in the *X*-*Y*-level, cut at the wheel center M (Figure 3).

The lines named in Figure 2 can easily be found here again and can be depicted geometrically through known values. "H′" is the vertical projection of the point H in the shown level. The respective sections are trigonometrically further explained in the figures.

In the following, the view from the rear upon the wheel axle a_R is illustrated as a cut through the wheel center M and the help point H (Figure 4). Hence, the cut level shown is the *Y*-*Z*-level, turned by the steering angle δ.

With the help of these geometrical correlations, camber- and toe-in with respect to the front wheel steering angle can be determined directly. For instance, when the coordinates of the points M and H of the wheel axle a_R are known, one can calculate the steering angle δ as well as the camber angle γ. From Figures 3 and 4, one gets the following correlation for the steering angle:

$$\delta = \arcsin \frac{x_H - x_M}{\sqrt{(x_H - x_M)^2 + (y_M - y_H)^2}} \qquad (1)$$

The toe-in angle for a left wheel is, according to the preceding definition (DIN 70000), obtainable by switching the algebraic sign. The camber angle can be obtained

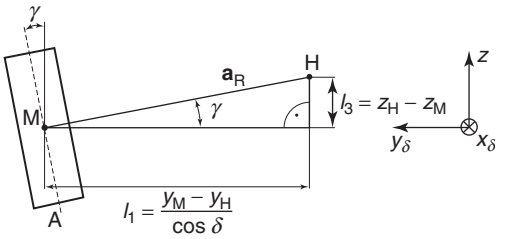

Figure 4. View from behind on the *Y*-*Z*-level of the left wheel.

likewise through the following equation:

$$\gamma = \arctan \frac{z_H - z_M}{\sqrt{(x_H - x_M)^2 + (y_M - y_H)^2}} \qquad (2)$$

In this case, the current coordinates of the wheel center point as well as of the help point H on the wheel axle are needed (Albers, 2009).

2.5 The ABE-core: determining the velocity situation

Now, it is possible to establish the core of the calculation program. Considering a solid body, such as a wheel carrier of a wheel suspension in the case given, its velocity situation is explicitly described by specifying the velocity $\vec{\mathbf{v}}_M$ in the wheel center point and $\vec{\boldsymbol{\omega}}_K$ of the wheel carrier; hence, it consists of six components:

$$\vec{\mathbf{v}} = (\vec{\mathbf{v}}_M, \vec{\boldsymbol{\omega}}_K)^T = (\mathbf{v}_{Mx}, \mathbf{v}_{My}, \mathbf{v}_{Mz}, \boldsymbol{\omega}_{Kx}, \boldsymbol{\omega}_{Ky}, \boldsymbol{\omega}_{Kz})^T \qquad (3)$$

Thus, for a clear calculation, six independent equations are needed as well. The translational velocity of any random point P_i in a body can be calculated directly if the distance between P_i to its point of reference (in this case the wheel center point M) is known as the *respective distance vector* $\mathbf{r}_i$. The current velocity situation $\mathbf{v}_i$ of a random point P_i is calculated through

$$\vec{\mathbf{v}}_i = \vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{\mathbf{r}}_i \qquad (4)$$

Figure 5 shows the necessary components.

With the calculation algorithm given, it is assumed that the connection rods of the suspension are stiff. Thus, the wheel-carrier- and the vehicle-based velocity can be correlated to each other. The velocity in the direction of the connection rod has to be identical on both sides. This is illustrated with a simple scheme (Figure 6; Albers, 2009).

One can clearly see that there are different velocities $\vec{\mathbf{v}}_i$ and $\vec{\mathbf{v}}_i'$ effective on the wheel-carrier-based point *i* and

on the vehicle-based point i' of a stiff connecting rod, the velocity in the direction of the rod ($\vec{\mathbf{v}}_{\mathbf{a}_i}$), however, has to be identical. The scalar velocity in the direction of the rod results in the common case from the scalar product from velocity vector and steering rod vector, which points from the vehicle to the wheel carrier:

$$\vec{\mathbf{v}}_i \cdot \vec{\mathbf{a}}_i = \vec{\mathbf{v}}'_i \cdot \vec{\mathbf{a}}_i \tag{5}$$

This equation is called the *connection rod requirement*. The connection rod vector $\vec{\mathbf{a}}_i$ is, just like the location vector $\vec{\mathbf{r}}_i$, known from the original coordinates of the wheel suspension. With Equations 4 and 5, the fundamental equation for this discussion is as follows:

$$(\vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{\mathbf{r}}_i) \cdot \vec{\mathbf{a}}_i = \vec{\mathbf{v}}'_i \cdot \vec{\mathbf{a}}_i \tag{6}$$

which puts the velocity situation of the wheel carrier in correlation to the wheel-carrier- and vehicle-based joints' velocities at the ends of the examined connection rod. This fundamental equation is called *common velocity equation* (CVE) and is an elementary core of the calculation program. The CVE is being used in many different forms and adjusted according to the specific needs (Albers, 2009).

The CVE, formulated for three different basic suspension variants, is as follows:

- Common five-rod suspension with spring element on the wheel carrier (5LR)
- Common five-rod suspension with spring element at a connection rod (5LL)
- McPherson strut (McP)

As an example, the CVE is developed and drafted for a five-rod suspension with connection of the spring element to the connection rod (5LL). For both the other basic types (5LR and McP), refer to the study by Albers (2009).

The CVE originates in its basic form (Matschinsky, 1992) but is further developed to adjust to other applications. Hence, the CVE is formulated in such a way that the spring element incrementally varies its length or the tie rod is incrementally shifted from the vehicle side. The two following moving patterns can be observed:

- *Spring action*: Change in length of the spring elements.
- *Steering action*: Moving of the vehicle-based tie rod joint (equals the connection to a rack and pinion gear box).

In between these two moving actions, on spring movements, the difference is not only that a different spring rod is affected than that on the steering (tie rod) but especially that the length of the spring rod is changed through the stepwise speed increment, whereas upon steering, the length of the tie rod is constant. Here, the steering speed increment is externally impacted, that is, from the vehicle-based side (from a translational operating steering gear box) to the wheel suspension system (Albers, 2009).

For both these common types of movements of the wheel suspension, which can perform independently from each other, the CVE will be developed in such a way that it can be used in a calculation algorithm.

2.5.1 *Derivation of the ABE-core of a wheel suspension system*

With a common five-rod suspension, as shown in Figure 5, the CVE can be freely set up for a spring movement with the indices 1 to 5 for the first five connection rods. The entire derivation originates from the study by Albers (2009).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto037
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The necessary sixth equation generally evolves from contemplating the spring element. This spring element is considered to be stiff in each incremental move and completes the linear equation system with the sixth equation. This spring equation has to be compiled independently from the type of movement.

In case of a spring movement, the spring element is moved out of its design position with the spring speed $\mathbf{v}_f$. Principally, this spring speed increment $\mathbf{v}_f$ is responsible for a change in position of the wheel suspension, as it induces the velocity $\vec{\mathbf{v}}$ of the wheel carrier. This again results in a velocity $\mathbf{v}_i$ on all wheel-carrier-based joints, which can be calculated with Equation 4. The wheel suspension system moves, that is, it experiences a change in position. The tie rod does not move in this case, it is said to be a "blocked steering."

A similar consideration is valid for the steering process at which the strut compression velocity $\mathbf{v}_f$ is put to zero. This activity is called a *blocked suspension*. The tie rod is moved at $\mathbf{v}_L$ and it induces a movement of the wheel carrier and, thus, the entire wheel suspension.

Generally speaking, at first, a scalar strut compression velocity $\mathbf{v}_f$ is defined, which points in the direction of the unit vector of the spring and is positive during compression from the design position. Put into the CVE according to Equation 4, the result is

$$\mathbf{v}_f = (\vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{\mathbf{r}}_F) \cdot \vec{\mathbf{e}}_F \tag{7}$$

with $\vec{\mathbf{r}}_F$ (distance vector from the wheel center to the spring function line) and $\vec{\mathbf{e}}_F$ (unit vector of the spring element). The connection rod vector of the spring is named with $\vec{\mathbf{a}}_6$ and points, as defined earlier, from the vehicle structure to the wheel carrier and to the pivot joint of one of the connecting rods, and thus contrarily to $\mathbf{v}_f$.

The case that the spring element is mounted directly to a wheel carrier can be expressed more easily. Here, a more complicated case with the connection of the spring to the connection rod is to be shown. It can easily be imagined that in such a case the connection point between the spring element and the connection rod (suspended rod) does not instantaneously follow the velocity situation of the wheel carrier but receives a coupled movement via the suspended rod. It is, thus, important for the development of the spring equation to include the information on where the spring element is mounted. For the derivation of the ABE-core, the following steering indices are defined: tie rod (1), spring element (6), suspended rod (5), as well as the remaining three connection rods (2, 3, and 4). Figure 7 shows the velocity plan of the suspended connection.

It is possible to apply the intercept theorem here to determine the relation of the values of the connection rod

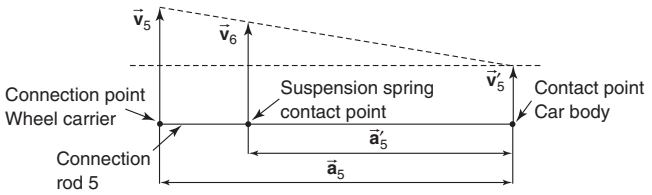

Figure 7. Application of the intercept theorem with a spring, acting to the connection rod. (Reproduced with permission from Albers, 2003. © Ingo Albers.)

vector $\vec{\mathbf{a}}_5$ as well as $\vec{\mathbf{a}}'_5$. The vector $\vec{\mathbf{a}}'_5$ is the connecting vector from the vehicle-based joint to the point of action of the spring at point 6. It is $\mathbf{a}_5 = |\vec{\mathbf{a}}_5|$ as well as $\mathbf{a}'_5 = |\vec{\mathbf{a}}'_5|$. The distance relation is viewed according to amount and converted to

$$\mathbf{v}_6 = \mathbf{v}'_5 + \frac{\mathbf{a}'_5}{\mathbf{a}_5}.(\mathbf{v}_5 - \mathbf{v}'_5) \tag{8}$$

With an introduced leverage $\mu_{HBV} = \frac{\mathbf{a}'_5}{\mathbf{a}_5}$, it comes out to

$$\mathbf{v}_6 = \mathbf{v}'_5 + \mu_{HBV}.(\mathbf{v}_5 - \mathbf{v}'_5) \tag{9}$$

As the spring compression speed $\mathbf{v}_f$ is divergent to the connection rod vector, it is

$$\vec{\mathbf{v}}_6 \cdot \vec{\mathbf{a}}_6 = -\mathbf{v}_f \cdot |\vec{\mathbf{a}}_6| \tag{10}$$

Fundamentally, for a spring element it is, according to the connection rod requirement equation 5

$$\vec{\mathbf{v}}_6 \cdot \vec{\mathbf{a}}_6 = \vec{\mathbf{v}}'_6 \cdot \vec{\mathbf{a}}_6 \tag{11}$$

In combination with Equations 9 and 10, this results in

$$[\vec{\mathbf{v}}'_5 + \mu_{HBV} \cdot (\vec{\mathbf{v}}_5 - \vec{\mathbf{v}}'_5)] \cdot \vec{\mathbf{a}}_6 = -\mathbf{v}_f \cdot |\vec{\mathbf{a}}_6| \tag{12}$$

These are as usual the common requirements of the superposition of translational and rotational speeds $\vec{\mathbf{v}}_5 = \vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{\mathbf{r}}_5$. With this information, the spring equation can be formulated step by step for the ABE-core from Equation 12:

$$\begin{aligned} &\Rightarrow [\vec{\mathbf{v}}'_5 + \mu_{HBV} \cdot (\vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{r}_5 - \vec{\mathbf{v}}'_5)] \cdot \vec{\mathbf{a}}_6 \\ &= -\mathbf{v}_f \cdot |\vec{\mathbf{a}}_6| \\ &\Longleftrightarrow (\vec{\mathbf{v}}_M + \vec{\boldsymbol{\omega}}_K \times \vec{\mathbf{r}}_5) \cdot \vec{\mathbf{a}}_6 = -\frac{1}{\mu_{HBV}} \cdot [\mathbf{v}_f \cdot |\vec{\mathbf{a}}_6| \\ &\quad + \vec{\mathbf{v}}'_5 \cdot \vec{\mathbf{a}}_6 \cdot (1 - \mu_{HBV}) \end{aligned} \tag{13}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto037
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

This equation is, component based, completed to

$$\begin{aligned}
&[\mathbf{v}_{\mathrm{M}x} + \boldsymbol{\omega}_{\mathrm{K}y} \cdot (z_5 - z_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}z} \cdot (y_5 - y_{\mathrm{M}})] \cdot (x_6 - x_6') \\
&+ [\mathbf{v}_{\mathrm{M}y} + \boldsymbol{\omega}_{\mathrm{k}z} \cdot (x_5 - x_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}x} \cdot (z_5 - z_{\mathrm{M}})].(y_6 - y_6') \\
&+ [\mathbf{v}_{\mathrm{M}z} + \boldsymbol{\omega}_{\mathrm{K}x} \cdot (y_5 - y_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{k}y} \cdot (x_5 - x_{\mathrm{M}})] \cdot (z_6 - z_6') \\
&= -\frac{1}{\mu_{\mathrm{HBV}}} \cdot \mathbf{v}_{\mathrm{f}} \cdot \sqrt{(x_6 - x_6')^2 + (y_6 - y_6')^2 + (z_6 - z_6')^2} \\
&= -\frac{1 - \mu_{\mathrm{HBV}}}{\mu_{\mathrm{HBV}}} \cdot [\mathbf{v}_{5x}' \cdot (x_6 - x_6') + \mathbf{v}_{5y}' \cdot (y_6 - y_6') \\
&\quad + \mathbf{v}_{5z}' \cdot (z_6 - z_6')] \qquad (14)
\end{aligned}$$

The CVE from Equation 6 represents, after completely writing the cross product with the indices $i = 1 \ldots 5$, the first five equations of the ABE-core

$$\begin{aligned}
&[\mathbf{v}_{\mathrm{M}x} + \boldsymbol{\omega}_{\mathrm{K}y} \cdot (z_i - z_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{k}z} \cdot (y_i - y_{\mathrm{M}})] \cdot (x_i - x_i') \\
&+ [\mathbf{v}_{\mathrm{M}y} + \boldsymbol{\omega}_{\mathrm{K}z} \cdot (x_i - x_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}x} \cdot (z_i - z_{\mathrm{M}}) \cdot (y_i - y_i')] \\
&+ [\mathbf{v}_{\mathrm{M}z} + \boldsymbol{\omega}_{\mathrm{K}x} \cdot (y_i - y_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}y} \cdot (x_i - x_{\mathrm{M}})] \cdot (z_i - z_i') \\
&= \mathbf{v}_i' = \mathbf{v}_{ix}' \cdot (x_i - x_i') + \mathbf{v}_{iy}' \cdot (y_i - y_i') + \mathbf{v}_{iz}' \cdot (z_i - z_i') \qquad (15)
\end{aligned}$$

with $\mathbf{v}_i'$ as external, vehicle-based joint moving speed (Albers, 2009).

This equation is, however, only valid when there are no internal connection rod extensions within the connection rods with the indices 1 to 5. To include those in the common matrix as well, the CVE is used once more:

$$\vec{\mathbf{v}}_i \cdot \vec{\mathbf{a}}_i = (\vec{\mathbf{v}}_{\mathrm{M}} + \vec{\boldsymbol{\omega}}_{\mathrm{K}} \times \vec{\mathbf{r}}_i) \cdot \vec{\mathbf{a}}_i = \vec{\mathbf{v}}_i' \cdot \vec{\mathbf{a}}_i \qquad (16)$$

The vehicle-based speed scalar product $\vec{\mathbf{v}}_i' * \vec{\mathbf{a}}$ is replaced by the connection rod change speed $\mathbf{v}_{\mathrm{LL}}$ multiplied with the value of the connection rod vector $\vec{\mathbf{a}}_i$. As the connection rod change speed $\mathbf{v}_{\mathrm{LL}}$ is contrary to the connection rod vector, it is

$$\vec{\mathbf{v}}_i \cdot \vec{\mathbf{a}}_i = -\mathbf{v}_{\mathrm{LL}} \cdot |\vec{\mathbf{a}}_i| \qquad (17)$$

From Equation 16, thus, it follows that

$$(\vec{\mathbf{v}}_{\mathrm{M}} + \vec{\boldsymbol{\omega}}_{\mathrm{K}} \times \vec{\mathbf{r}}_i) \cdot \vec{\mathbf{a}}_i = -\mathbf{v}_{\mathrm{LL}} \cdot |\vec{\mathbf{a}}_i| \qquad (18)$$

Solving the vector product, like in Equation 15, calculating the value of the connection rod vector $\vec{\mathbf{a}}_i'$ and performing the scalar multiplication, one gets the equations for the connection rods 1 to 5 in component form:

$$\begin{aligned}
&[\mathbf{v}_{\mathrm{M}x} + \boldsymbol{\omega}_{\mathrm{K}y} \cdot (z_i - z_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{k}z} \cdot (y_i - y_{\mathrm{M}})] \cdot (x_i - x_i') \\
&+ [\mathbf{v}_{\mathrm{M}y} + \boldsymbol{\omega}_{\mathrm{k}z} \cdot (x_i - x_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}x} \cdot (z_i - z_{\mathrm{M}})] \cdot (y_i - y_i') \\
&+ [\mathbf{v}_{\mathrm{M}z} + \boldsymbol{\omega}_{\mathrm{K}x} \cdot (y_i - y_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}y} \cdot (x_i - x_{\mathrm{M}})] \cdot (z_i - z_i') \\
&= \mathbf{v}_{\mathrm{LL}i} \cdot \sqrt{(x_i - x_i')^2 + (y_i - y_i')^2 + (z_i - z_i')^2} \qquad (19)
\end{aligned}$$

The left-hand sides of Equations 15 and 19 are identical, whereas they differ significantly on the right-hand sides. Equation 15 takes an external joint movement into consideration (point movement, short PM), whereas Equation 19 provides for an internal connection rod length change (LC). As both movements can only be performed separately, the common equation for the first five connection rod indices can be shown by superposition:

$$\begin{aligned}
&[\mathbf{v}_{\mathrm{M}x} + \boldsymbol{\omega}_{\mathrm{K}y} \cdot (z_i - z_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}z} \cdot (y_i - y_{\mathrm{M}})].(x_i - x_i') \\
&+ [\mathbf{v}_{\mathrm{M}y} + \boldsymbol{\omega}_{\mathrm{k}z} \cdot (x_i - x_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}x} \cdot (z_i - z_{\mathrm{M}})] \cdot (y_i - y_i') \\
&+ [\mathbf{v}_{\mathrm{M}z} + \boldsymbol{\omega}_{\mathrm{K}x} \cdot (y_i - y_{\mathrm{M}}) - \boldsymbol{\omega}_{\mathrm{K}y} \cdot (x_i - x_{\mathrm{M}})] \cdot (z_i - z_i') \\
&= [\mathbf{v}_i'] + [\mathbf{v}_{\mathrm{LL}i} \cdot \sqrt{(x_i - x_i')^2 + (y_i - y_i')^2 + (z_i - z_i')^2}\,] \qquad (20)
\end{aligned}$$

In this and in the spring equation 14, it is to be seen that next to the searched velocity components $\vec{\mathbf{x}} = (\mathbf{v}_{\mathrm{M}x}, \mathbf{v}_{\mathrm{M}y}, \mathbf{v}_{\mathrm{M}z}, \boldsymbol{\omega}_{\mathrm{K}x}, \boldsymbol{\omega}_{\mathrm{K}y}, \boldsymbol{\omega}_{\mathrm{K}z})^{\mathrm{T}}$, the velocities $\mathbf{v}_i'$ of the vehicle-based pivot joints as well as the spring compression velocity $\mathbf{v}_{\mathrm{f}}$ and the connection rod length change velocity $\mathbf{v}_{\mathrm{LL}i}$ are also unknown.

Equations 15 and 14 are separated into a matrix to create a linear equation system. It is shown to be

$$\mathbf{A} \cdot \vec{\mathbf{x}} = \vec{\mathbf{b}} \qquad (21)$$

with the square matrix $\mathbf{A} = \mathbf{A}_{(m \times n)}$ as well as the vector $\mathbf{b} = \mathbf{b}_{(m \times 1)}$ with $m, n = 1 \ldots 6$.

$$\begin{pmatrix} \mathbf{a}_{11} & \ldots & \mathbf{a}_{1n} \\ \ldots & \ldots & \ldots \\ \mathbf{a}_{m1} & \ldots & \mathbf{a}_{mn} \end{pmatrix} \cdot (\mathbf{v}_{\mathrm{M}x}, \mathbf{v}_{\mathrm{M}y}, \mathbf{v}_{\mathrm{M}z}, \boldsymbol{\omega}_{\mathrm{k}x}, \boldsymbol{\omega}_{\mathrm{k}z})^{\mathrm{T}} = \begin{pmatrix} \mathbf{b}_1 \\ \ldots \\ \mathbf{b}_m \end{pmatrix} \qquad (22)$$

To do so, the solution vector components from Equations 15 and 14 have to be isolated. For lines 1 to 6

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto037
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of matrix **A**, the following six row entries are to be valid:

$$\begin{aligned}
\mathbf{a}_{i1} &= (x_i - x_i') \\
\mathbf{a}_{i2} &= (y_i - y_i') \\
\mathbf{a}_{i3} &= (z_i - z_i') \\
\mathbf{a}_{i4} &= (y_i - y_\mathrm{M}) \cdot (z_i - z_i') - (z_i - z_\mathrm{M}) \cdot (y_i - y_i') \\
\mathbf{a}_{i5} &= (z_i - z_\mathrm{M}) \cdot (x_i - x_i') - (x_i - x_\mathrm{M}) \cdot (z_i - z_i') \\
\mathbf{a}_{i6} &= (x_i - x_\mathrm{M}) \cdot (y_i - y_i') - (y_i - y_\mathrm{M}) \cdot (x_i - x_i')
\end{aligned} \quad (23)$$

The first five entries of vector **b** are the result of Equation 15 for the indices 1 … 5:

$$\mathbf{b}_i = [\mathbf{v}_i'] + [\mathbf{v}_{\mathrm{LL}i} \cdot \sqrt{(x_i - x_i')^2 + (y_i - y_i')^2 + (z_i - z_i')^2}] \quad (24)$$

The sixth vector entry originates from Equation 14 and is to be enlarged by the term $\mathbf{v}_\mathrm{LL}$ through superposition

$$\begin{aligned}
\mathbf{b}_6 = &-\frac{1}{\mu_\mathrm{HBV}} \cdot \mathbf{v}_\mathrm{f} \cdot \sqrt{(x_6 - x_6')^2 + (y_6 - y_6')^2 + (z_6 - z_6')^2} \\
&-\frac{1 - \mu_\mathrm{HBV}}{\mu_\mathrm{HBV}} \cdot [\mathbf{v}_{5\mathrm{x}}' \cdot (x_6 - x_6') \\
&+\mathbf{v}_{5\mathrm{y}}' \cdot (y_6 - y_6') + \mathbf{v}_{5\mathrm{z}}' \cdot (z_6 - z_6')] \\
&+ \mathbf{v}_{\mathrm{LL}6} \cdot \sqrt{(x_6 - x_6')^2 + (y_6 - y_6')^2 + (z_6 - z_6')^2}
\end{aligned} \quad (25)$$

To generate a solvable linear equation system with six variables of this equation system, further boundary conditions, depending on the type of movement, have to be set.

Generally speaking, the body can be seen as stationary with every suspension or steering action. This is a true analog to many real suspension test benches.

For the conventional spring movement, all vehicle-based velocities $\mathbf{v}_i'$ are set to zero. In addition, there are no connection rod length changes except at the spring element; thus, all $\mathbf{v}_{\mathrm{LL}i}$ are set to zero. The spring compression velocity is a quotient, originating from the total spring travel and the number of calculation steps and is, thus, exactly defined. The matrix **A** is a pure geometrical matrix of the reviewed wheel suspension and stays unchanged. Vector **b** simplifies noticeably to

$$\begin{aligned}
&\vec{\mathbf{b}} = (0, 0, 0, 0, 0, 0, \mathbf{b}_6)^\mathrm{T} \text{with} \\
&\mathbf{b}_6 = -\frac{1}{\mu_\mathrm{HBV}} \cdot \mathbf{v}_\mathrm{f} \cdot \sqrt{(x_6 - x_6')^2 + (y_6 - y_6')\,(z_6 - z_6')^2} \\
&\quad - \frac{1 - \mu_\mathrm{HBV}}{\mu_\mathrm{HBV}} \cdot [\mathbf{v}_{5x}' \cdot (x_6 - x_6') + \mathbf{v}_{5y}' \cdot (y_6 - y_6') \\
&\quad + \mathbf{v}_{5z}' \cdot (z_6 - z_6')]
\end{aligned} \quad (26)$$

Matrix **A** and vector **b** are, thus, complete and definitely covered.

For a conventional steering movement, all connection rod length changes $\mathbf{v}_{\mathrm{LL}i}$ are set to zero. The spring compression velocity $\mathbf{v}_\mathrm{f}$ is set to zero as well. The tie rod bar of the wheel suspension is moved in *y*-direction, this is where the steering gear connects. The steering velocity $\mathbf{v}_1'$ (index 1 for the tie rod) is the quotient from the total traverse path related to the number of calculation steps. All other $\mathbf{v}_\mathrm{i}'$ are set to zero. This reduces vector **b** to an indicator of the steering velocity.

$$\vec{\mathbf{b}} = (\mathbf{v}_1', 0, 0, 0, 0, 0)^\mathrm{T} \quad (27)$$

Matrix **A** and vector **b** are, thus, complete and definitely covered for this case as well.

Next to the conventional analysis of the spring movements or steering actions, this calculation core can also be used for a tolerance or sensitivity analysis. It can be investigated how sensitive the system reacts to tolerances in the body-based pivot joints, for example, through production tolerances in body fabrication or differently long suspension arms. To do so, the spring compression velocity $\mathbf{v}_1$ as well as the steering velocity $\mathbf{v}_1'$ is initially set to zero.

For the analysis of different connection rod lengths, the connection rod length $\mathbf{v}_{\mathrm{LL}i}$ changes with the respective index as the set value for the calculation. For the tolerance analysis of the body pivot joints, the respective entry for the vehicle-based speeds $\mathbf{v}_\mathrm{i}'$ is chosen and defined. The tolerance fault can then be iteratively calculated through these new reference inputs.

2.6 Solution and embedding the ABE-core

With all elements of matrix **A** and vector **b** complete after Section 2.5, the solution vector is calculated in the ABE-core. In the programming used, the calculation via the inverted matrix turned out to be the fastest alternative. To do so, the initial system $\mathbf{A}^*\vec{\mathbf{x}} = \vec{\mathbf{b}}$ is multiplied with the inverted matrix on the right-hand side:

$$\begin{aligned}
&\mathbf{A}^{-1} \cdot \mathbf{A} \cdot \vec{\mathbf{x}} = \mathbf{A}^{-1} \cdot \vec{\mathbf{b}} \\
&\Longleftrightarrow \vec{\mathbf{x}} = \mathbf{A}^{-1} \cdot \vec{\mathbf{b}}
\end{aligned} \quad (28)$$

It is possible to calculate the inverted matrix $\mathbf{A}^{-1}$ only when matrix **A** is a regular and not a singular matrix. A squared matrix with the dimension *n* is considered regular only when the rank of the matrix is equal to the dimension *n* [BRO05]. Only then the matrix has *n* linear and independent equations. If the determinant det(**A**) unequal to zero, then

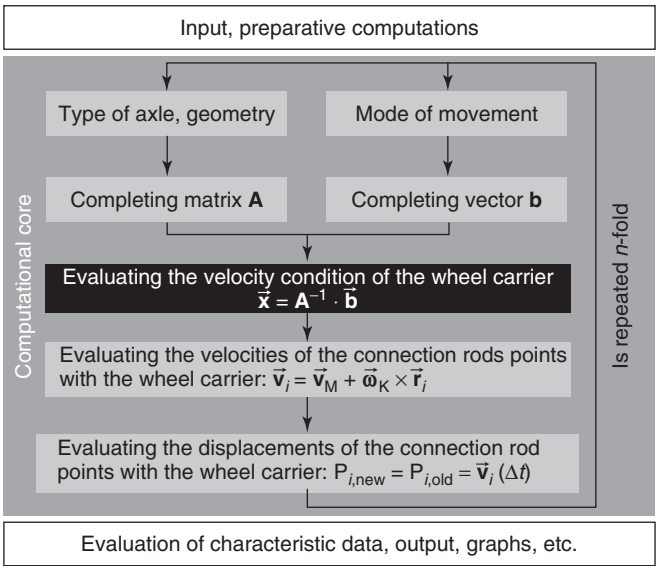

Figure 8. Embedding of the ABE-core.

the matrix is considered to be regular. That is why the determinant is checked before inverting the matrix.

The central ABE-core is centrally embedded to the total flow. It is very flexibly designed and programmed in its basic form as well as constantly called upon by different program modules. It is especially essential to program this calculation block efficiently in view of calculation speed (Figure 8).

This core can, for example, be programmed in Microsoft Excel using a VBA programming language and designed with a respective interface for input and output of data.

3 REVIEW

Chassis modeling and optimization is very often done by commercially available programs, which do not facilitate understanding of the theoretical relationship between input and output. This chapter describes a methodology that avoids these disadvantages and starts with the theoretical background of chassis design to formulate equations and explain the movements of suspensions under vertical and rotational inputs.

The equations, that both explain and describe the wheel movement, are finally programmed in Excel and the kinematic characteristics can be found. Changing the coordinates of the connection points within the suspension linkage, the new chassis characteristics can be easily found rapidly. This design tool, therefore, enables the optimization of chassis systems, even before any hardware has been built. In addition, the engineers can identify the relationship between their design changes and the new chassis behavior.

The technical background of all these procedures are described by Matschinsky (2000) and the computational transfer into a simple and fast simulation program is the merit of Albers (2009).

Gaskets and Sealing

Lucian M. Silvian
Purdue University, West Lafayette, IN, USA

1 HISTORY

The history of automotive sealing is closely related to the development of the engine. As the combustion ratio and combustion pressure increased, sealing the engine, especially the combustion chamber, became a challenge.

New materials were necessary to help in sealing. In the 1940s and 1950s, for example, a few weeks after purchasing, the cars would be returned to the dealers and the cylinder head-to-block assembly had to be retorqued to ensure a good seal of the combustion chamber. In the 1960s, new materials were developed for the cylinder head gasket, which did not require retorqueing.

Asbestos was one of the materials used for many engine sealing applications. In combination with other materials, it had good sealing characteristics over a wide range of temperatures. However, health issues prompted responsible sealing companies to remove asbestos from their gasket products.

In addition, beginning in the mid-1970s, the energy crisis, emission reduction, and worldwide competition required a different philosophy in engine design. Increasingly, the large, slow speed high torque engines used in American cars would be replaced by smaller, more fuel efficient, high speed engines that work under higher temperature, higher combustion pressure, and increased service life.

New lighter designs were needed, as engine designers removed material from cylinder heads and engine blocks. To further reduce weight, cast iron was often replaced by aluminum. First, there were the bimetal engines, usually a cast iron block and an aluminum cylinder head, and then more and more total aluminum engines were developed. Engine sealing became a more difficult challenge. New seal designs were needed that could withstand the harsher conditions and longer life requirements. Many engines migrated from composite gasket materials to multilayer steel gaskets.

Other applications such as valve covers, oil pans, and transmission pan gaskets are designed today using molded rubber and some plastic–rubber composites that also simplify engine assembly.

2 SURFACE TEXTURE ANALYSIS

To properly design a functional gasket, one must include the surface finish of the mating components. The irregularities in the surfaces keep the surfaces away from each other creating passages for fluids to flow. Gaskets are designed not only for new engines but also for the aftermarket. New engines are manufactured to a surface finish selected during the design. Engines that are repaired or rebuilt will invariably have rougher surfaces than those of new engines.

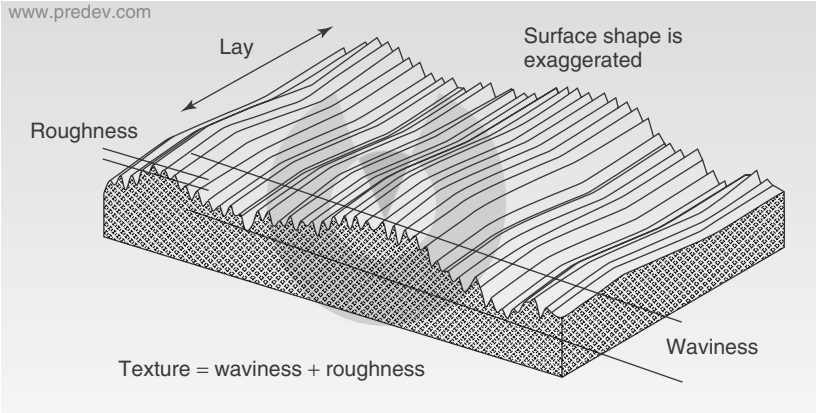

Figure 1. Surface texture characteristics. (Courtesy of Precision Devices, Inc.)

For example, during the 1980s, a typical cylinder head-and-block surface roughness was between 1.5 and 3 μm, whereas a typical surface roughness suggested for remachining was 3–4 μm. This difference in surface finish required different gaskets.

Surface texture is the combination of deviations from the nominal surface. Texture includes *roughness*, *waviness*, *lay*, *and form*. Each term is defined as follows.

Roughness, as seen in Figure 1, includes the finest (shortest wavelength) irregularities of a surface.

Roughness generally results from a particular production process, tool, or material condition. Figure 2 shows the roughness average R_a resulting from various manufacturing processes. One could guess that the lower R_a the higher the expense to produce it. Therefore, it is important for the designer to choose a surface roughness as high as required and as low as necessary.

Waviness includes the more *widely spaced (longer wavelength) deviations* of a surface from its nominal shape. Waviness is the result of machine or work deflections, vibrations, chatter, or various causes of strain in the material.

Texture includes roughness and waviness.

Form is the general shape of the surface, neglecting variations due to roughness and waviness (usually it is referred to as *form error*).

Lay refers to the predominant direction of the surface texture (Figure 3).

A profile is a two-dimensional picture of a three-dimensional surface similar to the representation of a sectioning place cutting the surface. Profiles are ordinarily taken perpendicular to the lay (Figure 4).

The traverse length (A + B + C) of a profile measurement, as indicated in Figure 5, is the total distance traveled by the profiling instrument's pickup during data collection. The evaluation length (B) is the entire length of a profile over which data has been collected. The evaluation length will ordinarily be shorter than the traverse length because of end effects in the travel (A) and (C): motors accelerating and decelerating, electrical filters settling down, etc.

To be of engineering value, surface traces are magnified moderately in the horizontal direction and significantly in the vertical direction in order to be presented on a computer screen or a paper. This difference, shown in Figure 6, leads to a very sharply undulating trace that easily deceives the uninitiated as to the actual shape of the surface.

3 GENERAL SEALING REQUIREMENTS

3.1 Creep

Creep is the tendency of materials to slowly deform under long-term stress that is below material's yield.

As indicated in the accompanying diagram, the creep of a material in time can be divided into four stages (Figure 7).

1. Zero stage is the creep that takes place at assembly. If measured precisely at the end of the torque operation, the torque is already dropping.
2. First stage, or primary creep, starts at a rapid rate and slows with time. This usually takes place and ends after a few hours to a few weeks. It is responsible for the majority of creep loss.
3. Second stage (secondary) creep has a relatively uniform rate. It is the stage that takes place during the life of the assembly. The rate is very slow and is not expected

to stop. Careful tests up to 1000 h have demonstrated that creep continues over the life of a gasketed joint.

4. Third stage (tertiary) creep has an accelerating creep rate and terminates by failure of material at time for rupture.

The factors that influence creep the most are application temperature and load. In the case of temperature and load variation such as seen in an internal combustion engine, the effect is even greater. As creep takes place, the joint relaxes, resulting in torque (clamping load) loss over time.

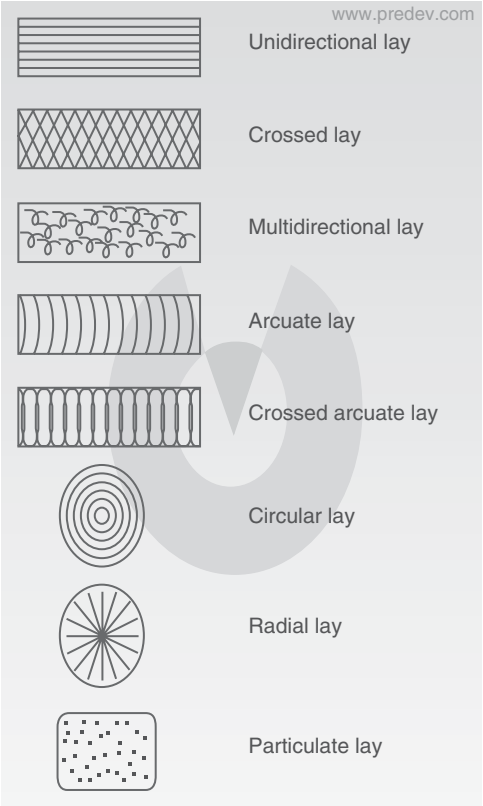

Figure 3. Typical lay. (Courtesy of Precision Devices, Inc.)

3.2 Bolted joint behavior

In an application, a bolted joint is composed of the flanges, bolts, and gaskets. As the clamp load, also called *preload*, is applied, by applying torque to the bolt, the bolt is stretched and the gasket is compressed.

The stress–strength diagrams of the bolt under tension and the gasket under compression could be conveniently arranged as shown in the diagram later.

Assume that the diagram represents a portion of a cylinder block, gasket, cylinder head, and bolt. As the bolt is tightened, it stretches in the linear relationship shown in Figure 9. The bolt behaves like a spring as shown in Figure 8.

The gasket, on the other hand, will compress following a curve as shown in Figure 9 (seal compression). Its behavior is determined by the gasket material and could be imagined as the combined performance of a spring and a dashpot or damper. There are several models to describe it; the most common are the Maxwell and Kelvin models (Figure 10).

For the time being, the deflection in the flanges has been neglected. This will add more complexity to the analysis of the system. At present, computer simulation through finite element analysis (FEA) can be used to analyze the complex behavior of a joint with very good results.

During the power stroke of the engine, the pressure pulse in the combustion chamber further stretches the bolt as shown in Figure 9, reducing the gasket load. If the gasket is unloaded, too much leakage will occur. A good gasket designer will consider this and design a gasket with minimum load to seal much below this point.

In addition, the temperature and cyclic load change the behavior of the gasket and after some time of operation, the stress–strength–shape of the gasket changes to follow the red curve in the Figure 9. Most gasket materials are made in part with elastomers. Elastomers are considered time-dependent materials. It is this behavior that further reduces the load on the gasket toward the minimum load to seal. The designer has to consider this as well when designing gaskets.

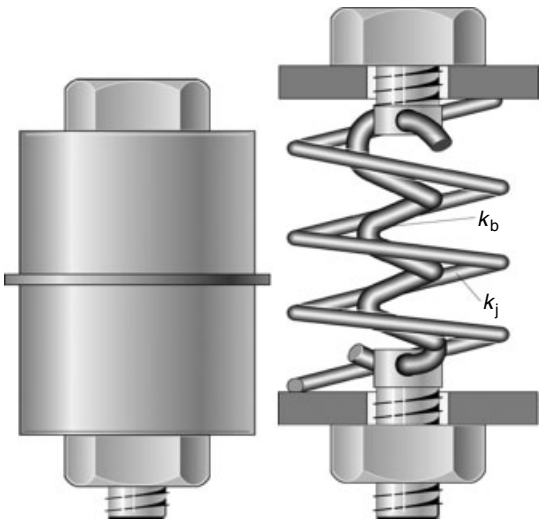

Figure 8. A bolted joint diagram.

3.3 Recovery

The next consideration is what takes place when a seal is loaded and unloaded. Most of the materials used to make gaskets will behave as shown in Figure 11. This is called *hysteresis*. If the load is cyclical, the area under the curve will eventually be reduced. In an internal combustion engine, during the power stroke, as the bolt is stretched, the gasket material is unloaded, and material recovery is essential in maintaining load in the joint, thus providing a permanent seal.

4 GASKET DESIGN AND MATERIAL SELECTION

4.1 Cylinder head gasket

The cylinder head gasket is the most complex gasket in an engine application. It is required to seal combustion gasses at medium to high temperature and high pressure. Peak combustion pressure starts at about 50 bar in gasoline engines and may be well over 200 bar in high compression diesel engines (Figure 12).

The same gasket seals coolant transfers between the cylinder block and the cylinder head. In many cases, it throttles the flow of coolant to balance coolant flow from one cylinder to another, thus creating a pressure differential up to 6 bar on the gasket, which may apply high forces on the exposed area of the gasket.

Finally, the cylinder head gasket must seal the oil transfer passages between the cylinder block and head.

The cylinder head and block are not designed with uniform thickness throughout, so the deflection of both after assembly creates nonuniform loading on the gasket.

The design pattern of the exhaust and intake valves poses an added challenge as the exhaust valves of adjacent cylinders are often placed next to each other. This creates a hot spot in the thin gasket bridge between two cylinders and a much cooler bridge between two intake valves at the adjacent bridge. This also must be considered during the design.

The head bolt pattern is often defined based on the other engine considerations, with little input from the gasket designer. As the cylinder bore increases beyond the span between head bolts, there may be inadequate and unequal clamping load around the combustion chamber perimeter.

The surface finish of the cylinder head and block again must be considered when selecting a cylinder head gasket design. The considerations identified here result in different requirements in different areas of the gasket.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

4.1.1 The body

The body of the gasket could be made as a layered composite: a metal substrate called *core* that provides structure and stiffness and soft facing materials on both sides of the core that provide the necessary seal to the face irregularities of the cylinder head and block. The facing material is usually porous. In the application, load is applied to compress the materials and reduce the porosity. If the clamp load offered by the bolts is not enough, enhancements to the gasket body are required.

There are generally two methods of making the composite:

Chemical bonding (Figure 13): the facing material is chemically bonded to the core. It is usually done using laminator equipment. The core is cleaned by a chemical process to insure that its surface is free of any rust, grease, or other foreign materials. The bond that could be water or solvent based is applied to the core, and the facing material is laminated on both sides of the core. Pressure and temperature to cure the bond are required. The advantage of this method is that the body offers uniform loading limited only by the facing material density.

The disadvantages are that if cleaning and curing are not done exactly as prescribed, delamination of the facing material could occur in service.

Perforated core or mechanical bond (Figure 14): the metal substrate is pierced on both sides with a piercing machine. The facing material is applied on both sides of the perforated core and the composite is laminated together to a finished body thickness; as the perforations bend around the material they provide a mechanical bond (Figure 15).

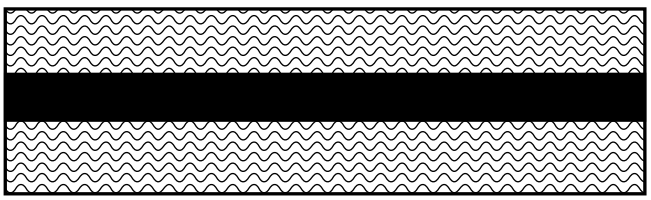

Figure 13. Layered composite made by chemical bonding. (Courtesy of Federal Mogul.)

Figure 14. Perforated core facing material. (Courtesy of Federal Mogul.)

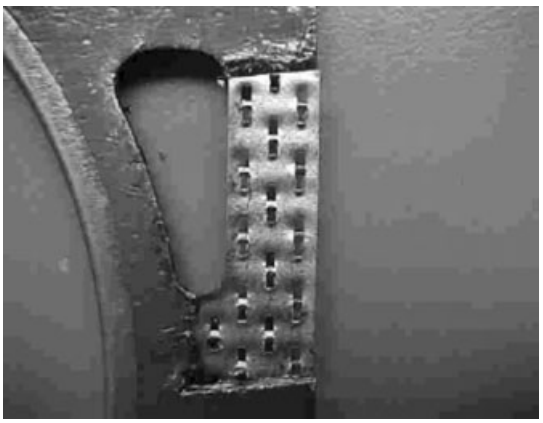

Figure 15. Exposed core. (Compliments of LFP Technologies.)

The density of perforations (number of perforations per square inch) and geometry determine the final stiffness of the gasket body. The advantage of this type, which is a mechanical bond, is that it will not require a very thorough cleaning of the metal surface as required for chemically bonded composite fabrication. The disadvantages are some nonuniformity of loading on the body, and in the narrow areas of the gasket, there may not be enough perforations to keep the facing material attached to the core and the facing material could move laterally.

Facing materials used in both cases are called "*paper*" materials. They are made with special clays and fibers such as Kevlar and elastomers. They are called *papers* because they are made using the same process as the paper gaskets.

Graphite has been used since the 1980s as a facing material. It has the advantage that it could be densified during the lamination process to the desired density for improved sealing. Once the right density is achieved, the gasket requires very little load to properly seal. The disadvantage of graphite is that while it has good mechanical properties in the surface directions (X and Y), it has poor mechanical properties in the vertical direction (Z). Graphite is used in both chemically bonded and mechanically clinched forms.

Most of these facing materials are time-dependent materials. The properties change with time and deteriorate over the life of an engine.

As engines are designed today for longer and longer life cycles, most of these facing materials are being replaced by multilayer gasket materials. These gaskets have the advantage that they can be used with much lower deterioration, meeting increased engine life to overhaul expectations.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

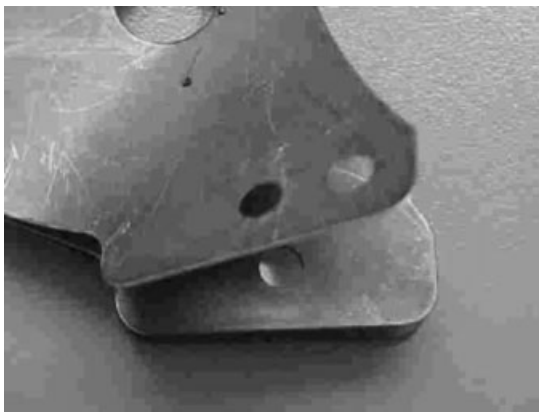

Figure 16. Multilayer metal gasket. (Compliments of LFP Technologies.)

Multilayer gaskets are made using two or three layers of metal as shown in Figure 16. They increase the life of the engine but require better engine surface preparation resulting in a required R_a under 1.016 μm. These gaskets are less conformable and need more uniform loading across the engine head and block and more uniform deck thickness.

When the total load developed by the bolts is not enough to compress the gasket body to perform a good seal, enhancements are designed into the gasket body to help seal.

Screen printing, generally using elastomers such as silicone, increases the density and seal under the screened bead, reducing the load required to seal. It can be used to vary load distribution on the gasket body and selectively build up gasket thickness (Figures 17 and 18).

For multilayer gaskets, beads are designed into the body to mechanically upset the material as shown in Figures 19 and 20. This improves the sealing at problem locations (high temperature gas openings and high pressures). It is also used to reduce bending of joint flanges.

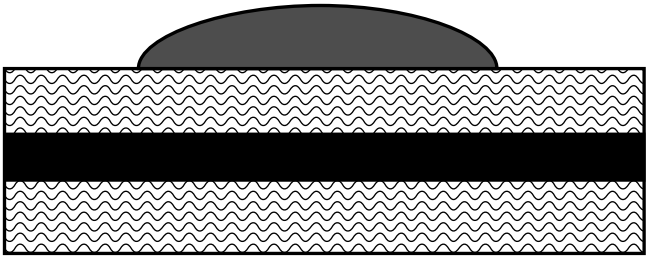

Figure 18. Screen printing. (Complements of Federal Mogul.)

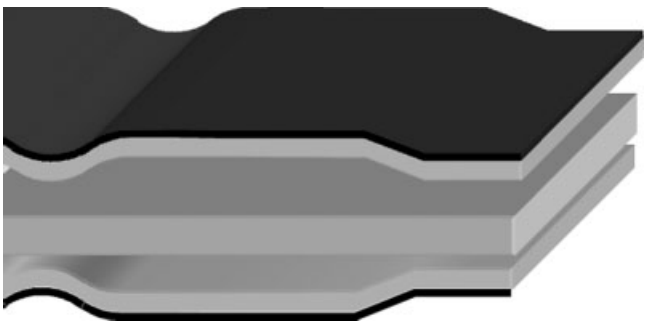

Figure 19. Multilayer metal construction. (Complements of Federal Mogul.)

Coatings are applied to the gasket body to help surface sealing. There are primarily two types of coatings: microsealing and antifriction. Microseal coatings are used as the name suggests to seal surfaces reducing the need for higher clamping loads. They are in general silicone coatings, but some other elastomers are used depending

on the requirements. An example is a coating needed to seal during engine initial operation such as during the final engine inspection. Once the gasket is exposed to heat for 5–10 min, the gasket will take over and seal for the life of the engine.

Antifriction coatings are used in bimetal or all aluminum engines. The aluminum expands when heated at twice the rate of steel. The metal substrate of the gasket is steel; the aluminum surface irregularities would embed into the soft facing material and would tend to move the facing as the engine heats up thus tearing the facing material apart. In general, these coatings contain molybdenum disulfide and graphite (Figure 21).

4.1.2 Combustion seal

The gasket body seals the coolant and lubricant but the higher pressure and temperature of the combustion chamber requires further measures.

4.1.2.1 General combustion seal. For typical gasoline engines, there is an eyelet made of metal, usually steel. This eyelet or armor has two functions, the first of which is to increase loading. This is accomplished by the additional thickness of the eyelet material. During initial gasket installation, this area will be loaded first and the soft material under the armor will be compressed much more than the rest of the body, thus creating a much higher unit stress. The thickness and the width of the armor together with a precoining operation are essential to the load distribution on the combustion seal and the load balance between the body and the combustion (Figure 22).

The second reason for the combustion eyelet is to protect the facing material from the combustion heat.

For high performance gasoline engines and diesel engines, the addition of the combustion armor alone does not produce adequate clamping loads because of the increased combustion pressure. A round wire ring is then attached to the gasket along with the combustion armor, as shown in Figure 23. In this case, the wire ring dimensional tolerances are critical. The load on the gasket body and rings must be carefully balanced. Computer programs are used to determine the adequate load distribution between the combustion and the gasket body.

In the case of aluminum flanges, further care must be taken to avoid material yielding. Depending on the application, the wire rings are made of steel, stainless steel, or copper.

4.1.2.2 Wire rings. The wire rings are used with a composite body as presented earlier. When multilayer steel designs are used, the combustion seal is developed by

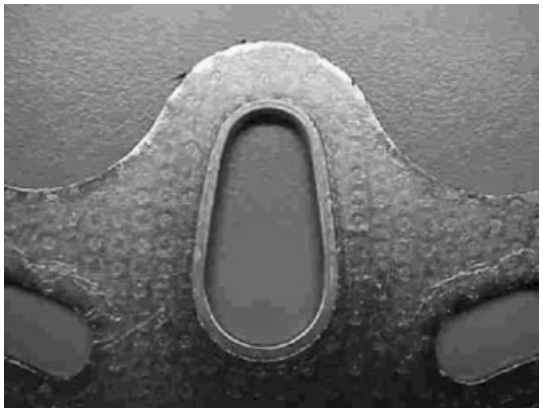

Figure 25. Eyelet used to seal an oil passage in a cylinder head gasket. (Compliments of LFP Technologies.)

mechanically upsetting the material of one of the layers and using a second layer to fold over to create an eyelet (Figure 24).

4.1.3 Oil sealing

Oil sealing on the cylinder head gasket is achieved in many ways. One way as shown in Figure 25 is using a metal eyelet over the gasket body. The eyelet thickness is important in balancing the load on the oil seal and the other openings close to it.

4.2 Intake manifold

The intake manifold gasket seals fuel–air mixture, coolant, and sometimes exhaust gas recirculation (EGR). Many designs are made using similar composite bodies as used for cylinder head gaskets. As the stresses in these gaskets are less than that of the cylinder head gasket, facing materials used may be less expensive. For example, instead of using Kevlar fiber that is very expensive materials with other, less expansive fibers could be used.

For "V" engines, the installation of the intake manifold creates a particular challenge. If the bolt distribution and installation is not developed correctly, it may lift the cylinder head from the cylinder head–gasket–block assembly producing coolant leaks.

4.3 Exhaust gasket

Exhaust gaskets are subjected to high temperatures and flange deflection. The body consists of fiber facing materials or graphite applied on both sides or sandwiched between perforated metals as shown in Figure 26. There are two basic designs: independent gaskets for each port and a single exhaust gasket construction called a *header*.

There are also some single and multilayer exhaust gaskets incorporating embossed designs as shown in Figures 27 and 28. Because of high temperatures, the metal gaskets are made of stainless steel full hard or super hard.

Metal exhaust gaskets work very well and maintain seal if designed properly.

Figure 27. Single layer embossed metal.

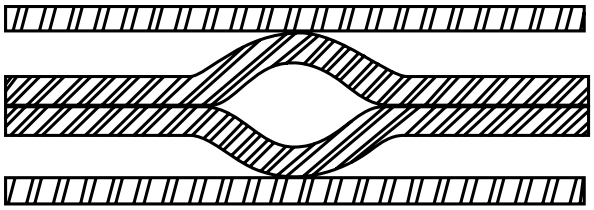

Figure 28. Multilayer embossed metal. (Courtesy of Federal Mogul.)

4.4 Valve cover, oil pan, and transmission pan gaskets

Each of these gaskets is designed to seal oil at low pressures. In the past, the valve covers and oil pans were made of sheet metal and the gaskets were made of cork or cork rubber. Short bolts and vibration were producing very large torque loss resulting in leakage. At present, the covers are more typically die castings that provide added rigidity, and the gaskets are molded elastomers as shown in Figure 29.

In some modern designs, valve covers are made of plastic and the gaskets are molded in place. In this case, torque limiters (load limiters) are required to prevent cracking around the bolt holes and to distribute the load evenly. Torque limiters are inserted during assembly or are molded in place during gasket fabrication (Figure 30).

4.5 O-Rings

An O-Ring is a seal that is in the shape of a torus (doughnut) (Figure 31). It is made of an elastomer, polytetrafluoroethylene (PTFE), or another thermoplastic. It could be solid or hollow. It is used to seal fluids. In engine applications, it is usually used to seal fuel.

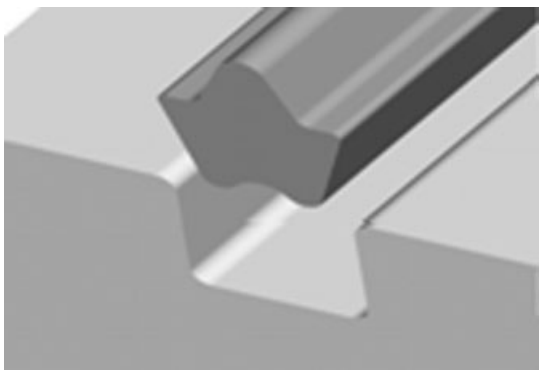

Figure 29. Elastomer molded gasket installation on a cast valve cover. (Compliments of Federal Mogul.)

Figure 30. Torque/load limiters inserted in a molded rubber gasket. (Compliments of Federal Mogul.)

When discussing O-Rings, one must consider the assembly, the O-Ring, and the gland. The gland is cut into one of the flanges and its dimensions are designed for proper function (Figure 32).

The O-Ring is subjected to two stresses: the clamping force, which is produced by the surrounding flanges, and the internal pressure, which is created by the fluid that is supposed to be sealed.

The elastomer is viscoelastic; it will compress little and it will deflect a lot, filling the groove and closing

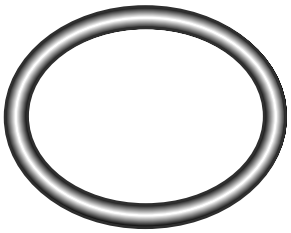

Figure 31. O-Ring.

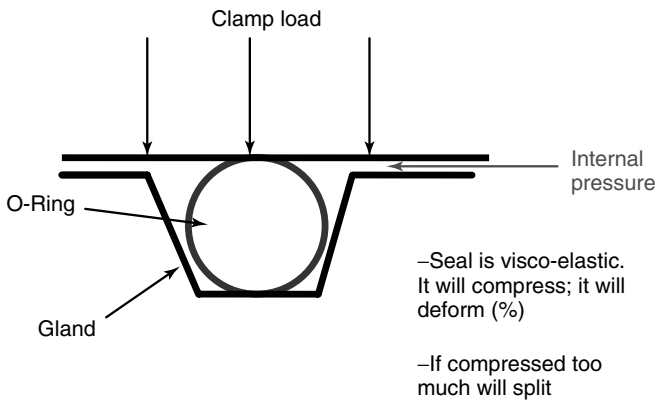

Figure 32. O-Ring and gland assembly.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

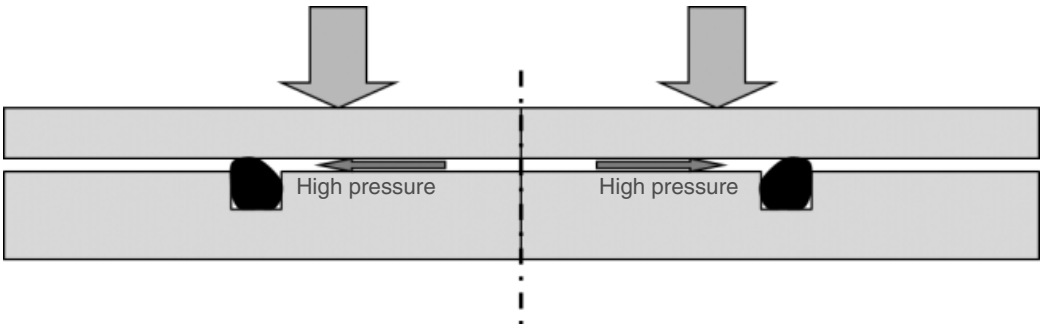

Figure 33. O-Ring deforms under high internal pressure.

any leak passage. If the internal pressure is high enough, the O-Ring will deform into the narrow gap between the flanges.

As the pressure increases, a small portion of the O-Ring may enter into the narrow gap as shown in Figure 33. This is actually the pressure limit of the O-Ring. If the pressure is high, in general above 100 bar, backup rings may be needed.

In static seal applications, the flanges are not subjected to movement relative to each other except by the fluid pressure, temperature changes, and vibration. The O-Rings are usually subjected to constant or pulsating internal pressure in one direction only. An example of a static seal application is sealing fuel lines.

Very important when determining the right O-Ring is to determine the compatibility between the O-Ring material and the fluid it seals. This is important especially today when there is a lot of research on synthetic fuels and oils for automotive and aerospace industries.

5 TEST METHODS

There are many tests used in industry for gasket materials and for design and development of gaskets: some of these tests are standardized under the American Society for Testing Materials (ASTM). Others are developed for a very specific purpose by the gasket manufacturer and usually are approved by the customer before being incorporated into a test program.

5.1 Gasket material tests and their importance

Table 1 shows some of the tests that are suggested and their reasons.

5.1.1 Sealability

Sealability is the most important property and the main reason we use gaskets. Many tests were developed by material and gasket companies for their own purpose, and

Table 1. Standard ASTM and typical tests perform on materials during the design and development of gaskets.

Property To Be Tested	Test Method	Importance and Significance
Sealability	ASTM F37	Resistance to fluid passage
Heat resistance	Exposure testing at elevated temperatures	Resistance to thermal degradation
Fluids compliance	ASTM F104 and F146	Compatibility to fluids
Antistick characteristics	Fixture testing ASTM F607 or as agreed with the customer	Ability to release from the flanges during disassembly
Stress versus compression, spring rates	Load frame testing	Determining loading/compression for sealing the different fluids
Compressibility and recovery	ASTM F36 (sheet) and ASTM F805 (composites)	Determine the stress–strain characteristics for proper load distribution
Creep relaxation and compression set	ASTM F38 and D395	Related to clamp load retention and subsequent loss of sealing
Crush and extrusion properties	Compression test using load frame machines	Verifying the resistance at high loading on gasket narrow areas at room and elevated temperatures

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

some of these tests were adopted by ASTM. The universal test procedure is ASTM F37. Test method A is restricted to liquid leakage measurement. Method B may be used for liquid as well as gas leakage measurement.

Both methods use test specimens, most of the time doughnut shaped, sandwiched, and compressed to a specific "clamp" load, between the surfaces of two smooth steel plates. Fluid pressure is applied to the center of the doughnut. Leakage rate is observed at the outside of the doughnut. More sophisticated test fixtures include pressure transducers to measure pressure decay as a measure of leakage rate.

During the development of a gasketed joint surface, profile of the steel plates may be changed to resemble the surface of the flanges used in the real application. This step is important as it may reduce problems during production start up.

5.1.2 Heat resistance

Some engine applications require high temperatures or high temperature gradients for prolonged periods of time. Thermal degradation of materials could result in leakage that, in some cases, could have catastrophic effects on engine operation. Sealing companies have developed proprietary test methods to evaluate the ability of gasket materials to perform under those conditions.

5.1.3 Antistick capabilities

Antistick capabilities are necessary for gasket removal during engine repairs. If the gasket material sticks to the flanges, scraping off the materials may cause damage to the mating flanges. More importantly, the combination of surface finish with aluminum flanges during heating and cooling cycles could produce a scraping effect on the gasket, resulting in gasket failure.

Various test methods have been developed to determine antistick properties of different materials under various environments. ASTM 607 provides a means of determining the degree to which the gasket material, under compressive load, adheres to metal surfaces. Other methods exist that could determine the friction coefficient under different clamp loads.

5.1.4 Stress versus strain

Stress versus strain, usually called *stress versus compression*, is important as adequate stress is required at various locations. Stress and compression of materials are performed in a load frame. One example of this test equipment is the Instron (Figure 34). It is mechanically

Figure 34. Instron with mechanical jaws set for tensile test. (Photo courtesy of Instron®.)

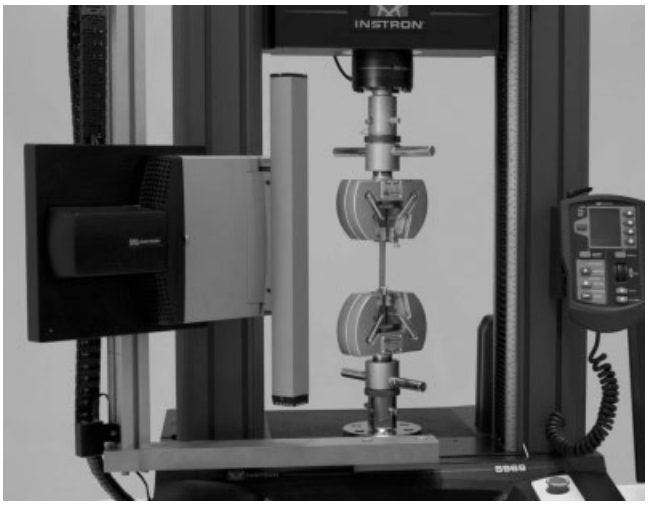

Figure 35. Environmental Chamber. (Photo courtesy of Instron®.)

actuated allowing for the compression or stretch of materials. Adding an environmental chamber, Figure 35 would make the instrument more versatile as it would give the capability of testing materials at different temperatures.

To improve the accuracy of the test, a strain gage is added to the system. As load is increased, strain is not influenced by machine deflection, but strain is measured directly as the material is deformed. This is shown in Figure 36.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

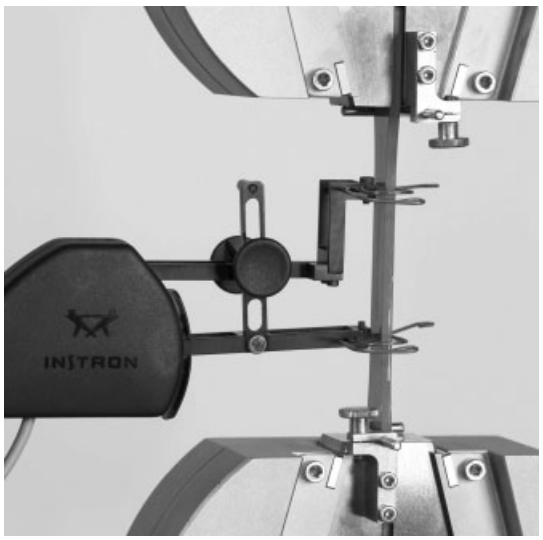

Figure 36. Strain Gage for improved accuracy of measuring the strain. (Photo courtesy of Instron®.)

5.1.5 *Compressibility and recovery*

The recovery is important because the gasket material has to follow flanges movement and deformation. The ASTM A36 test determines the short-time compressibility and recovery of gasket materials at room temperature. Its limitation comes from the fact that most materials' properties change in time. Long-term tests have to be added during the development to ensure gasket performance over the life of the application.

5.1.6 *Creep relaxation and compression set*

Creep relaxation and its relation to torque loss have been discussed earlier. ASTM F38 "Standard Test Method for Creep Relaxation of Gasket Material" is the standard test.

The compression set is determined by measuring a gasket thickness, clamping it in a fixture, subjecting the assembly to a specified temperature profile, disassembling the fixture, and measuring the recovered thickness of the material.

Compression thickness is calculated using the relationship:

$$\frac{T_o - T_f}{T_o} \times 100 = \text{Percent compression set} \qquad (1)$$

where T_o is the original thickness and T_f is the final thickness.

The compression set results in torque loss, thus resulting in stretch loss of the clamping bolts

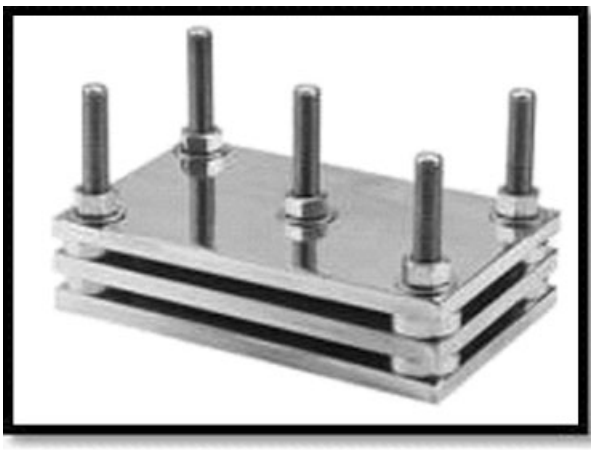

Figure 37. Split resistance fixture.

5.1.7 *Crush and extrusion resistance*

In some cases, certain locations on the gaskets may be subject to very high stresses that may create extrusion. An example may be the narrow area between two adjoining cylinders. Testing for such a phenomenon requires compression test machines and may require specially designed fixtures. One method for testing materials is shown in Figure 37. The test is accomplished using small-diameter steel wire to apply localized stress on materials. In addition, high temperature and sealed-medium conditions are simulated by presoaking the material and then heat soaking the material.

5.2 Gasket testing

Once the material's compatibility to the application and environmental conditions are verified, the designer determines gasket construction, dimensions, and shape. Prototype samples are made and gasket testing begins.

There are two types of testing that should be done:

- Bench testing
- Application or engine testing.

5.2.1 *Bench testing*

Bench testing uses components such as mating flanges along with the gasket, assembled and subjected to different tests to simulate application conditions. Bench testing should be performed ahead of engine tests to weed out gasket designs. Some of these tests are presented in the following sections.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.2.1.1 Steam tests. Steam tests are used to perform short-duration thermal cycles. Saturated steam and cold water are alternatively circulated through the cooling passages.

5.2.1.2 Vibration tests. Vibration tests are used to simulate actual unit vibration. Such tests are very useful for oil pan and transmission pan gaskets. The vibration table, or shaker, is equipped to load the assembly with specific programs of vibration frequency and amplitude. The unit can be installed in an environmental chamber where the temperature can simultaneously be cycled.

5.2.1.3 Oven test. Hot oven and environmental chambers are used to evaluate sealing performance of gaskets. Some environmental chambers are large enough to accommodate an entire engine and have cycling temperature capabilities from -40°C to 315°C. Environmental chambers are also used to study the effect of flange expansion and antistick capabilities of some coatings.

5.2.2 Application tests

5.2.2.1 Dynamometer test. Automotive and gasket companies have developed several dynamometer tests specifically to evaluate gaskets and seals. They are component driven; several tests were developed specifically for the cylinder head gasket. As an example is the "200-cycle deep thermal cycle" test, developed to evaluate designs under very severe temperature conditions. The coolant is cooled to -28°C and then the engine starts and runs until the temperature reaches 104°C. The engine then stops and coolant is cooled to -28°C. The cycle is designed for a duration of 30 min, and the test runs for 100 h. The most severe part of the test is when, during the heat up the thermostat opens and coolant at -28°C hits the hot gasket. At the end of the test, the combustion chamber is pressurized to 76 bar. It has to be maintained pressure for 10 min. The coolant system is pressurized to 8 bar. The pressure must be maintained for 10 min.

5.2.2.2 Vehicle testing. Vehicle testing is typically done by the automobile manufacturer. Some automotive companies select, statistically, vehicles as they come off the assembly line and form groups of vehicles (fleets). One fleet will be send to a warmer climate and one fleet to a colder climate. Those vehicles are usually leased for up to 160,000 km. As they are retrieved at the end of the lease, the vehicles are returned to the manufacturer and disassembled, and the parts are evaluated. Problem parts are returned to the suppliers and analyzed, and prog rams to improve and resolve issues are put in place.

6 NEW METHODS OF EVALUATING AND ANALYZING DESIGNS

6.1 Failure mode and effect analysis

Potential failure mode and effect analysis (FMEA) is a systemized group of activities intended to:

1. Recognize and evaluate potential failure modes and causes associated with the design and manufacturing of a product.
2. Identify the actions that could eliminate or reduce the chance of potential failure occurring.
3. Document the process. Determines ahead of time what a design must do.

Engineers used the FMEA since the post-World War II era of the 1950s. This era is known for rapid technological advances, but product reliability did not keep up with the advancing technology. At that time, it was primarily used in the aerospace industry (Figure 38).

The main elements are

- failure mode
- possible cause
- effect of failure
- design verification.

They are applied in the order shown in Figure 39.

Figure 38. Environmental chamber.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto040
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

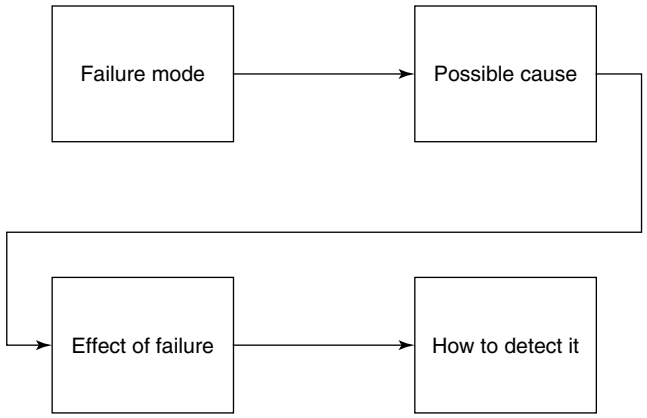

Figure 39. FMEA methodology.

In evaluating the elements, one needs to determine the risk of a failure. The risk is assessed as follows:

- severity
- occurrence
- probability of detection
- RPN—risk priority number.

For each potential failure, a risk number is associated with severity, occurrence, and probability of detection; by multiplying those numbers, an RPN is established. The team will work on the potential failure with the higher numbers.

For each potential failure, a test must be established that would verify the design. At the end of the process, the team tallies the entire test program. This becomes the Design Verification Process and Report (DVP&R), which is the test program to verify the design.

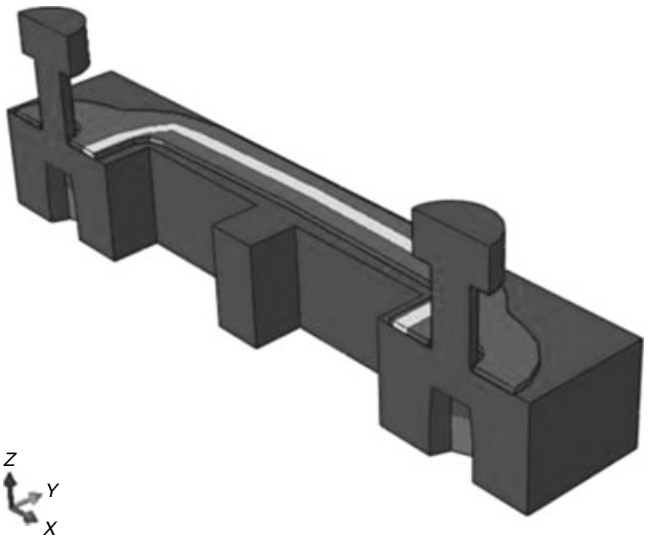

Figure 41. Gasket with the silicone bead represented by gray color. (Courtesy of SIMULIA.)

It is a systematic approach very useful, if it is done right, for younger, less experienced engineers, and designers. It is also useful when new approaches, materials, or designs are being developed, and there is little or no previous experience. FMEA is used for manufacturing processes as well.

6.2 Finite element analysis

During the design process, many alternative designs and options are identified. Testing all those designs is expensive and time-consuming. As competition pushes us to develop products in record time, new methods of analyzing designs and reducing the number of design iterations are needed.

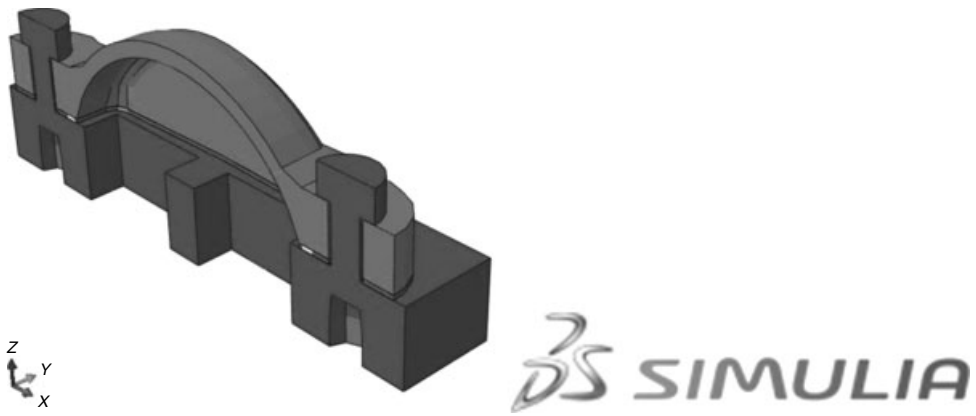

Figure 40. Modeling coolant assemblage with a gasket sandwiched. (Courtesy of SIMULIA.)

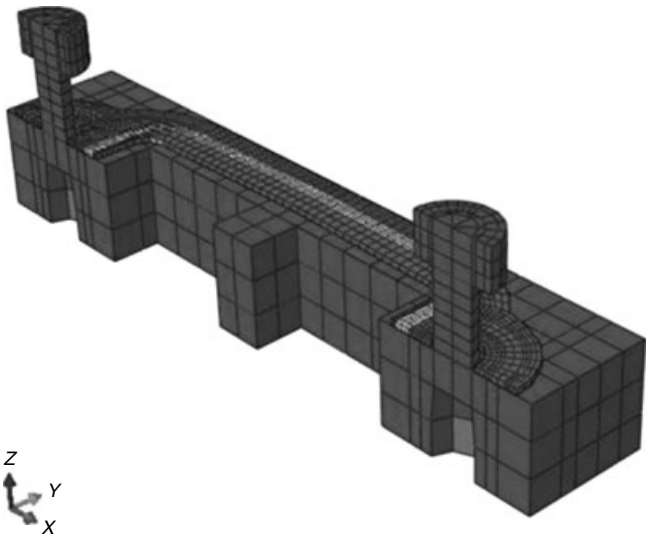

Figure 42. Gasket modeled with the gasket elements. (Courtesy of SIMULIA.)

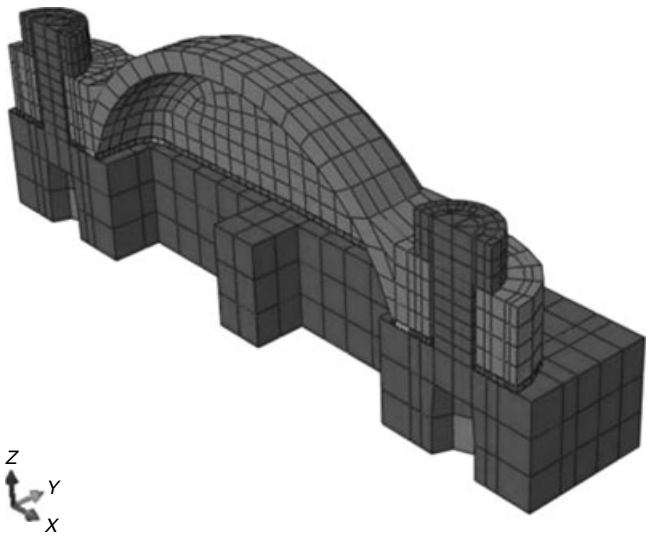

Figure 43. Finite element mesh of the model and the gasket elements. (Courtesy of SIMULIA.)

FEA can help reduce the number of designs by simulating the gasket design and understanding interactions with the mating parts. Designs and materials can be changed in the model so design ideas can be screened without necessitating making real parts and testing them.

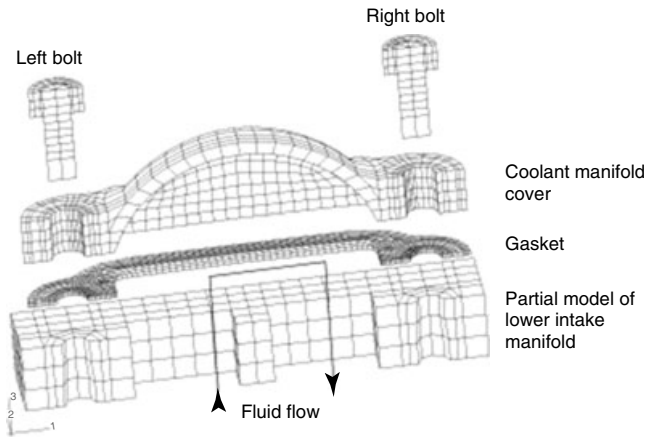

Figure 45. Coolant manifold assemblage. (Courtesy of SIMULIA.)

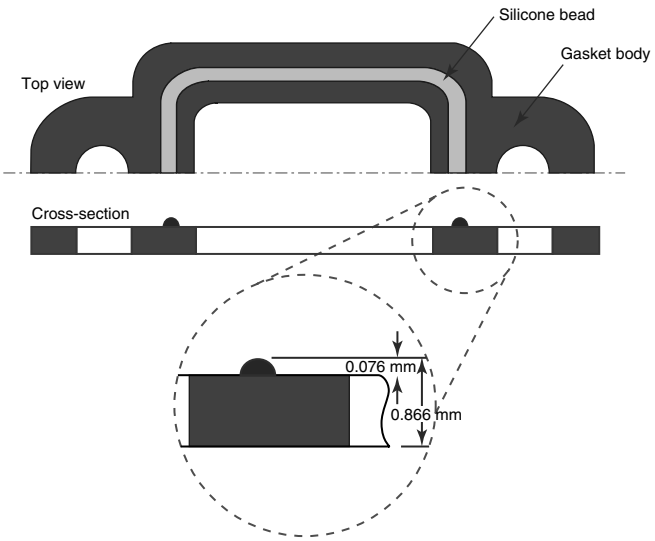

Figure 46. Schematic representation of a silicone bead indicated. (Courtesy of SIMULIA.)

The following is an example of an FEA application to coolant gasket modeling.

The gasket has to seal coolant in an assembly shown in Figure 40. Because the distance between the bolts is large, a flat gasket may not be able to seal in the center region. Therefore, the designer proposed a silicone bead to be added to the gasket as shown in Figure 41. The objective

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 47. Contact pressure after the initial fastening. (Courtesy of SIMULIA.)

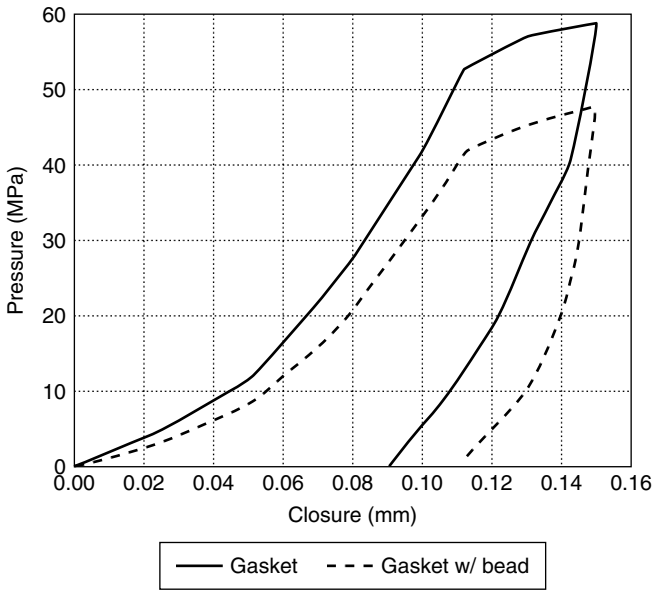

Figure 48. Pressure versus closure behavior for the gasket and gasket with silicone bead. (Courtesy of SIMULIA.)

was to determine the dimensions for the silicone bead and the thickness of the lower flange.

After the model was created, the next step was to create the mesh of the components (Figure 42) and the mesh of the assembly (Figures 43 and 44). Figure 45 shows the passage of coolant through the assembly and the area that needs to be sealed. As the design iterations progress, the bead height is developed and the height is established as shown in Figure 46.

The bead height is tested by simulating the assembly during initial fastening (Figure 47). Loading is represented by color, with higher loading represented by red and lower loading by blue.

Figure 48 shows the loading required to seal with and without the silicone bead. It is clear that adding the silicone bead reduces the required load and therefore reduces bending thus improving sealing. The bead had a recovery capability built into the structure and was expected to perform better than the gasket only design.

The FEA model should be tested under bench test to prove its validity. Companies developing FEA software are maturing in the industry. Special attention must be taken when choosing the software to run FEA because, as discussed earlier, besides the materials' stress–strain curves that could be generated easily today, one must consider the time-dependent nature of these materials. This is not easily simulated by all of the software programs that are in the market today.

General Requirement of Traction Motor Drives

Ming Cheng[1] and C.C. Chan[2]

[1]*Southeast University, Nanjing,China*
[2]*The University of Hong Kong, Pokfulam, Hong Kong*

1 INTRODUCTION

The traction motor drive is the heart of electric vehicles (EVs). Its role is to convert electric energy to mechanical energy or vice versa, thus to interface energy source (such as batteries) with vehicle wheels. In motor mode, the electrical energy from the battery is converted to mechanical energy such that the vehicle overcomes aerodynamic drag, rolling resistance drag, and inertia resistance. In generator mode, it converts mechanical energy to electrical energy such that the kinetic energy released during vehicle deceleration is converted to electrical energy to charge the battery. Hence, the electric motor drive is the core technology for electric, hybrid, and fuel cell vehicles.

It should be emphasized that traction motors are different from traditional industrial motors due to the fact that traction motors usually require frequent start/stop, high rate of acceleration/deceleration, high torque low speed hill climbing, low torque high speed cruising, and very wide-speed range of operation, whereas industrial motors are generally optimized at the rated conditions. Thus, traction motors are so unique that they are deserved to form an individual class. Hence, the general requirements of traction motor are significantly different from those of industrial motors. Their major differences in load requirement, performance specification, and operating environment are as follows (Chan and Chau, 2001; Chau, Chan, and Liu, 2008; Zhu and Howe, 2007):

- Traction motors need to offer four to five times the rated torque for temporary acceleration and hill climbing, whereas industrial motors generally offer twice the rated torque for overload operation.
- Traction motors need to achieve four to five times the base speed for highway cruising, whereas industrial motors generally achieve up to twice the base speed for constant-power operation, where the base speed is the speed at which the motor delivers the rated torque with the rated voltage.
- Traction motors should be designed according to the vehicle driving profiles and drivers' habits, whereas industrial motors are usually based on a typical working mode.
- Traction motors demand both high power density and good efficiency map (high efficiency over wide speed and torque ranges) for the reduction of total vehicle weight and the extension of driving range, whereas industrial motors generally need a compromise among power density, efficiency, and cost with the efficiency optimized at a rated operating point.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

- Traction motors desire high controllability, high steady-state accuracy, and good dynamic performance for multiple-motor coordination, whereas only special-purpose industrial motors desire such performance.
- Traction motors need to be installed in mobile vehicles with harsh operating conditions such as high temperature, bad weather, and frequent vibration, whereas industrial motors are generally located in fixed places.

Thus, the general requirements of the traction motor drives can be summarized as follows:

1. high torque density and power density;
2. very wide speed range, including constant-torque and constant-power regions;
3. high efficiency over wide torque and speed ranges;
4. high torque for low speed starting and climbing and high power for high speed cruising;
5. fast torque response;
6. multiquadrant operation ability, including forward motoring, forward braking, backward motoring, and backward braking;
7. high reliability and robustness for vehicular environment;
8. low acoustic noise;
9. reasonable cost.

From the functional point of view, a traction motor drive can be divided into two parts—electrical and mechanical. The electrical part consists of the subsystems of motor, power converter, and electronic controller, whereas the mechanical part includes the subsystems of mechanical transmission (optional) and vehicle wheels. The boundary between the electrical and mechanical parts is the air-gap of the motor, where electromechanical energy conversion takes place. The power converter supplies the motors with proper voltage and current and regulates the power flow between the energy source and the electric motor for motoring and regeneration. The electronic controller commands the power converter by providing control signals to it, and then controls the operation of the electric motor to produce proper torque and speed, according to the command from the driver. The electronic controller can be further divided into three functional units—sensor, interface circuitry, and processor. The sensor is used to translate the measurable quantities, such as current, voltage, temperature, speed, torque, and flux, into electronic signals through the interface circuitry. These signals are conditioned to the appropriate level so as to be fed into the processor. The processor output signals are usually amplified via the interface circuitry to drive power semiconductor devices of the power converter. The functional block diagram of a traction motor drive is shown in Figure 1.

2 CLASSIFICATION

As illustrated in Figure 2, those traction motors applicable to EVs can be classified into two main groups, namely the brushed motors and the brushless motors. The former simply denote that they generally consist of the commutator and brushes, mainly traditional DC (direct current) motors, whereas the latter have no brushes.

2.1 DC motor

Traditionally, DC brushed motors have been loosely named as DC motors. There are typically four types of wound-field DC motors, depending on the mutual interconnection between the field and armature windings, namely separately excited, shunt excited, series excited, and compound excited. By replacing the field winding of DC motors with permanent magnet (PM), PM DC motors are generated, which permit a considerable reduction in stator diameter due to the efficient use of radial space and an increase in motor efficiency due to the elimination of the copper loss in field windings. Owing to the low permeability of PMs, armature reaction is usually reduced and commutation is improved. The control principle of DC motor is simple because of the orthogonal disposition of field and armature magnetomotive forces (mmfs).

However, the principle problem of DC motors, due to their commutators and brushes, makes them less reliable and unsuitable for maintenance-free operation and high speed. In addition, winding-excited DC motors have low specific power density. Nevertheless, because of their ability to achieve high torque at low speeds and because they are easy to control, DC motors have ever been prominent in the electric propulsion system. Actually, various types of DC motors, including series, shunt, separately excited, and PM excited, have ever been adopted by EVs.

Recently, technological developments have pushed brushless motors to a new era, which offer the advantages of higher efficiency, higher power density, lower operating cost, increased reliability, and being maintenance-free over DC brushed motors. Thus, brushless motors have now become more attractive in traction motor drive for EVs.

2.2 Induction motor

The induction motor (IM) is a widely accepted brushless motor for EV application because of its robust structure, low cost, high reliability, high efficiency, and free from maintenance as compared with the DC motor drive. There are two types of IMs, namely, wound-rotor and squirrel-cage motors. Because of the high cost, need for maintenance, and lack of sturdiness, wound-rotor IMs are less attractive than their squirrel-cage counterparts, especially for electric propulsion in EVs. Hence, the most common types of rotors for IM are the squirrel cage in which aluminum bars are cast into slots in the outer periphery of the rotor. The aluminum bars are short-circuited together at both ends of the rotor by cast aluminum end rings, which also can be shaped as fans. Figure 3 shows the cross section of an IM.

An inverter is used to control the motor so that the desired torque can be delivered for a given driving condition at a certain speed. Advanced control methodologies, such as field-oriented control (FOC) or vector control and direct torque control (DTC), are popular in IM control for traction applications.

The main advantages of IM include:

1. Robust structure and relatively low cost;
2. Light weight, small volume, and high efficiency.

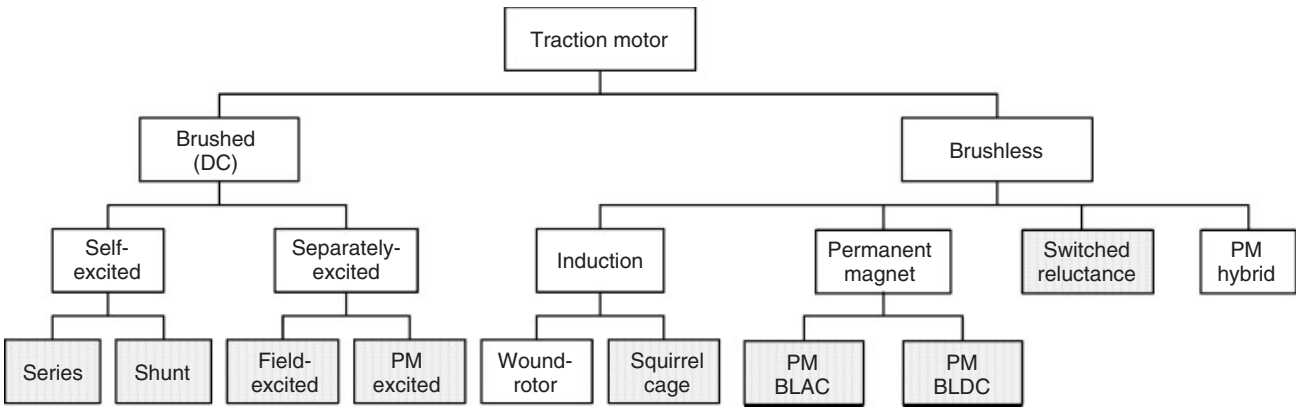

Figure 2. Classification of traction motors.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

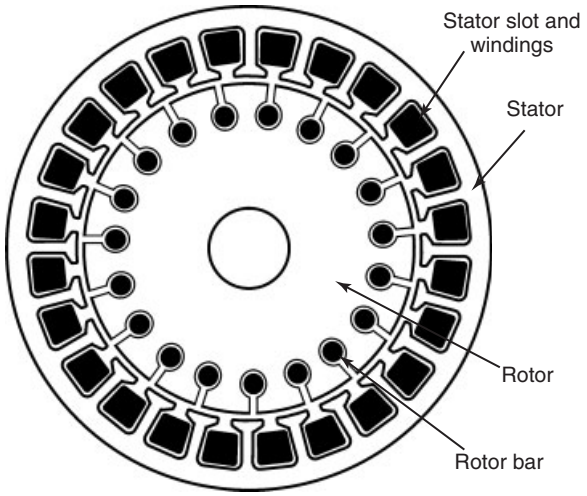

Figure 3. Induction motor with squirrel cage.

The disadvantages include:

1. The limited constant-power range (only 2–3 times the base speed);
2. Relatively difficult control schemes due to the variable equivalent parameters.

2.3 Permanent magnet brushless motor

Permanent magnet brushless motors (PMBLMs) include sinusoidal and trapezoidal back electromotive force (EMF) machines. From control point of view, they are divided into brushless direct current (BLDC) and brushless alternate current (BLAC) motors. Generally, a trapezoidal back EMF waveform in BLDC or a sinusoidal back EMF waveform in BLAC is needed so as to achieve high torque density and low torque pulsation. The PM BLAC motor with sinusoidal back EMF is also called *PM synchronous motor*. As they are essentially synchronous motors, the PM BLAC motor can run from a sinusoidal or pulse width modulation (PWM) supply without electronic commutation.

When PMs are mounted on the rotor surface, they behave as non-salient synchronous motors because the permeability of PMs is similar to that of air. By burying those PMs inside the magnetic circuit of the rotor, the saliency causes an additional reluctance torque, which leads to facilitating a wider speed range at constant-power operation. Figure 4 illustrates the typical topologies of the PM brushless motors. Similar to IMs, those PM synchronous motors usually employ FOC or DTC for high performance applications. Because of their inherent high power density and high efficiency, the PM motors are the choices for traction motor drives in EV applications.

The PM BLDC motors are fed by rectangular alternate current (AC) and hence are also called *rectangular-fed PM brushless motors*. The most obvious advantage of these motors is the removal of brushes, leading to elimination of many problems associated with brushes. The PM BLDC motor has surface-mounted magnets on the rotor and a concentrated fractional stator winding, which results in a low copper loss. Different from PM synchronous motors, these PM BLDC motors generally operate with shaft position sensors. Recently, sensorless control technologies have been developed.

The main advantages of PM brushless motors are:

1. Light weight, small volume, and high power density as the magnetic field is excited by high energy PMs.
2. High efficiency and high reliability.

The main disadvantages include:

1. Comparatively narrow range of constant-power operation due to the difficulty in weakening the air-gap flux. By using some new schemes, the speed range can reach three times the base speed. However, the PM may suffer from demagnetization and possible fault.
2. Relatively high cost due to PM materials, especially in high power application.

It should be emphasized that all the PM machines mentioned above have the magnets located in the rotor and are referred to as *rotor-PM machines*, which are predominated in EV applications due to their outstanding advantages. However, the magnets usually need to be protected from the centrifugal force by employing a retaining sleeve made of either stainless steel or non-metallic fiber. The rotor temperature rise may be a problem due to poor thermal dissipation, which may cause irreversible demagnetization of magnets and ultimately limit the power density of the machine. Recently, in contrast, a new type of PM machines having magnets in stator, referred to as *stator-PM machines*, have reemerged and developed, which can overcome the problems suffered by rotor-PM counterparts (Cheng *et al.*, 2011). Conceptually, the stator-PM machines employ the polarized reluctance principle, in which the torque and EMFs are resultant from the flux-switching action of rotor saliencies on a unipolar flux produced by PMs in the stator. As there are no PMs or windings in rotor, these stator-PM machines are mechanically simple and robust, hence suitable for high speed operation. Compared with conventional rotor-PM brushless machine topologies, generally, it is easier to limit the temperature rise of the magnets as heat is dissipated more effectively from the stator. According to the location of the PMs in stator, they can be classified as the

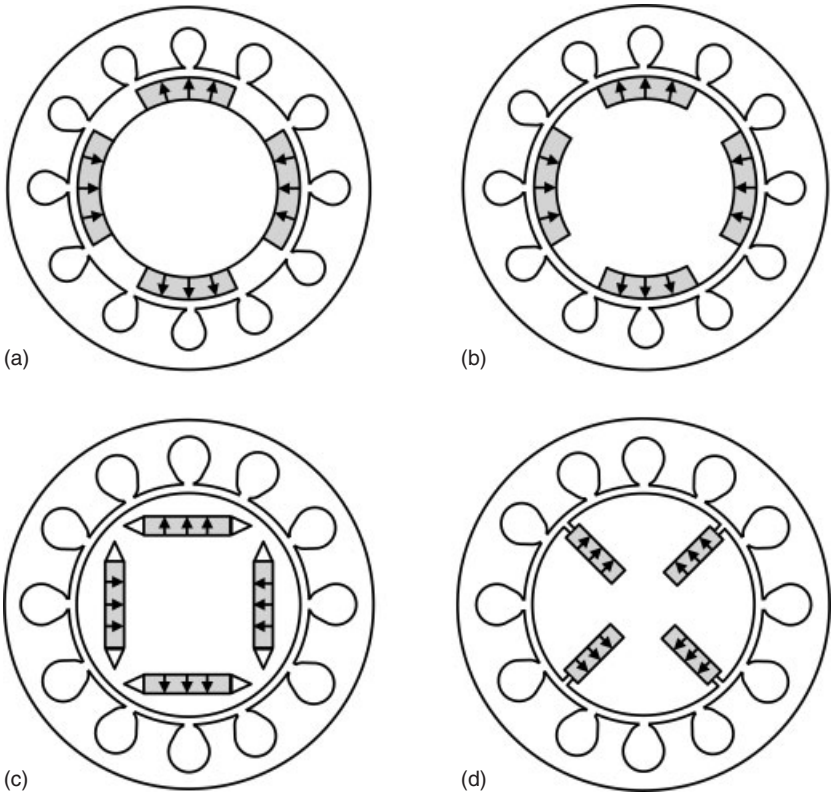

Figure 4. Typical topologies of PM brushless motors. (a) Surface mounted; (b) surface inset; (c) interior radial; (d) interior circumferential.

doubly salient permanent magnet (DSPM) machine (Liao, Liang, and Lipo, 1995; Cheng, Chau, and Chan, 2001), flux-reversal permanent magnet (FRPM) machine (Deodhar *et al*., 1996), and flux-switching permanent magnet (FSPM) machine (Hoang, Ben-Ahmed, and Lucidarme, 1997). They have been recognized to have considerable potential for EV applications.

1. *Doubly Salient PM Machine*. In this DSPM machine, the PMs are located in stator back-iron. Figure 5 shows a 12/8-pole DSPM machine topology (with 12 stator poles and 8 rotor poles). The variation of the flux linkage with each coil as the rotor rotates is unipolar, while the back EMF waveform tends to be trapezoidal. Thus, this topology is more suitable for

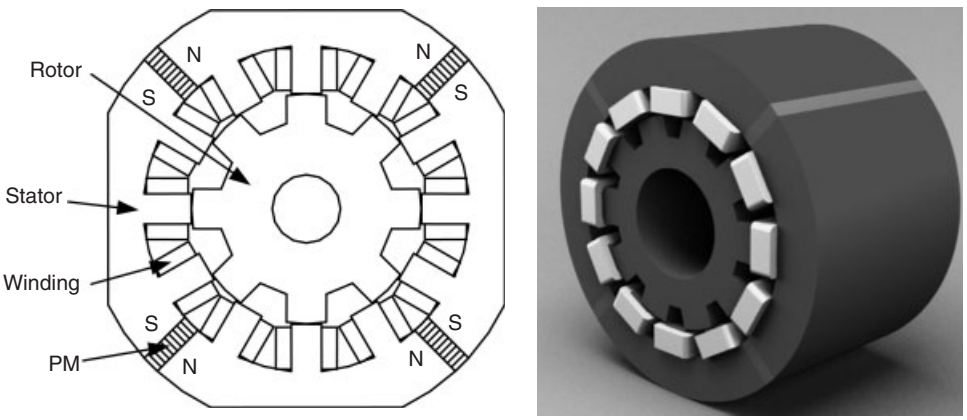

Figure 5. 12/8-pole DSPM machine.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

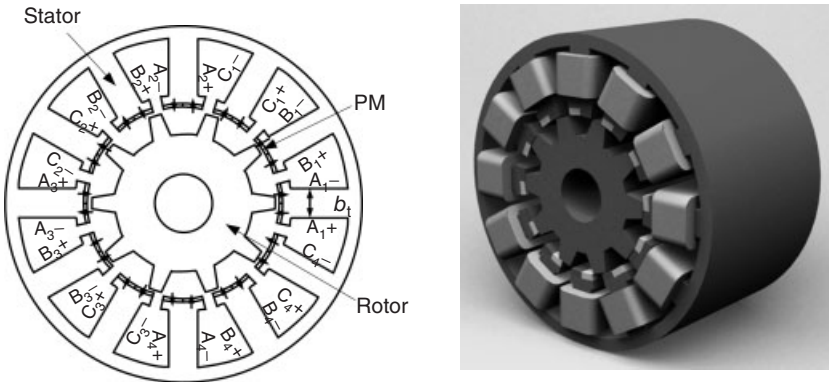

Figure 6. FRPM machine.

BLDC operation. However, a major disadvantage of the DSPM motor is relatively low torque density as compared to that of other PM brushless machines.

2. *Flux-Reversal PM Machine*. The FRPM machine has the magnets located on the surface of stator teeth and concentrated windings. Figure 6 illustrates a 12/10-pole FRPM machine topology. Each stator tooth has a pair of magnets of different polarity mounted at its surface. When a coil is excited, the field under one magnet is reduced while that under the other is increased, and the salient rotor pole rotates toward the stronger magnetic field. The flux linkage with each coil reverses polarity as the rotor rotates. Thus, the phase flux linkage variation is bipolar, whereas the phase back EMF waveform is, again, essentially trapezoidal. Thus, it is also suitable for BLDC operation mode. Additionally, the FRPM machine offers fault-tolerance capability due to its natural isolation between the phases. Such a machine topology exhibits a low winding inductance, while the magnets are more vulnerable to partial irreversible demagnetization. In addition, significant eddy current loss may be induced in the magnets, which also experience a significant radial magnetic force. Furthermore, as the air-gap flux density is limited by the magnet remanence, the torque density may be compromised.
3. *Flux-Switching PM Machine*. In this FSPM machine, the stator consists of U-shaped laminated segments between which circumferentially magnetized PMs are sandwiched, while the direction of magnetization is being reversed from one magnet to the next. Figure 7 shows a 12/10-pole FSPM machine topology. Each stator tooth consists of two adjacent laminated segments and a PM. Thus, flux-concentration can be readily incorporated, so that low cost ferrite magnets can be employed (Zhu and Howe, 2007). In addition, in contrast to conventional PM brushless machines, the influence of the armature reaction field on the working point of the magnets is minimal. As a consequence, the electric loading of FSPM machines can be very

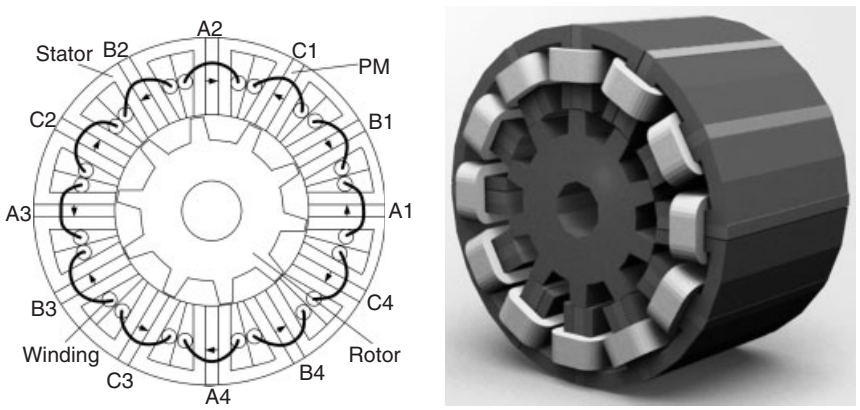

Figure 7. FSPM machine.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

high. Therefore, as the phase flux linkage waveform is bipolar, the torque capability is significantly higher than that of a DSPM machine (Hua *et al*., 2005). Due to the reluctance difference between the two pairs of coils composing a phase, the resultant phase EMF waveforms are essentially sinusoidal without any additional measures (Hua *et al*., 2007), making them more appropriate for BLAC operation. In addition, as a high per unit winding inductance can readily be achieved, such machines are eminently suitable for constant-power operation over a wide speed range.

2.4 PM hybrid motor

Although the PM brushless motors possess the highest efficiency and power density over the others, they suffer from a difficulty in flux control. Hence, the current phase angle has to be progressively advanced as the speed is increased above the base speed so that a demagnetizing d-axis current component is produced which reduces the flux linkage. Ultimately, however, this may cause partial irreversible demagnetization of the magnets. At the same time, due to the inverter voltage and current limits, the torque-producing q-axis current component has to be reduced correspondingly. Consequently, the torque and power capabilities are limited (Zhu and Howe, 2007). Thus, a compromise has to be made between the low speed torque capability and high speed power capability. Hybrid PM and field current excitation has been shown to be beneficial in improving the power capability in the extended speed range, enhancing the low speed torque capability, and improving the overall operational efficiency. Figure 8 shows PM hybrid motors with rotary and stationary PMs, respectively (Chan *et al*., 1996; Zhu and Cheng, 2010). The PM hybrid motor is a special type of PM brushless motors. In this motor, an auxiliary DC field winding is so incorporated that the air-gap flux is a resultant of the PM flux and field-winding flux. These PM hybrid motors offer many attractive features due to the presence of the hybrid field:

1. By changing the polarity and magnitude of the DC field current, the air-gap flux density can be easily controlled.
2. By realizing flux strengthening, the machine can offer the exceptionally high torque, which is very essential for cold cranking HEVs (hybrid electric vehicles) or providing temporary power for vehicular overtaking and hill climbing.

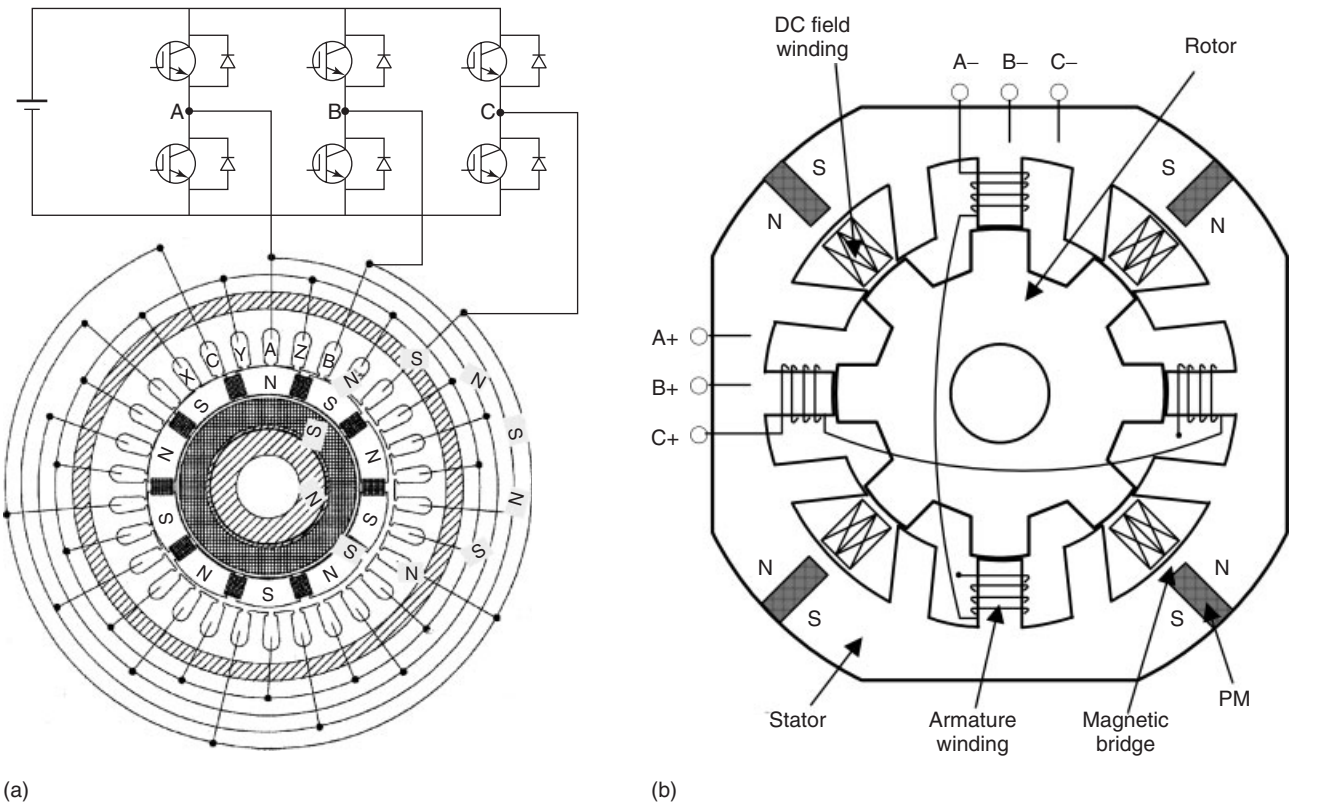

Figure 8. Hybrid PM machine. (a) Rotary PMs; (b) stationary PMs.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3. By realizing flux weakening, the machine can offer the exceptionally wide-speed constant-power range, which is very essential for EV cruising.
4. By online tuning the air-gap flux density, the machine can maintain a constant voltage output under generation or regeneration over a very wide speed range, which is very essential for battery charging of various EVs.
5. By online tuning the air-gap flux density, the machine can also offer efficiency optimizing control (EOC), which is highly desirable for EVs.

2.5 Switched reluctance motor

The switched reluctance (SR) motors have been recognized to have considerable potential for EV applications. They have the definite advantages of simple construction, low manufacturing cost, inherent fault tolerance, and outstanding torque-speed characteristics for EV propulsion. Figure 9 shows the schematic of an 8/6-pole SR motor. Although they are simple in structure, it does not imply any simplicity of their design and control. Because of the heavy saturation of pole tips and the fringe effect of poles and slots, their design and control are difficult and subtle. Moreover, they usually exhibit relatively high acoustic noise, vibration, and torque ripple problems. Traditionally, the SR motors operate with shaft sensors to detect the relative position of the rotor to the stator. These sensors are usually vulnerable to mechanical shock and sensitive to temperature and dust, and thus reduce the reliability of the SR motors and constrain some applications. Recently, sensorless technologies have been developed for the SR motors.

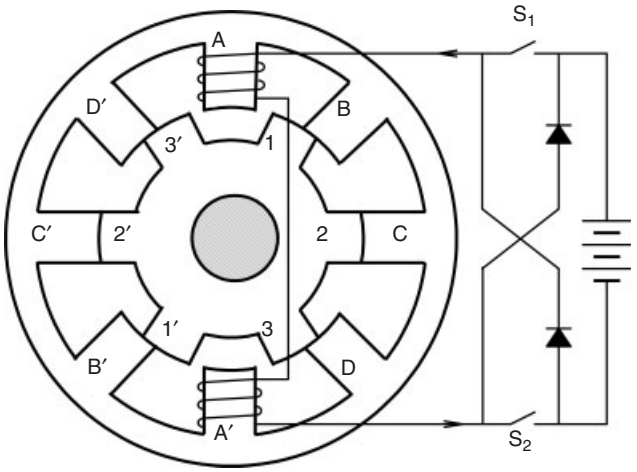

Figure 9. Basic structure of switched reluctance motor drive (only one phase winding shown).

Table 1. Applications of traction motors in EVs.

Honda Civic	PM BLDC motor

The motor types that have ever been adopted by recent EVs are indicated by shaded blocks in Figure 2. Table 1 also illustrates their recent applications in EVs.

In order to evaluate the aforementioned traction motor types, a point grading system is adopted. The grading system consists of six major characteristics and each of them is graded from 1 to 5 points. As listed in Table 2, this evaluation indicates that IMs and PM brushless motors are relatively most acceptable. When the cost of PM material has significant improvements, the PM brushless (including AC or DC) motors will be most attractive. Conventional DC motors seem to be losing their competitive edges, whereas both SR and PM hybrid motors have increasing potentials for EV propulsion.

3 DESIGN CONSIDERATION OF TRACTION MOTOR

3.1 Basic consideration

The basic consideration of motor design includes magnetic loading—the peak of fundamental component of radial flux density in the air-gap of the motor, and electric loading—the total rms current per unit length of periphery of the motor or ampere-turns per unit periphery; power per unit volume and weight; torque per unit volume and weight; flux density at each part of the magnetic circuit; speed, torque, and power; losses and efficiency; and thermal design and cooling.

The corresponding key issues are better utilization of steel, magnet, and copper; better electromagnetic coupling between stator and rotor; better geometry and topology; better thermal design and cooling; understanding the limits on the motor performance; and understanding the

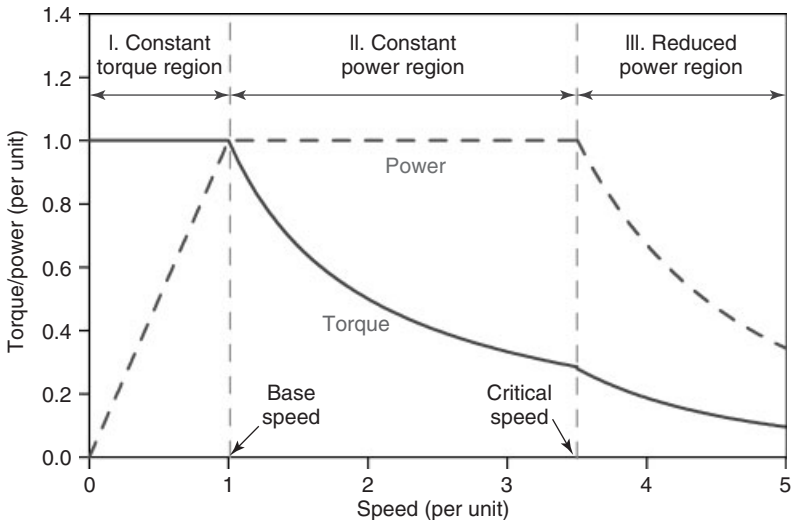

Figure 10. Ideal torque/power-speed characteristics of traction motor.

relationship among geometry, dimensions, parameters, and performance, thus to achieve higher power per unit weight, higher torque per unit weight, and better performance.

Traction motor drives for EVs should be designed, as close as possible, to the ideal torque/power-speed characteristics as shown in Figure 10. In the constant-torque region I, the maximum torque capability is determined by the current rating of the inverter, while in the constant-power region II, flux-weakening or commutation phase advance has to be employed due to the inverter voltage and current limits. In region III, the torque and power are reduced due to the increasing influence of the back EMF.

3.1.1 Sizing equation

The first important task in the design of a traction motor is to calculate the size of the motor. In the following, a PM motor will be taken as an example to illustrate the key points of design.

Neglecting the stator resistance, the input power of a PM motor can be expressed as

$$P_1 = mIV\cos\varphi = mIE_0\cos\delta \tag{1}$$

where φ is the power factor angle and δ is the inner power angle (the angle between the back EMF and the current). In addition, the back EMF can be expressed as

$$E_0 = \sqrt{2}\pi f K_w W \Phi \tag{2}$$

where W is the number of winding turns in series per phase, Φ is the total air-gap flux per pole, and K_w is the winding factor. Substituting Equation 2 into Equation 1 yields

$$P_1 = mE_0 I\cos\delta = mI\cos\delta\cdot\sqrt{2}\pi f K_w W\Phi \tag{3}$$

The output power of the traction motor can be obtained by multiplying the input power with efficiency η,

$$P = \eta P_1 = \sqrt{2}\pi\eta m f K_w W I\Phi\cos\delta \tag{4}$$

The electric loading (or linear current density along the inner stator surface) is A (A/m) and the inner diameter of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the stator is D. Then

$$2mWI = \pi DA \tag{5}$$

The total flux per pole can be expressed in terms of air-gap flux density B:

$$\Phi = \frac{\pi Dl}{2p} B\alpha \tag{6}$$

where p is the number of pole pairs, l is the stack length of the stator, α is the pole arc factor which equals to the ratio of pole enclosure to the pole pitch, and B is the air-gap flux density. To achieve the maximum power, the inner power angle δ can be set to 0. Substituting Equations 5, 6 and $f = pn/60$ into Equation 4 yields

$$P = m\eta \frac{\pi DA}{2mW} \sqrt{2}\pi K_w \frac{pn}{60} W \frac{\pi Dl}{2p} B\alpha \tag{7}$$

Therefore, the sizing equation for PM motors can be obtained as

$$D^2 l = \frac{60}{\sqrt{2}\pi^3} \frac{4}{\alpha\eta K_w} \frac{P}{AB} \frac{1}{n} \tag{8}$$

For other type of traction motors, similar sizing equation can be derived. As K_w, A, and B are in a relatively narrow range for all types of motors, Equation 8 shows that the effective volume of a motor is proportional to power P and inversely proportional to speed n. Considering that $P = \frac{2\pi n}{60} T$, we have

$$D^2 l \propto \frac{P}{n} \propto T \tag{9}$$

where T is the torque. In other words, the size of an electric motor is proportional to its torque rating.

3.1.2 *Selection of A and B*

In Equation 8, both A and B are experience-based selections. The magnetic loading B shows the utilization of magnetic material (silicon steel) and its value is limited by the magnetic saturation in teeth and yoke and the iron loss. A higher B means less magnetic material but higher magnetic losses. The electric loading A shows utilization of electric material (copper or aluminum). A higher A means less copper material but higher electric losses. Ambient temperature, operating frequency, and cooling method can impact the selection of A and B (Mi, Masrur, and Gao, 2011).

Typical range for A is 10 kA/m for small air-cooled motors, and up to 100 kA/m for liquid-cooled motors. The typical range for B is about 0.4 T for small motors, and up to 1.2 T for high density motors. Generally, large motors will have larger values of A and B.

3.1.3 *Speed rating of the traction motor*

It can be seen from Equation 9 that the motor volume is inversely proportional to rotor speed. Hence, a higher speed rating means a smaller motor size. However, a higher speed means a higher operating frequency, which results in more magnetic losses (eddy current and hysteresis losses). Smaller values of A and B may be necessary to limit the loss in high speed motors. For example, a four-pole 1500 r/min motor operates at 50 Hz, but a four-pole 15000 r/min motor operates at 500 Hz. As eddy current loss is proportional to f^2, and hysteresis loss is proportional to f^α $(1 < \alpha < 2)$, if the same magnetic flux density is chosen for the two motors, then the losses in the high speed motor will be many times that of the low speed one even if the size of the high speed motor is much smaller. This is because the eddy current loss increases 100 times, but size ($D^2 l$) reduces by only factor of 10 (Mi, Masrur, and Gao, 2011).

3.2 System consideration

Electrical machine design cannot be undertaken in isolation, but must account for the control strategy and the application requirements. Hence, a system-level design approach is essential for traction motors.

Vehicle operation consists of three main segments. They are (i) the initial acceleration; (ii) cruising at vehicle rated speed; and (iii) cruising at the maximum speed. These three operations set the basic design constraints for the EV and HEV drivetrain.

Apart from satisfying the aforementioned special requirements, the design of traction motors also depends on the system technology of EVs. From the technological point of view, the following key issues should be considered (Chan and Chau, 2001):

1. *Single- or Multiple-Motor Configurations*. One adopts a single motor to propel the driving wheels, while another uses multiple motors permanently coupled to individual driving wheels. The single-motor configuration has the merit of using only one motor with the minimum corresponding size, weight, and cost. On the other hand, the multiple-motor configuration takes the advantages of reducing the current/power ratings of individual motors and evenly distributes the total motor size and weight. Moreover, the multiple-motor one needs additional precaution to allow for fault tolerance

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

during the electronic differential action. The comparison between single- and dual-motor configurations is listed in Table 3. As these two configurations have their merits, both of them have been employed by modern EVs. For examples, the single-motor configuration has been adopted in the GM EV1, whereas the dual-motor configuration has been adopted in the NIES Luciole.

2. *Fixed- or Variable-Gearing Transmissions*. It is also classified as single-speed and multiple-speed transmissions. The former adopts single-speed fixed gearing, while the latter uses multiple-speed variable gearing together with the gearbox and clutch. On the basis of the fixed-gearing transmission, the motor should be so designed that it can provide both high instantaneous torque (3–5 times the rated value) in the constant-torque region and high operating speed (3–5 times the base speed) in the constant-power region. On the other hand, the variable-gearing transmission provides the advantage of using conventional motors to achieve high starting torque at low gear and high cruising speed at high gear. However, there are many drawbacks on the use of variable gearing such as the heavy weight, bulky size, high cost, less reliable, and more complex. Table 4 gives a comparison of fixed-gearing and variable-gearing transmissions (Chan and Chau, 2001). Currently, almost all the modern EVs adopt fixed-gearing transmission.
3. *Geared or Gearless*. The use of fixed-speed gearing with a high gear ratio allows traction motors to be designed for high speed operation, resulting in high power density. The maximum speed is limited by the friction and windage losses as well as the tolerance of drive axle. On the other hand, traction motors can directly drive the transmission axles or adopt the in-wheel drive without using any gearing (gearless operation). However, it results in the use of low speed outer-rotor motors, which generally suffer from relatively low power density. The breakeven point is whether this increase in motor size and weight can be outweighed by the reduction of gearing. Otherwise, the additional size and weight will cause suspension problems in EVs. Both of them have been employed by modern EVs. For examples, the high speed geared inner-rotor in-wheel motor has been adopted in the NIES Luciole while the low speed gearless outer-rotor in-wheel motor was adopted in the TEPCO IZA. Nevertheless, with the advent of compact planetary gearing, the use of high speed planetary-geared in-wheel motors is becoming more attractive than the use of low speed gearless in-wheel motors.
4. *System Voltage*. The design of traction motors is greatly influenced by the voltage level of the EV system. Reasonable high voltage motor design can be adopted to reduce the cost and size of inverters. As different types of EVs adopt different system voltage levels, the design of traction motors needs to cater for different EVs. Roughly, the system voltage is governed by the battery weight that is about 30% of the total vehicle weight. In practice, higher power motors adopt higher voltage levels. For examples, the GM EV1 adopts the 312 V voltage level for its 102 kW motor, the Reva EV adopts the 48 V voltage level for its 13 kW motor, whereas Nissan Leaf adopts 360 V voltage level for its 80 kW motor.
5. *Integration*. The integration of the motor with the converter, controller, transmission, and energy source is prime, important consideration. The traction motor designer should fully understand the characters of these components, thus to design the motor under these given environments. It is quite different from the normal standard motors under standard power source for normal industrial drives.

Table 3. Comparison of single- and dual-motor configurations.

	Single-Motor	Dual-Motor
Cost	Lower	Higher
Size	Lumped	Distributed
Weight	Lumped	Distributed
Efficiency	Lower	Higher

Cost	Lower	Higher
Size	Smaller	Larger
Weight	Lower	Higher
Efficiency	Higher	Lower
Reliability	Higher	Lower

3.3 Efficiency

The efficiency may be classified into two types, namely energy efficiency and power efficiency. The energy efficiency η_e is the ratio of energy output E_{out} to energy input E_{in}, whereas the power efficiency η_p is the ratio of power output P_{out} to power input P_{in}. So, they can simply be

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

expressed as:

$$\eta_e = \frac{E_{out}}{E_{in}} \tag{10}$$

$$\eta_p = \frac{P_{out}}{P_{in}} \tag{11}$$

For industrial operation, these two efficiencies may not be necessarily distinguishable. On the contrary, for vehicular operation, there is a significant difference because the power efficiency varies continually during the operation of most vehicles. Thus, it is necessary to delineate the power efficiency associated with the speed and torque conditions. Instead of using a particular operating point (such as rated power at rated torque and rated speed) to describe the power efficiency of a vehicle subsystem or component, an efficiency map is generally adopted. Figure 11 shows typical efficiency maps of a three-phase IM and a PM BLDC motor for propelling an EV. Hence, the energy efficiency can be derived by summing powers over a given time period.

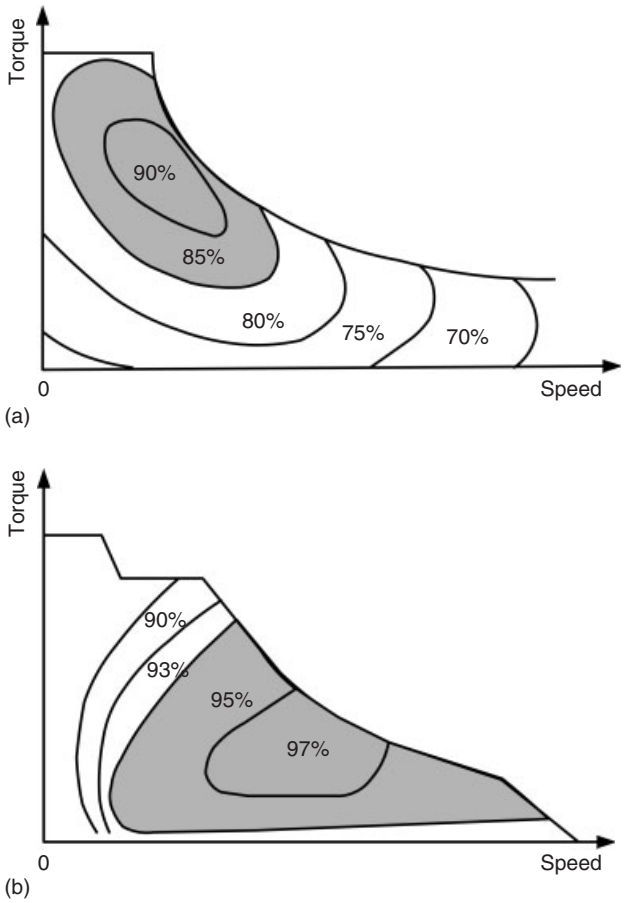

Figure 11. Typical power efficiency maps of EV traction motors. (a) Induction motor; (b) PM BLDC motor.

4 CONTROL CONSIDERATION OF TRACTION MOTOR DRIVE

4.1 Power electronics

4.1.1 Power devices

In the past decades, power semiconductor device technology has made tremendous progress. These power devices have grown in power rating and performance by an evolutionary process. Among existing power devices, the power diode behaves as an uncontrolled switch, whereas the others are externally controllable. Some of the more commonly used controllable devices are as follows:

- silicon-controlled rectifier (SCR), also known as *the thyristor*;
- gate turn off thyristor (GTO);
- bipolar junction transistor (BJT);
- metal-oxide semiconducting field effect transistor (MOSFET);
- insulated gate bipolar transistor (IGBT);
- static-induction transistor (SIT);
- static-induction thyristor (SITH);
- metal-oxide semiconducting-controlled thyristor (MCT).

In selection of power devices for traction motor drive, the following factors should be considered (Chan and Chau, 2001):

- *Ratings*. The voltage rating is based on the battery nominal voltage, maximum voltage during charging, and maximum voltage during regenerative braking. On the other hand, the current rating depends on the motor peak power rating and number of power devices connected in parallel. When paralleling these devices, on-state and switching characteristics have to be matched.
- *Switching Frequency*. Switching at higher frequencies can bring down the filter size and help meet the electromagnetic interference (EMI) limitation requirements. Over the switching frequency of 20 kHz, there is no acoustic noise problem.
- *Power Losses*. The on-state conduction drop or loss should be the minimum while the switching loss should be as low as possible. As higher switching frequencies increase the switching loss, switching the device at about 10 kHz seems to be an optimum for efficiency, power density, acoustic noise, and EMI considerations.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- *Base/Gate Drivability*. The device should allow for simple and secure base/gate driving. The corresponding driving signal may be either triggering voltage/current or linear voltage/current. The voltage-mode driving involves very little energy and is generally preferable.
- *Dynamic Characteristics*. The dynamic characteristics of the device should be good enough to allow for high dv/dt capability, high d*i*/d*t* capability, and easy paralleling. The internal antiparallel diode should have similar dynamic characteristics as the main device.
- *Ruggedness*. The device should be rugged to withstand a specific amount of avalanche energy during overvoltage and be protected by fast semiconductor fuses during overcurrent. It should operate with no or minimal use of snubber circuits. As EVs are frequently accelerated and decelerated, the device is subjected to thermal cycling at frequent intervals. It should reliably work under these conditions of thermal stress.
- *Maturity and Cost*. As the cost of power devices is one of the major parts in the total cost of traction motor drive, these devices should be economical.

Taking into account the above factors, the GTO, power BJT, power MOSFET, IGBT, and MCT are preferable for traction motor drive. The thyristor is not considered because it requires additional commutating components to turn off and its switching frequency is limited to 400 Hz. The SIT and SITH are also excluded because of their normally turn-on property and limited availability. In order to evaluate their suitability, a point grading system is adopted, which consists of eight major characteristics and each of them is graded from 1 to 5 points. From Table 5, the power MOSFET, IGBT, and MCT score high points indicating that they are particularly suitable for traction motor drive. Due to its highest score, the IGBT is almost exclusively used for modern traction motor drives. Nevertheless, the power MOSFET has also been accepted for those relatively low power electric tricycles and bikes.

4.1.2 Power converters

Power converters are usually classified by their input and output. As the input and output of a power converter can be either AC or DC, there can be four types of power converters:

- DC–DC converter
- DC–AC inverter
- AC–DC rectifier
- AC–AC cycloconverter.

The first three types of power converters are used in traction motor drives. The fourth type, AC–AC cycloconverters, is only used in high power AC–AC systems to control the voltage magnitude and frequency of large motors. However, AC–AC conversion involving an AC–DC circuit and a DC–AC circuit is not unusual. Depending on the power train configuration, a traction motor drive may involve one or more types of power converters.

A power converter typically consists of four parts: switching and peripheral circuits, filtering circuits, control circuits and feedback, and an optional user interface, as shown in Figure 12. The main circuit consists of power semiconductor devices (switches and diodes) and peripheral circuits. The semiconductor switches are controlled to turn on and turn off at a frequency ranging from a few kilohertz to a few tens of kilohertz for traction motor drives. Power converters usually involve LC low pass filters that will filter out the high frequency components of the output voltage and let the low frequency components or DC component pass to the load side. The control and feedback circuits typically involve the use of microcontrollers and sensors. Traction motor drive applications usually involve feedback torque control. Current feedback is usually necessary.

The DC–DC converters are also known as *DC choppers*, which are used for DC motor drives. Initially, DC choppers were introduced in the early 1960s using force-commutated thyristors that were constrained to operate at low switching frequency. Due to the advent of fast-switching power devices, they can now be operated at tens or hundreds of kilohertz. In electric propulsion applications, two-quadrant DC choppers are desirable because they convert battery DC voltage to variable DC voltage during the motoring mode and revert the power flow during regenerative braking. Furthermore, four-quadrant DC choppers are employed for reversible and regenerative speed control of DC motors. A four-quadrant DC chopper is shown in Figure 13.

The DC–AC inverters are generally classified into voltage-fed and current-fed types. Because of the need

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

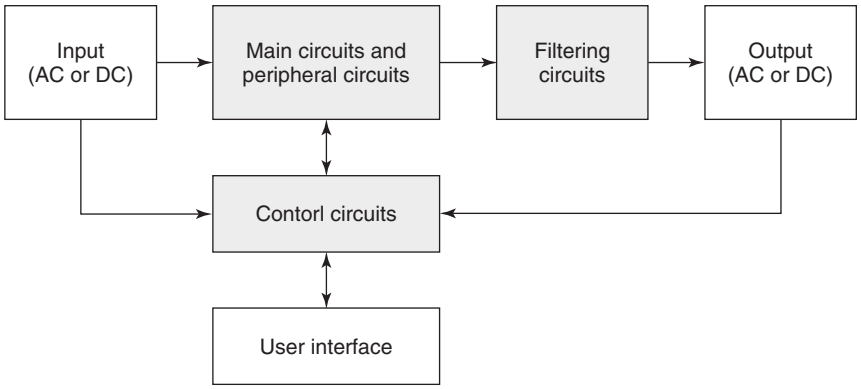

Figure 12. Schematics of power converter.

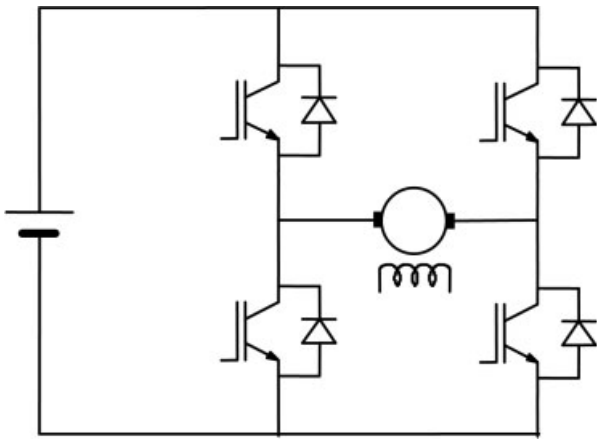

Figure 13. Four-quadrant DC chopper.

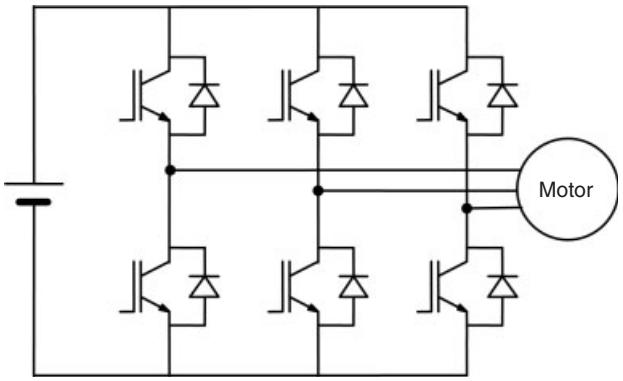

Figure 14. Three-phase full-bridge voltage-fed inverter.

of a large series inductance to emulate a current source, current-fed inverters are seldom used for traction motor drives. In fact, voltage-fed inverters are almost exclusively used because they are very simple and can have power flow in either direction. A typical three-phase full-bridge voltage-fed inverter is shown in Figure 14. Its output waveform may be rectangular, six-step, or PWM, depending on the switching strategy for different applications. For example, a rectangular output waveform is produced for a PM BLDC motor, whereas a six-step or PWM output waveform is produced for an IM. It should be noted that the six-step output is becoming obsolete because its amplitude cannot be directly controlled and its harmonics are rich. On the other hand, the PWM waveform is harmonically optimal and its fundamental magnitude and frequency can be smoothly varied for speed control.

In the last decades, numerous PWM switching schemes have been developed for voltage-fed inverters, focusing on the harmonic suppression, better utilization of DC voltage, tolerance of DC voltage fluctuation as well as suitability for real-time and microcontroller-based implementation. These schemes can be classified as voltage-controlled and current-controlled PWM. The state-of-the-art voltage-controlled PWM schemes are natural or sinusoidal PWM, regular or uniform PWM, harmonic elimination or optimal PWM, delta PWM, carrierless or random PWM, and equal-area PWM. On the other hand, the use of current control for voltage-fed inverters is particularly attractive for high performance motor drives because the motor torque and flux are directly related to the controlled current. The state-of-the-art current-controlled PWM schemes are hysteresis-band or band-band PWM, instantaneous current control with voltage PWM, and space vector PWM.

4.1.3 Emerging power electronic devices

The present silicon (Si) technology is reaching the material's theoretical limits and cannot meet all the requirements of vehicle applications in terms of compactness, light weight, high power density, high efficiency, and high

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

reliability under harsh conditions. The silicon carbide (SiC), new semiconductor material, with the potential increased power density and high temperature capability makes it an ideal candidate in traction motor drive applications (Kelley, Mazzola, and Bondarenko, 2006).

SiC power devices have much lower switching and conduction losses and can operate at much higher temperature than comparable Si power devices. Hence, a SiC-based power converter will have a much higher efficiency than that of a Si-based one at the same switching frequency. Alternatively, a higher switching frequency can be used to reduce the size of the magnetic components in a SiC-based power converter. In addition, because SiC power devices can be operated at much higher temperatures without much change in their electrical properties, ease of thermal management and high reliability can be achieved.

4.2 Control strategies

Conventional linear control, such as PID, can no longer satisfy the stringent requirements of high performance motor drives. In recent years, many modern control strategies have been developed. The state-of-the-art control strategies that have been proposed for motor drives are DTC, EOC, artificial intelligent control (AIC), position-sensorless control (PSLC), and so on (Chau, Chan, and Liu, 2008).

4.2.1 *Direct torque control*

The DTC is becoming attractive for traction motor drives, particularly for those equipped with dual-motor propulsion which desires fast torque response. It does not rely on current control and depends less on parameters. For the PM BLAC drives, the DTC controls both the torque and the flux linkage independently. The controller outputs provide proper voltage vectors via the inverter in such a way that these two variables are forced to predefined trajectories. The control block diagram of the DTC is shown in Figure 15a.

4.2.2 *Efficiency-optimizing control*

The EOC of motor drives is highly desirable for traction motor drives as their on-board energy storage is very limited. Different types of motor drives may employ different ways for efficiency optimization. For the rotor-PM BLAC drives, the EOC can be achieved by online tuning the input voltage or the *d*-axis armature current I_{2d} to minimize

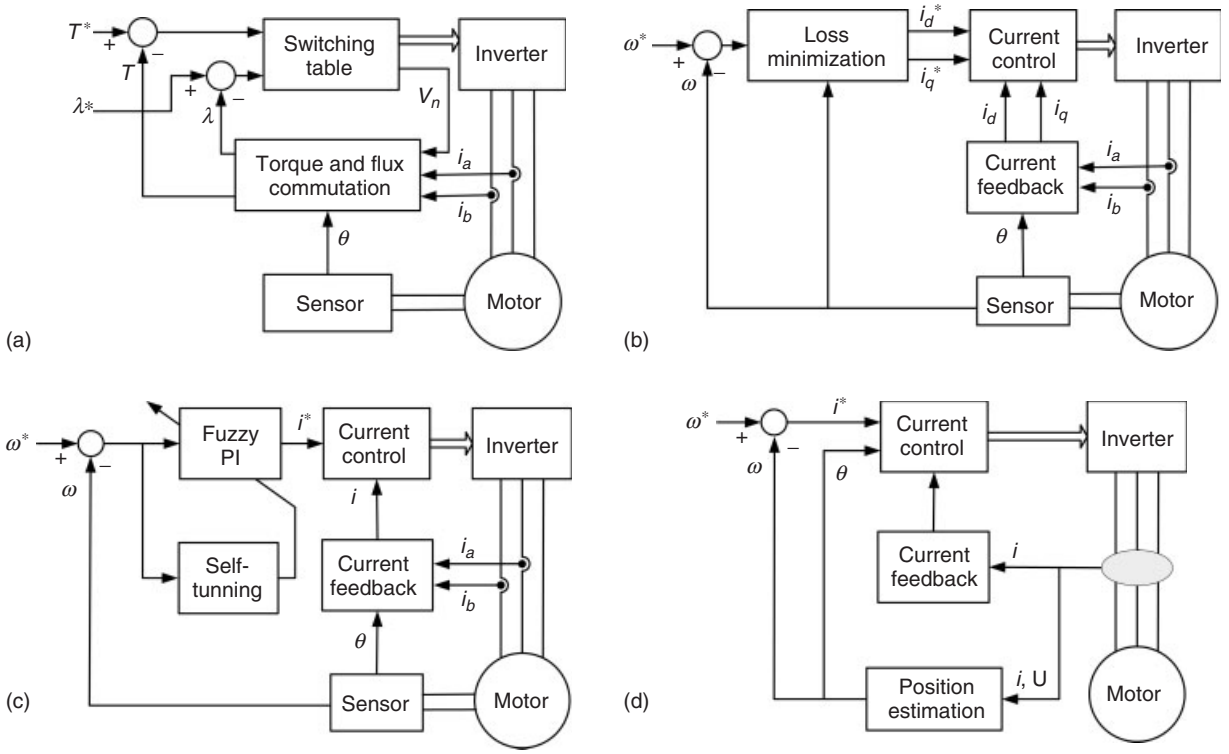

Figure 15. Control block diagrams. (a) DTC; (b) EOC; (c) AIC (fuzzy PI); (d) PSLC.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto041
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the total losses P_{loss} (Cavallaro *et al*., 2005)

$$P_{\text{loss}}(I_{2\text{d}}, T, \omega) = P_{\text{cu}}(I_{2\text{d}}, T, \omega) + P_{\text{Fe}}(I_{2\text{d}}, T, \omega) \qquad (12)$$

where P_{Cu} is the copper loss and P_{Fe} is the iron loss for the given torque T and speed ω. It can be found that there is a unique optimal operating point. In particular, the minimum total losses occur at a lower d-axis armature current than that of the minimum copper loss, hence illustrating that the maximum torque per ampere control cannot maximize the efficiency of the PM BLAC drives. Figure 15b shows the control block diagram of the EOC. For the hybrid PM BLAC drive incorporating with an additional DC field winding, the EOC can be easily achieved by tuning the polarity and magnitude of the DC field current (Shu, Cheng, and Kong, 2008).

4.2.3 *Artificial intelligent control*

All artificial-intelligence-based control strategies, such as fuzzy logic control, neural network control, neuro-fuzzy control, and genetic control, are classified as AIC. Among them, the fuzzy logic control and the neural network control are most mature and attractive as they can effectively handle the system's nonlinearities and sensitivities to parameter variations. Figure 15c shows the block diagram of the fuzzy PI (proportional-integral) control.

4.2.4 *Position-sensorless control*

In order to achieve high performance for traction motor drives, position feedback is almost mandatory. The position sensor is usually either a three-element Hall-effect sensor or an optical encoder, which are high cost, fragile elements. In order to get rid of the costly and bulky position sensor, PSLC is becoming attractive. Moreover, position-sensorless technology can effectively continue the operation of the system in case the position sensors lose their function. This is crucial in some applications, such as military vehicles.

There are various PSLC techniques. The majority of them are based on the voltage, current, and back EMF detection. These techniques can be primarily grouped into four categories (Ehsani, Gao, and Emadi, 2010):

1. Those using measured currents, voltages, fundamental machine equations, and algebraic manipulations.
2. Those using observers.
3. Those using back EMF methods.
4. Those with novel techniques not falling into the previous three categories.

It should be noted that the PSLC can be readily incorporated into other control strategies such as the EOC, the DTC, and the AIC.

4.2.5 *Comparison of control strategies*

As shown in Table 6, the aforementioned control strategies are compared in terms of their major advantages, major disadvantages, and typical techniques (Chau, Chan, and Liu, 2008). As there are many possible strategies for the AIC, the self-tuning fuzzy PI control (Cheng, Sun, and Zhou, 2006) is used for exemplification. Finally, some sample results of these control strategies have illustrated that the EOC can achieve the minimum total losses (Cavallaro *et al*., 2005), the DTC can provide direct bang–bang control of torque (Pascas and Weber, 2005), the AIC can achieve fast and accurate response, and the PSLC can offer accurate estimation of rotor position.

5 CONCLUSION

In this chapter, the general requirement for traction motor drives in EVs has been presented. The potential candidates

Table 6. Comparison of control strategies.

	Advantage	Disadvantage	Techniques
DTC	Fast torque response; no need for current control; less parameter dependence	Cause errors due to drift flux linkage estimation, and variation of stator resistance	Generate the voltage vectors using independent torque and flux computations
EOC	Minimize the overall losses; no need for accurate loss model; work for wide speed and torque range	Originate system oscillation or convergence problem	Control the input voltage or d-axis armature current; control DC field current
AIC	Flexible control algorithms; adapt nonlinearities and parameter variations	Require expert knowledge or intensive computation and sophisticated hardware	Incorporate fuzzy logic, neural network, and other AI into traditional controls
PSLC	Eliminate position sensor, hence reduce system size and cost; readily merge into other controls	Require intensive computation and sophisticated hardware	Estimate the position based on motional EMF, inductance variation, or flux linkage variation

for a traction motor for EVs have been evaluated according to the major requirements of an EV electric propulsion system. Design consideration of traction motors is described. Power devices and power converters for traction motor drives are discussed and evaluated. Control strategies for traction motor drives are presented and compared.

Currently, the PM motors and cage IMs present better comprehensive performance than others, hence are highly dominant in recently released EVs (de Santiago *et al*., 2012), whereas the DC motors are losing attraction though still in use in some small vehicles, and switched reluctance motors and stator-PM motors are gaining much interest.

Thanks to persistent hard work of both academic and industrial communities in the past years, the performance of traction motors for EVs has been improved greatly. With quick development of industry technology, motor drives in EVs would meet with new renovations. The development trends of the traction motor drive in EVs may include the following:

1. *High Speed Motors*. By increasing the speed, the size of electric motors may be reduced greatly, viz. higher power from smaller machines and redesigning for increased material utilization. Some companies have started to focus on high speed of 16,000 r/min PM motors that can achieve field weakening within the structure of the motor and eliminate the need for a DC–DC boost converter.
2. *Redundant and Fault-Tolerant Motor Structure*. Continued operation of motor drive is an essential requirement in EV application. Therefore, the need for high degree of reliability in motor drive system has inspired much research in the area. To achieve high reliability, redundant or conservative design techniques have been employed in many motor drives.
3. *Novel Manufacture Techniques*. To achieve high power density, high efficiency, and low cost motors for EVs, the manufacture technique of motors is being improved. The segmented stator and concentrated winding are examples. In addition, using flat wire to replace round wire in motor windings can increase slot filling factor, enabling both a higher torque constant and a lower copper loss.
4. *Novel Machine Topologies with Composite Structures and New Materials*. For traditional machines, each has its own merits and demerits. The composition of different machines may significantly improve the performance. Hence, the traction machines that consist of different structures may be noticed in the next step.

EVT and E-CVT for Full Hybrid Electric Vehicles

Yuan Cheng[1] **and Ming Cheng**[2]

[1]*Harbin Institute of Technology, Harbin, China*

1 INTRODUCTION

With ever-increasing concerns on energy shortage and environmental protection, hybrid electric vehicles (HEVs) have become globally attractive. They take the distinct advantages of lower fuel consumption and emissions than internal combustion engine vehicles (ICEVs), whereas longer driving range and easier refuel than battery electric vehicles (BEVs) (Chau and Chan, 2007).

According to the level of electric power contribution in the total propulsion power, HEVs can be classified into micro, mild, and full hybrids. Among these hybrid vehicles, full hybrids have the greatest electric power fraction and possess all hybrid features, such as electric launch, idle stop, regenerative braking, and so on. These features enable ICE to operate at its efficient regions and achieve high fuel economy and low emissions.

The Toyota Prius HEV is a typical full hybrid vehicle, in which an ICE and a pair of electric machines (EMs) are adopted. As the core of the Toyota hybrid system (THS), a planetary gear (PG) is used to connect three power plants. By adopting the PG, electric driving force and ICE driving force can be effectively split and combined, giving more freedom to optimize power flows and reduce fuel consumption. The THS system is also known as *electronic-continuously variable transmission* (*E-CVT*) as the ICE power can be transferred to the vehicle seamlessly and smoothly. But different from the mechanical CVT, the E-CVT is implemented in the way of electric drives instead of mechanics, hydraulics, or hydromechanics.

Many different E-CVT concepts have been put forth through various combinations of PGs, EMs, ICE, and so on (Miller, 2006; Wang, Cheng, and Chau, 2009). But recently, a novel transmission, called *electric variable transmission* (*EVT*), has been proposed, which also realizes the power split function without the aid of PGs (Hoeijmakers and Ferreira, 2006). By integrating a double-rotor EM cascaded with another EM, the EVT not only implements a transmission of the ICE power but also opens a gate enabling the input and output of electric power. These features make EVT a competitive HEV solution with a highly integrated function of CVT, starter, and generator.

In this chapter, the system architectures and operating principles of both EVT and E-CVT propulsion systems have been introduced.

2 THE E-CVT PROPULSION SYSTEMS

According to different system architectures, the E-CVT can be sorted into two categories, input power split and compound power split (Miller, 2006).

ISBN: 978-0-470-97402-5

2.1 Input split E-CVT

In the input split E-CVT, there exists a power split device (namely PG) at the transmission input. For example, the HEVs developed by Toyota and Ford fall into this category.

2.1.1 *Toyota E-CVT system*

Figure 1a shows the PG used in Toyota E-CVT propulsion system. The Toyota E-CVT mainly consists of a PG, a battery pack, two power converters, and two EMs. The PG consists of a set of gears, namely, the ring gear, the sun gear, the carrier gear, and several pinion gears. As shown in Figure 1b, the ICE is linked to the carrier gear, the EM1 is connected to the sun gear, and the EM2 is connected to the ring gear and then to the vehicle. The PG splits the ICE power into electric power flow and mechanic power flow. On one hand, a portion of the ICE power can be transferred from the carrier gear directly to the ring gear and then to the vehicle. On the other hand, the electric power flow converts the rest of the ICE power into the electrical form through the EM1. The electric power can either charge the battery or supply the EM2. The power converters share a common DC bus, to which the battery pack is connected. The battery can release/absorb the electric power to/from the DC bus in different operating modes. The Toyota E-CVT system is also well known as a *series and parallel hybrid electric vehicles* (*SP-HEV*). It involves the features of series and parallel hybrids, and many operating modes are possible in order to enhance the system performance and reduce the fuel consumption.

Due to the mechanical connection through the PG, the speed and torque relationships between different components in steady state can be expressed as:

$$T_{\mathrm{d}} = T_{\mathrm{EM2}} + \frac{\rho}{1+\rho} T_{\mathrm{ICE}} \tag{1}$$

$$T_{\mathrm{EM1}} = \frac{1}{1+\rho} T_{\mathrm{ICE}} \tag{2}$$

$$\Omega_{\mathrm{ICE}} = \frac{\rho}{1+\rho} \Omega_{\mathrm{EM2}} + \frac{1}{1+\rho} \Omega_{\mathrm{EM1}} \tag{3}$$

where T_{d} is the driveline torque and Ω_{EM1}, T_{EM1}, Ω_{EM2}, T_{EM2}, Ω_{ICE}, T_{ICE} are the speed and torque of EM1, EM2, and ICE respectively. ρ is the basic ratio of the PG.

From Equation 3, it can be seen that there are two independent variables among three speeds. As the EM2 is linked to the vehicle, its speed is proportional to the vehicle speed. Therefore, Ω_{EM1} can be chosen as an independent variable, which can be controlled to optimize the ICE speed. In the same manner, the EM2 torque can be controlled independently in order to optimize the ICE torque. Therefore, by properly controlling the speed and the torque of both EM1 and EM2, the ICE can be operated independent of the road load and at its optimal region.

DOI: 10.1002/9781118354179.auto042
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.1.2 *Ford E-CVT system*

The architecture of Ford E-CVT propulsion system is shown in Figure 2. Besides the PG at the transmission input, an output torque multiplier gear set is added. The steady state relationship between the ICE, the EM2, and the driveline torque can be expressed as:

$$T_{\mathrm{d}} = \frac{N_2}{N_1} T_{\mathrm{EM2}} + \frac{\rho}{1+\rho} \frac{N_2}{N_3} T_{\mathrm{ICE}} \tag{4}$$

where N_1, N_2, and N_3 are the teeth numbers of output gear set. From Equation 4, it can be seen that the Ford E-CVT is very similar to the Toyota HEV. However, a boost output torque can be achieved due to the adoption of the output gear, which provides further advantages to reducing the ICE and EM2 torques.

2.2 Compound split E-CVT

Compound split E-CVT has also been presented in recent years. Such a compound split can be obtained by replacing the output gear in the Ford E-CVT system with a second PG. Because of variable structure control, such a compound split system has more flexibility of power distribution in addition to the capability to output higher torque. An example can be seen in the GM E-CVT system, which is originally developed by Allison for GM as a hybrid heavy-duty transmission.

The GM E-CVT propulsion system is shown in Figure 3, which is mainly composed of three clutches, two PGs, two EMs, two power converters, and a battery pack (Miller, 2006). The compound split E-CVT is also known as *two-mode system* defined in both low speed and high speed ranges. By means of engaging or disengaging different clutches, the E-CVT propulsion system can transform its architecture so that the output torque can meet the road load demand.

When vehicles run in low speed or in city driving mode, both Clutch 1 and Clutch 3 are engaged whereas the Clutch 2 is disengaged. The system becomes input split type in operation. The PG1 attached to the ICE works as an input power split type, whereas the PG2 coupled with the

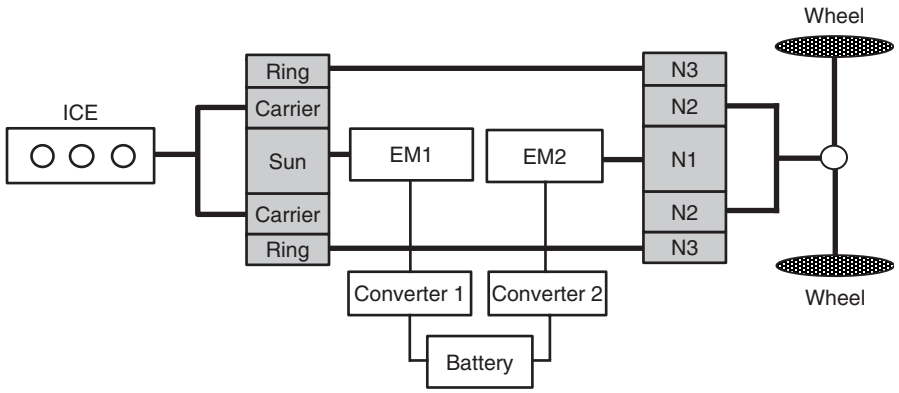

Figure 2. Ford E-CVT propulsion system.

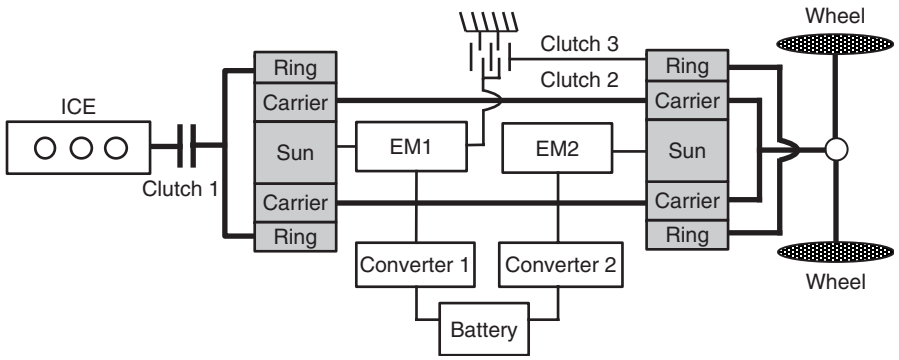

Figure 3. GM-Allison E-CVT propulsion system.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto042
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

driveline is in charge of output torque coupling. The steady state relationship between the ICE torque and the driveline torque can be expressed as:

$$T_d = \left(1 + \frac{1}{\rho_1}\right) T_{ICE} + (1 + \rho_1) T_{EM2} \tag{5}$$

where ρ_1 is the input PG ratio.

In highway driving mode, both Clutch 1 and Clutch 2 are engaged whereas Clutch 3 is disengaged. This kind of operating mode is called *compound split*, in which the input and output PGs perform the function of power split together. The steady state relationship between the ICE torque and the driveline torque can be expressed as:

$$T_d = \frac{1}{1 + \rho_2} T_{EM2} - \frac{1}{\rho_1 \rho_2 (1 + \rho_2)} T_{ICE} \tag{6}$$

where ρ_2 is the output PG ratio.

Through combinations of PGs and clutches, various compound split systems can also be found, such as eVT from Timken, IVT from Renault, and the hybrid power train from Geely (Miller, 2006; Tenberge *et al*., 2010).

It should be noticed that the power split devices adopted in most of the E-CVT propulsion systems are simple PGs, as shown in Figure 1. Currently, an example of heavy-duty power train using Ravigneaux Geartrain (RG) can also be found (Syed *et al*., 2010). Shown in Figure 4, the RG is a compound geartrain consisting of two simple PGs, PG1 and PG2. The PG1 consists of a ring gear, a large sun gear, and outer pinion gears. The PG2 shares the common ring gear with PG1 and the inner pinion gears are meshed with a smaller sun gear. The inner and outer pinion gears are meshed with each other and connected independently with a planet carrier. In comparison to the E-CVT systems utilizing two individual simple PGs, the RG is more compact and has more degrees of freedom to optimize the operation of different power sources.

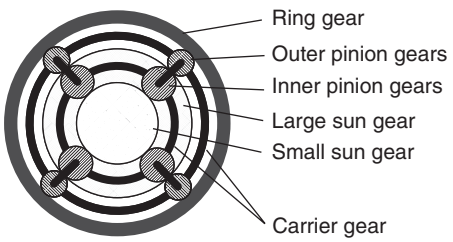

Figure 4. The ravigneaux gear.

3 THE EVT PROPULSION SYSTEMS

Although possessing both advantages of series and parallel HEVs, the structures of E-CVT are relatively complicated and costly. Recently, a family of EVT propulsion systems is being actively developed. Illustrated in Figure 5, the key to the EVT system is to make use of a double-rotor machine (DRM) to split the ICE power into electric power flow and mechanical power flow. Compared with the E-CVT system, it is also an input power split power train. However, due to the elimination of the PGs, the mechanical wear and audible noise associated with the EVT propulsion systems can be eliminated.

3.1 Configuration and operating principle

As shown in Figure 5, the EVT propulsion system is composed of a DRM, two power converters, and a battery pack. The DRM has three parts: the stator (S), the inner rotor (IR) with individual windings, and the outer rotor (OR) with permanent magnets (PMs) or squirrel cages. The DRM can be seen as an integrated electromechanical converter consisting of two concentrically arranged EMs. The inner machine EM1 is a DRM, which consists of the IR and the inner part of OR. The outer machine EM2 is a normal EM, which consists of the stator and the outer part of OR. The IR is attached to the ICE shaft, and the OR is connected to the driveline and then to the vehicle.

Owing to the two independent rotatory parts, the ICE power P_{ICE} can be divided into two parts at the EM1. One part is electrical power P_{elec}, which reaches the EM2 through the slip rings and the power converters. The other is mechanical power P_{mech}, which is directly coupled to the EM2 and used to propel the vehicle. In fact, the "mechanical" power is transmitted not through mechanical connection but through the action–reaction electromagnetic torque between the two rotors of the EM1. It should be noted that, if the EM1 is not in an active state, the "mechanical" power does not exist any longer.

In steady state, due to the action and reaction, the ICE torque is equal to the electromagnetic torque of the EM1, $T_{ICE} = T_{EM1}$. Therefore, without considering losses, the relationship between the ICE power P_{ICE} and the EM powers, P_{EM1} and P_{EM2}, can be expressed as:

$$P_{ICE} = T_{ICE}\Omega_{ICE} = P_{mech} + P_{elec} \tag{7}$$

$$P_{mech} = T_{EM1}\Omega_{EM2} = T_{ICE}\Omega_{EM2} \tag{8}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto042
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

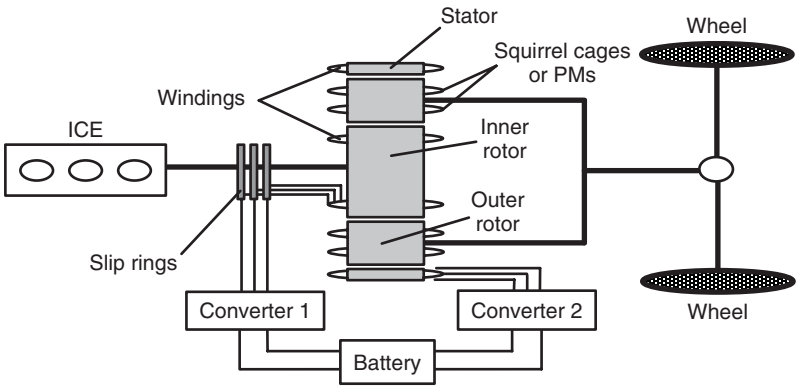

Figure 5. The EVT propulsion system.

$$P_{\text{elec}} = P_{\text{EM1}} = P_{\text{EM2}} = P_{\text{ICE}} - P_{\text{mech}} = T_{\text{ICE}}(\Omega_{\text{ICE}} - \Omega_{\text{EM2}}) \quad (9)$$

where Ω_{ICE} and Ω_{EM2} are the speeds of the ICE and the EM2, respectively. Due to the two rotator parts, the actual EM1 speed is the difference between the ICE and the EM2, $\Omega_{\text{EM1}} = \Omega_{\text{EM2}} - \Omega_{\text{ICE}}$. The generated electric power P_{elec} can produce the torque on the EM2 machine

$$T_{\text{EM2}} = \frac{P_{\text{elec}}}{\Omega_{\text{EM2}}} = \frac{T_{\text{ICE}}(\Omega_{\text{ICE}} - \Omega_{\text{EM2}})}{\Omega_{\text{EM2}}} \quad (10)$$

Therefore, the final driving torque is

$$T_{\text{d}} = T_{\text{EM1}} + T_{\text{EM2}} = T_{\text{ICE}} + \frac{T_{\text{ICE}}(\Omega_{\text{ICE}} - \Omega_{\text{EM2}})}{\Omega_{\text{EM2}}} = \frac{T_{\text{ICE}}\Omega_{\text{ICE}}}{\Omega_{\text{EM2}}} = iT_{\text{ICE}} \quad (11)$$

where i is the EVT speed ratio. It can be seen that the EVT can also work as a CVT. But different from the E-CVT, the EVT implements the CVT function by directly controlling the speed and the torque of the EM1 and EM2 machines without introducing the PG. More specifically, the EM1 adopts speed control to balance the difference between the required speed Ω_{d} at the driveline and the optimal speed Ω_{ICE} of the ICE. In the same manner, the EM2 adopts torque control to balance the difference between the required torque T_{d} at the driveline and the optimal torque T_{ICE} of the ICE. Figure 6 illustrates such a control strategy. The optimal operating line (OOL) shows the ICE optimal operating line, along which the ICE has the best efficiency in all operating points with the same powers. P_{d} shows the required operating point at the driveline shaft, and P_{ICE} is the actual operating point offered by the ICE with the same output power as P_{d}. Through controlling the EVT, the ICE

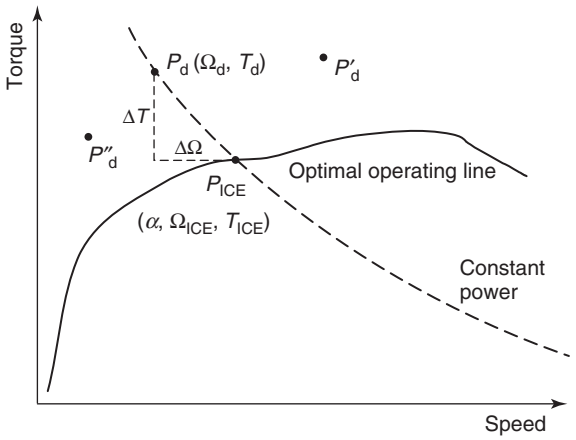

Figure 6. The EVT control strategy.

can be operated independent of the driving conditions and achieve the best efficiency (Cheng *et al.*, 2007). This OOL operation principle is exactly the same as in CVTs where it is realized by continuously changing the transmission ratio between input and output shafts.

If the ICE power cannot fulfill the desired driving power, the battery can release power to boost the driving force. In this case, P_{d} moves to P'_{d}. Alternatively, the battery can absorb the regenerative braking energy when the vehicle decelerates, and P_{d} moves to P''_{d}. With this function, the EVT can work in hybrid mode or starter and generator mode. The power flows of EVT in different operating modes have been illustrated in Figure 7.

3.2 Different topologies of EVT

Although the name of the EVT was first presented by Prof. Hoeijmakers based on induction machines (IMs) (Hoeijmakers and Ferreira, 2006), various machine types can

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto042
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

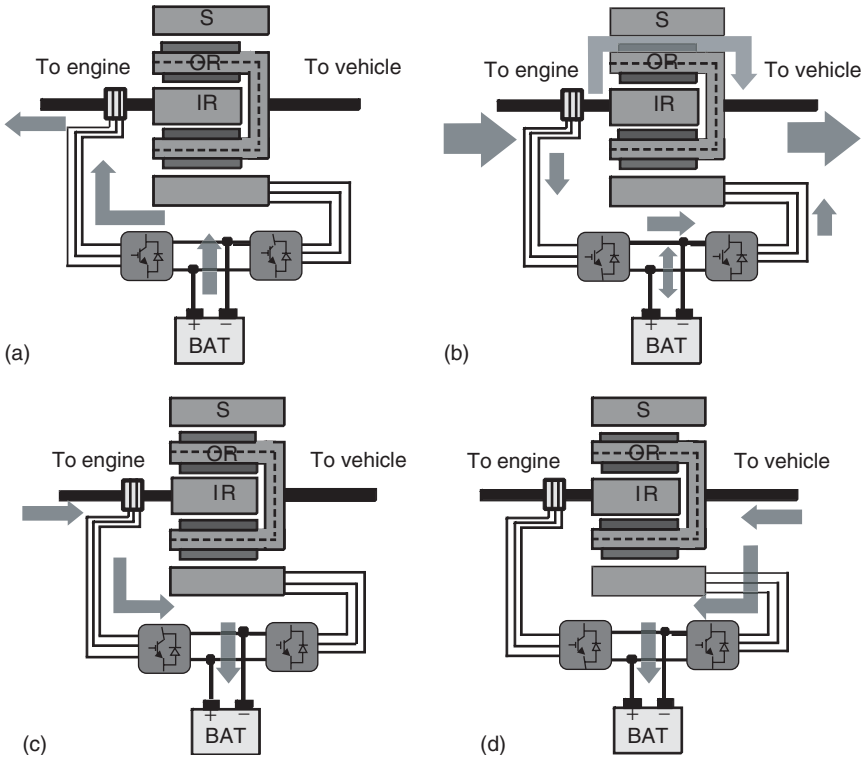

Figure 7. Power flows of EVT in different operating modes. (a) Starter mode, (b) hybrid mode, (c) generator mode, and (d) regenerative braking.

be conceptually introduced into the EVT concept. Similar designs can be found by using PM machines, switched reluctance machines (SRMs), and so on. Axial–axial field type or compound structures have also been studied in order to enhance the EVT performance as well as conventional topologies with radial–radial field distribution.

3.2.1 Radial–radial field topology

Currently, most of the EVTs adopt this topology, in which both the EM1 and the EM2 have radial air gap field distribution. For this topology, there are individual polyphase windings on the stator and the IR. According to the structures of the OR, the EVT can be based on IM machines, PM machines, or SRM machines, as shown in Figure 8.

Figure 8a shows an IM-based EVT, which has two separate layers of squirrel cages in the outer and inner part of the OR. Operating on the principle of electromagnetic induction, IMs are considered robust, low cost, and mature. Good dynamic performance can be achieved by adopting field-oriented control (FOC) or direct torque control (DTC). Replacing the squirrel cages with PMs leads to the PM-EVT with inherent advantages of high efficiency and high torque density, as shown in Figure 8b. PMs can be located on the surfaces or the interior of the OR according to performance requirements. In this case, the PM-EVT can be considered the combination of two separate permanent magnet synchronous machines (PMSMs) and be controlled independently according to the control strategy (Nordlund and Sadarangani, 2002). Instead of two layers, one-layer PM can also be adopted on the OR. In this case, PM-EVT has a uniform field in outer and inner air gaps and strong magnetic interference exists between its stator and IR. The EM1 and EM2 cannot be controlled independently. As an example of such a one-layer PM-EVT, dual mechanical ports machine (DMPM) is being developed (Xu, 2005). With structures of doubly salient poles in EM1 and EM2 machines, EVT can also have SRM versions, as shown in Figure 8c. The SRM-EVT runs through the magnetic reluctance torque rather than the electromagnetic torque. SRM-EVT offers the advantages of low cost, simple structure, high power density in low speed structure, and so on. However, due to the discontinuous torque and high ripple, SRM can cause vibration and also acoustic noise.

3.2.2 Axial–axial field topology

In order to save more space under the vehicle hood or enhance performances, the EVT could also transform into an axial–axial field version as shown Figure 9 (Zheng *et al.*,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto042
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

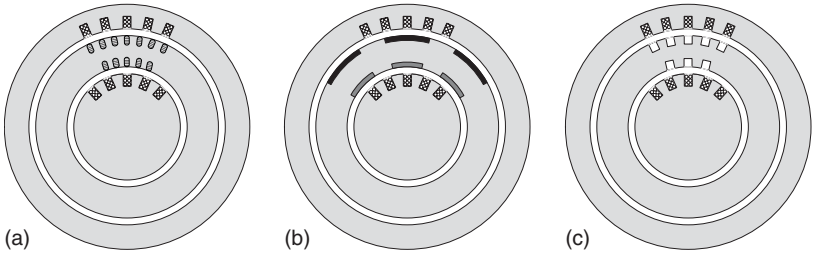

Figure 8. Different machine-based EVTs of radial–radial field topology. (a) IM-EVT, (b) PM-EVT, and (c) SRM-EVT.

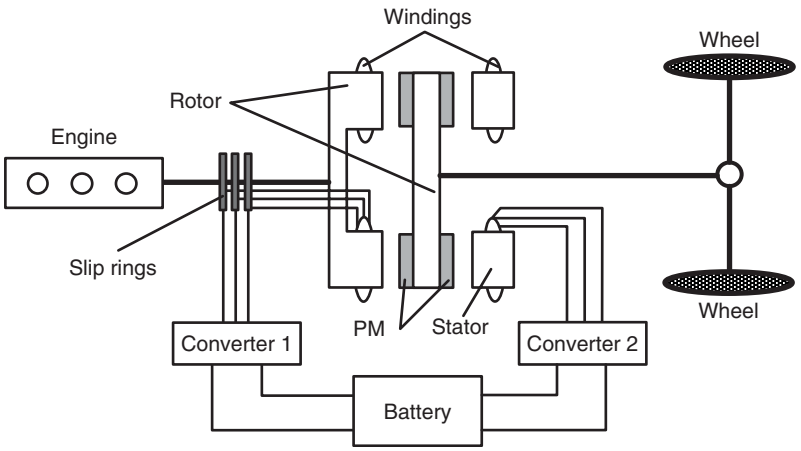

Figure 9. Axial–axial EVT propulsion system.

2008a). The left rotor, the middle rotor, and the right stator function exactly as the IR, the OR, and the stator in the radial–radial version. The EM1 and EM2 become axial flux disk machines. Obviously, different machine types can be adopted in the axial–axial EVT version.

3.2.3 *Compound topology*

No matter the EVT propulsion system is based on IMs, PM brushless machines, SRMs, or radial–radial and axial–axial topologies, the magnetic fields in the two air gaps are coupled to certain extent and interference with each other (Zheng *et al*., 2007). Such a magnetic coupling will degrade the independency of two EMs and consequently affect the controllability of the EVT system. By combining radial and axial field topologies, the field coupling can be completely ignored. An example of axial–radial field topology EVT is shown in Figure 10. It employs a DRM with axial flux in the first stage and another radial flux machine in the second stage (Zheng *et al*., 2008b). Due to its decoupling nature between the first stage and the second stage, the EVT propulsion system can provide better controllability.

Several topologies are also possible, such as radial–axial topology, axial/radial–radial topology, and so on.

3.2.4 *Brushless EVT system*

In order to feed electricity into the DRM, slip rings and carbon brushes have to be used in the EVT. However, the complication and maintenance associated with slip rings and brushes degrade the reliability and the efficiency of the EVT system. Therefore, one of the development trends of the EVT systems is to eliminate the slip rings and the brushes.

Very recently, a double-stator PM brushless EVT propulsion system has been proposed. As shown in Figure 11, a double-stator machine is used to split the ICE power. Two power flows are possible from the ICE to the wheels:

1. from the outer stator of the first-stage machine, Converter 1 and Converter 2 to the second-stage machine;
2. from the inner stator of the first-stage machine, Converter 3 and Converter 2 to the second-stage machine.

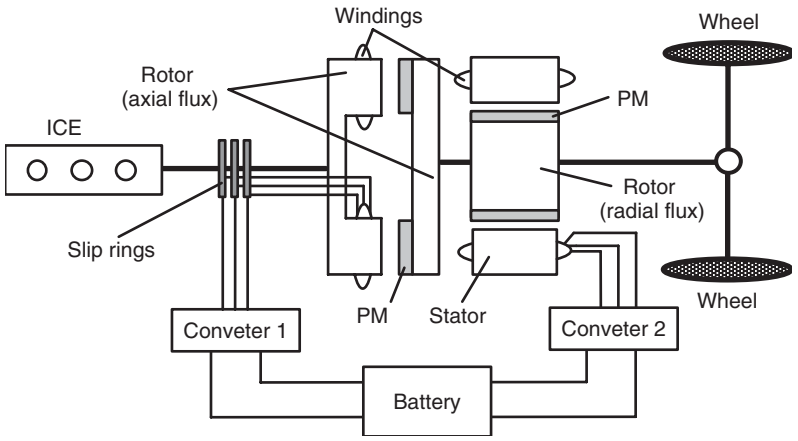

Figure 10. Axial–radial EVT propulsion system.

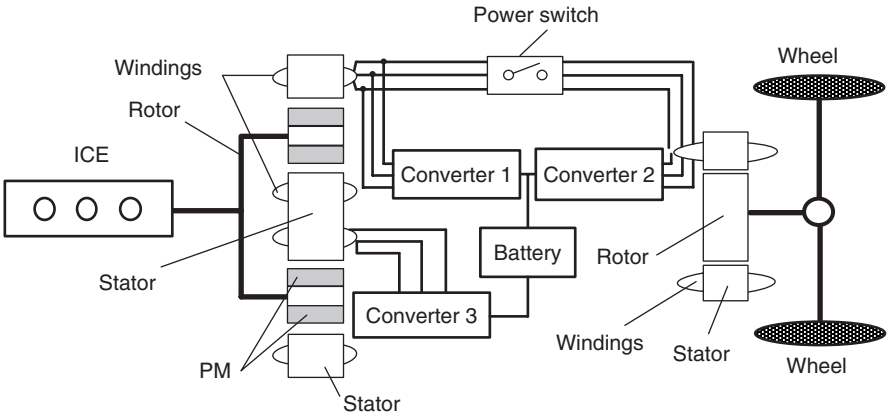

Figure 11. Double-stator PM brushless EVT propulsion system.

The first-stage machine is a double-stator PM machine, and the second-stage machine is an IM or a PM brushless machine. All the power converters are standard three-phase inverters. The outer stator transfers a major part of the ICE power and the inner stator performs power split control using the battery pack as a buffer (Wang *et al*., 2008, 2011).

By properly controlling the two power converters, the ICE can operate at constant speed while the wheel speed varies with the road load profile and driver's control, hence offering the merit of continuously variable gearing. When there is no need to perform power split, the system efficiency can be further improved by using a power switch to directly transfer the ICE power from the outer stator of the first machine to the second machine.

Compared with the double-rotor counterparts, this double-stator PM brushless EVT propulsion system possesses the advantages of improved reliability.

4 CONCLUSION

In this chapter, various EVT and E-CVT propulsion systems have been introduced. Both EVT and E-CVT can realize the power split function and optimize the vehicle power flows. Currently, with the aid of PG, the E-CVT is more mature. Successful cases such as Toyota Prius HEVs have appeared in markets for many years. In addition, many innovative E-CVT concepts are also in development. However, the E-CVT system is relatively complicated because of the power split devices.

As a promising HEV power train, the EVT eliminates mechanical transmission and the clutches, which eliminates the mechanical wear and noise and simplifies the system structure. From the overview of state of the art, PM-EVT has become more attractive than other machine types due to higher efficiency and torque density of PM machines. Moreover, the application of PMs in the EVT leads to

various topologies as well as interesting issues of machine design and control. However, the existence of slip rings and brushes reduces the reliability and the efficiency of the EVT system.

Micro, Mild, and Full Hybrids

Thomas Pels and Carsten Kaup

AVL Schrick GmbH, Remscheid, Germany

1 INTRODUCTION

At present, there is no common opinion about the classification of micro, mild, and full hybrids even among automotive experts. Sometimes, the proposed differentiation is the rated power of the electric drive or rated power versus vehicle weight. Other examples suggest to distinguish based on the power ratio between electric drive and combustion engine.

This article provides an explicit definition, based on hybrid powertrain functions. The basic functionalities and their typical characteristics will be explained in detail. Consequently, this article helps to avoid misinterpretations when discussing about hybrid electric vehicles (HEVs).

2 CLASSIFICATION OF MICRO, MILD, AND FULL HYBRIDS

HEVs can be classified into micro, mild, and full hybrids. Table 1 shows the classification of HEVs, differentiated by powertrain functionality that can be categorized into three functional groups. Energy management contains functionalities to improve the efficiency of energy conversion or to reduce the waste of energy within the powertrain. Torque management implies the torque split in between the internal combustion engine (ICE) and the electric drive to operate the power sources within its optimal operation areas. The pure electric propulsion and its specific functionality are covered by the third group. The main motivation is the reduction of GHG emissions and the improvement of air quality, especially in urban areas.

On the basis of these classifications, range-extended electric vehicles (REEVs) can be categorized as full hybrids, whereas battery electric vehicles (BEVs) are actually not hybrids at all. The basic functions of all three groups are given in Table 1.

All additional functions and new functionalities, which might be relevant in the future, are referred to those functional groups. For instance, battery charging from the grid to enhance the all-electric driving range (plug-in hybrid functionality) is associated with electric propulsion. The basic functionalities will be explained more in detail within the next section.

3 DESCRIPTION OF BASIC POWERTRAIN FUNCTIONALITIES

3.1 Stop&start function

When a vehicle is stopped, for instance, at red traffic light or in traffic jam, a lot of energy is wasted to keep the engine

Table 1. Classification of hybrids.

Functional Groups	Basic Functionalities	Micro Hybrid	Mild Hybrid	Full Hybrid
Energy management	Stop&start Smart charging	×	×	×
Torque management	Regenerative brake Torque assist/boost	—	×	×
Electric propulsion	Pure electric drive Charge sustaining by ICE	—	—	×

The energy management functionalities of micro hybrids mentioned earlier do not require two power sources or two energy sources in all cases. Therefore, micro hybrids are not necessarily hybrid electric vehicles per definition.

running that can be significantly reduced or eliminated by implementing stop&start functionality. This function simply cuts off the engine when no propulsion torque is required, although it needs to be ensured that the engine stop is only executed after assessing the needs of auxiliary supply and engine conditions. Vehicle auxiliaries require energy whether it is mechanical or electrical, for example, for onboard power supply, air conditioning, power steering, or brake boosting. Concerning the combustion engine for instance cooling requirements and catalyst temperatures must also be considered.

The driver is the main actor for the stop&start functionality. Control units evaluate brake pedal and accelerator pedal positions as well as transmission states (such as clutch or gear positions) to decide whether it is appropriate to stop or restart the engine. The variety of hybrid electric vehicle architectures leads to a huge diversity in this functionality. Stop in gear versus stop in neutral and restart triggered by brake versus clutch triggered are typical examples for different strategies that significantly influence the fuel economy potential.

Apart from the drivers input, further system relevant signals contribute to the stop&start controls. Battery conditions such as state of charge (SOC) or state of health (SOH), electrical power demand, cabin heating, and cooling requirements are just some examples for further function initiators or inhibitors.

3.2 Smart charging

The operation of vehicle, independently of whether it is conventional or a hybrid electric vehicle, requires electrical power to supply the 12 V consumers. Unless the car is not a plug-in hybrid, the required energy must ultimately be generated from the combustion engine. In a conventional car, the alternator controller keeps the output voltage on a defined constant level. An intelligent control strategy (=smart charging) means not only to control the alternator on a constant set point but also to control the output voltage on different levels, depending on the driving condition (for instance, at full load, idle, and braking). This leads to a more efficient energy flow and helps to reduce fuel consumption.

Smart charging needs a battery monitoring system that helps to avoid the most common cause of vehicle breakdown—a flat battery. The battery monitoring system measures the battery voltage, current, and temperature and calculates from these all the information that reflects the condition of the 12 V battery (SOC and SOH). The smart charging function uses these values to guarantee a sufficient and continuous level of battery energy, so that the vehicle can be operated reliably under all conditions, even after a long stationary period. In hybrid vehicles, two different systems manage the smart charging control functionality. Some HEVs directly control electrical generators to convert mechanical energy to 12 V electrical energy, whereas others are using a DCDC converter to transform high voltage from the HV battery to the vehicle's electrical system voltage. In both cases, the hybrid master controller is responsible for arbitrating electrical energy transfer.

Besides the battery monitoring system mentioned earlier, it is mandatory to evaluate the vehicle operation mode to improve the overall fuel economy. The hybrid controller collects information about engine load, driver torque demand, and brake position to determine the target voltage, which is subsequently allocated to the 12 V battery and 12 V consumers.

3.3 Regenerative brake

During braking or vehicle coast down, some hybridized powertrain systems have the capability to recuperate energy by converting the vehicle's kinetic energy to electrical energy, which will be stored in an energy storage device (the most common energy storage device is an electrochemical battery). This functionality is called *recuperation* or *regenerative braking*. Energy is regained for free instead of being wasted to heat at the mechanical brakes or to the drag of the engine. The amount of energy and therefore the recuperation efficiency depends on the powertrain architecture and the brake system. Some brake systems provide

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto046
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

active blending between a mechanical and an electrical brake system that increases significantly the utility of recuperation where others allow only parallel braking and use only part of the overall potential.

Independent of the technical solution, the system needs to assure that regenerative braking is not jeopardizing the vehicle's braking ability on varying road surfaces. Thus, the hybrid controls have to ensure the driver input and ABS and ESP signals as well as the torque/power limitations that are reflected in the recuperation algorithm. The challenging task, especially for systems without brake blending capabilities, is to guarantee reproducible brake behavior independently of the charge acceptance condition of the HV battery. Mandatory for this functionality is an accurate battery monitoring without violating the battery limits in terms of energy and charging power thresholds.

3.4 Torque assist/boost

ICEs have typically low fuel economy at high engine speed, at moderate loads, or at high dynamic response. In hybrid electric vehicles, the additional power source can assist (boost) the combustion engine. Hence, the boost functionality gives the opportunity to avoid high dynamic engine torque response and therefore to operate more efficiently. In addition, NO*x* emission peaks of diesel engines in transient engine operation can be avoided or at least significantly reduced.

Similarly, with the aim to increase overall efficiency, powertrain design utilizes downsizing and downspeeding. Downsizing is a measure to increase the specific engine loads. Downspeeding helps to lower the engine speed and increases the loads at the same time. Both of which may negatively influence the drivability because these measures limit the engine torque reserve. As mentioned earlier, with the help of an electrical motor to support the combustion engine, this impact can be reduced or even eliminated. The boost function can also be used to realize alternative combustion systems, such as using the Atkinson or Miller cycle without degradation of either power or torque response at lower engine speeds. There are many more powertrain functionalities to increase comfort or efficiency where the electric boost of the second electric power source is acting as an "enabler." Electric four-wheel drive with the help of an electric axle or the electric compensation of torque interruptions of automated manual transmissions during gear shifting are just a few examples.

3.5 Pure electric drive

Pure electric driving means—vehicle propulsion and accessories powered by the battery with the combustion engine off. In a conventional powertrain, the combustion engine has to provide the power according to the driver's demand. Therefore, ideally the engine should have high efficiency in all operation modes such as idling or cruising at constant velocity or acceleration. Both gasoline and diesel engines have their peak efficiency typically at high loads and moderate engine speeds. In a conventional powertrain, the engine is working seldomly at the best specific operation point, which results in lower average efficiency, especially in city traffic. With this in mind, pure electric driving can help to increase the fuel efficiency in a hybrid electric vehicle. Furthermore, this functionality enables zero emission driving that may be needed for accessing dedicated restricted areas.

The hybrid supervisory controller determines the propulsion torque demands and enables the pure electric drive operation based on the accelerator pedal and brake pedal movement, selected driving mode and selected driving direction, and the torque/power limitations of the hybrid components.

Depending on the actual SOC of the battery, the supervisory controller decides between pure electric and charge sustaining mode, which will be described in the following section.

3.6 Charge sustaining mode

Once the electrical energy of the HV battery drops below a certain SOC threshold, the ICE provides energy, depending on the powertrain architecture, to a generator or direct to the wheels to extend the driving range. In most conditions, the power is primarily used for propulsion. On an average basis, the combustion engine will maintain the HV battery at a minimum SOC for extended range operation. Occasionally, the energy produced by the engine is used to recharge the battery. In either case, the distribution is controlled by the hybrid supervisory controller according to the SOC and health of the HV battery pack and the required traction power.

4 EXAMPLES OF MICRO, MILD, AND FULL HYBRID ARCHITECTURES

4.1 Micro and mild hybrid families

Hybrid powertrain functionalities can be realized with a wide variety of powertrain architectures and technical solutions, as mentioned earlier. In general, micro and mild hybrids have no ZEV range and use parallel hybrid architectures. In these configurations, the electric motor

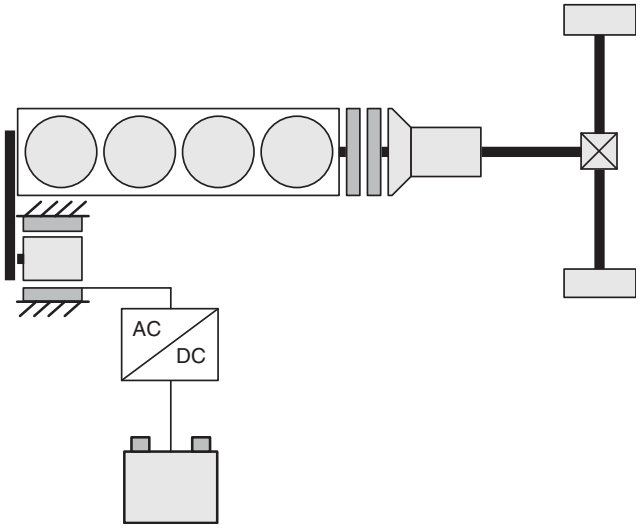

Figure 1. Micro hybrid in belt starter generator architecture.

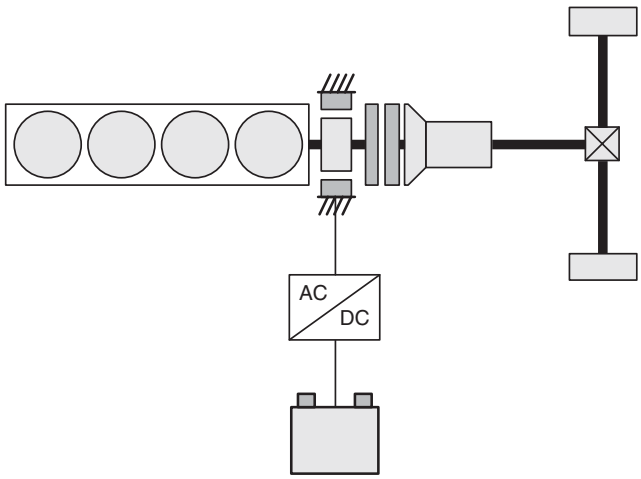

Figure 2. Mild hybrid in crankshaft starter generator architecture.

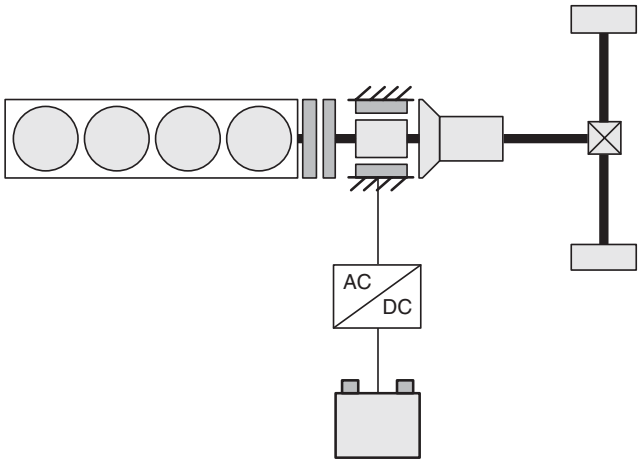

Figure 3. Mild or full hybrid with transmission-integrated E-motor.

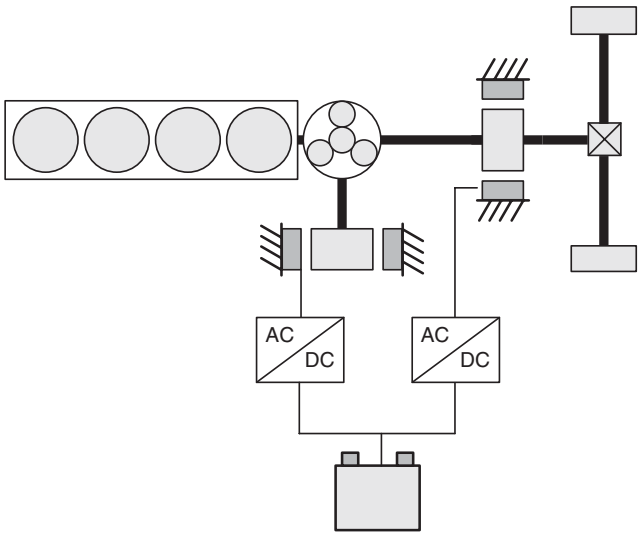

Figure 4. Full hybrid with power split configuration.

is usually a belt-driven starter generator or an integrated crankshaft starter generator (Figures 1 and 2).

Alternative to starter generators, Figure 3 shows a parallel hybrid configuration where the electric motor is integrated into the transmission. Especially, in this architecture, depending on the electric motor size, this powertrain offers also full hybrid functionality.

4.2 Full hybrid configurations

A power split concept (Figure 4) features a planetary gear set to split the power of the combustion engine into a mechanical path (directly to the wheels) and an electrical path (the generated electrical energy is either stored in a battery or is used to power a traction motor mechanically connected to the wheels).

An alternative concept for full hybrids is the parallel hybrid architecture (Figure 5). The parallel hybrid powertrain with an electric machine mounted directly to the crankshaft of the combustion engine with one or two clutches in line (before and/or after the electric motor) offers benefits when being added to an existing conventional drive train.

In the series hybrid configuration (Figure 6), the ICE is mechanically disconnected from the drive train and charges the battery through a generator to overcome the limitations of the battery's energy content.

5 IMPACT OF POWERTRAIN ARCHITECTURE AND TECHNICAL SOLUTIONS ON THE CLASSIFICATION OF HYBRIDS

Hybrid powertrain functionalities can be realized with a wide variety of powertrain architectures and technical solutions, as mentioned earlier.

However, there is no impact of the (detailed) technical solution on the classification of a hybrid electric vehicle as the classification is purely related to system functionalities. Furthermore, it is not dependent on the specific realization of the functions. For example, a boost function can be implemented using a belt-driven or a crankshaft-mounted electric motor, alternatively using a transmission-integrated EM or a wheel hub motor. Moreover, the electric machine itself can be realized as an induction motor, permanent magnet synchronous machine, switched reluctance machine, transversal flux machine, and so on. Of course, there is a significant influence of technical features and component characteristics (e.g., efficiency) on the potential of the hybrid functions (e.g., fuel consumption), but this is not decisive for the classification.

This context applies also for different powertrain architectures, such as series, parallel, or complex structures. The drive train configuration and the position of the electric machine(s) might have an impact on the envisaged potentials of functionalities but not necessarily on its classification according to Table 1. For example, the fuel consumption reduction potential of a regenerative brake function depends (among others) on the ability to switch off the combustion engine while decelerating—characterized by the hybrid powertrain architecture.

It is obvious that there are exceptions as specific hybrid functionalities require dedicated attributes from the powertrain architecture, such as the ability to disconnect the combustion engine from the drive train to enable pure electric drive.

6 SUMMARY AND CONCLUSION

Many hybrid architectures and technical solution exist and many different approaches classify micro, mild, and full hybrids. Classification by rated power of the electric drive

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto046
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

or rated power versus vehicle weight is not really sufficient because it is impossible to define clear borders.

Currently, we do not have dedicated legislation prescribing specific component characteristics or properties, such as minimum rated electrical power to be installed or the like thought this might change in the future. The electrification of the powertrain offers new functionalities to improve fuel economy, reduce emissions, or enhance driveability. For this reason, the generic classification based on powertrain functions remains more flexible, especially if the associated statutory requirements are not harmonized worldwide.

Range Extender Ev

Frank Beste, Günter Fraidl, Vincent Benda, and Martin Atzwanger
AVL List GmbH, Graz, Austria

1 INTRODUCTION

Replacement of fossil fuels by regenerative and, therefore, CO_2-neutral energy sources is the long-term motivation for sustainable mobility. While hydrogen as energy carrier together with the fuel cell technology have been the focus during recent years, the focus now shifts toward battery electric mobility in pure electric or hybrid configuration. The enhanced development of the Li-ion battery technology started with consumer cells (laptop, mobile phone, etc.) many years ago. The Li-ion technology is now being adapted for the needs of high energy cells for automotive purposes. However, even with this development history, essential limitations of energy density and cost of automotive battery systems remain.

First results from battery electric vehicle (BEV) fleet testing are available and influence the assessment of different drivetrain electrification approaches. Not only the reduced all-electric range (AER) under real-world conditions but also the restrictions to the recharging of the high voltage (HV)-battery result in a subjective "range anxiety." The recent efforts to develop local zero-emission mobility focus on plug-in hybrids with full purpose driving performance and BEVs as the only real zero-emission vehicle for mega city mobility. Now, developers increasingly consider the range extender (RE) approach as a solution for secure and cost-efficient range extension for BEVs (List, 2009).

2 REALITY OF BEVS

The simple comparison of published data of nominal BEV, AER, and HV-battery capacity answers the basic question about such vehicles—with increasing AER, the HV-battery capacity, weight, box dimension, and cost need to increase significantly (Figure 1).

In most cases, the published data does not consider real-world driving conditions. Published CO_2 emission specifications are generated with vehicles in minimum resistance and optimum weight configuration in standardized but not always practice-oriented test cycles. If these values are assessed with characteristic vehicle weight and drive resistances, as known from conventional vehicles, then the NEDC (New European Drive Cycle) requires increased battery capacities for the same AER.

This is even more valid if a realistic drive cycle for mega city application is considered. One example that better fits these BEV-use characteristics is the NYCC (New York City Cycle) with stop-and-go traffic, a much lower average speed, and high dynamic requirements. Even with the utilization of brake energy recuperation and without any air-conditioning or heating, the NYCC requires an

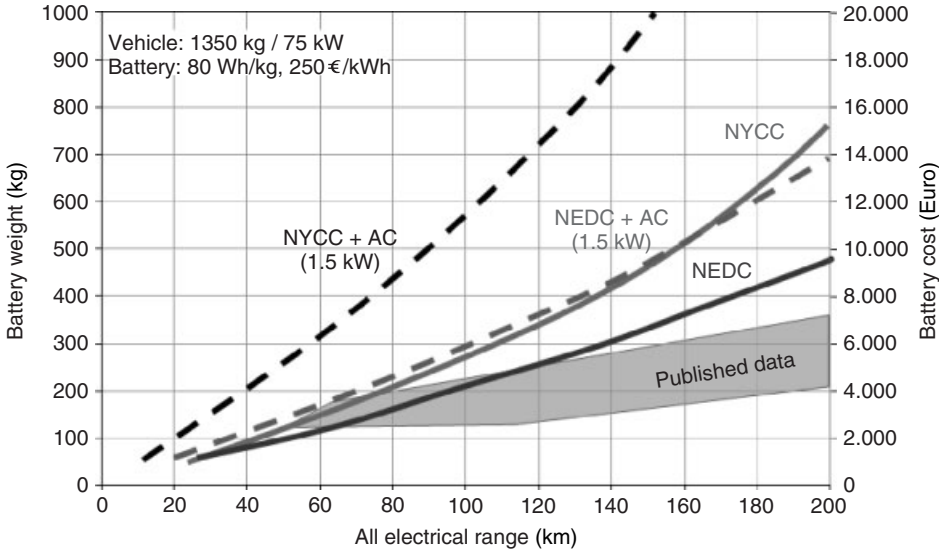

Figure 1. Influence of the AER on battery capacity, weight, and cost (simulation).

additional, approximately 40%, increase in the HV-battery energy content in comparison to the NEDC.

Furthermore, any air-conditioning or heating requirements for the passenger compartment have much higher effect on the AER than known from conventional vehicles. Assuming a vehicle operation at 32°C ambient temperature and 21°C in the passenger compartment, a reduction of the AER between 25% (NEDC) and 50% (NYCC) can be expected. A BEV capable of about 200-km AER in the NEDC without air-conditioning or heating reaches only about 60-km AER in the NYCC with worst-case consideration of auxiliary consumers such as air-conditioning. If a minimum range of 100 km must be reached under severe conditions, an HV-battery weight of about 500–600 kg results. With such a weight growth, the vehicle structure and the performance of the electric traction motor also need to be enhanced. As only 20–35% of the weight-driven additional traction energy can be recuperated, the increase in HV-battery size cannot fully be accounted for additional AER. Even with the production scale driven optimistic prognosis for a specific battery-cell cost reduction down to 250, €/kWh the HV-battery is still the most significant cost burden for the economic operation electric mega city vehicles (MCVs).

A more differentiating picture of advantages and disadvantages of BEVs results from a vehicle start at cold ambient condition. For conventional vehicles, the significantly increased fuel consumption at cold start primarily results from heating the internal combustion engine (ICE) and transmission and from the rich fuel mixture of gasoline engines. Nevertheless, for gasoline engines, and with some limitations for diesel engines, the ICE generates sufficient additional heat for the passenger compartment. Owing to the slightly extended ICE warm-up phase for the passenger compartment heating, the cold-start fuel consumption increases, but can be neglected in relation to the total energy consumption.

For BEVs, the rather high efficiency of the electric traction motor and inverter at low system temperatures does not generate sufficient additional waste heat to supply the passenger compartment. An additional electric heating device for the passenger compartment is necessary. For the BEV cold start, the increase in energy consumption does not result from efficiency losses of the traction system but from the heating of the passenger compartment (Figure 2).

The further reduction of the ambient cold-start temperatures below −10°C also effects the HV-battery's ability to deliver the required performance for the electric traction motor. The question "driving or heating" can become relevant for the driver. Such issues are unknown for conventional vehicles and not accepted by the customer. Furthermore, at such low temperatures, the HV-battery-charging ability also suffers. This must be considered for the vehicles recuperation strategy. Therefore, a volume production of BEVs seems feasible with two strategies:

1. Vehicle design with sufficient HV-battery capacity: for typical everyday AER requirements, the HV-battery is oversized. Together with weight, package, and cost limitations, no vehicle-use flexibility comparable to conventional vehicles seems feasible. A "change of mind" and "adaption for drive behavior" is required. Risks for the vehicle availability are simple user

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

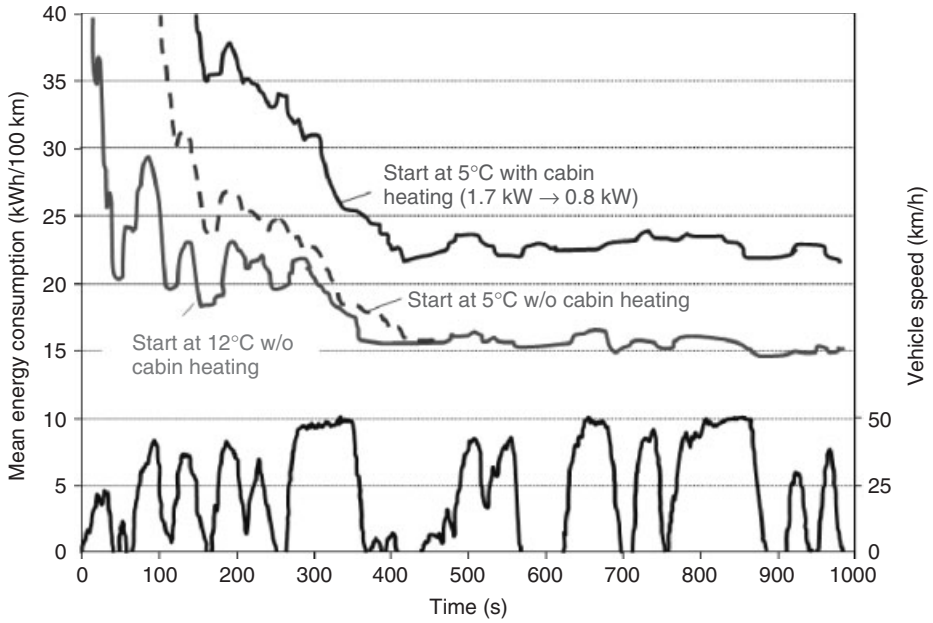

Figure 2. Specific energy consumption of BEVs at cold start.

mistakes such as insufficient charging or unexpected demands.

2. Design of the HV-battery for the typical everyday AER requirement and consideration of an additional RE system for the further energy requirements: for the definition of the typical daily AER requirement, different analyses exist. For an industrialized country with a dense population such as Germany, 70–80% of all daily driving range requirements are below 50–60 km (IVT, 2004). For MCVs, this percentage is expected to be even higher. Such AER requirements and real-world conditions can be solved at acceptable battery weight, cost, and box dimension. The RE is the enabler for a broad market acceptance for electric mobility (Figure 3).

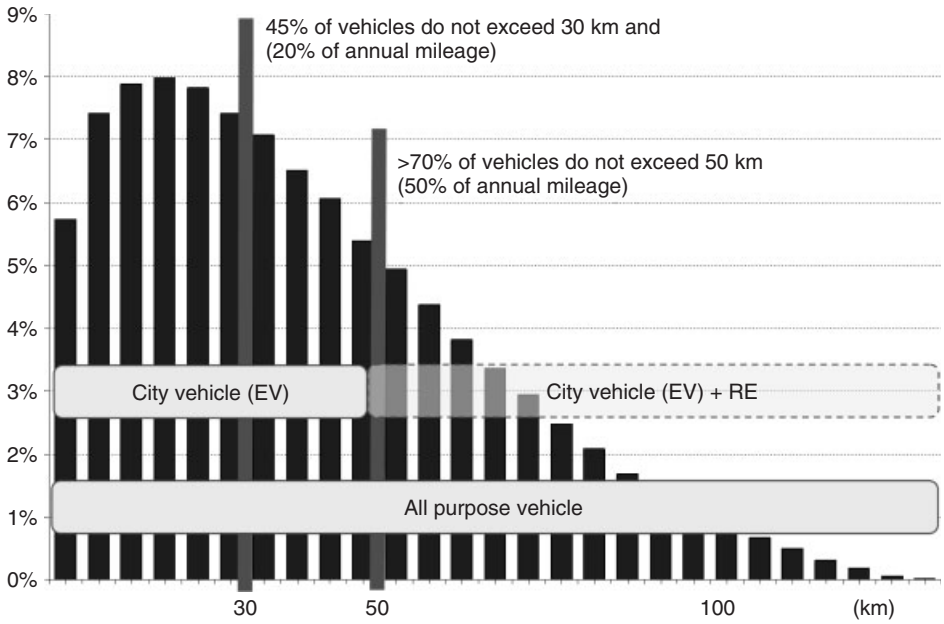

Figure 3. Statistics of all daily driving requirements in Germany (IVT, 2004). (Reproduced with permission from AVL.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047

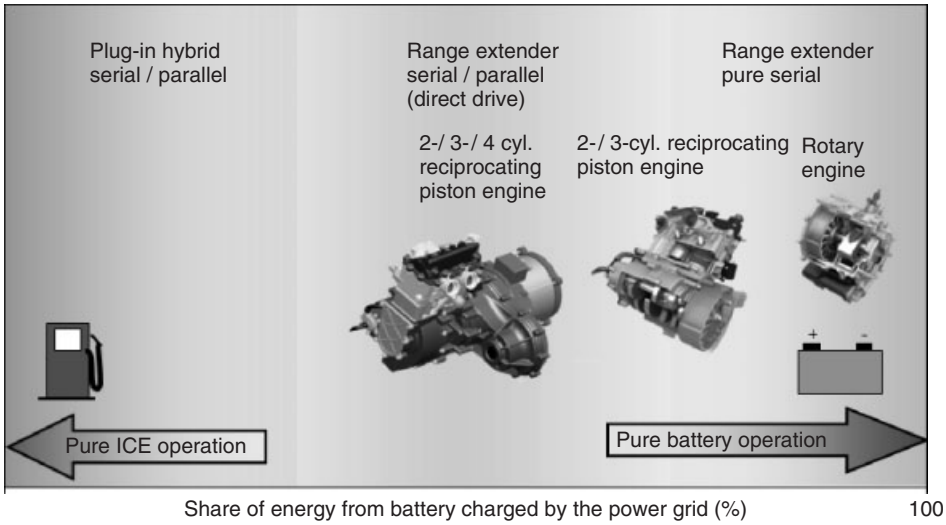

Figure 4. Dependence of different drivetrain configurations from the share of battery electric driving.

Conventional drivetrains with ICE meet a wide variety of customer usage profiles. The electrified drivetrain requires a stronger focus on the relevant use case and vehicle concept targets. For any hybrid configuration, this is especially true for the contribution of the plug-in-charged HV-battery in relation to the energy delivered from the ICE. The differentiation of technical concepts requires more variants than known in conventional drivetrains (Figure 4).

For "full purpose vehicles," wide parts of the usage profiles have to be propelled by the ICE, and high requirements on performance and the total vehicle range potential have to be fulfilled. The best technical approaches for these requirements are plug-in hybrid solutions with parallel configuration of ICE and electric traction motor. The required ICE performance level needs to be in the same range or even higher than that of the electric traction motor as battery electric and long-range ICE driving will be required.

With an increased share of battery electric driving, a series or serial hybrid RE system would allow to utilize the key advantages of the electric drivetrain for the wide majority of daily drive distances without losing the flexibility given by an ICE-driven energy source. The required performance level of the ICE in series or serial configuration needs to be lower than the peak performance of the electric traction motor by a factor 2–4, as only average energy demands need to be supplied. In comparison to parallel plug-in hybrids, the reduced RE performance allows a very compact and cost-efficient design and more flexible system integration in the vehicle. The disadvantage of additional efficiency losses by the double energy conversion (mechanical power from the ICE → electric power from the generator → mechanical power from the electric traction motor to drive the wheels) can only be accepted, if the intended use of RE system is limited to a small part (10–30%) of the main BEV operation.

In general, the term *range extender* is used for a variety of technical concepts, including series or serial hybrids with low electric range, parallel plug-in hybrids, and BEVs with an additional emergency or limp-home functionality. The best configuration depends on the share of battery electric driving. The consequent development of plug-in hybrids toward increased AER is given by a switchable parallel/series or serial hybrid solution, which avoids energy conversion losses at higher traveling speeds by the switchable parallel ICE configuration (Grebe, 2009; Steiger, 2009; Najork *et al*., 2009). For vehicles with clear focus on the pure battery electric driving, the series or serial configuration should be preferred (Fischer, 2009; Beste *et al*., 2009).

When considering these alternative technologies, the pure BEV seems to be limited to niche applications. It can be questioned, if broad market acceptance as required for volume production can be reached with the described restrictions for the driver and the rather high purchase price. It seems as if higher sales numbers for BEVs are only possible with significant governmental funding and/or city access restrictions for ICE-driven vehicles.

3 TECHNICAL RE-CONCEPT SELECTION

For a range-extended electric vehicle (REEV), the daily driving needs define the HV-battery size (e.g., 50-km range and ≤100 km/h). The required energy reserve is supplied

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

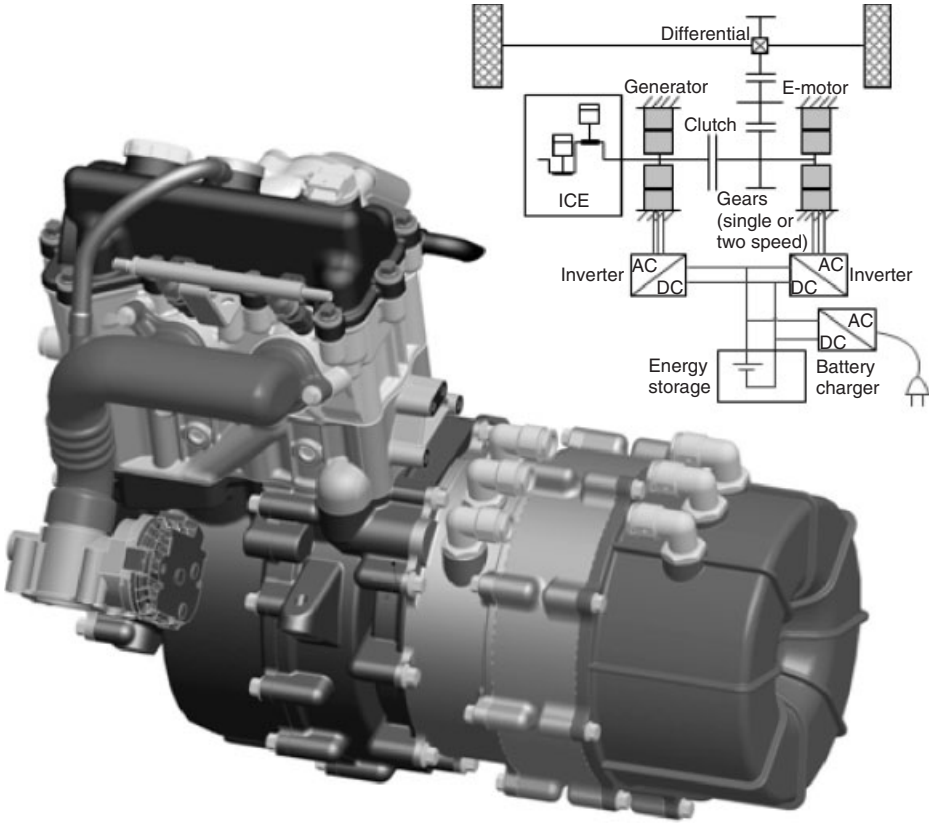

Figure 5. RE concept with switchable parallel/series or serial ICE configuration

by the ICE of the RE system. The battery cost of a REEV can become independent of the total vehicle range potential. The selection of the best technical approach for the RE system is driven by the intended vehicle usage profile, legislative requirements, and the continuation of existing production facilities and technologies of the system manufacturer. However, the main driver is the vehicle concept.

3.1 Vehicle concept starting from conventional vehicle architecture

The RE system is an extended hybridization level that enhances the vehicle's AER ability together with the plug-in functionality and an increased battery size. Because of the switchable series or serial/parallel configuration, the generator performance can be lower than that of the ICE [e.g., by 30% (Najork *et al*., 2009) to 60% (Steiger, 2009)] but requires a wider operation range. The ICE should primarily be activated at higher vehicle speeds and ambient noise. The ICE operation strategy should be defined in accordance with the vehicle speed and load-connected noise expectations of the driver to minimize acoustic problems. The ICE can be derived from existing production engines to limit development efforts and production cost (Fraidl *et al*., 2009; Steiger, 2009; Najork *et al*., 2009). Figure 5 shows a new specific ICE design that has been done for the needs of the switchable parallel/series or serial ICE configuration. The two-cylinder in-line four-stroke ICE has been optimized for production cost and efficiency.

3.2 Vehicle concept starting from a BEV

The RE system is a chemical-electric energy conversion device that supplies energy to the electric traction motor in parallel to the HV-battery. It is an extension of the HV-battery capacity and has a similar functionality as an emergency power generator for a BEV limp-home functionality. These boundary conditions for the RE system integration support the pure series or serial configuration of the ICE. With a vehicle operation strategy that considers the HV-battery to cover the dynamic peak-load demands, the RE performance can be defined by the factor 2–4 lower than the peak performance of the electric traction motor. The required RE performance is defined by the average performance demand at a predefined vehicle layout speed.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In comparison to conventional drivetrains, the following key requirements for the design of the RE system result:

- The RE will need to start automatically, when the HV-battery state of charge (SOC) drops below a predefined minimum HV-battery energy reserve or if required by the system operation strategy. Therefore, ICE operation is decoupled from the very silent driving experience of an electric vehicle and should not or only secondarily be noticeable by the customer. Excellent NVH (noise, vibration, and harshness) properties are the decisive key requirement for customer acceptance.
- For the most part of the vehicle usage, the battery electric driving, the RE reduces the vehicle efficiency by its additional weight. Lightweight design for the RE and its vehicle integration are essential.
- The operation strategy allows to run the RE system in only a few load points without any significant transient or idle requirements. Additional specific fuel efficiency advantages and unconventional ICE concepts become possible.

In addition to the mandatory safety and legislative requirements (emission targets, etc.), the priorities for a series or serial RE development can be summarized:

- Lowest acoustic radiation and excitation
- Dependable system availability even after a long stand-still
- Compact package and high power density
- Low system costs, good vehicle integration properties, and performance scalability
- High system efficiency.

Another design criterion for the RE is its power output. This depends on several factors. The maximum power of the vehicles electric propulsion motor is primarily defined by vehicle acceleration- and climbing requirements. These peak power requirements are significantly higher, than the continuous power requirements. The RE can have a smaller power level if the HV-battery energy reserve can cover the required dynamic power peaks. Figure 6 shows a dimensioning diagram. Plotted are driving resistance curves for several grades. The dotted lines represent the total demanded power including the use of auxiliaries. The selected vehicle (1.475 kg fully occupied) requires a constant velocity of 100 km/h and a propulsion power of 13 kW, correlating with an approximately 15 kW total electric power supply requirement. With an HV-battery energy reserve of 2 kWh, the total combined power allows a driving distance of 21 km at a 2% slope at 100 km/h. It also can be determined what constant speeds are possible at certain slopes and how much acceleration can be performed at a given vehicle speed (Fischer, 2009).

It is also essential to determine the vehicle's remaining abilities, if the HV-battery energy reserve has been depleted. For this "miss-use" of the originally intended

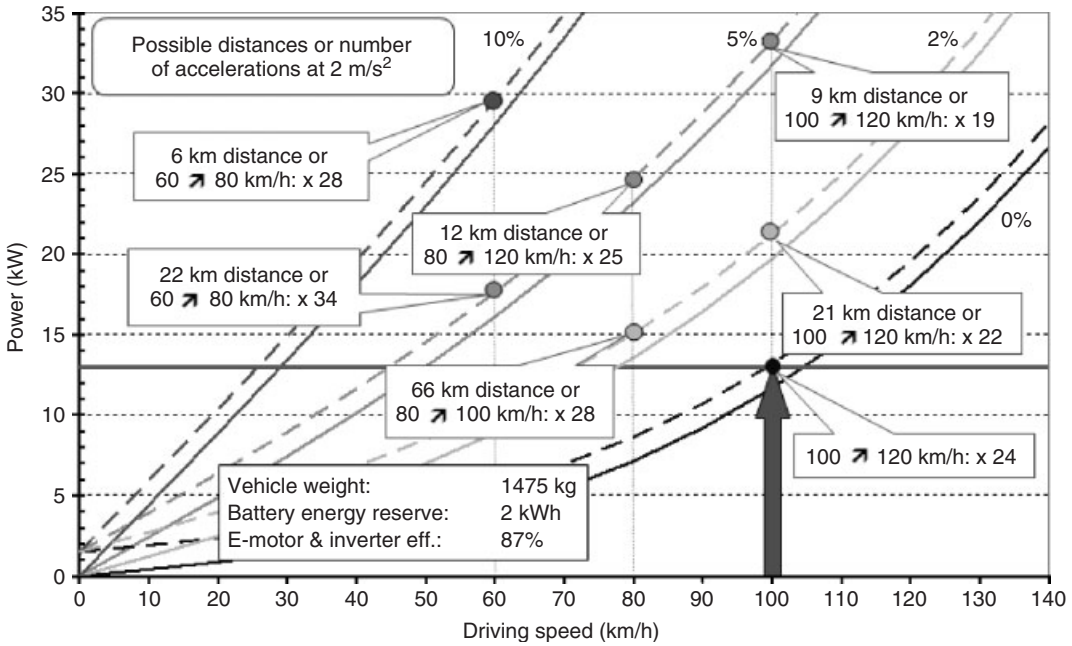

Figure 6. AVL pure range extender—performance requirements/benefit of energy reserve

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

operation range of the REEV, the RE gets into a limp-functionality with a reduced vehicle performance according to the performance definition of the RE. Potentially critical vehicle operations are:

- Remaining acceleration ability of the maximum-weight vehicle at very steep grades (>14%) and a vehicle speed of 30 km/h
- Maximum highway speed at typical highway grades (~5%) should be above 100 km/h to allow passing of trucks, and so on.

The "miss-use" situations with depleted HV-battery should be avoided by the vehicle status information provided to the driver. Nevertheless, an additional high power "emergency" or "highway" load point of about 25 kW for the described vehicle specification can help avoid critical vehicle situations, but would not meet the tight NVH and efficiency targets of the normal RE operation points.

4 RANGE EXTENDER AS HIGHLY INTEGRATED PERFORMANCE MODULE

The RE as a self-regulating auxiliary power supply unit for BEVs can be consequently optimized for operation at few load points by a specific system design of the generator-starter (GS) and the ICE. Reduced development effort, reduced system complexity, and optimized fuel efficiency at its predefined operation points are essential advantages. The complete functional, mechanical, thermal, and control-specific integration of the ICE and the GS and minimum interfaces with the vehicles (electric power connections, control signals, fuel supply, cooling and mechanical mountings) allow diverse vehicle applications at a low development effort.

An essential step of further concept definition is the comprehensive comparison of alternative concept approaches for the system core functionalities. Figure 7 shows an extract of the concept assessment for the most promising ICE concepts that have been derived from the first and very open assessment loop of known technologies. The boundary condition to meet the most stringent existing and future emission legislations requires significant effort and cost for two-cycle approaches with single cylinder or boxer configurations. Four-cycle gasoline concepts will meet the requirements with the lowest additional development effort and support the utilization of existing production facilities.

Fuel cell RE concepts are not mentioned in detail. Their key advantages are that no additional energy conversion from shaft power to electric power is required and that fuel cells reach best NVH and emission properties. Nevertheless, for the RE technology, key requirements are the reduced production cost compared to the alternative bigger HV-battery and the possibility to rapidly fill up the fuel tank at any gas station. The current fuel cell development status and the need for hydrogen do not support these targets. For these reasons, fuel cell REs are not discussed in detail.

The rotary piston engine (RPE) generally exhibits concept-specific advantages regarding power density, acoustics radiation, and compactness. In addition, the known dominant concept-specific disadvantages such as HC raw emissions, durability of the apex seals, and elevated fuel consumption can be avoided completely or

at least considerably by the described special RE requirements. This presents the RPE as a concept alternative with good potential compared to rather conventional approaches. Besides the described development priorities, the ICE concept must also be assessed with regard to the share of RE operation for the intended vehicle concept.

For an RE system operation share of above 20–30% of the total vehicle operation, the RPE results in higher total CO_2 emissions because of its engine concept-related specific fuel consumption (SFC), which is about 6–10% worse. Figure 8 considers CO_2 emissions from ICE operation and from plug-in charging according to the German power-plant mix of 625 grCO_2/kWh and an assumed charging efficiency of 95%.

If the REEV is mainly operated in the original intended battery electric mode, the compactness and the weight advantage of the RPE approach compensates the disadvantage of the RPE SFC and results in a vehicle CO_2 advantage for this concept.

For the GS system, the permanent magnet synchronous machine (PMSM) technology is advantageous because of its compactness, high electric efficiency, and comparably low development risks (Figure 9).

Figure 10 summarizes the selected friction-optimized two-cylinder four-cycle in-line gasoline engine because of

its similarity to existing production engines and the single rotary piston RPE. The following design concepts represent the most compact integration of ICE and GS. Significant advantages in box size and weight can be achieved in comparison to RE systems with existing automotive engines.

4.1 ICE—two-cylinder in-line gasoline engine

The two-cylinder engine concept (Figure 11) considers the boundary conditions for excellent NVH, high efficiency, and engine friction as well as low production cost by the following main features (Atzwanger *et al*., 2010):

Excellent NVH:

- 90° crankpin offset and balancer shaft
- Integrated exhaust manifold in cylinder head.

High efficiency and low engine friction:

- Roller bearings on main and balancer shaft bearings as well as on the camshaft

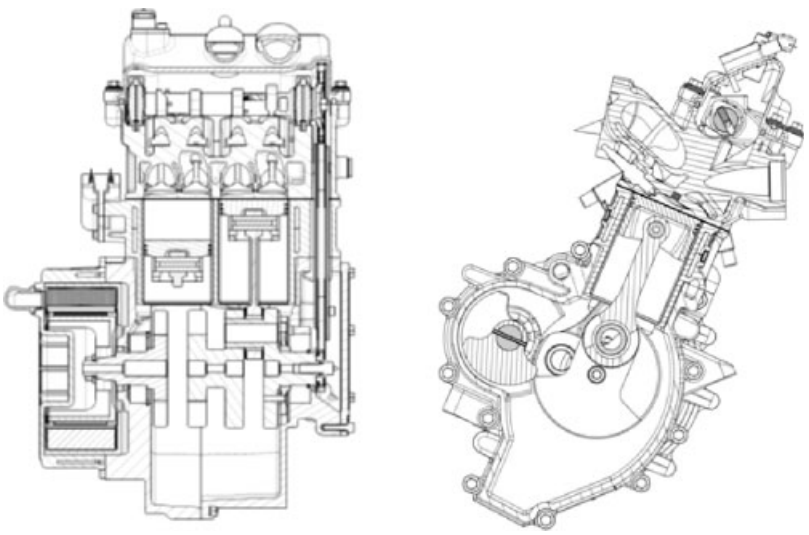

Figure 11. Design example for RE with two-cylinder in-line gasoline engine

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047

- Nonpressurized lubrication without oil pump
- Two-valve direct acting valvetrain.

Low production cost:

- Two-bearing crankshaft and camshaft design
- No oil pump
- Integrated high pressure die cast crankcase—generator housing
- 2 V direct acting valvetrain
- Integrated exhaust manifold.

To fit the very limited available space for an RE unit, the engine architecture allows installation angles of up to 45° (Table 1).

The thermodynamic layout of the engine considers the set power target of up to 18 kW. Using FMEP (friction mean effective pressure) values, which consider the friction-optimized engine architecture, the achieved SFC values for this engine are in the range 250–260 g/kWh @ 5000 rpm at a BMEP (break mean effective pressure) of 7 bar. For this engine load, it is possible to operate the engine at a stoichiometric air–fuel ratio ($\lambda = 1$) without exceeding the set limits of maximum 850°C exhaust gas temperature. The predicted peak firing pressure in the cylinder is 55 bar.

In contrast to well-established concepts such as bed plate or deep skirt crankcase design, a vertical split crankcase with separate cylinder unit was chosen, which is usually based on motorcycle applications. The crankcase consists mainly of two pieces, the right and the left sides with a split line in the middle, having a short offset to ensure a bolting possibility for the middle two-cylinder head bolts. The advantage of such a design is that a reduced number of parts are required because of the omission of the bearing caps and the resulting less complex production This layout also gives the opportunity for pressed-in main roller bearings, which reduces the required number of parts (e.g., circlips and the machining associated with axial fixation).

The crankshaft is designed as a built assembly that is also common in motorcycle applications. The inner two counterweights form one part that is connected to the outer counterweights via press-fit crankpins. This enables roller-supported connecting rods, which ensures low crank-train friction in combination with the omission of the pressure oil circuit and a simplification of crankshaft machining (no long thin pressure oil drillings) (Figure 12).

The 90° crankpin offset configuration shows a balancing of second-order mass forces, so only first-order mass forces remain as the first- and second-order moments can be neglected. For this engine concept, the free first-order mass forces are balanced by one balancer shaft driven by the crankshaft with engine speed (Figure 13). To reduce NVH, a zero-backlash gear is used. The balancer weights on the balancer shaft offset each other by 90°. The shafts roller bearings are lubricated by the oil mist in the crankcase.

Following the target of a simple friction-optimized engine concept, the cylinder head is a two-valve, single overhead camshaft concept. The camshaft is supported only by two needle bearings to further optimize engine friction. The camshaft operates mechanical tappets to actuate one intake and one exhaust valve per cylinder. In the camshaft, a simple decompression device as also known from motorcycle engines is integrated to reduce the required starting energy. This mechanism opens the exhaust valves during the compression stroke slightly at low speeds of the camshaft. At higher engine speeds, the mechanism is deactivated by centrifugal forces. The exhaust manifold is integrated into the cylinder head and is cooled by the cylinder head coolant jacket. This design leads to a very compact design of the top end of the engine. In addition, the temperature of the exhaust gas is reduced (Figure 14).

The GS, considered a PMSM, is integrated into the engine housing. The stator is pressed-fit into the engine crankcase and the cooling circuit is shared with the cooling circuit of the ICE. The rotor is mounted on the rear end of

the crankshaft. This gives the possibility to further reduce the number of parts and assembly effort.

4.2 ICE—single-rotor RPE

To fulfill the unique RE requirements, a new and dedicated RPE design is required. Figure 15 shows the RPE in a compact common-shaft assembly with the GS. The thermodynamic layout was carried out for the quasi-stationary operation at the demanded electric output power of 15 kW. The defined engine speed of 5000 rpm represents an optimum regarding efficiency and NVH. The specific displacement of 254 ccm represents a compromise among the boundary conditions, low fuel consumption, little wear, beneficial airborne sound emissions, and required potential for a further performance increase. The thermodynamic simulation also shows that different levels of performance in the range 15–25 kW can be achieved with a unified geometry by increasing mean effective pressure and engine speed. By extending the rotary piston width by 20 mm, the displacement increases to 357 ccm and the potential electric output to approximately 36 kW (Figure 16, Table 2).

The centrally positioned common shaft of the RPE and the GS allows a compact design of the core unit. The high degree of shaft bending stiffness due to the short shaft length allows the elimination of the GS-sided third roller bearing. The low friction roller bearing design reduces the oil pump requirements down to the needs for the pressure-less rotary piston cooling and lubrication of rotary piston seals. An integrated unbalance in the rotor carrier of the GS and a second balancing weight at the other shaft end eliminate the unbalance in the rotary piston and so fulfill the high NVH demands.

The joint cooling circuit of the ICE and the GS is integrated in a tubeless common housing. Owing to the low acceptable temperature level of the GS and the power electronics, the coolant temperature level is considerably lower ($<75^{\circ}$C) than that for typical conventional ICE configurations. This requires an adequate design of the friction-relevant components. In the RPE segment of the housing, only the "hot" part of the trochoid that experiences the heat transfer from the combustion is cooled. The temperature of the "cold" part is regulated by material heat conduction. The trochoid surface and the oil temperature are important for the wear and friction of the sealing components. The oil temperature lies at a higher level compared to the cooling medium temperature as oil is used for rotor-piston cooling.

The limited number of engine operation points for the pure series or serial hybrid configuration allows optimizing the thermodynamic layout. For the RPE, for example, the Atkinson cycle can be adapted. The late exhaust-port opening and the extended expansion phase not only reduces

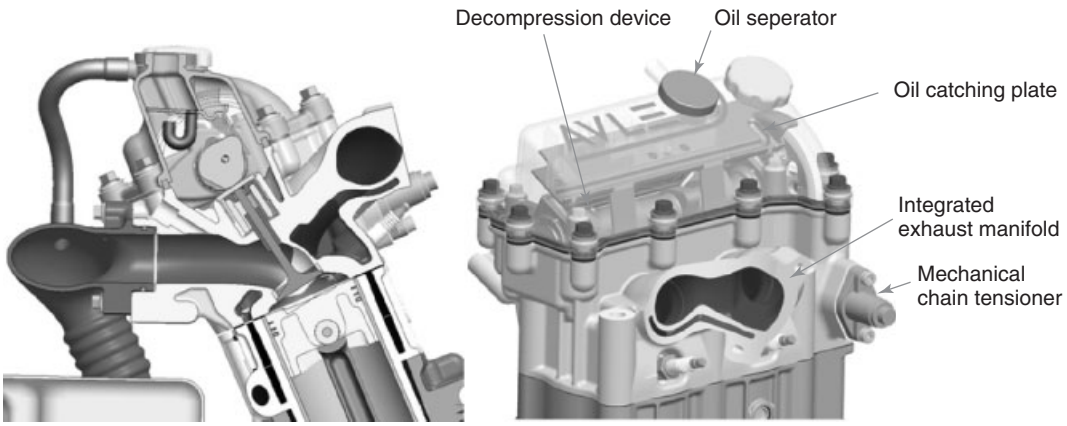

Figure 14. Cylinder head assembly.

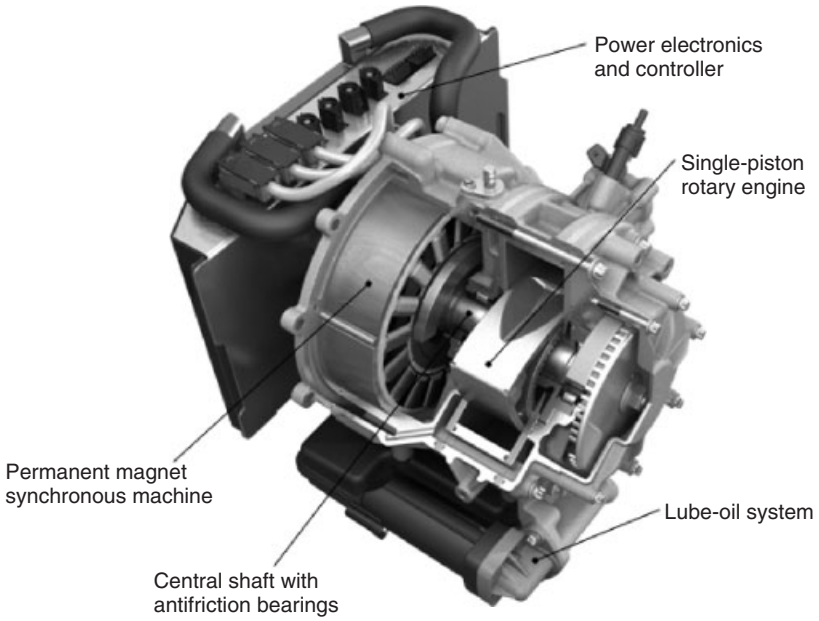

Figure 15. Design example for RE with single rotor-piston RPE.

exhaust gas temperatures and improves SFC and HC emissions but also reduces the acoustic relevant pressure pulses in the exhaust system. The achievement of future legislative emission targets by the definition of an optimum engine start procedure and the engine calibration requires comprehensive model-based simulation and test-bed validation.

4.3 Generator-starter and control system

The GS used in the RE has to fulfill requirements different from those of the electric propulsion motor of the vehicle. The required functions are basically limited to a fast and vibration-poor start of the ICE and the generation of electrical energy in a very limited operation range. This is possible with known technologies. However, the central demand for a very compact, efficient RE module with minimum production costs, which is optimized for the vehicle operation and achieves the demanded robustness, requires intensive development work. The system optimization regarding the reduction of overall package volume, weight, and costs has to be accomplished by an adequate detail design and simulation. The GS has to be designed for the required electrical power output in the HV-battery voltage range, for example, 15 kW in a voltage range

Cooling system	Single circuit liquid cooling, integrated ICE and GS cooling
Communication	CAN bus
Sound emission (outside vehicle)	65 dBA (lm averaged sound pressure)
System weight (ICE + GS core module)	70 kg (35 kg)
Interfaces range extender—vehicle	HV and 12 V connector, CAN bus, fuel supply, Cooling, acoustic decoupled system mounts

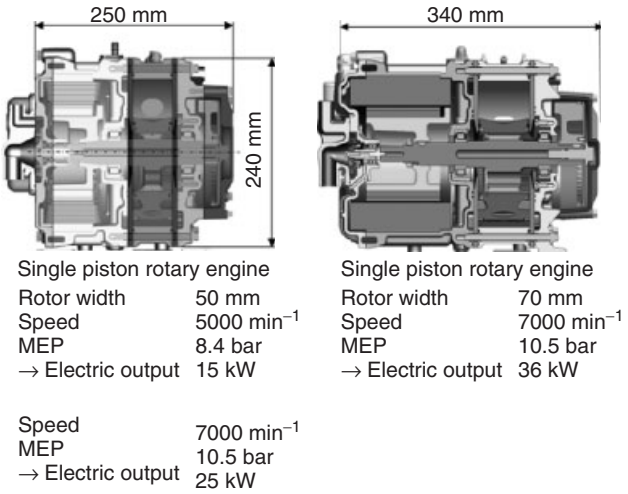

Figure 16. Core module of range extender system for 36-kW electric power @ 7000 rpm

320–420 V (12 kW at 250 V). The GS achieves a machine efficiency of up to 96%. Further performance classes can be obtained by scaling and adaptation of the GS design. Special attention is required for the additional thermal and vibration loads by the ICE on the electric components. For optimum cooling conditions, the cold coolant first enters the power electronics module and the integrated GS cooling jacket and is then guided to the directly connected ICE housing.

The integrated module control of the RE merges the functionality of the power electronics, the GS controller, the ECU, and the hybrid logics in a common device. Expensive and sensitive sensors such as the ICE shaft position determination can be avoided by the fixed coupling of the ICE and the GS. Figure 17 shows the control system layout for the RE.

5 RE VEHICLE INTEGRATION

Targets for the integration of an RE system into the vehicle are:

- No restriction to passenger compartment and trunk
- Package flexibility with alternative drivetrain versions (pure BEV, conventional drivetrain, etc.)
- Utilization of stiff chassis areas to support a low acoustic chassis excitation by the RE system
- Reduction of auxiliary components such as mounts, HV cables, connectors, cooling lines, and so on
- Low impact on vehicle chassis design to avoid expensive additional tooling
- Integration of system assembly process with assembly of drivetrain alternatives
- Vehicle crash requirements
- Vehicle system safety and electromagnetic radiation (EMR) requirements
- Axle load distribution requirements.

The compact box dimensions of the RE system support the system integration even with compact cars. Figure 18 shows two alternative integration concepts. The definition of the best RE integration depends on the vehicle architecture and the intended strategy:

System integration in separate and independent RE module for flexible vehicle packaging:

- flexibility BEV versus REEV
- vehicle package flexibility.

System integration in engine compartment together with electric traction motor system:

- assembly similar to conventional vehicle
- axle load distribution rather similar to conventional drivetrain system

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Figure 19. Design example for RE module.

is intended for the assembly underneath the vehicle trunk. This integration includes:

- RE core module (ICE, GS, mounting frame, and engine-mounted auxiliaries)
- Intake system
- ICE and GS control unit
- GS inverter system
- Connectors for the RE/vehicle interface (HV cables, cooling, 12 V supply, CAN, system mounts, fuel line, and fuel evaporation control system)
- Acoustic sealed RE encapsulation
- Exhaust system with three-way catalyst.

The intake system, the exhaust system, and the damping elements of the module mounts are optimized by detailed acoustic simulation to accomplish an averaged outside 1-m sound pressure of 65 dBA at the back of the vehicle and an interior level of 58 dBA at the codrivers ear. For the early development of the acoustic damping of the RE enclosure, the interior of the box is excited via loudspeaker using a measured sound sample of the ICE. The transfer functions of the relevant components have to be optimized.

Encapsulation of RE module:

- RPE or reciprocating piston ICE with low mechanical excitation levels
- Sealed RE encapsulation as acoustic shield to reduce airborne sound radiation
- Elastic mounting of RE module in vehicle.

Acoustic damping of intake system:

- Three resonators tuned for first three orders at the low noise operation point
- Intake system integrated in RE module
- Decoupled mounting of intake system within RE module.

Acoustic damping exhaust system:

- Integration of reflection damper
- Four resonators (tuned for first four orders at the low noise operation point)
- Absorption damper (for high frequency range).

Acoustic optimization of vehicle integration:

- Additional absorption and damping elements for weak vehicle structures
- Sealed cover of RE module lid
- Isolated mounting of auxiliaries (cooling pump, fan, etc.).

6 REAL-LIFE TESTING OF THE RANGE EXTENDER

For real-life testing, an RE system with RPE and 15 kW electric power at 5000 rpm was integrated in a demonstrator vehicle that has been built on the BMW Mini basis. This electric vehicle is designed as an MCV and has been equipped with a 12-kWh Li-ion HV-battery, which allows a battery electric driving range of 50 km city driving. The described 15 kW RE module and a fuel tank of about 12 l guarantees independency for an additional range of at least 200 km. Propelled by a permanent magnet synchronous motor with 75 kW peak power, the vehicle accelerates from 0 to 100 km/h in about 12 s (0–60 km/h in 5.4 s) and accomplishes a continuous maximum speed of 100 km/h with a peak vehicle speed exceeding 130 km/h.

6.1 Acoustic properties

Besides the absolute acoustic sound pressure by the RE, a good customer acceptance also requires the consideration of psychoacoustic effects. Subjective feedback from test-drives indicates that a continuous single-point operation of the RE system at specific transient vehicle situations such as deceleration can irritate the driver. This is also indicated by the interior sound analysis (Figure 20). With a strict continuation of the 15 kW@5000 rpm load point below vehicle speeds of 50–60 km/h, the RE becomes the dominant issues for acoustic convenience. The subjective noise perception can be improved by some degree of

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

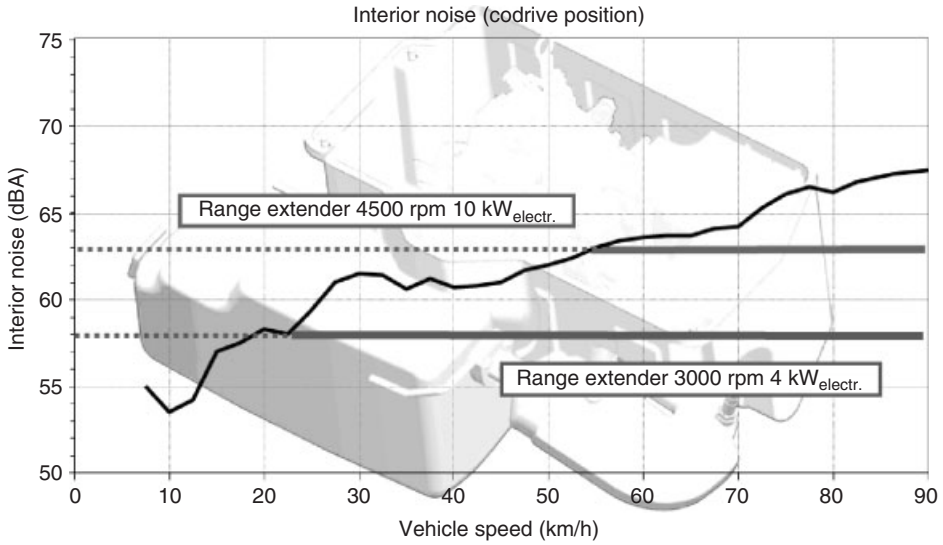

Figure 20. Acoustic analysis in the passenger compartment for pure battery electric driving with different RE load points.

tracking the vehicle speed with the RE speed or by the definition of different RE load points according to vehicle speed and energy requirement of the vehicle. For high speed driving, the general vehicle noise level allows an additional high power load point of the RE by increasing engine speed and mean effective pressure to avoid HV-battery depletion, even at highway driving speeds. Relevant RE load points for an MCV could be:

- Stop-and-go traffic; 4–5 kW @ 3000 rpm
- City driving; 10 kW @ 4000 rpm
- Extra-urban driving; 15 kW @ 5000 rpm
- Highway driving; 25 kW @ 6500 rpm.

Figure 21. Vehicle cold-start calibration

6.2 Vehicle cold start and defrosting

Known issues of BEVs at very cold ambient conditions can also be improved by adapted RE operation strategies to provide the required electric power to operate the vehicle and heat for passenger cabin and HV-battery heating. Because of the reduced charging ability of the HV-battery at low system temperature, the RE is operated at a low load operation point. The fuel consumption is higher than for best-point operation of the RE, but the acoustic properties are acceptable even at vehicle standstill. As the RE operation strategy allows to operate the RE at vehicle standstill only for extreme situations, the fuel consumption disadvantage can be accepted (Figure 21).

6.3 Energy management and fuel consumption

The differentiated 55-km AVL test-drive cycle with city, extra-urban, and highway driving has been used to compare the REEV technology with conventional drivetrains. Uphill gradients with an altitude difference of about 150 m for the highway part and 200 m for the extra-urban part have also been considered.

To evaluate the REEV concept, a limited HV-battery capacity of 7 kWh usable energy and a reduced RE output of 10 kW electric power have been considered. With these limitations and at winter time conditions, the test cycle and especially its uphill gradients require the development

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto047
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

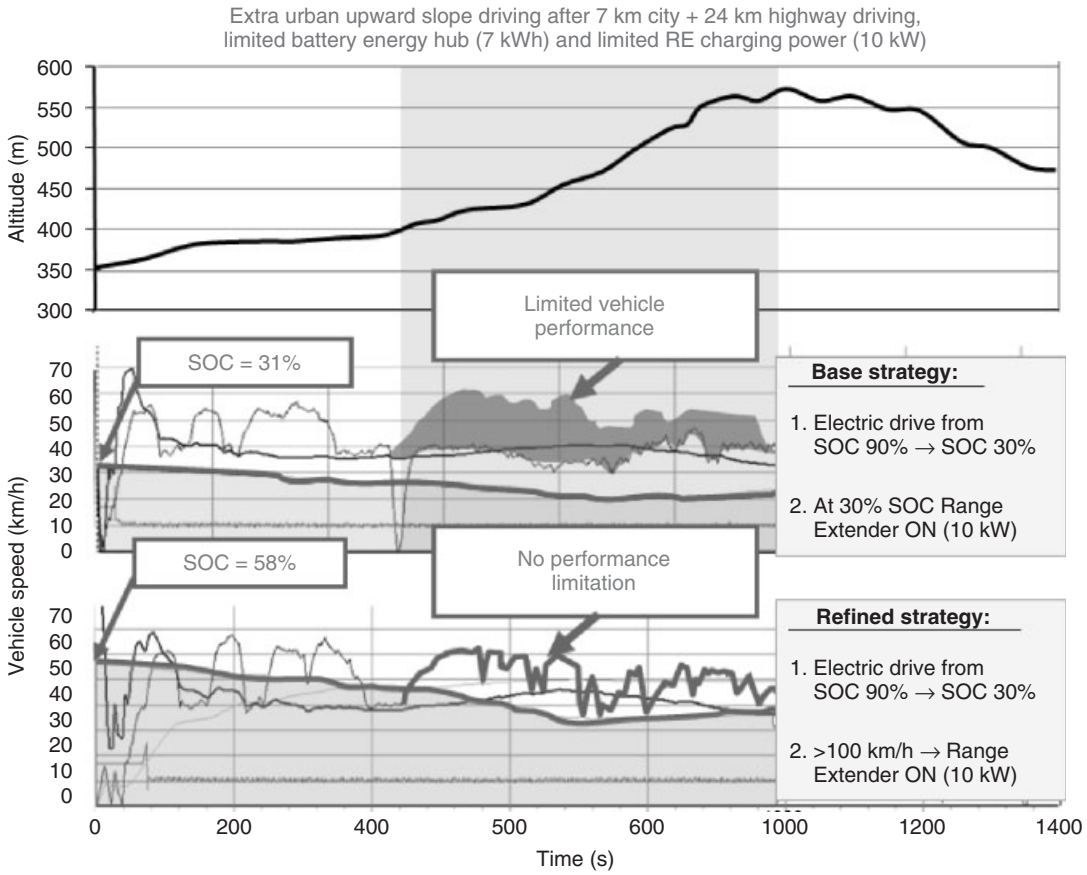

Figure 22. Analysis of the minimum required RE output and HV-battery capacity in dependence of the RE operation strategy.

of an effective RE operation strategy. For a simple HV-battery SOC-driven RE operation strategy, the available limited 10 kW RE output would not be sufficient to manage the uphill gradients with standard traffic speeds when the battery is depleted (Figure 22).

An advanced RE total-range-oriented operation strategy that also considers vehicle speed and energy consumption would activate the RE much earlier (in this case, during highway driving) and avoids noticeable power restrictions for the driver even with the predefined RE output and HV-battery capacity limitations. Further refinement of intelligent operation strategies is one of the key engineering challenges and could also consider GPS (global positioning system) data to support customer-accepted REEV concepts with minimum battery capacity and RE output.

For the direct comparison with conventional drivetrain concepts, an identical BMW Mini with 1.4 l NA engine with fully variable valvetrain, start–stop strategy, and intelligent battery management to recuperate brake energy has been defined. The REEV concept results in an estimated add-on vehicle weight of about 150 kg. The prototype status of the tested car did not allow full weight optimization and resulted in a prototype add-on weight of about 300 kg in comparison to the conventional reference car. To compare the CO_2 emissions of both concepts, the electric energy of the plug-in charging has been considered according to the German power-plant mix with 625 grCO_2/kWh.

For cold start at ambient temperatures of 0°C and city driving conditions, the REEV shows significant CO_2-emission advantages even with battery electric cabin heating (Figure 23). In contrast to the conventional vehicle, a high proportion of the electric energy consumption of the REEV is due to the cabin heating. This part could be reduced by utilizing the RE waste heat. Advantage of the REEV is its ability for recuperating the brake energy. For city driving, 20–25% can be achieved.

If the test vehicles are preconditioned at 20°C and without cabin heating, the CO_2-emission advantage is even higher (Figure 24). Even for an assumed empty HV-battery condition and a continuously running RE (= "miss-use"), the CO_2 emissions are on a similar level for both concepts.

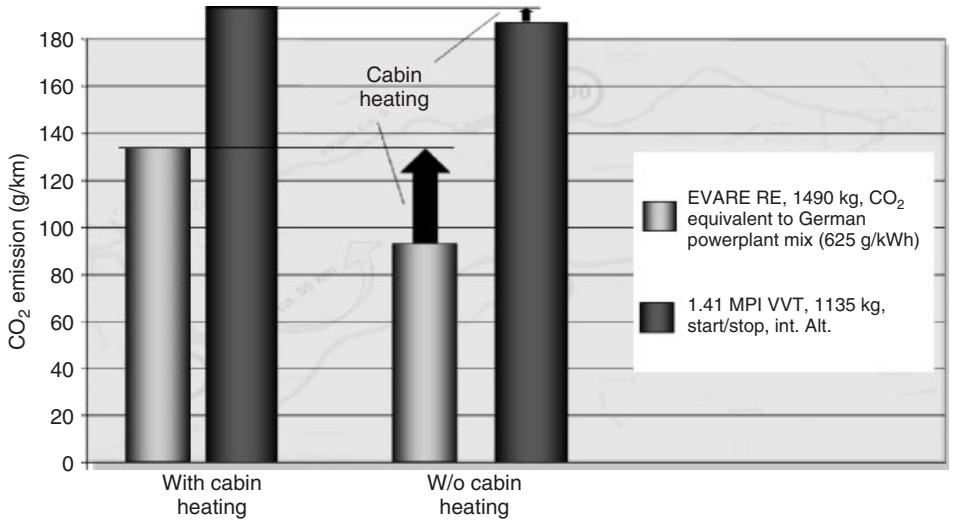

Figure 23. City test-drive at low ambient temperature—cold start.

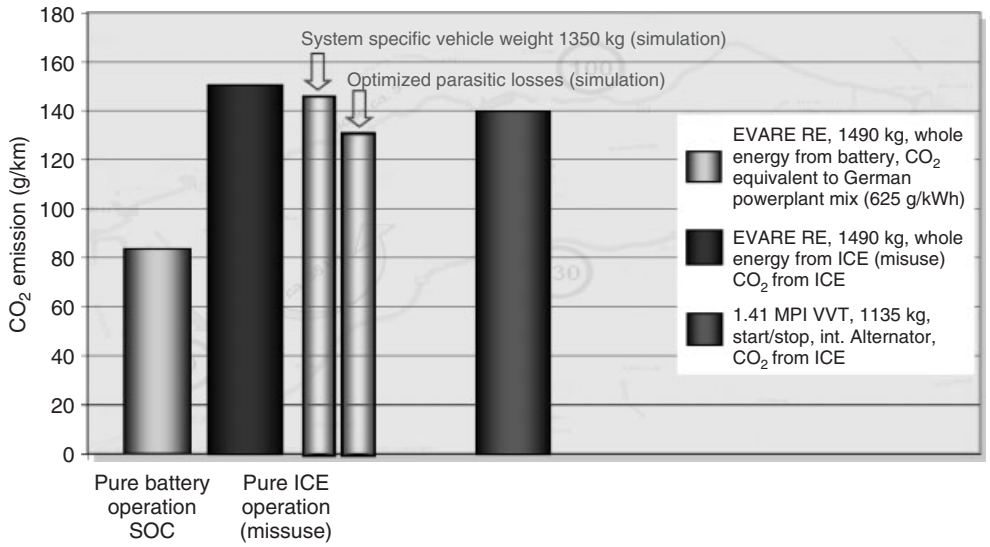

Figure 24. City test-drive with 20°C preconditioned vehicles—hot start.

The effect of further improvement by reducing the vehicle weight and parasitic losses has been simulated.

These circumstances are different in the extra-urban and highway sections of the AVL test cycle. Owing to the higher average load level according to the required traction motor performances (Figure 25), the ICE typical low load fuel consumption disadvantage is of less relevance. These sections of the test cycle also have less potential for recuperation of brake energy. These effects result in a reduced CO_2-emission advantage for the battery electric operation. Correspondingly, the CO_2 emission of the REEV with all energy generated by the RE (=miss-use) is above the emission level of the conventional vehicle. The good SFC property of the conventional vehicle, efficiency disadvantages by the double energy conversion of the series or serial hybrid architecture, and the high REEV weight are the dominant effects (Figure 26).

7 SUMMARY AND CONCLUSION

In summary, the test-drive results show that pure series or serial hybrid REEV architecture can be a cost-efficient concept for MCV applications that focus on the battery

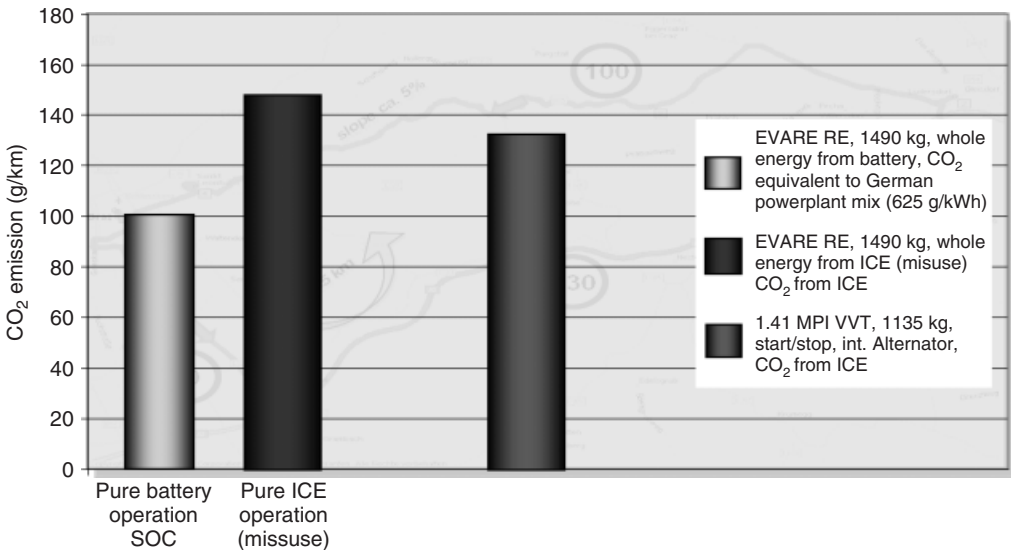

Figure 26. Extra-urban test-drive

electric driving range. For vehicle concepts with more focus on extra-urban and highway driving, an RE concept with switchable direct drive should be preferred to reduce efficiency losses.

Of significant influence on the overall REEV efficiency are also the parasitic losses by auxiliary component efficiencies and the weak thermal isolation of today's vehicle and battery concepts. Improvements and the utilization of synergies such as the reuse of waste heat of the electric traction system are cost-efficient and directly improve the AER.

A further significant contribution to the success of future REEVs is less connected to the hardware but is given by an intelligent system vehicle operation strategy. By

a predictive and driver-demand-oriented operation of the RE, the requirements for the HV-battery capacity and the RE output performance can be reduced for maximum cost efficiency and system weight efficiency. This requires a precise prediction of the energy requirement for the intended route and direct information to the driver about remaining vehicle range and the effect of the recent driving habits. Beside GPS and ambient temperature data, the energy consumption and vehicle range prediction should also consider "learned" data about the driver's preferences and usual routes.

With a well-developed combination of RE, HV-battery, and operation strategy, the REEV approach can be the enabler for affordable and locally emission-free electric mobility.

Batteries Indication and Management

Bernhard Kortschak
AVL List GmbH, Graz, Austria

1 INTRODUCTION

The traction battery for a full electric vehicle (EV) is the primary energy storage device, and as such, it is one of the key components of the possible future propulsion systems. Even for hybrid electric vehicles (HEVs) or plug-in EVs, the battery plays a key role in the improvement of the fuel economy. The precise indication and management is mandatory for the fulfillment of its application-specific function and purpose. In addition, only proper management ensures that the expected lifetime can be achieved as inappropriate use can lead to significant battery degradation or even to safety critical conditions.

The following subsections introduce the main indicators for the state of the battery and the management functionalities of the battery. In addition, the hardware and software system architecture is presented.

1.1 Battery indication

The main battery characteristics, which are used in the context of electrification, are the state-of-charge (SoC), the state-of-health (SoH), and the state-of-function (SoF), and these states are explained briefly in the following subsections. Battery indication, in a wider sense, also includes the monitoring of the components in the battery pack and of the safety relevant subsystems, such as interlock circuit or isolation monitoring.

1.1.1 State-of-charge

The SoC is defined as the percentage of the maximum possible charge that is present in the battery.

This value is one of the main measures of the state of the battery and it is used for the control of the energy distribution in an HEV or full EV. Its precise determination was one of the key research topics in the past and there are still some open aspects that need to be addressed when it comes to a reliable and robust estimation under the boundary condition of a traction battery.

1.1.2 State-of-health

The SoH is a measure of the condition of the battery compared to a fresh battery.

This measure reflects the state of the battery in terms of capacity loss or in terms of increase in resistance over the battery lifetime. This value shows how much of the lifetime has been spent or is still remaining and indicates if the battery must be replaced by a new one. This measure can be expressed either in terms of years or as a percentage of

battery degradation. Actually, this indicator and its precise definition are depending on the actual type of application because the end-of-life (EoL) criterion of the battery can be defined only in the context of its application.

1.1.3 State-of-function

The SoF consists of measures for the ability to fulfill the application-specific function of the battery.

Depending on the application, the battery must fulfill a specific functionality. The measures of fulfillment can be summarized as SoF. Again, these measures are application specific but examples of common indicators are as follows: peak power capability (e.g., 2, 10, and 30 s charging/discharging power and current limits), cold cranking performance, and remaining energy content of the battery (measured in terms of watthours). These measures are often a prediction of future function fulfillment under predefined boundary conditions. For instance, the peak power capability is a prediction of the battery performance under the assumption of a constant battery load for the next few seconds.

1.2 Battery management

The term *battery management* summarizes all control relevant aspects. This chapter focuses on the ability of directly influencing the battery operation by the battery main controller. On the basis of the indicators defined earlier, the battery controller has an indirect influence on the battery operation, for example, in which SoC window the battery is operated. However, the decision on the actual energy distribution is commonly carried out by the main powertrain controller (Section 2), which is responsible for controlling the propulsion system (its discussion is out of the scope of this chapter, see Energy Management Systems of EVs and Energy Management Systems of HEVs for details). The battery main controller can directly influence the following three actuators.

1.2.1 Activating the charge equalization circuit

The charge equalization circuit is responsible for an equalized and balanced state of the individual cells in a battery pack. This kind of circuit is usually present in lithium-ion-based battery packs and packs consisting of electrical double-layer capacitors (EDLCs). For these types of packs, the SoC of the cells will drift apart over time. The equalization of the cell states must be managed by an external electric circuit and its activation is usually triggered by an external command. The equalization can be realized by two different hardware concepts, namely the active balancing or passive balancing systems.

1.2.2 Controlling the contactors

Two contactors are used for a physical disconnection of the battery pack during the time when the vehicle is parked or under service. In addition, the disconnection can be triggered by the battery controller to avoid safety critical situations for the battery. This emergency switch off must be the last measure for the battery main controller to influence the operation of the battery pack as this heavily influences the operation of the vehicle. Before the contactors are closed, the direct current (DC) link capacitor must be charged up to the battery voltage. This is done by a precharge unit activated by an additional contactor.

1.2.3 Thermal management

Depending on the system architecture, the battery enclosure contains the actuators for the cooling and heating of the battery. As such, the battery main controller can activate a fan for air cooling or a pump for liquid cooling, respectively.

1.3 System architecture of the battery management system

The battery management system (BMS) is responsible for carrying out the functions for the battery indication and management as defined earlier. This system consists of hardware and software and can be split into several layers as visualized in Figure 1. The battery controller is placed on top of the BMS hardware. Commonly used terms for this controller are battery control unit (BCU) and battery module/management controller (BMC). For a distributed system, a subcontroller is present that is responsible for the measurement and charge equalization of a subset of cells (modules). This subcontroller is often called *module control unit* (MCU), *cell supervising circuit* (CSC), or *cell supervising electronics* (CSE). These subcontrollers are usually mounted close to the cells and are used to measure the cell voltages and the temperatures and incorporate safety functions such as over- and undervoltage protections of cells, and they include the charge equalization circuit. Other possible hardware architectures are discussed in Section 2.2.

From a software point of view (see the upper part of Figure 1), the BCU software can be split into two main

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

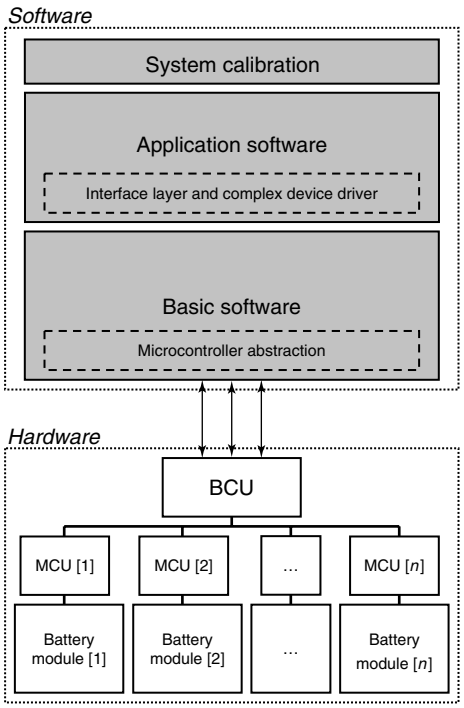

Figure 1. Battery management system—system architecture. (Reproduced by permission of AVL List GmbH.)

layers. The lower layer consists of the basic software that includes the real-time operating system, the low level device drivers for the direct inputs and outputs, and the communication stack, for example, for the CAN (controller area network) bus. Within this layer, an abstraction of the hardware is performed so that the upper layer can be designed independently from the hardware. The upper software layer contains the application software. This part of the software is responsible for the implementation of the high level functions, such as the estimation of the SoC. BMSs according to this structure are highly modular and offer the flexibility that these systems can be applied to different applications. The application software, for instance, can be easily extended by customer-specific code. At last, the software must be calibrated for the cells used in the battery and for the specified vehicle.

The total system costs can be reduced if functions of the application software are embedded into the powertrain controller (see Section 2.2.4 for details). As a result, the size and the complexity of the controller on the battery side can be reduced. In addition, the calibration is easier if all application-specific functions are placed together in a single control unit.

2 HARDWARE ARCHITECTURE

The BCU, as the main controller of the battery, has two major interfaces (see Hybrid Systems and High Voltage Components). Firstly, the BCU communicates with the vehicle control architecture. A CAN interface is usually offered by the BCU and data is exchanged with the powertrain control unit as shown in Figure 2. In the case of an HEV, this controller is often referred to hybrid control unit (HCU). Secondly, the BCU communicates with subsystems inside the battery or is directly connected to battery components (Figure 3).

This section concetrates on the interface to the components inside the battery enclosure. Section 2.1 presents these components followed by a subsection, which describes the possible architectures of the control system. Section 2.3 compares the possible hardware solutions for the charge equalization circuit.

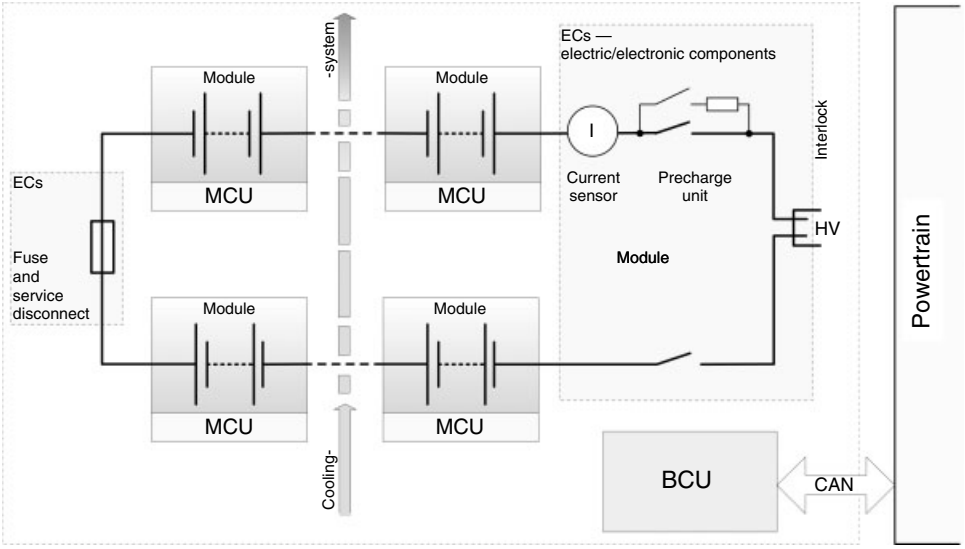

Figure 3. Battery control unit and the battery interior components and subsystems. (Reproduced by permission of AVL List GmbH.)

2.1 Components of battery management systems

The following components are part of the BMS (see, e.g., Pichler *et al*., 2007). In general, they are placed inside the enclosure of the battery pack (Figure 3).

Some components are part of the power system and must carry the main battery current. In this case, the components must be designed to withstand the continuous and peak currents. For a passenger HEV or EV, a typical value for the continuous battery current is 100 A, whereas the peak current can reach values of 250–350 A (both values depend on the specific application).

2.1.1 Current sensor

The pack is equipped with either one or two current sensors. They have to measure the pack current in a wide measurement range. In addition, the integration of the current must be accurate over a long period of time, because an offset would directly influence the accuracy of the SoC calculation. For this reason, the current sensors for traction batteries often offer two or more measurement ranges. Typical sensors are based on a shunt and provide very precise measurements. Other types of sensors, such as hall-effect sensors, can be used as backup devices.

2.1.2 Main contactors

The main contactors are used for a physical disconnection of the battery pack and therefore provide a galvanic isolation. In addition, they offer the possibility to force a shutdown of the battery for emergency reasons. It is important to note that this emergency shutdown under load is not the main function of these components and, as such, they can usually only withstand a few switching cycles under these conditions. On the other hand, the contactors for traction batteries must be small and light weight compared to their counterparts in other applications. Protection measures must be included so that these contactors can safely disconnect the battery from the system under all operating conditions (e.g., for very high peak currents). In order to ensure a precise diagnosis, the voltage across these contactors can be measured so that an increase in the resistance can be detected. Another effect, which should be monitored, is the decrease in the insulation resistance over time because of evaporated metal inside the contactor.

2.1.3 Precharge unit

A precharge unit must be activated before the main contactors can be closed. It consists of a precharge relay and an appropriate power resistor. The purpose of the precharge unit is the charging of the DC link capacitor of the electrical system and to reduce the inrush current. The main contactors can be safely closed if the voltage difference between battery and DC link capacitor is below a predefined threshold. This procedure ensures that the lifetime of the main contactors can be achieved.

2.1.4 Fuse

The main contactors can be used for an emergency power down of the system. These contactors can provide this

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

functionality only up to a certain current limit (e.g., a few 100 A). Above this limit, the contactors must not be opened as a disconnection can lead to a destruction of these components. As such, additional measures must be applied and a fuse can be used for currents, for example, during a short circuit. The short-circuit current of a lithium-ion battery can reach values of 3000–7000 A and it is of importance that the contactors can withstand this overcurrent situation for some time because the fuse needs a specific amount of time unless it can break the connection.

2.1.5 *Service disconnect*

The battery can be equipped with a service disconnect. This switch can be removed for vehicles under maintenance in order to break the electrical connection in the middle of the battery pack. Thus, only two strings of cells remain with half the system voltage.

2.1.6 *Cell bypass device*

Currently, bypass devices on the cell or module level are under research. A cell with a failure can be shorted by this device. This concept makes sense under the assumption that common cell failures will lead to a cell internal disconnection (an open circuit). Under this condition, the pack can still be used with only limited effects on the overall performance of the battery. High costs are currently one of the challenging aspects of this technology.

2.1.7 *Isolation monitoring system*

The battery terminals and the cells will be electrically isolated to the vehicle conductive structure because of safety requirements for voltages above 60 V DC. The isolation monitoring system is part of the overall safety system and it will prevent the usage of the battery in case of isolation failures. The monitoring system periodically measures the insulation resistance (leakage resistance). In typical applications, the measurement range for this resistance is between several 10 kΩ up to several 1 MΩ. Another term, which is commonly used for this system, is *insulation resistance monitoring system*.

2.1.8 *Connector and interlock circuit*

The connectors from the battery to the other electrical components can include additional signal wires so that an interlock system can be implemented. These signal wires are used for monitoring the correct connection and wiring between components. The battery is switched off as soon as a failure is detected, for instance in case of a disconnection of the battery or in case of a failure in the power cables. The electronic circuit can be part of the BMS or it can be placed in other parts of the electrical system.

2.1.9 *Thermal subsystem*

For cooling and heating, the battery can be equipped with a thermal system for air or liquid cooling. For air cooling, the BMS can often control a fan; however, for liquid cooling, the system is often connected to the air-conditioning system. In this case, the activation of the pump is out of the scope of the battery controller. In each case, the battery is equipped with a number of temperature sensors, such as a temperature sensor for the cells, for the inlet/outlet temperatures of the cooling system, and for temperature measurements on the printed circuit board (PCB). In addition, the battery can be equipped with a PTC (positive thermal coefficient) heater or similar heating devices for cold temperatures.

2.1.10 *Subcontrollers on module level*

Depending on the controller architecture, the BMS can consist of the main controller and subcontrollers, which are responsible for the monitoring and controlling a subset of cells. The different possibilities are discussed in Section 2.2.

2.2 Centralized versus distributed controller architecture

In traction batteries consisting of cells based on lithium-ion technology or EDLCs, all cells must be monitored individually and the charge balance between these cells must be managed by an external circuit. For this reason, all cells are connected to the BMS for cell voltage measurements and for the purpose of charge equalization. In addition to the cell connection, a large number of temperature sensors, for example, one sensor for each cell, are located in the pack.

In order to reach the required voltage level, the number of cells in series connection can exceed 100 pieces for an HEV, plug-in HEV, or EV application. In case of a centralized system, all wires are connected to a single PCB, which introduces a high complexity for the wiring harness. On the other hand, the wiring effort can be reduced in a distributed system of subcontrollers, where each subcontroller is responsible for a subset of cell voltage and cell temperature sensors. Different degrees of centralized and distributed systems are visualized in Figure 4, which are explained in detail in the following subsections.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

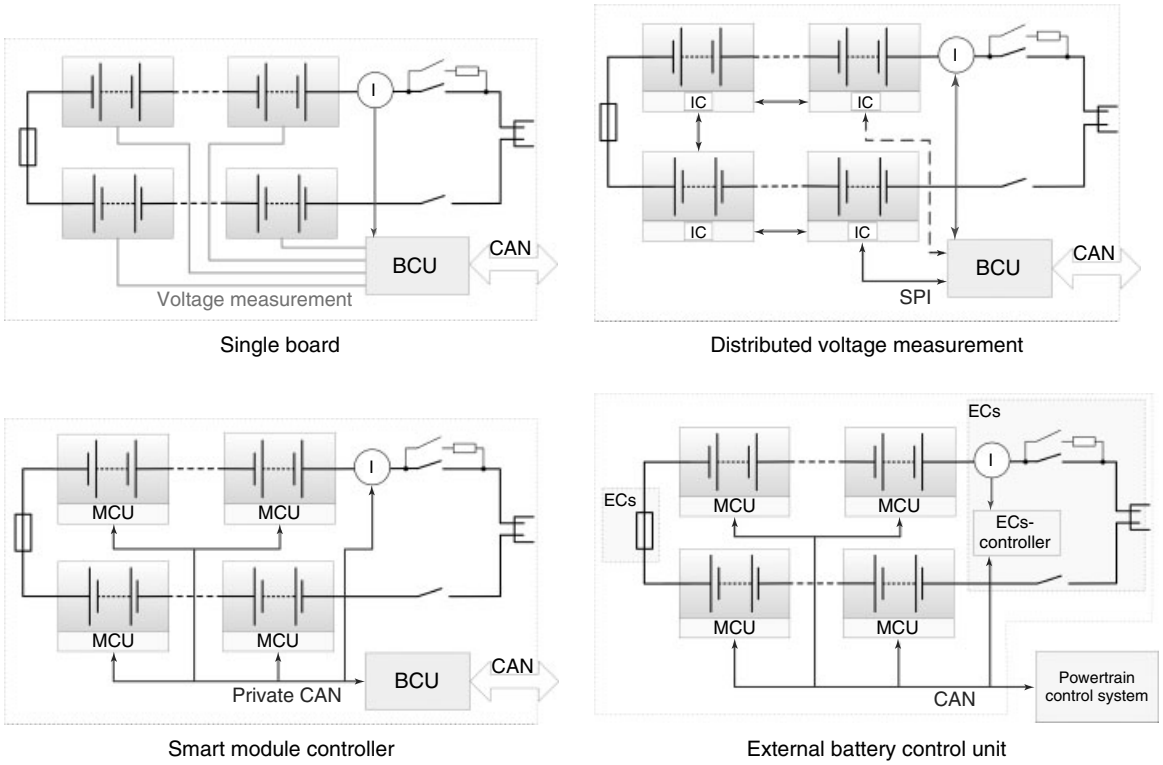

Figure 4. Different complexities of the controller architecture. (Reproduced by permission of AVL List GmbH.)

In all cases, specialized integrated circuits (ICs) can be utilized for the purpose of monitoring the cell voltages and for the charge equalization. The use of ICs for cell monitoring significantly reduces the total system costs and increases the reliability as the number of components is decreased. Several manufacturers offer possible solutions for the monitoring of traction batteries. A bus system is required for the information transfer between the different PCBs for a distributed system. The simple SPI (serial peripheral interface) communication is not appropriate for long wires in a harsh environment. Despite proprietary communication systems, CAN offers a robust communication between the different boards with the drawback of higher costs.

2.2.1 *Single board*

All relevant electronics are placed on a single board. All wires from the cells and temperature sensors must be routed to this board. This solution is attractive for small and highly integrated battery packs and the onboard communication between the BCU and the cell monitoring ICs can be solved by SPI. However, the wiring harness is getting more and more complex as the size of the battery pack increases with the number of cells. In addition, measurements over long cables are prone to disturbances and active balancing systems over long cables can introduce problems with respect to electromagnetic interference. The board itself must be designed for voltages up to several 100 V, and the computational power of the BCU must be sufficient to process all input data.

2.2.2 *Distributed voltage measurement*

For larger packs, the cell monitoring ICs can be placed locally close to the modules and this reduces the number of connections to the main PCB. These modules can consist of 6–16 cells in series connection and some space must be reserved on these modules for the additional electronics. A smaller number of cells per module and a reduced voltage simplify the handling of these modules, if they are built as physically separated units.

In this solution, the module electronic is responsible for data acquisition and execution of the charge equalization. The BCU contains all required software and processes and manages all information. The development of a robust communication system is one of the major issues. Proprietary solutions exist, which connect the individual module controllers with the BCU by a daisy-chain-like connection. An SPI similar interface is used, but it has to be extended to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

be able to provide the required galvanic isolation between the different modules. The communication system must support a high bandwidth as all voltages and temperatures are to be transmitted over this line and so this system is sensible to disturbances. Despite this issue, this architecture offers a very flexible and cheap solution suitable for all different applications.

2.2.3 *Smart module controllers*

This solution consists of a master/slave controller architecture. Small microcontrollers are placed on the module boards, which are communicating with the BCU by CAN bus. The utilization of the CAN bus offers a robust solution to the bandwidth problem. The controller on the module side can be kept small, for example, an 8-bit controller can be utilized in order to minimize the additional costs. As such, the BCU is still responsible for all data processing, but the controller on the module level can take over some small tasks, for example, the protection of the cells against over- and undervoltage. These controllers can also monitor the main controller and a high level monitoring concept can be realized without the utilization of dual-core processors for the BCU. For this monitoring purpose, an additional hardwired line is required so that the module controllers are able to force the contactors to open in a case of a serious system failure.

Even more software functionalities can be moved from the BCU to the module controllers, but in this case more computation power is required, for example, 16-bit microcontrollers can be used. For this option, high level functions such as the estimation of the SoC are performed on a module level. In addition, self-diagnostic of the modules is possible and, from a software point of view, the modules can be exchanged in service easily. The BCU can be equipped with a smaller and cheaper processor but this hardly pays of the additional costs on the module side. A smart solution is also required for software updates and for calibration so that it is not required to flash and calibrate each module controller individually.

2.2.4 *External battery control unit*

The BCU in the options above is responsible for the direct control of the battery electric. Thus, the PCB consists of two areas, a lower voltage part (microcontroller and related components) and a higher voltage part (battery voltage measurement and isolation monitoring). Both areas must be separated by an isolation barrier. The BCU is therefore a battery-specific controller board.

On the other hand, it is possible to design a small controller, which is responsible for the battery-related functions, that is, this controller is directly connected to the electric and electronic battery components. The BCU itself is reduced to a standard controller, which communicates with the battery by CAN bus and which can be placed outside of the battery housing. A dedicated BCU is not even required, if enough processor resources are available on other controllers in the vehicle, for example, in the main powertrain controller.

2.3 Passive and active balancing systems

The SoC levels of the cells within a battery pack will drift apart over time. The main reasons for this drift are as follows: different self-discharge rates, different cell capacity values, and different Coulomb efficiencies. The self-discharge rate is relevant during standstill periods, whereas the two other effects apply during the usage of the battery. In addition, the cells age at different rates because of the individual initial conditions of the cells, for example, impurities in the cell production, or because of different operating conditions during cell usage, for example, temperature gradients inside the battery. This leads to a further increasing spread in the cell characteristics over lifetime.

A balancing system consisting of a charge equalization circuit can offset these differences unless to a certain point, where the spread is significant and the balancing current is not sufficient anymore. The resulting SoC differences will lead to limitations during the usage of the battery pack. For instance, during charging, the cell with the highest SoC will reach the upper voltage limitation before all other cells are completely charged up. A similar situation will occur during discharging and both effects together will reduce the available energy content of the battery.

The charge equalization between the cells can be activated by the BMS. Despite this activation, different hardware concepts for the charge equalization circuit exist. An overview can be found in Daowd *et al*. (2011), which provides an overview of advantages and disadvantages of 18 possible hardware topologies. Principally, two different concepts are possible, namely the passive balancing system and the active balancing system. Passive systems are only capable to discharge individual cells, whereas the cells in active systems can be discharged and charged depending on the operating mode of the system.

Figure 5 shows the effect of this principle difference between the two concepts. In an unbalanced state, the cells show a different level of SoC. In this example, only three cells are displayed for the sake of simplification, whereas the first cell has the highest SoC compared to the third cell with the lowest SoC level. With a passive balancing

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

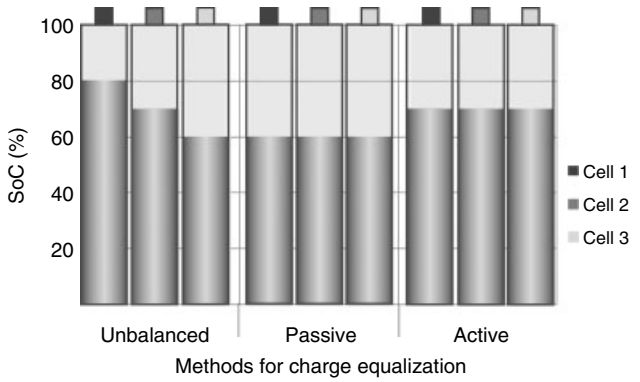

Figure 5. Impact of passive and active balancing methods on the cell charge level. (Reproduced by permission of AVL List GmbH.)

system, it is only possible to discharge cells. As such, the first and second cell must be discharged unless they reach the SoC level of the worst cell. In this example, the worst cell is the cell number 3. The power during discharging is dissipated and this reduces the overall efficiency of the system. With an active balancing system, it is possible to discharge cell number 1 and to charge cell number 3, such that all cells are matched to an average SoC level. The active balancing circuit will transfer the charge between the cells with a specific efficiency and the average SoC after balancing will be less than the average before balancing. Nevertheless, this system is more effective compared to passive balancing.

Balancing systems can be designed not only for currents of several 100 mA but also for currents up to several 1 A. Balancing boards for higher currents yield to complex electronic circuits compared to small balancing systems and therefore to higher cost. The optimal balancing current depends mainly on the capacity of the cells in use and of the expected differences in the cell-to-cell characteristics at EoL.

Passive balancing systems offer the opportunity to activate the balancing for each cell independently, whereas active systems are usually restricted to certain operating modes. In other words, on active balancing systems, it is usually not possible to apply the balancing to several cells of a module in question at the same time. In this case, balancing of several cells must be performed in consecutive steps. This must be considered for the sizing with respect to the maximum current of the balancing circuit. In addition, active balancing systems offer good efficiencies for transferring charge from one to another cell. However, owing to restriction in the operating modes, it can occur that the charge must be transferred over several cells as described earlier. In this case, the efficiencies of each balancing activity must be multiplied yielding significantly lower system efficiency under real operating conditions.

The different balancing concepts are briefly discussed as follows.

2.3.1 *Passive balancing—dissipative resistors*

For passive systems, shunts, which are placed in parallel to the cells, can be activated. Depending on the SoC level of the cells, these shunts are switched on or off. Several cells can be discharged at once, but the overall heat generated on the PCB must be dissipated properly.

2.3.2 *Active balancing—charge shuttling*

One possible concept of shuttling the charge between the cells is the concept of a *flying capacitor*. A capacitor can be consecutively switched in parallel to the cells (see Figure 6 for a possible schematic). Cells with higher SoC, and thus with a higher voltage level, will charge up the capacitor, whereas cells with lower voltage will be charged up by the capacitor. The switching pattern between the cells can be fixed in advance or an intelligent logic can pick out the cells that need to be balanced. High peak currents can occur during charging and discharging, if the voltage levels are significantly different. On the other hand, hardly any balancing takes place if the voltages of the cells are similar. This can lead to problems for technologies, where the SoC

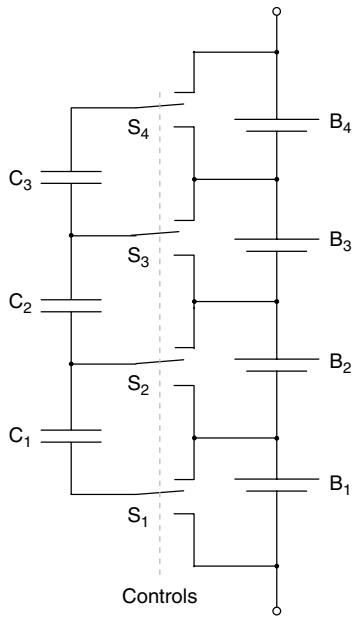

Figure 6. Sketch of a balancing concept with flying capacitors C_1–C_3 for four cells B_1–B_4. Note: Switches S_1–S_4 can stay in three states (upper/lower connection, respectively, and open). (Reproduced by permission of AVL List GmbH.)

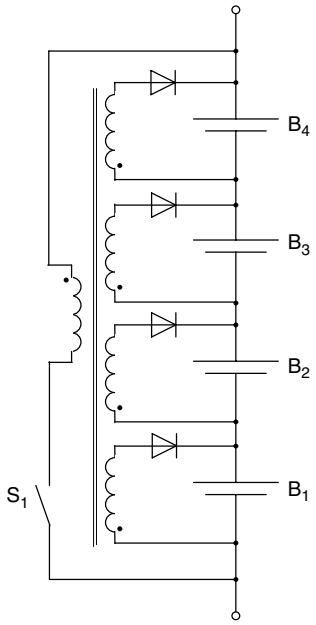

Figure 7. Sketch of balancing concept for four cells B_1-B_4 with a shared transformer with a switch S_1 on the primary side. (Reproduced by permission of AVL List GmbH.)

has only a small impact on the open circuit voltage (OCV) especially if the battery is used within a small SoC window like in an HEV. For EDLCs, this method can be applied successfully.

2.3.3 Active balancing—energy converters

Active balancing systems can be realized using inductors or transformers. Several concepts using transformers can be considered. For the *switched transformer* concept, a flyback converter is used consisting of a transformer where the primary side can be connected to the module or pack terminals, respectively, and the secondary side of the transformer can be connected to one of the single cells. The primary and secondary sides are switched on and off allowing an appropriate charge transfer between the cells. For the *shared transformer* concept, a similar principle is used. In this case, as many secondary windings are used as cells, which need to be balanced (Figure 7).

3 SOFTWARE ARCHITECTURE

The BCU is the main device for the management and evaluation of the battery measurements in order to provide the information about the state of the battery to the vehicle. In addition, it controls the battery contactors, the charge equalization, and fans and pumps for the thermal management. One of its major functions is the estimation of the SoC and the SoH and the prediction of the battery performance, that is, the SoF.

The main functions of the software can be summarized as follows (Pichler *et al*., 2007):

- state estimation of the battery modules (SoC and SoH);
- prediction of battery performance (SoF);
- control of the charge equalization;
- measurement signal processing (mainly current, voltage, and temperature);
- safety relevant monitoring (interlock circuit monitoring and isolation monitoring);
- fault detection and error management;
- communication with vehicle and module controller boards.

3.1 Software modules

The software of the controller can be split into different layers (Figure 8), whereas the first layer includes the basic software with the hardware-dependent functionalities, for instance the device drivers, the transfer layers for different communication systems such as LIN (local interconnect network) or CAN, the memory management, and the operating systems. On top of the basic software is the applications software with the high level functions. The high level functions are structured in software modules with defined inputs and outputs. These modules can be used in a very flexible way, for example, they can be exchanged by application-specific software modules, or they can be placed in different controllers if required. A possible structuring into software modules could be

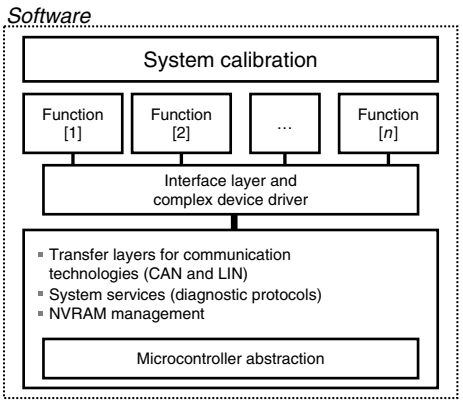

Figure 8. Basic software and application software in the BCU. (Reproduced by permission of AVL List GmbH.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as follows (compare with Languang *et al*., 2013, with a slightly different structuring).

3.1.1 BCU control

This module consists of the main state machine of the BCU. The BCU state can switch between different operating modes, such as initialization, running, after-run, or shutdown.

3.1.2 Error management

A diagnostic function monitors all input and output ports of the BCU. An error management is responsible for proper reactions in case of any signal errors.

3.1.3 Safety monitoring

A safety concept can be required depending on the required ASIL (automotive safety integrity level) classification (Section 4). Additional monitoring levels exist, which are double checking the results of the other software modules.

3.1.4 Communication

The communication module is responsible for the CAN communication to the vehicle and, if required, to the subcontrollers in the battery.

3.1.5 Contactor control

This software module is responsible for the opening and closing of the main battery contactors. In addition, this function will control the precharge unit.

3.1.6 Battery protection

The battery must be operated within a safe operation area. This function prevents an inappropriate use of the battery with respect to current, voltage, power, temperature, or SoC limitations.

3.1.7 Electrical hazard protection

This module provides protection against electrical hazards and handles the isolation monitoring, the monitoring of interlock system, and service disconnect switch.

3.1.8 Battery state calculation

One of the main functions is the observation of the state of the battery and the calculation of the SoC, SoF, and SoH. A detailed explanation of this function is given in Section 3.2 to 3.5.

3.1.9 Balancing control

The charge equalization circuit is activated depending on the actual state of the cells. The balancing activity can be triggered based on the relative comparison of cell voltage levels or by comparing cell SoC levels (Section 3.2). By considering the differences in SoC and in the actual capacity of the cells, the balancing strategy can be even further improved to balance according to a uniformity of the remaining (usable) cell capacity.

3.1.10 Thermal management

The thermal management includes the monitoring of the cell and module temperatures and, if available, the activation of fans and/or pumps for the cooling and heating of the battery.

3.2 Methods for state estimation (SoC)

The SoC is calculated by dividing the charge present in the battery Q by the maximum possible charge $Q_{\max}$. This relationship is described by Equation 1 and the SoC is expressed as a value between 0% and 100%.

$$\mathrm{SoC} = \frac{Q}{Q_{\max}} \cdot 100\% \tag{1}$$

It is important to note that the SoC of lithium-ion batteries cannot be measured directly and that the correct value also depends on the measurement procedure, for example, by the test temperature.

In the past, several methods have been developed for the purpose of SoC calculation. A good overview of the possible methods can be found in Languang *et al*. (2013), which includes a brief discussion of the advantages and disadvantages of the different methods and the resulting estimation errors. Another overview can be found in Zhang and Lee (2011) with additional subsections for the capacity and the lifetime prediction. The possible SoC estimation methods can be classified as follows.

- discharge test;
- Coulomb counting (ampere-hour counting);
- OCV measurement;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- impedance measurements (with electrical impedance spectroscopy, EIS);
- algorithms based on neural networks;
- heuristic interpretation of measurements, for example, by fuzzy logic;
- model-based estimation methods, for example, by Kalman filter, or other state observers.

In literature, different approaches are described based on ampere-hour counting or by utilization of the relationship between SoC and OCV. However, these methods are not reliable for a precise determination of the SoC in the case of traction batteries because of the following facts:

- The voltage and current measurements are inaccurate and noisy. An offset in the current measurement will lead to significant errors in the calculation of the battery charge.
- The battery characteristics change significantly especially at low temperatures. However, the cell and the sensor temperature will be different even if the sensor is mounted close to the cells.
- Batteries in HEV application are usually operated in a small SoC range only. Thus, it is not possible to reset the charge counter because the battery is possibly never fully charged.
- For some lithium-ion technologies, such as LFP (lithium iron phosphate) or LTO (lithium titanate oxide), the cells show a very good performance over a wide range of SoCs. In other words, the battery characteristics over SoC are very similar and the measurements contain only limited information about the actual SoC (Figure 9).
- Some technologies, such as LFP, show hysteresis effects on the relationship between the OCV over the SoC (the hysteresis is not shown in Figure 9).

Promising methods rely on a battery model and utilize an observer design for estimating the internal states of this model (e.g., see Plett (2006) for a sigma-point Kalman filter or Kim (2005) for a sliding mode observer). Section 3.3 provides further details about the advantages of a model-based estimation of the SoC.

On the other hand, model-based algorithms are computationally very demanding. Thus, simplifications are required for an SoC estimation for all cells. For example, these SoC values are used for the correct activation of the charge equalization circuit. However, the precise estimation of the SoC in the cells is difficult especially while operating the vehicle. During operation, a voltage drop occurs during charging and discharging and differences in the cell resistances yield to inaccurate predictions of the cell states, if the predication is based on the cell voltage level only. Thus, the algorithms for controlling the charge equalization circuit must consider this effect in order to avoid an inappropriate activation of the balancing.

3.3 Model-based SoC algorithms in detail

In order to achieve high accuracy, model-based algorithms can be used, for example, Kalman filter or nonlinear adaptations of this filter, for example, sigma-point Kalman filter or extended Kalman filter (EKF). Kalman filters have played an important role in controls of various systems and this technique has proved to be extremely adequate for many HEV and EV applications.

In order to adapt the internal states of the model, the outputs of the battery model are compared with the measurement results. The observer iteratively updates the battery states and parameters such that the model outputs fit to the measurements.

The model, used for this approach, consists of an electrical battery model and a thermal model. An initial (offline) parameter identification technique is required. The parameters, which are often considered in these models, depend on SoC, temperature, current rates, life cycle, or duty cycle. The battery model should fulfil the following requirements:

- The model must be suitable for online calculation.
- A simple model is preferred because of restrictions of computation time and memory.
- The model must cover the whole battery operating range, that is,
  - temperature range,
  - SoC range,
  - current range, and

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

  - dynamic range of battery operation (from pulses of seconds to constant current over minutes).
- The model parameters must be adapted over lifetime such that the changing characteristics over battery life are considered.

The Kalman filter performs two different calculation steps. In the prediction step, the battery voltage and its uncertainty are predicted based on the measured current. In the update step, the state estimates are updated according to the difference between the predicted voltage and the measured battery voltage.

Despite of having advantages, the Kalman filter has some disadvantages too. The disadvantages can be summarized as follows:

- High memory consumption and computation time.
- Floating point operations are required (a fixed-point implementation is challenging for nonlinear systems).
- The joint estimation of states and parameters can lead to stability problems (Hu *et al*., 2012, and Andre *et al*., 2013).
- It is difficult to quantify the accuracy.
- The battery dynamics cannot be described perfectly and thus model errors cannot be avoided.

Especially the accuracy of the SoC method is difficult to define. First, a definition and measurement procedure for the accuracy is required. In addition, the accuracy depends on many influencing factors, such as

- sensor quality (sensor noise and offset);
- quality of signal processing (antialiasing filter, digital signal processing, and time jitter between voltage and current signals);
- quality of battery model (model errors);
- calibration of the battery model (calibration errors);
- choice of estimation method (approximation method for nonlinear system);
- calibration parameters of the observer.

On the other hand, these model-based estimators are usually robust and quite efficient. In addition, some estimators, such as the Kalman filter, can also provide error bounds on the estimates.

3.4 State-of-function

The definition of the SoF depends on the application. In HEV, the battery is used for boosting and recuperation of brake energy. As such, the power of the battery is one of the major measures for its functionality. Thus, the SoF includes indicators for

- peak charging/discharging current (for 2, 10, 30 s, or similar);
- peak charging/discharging power (for 2, 10, 30 s, or similar);
- cold cranking performance (if required);
- maximum and minimum pack voltages;
- indicators for derating due to low or high battery temperature.

For EVs, additional measures are important. Thus, the SoF can include indicators such as

- remaining charge assuming a specific load profile and/or
- remaining energy assuming a specific load profile.

The SoF can be calculated using predefined maps, for example, by storing the maximum charge power in a map over SoC, temperature, and SoH. On the other hand, the SoF can be predicted using model-based techniques, which utilize the state estimation and battery model of the SoC calculation as described in Section 3.3.

3.5 State-of-health

Similar to the definition of the SoF, the SoH can be defined depending on the usage of the battery in an HEV or EV. In the HEV, the SoH is usually an indicator for the increase in the battery resistance. The EoL of the battery is reached, if the battery power is limited by its resistance value. The calculation of the SoH can be performed as defined in Equation 2, whereas the SoH depends on the actual resistance value R, on the resistance at beginning-of-life (BoL) R_{BoL} and at EoL R_{EoL}, respectively.

$$\mathrm{SoH} = \frac{R_{\mathrm{EoL}} - R}{R_{\mathrm{EoL}} - R_{\mathrm{BoL}}} \cdot 100\% \tag{2}$$

For this calculation, the SoH is defined as 100% for a new battery and reaches 0% at EoL. The calculation assumes a linear relationship between increase in battery resistance and SoH. Other solutions incorporate nonlinear relationships between the battery characteristics and the battery life, which is usually a more realistic assumption of real-world battery degradation.

In EVs, on the other hand, the main indicator for the SoH is the capacity loss, which can be between 20% and 30% at EoL. For this kind of applications, the SoH can be calculated, if the actual battery capacity C is known and when this value is compared with the capacity at

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

BoL and EoL (C_{BoL} and C_{BoL}, respectively), as defined in Equation 3.

$$\mathrm{SoH} = \frac{C - C_{\mathrm{EoL}}}{C_{\mathrm{BoL}} - C_{\mathrm{EoL}}} \cdot 100\% \tag{3}$$

It is important to notice that additional measures for the SoH exist. For instance, the cells in the battery will degrade differently. In addition, the weakest cell will limit the minimum/maximum values for the battery voltage, current, and temperature. Thus, the SoH can be defined as the relative difference between the individual cell characteristics of the battery. Another measure for the health of the battery is the increase in the self-discharge rate of the battery over time. A corresponding SoH value can be derived in a similar approach as shown in the calculations earlier.

3.6 Thermal management

The thermal management of batteries is the base for an effective operation in all climates. The BMS calculates the thermal energy transport and the need for heating or cooling including all measurements and diagnostic functions, for example, a temperature measurement plausibility check. The system of the battery thermal management subdivides in the following main functions:

- Sensor value conditioning
  - Convert voltage signals to temperature or pressure signals
  - Electrical check of sensor values
  - Filtering of physical values
  - Plausibility check
- Thermal modeling
  - Calculation of cell/module temperature values
  - Calculation of heat transfer between cells and coolant
  - Calculation of coolant temperature values
- Thermal controlling
  - Components switch on and off (e.g. fan)
  - Plausibility check of requests
  - Compare and reach temperature targets.

In detail, the software module acquires the temperatures via thermal sensors and calculates the coolant temperature at specific points. Moreover, a detailed evaluation can estimate the cell internal temperatures at critical points. The fan and pump control values are calculated and checked for plausibility.

The placement of the temperature sensors is very much depending on the type of cell (pouch cell, cylindrical or prismatic cell) and the design of the battery pack (see Rechargeable Battery Basics). Therefore, the placement is supported by results of thermal simulations with finite element analysis (FEA). Especially for pouch type cells, the placement is critical as the thermal conductivity of the pouch surface is worse than for other types of cells.

Bad cell-to-cell connections can lead to critical hot spots at the cell terminals. These hot spots are difficult to detect, if the battery pack is not equipped with a high number of temperature sensors. In order to improve the reliability of the cell diagnostic and the response time in case of connection failures, a monitoring of the cell resistance values could be applied in addition to temperature measurements.

4 FUNCTIONAL SAFETY

Each function has the potential risk to fail and might cause harm (see Battery safety for lithium batteries in vehicle applications). In case of batteries, the lithium technology is especially very sensible to over-/undervoltage, over-/undercharge, and over-temperature conditions. Therefore, the battery control system must be made safe with respect to malfunctions as an incorrect usage of the battery can lead to safety critical situations.

The impact of the conditions mentioned earlier is depending on the cells, which are applied in the battery. The safety properties of the cells itself can be classified into hazard levels, for example, defined by European Council for Automotive R&D (EUCAR). These levels describe the impact and the mechanical, thermal, and chemical hazards on a cell level. It is clear that safety critical cells need more efforts on the control side than BMSs, which are used for very mature and safe cells. As such, the technical solution itself may vary between the different suppliers.

Section 4.1 focuses on the concept phase in the development process, whereas Section 4.2 describes the possible technical implications on the BMS.

4.1 Functional safety in the BMS concept phase

The standard ISO26262 can be used during the development of a BMS. Despite mandatory processes during the development, this standard also covers the life cycle of the product including the production and the usage phase. A detailed discussion is out of the scope of this work, but three development steps during the concept phase are mentioned in this subsection, namely the hazard analysis and risk assessment, the determination of the ASIL, and the development of the function safety concept.

The aim of the hazard analysis and risk assessment is the identification and the categorization of potential

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto048
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

hazards. During the assessment, different risk parameters are defined, namely the severity, the exposure, and the controllability. In a consecutive step, safety goals and their assigned ASIL are determined by a systematic evaluation of these hazardous situations. Finally in the last step, a functional safety concept for the BMS can be derived.

Depending on the ASIL of the system, different requirements of the control system can be derived. One of three basic technical solutions can be selected according to the ASIL, but the detailed concept must be appropriately developed for the specific application. For ASIL A, the first level, a simple hardware (HW) watchdog could be sufficient. For ASIL B and C, a high level monitoring concept could be implemented, whereas for ASIL D, a dual-processor system could be the proper solution for the high safety demands.

4.2 Possible technical implications on the battery management system

It seems to be reasonable that a BMS is classified as safety relevant system. As such, a three-level monitoring concept could be implemented, for example, by implementing safety critical functions and diagnosis on the first level, by implementing a process monitoring on the second level, and by processor monitoring on the third level (see, e.g., Schwertfuehrer (2003) for a further description).

Possible technical solutions for the monitoring on the second level could include the following functionalities:

- CAN diagnostic monitoring (e.g., via checksum and alive counter),
- pack current monitoring,
- cell voltage monitoring,
- cell temperature monitoring,
- isolation monitoring, and
- fault reaction monitoring.

For the third monitoring level, a diagnosis of the main processor of the BCU can be implemented. For distributed controller architectures, a safety communication between the controllers can be implemented such that the different controllers monitor their activity and the correctness of their calculations. For instance, an additional monitoring can be implemented to ensure the correct program flow and the validity of the measured cell voltages. For this reason, the safety communication could include a question–answer game between module controller and BCU, for example, over the CAN bus. In addition, module controller can include redundant safety relevant functions, for example, for the opening of the main contactors in case of a severe overvoltage condition. The correct execution of this emergency switch-off functionality itself can be tested during the initialization phase of the battery. For a centralized system, the BCU can be supported by an additional microcontroller or by an application-specific integrated circuit (ASIC), which is responsible for the processor monitoring.

5 CONCLUSION

This chapter presented the concepts for the realization of a battery indication and management system. In the first chapter, the main indicators for the state of the battery have been defined, namely the SoC, the SoH, and the SoF, and the main tasks for the battery management have been identified.

The hardware was explained by discussing the different components, which are part of the BMS. In addition, different concepts for the controller architecture have been presented and the advantages and disadvantages of centralized and distributed systems have been examined. For the required charge equalization between the cells, concepts based on active and passive balancing systems have been introduced.

The presentation of the software used a structuring into different software modules. The focus of this section was the explanation of methods for the battery state calculation and the explanation of the thermal management. For the SoC, different possible algorithms have been listed and the model-based algorithm has been discussed in detail. A brief explanation of the implications of a functional safety concept concluded this chapter.

EV Powertrain Configurations

K.T. Chau
The University of Hong Kong, Pokfulam, Hong Kong

1 INTRODUCTION

Previously, the electric vehicle (EV) was mainly converted from the internal combustion engine vehicle (ICEV), simply replacing the combustion engine by the electric motor while retaining all the other components. This converted EV has been faded out because of the drawback of heavy weight, loss of flexibility, and degradation of performance. At present, the modern EV is purposely built. This purpose-built EV is based on original body and frame designs to satisfy the structural requirements unique to EVs and to make use of the greater flexibility of EV powertrain.

Compared with the ICEV, the EV enjoys a much more flexible configuration. This flexibility is due to several factors that are provided by the EV. First, the power flow in the EV is mainly via flexible electrical wires rather than bolted flanges or rigid shafts. Thus, the concept of distributed electrical subsystems in the EV is really achievable. Second, different EV powertrain configurations such as single-motor drives and multiple-motor drives involve a significant difference in both hardware count and control complexity. Third, different electric motors such as the direct current (DC) and alternating current (AC) motors work with different power converters for electric propulsion (Chau and Wang, 2005). Fourth, different energy sources such as the batteries, fuel cells, capacitors, and flywheels (Chau, Wong, and Chan, 1999; Chau and Wong, 2001) interact with different power converters. The corresponding refueling systems also involve different hardware and mechanism. For example, the batteries can be electrically recharged via conductive or inductive means, or can be mechanically swapped and then recharged centrally.

Figure 1 shows the general system configuration of the EV, consisting of three major systems—EV powertrain, EV energy system, and EV auxiliary system, where a mechanical link is represented by a double line, an electrical link is represented by a thick line, a control link is represented by a thin line, and the arrow on each line denotes the direction of electrical power flow or control signal flow. The EV powertrain comprises the electronic controller, the power converter, the electric motor, and the transmission. There are bidirectional control links among the electronic controller, the power converter, and the electric motor, indicating that the electronic controller functions to control both the power converter and the electric motor and to import their feedback signals such as voltage, current, speed, and temperature. On the other hand, the electronic controller generally does not control the transmission, but collects its feedback signals such as speed and temperature for control purposes. It should be noted that the transmission may be totally removed, so-called direct-drive, if the electric motor adopts low speed high torque design.

The EV energy system involves the rechargeable energy source, the energy management unit, and the energy refueling unit. The energy management unit functions to manage and monitor the energy source, and then to communicate internally with the energy refueling unit

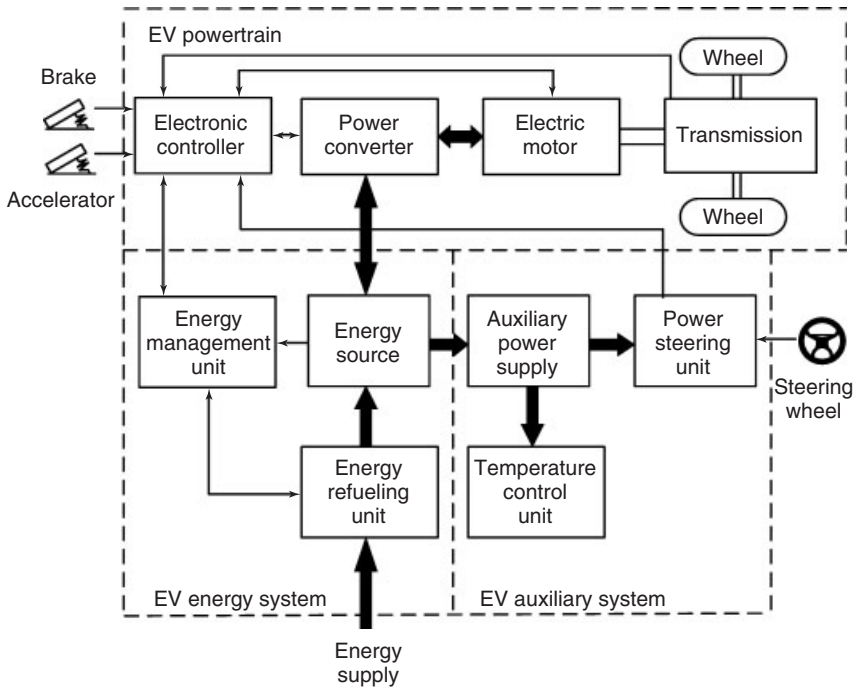

Figure 1. General EV system configuration.

and externally with the electronic controller of the EV powertrain. The energy refueling unit functions to regulate the external energy supply for refueling the energy source. In terms of power flow, the energy source provides the necessary power to the power converter of the EV powertrain for electric propulsion, and the required power for the EV auxiliary system. Typically, a lithium-ion battery is selected as the energy source. The corresponding energy management unit and refueling unit becomes the battery management unit and battery charger, respectively.

The EV auxiliary system consists of the auxiliary power supply, the power steering unit, and the temperature control unit. The auxiliary power supply provides the necessary power with different voltage levels for all EV auxiliaries, especially for power steering and temperature control. The power steering unit functions to determine how sharply the vehicle should turn for cornering in accordance with the angular position of the steering wheel. Moreover, it sends the steering information to the electronic controller of the EV powertrain to perform necessary speed control of the electric motor. The temperature control unit, which generally consists of a cooler and a heater, functions to control the temperature of the vehicle compartment. More importantly, the cooler and heater need to keep the battery pack working at a proper temperature range. If the battery is too hot, it can deteriorate the battery life or even cause the EV to stop working. At very hot temperatures, the battery pack may explode. If the battery is too cold, the EV can be sluggish or its driving range may drop significantly. Moreover, at very low temperatures, the battery may not be able to accept recharging.

On the basis of the control inputs from the brake and accelerator pedals, the electronic controller provides proper control signals to switch on or off the power devices of the power converter that functions to regulate power flow between the electric motor and the energy source. The backward power flow is due to regenerative braking of the EV and this regenerative energy can be stored in the rechargeable energy source. Notice that most available EV batteries as well as capacitors and flywheels readily accept regenerative energy. The energy management unit cooperates with the electronic controller to control regenerative braking and its energy recovery.

In this chapter, viable EV powertrain configurations will be classified into two groups—one is based on the variations in motor topologies while another is based on the variations in system topologies. The corresponding discussion will be focused on their basic principle and qualitative comparison.

2 MOTOR TOPOLOGY VARIATIONS

The group of viable EV powertrain configurations due to the variations in motor topologies (Chau, Chan, and Liu, 2008;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto049
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Chau, 2009) will be split into the DC, AC, and switched reluctance (SR) types. All these electric motors have been accepted for the EV powertrain.

2.1 DC powertrain

The DC powertrain has ever been widely used for EVs. As shown in Figure 2, it consists of the electronic controller, the DC motor, the DC–DC converter, and the transmission. The key components are the DC motor and the DC–DC converter.

Figure 3 shows the basic topology of the DC motor. On the basis of the methods of field excitation, it can be further split into the self-excited DC and separately excited DC types. On the basis of the source of field excitation, it can also be grouped as the wound-field DC and permanent magnet (PM) DC types. As determined by the mutual interconnection between the field winding and the armature winding or the use of PM excitation, the whole family consists of the separately excited DC, shunt DC, series DC, and PM DC types. All types of the DC motor suffer from the same problem due to the use of commutators and brushes. Commutators cause torque ripples and limit the motor speed, whereas brushes are responsible for friction and radio-frequency interference. Moreover, due to the wear and tear, periodic maintenance of commutators and brushes is always required. These drawbacks make them less reliable and unsuitable for maintenance-free operation. The major advantages of the DC motor are the maturity and simplicity.

When the DC–DC converter adopts the chopping mode of operation, it is usually named as the DC chopper. This DC chopper can be classified as the first-, second-, two-, and four-quadrant versions. The first-quadrant DC chopper is suitable for motoring and the power flow is from the source to the load, whereas the second-quadrant one is for regenerative braking and the power flow is out from the load into the source. As regenerative braking is very essential for EVs that can significantly extend the vehicle driving range,

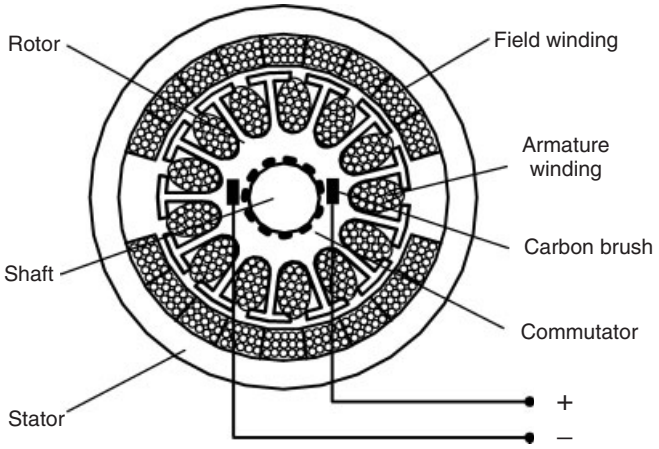

Figure 3. DC motor topology.

the two-quadrant DC chopper is preferred as it is suitable for both motoring and regenerative braking. Moreover, instead of using mechanical contactors to achieve reversible operation, the four-quadrant DC chopper shown in Figure 4 can be employed so that motoring and regenerative braking in both forward and reversible operations are controlled electronically.

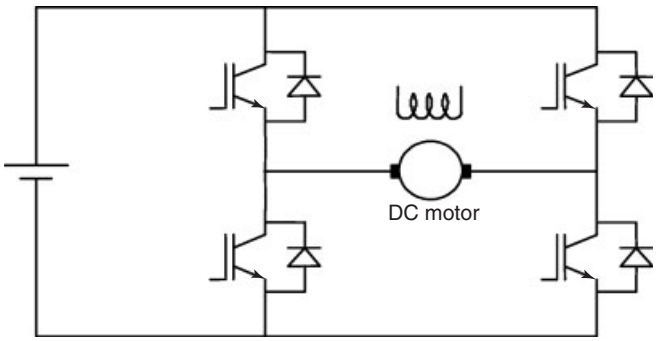

Figure 4. Four-quadrant DC chopper topology.

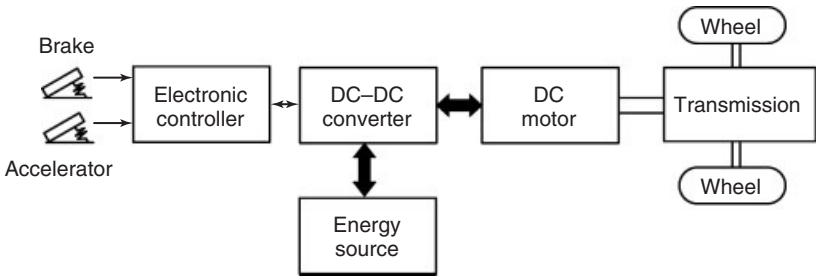

Figure 2. DC powertrain configuration.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto049
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In short, the DC powertrain takes the merits of being mature and simple, but suffers from the demerits of relatively low efficiency and need for maintenance. So, this powertrain is becoming obsolete for modern EVs.

2.2 AC powertrain

The AC powertrain is widely adopted for EVs. As shown in Figure 5, it consists of the electronic controller, the AC motor, the pulse-width modulation (PWM) inverter, and the transmission. The corresponding AC motor includes two major types—namely the induction motor and the PM brushless motor.

At present, the induction motor powertrain is the most mature technology among all AC powertrains. There are two types of induction motors, namely the wound-rotor and the cage-rotor. Because of high cost, need for maintenance, and lack of sturdiness, the wound-rotor induction motor is less attractive than the cage-rotor counterpart. As shown in Figure 6, the cage-rotor induction motor is loosely named as the induction motor for EV powertrain. Apart from the common advantages of AC machines such as the brushless and hence maintenance-free operation, the induction motor possesses the definite advantages of low cost and ruggedness.

The PM brushless motor is becoming more and more attractive for EV powertrain. It possesses the definite advantages of higher efficiency and higher power density than the induction motor. Nevertheless, it suffers from the drawbacks of relatively high PM material cost and uncontrollable PM flux. On the basis of the back electromotive force (EMF) and current waveforms, the PM brushless motor can be divided into two main types (Pillay and Krishnan, 1988)—the PM brushless alternating current (BLAC) and the PM brushless direct current (BLDC). The PM BLAC motor is fed by sinusoidal AC current while the back EMF waveform is sinusoidal, whereas the PM BLDC motor is fed by rectangular AC current while the back EMF waveform is trapezoidal. Actually, the PM BLAC motor is usually called the *permanent magnet synchronous machine* (*PMSM*) (Chan and Chau, 1996). As the interaction between trapezoidal EMF and rectangular current in the motor can produce higher torque product than that produced by sinusoidal EMF and sinusoidal current, the PM BLDC motor possesses higher power density than the PMSM (Gan *et al*., 2000). Meanwhile, the PM BLDC motor has a significant torque pulsation (Kim, Kook, and Ko, 1997), whereas the PMSM produces an essentially constant instantaneous torque or so-called smooth torque like a wound-rotor synchronous motor. According to the position of PMs in the rotor, PM brushless motors have many possible topologies such as the surface-mounted, surface-inset, interior-radial, and interior-circumferential. Figure 7 shows a typical interior-radial PM brushless motor topology. Each PM brushless motor topology can operate at both the BLAC and the BLDC modes if the torque density, torque smoothness, and efficiency are not of great concern.

The voltage-fed PWM inverter shown in Figure 8 is almost exclusively used for AC powertrain. The inverter topology highly depends on the technology of power

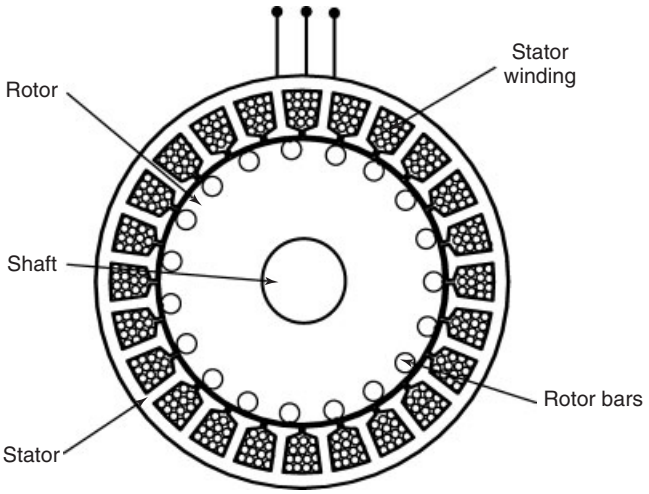

Figure 6. Induction motor topology.

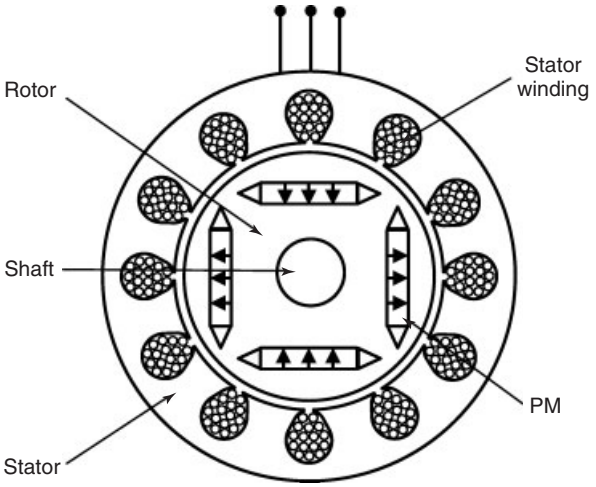

Figure 7. PM brushless motor topology.

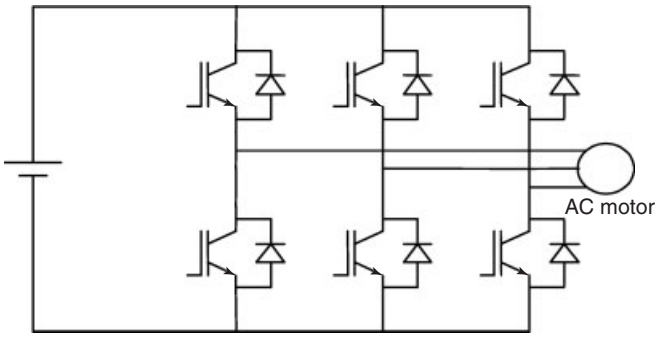

Figure 8. PWM inverter topology.

devices. At present, the insulated gate bipolar transistor (IGBT)-based inverter is most attractive. The inverter design is generally governed by the ratings of power devices and the selection of switching schemes. The ratings of power devices are based on three criteria: first, the voltage rating is at least twice the nominal supply voltage because of the voltage surge during switching; second, the current rating is large enough so that there is no need to connect several power devices in parallel; and third, the switching speed rating is sufficiently high to suppress motor harmonics and acoustic noise levels. The power module is normally a two-in-one or even six-in-one type, namely two or six devices are internally connected with an antiparallel diode across each device, to minimize wiring and stray impedance. On the other hand, the selection of switching schemes depends on the motor types. For the induction motor and the PM BLAC motor, the corresponding switching schemes are similar, aiming to provide a near-sinusoidal AC current with the minimum switching loss and acceptable harmonic distortion. For the PM BLDC motor, the corresponding switching scheme aims to provide a rectangular AC current under the two-phase 120° conduction mode or the three-phase 180° conduction mode (Zhu and Howe, 2007).

2.3 SR powertrain

The SR powertrain is occasionally adopted for EVs. As shown in Figure 9, it consists of the electronic controller, the SR motor, the SR converter, and the transmission. Although the concept of variable reluctance was adopted for electric motors over a century, the SR motor could not realize their full potential until the advent of power electronics. Figure 10 shows a typical three-phase 6/4-pole SR motor, where there are six salient poles in the stator and four salient poles in the rotor. Because of the salient nature of both the stator and rotor poles, the inductance of each phase varies with the rotor position. The operating principle of the SR motor is based on the "minimum reluctance" rule.

Differing from the PWM inverter for AC motors, the power converter for the SR motor does not need to provide bipolar operation. Many converter circuits have been developed in attempts to reduce the number of power devices and take full advantage of unipolar operation. However, when the device count is reduced, there is a penalty in the form of lower controllability, lower

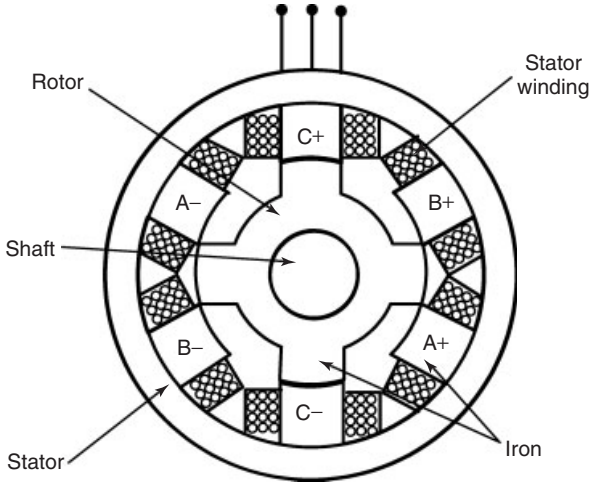

Figure 10. SR motor topology.

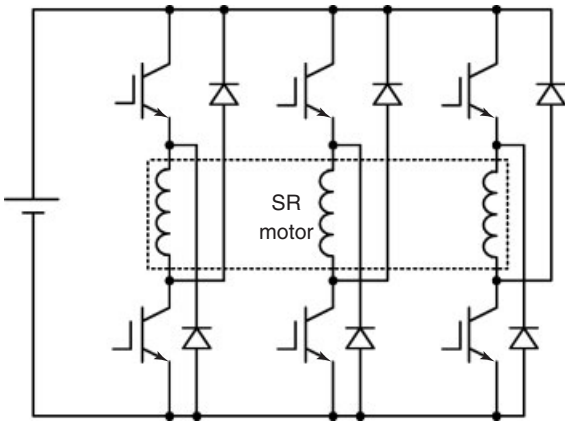

Figure 11. SR converter topology.

reliability, lower operating performance, or extra passive components. The SR converter shown in Figure 11 is well suited for the SR powertrain. It utilizes two power devices to independently control the current of each phase and two freewheeling diodes to return any stored magnetic energy to the energy source. As this circuit topology needs two power devices per phase, the converter cost is relatively higher than that with less power devices. However, this bridge arrangement allows control of each phase winding independent of the state of other phase windings. Thus, it is possible to allow for phase overlapping so as to increase the torque production and to extend the constant-power operating range of EVs.

3 SYSTEM TOPOLOGY VARIATIONS

The group of viable EV powertrain configurations due to the variations in system topologies (Chan and Chau, 2001) will be split into the converted EV and purpose-built EV types. The purpose-built EV type is further divided into the single-motor and multiple-motor types. All these system topologies have been adopted for the EV powertrain.

3.1 Converted powertrain

Figure 12 shows the earliest EV powertrain configuration which is a direct conversion from the existing ICEV adopting longitudinal front-engine front-wheel drive. It consists of an electric motor, a clutch, a gearbox, and a differential (Unnewehr and Nasar, 1982). The clutch is a mechanical device that is used to connect or disconnect power flow from the electric motor to the wheels. The gearbox is another mechanical device that consists of a set of gears with different gear ratios and a gear shifting mechanism. By incorporating both the clutch and the gearbox, the driver can shift the gear ratios and hence amplify the torque going to the wheels. The wheels have the high torque low speed features in the lower gears and the high speed low torque features in the higher gears. The differential is a mechanical device that enables the wheels to be driven at different speeds when cornering—the outer wheel covering a greater distance than the inner wheel.

The key component of this converted powertrain configuration is the gearbox. By using a combination of clutch and gearbox, variable gearing can be accomplished. The purpose of variable gearing is to provide multiple-speed transmission, namely achieving wide ranges of speed and torque using different gear ratios. Generally, four-speed transmission is used for passenger cars. When the clutch is engaged, the electric motor and the gearbox are coupled

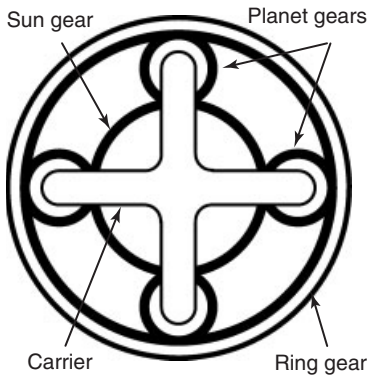

Figure 14. Planetary gear.

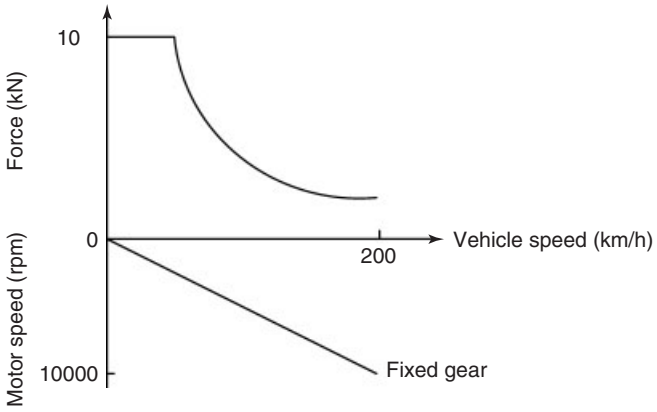

Figure 15. EV force-speed characteristics with fixed gearing.

together and power transmission is enabled. When it is disengaged manually or automatically, the power transmission is interrupted so that the gear ratio in the gearbox can be shifted. For the ICEV, there is no alternative to the use of variable gearing as the combustion engine cannot offer the desired torque-speed characteristics such as high torque for hill climbing and high speed for cruising without using multiple-speed transmission. Figure 13 shows the typical force-speed characteristics of a combustion engine with four-speed transmission. For the EV, the employment of variable gearing to achieve multiple-speed transmission used to be controversial. For the EV converted from the ICEV, the use of variable gearing was claimed to be natural because both gearbox and clutch are already present and their maintenance costs are minor. However, the concept of converted EV is obsolete as it cannot fully utilize the flexibility and potentiality offered by the EV. It was also claimed that the use of variable gearing can enhance the electric motor achieving regenerative braking and high efficiency operation over a wide speed range. With the advances of power electronics and control algorithms, both regenerative braking and high efficiency operation of electric motors can be handled by electronic means rather than mechanical means.

3.2 Single-motor-geared powertrain

Fixed gearing means that there is a fixed gear ratio between the electric motor and the driving wheels. Practically, fixed-gearing transmission is usually based on planetary gearing. As shown in Figure 14, a planetary gear consists of a sun gear, several planet gears, a planet gear carrier, and a ring gear. It takes the advantages of strong, compact, high efficiency, high speed-reduction ratio, and in-line arrangement of input and output shafts over the conventional parallel-shaft variable gearset. Moreover, modern electric motors with the use of fixed gearing can readily offer the desired torque-speed characteristics for vehicular operation. Figure 15 shows typical force-speed characteristics of an EV with fixed gearing, consisting of constant-torque operation for acceleration and hill climbing as well as constant-power operation for high speed cruising.

By replacing the gearbox with fixed gearing and hence removing the clutch, the longitudinal single-motor-geared powertrain is resulted. Figure 16 shows this arrangement which consists of an electric motor, a fixed gear, and a differential. Notice that this configuration is not suitable for the ICEV as the engine by itself, without the clutch and gearbox, cannot offer the desired torque-speed characteristics. The removal of variable gearing can significantly reduce the overall complexity, size, weight, and cost of the transmission. Moreover, the absence of gear changing, irrespective of whether it is manual or automatic, can greatly

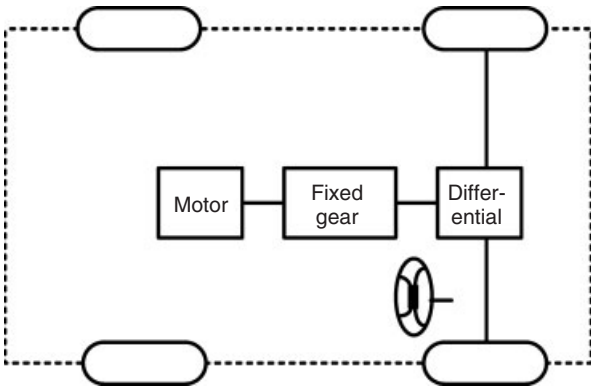

Figure 16. Longitudinal single-motor-geared powertrain configuration.

enhance smooth driving and transmission efficiency. Therefore, modern EVs almost exclusively adopt fixed gearing rather than variable gearing.

Borrowing the concept from the transverse front-engine front-wheel drive of the existing ICEV, the electric motor, fixed gear, and differential can be integrated into a single assembly while both axles are connected to the driving wheels. Figure 17 shows this transverse single-motor-geared powertrain configuration which takes the advantages of more compact size and higher transmission efficiency than its longitudinal counterpart. In fact, this configuration is the most commonly adopted powertrain by modern EVs.

3.3 Multiple-motor-geared powertrain

A differential is a standard component for conventional ICEVs and this technology can be carried forward to the EV field. When a vehicle is rounding a curved road, the outer wheel needs to travel on a larger radius than the inner wheel. Thus, the differential adjusts the relative speeds of the wheels; otherwise, the wheels will slip which causes tire wear, steering difficulties, and poor road holding. For all ICEVs, whether front- or rear-wheel drive, a mechanical differential is mandatory. Notice that this mechanical differential is not only bulky and heavy but also complicated and lossy.

For EVs, it is possible to dispense with a mechanical differential. By separately coupling two or even four electric motors to the driving wheels, the torque of each motor can be independently controlled in such a way that the differential action can be electronically achieved when cornering. Figure 18 shows the principle of electronic differential in which two electric motors, so-called dual motors, are employed. This arrangement can totally eliminate the mechanical differential, hence reducing the overall size and weight as well as improving the cornering control and transmission efficiency.

Figure 19 shows the dual-motor-geared powertrain configuration in which dual motors separately drive the driving wheels via fixed gearing. The differential action when cornering is electronically provided by the dual motors operating at different speeds. Unlike the choice between variable gearing and fixed gearing, the selection of

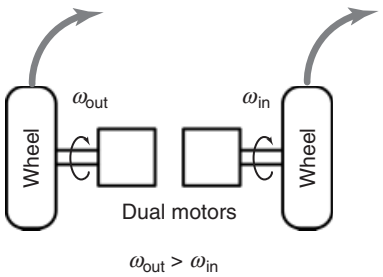

Figure 18. Principle of electronic differential.

either a single-motor drive with a mechanical differential or a dual-motor drive using electronic differential is still controversial. Positively, the removal of a mechanical differential can reduce the overall size and weight while the electronic differential can accurately control the motor torques so as to achieve better performance during cornering. Negatively, the use of an additional motor and power converter causes an increase in the initial cost while the reliability of the electronic controller to accurately control the dual motors at various driving conditions is a concern. In recent years, the reliability of this electronic controller has been greatly improved by incorporating the capability of fault tolerance. For instance, the electronic controller can utilize three independent microprocessors. Two of them are used to separately control the motor torques for the left and right wheels while the remaining one is used for coordination and fault-tolerant control. All of them watch one another to improve the reliability.

3.4 Multiple-motor-geared in-wheel powertrain

In order to further shorten the mechanical transmission path from the electric motor to the driving wheel, the electric motor can be placed inside a wheel. This arrangement is the so-called in-wheel motor. Figure 20 shows the dual-motor-geared in-wheel powertrain configuration in which fixed planetary gearing is employed to reduce the motor speed to the desired wheel speed. It should be noted that planetary gearing offers the advantages of a high speed-reduction ratio as well as an in-line arrangement of input and output shafts.

In general, the electric motor for this configuration is a high speed inner-rotor motor while the high speed-reduction planetary gear is adopted which is mounted between the motor shaft and the wheel hub. Typically, this motor is purposely designed to operate over 10,000 rpm so as to give a high power density. This operating speed is mainly limited by the friction and windage losses as well as the transmission tolerance. Thus, the corresponding planetary gear ratio is of about 10 : 1 (Mellor, Allen, and Howe, 1996) to provide the wheel speed range from zero to about 1000 rpm. Apart from adopting a single-stage high reduction ratio which is demanding in construction, a two-stage planetary gear can also be employed. Inevitably, the use of mechanical gearing for speed reduction involves the transmission loss, wear-and-tear problem, and regular lubrication. It should be noted that for the high speed design, the operating frequency can be up to a kilohertz. The operating voltage should be sufficiently large to maintain the back EMF at the high rated speed.

3.5 Multiple-motor gearless in-wheel powertrain

By fully abandoning any mechanical gearing, the in-wheel drive can be realized by installing a low speed outer-rotor electric motor inside a wheel. Figure 21 shows the dual-motor gearless in-wheel powertrain configuration in which the outer rotor is directly mounted on the wheel rim. Thus, speed control of the electric motor is equivalent to the control of the wheel speed and hence the vehicle speed.

Figure 22 shows the schematic of this in-wheel motor which is a low speed outer-rotor motor. This low speed outer-rotor motor has the definite advantages of simplicity and gearless, hence offering high transmission efficiency and free from maintenance. However, because of the inherent low speed requirement of wheel rotation, typically up to 1000 rpm, the electric motor has to adopt

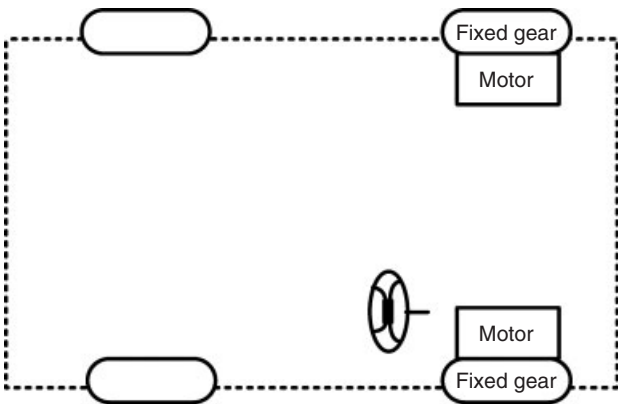

Figure 20. Dual-motor-geared in-wheel powertrain configuration.

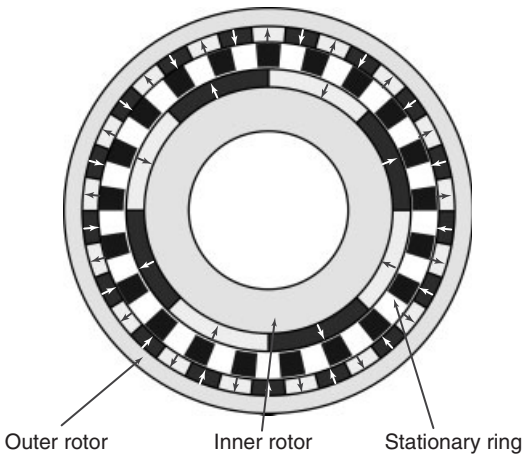

Figure 23. Coaxial magnetic gear.

the low speed design—namely, low operating frequency or large number of poles. In general, such low speed design suffers from the drawbacks of increased size, weight, and cost.

In recent years, the concept of gearless has been extended to magnetic gears because they fundamentally differ from the mechanical gears and solve their mechanical problems. Namely, they inherently offer the merits of high transmission efficiency, no wear-and-tear problem, free from maintenance, and physical isolation between input and output (Atallah and Howe, 2001). Figure 23 shows the schematic of a coaxial magnetic gear in which the inner rotor is mounted with PMs for high speed input, the outer rotor is also mounted with PMs for low speed output, and the torque transmission between two rotors is based on PM flux modulation via the stationary ferromagnetic ring (Jian *et al*., 2009). By artfully integrating this magnetic gear into a PM brushless motor, the magnetic-geared in-wheel motor is resulted in which the low speed output requirement for direct-drive and the high speed rotating field requirement for motor design can be achieved simultaneously (Chau *et al*., 2007). Figure 24 gives the schematic of this magnetic-geared in-wheel motor. Compared with the planetary-geared in-wheel motor, this in-wheel motor offers the outer-rotor topology with reduced size and weight, while eliminating all the drawbacks due to the planetary gear. The artfulness is the share of a common PM rotor, namely the outer rotor of the PM brushless motor and the inner rotor of the coaxial magnetic gear. The operating principle of this magnetic-geared in-wheel motor is actually similar to that of the planetary-geared in-wheel motor. For instance, the stator is initially fed by high frequency power supply to produce high speed rotating field and hence creating high speed rotation at the inner rotor; then the magnetic gear steps down the inner-rotor speed, and hence boosts up the outer-rotor torque for direct-driving of the wheel.

ACKNOWLEDGMENTS

The author would like to express heartfelt thanks to all group members of the International Research Center for EVs for their contributions to this chapter. He expresses his indebtedness to Joan and Aten for their support all the way.

EV Powertrain Parameters

K.T. Chau
The University of Hong Kong, Pokfulam, Hong Kong

1 INTRODUCTION

The electric vehicle (EV) powertrain consists of the electronic controller, the electric motor, the power converter, and the mechanical transmission. In contrast, the internal combustion engine vehicle (ICEV) powertrain consists of the electronic controller, the combustion engine, and the transmission. The core difference between them is the electric motor versus the combustion engine. Although both of them serve to produce the driving torque, their principles of operation and hence parameters are fundamentally different. For instance, the combustion engine power is normally described by the engine displacement in cubic centimeter (cc) or liter (L), whereas the electric motor power is always in kilowatt (kW). Thus, the EV powertrain parameters are mainly extended from the electric motor (Chan and Chau, 2001), rather than borrowed from the well-established definitions used for the ICEV powertrain (Bosch, 2007).

2 MASS AND SIZE PARAMETERS

Among various components of the EV powertrain, the electronic controller has virtually no influence on the overall mass and size of the powertrain. On the contrary, the transmission dominates the overall mass and size especially when adopting the mechanical differential (Duffy, Stockel, and Stockel, 1988). Notice that the transmission is optional, depending on the type of electric motor and the number of electric motors adopted. In addition, the power converter essentially exhibits the same mass and occupies the same size for the same type of powertrain, again depending on the type of electric motor used (Chau and Wang, 2005). For instance, the converter for the direct current (DC) motor powertrain is lighter and smaller than the inverter for the alternating current (AC) motor powertrain, whereas various inverters have similar mass and size for the AC motor powertrain. Therefore, the electric motor plays a very important role on the overall mass and size of the powertrain.

The electric motor aims to be as light and small as possible for a given output power, hence offering high gravimetric power density and high volumetric power density, respectively. The former one is usually termed the *specific power* in kilowatt per kilogram, whereas the latter one is loosely termed the *power density* in kilowatt per liter. For the EV powertrain, the specific power is more important as it directly affects the driving range of the EV, which is much shorter than that of the ICEV. The corresponding specific power depends on three main factors: the motor type, the cooling method, and the motor speed.

There are three major types of electric motors that are adopted by the EV powertrain, namely, the DC motor, the AC motor, and the switched reluctance (SR) motor (Chau, 2009). The AC motor includes the induction motor and the permanent magnet (PM) brushless motor

(Chau, Chan, and Liu, 2008). The DC motor needs to incorporate the commutator and carbon brushes, suffering from heavy weight and bulky size. The AC motor and the SR motor take the definite advantages of higher specific power and higher power density. Because of the use of high energy PM materials, the PM brushless motor offers the highest specific power. Figure 1 gives an indicative comparison of the specific power of different types of electric motors with respect to the motor power.

Basically, there are two types of cooling methods for the electric motor—air cooling and liquid cooling. The liquid cooling includes the water cooling and the oil cooling. The advantages of using water cooling over air cooling are its higher specific heat capacity and higher thermal conductivity. On the other hand, the oil cooling outperforms the water cooling due to the fact that oil offers higher boiling point than water so as to be able to cool parts with temperature higher than 100°C, and oil is an electrical insulator that can be in direct contact with electrical parts. When the electric motor is liquid cooled, the heat dissipation can be effectively removed from the motor. Hence, the corresponding electric loading and magnetic loading can be significantly increased; thus, even taking into account the additional weight of the cooling system, the overall specific power can be improved. Figure 2 gives an indicative comparison of the specific power of the electric motor using different cooling methods with respect to the motor power.

The mass and size of the electric motor are strongly influenced by the motor speed. In general, the higher the motor speed, the lighter the motor mass and the smaller the motor size are resulted. It is because of the fact that the motor speed depends on the rate of change of electromagnetic field in the electric motor, and the use of fast-changing field can reduce both the copper material for armature windings and the iron material for magnetic flux paths. Thus, the high speed motor design is particularly attractive for the EV powertrain. Even taking into account the additional reduction gear to scale down the motor speed to the wheel speed, the overall mass and size of the high speed motor plus its built-in reduction gear can be lighter and smaller than that of the low speed motor. Table 1 gives an indicative comparison of the mass and size of an induction motor at the same power under different speeds.

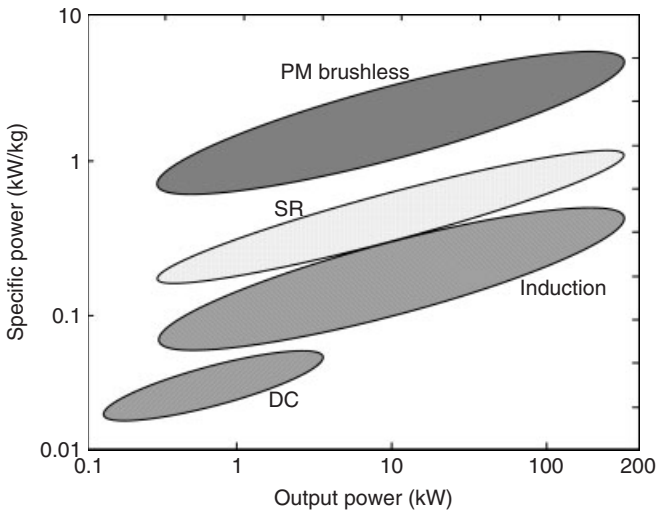

Figure 1. Comparison of specific power of electric motor using different types.

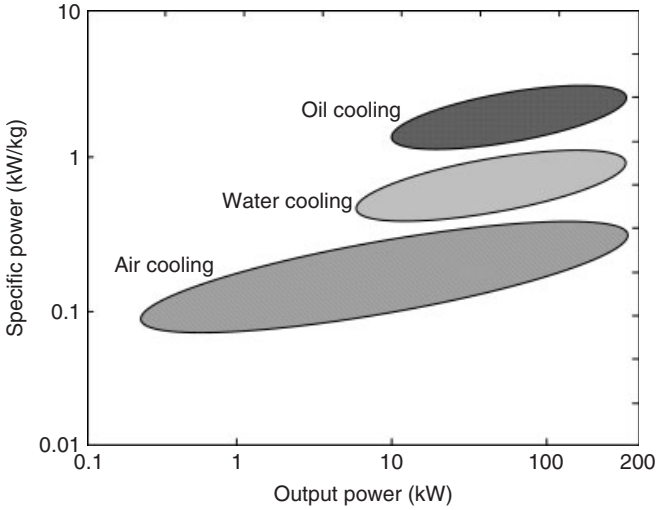

Figure 2. Comparison of specific power of electric motor using different cooling methods.

Table 1. Comparison of mass and size of induction motor using different speeds.

Speed (rpm)	Mass (kg)	Volume (L)
750	570	240
1000	415	165
1500	310	121
3000	270	92

3 FORCE AND TORQUE PARAMETERS

In general, the force and torque parameters of the EV powertrain are borrowed from the well-established definitions used for the ICEV powertrain (Fenton, 1996; Lucas, 1996; Newton, Steeds, and Garrett, 1996). Figure 3 shows the force components that the EV powertrain must provide for the vehicle to travel, which include the road load F_{load}

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto050
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

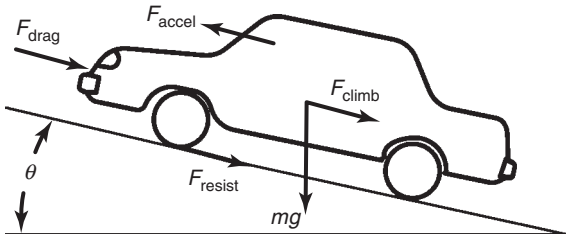

Figure 3. EV powertrain force.

and the acceleration force F_{accel}. This road load consists of three main components as described by Equation 1—the aerodynamic drag force F_{drag}, the rolling resistance force F_{resist}, and the climbing force F_{climb} (Unnewehr and Nasar, 1982):

$$F_{load} = F_{drag} + F_{resist} + F_{climb} \quad (1)$$

The aerodynamic drag force is due to the drag upon the vehicle body when moving through the air. Its composition is due to three aerodynamic effects: namely, the skin friction drag due to the air flow in the boundary layer; the induced drag due to the downwash of the trailing vortices behind the vehicle; and the normal pressure drag that is proportional to the vehicle frontal area and speed. In general, the skin friction drag and the induced drag are usually much smaller than the normal pressure drag. Thus, this aerodynamic drag force can be described by Equation 2 as:

$$F_{drag} = \frac{1}{2}\rho_{air} C_{drag} A_{front} (v + v_{wind})^2 \quad (2)$$

where C_{drag} is the aerodynamic drag coefficient (dimensionless), ρ_{air} is the air density in kilogram per cubic meter, A_{front} is the vehicle frontal area in square meter, v is the vehicle speed in meter per second, and v_{wind} is the head wind speed in meter per second. In general, ρ_{air} is taken as 1.23 kg/m^3 although it is dependent on the altitude. On the other hand, C_{drag} varies significantly, ranging from 0.2 to 1.5. For instance, a sport car has C_{drag} from 0.2 to 0.3, a sedan from 0.3 to 0.5, a van from 0.5 to 0.6, a bus from 0.6 to 0.7, and a truck from 0.8 to 1.5. Figure 4 shows the force and hence power requirements to overcome different aerodynamic drags (from 0.2 to 0.5 with step size 0.1) of a typical passenger car in which ρ_{air} is 1.23 kg/m^3, A_{front} is 2 m^2, and v_{wind} is zero. It can be observed that the aerodynamic drag squarely increases with the vehicle speed, and the corresponding power consumption becomes very significant at high speeds.

The rolling resistance force is due to the work of deformation on the tire and the road surface. The deformation on the tire heavily dominates the rolling resistance, whereas the deformation on the road surface is generally insignificant. Factors that affect the rolling resistance are the tire type, the tire pressure, the tire temperature, the vehicle speed, the tread thickness, the number of plies, the mix of the rubber, and the level of torque transmitted. Among them, the tire type and the tire pressure are relatively more dominant. This rolling resistance force can generally be described by Equation 3 as:

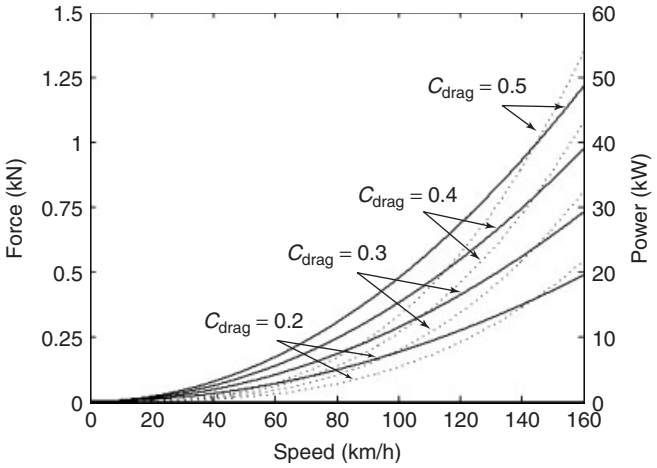

Figure 4. Force and power requirements to overcome different aerodynamic drags.

$$F_{resist} = mg\, C_{resist} \cos\theta \quad (3)$$

where m is the vehicle mass in kilogram, g is the gravitational acceleration equal to 9.81 m/s^2, C_{resist} is the rolling resistance coefficient (dimensionless), and θ is the angle of incline in degree or radian (Tabbache, Kheloui, and Benbouzid, 2010). In general, the C_{resist} of radial-ply tires is about 0.013, which is lower than that of cross-ply tires, about 0.018. It also varies inversely with the tire pressure—namely, the higher the tire pressure, the lower the C_{resist}. Figure 5 shows the force and hence power requirements to overcome different rolling resistances (from 0.005 to 0.02 with step size 0.005) of a typical passenger car in which m is 1000 kg and θ is zero degree. It can be observed that the rolling resistance is independent of the vehicle speed, and the corresponding power consumption is generally less significant than that of the aerodynamic drag especially during high speed operation.

The climbing force is simply the climbing resistance or downward force for a vehicle to climb up an incline. This force can be represented by Equation 4 as:

$$F_{climb} = mg \sin\theta \quad (4)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto050
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

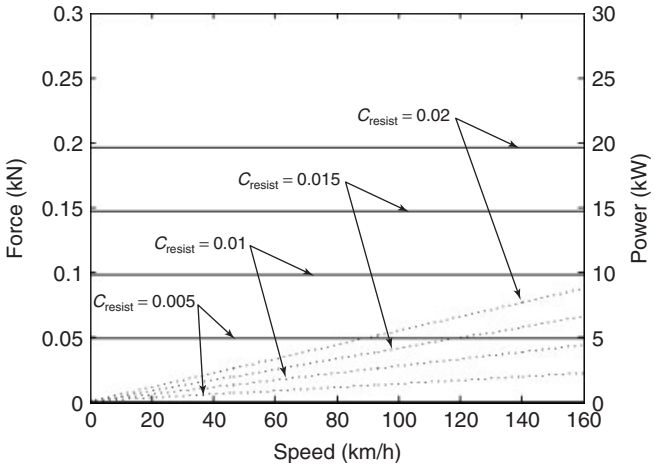

Figure 5. Force and power requirements to overcome different rolling resistances.

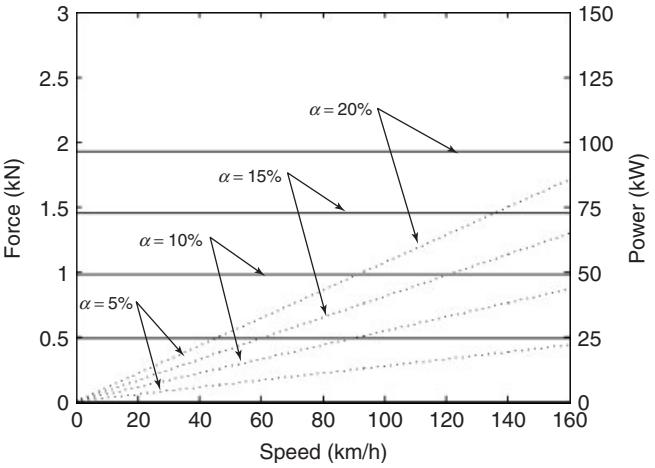

Figure 6. Force and power requirements to overcome different gradeabilities.

Usually, the incline is expressed as a percentage gradeability α, which is given by:

$$\alpha = \frac{H}{D} \times 100\% \tag{5}$$

where H is the vertical height of the road over the horizontal distance D. From Equation 5, θ and α are related by:

$$\theta = \tan^{-1}\left(\frac{\alpha}{100}\right) \tag{6}$$

For example, making use of Equation 6, the gradeability of 20% is equivalent to the angle of incline of 11.3°. The maximum gradeability denotes the maximum incline that a vehicle can climb at essentially zero speed. Figure 6 shows the force and hence power requirements of a typical passenger car to overcome different gradeabilities (from 5% to 20% with step size 5%) in which m is 1000 kg. It can be observed that the climbing force increases remarkably with the gradeability, and the corresponding power consumption is generally much higher than that of the aerodynamic drag and the rolling resistance. Notice that the climbing force will be negative when the vehicle is going download.

When the EV is accelerating or decelerating, the acceleration force F_{accel} can be expressed as:

$$F_{accel} = k_m ma \tag{7}$$

where a is the acceleration of the vehicle and k_m denotes a correction factor that there is an apparent increase in vehicle mass due to the inertia of rotational masses. Typically, k_m is about 1.05 which is equivalent to increase in the mass by 5%. When it is under deceleration or braking, a becomes negative. Figure 7 shows the force and hence

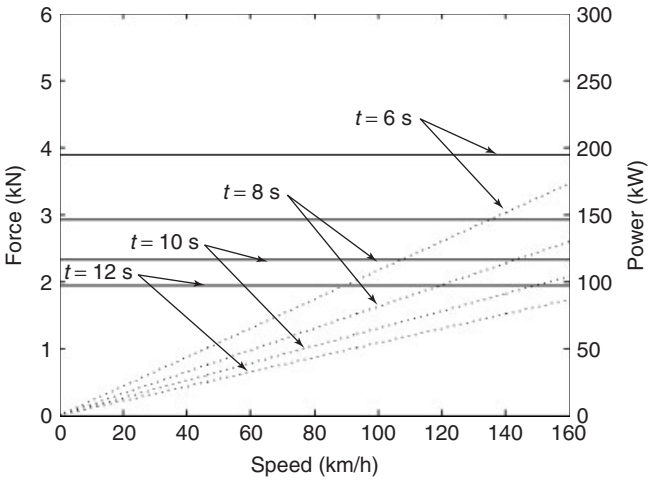

Figure 7. Force and power requirements to provide different acceleration rates.

power requirements of a typical passenger car to offer different acceleration rates (0–80 km/h from 6 to 12 s with step size 2 s) in which m is 1000 kg and k_m is 1.05. It can be observed that the acceleration force is essentially independent of the vehicle speed, and the corresponding power consumption becomes significant when high acceleration rate is demanded. Notice that the acceleration rate can also be represented by the required time from zero speed to 40 or 60 km/h.

By using Equations 1–4 and 7, the motive force F that the EV powertrain must provide at the wheel can be obtained as:

$$F = F_{load} + F_{accel} = (F_{drag} + F_{resist} + F_{climb}) + F_{accel} \tag{8}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto050
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

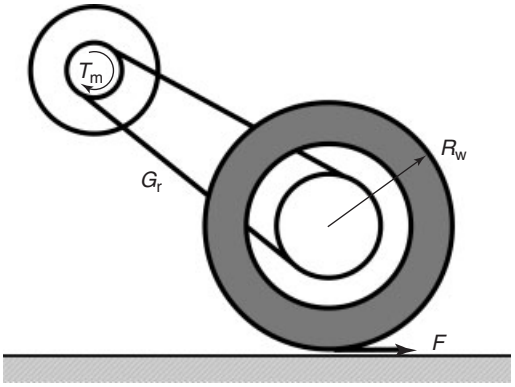

Figure 8. EV powertrain torque.

In general, the electric motor of the EV powertrain is rotational, rather than linear. The above linear motive force at the wheel needs to be translated as the rotational torque at the electric motor. Figure 8 shows the model to describe the transmission between the electric motor and the wheel. Thus, the motor torque T_m can be expressed in terms of Equation 8 as:

$$T_m = \frac{F\,R_w}{G_r} \tag{9}$$

where R_w is the radius of the wheel and G_r is the overall gear ratio of the EV powertrain from the electric motor to the wheel axle.

4 POWER AND ENERGY PARAMETERS

In transportation, the unit of energy is usually in kilowatt-hour (kWh) which is a non-SI unit rather than the SI unit joule (J), because the latter is too small for such application. To assess the energy consumption of a vehicle, the energy per unit distance in kilowatt-hour per kilometer is generally used. This unit can be applied to both the ICEV and the EV. However, an ICEV driver generally has no idea about the kWh and prefers a physical unit of fuel volume such as liter. So, the energy consumption unit of the ICEV is usually in liter per kilometer. On the other hand, the energy parameter of the ICEV can also be expressed as the distance per unit volume of fuel, the so-called fuel economy. The corresponding SI unit is in kilometer per liter. For the EV, the original energy consumption unit in kilowatt-hour per kilometer becomes suitable because the fuel for recharging the battery is electricity which can directly be measured in kilowatt-hour. The corresponding fuel economy is expressed in kilometer per kilowatt-hour. When the EV is fed by fuel cells, the corresponding fuel may be compressed gaseous hydrogen, liquid hydrogen, or even liquid methanol; hence, the energy consumption unit in liter per kilometer and the fuel economy unit in kilometer per liter become applicable.

4.1 Efficiency parameters

The energy efficiency η_e is the ratio of energy output E_{out} to energy input E_{in} as defined in Equation 10, whereas the power efficiency η_p is the ratio of power output P_{out} to power input P_{in} as defined in Equation 11:

$$\eta_e = \frac{E_{out}}{E_{in}} \tag{10}$$

$$\eta_p = \frac{P_{out}}{P_{in}} \tag{11}$$

For industrial operation, these two efficiencies may not be necessarily distinguishable. On the contrary, for the EV powertrain, there is a significant difference between these two efficiencies because the power efficiency varies continually during the operation of the vehicle. Thus, it is necessary to delineate the power efficiency associated with the speed and torque conditions. Instead of using a particular operating point such as the rated power at the rated torque and the rated speed to describe the power efficiency of the EV powertrain, an efficiency map is generally adopted in which the power efficiency, loosely termed the *efficiency*, is plotted as various contours on the torque–speed plane. Consequently, the energy efficiency can be deduced by summing powers over a given time period.

Among the three major types of electric motors for the EV powertrain, namely the DC motor, the induction motor, and the PM brushless motor, the DC motor has the worst efficiency map, the PM brushless motor has the best one, whereas the induction motor has the one probably in between them. Figures 9–11 show their typical efficiency maps for the EV powertrain in which the limits are under continuous load. It can be observed that the PM brushless motor offers not only the highest efficiency but also high efficiencies over a wide range of speed and torque.

Regenerative braking is a definite advantage of the EV over the ICEV. During braking, the motor operates in the regenerative mode, which converts the reduction in kinetic energy during braking into electrical energy, hence recharging the battery. On average, the amount of convertible energy is only up to 40% (Larminie and Lowry, 2003). Assuming that the overall efficiency of the EV powertrain is about 70%, the amount of energy actually stored in the battery is only up to 28%. This is known as the *regenerative braking efficiency*. Similar to the motoring case, in order to

accurately depict the value at different torques and speeds, a regenerative braking efficiency map should be adopted.

4.2 Load parameters

The power rating of electric motors depends on the load condition, which in turn depends on the specific application. For the EV powertrain, the corresponding power rating is generally specified by three types of load duty: continuous, intermittent, and temporary. For the same motor, the power ratings under various load duties are different. Typically, the power rating under the continuous load is the lowest among the three types of load duties, whereas the rating under the temporary load is the highest.

The continuous load of the electric motor means that the specified power can be maintained continuously or with a practical duration that is much longer than the thermal time constant. As depicted in Figure 12, it can be seen that the temperature of the electric motor rises from the initial temperature and reaches the thermal equilibrium within the practical duration of the continuous load.

The temporary load of the electric motor means that the specified power under the specified duration does not cause the motor temperature to reach the thermal equilibrium, and then with a subsequent duration that lasts until the motor temperature is no more than 2 K from the initial temperature

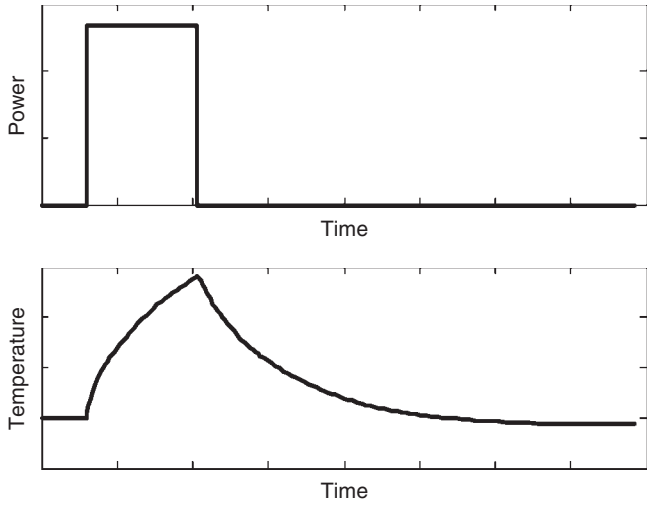

Figure 13. Temporary load of electric motor.

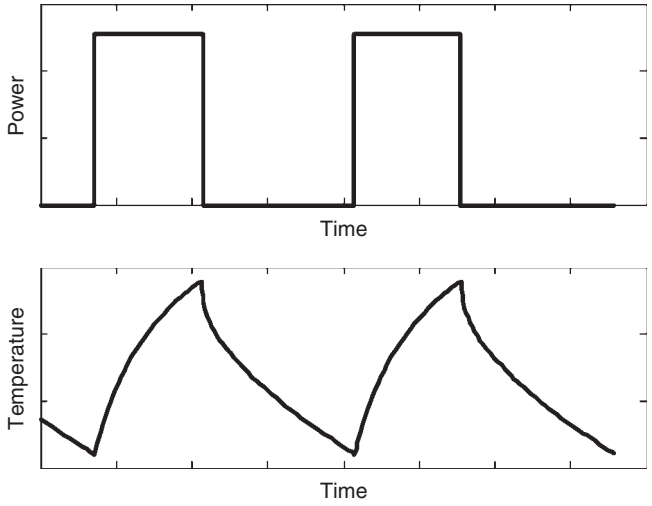

Figure 14. Intermittent load of electric motor.

(Rockwell Automation, 1996). As depicted in Figure 13, it can be seen that the motor temperature rises abruptly in the presence of high temporary power and then gradually cools down to almost the initial temperature. Typically, the temporary power of the electric motor is quoted together with the operating time period of 10, 30, 60, or 90 min. Compared to the continuous power rating, the temporary power rating is usually higher. Moreover, the shorter the operating time period, the higher the temporary power of the electric motor.

The intermittent load of the electric motor means that the specified power under the specified duration does not cause the motor temperature to reach the thermal equilibrium, and then with a subsequent duration which lasts until the motor temperature returns to the original cyclic temperature. As depicted in Figure 14, it can be seen that the motor temperature cyclically swings between two temperature limits. The intermittent power of the electric motor is quoted together with the load period and the cyclic period, or with the percentage duty cycle and the cyclic period. Typically, the percentage duty cycle quoted is 15%, 25%, 40%, or 60%. Compared to the continuous power rating, the intermittent power rating is usually higher. On the contrary, as the electric motor does not have sufficient time to gradually cool down to the initial temperature, the intermittent power rating is generally lower than the temporary power rating.

Figure 15 shows the torque–speed capabilities of a typical induction motor under different loads—continuous, temporary, and intermittent. Firstly, the continuous capability is the most conservative one which is particularly essential for the powertrain to provide the EV long-term hill climbing. Secondly, the temporary capability is the most aggressive one which is particularly worthwhile for the powertrain to describe the overtaking capability of the EV. Thirdly, the intermittent capability is the most useful one for the powertrain to satisfy the operation of urban driving which is essentially in periodic nature.

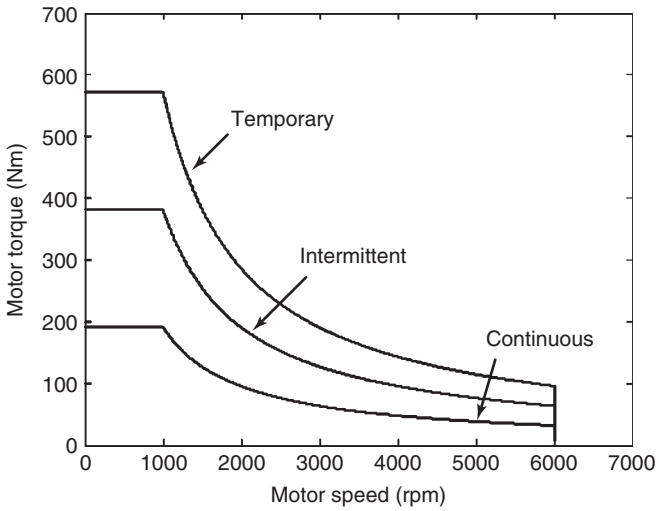

Figure 15. Torque–speed capabilities at different loads of electric motor.

5 DRIVING-CYCLE PERFORMANCES

For the EV, the driving range per charge is the most important parameter to assess the vehicle performance. The reason is simply that the range of a 1500-cc ICEV can be about 500 km per refuel, whereas the range of an EV is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

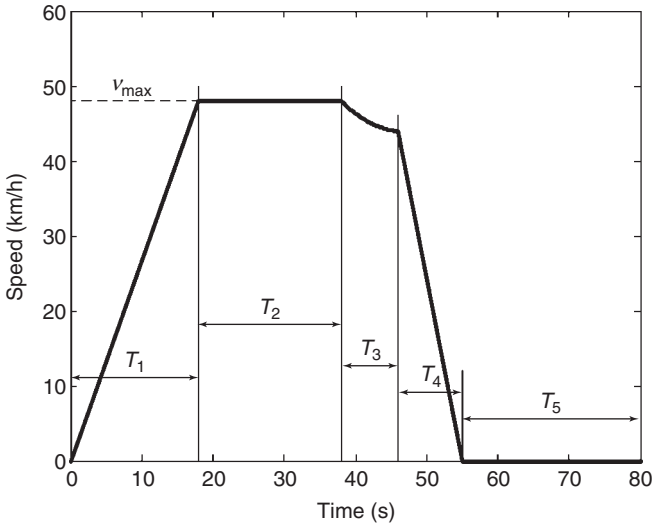

Figure 16. SAE J227a cycles.

only about 100–200 km per charge, which may not satisfy a normal driver's expectation. There are two main types of assessment that can be performed. The first type is based on the constant-speed test, whereas the second type is based on the driving-cycle test. These two tests are not only to assess the driving range per charge but also to evaluate the performance of the EV powertrain.

The constant-speed test normally assumes that the EV operates at certain constant speed such as 40 or 60 km/h, without considering any start, stop, acceleration, or deceleration. In reality, no vehicle is really driven at constant speed. Because of this ideal condition, the driving range per charge and the performance of the EV powertrain are too optimistic, if not unrealistic. The driving-cycle test is developed, which can provide a more realistic and practical condition to assess the EV and its powertrain. So far, there is no universal driving cycle that has been accepted by different automakers in different countries. In fact, different countries or even cities may have their own driving cycles for testing.

A well-known driving cycle that was specifically developed for the EV in the 1970s is the Society of Automotive Engineers (SAE) J227a driving cycle. It has four versions with different power requirements and maximum speed requirements, which are named as the J227a-A, -B, -C, and -D cycles. Figure 16 shows the general speed profile of this SAE J227a driving cycle. It consists of the acceleration stage, the constant-speed stage, the coasting stage, and the braking stage. Notice that the motive force is set to zero during the coasting stage. The details of all four versions are summarized in Table 2. The most commonly used one is the SAE J227a-C cycle, which is particularly useful for the design of the EV and its powertrain.

The federal urban driving schedule (FUDS) is the most common driving cycle used in the United States. It is also called the *federal test procedure 72* (*FTP-72*). It is a standard driving cycle lasting 1500 s, and for each second, there is an individual speed as depicted in Figure 17. This FUDS was developed originally to evaluate the noxious emissions of the ICEV and was based on a profile derived from the statistical flow of traffic patterns in Los Angeles. It simulates an urban route of 12.07 km with frequent starts and stops, the maximum speed of 91.2 km/h, and an average speed of 31.5 km/h. Thus, it is widely used to

evaluate the fuel economy of urban or city driving. There are some simplified versions of the FUDS (Larminie and Lowry, 2003), such as the simplified federal urban driving schedule (SFUDS) as depicted in Figure 18. This SFUDS only lasts 360 s and has only 360 data points, while offers the same average speed, the same proportion of stationary, the same maximum acceleration, and the same maximum braking. Thus, the SFUDS takes the advantage that it is less computational demanding than the FUDS while giving a similar result when it is used for simulating the driving range. On the other hand, the federal highway driving schedule (FHDS) is the driving cycle developed to typify rural or cross-country driving in the United States. As depicted in Figure 19, the FHDS lasts 765 s and maintains nonstop high speed operation for highway driving.

In the European Union, the vehicle is commonly tested using two kinds of driving cycles. The first one is the urban driving cycle known as the *ECE-15* (Economic Commission for Europe), which was introduced in 1999. It was devised to represent city driving conditions in Paris or Rome. As shown in Figure 20, it simulates an urban trip of 4052 m at an average speed of 18.7 km/h and the maximum speed of 50 km/h. It is particularly useful for testing urban driving performance of the EV. The second one is the extra-urban driving cycle (EUDC). As shown in Figure 21, it simulates a suburban trip that lasts 400 s at an average

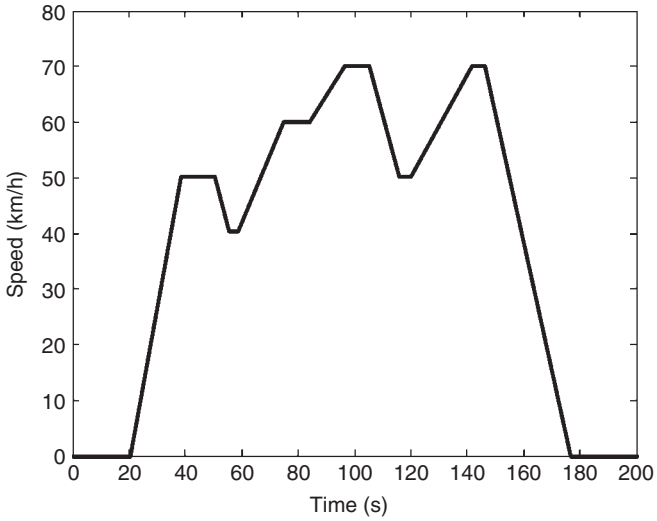

Figure 24. Japan 15 mode.

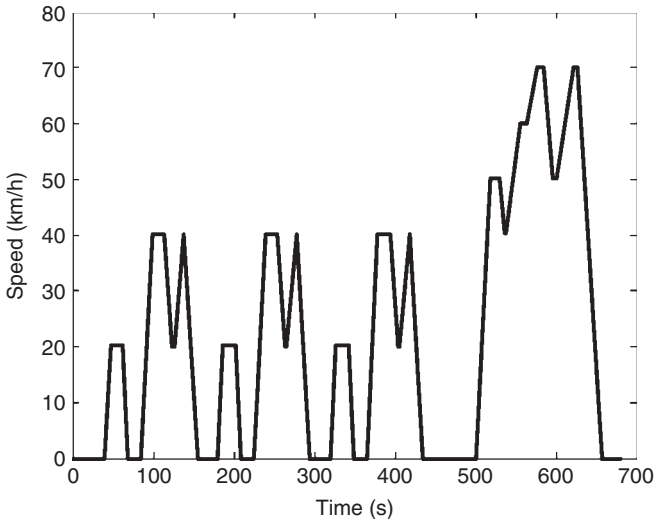

Figure 25. Japan 10–15 mode.

speed of 62.6 km/h and the maximum speed of 120 km/h. Furthermore, the new European driving cycle (NEDC) is the driving cycle that incorporates four repeated ECE-15 driving cycles and an EUDC. As shown in Figure 22, the NEDC is supposed to represent the typical usage of a vehicle in Europe.

In Asia, the most widely used standard driving cycles are developed in Japan. As depicted in Figure 23, the Japan 10 mode represents an urban driving cycle that covers a distance of 0.664 km at an average speed of 17.7 km/h, and lasts 135 s with the maximum speed of 40 km/h. On the other hand, as depicted in Figure 24, the Japan 15 mode denotes a combination of the urban and extra-urban route with the maximum speed of 70 km/h. Similar to the NEDC for the European Union, the Japan 10–15 mode incorporates five cycles—first the 15 mode, then three times the 10 mode, and at last again the 15 mode. The assessment is normally based on the last four segments (three 10 mode + one 15 mode) as depicted in Figure 25, in which the distance is 4.16 km, the average speed is 22.7 km/h, and the duration is 660 s. As a regulation, the driving range of EVs in Japan has to be evaluated by using this driving cycle.

In addition to the above homologated driving cycles for EVs, it is also important to take into account vehicle use

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in realistic driving conditions. It is particularly important that the energy consumption of EVs greatly depends on the driving profiles and conditions. EV manufacturers are actually facing with the challenge of convincing their potential customers over the limited driving range per charge. Thus, it is necessary to consider other real-world driving cycles to assess the EV performances, including the urban, extra-urban, and highway driving conditions. There are many representative cycles for real-world driving conditions (Barlow *et al*., 2009). Among them, the Artemis driving cycles that were developed within the European 5th Framework project, Assessment and Reliability of Transport Emission Models and Inventory Systems (ARTEMIS), are widely accepted in Europe, which well describe various real-world driving conditions, such as the Artemis Traffic Jam for congested urban traffic, the Artemis Urban for urban traffic, the Artemis Road for road conditions at extra-urban traffic, and the Artemis Motorway for highway traffic (Zaccardi and Le Berr, 2012). Considering this variety of driving cycles, it is not straightforward to select the most relevant cycles.

The EV powertrain needs to satisfy both the torque demand and the power demand of the EV imposed by the driving cycle. For instance, based on the driving cycle with speed versus time, the required motive force and hence the required motor torque can be deduced by using Equations 2, 3, 7, and 9:

$$T_{\mathrm{m}} = \frac{R_{\mathrm{w}}}{G_{\mathrm{r}}}(F_{\mathrm{drag}} + F_{\mathrm{resist}} + F_{\mathrm{accel}}) \tag{12}$$

Consequently, the required average power P_{av} that the EV powertrain needs to produce is given by:

$$P_{\mathrm{av}} = \frac{1}{T}\int_0^T (F_{\mathrm{drag}} + F_{\mathrm{resist}} + F_{\mathrm{accel}})\, v \, \mathrm{d}t \tag{13}$$

where T is the duration of the driving cycle.

1 INTRODUCTION

Electric vehicles (EVs) offer high energy efficiency, allow diversification of energy resources, enable load equalization of power systems, deliver zero local and minimal global exhaust emissions, and operate quietly. However, there are two major barriers hindering the commercialization of EVs, namely, short driving range and high upfront cost. These barriers cannot be easily solved by the available EV energy source technologies, including batteries, fuel cells, capacitors, and flywheels. The hybrid electric vehicle (HEV), incorporating the engine and electric motor, has been introduced as an interim solution.

The HEV greatly extends the limited EV driving range by two to four times and offers rapid refueling by liquid gasoline or diesel. Moreover, the HEV requires no change in the energy supply infrastructure. The HEV cannot deliver zero-emission driving such as the battery electric vehicle (BEV) does and has a more complex architecture. Nevertheless, the HEV offers more efficiency and correspondingly lower emissions than the internal combustion engine vehicle (ICEV) while having comparable driving range. With the assist of electric motors, the engine in an HEV can operate in its most efficient mode, yielding low emissions and low fuel consumption. Some HEVs may also be purposely operated as an EV for a short period of time in the zero-emission zone. The HEV is not only an interim solution for implementation of zero-emission vehicles but also a practical solution for commercialization of super ultralow emission vehicles.

1.1 Definition of HEV

The demand for vehicles with substantially higher fuel economy and lower vehicular emissions has motivated the development of HEVs, fuel cell electric vehicles (FCEVs), and BEVs for a number of years. The first production HEV available to the public was the Toyota Prius. The Prius was sold successfully in Japan since late 1997 and in the United States since 1999. Nowadays, HEVs are taking center stage, whereas BEVs are used in some niche areas where shorter distances are traveled. The available HEV models encompass light-duty cars and trucks, sports utility vehicles, delivery trucks, transit buses, and line-haul trucks.

The available definition of HEV is not clear. As proposed by Technical Committee 69 (Electric Road Vehicles) of the International Electrotechnical Commission, an HEV is a vehicle in which propulsion energy is available from two or more kinds or types of energy stores, sources, or converters, and at least one of them can deliver electrical energy. On the basis of this general definition, there are many types of HEVs, such as the engine and battery, battery and fuel cell,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

battery and capacitor, battery and flywheel, and battery and battery hybrids. However, the above-mentioned definition is not well accepted. To avoid confusing readers, specialists prefer using the HEV to represent a vehicle only adopting the energy source combination of an engine and battery. For example, a battery and fuel cell HEV is simply referred to as a *fuel cell EV*. The term HEV in this chapter refers only to the vehicle adopting both an engine and electric motor in the drivetrain, whereas the petroleum fuel (gasoline and diesel) and battery both are the energy source (Kabza, 2009; Chau and Wong, 2002).

The basic principle of HEV design is the coordination of the electric propulsion system and the internal combustion engine (ICE) system. An HEV is designed to meet the performance, including acceleration, gradeability, and minimum range, of a comparable baseline ICE vehicle (Chan *et al*., 2009).

This chapter gives an overview of features of ICE and electrical powertrains in an HEV and the main functionality of HEVs. Consideration of drivetrain design and operating models of HEVs are discussed to elaborate novelties of different HEVs.

1.2 History of hybrid electric vehicles

In 1801, Richard Trevithick built a steam-powered carriage, opening the era of horseless transportation. The first battery-powered electric bicycle was built by Thomas Davenport in 1834. It was powered by a nonrechargeable battery and used on a short track. In 1838, Robert Davidson built a nonrechargeable battery-powered electric locomotive. After the invention of the lead-acid battery in 1859, David Salomons built a rechargeable battery-powered electric vehicle in 1874. The first gasoline-powered ICE vehicle was built in 1885 and the first HEV was presented by J. Lohner and F. Porsche in 1901 (Chan and Chau, 2001). By 1920, Henry Ford's assembly line and the arrival of the self-starting petrol engine resulted in the rapid decline of hybrid cars (Chan, 2007).

The ICE vehicle outperformed the EV and HEV in the automotive century because there was no high performance battery for EVs and HEVs to overcome four major barriers to commercialization, short driving range, long charge time, long recharge time, and high lifecycle cost (Chan and Chau, 2001). The rekindling of interests in EVs started at the outbreak of energy crisis and oil shortage in the 1970s. The actual revival of EVs was due to the ever-increasing concerns on energy conservation and environmental protection throughout the world in the 1990s.

The first production HEV was commercialized in 1997. The world's first modern hybrid vehicle was sold in Japan in 1997, the Toyota Prius. In 1999, the Honda Insight became the first hybrid vehicle sold in the United States. Combined with the release of the Honda Civic Hybrid, vehicles that offered some of the benefits of battery electric vehicles to conventional ICEs were available to the public. Since then, many of the major automakers have offered hybrid vehicles in their lineup (Chan, 2007). Development of the plug-in hybrid electric vehicle (PHEV) accelerated in 2006 because of its potential to reduce oil dependence. The PHEV can deliver pure electric operations by the motor and batteries and can also be recharged from the power grid such as a BEV. The PHEV operates in pure electric mode when the battery's state of charge (SoC) is high and switches to HEV mode when the SoC is lower than a threshold value at 10–50% dependent on specification and battery capacity.

2 FEATURES OF ENGINE AND ELECTRICAL POWERTRAINS

The ICE has relatively low thermal and mechanical efficiencies, and much of the energy of the fuel is dissipated as heat. Figure 1 illustrates that in gasoline-powered vehicles about 62.4% of the fuel's energy is lost in the ICE (USDOE, 2011a; Taylor, 1998). The top three losses, accounted for 85.4% of total energy dissipation, are engine losses (62.4%), engine idling loss (17.2%), and energy dissipation in acceleration and braking (5.8%).

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

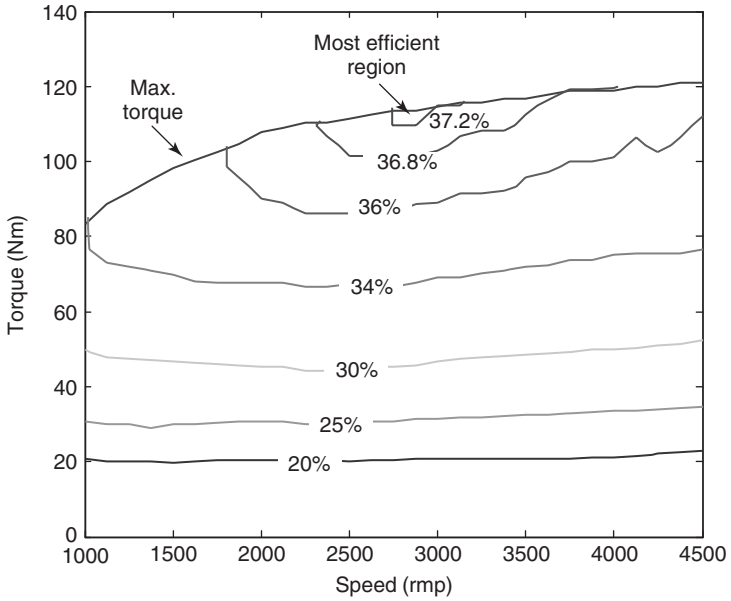

Figure 2. Engine performance and efficiency.

2.1 Efficiencies of ICE and electric motor

The ICE is intrinsically very inefficient at converting the fuel's chemical energy to mechanical energy, losing energy to engine friction, pumping air into and out of the engine, and wasted heat. Figure 2 shows efficiency contours of a typical gasoline engine. The thermal efficiency of this engine is low with a maximum efficiency of 37.2% and it can only operate in the most efficient area occasionally. In addition, energy is lost during idling. The fuel economy of ICEVs in city driving is lower than that in highway driving.

Technologies such as using lighter materials in the powertrain, reducing the vehicle exterior's drag coefficient, optimizing the engine cooling system, low rolling resistance tires, lower friction lubricants, locking torque converters in automatic transmissions to reduce slip and power losses, continuously variable transmissions (CVTs), overdrive gears, engine combustion optimization, and cylinder deactivation can reduce the engine losses. Moreover, diesel engines have inherently lower losses and are generally one-third more efficient than their gasoline counterparts. This is largely due to the higher compression ratios of diesel engines and higher density of diesel fuel. Diesel engines typically have lower power to weight ratios than comparable spark ignition engines. Recent advances in diesel technologies and fuels are making diesels very competitive.

Addition of an electric motor boosts the vehicle's overall efficiency to higher than that of the diesel engine. The electric motor does not consume energy at standstill and it has higher efficiency than the ICE. Figure 3 shows the

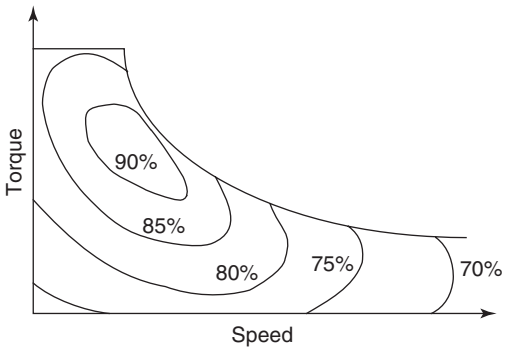

Figure 3. Motor performance and efficiency.

efficiency contour profiles of a typical induction motor for vehicular applications. Comparing with the efficiency contour profiles of a typical gasoline engine in Figure 2, the electric motor can achieve higher efficiencies. The electric motor also has maximum torque at zero and low speeds and it allows bidirectional energy flow such that mechanical energy can be converted into electrical energy and stored in the traction batteries by regenerative braking. Hence, the hybridization of electric motors and the ICE in an HEV can significantly boost efficiency of the vehicle drivetrain and thus reduce oil consumption and emissions.

2.2 Regenerative braking

Regenerative braking is a unique feature of an electrical powertrain that allows the motor drive to convert a vehicle's

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

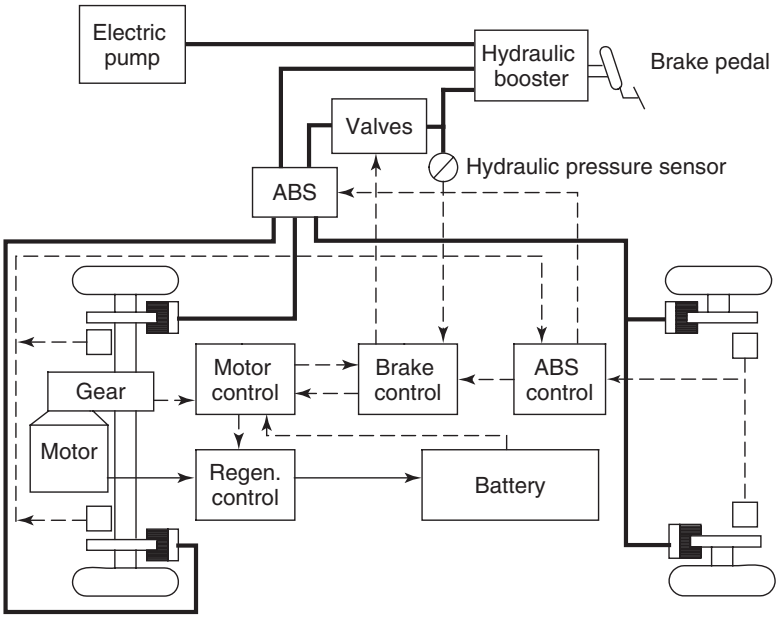

Figure 4. Configuration of a regenerative-hydraulic braking system in the electrical drivetrain.

kinetic energy to electrical energy during braking and in replacing engine braking. The converted electrical energy is stored in receptive energy sources such as batteries or ultracapacitors to supplement the ICE or extend all-electric driving range. If the rechargeable sources are fully charged, regenerative braking can no longer be applied and the vehicle can be slowed by the conventional friction braking system.

In general, the regenerative braking system is activated when the vehicle throttles off deceleration at highways or its brake pedal is pressed during braking. The total braking torque is the sum of the regenerative braking torque and the friction braking torque. The control of their distributions aims to provide the driver the same braking feel as that in conventional ICEVs while maintaining maximum regenerative braking.

In order to realize the above-mentioned requirements, a regenerative-hydraulic hybrid braking system can be configured as shown in Figure 4. By employing the electric pump, the hydraulic booster produces the desired hydraulic braking pressure that is activated by the driver's brake pedal operation. The brake control is used to collaborate with the motor control to produce the regenerative braking torque as well as the desired hydraulic braking torque on the front and rear wheels. During regenerative braking, the regenerative control recovers the kinetic energy for battery charging. The antilock braking system (ABS) control and its valves are the same as that in conventional ICEVs.

2.3 Power boost

HEVs allow both the engine and the electric motor to supplement each other in delivering power to drive the vehicle. The engine and electric motor can be coupled to the drive shaft of the wheel mechanically or electrically, such that the propulsion power may be supplied by the engine, the motor, or both. If the HEV is propelled by both the engine and the motor, the motor assists the engine during vehicle acceleration for maximization of engine fuel economy by shifting engine's torque and speed to the most efficient region as shown in Figure 2.

2.4 Energy saving potential

The electrical drivetrain boosts an HEV's fuel economy in the following ways:

- assist vehicle launch and acceleration when the vehicle is propelled by both the engine and the motor;
- assist load enhancement for the ICE for faster warm up and better efficiency;
- undertake regenerative braking; and
- deliver pure electric driving for certain period of time.

The energy saving potential of HEVs achieved by an electrical powertrain is shown in Figure 5. The HEV can boost the fuel economy from its ICE counterpart by about 6% by reducing the energy losses during idling and stop and

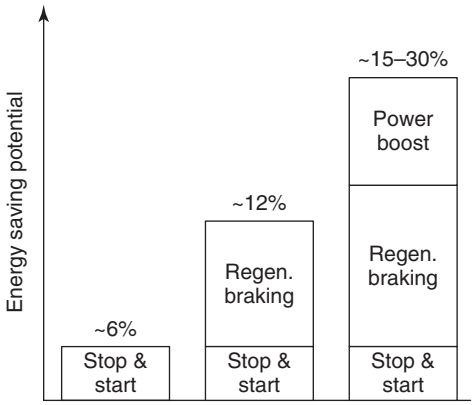

Figure 5. Energy saving potential in HEVs.

start in city driving. An additional 6% of energy savings can be achieved by regenerative braking. By optimizing efficiency of the ICE, an HEV can achieve an aggregated savings potential of 15–30% in fuel consumption relative to the ICE vehicle, subject to the vehicle design and energy management strategies. Table 1 lists fuel consumption of HEVs and their comparable ICE models in the United States (USDOE, 2011b). The HEVs achieved a reduction of 8.4–46.7% in fuel consumption in the urban diving cycle and a lower reduction of 3.9–20.3% in the highway driving cycle. In testing the fuel consumption, the vehicle is tested on a dynamometer. When the engine or motor and transmission drive the wheels, the momentum is passed to the dynamometer; as a result, the vehicle does not move. A professional driver runs the vehicle through two standardized driving schedules, one each to simulate city and highway driving cycles. The driver has to maintain the mandated pace via a real-time computer display.

2.5 Electrical drivetrain design

The design of energy management strategies for HEVs involves different considerations. Some key considerations are summarized in the following:

- *Optimal Engine Operating Line*. In case, the engine needs to deliver different power demands, the corresponding optimal operating points constitute an optimal operating line. Figure 6 shows a typical optimal operating line of an engine, in which the optimization is

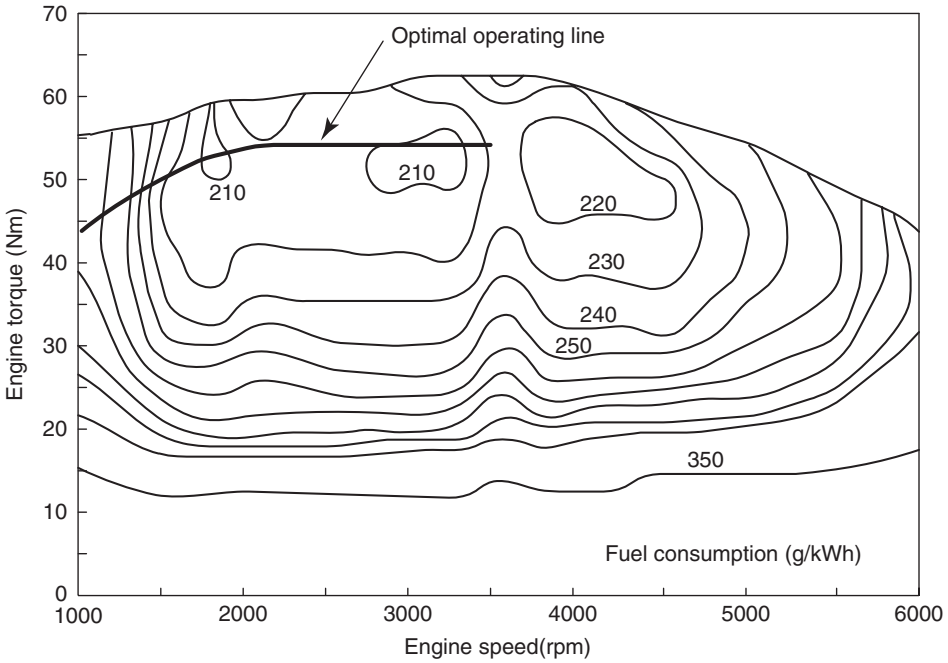

Figure 6. Optimal operating line in an engine fuel consumption map.

based on the minimum fuel consumption, which is equivalent to maximum fuel economy.

- *Optimal Engine Operating Region*. The engine has a preferred operating region on the torque–speed plane, in which the fuel efficiency remains optimum.
- *Minimum Engine Dynamics*. The engine operating speed needs to be regulated in such a way that any fast fluctuations are avoided, hence minimizing the engine dynamics.
- *Minimum Engine Speed*. When the engine operates at low speeds, the fuel efficiency is very low. The engine should be cutoff when its speed is below a threshold value.
- *Minimum Engine Turn-On Time*. The engine should not be turned on and off frequently; otherwise, it results in additional fuel consumption and emissions. A minimum turn-on time should be set to avoid such drawbacks.
- *Proper Battery Level*. The onboard battery level should be sized properly so as to provide sufficient power for acceleration and accept regenerative power during braking or going downhill.
- *Safe Battery Voltage*. The battery voltage may be significantly altered during discharging, generator charging, or regenerative charging. This battery voltage should not be too high or too low; otherwise, the battery may be permanently damaged.
- *Geographical Policy*. In certain cities or areas, the HEV needs to be operated in the pure electric mode. The changeover could be controlled manually or automatically.

The mature electric motors utilized in HEVs include the permanent magnet (PM) motor and induction motors. Main considerations of motors for vehicular applications are torque and power densities, wide range of speed (including constant torque and constant power operations), efficiency over a wide range of speeds, reliability, and robustness. PM motors possess high efficiency, high torque, and high power density; however, they have a short constant power range and their stator winding generates a back electromotive force (EMF). Induction motors offer simplicity, robustness, and a wide range of speeds; however, owing to rotor loss, these motors have lower efficiencies and must be larger than PM motors of similar capability.

The battery is a critical part in any HEVs. The battery has to be intrinsically tolerant of abusive conditions such as overcharge, short circuit, crush, fire exposure, mechanical shock, and vibration. A typical battery pack may contain cells in different series or parallel combination in a vehicle battery system; thus, cells' SoCs have to be balanced to prevent undercharge and overcharge. The key requirements for vehicle batteries are high specific energy and high specific power, long cycle life, high efficiency, wide operating temperature, and low cost for commercialization. The viable batteries for vehicle applications consist of the valve-regulated lead acid (VRLA), nickel–cadmium (Ni–Cd),

nickel–zinc (Ni–Zn), nickel-metal hydride (Ni-MH), zinc/air (Zn/Air), aluminum/air (Al/Air), sodium/sulfur (Na/S), sodium/nickel chloride ($Na/NiCl_2$), lithium metal-polymer (LiM-polymer) and lithium-ion (Li-ion) batteries. The Ni-MH battery has been widely equipped in most commercial HEVs. The specific energy and specific power of these batteries are shown in Figure 7.

The Li-ion battery, with advanced positive electrode and negative electrode materials, is a promising battery for HEVs. The advanced positive electrode materials are $LiCoO_2$, $LiMn_2O_4$, $LiFePO_4$, lithium nickel manganese cobalt (NMC) oxide ($LiNiMnCoO_2$), and lithium nickel cobalt aluminum (NCA) oxide ($LiNiCoAlO_4$). The mature negative electrode materials are graphite and titanate. Table 2 shows the potential Li-ion batteries for vehicle applications.

3 DRIVETRAIN TOPOLOGIES OF HEVS

The HEV can be divided into series, parallel, series–parallel, and complex hybrids with reference to their drivetrain topologies. Figure 8 shows the corresponding functional block diagrams, in which the electrical link is bidirectional; the fuel link is unidirectional and the mechanical link (including clutches and gears) is also bidirectional. The series hybrid couples the engine with the generator to produce electricity for pure electric propulsion, whereas the parallel hybrid couples both the engine and the electric motor with the transmission via the same drive shaft to propel the wheels. The series–parallel hybrid is a direct combination of both the series and parallel hybrids. On top of the series–parallel hybrid operation, the complex hybrid can offer additional and versatile operating modes by adding one more electric motor to deliver four-wheel drive (4WD) operations.

Table 2. Advanced Li-ion batteries for vehicle application.

Positive Electrode	Negative Electrode	Manufacturers	Key Feature
LiCoO2	Graphite	Sony	Mature
LiMn2O4	Graphite	NEC, GS, Yuasa, LG	High power
NCA/NMC	Graphite	SAFT, Samsung, Sanyo, Evonik	High energy
LiFePO4	Graphite	A123, Valence Tech, BYD	Highly stable
LiMn2O4	Titanate	Toshiba, Enerdel	High discharge rate

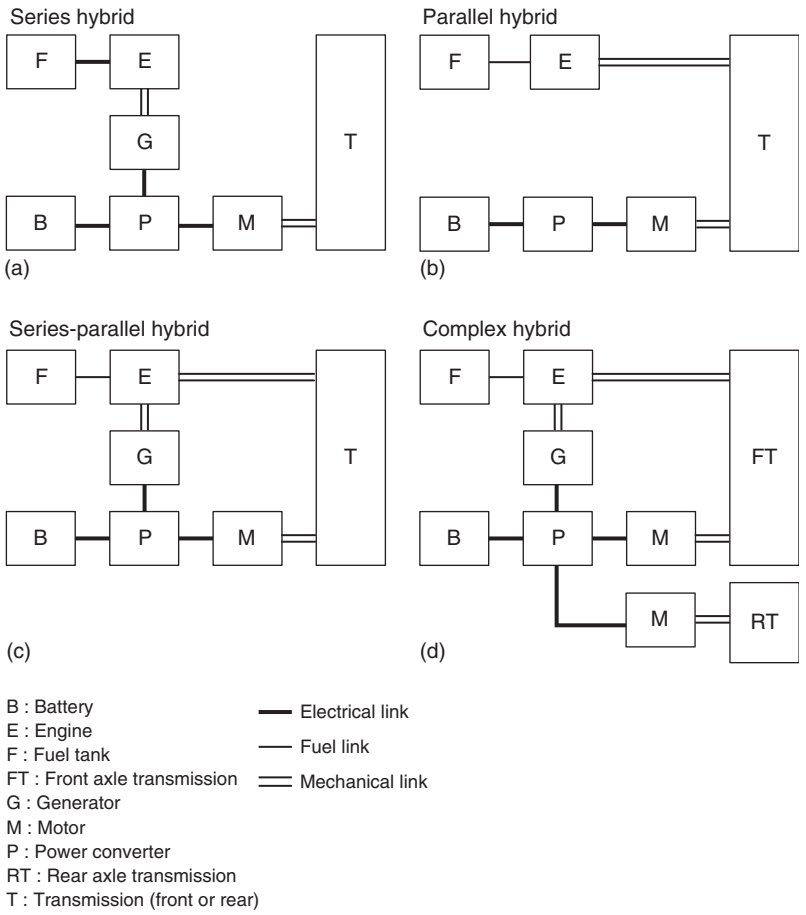

Figure 8. Classification of HEVs.

3.1 Series hybrid system

The series hybrid is the simplest kind of HEV. The engine's mechanical output is first converted into electricity using a generator. The converted electricity either charges the battery or bypasses the battery to drive the motor so as to propel the wheels. Conceptually, it is an engine-assisted EV, aiming to extend the driving range comparable with that of the ICEV. The generator is connected with the electrical drivertrain by wire such that it has the definite advantage of flexibility for locating the engine generator set. Although it has an added advantage of simplicity of its drivetrain, the series HEV is solely propelled by the electric motor, whereas the electrical energy is provided by the onboard battery or by the engine via the generator. Another disadvantage is that all these propulsion devices must be sized for maximum sustained power if the series HEV is designed to climb a long grade.

In the series hybrid system, the energy flow can be illustrated by four operating modes as shown in Figure 9. During startup, normal driving or acceleration of the series HEV, both the engine (via the generator) and the battery deliver electrical energy to the power converter that drives the electric motor and then the wheels via the transmission. It can also operate in an EV mode in the charge-depleting mode. At light loads, the engine output is greater than the output required to drive the vehicle so that the generated electrical energy is also used to charge the battery until the battery capacity reaches a proper level. During braking or deceleration, the electric motor acts as a generator that transforms the kinetic energy of the wheels into electricity, hence charging the battery via the power converter. In addition, the battery can be charged by the engine via the generator and power converter, even when the vehicle is standstill.

3.2 Parallel hybrid system

As opposed to the series hybrid, the parallel HEV allows both the engine and the electric motor to deliver power

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

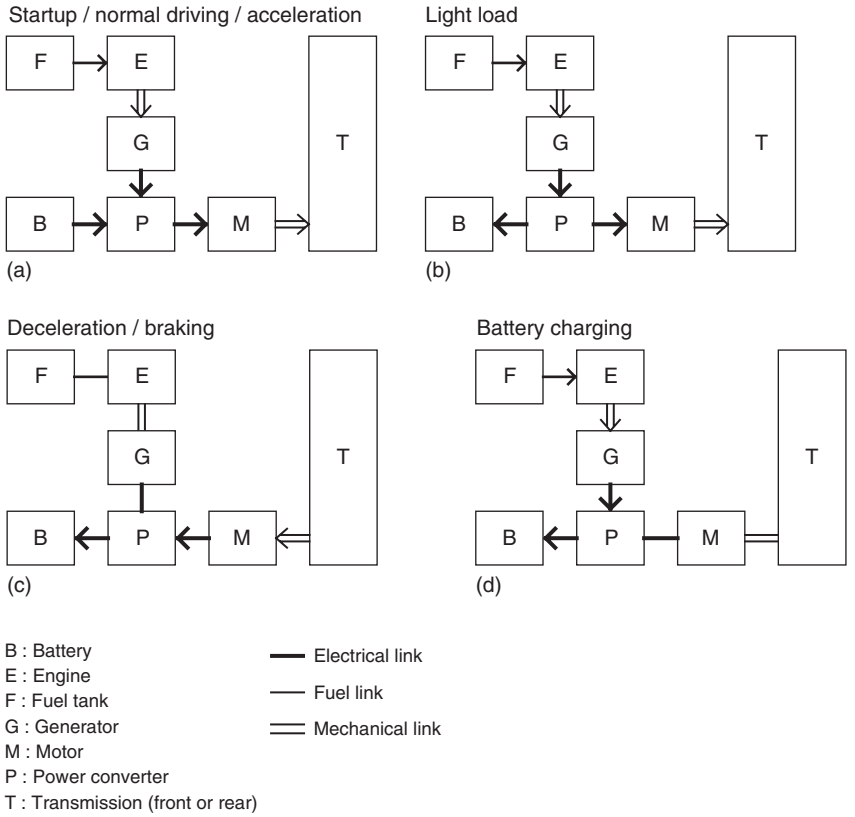

Figure 9. Operating models of series hybrids.

in parallel to drive the vehicle. Both the engine and the electric motor are generally coupled to the drive shaft of the wheels via two clutches such that the propulsion power may be supplied by the engine, the electric motor, or both. Conceptually, it is an electrically assisted ICEV for achieving lower emissions and fuel consumption. The electric motor can be used as a generator to charge the battery by regenerative braking or absorbing power from the engine when its output is greater than that vehicle demand. The parallel hybrid needs only two propulsion devices—the engine and the electric motor. Another advantage over the series case is that a smaller engine and a smaller electric motor can be used to get the same performance until the battery is depleted. The Honda Civic Hybrid is a parallel HEV, which is propelled by a 1.3 L ICE and a 12 kW electric motor integrated into the powertrain to boost efficiency of the engine.

Operating modes of a parallel HEV are illustrated in Figure 10. During startup or full-throttle acceleration, both the engine and the electric motor propel the vehicle. Typically, the power distribution between the engine and the electric motor is 80% to 20%. During normal driving, the engine solely supplies the necessary power to propel the vehicle, whereas the electric motor remains in the off mode. The parallel HEV can also run in EV mode in the charge-depleting mode. During braking or deceleration, the electric motor acts as a generator to charge the battery via the power converter. In addition, as both the engine and the electric motor are coupled to the same drive shaft, the battery can be charged by the engine via the electric motor when the vehicle is at light load.

3.3 Series–parallel hybrid system

In the series–parallel hybrid, the configuration incorporates the features of both the series and parallel hybrids. It has advantageous features of both the series and parallel hybrids, but it is relatively more complicated and costly. The Toyota Prius is the first series–parallel HEV on the market. The series–parallel hybrid has more freedom to boost the system efficiency of the vehicle. Figure 11 shows a typical series–parallel hybrid system and six operating modes. During startup and driving at light load, the battery solely feeds the electric motor to propel the vehicle while the engine is in the off mode. For full-throttle acceleration and normal driving, both the engine and the electric motor

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

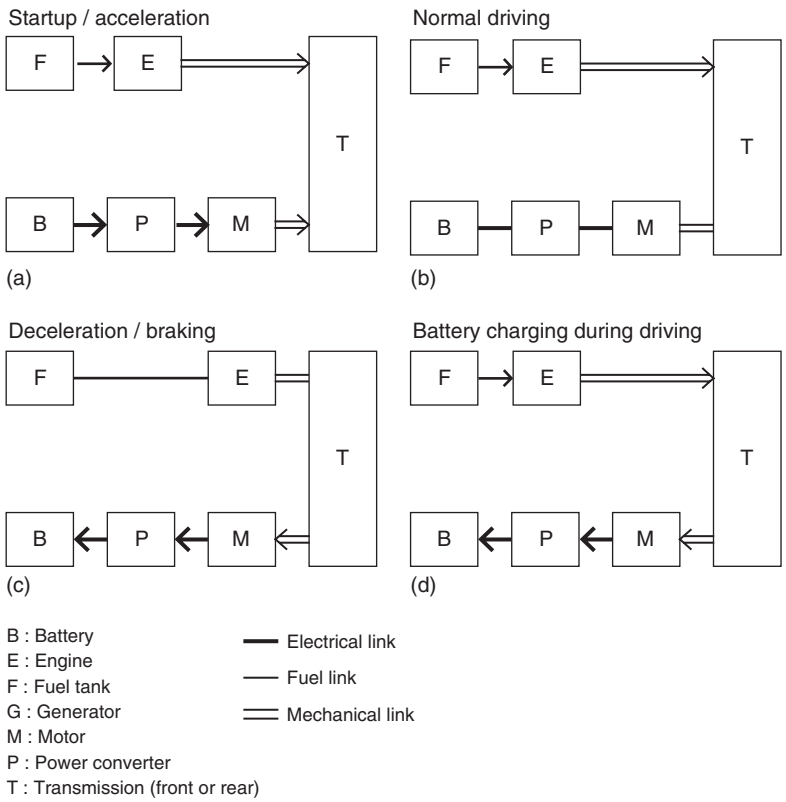

Figure 10. Operating modes of parallel hybrids.

work together to propel the vehicle. The electrical energy used for full-throttle acceleration comes from both the generator and the battery, whereas the energy used for normal driving is solely from the generator driven by the engine. Notice that a planetary gear is usually employed to split the engine output for propelling the vehicle and driving the generator. During braking or deceleration, the electric motor acts as a generator to charge the battery via the power converter. Moreover, for battery charging during driving, the engine not only drives the vehicle but also the generator to charge the battery. The engine can also charge the battery at standstill.

3.4 Complex hybrid system

As reflected by its name, this system cannot be classified into the above-mentioned three hybrids. As shown in Figure 8, the complex hybrid seems to be similar to the series–parallel hybrid; however, the key difference is the bidirectional power flow of the electric motor in the complex hybrid, comparing to the unidirectional power flow of the generator in the series–parallel hybrid. This is also known as a *through the road* hybrid when there is no propeller shaft connection. This bidirectional power flow can allow for versatile operating modes, especially the three propulsion power (owing to the engine and two electric motors) operating mode that cannot be offered by the series–parallel hybrid. Similar to the series–parallel HEV, the complex hybrid suffers from higher complexity and costliness. The Lexus RX 400 h was built with this topology. The front wheels of the RX 400 h are propelled by both the 3.3 L ICE and the 123 kW electric motor in the series–hybrid mode, whereas the rear wheels are propelled by a 50 kW electric motor. There is no direct mechanical coupling between the ICE and the 50 kW rear motor but they are electrically connected by the 82 kW generator.

The energy management system of the complex hybrid is focused on the dual-axle propulsion system. In this system, the front-wheel and rear-wheel axles are separately driven. There is no propeller shaft to connect the front and rear wheels, so it enables a more lightweight propulsion system and increases the vehicle packaging flexibility. Moreover, regenerative braking on all four wheels can significantly improve the vehicle fuel efficiency.

Figure 12 shows a dual-axle complex hybrid system, where the front-wheel axle is propelled by a hybrid drive-train and the rear-wheel axle is driven by an electric motor. There are six operating modes. During startup, the battery

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

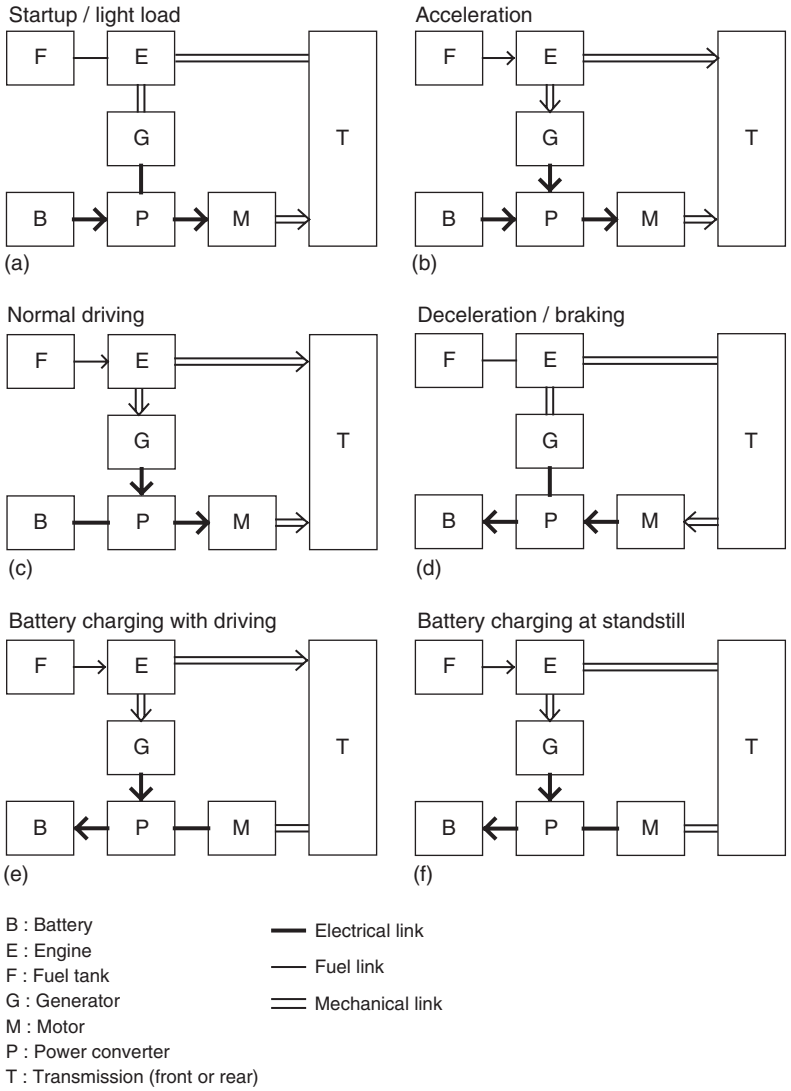

Figure 11. Operating models of series–parallel hybrids.

delivers electrical energy to feed both the front and rear electric motors to individually power the front and rear axles of the vehicle while the engine is off. For full-throttle acceleration, both the engine and front electric motor power the front axle, whereas the rear electric motor drives the rear axle. Notice that this operating mode involves three propulsion devices (one engine and two electric motors) to simultaneously propel the vehicle. During normal driving and/or battery charging, the engine output is split to power the front axle and to drive the electric motor, which works as a generator to charge the battery. The engine, front electric motor, and front axle can be mechanically coupled by planetary gear sets. When driving at light load, the battery delivers electrical energy to the front electric motor only to drive the front axle, whereas both the engine and rear electric motor are off. During braking or deceleration, both the front and rear electric motors act as generators to simultaneously charge the battery. A unique feature of this dual-axle system is the capability of axle balancing. In case the front wheels slip, the front electric motor works as a generator to absorb the change of engine output power. Through the battery, this power difference is then used to drive the rear wheels to achieve axle balancing.

Figure 13 shows another dual-axle complex hybrid system, where the front-wheel axle is driven by an electric motor and the rear-wheel axle is propelled by a hybrid drivetrain. Focusing on vehicle propulsion, there are six operating modes. During startup, the battery delivers electrical energy only to the front electric motor that in turn drives the front axle of the vehicle, whereas both the engine

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

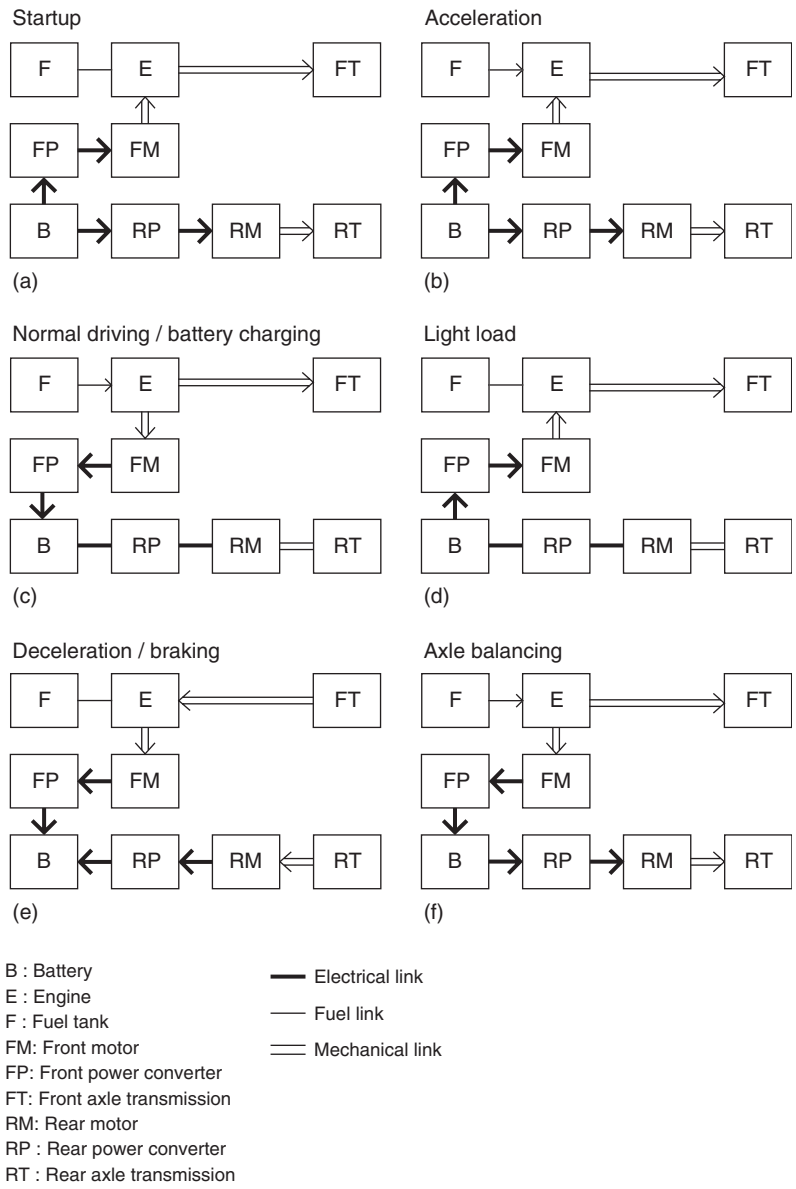

Figure 12. Operating modes of dual-axle (front-hybrid rear-electric) complex hybrids.

and rear electric motor are off. Once the vehicle moves forward, the battery also delivers electrical energy to the rear electric motor raising the engine speed, thus starting the engine. For full-throttle acceleration, the front electric motor drives the front axle, whereas both the engine and rear electric motor work together to propel the rear axle. Therefore, the three propulsion devices (one engine and two electric motors) propel the vehicle simultaneously. During normal driving, the engine works alone to propel the rear axle of the vehicle. During braking or deceleration, both the front and rear electric motors act as generators to simultaneously charge the battery. For battery charging during driving, the engine output is split up to propel the rear axle and to drive the rear electric motor (which works as a generator) for charging the battery.

4 FUNCTIONALITY OF HEVS

According to the level of electric power contribution and functionalities of the electrical powertrain, HEVs can be classified into micro hybrid vehicle (MHV), mild hybrid electric vehicle (MHEV), full hybrid electric vehicle (FHEV), and PHEV. The battery is also an important

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

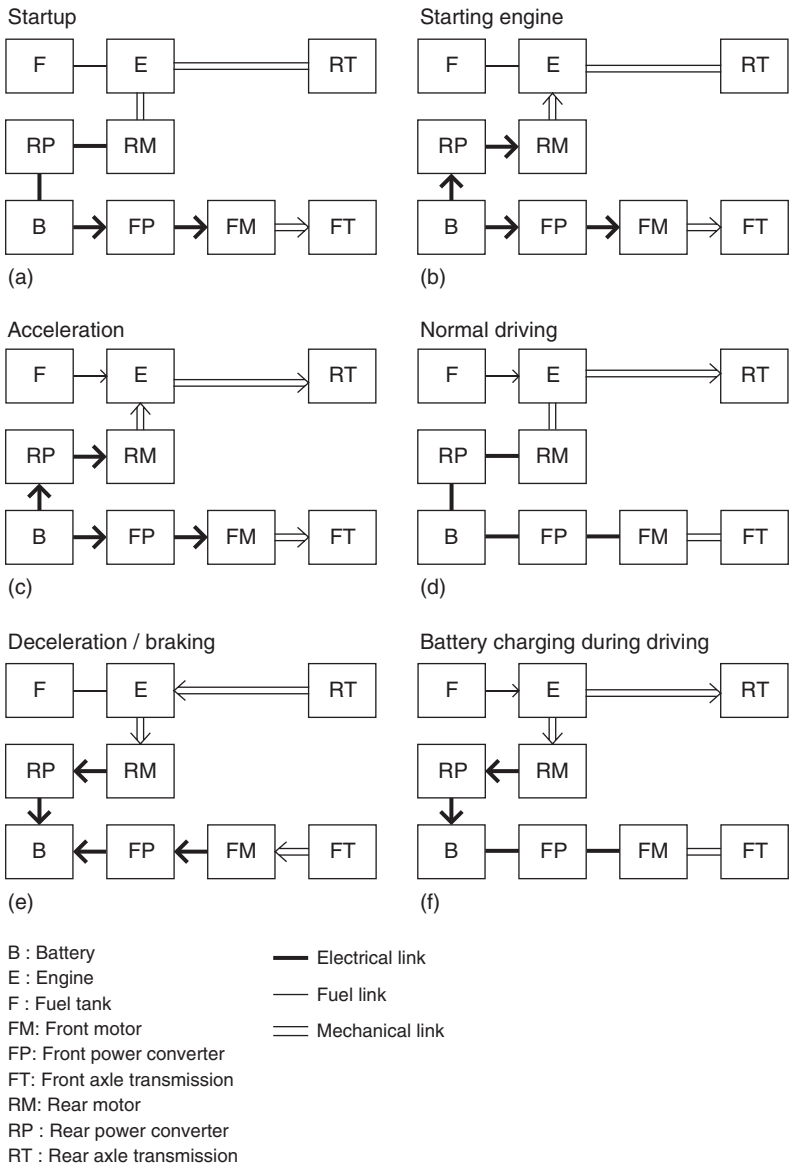

Figure 13. Operating modes of dual-axle (front-electric rear-hybrid) complex hybrids.

component of these HEVs but the requirements for power, energy, cycle life, and system voltage are different. Degree of hybridization of the electrical powertrains and the favorable battery voltages are shown in Figure 14. The operating voltage is raised to increase the discharge power of the battery and to minimize the current and conductor weight.

4.1 Micro hybrid vehicle

The MHV has an electric motor with peak power of about 2.5 kW. The electrical powertrain is driven by a battery system at 12–42 V. The motor is small and simple in structure and serves a function similar to the starter and alternator in an ICE vehicle. The electrical and engine powertrains in an MHV are governed by an automatic stop–start mechanism, in which the engine shuts down under vehicle braking and rest. The battery is recharged with the engine with a conventional generator. The MHV is favorable for city driving, where there are frequent stops and starts. An MHV's fuel economy can be 5–10% higher than that of an ICE vehicle in city driving. The Citroen C3 is an MHV using the Valeo motor system. The battery discharges frequently in cranking the engine in MHVs. Thus, there is a demand for high cycle life for batteries in MHVs. When the functionality of a "micro hybrid" is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

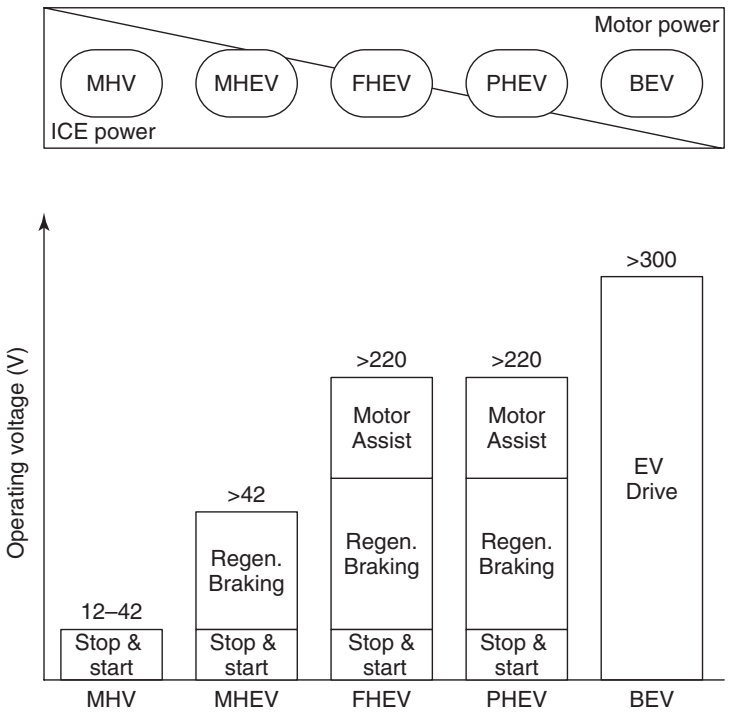

Figure 14. Operating voltages of electrical drivetrains in HEVs.

simply to provide stop–start, it is not really a hybrid as there is no contribution to propulsion from the motor. Examples of MHEVs are Honda Insight Hybrid and Civic Hybrid.

4.2 Mild hybrid electric vehicle

The MHEV has a more powerful electrical powertrain than an MHV's. The typical electric motor power of a sedan MHEV is about 10–20 kW at 100–200 V. The motor is directly operated with the engine. The motor has a large inertia such that it can replace the original flywheel of the engine. The motor and the engine are generally coupled in parallel. The electrical powertrain is designed to crank the engine and offer regenerative braking during braking. There are demands of high specific power and long service life for batteries in MHEVs. The battery's charge and discharge power depend on its SoC. The battery's discharge power decreases with its SoC. The minimum operating SoC is around 40–50% to uphold sufficient power for launch and acceleration support. On the other hand, the battery's recharging power drops when the SoC is high; thus, the maximum operating SoC is regulated at around 70–80% to maintain sufficient recharge power for regenerative braking. Typically, the batteries operate in an SoC window between 40% and 70%. Comparing with an ICE vehicle, the MHEV can boost the fuel economy by 20–30% in city driving.

4.3 Full hybrid electric vehicle

The FHEV has a high power electrical powertrain to drive the vehicle purely by electricity in a short driving range. The typical electric motor power for sedan FHEV is about 50 kW at 200–350 V. Generally, the motor, generator, and engine are coupled in series–parallel configuration. With the aid of power split devices, which are mainly built by planetary gear sets and clutches, the energy management system of the engine, motor, and generator is designed to maximize energy efficiency and minimize emissions.

The FHEV can be driven in pure EV mode and hybrid mode. The electrical powertrain assists the engine, not only at the starting, but also during acceleration in the hybrid model, which is also called *charge sustaining mode*. In the charge-sustaining mode, the battery is recharged not only by regenerative braking but also by the engine to maintain the SoC in a high and narrow window. The FHEV can achieve higher fuel economy than that of the ICE vehicle by 30–50% in city driving. Examples of FHEVs are the Ford Escape Hybrid, GM Volt, Toyota Prius, Toyota Highlander, and Lexus RX 400h.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto051
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

4.4 Plug-in hybrid electric vehicle

The PHEV is similar to that of an FHEV. The key differences are the additional battery pack and the functionality of grid recharging. In addition to the charge-sustaining mode, the PHEV can also operate in the charge-depletion mode, in which the PHEV operates in pure EV mode. Thus, the battery SoC drops in the charge-depletion mode.

The electrical drivetrain of a PHEV works in a high voltage at 220–350 V. The battery energy capacity in PHEVs is the largest among all HEVs, and it is determined by the designated pure electric driving range. The PHEV operates in the charge-depletion mode first and then the charge-sustaining mode. In the charge-depletion mode, the battery SoC decreases from 100% to a threshold SoC (typically 20–30%), which triggers the operation mode change. In the charge-sustaining mode, the battery SoC oscillates around the threshold SoC. The battery is recharged from the grid at the end of the trip. Similar to the EV, the PHEV suffers from complexity and costliness. However, the PHEV delivers longer driving range than the EV's that is comparable to conventional ICEs.

The BYD F3DM is the world's first mass production PHEV, which went on sale to the government agencies and corporations in China in December 2008. Toyota also worked on a plug-in version of the Prius. The plug-in Prius was converted from the Prius by adding additional 1.3 kWh battery pack into the car and a charging unit. A PHEV can also be implemented in a series hybrid topology. The GM Chevrolet Volt is a series hybrid PHEV, which is also called *extended-range electric vehicle* (*EREV*). The EREV is driven by one sole electrical powertrain, powered by the battery and a small engine.

5 CONCLUSIONS

The chief advantage of HEV technology is that it reduces fuel consumption relative to standard ICEVs and subsequently reduces emissions associated with fuel combustion. HEV technology can take advantage of benefits resulting from the coupling of electric motors with an ICE.

The electric motor is more efficient than an engine, does not consume energy at standstill, and delivers maximum torque at zero and low speeds. With the electric motor, the HEV can further reduce fuel consumption by shutting off the engine during idle and restarting the engine in a start–stop system. Regenerative braking can further reduce fuel consumption by converting the vehicle's kinetic energy, which is usually dissipated as heat in the brakes, into electrical energy that can recharge the vehicle's traction battery. The presence of an electric motor also allows for reducing the size of the ICE that can be tuned and controlled to operate at more efficient levels. Optimized ICE operation results in reduced maintenance costs by way of less mechanical wear. The presence of sophisticated electrical components such as energy storage devices, motors, and power converters unavoidably increases the cost of HEVs.

HEVs are designed for functionality and the vehicle market; therefore, there are MHs, MHEVs, FHEVs, and PHEVs. All these HEVs can have a series, parallel, series–parallel, or complex drivetrain. HEV development is driven by advances in ICEs improving combustion with the aid of automotive electronics and by the development of an advanced electric drive and its optimized integration with ICE.

Regenerative Braking Systems

Akira Sakai, Tetsuya Miyazaki, Takahiro Okano, Kazunori Nimura, and Daisuke Nakata

Toyota Motor Corporation, Toyota, Japan

1 INTRODUCTION

In response to growing demands to reduce CO_2 emissions, recent years have seen rapid progress in the development of next-generation vehicles such as hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), electric vehicles (EVs), and fuel cell vehicles (FCVs). Most next-generation vehicles use electrical energy, and one of their primary features is regenerative braking that generates braking force by using motors as generators during deceleration.

The function of the novel braking systems installed in these vehicles is to improve fuel efficiency through regenerative braking and to secure both braking and dynamic performance.

Furthermore, regenerative braking has also been adopted in vehicle categories other than HEVs, EVs, and the like. These include vehicles with front-wheel drive (FWD), rear-wheel drive (RWD), and all-wheel drive (AWD) systems (AWD systems include mechanically coupled and independent front/rear wheel types). Consequently, the amount of regenerative braking force with respect to the motors and battery capacity and the types of axles where regenerative braking can be applied have increased. In response to these trends, braking systems are becoming more diverse.

Moreover, to further improve fuel efficiency, HEVs use a wide range of technology for stopping the engine when it is not needed as a source of motive power, such as when the driver is not operating the accelerator pedal. In addition, as EVs and FCVs do not have an engine, the braking systems in these types of vehicles must be developed to secure the necessary braking performance without using engine intake vacuum.

This chapter details the requirements of braking systems in accordance with the purpose of the vehicle and describes the configuration and controls of braking systems to achieve these requirements.

2 REGENERATIVE BRAKING IN HEVs AND EVs

2.1 Regenerative braking and its uses

The term *regenerative braking* refers to the functions of braking devices that convert kinetic energy to another form of energy during deceleration or the like, recover and store that energy, and use the resistance generated during this process as braking force. Recovering and reusing kinetic energy, which is normally wasted in conventional friction braking as heat, enables more efficient energy usage. Regenerative braking is already in widespread use

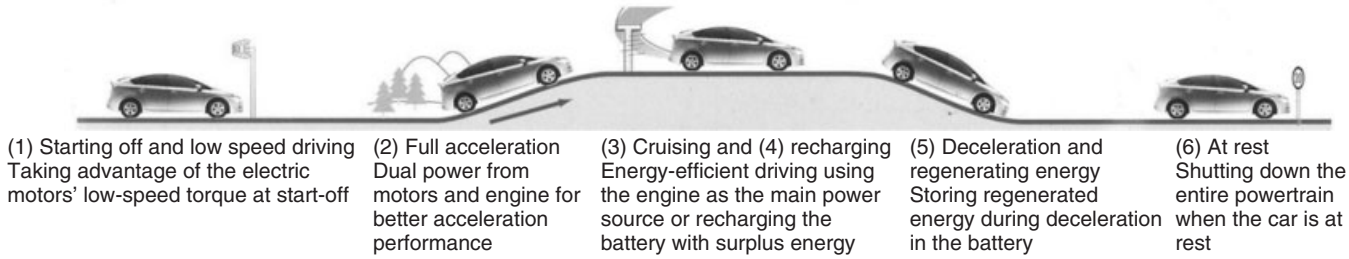

Figure 1. Examples of HEV driving patterns.

in trains (bullet trains, conventional railways, subways, and streetcars), elevators, electrically assisted bicycles, and so on. These systems recover kinetic energy as electrical energy by using motors to generate power during braking and achieve deceleration using the generation resistance.

Since Toyota Motor Corporation released the Prius HEV in 1997, various PHEVs and EVs have also entered mass production. Most of these vehicles are equipped with motors and a battery for storing electrical energy. Figure 1 shows some examples of HEV driving patterns (Hano and Hakiai, 2011).

Typically, regenerative braking in a vehicle uses the motors (or generators) to convert the vehicle's kinetic energy into electrical energy, which is then stored in the battery and used to assist driving force or the like (Figures 2 and 3). In some cases, capacitors may also be used to store energy. In addition to driving force assistance, the stored electrical energy can also be supplied to other auxiliary electrical equipment.

Regenerative braking helps improve fuel efficiency and extend the cruising range of the vehicle. The frequency of deceleration events that waste kinetic energy as heat is particularly high in urban driving and other driving patterns with repeated acceleration and deceleration. The merits of regenerative braking are therefore easy to obtain in these patterns as there are many opportunities to recover energy that is normally wasted.

Regenerative braking is reported to have a 10–25% fuel efficiency improvement effect in current mass-produced HEVs and EVs (Nakamura *et al*., 2002; Nakata *et al*., 2009).

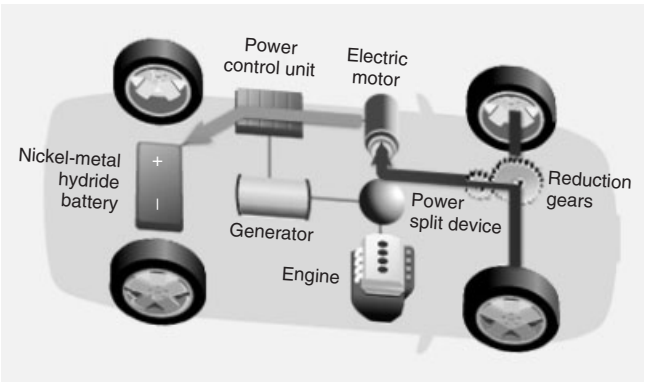

Figure 2. Example of energy flow during regenerative braking.

2.2 Characteristics of regenerative braking in vehicles

The motor torque during regenerative braking can be expressed using the following equation.

$$\text{Motor torque (Nm)}(\propto \text{braking force}) = \frac{\text{generation efficiency} \times \text{generated power (W)}}{[\text{motor speed (1/sec)}\ (\propto \text{vehicle speed})]}$$

In general terms, the restrictions when adopting regenerative braking in a vehicle are as follows.

2.2.1 *Dependence on vehicle speed*

The possible regenerative braking force differs depending on the vehicle speed (line (a) in Figure 4). In general terms, the possible regenerative braking force is relatively lower in higher speed driving. In addition to the output characteristics of the motors, the power generated by the motors during regenerative braking is restricted by the capacity of the battery to accept charge, the processing capacity of the inverter, and so on.

2.2.2 *Braking force while vehicle stopped*

Regenerative braking requires the generation motors to be rotating (line (b) in Figure 4). As the vehicle cannot generate power while stopped, regenerative braking cannot be used.

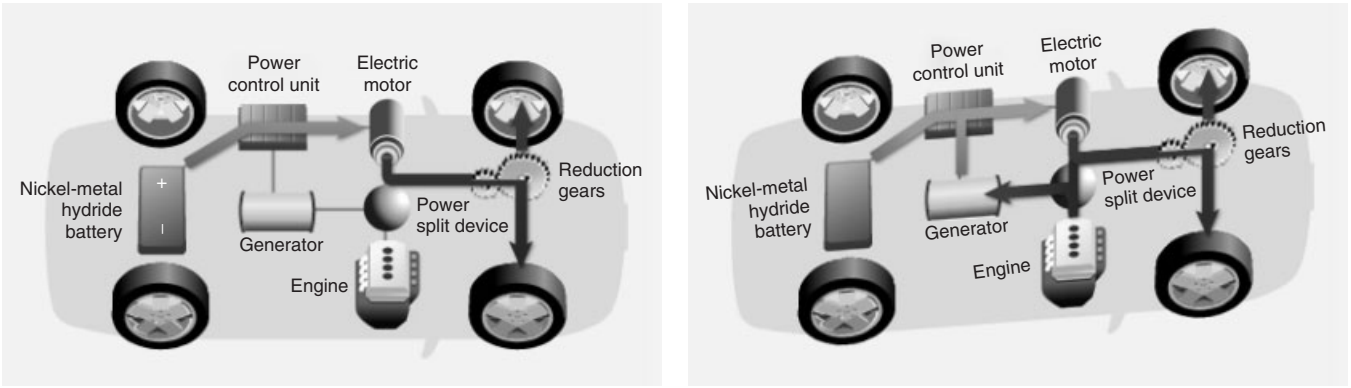

Figure 3. Example of energy flow during driving force assistance. (a) Starting off and low speed driving. (b) Full acceleration.

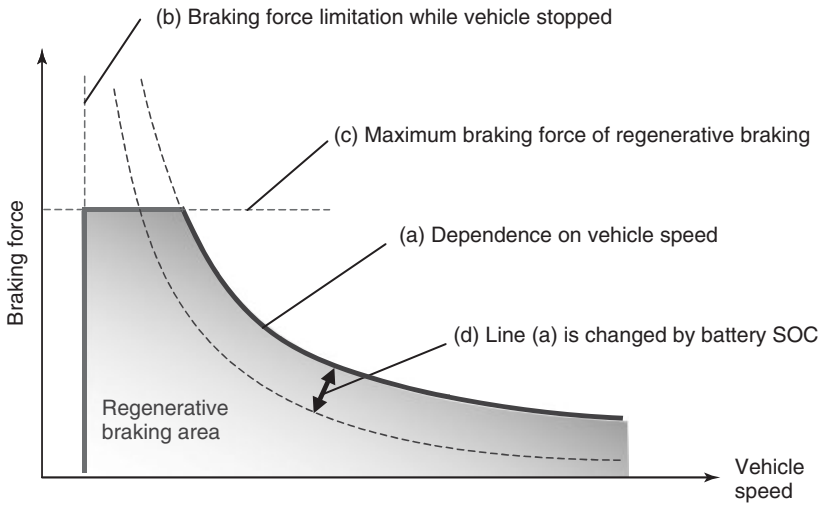

Figure 4. Illustration of possible regenerative braking force.

2.2.3 Maximum braking force of regenerative braking

Conventional friction braking is generally capable of generating a maximum deceleration of approximately 1 G (line (c) in Figure 4). In contrast, regenerative braking force is transferred as torque from the generation motors via parts such as the driveshaft, transmission, and the like. The regenerative braking force is often restricted from the standpoints of the characteristics of these transmission systems and energy efficiency.

2.2.4 Battery state of charge (SOC)

Most HEVs and EVs control the charging process to maintain the battery state of charge (SOC) within a certain range (line (d) in Figure 4). For this reason, the amount of charge is restricted if the SOC is close to the upper limit of control. In this case, the regenerative braking force is restricted as the amount of power generated from regenerative braking that can be accepted by the battery is reduced.

2.3 Characteristics of vehicles with regenerative braking

Table 1 shows a list of HEVs and EVs, categorized by drive system (engine and motors), battery capacity, and EV driving capability.

2.3.1 Hybrid electric vehicles

There are many examples of HEVs that can be categorized as either mild or strong HEVs depending on the capacity of the motors and battery.

Strong HEVs are equipped with comparatively large motors and have a large-capacity battery to allow the vehicle to be driven as an EV for a certain distance. Strong HEVs recover large amounts of energy through regenerative braking using the motors and achieve large improvements in fuel efficiency by reusing this energy while driving.

Mild HEVs are equipped with a comparatively small motor, which is used to restart the engine when the vehicle starts moving and to provide driving force assistance. Mild HEVs have a relatively small-capacity battery, which limits the amount of energy recoverable by regenerative braking.

Micro HEVs do not have a motor for assisting vehicle drive. These vehicles only have an idling stop function and regenerative braking using a generator. Regenerative braking in most micro HEVs uses a conventional generator (i.e., the alternator) to charge the auxiliary battery (12 V). The recovered energy is used to improve fuel efficiency by restarting the engine when the vehicle starts to move and to power auxiliary electrical devices such as the air conditioning. Micro HEVs are usually not categorized as HEVs due to the lack of a drive motor. The energy recoverable by regenerative braking is further restricted as a result.

2.3.2 *Plug-in hybrid electric vehicles*

Unlike strong HEVs, PHEVs are capable of being charged from external sources. Consequently, PHEVs are equipped with a larger capacity battery and have a much longer EV cruising range. The regenerative braking force may be restricted when the battery SOC is close to its upper limits due to external charging.

2.3.3 *Electric vehicles*

EVs have an even larger battery capacity than PHEVs. EVs are not generally equipped with an engine, but one may be provided as a range extender. Regenerative braking plays an extremely important role in EVs due to their short cruising range caused by the lower energy density of batteries compared with fossil fuels.

2.4 Characteristics of regenerative braking depending on drive system

Similar to conventional vehicles equipped with an engine, HEVs and EVs have been developed with various types of drive systems. Table 2 shows a list of some typical examples.

2.4.1 *Front-wheel drive*

In a FWD HEV or EV, the motor is connected only to the front wheels. As a result, regenerative braking acts on the front wheels only. However, regenerative braking cannot provide sufficient braking force in every case. Therefore, when regenerative braking is used to provide some of the service braking force, friction braking is used to compensate

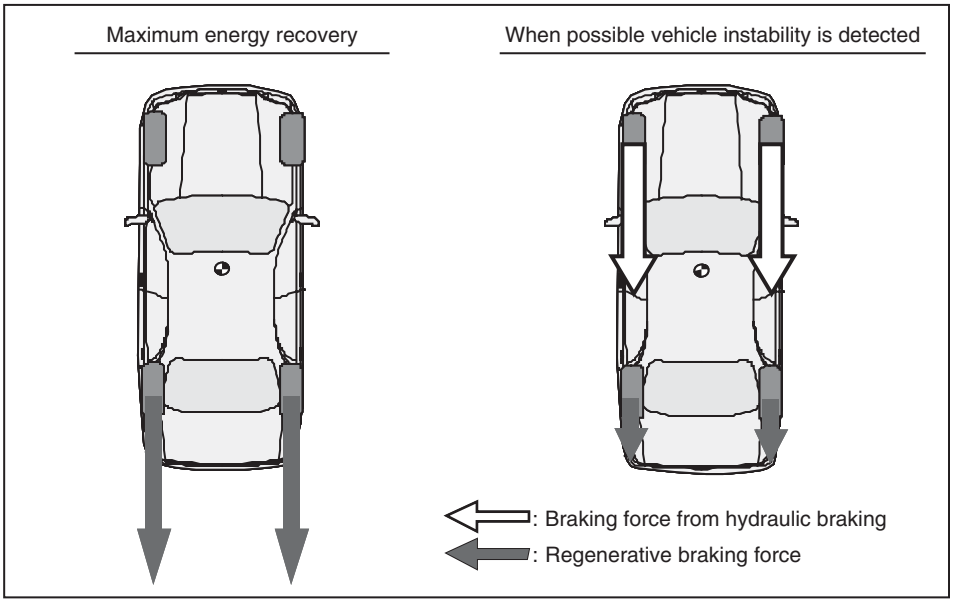

Figure 5. Example when vehicle stability is affected during regenerative braking (RWD vehicle.)

for any insufficiency from regenerative braking at the front wheels and to provide the braking force for the rear wheels.

2.4.2 Rear-wheel drive

In a RWD HEV or EV, the motor is connected only to the rear wheels. As a result, regenerative braking acts on the rear wheels only. In the same way as a FWD HEV or EV, regenerative braking cannot provide sufficient braking force by itself in every case. Therefore, when regenerative braking is used to provide some of the service braking force, friction braking is used to compensate for any insufficiency from regenerative braking at the rear wheels and to provide the braking force for the front wheels.

2.4.3 All-wheel drive

In an AWD HEV or EV, motors are connected to all four wheels, which enable the application of regenerative braking to each wheel. As a result, larger amounts of energy can be recovered by regenerative braking than in a FWD or RWD system. There are various types of AWD systems. When separate motors are provided for the front and rear wheels, the regenerative braking force can be adjusted independently, thereby allowing braking force to be distributed optimally between the front and rear wheels. In contrast, in AWD systems in which the front and rear wheels are mechanically coupled, the regenerative braking distribution is restricted by the torque distribution of the front and rear wheels.

When braking is performed by regenerative braking alone, the braking force distribution to the front and rear wheels differs from that in a conventional vehicle depending on the drive system. This has an effect on vehicle stability. To help resolve this issue, vehicle behavior is detected by various sensors. In situations where vehicle stability might be affected, the desired braking force distribution to the front and rear wheels is achieved by utilizing friction braking (Figure 5).

The following section describes the technology used in vehicles with regenerative braking systems.

3 BRAKING SYSTEMS OF HEVs AND EVs

This section describes the requirements of braking systems in HEVs and EVs. The fundamental requirement of the braking system in an HEV is to guarantee the same level of safety and comfort as the braking system in a gasoline vehicle (referred to below as a *conventional braking system*). At the same time, it is preferable that the braking system also includes a function to help improve fuel efficiency through the use of regenerative braking and the reduction of fuel consumption by enabling the engine to be stopped whenever possible. Therefore, the following sections discuss the requirements for a braking system from the standpoints of safety, comfort, and fuel efficiency improvement.

Figure 6. Securing boost vacuum by electric pump.

3.1 Types of functions to boost pedal effort in braking systems

Braking systems require a boost function to supplement the effort applied to the brake pedal by the driver. Most gasoline vehicles generally achieve this function through a vacuum booster using vacuum generated by the engine as the engine is always in operation in a conventional vehicle.

However, HEVs do not require constant operation of the engine to power the vehicle. In these cases, the engine is stopped to improve fuel efficiency. In a braking system that relies on the engine to generate vacuum for boost, engine operation is required if there is insufficient vacuum to provide the assist in accordance with the driver's brake pedal operation. This is not preferable in an HEV from the standpoint of fuel efficiency. Furthermore, this vacuum is not available in EVs, which have no engine.

Consequently, it is important for the braking systems in HEVs and EVs to achieve a boost function without relying on engine intake vacuum while also improving fuel efficiency. These two aims must be achieved to a high level of performance. There are the following two approaches for achieving a boost function without relying on engine operation.

3.1.1 Using electric pump to secure boost vacuum

In this method, the vacuum for boost is generated by an electric pump instead of the engine. A vacuum sensor in the braking system detects the boost vacuum level and drives the electric pump when the level is below a certain threshold. Figure 6 shows an example of this pump (von Albrichsfeld and Karner, 2009).

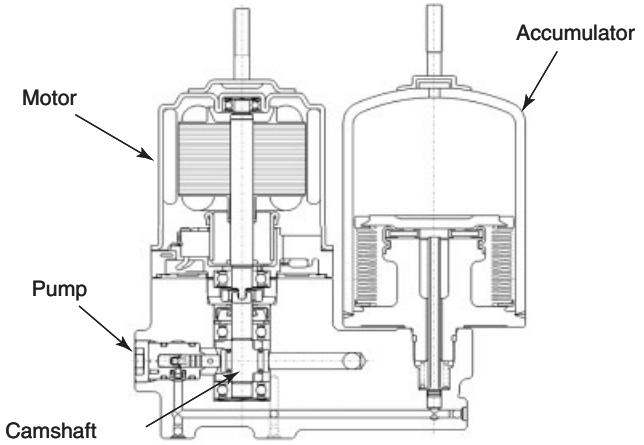

Figure 7. securing high-pressure brake fluid for boost by electric pump.

3.1.2 Using electric pump and accumulator pressure for boost

In this method, high pressure brake fluid is stored in an accumulator by an electric pump and used for generating boost. Figure 7 shows a typical example of this system, which consists of a motor, pump, and accumulator. The motor turns a camshaft to drive a pump, which dispenses high pressure brake fluid into an accumulator for storage (Nakata *et al*., 2009).

3.1.3 Using electric motor thrust as boost

Unlike the two methods described above, this method drives an electric motor when assist is required without relying on a unique braking power source. Instead, this method provides assist directly from the driver's brake pedal operation. In other words, electrical energy stored in the battery is used as the source of the boost (Fujiki *et al*., 2011) (Figure 8).

3.1.4 Using engine drive when engine vacuum is insufficient

In this method, a vacuum sensor such as that described in Section 3.1.1 is added to a conventional braking system. Then, the engine is driven when the boost vacuum falls below a certain threshold. Although this is the lightest method, it requires engine operation to secure the boost vacuum.

If regenerative braking torque is used independently of service braking in an HEV, the requirements for a braking system can be satisfied by adding a boost function using either of the above four methods to a conventional braking system. However, the requirements for an EV or

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

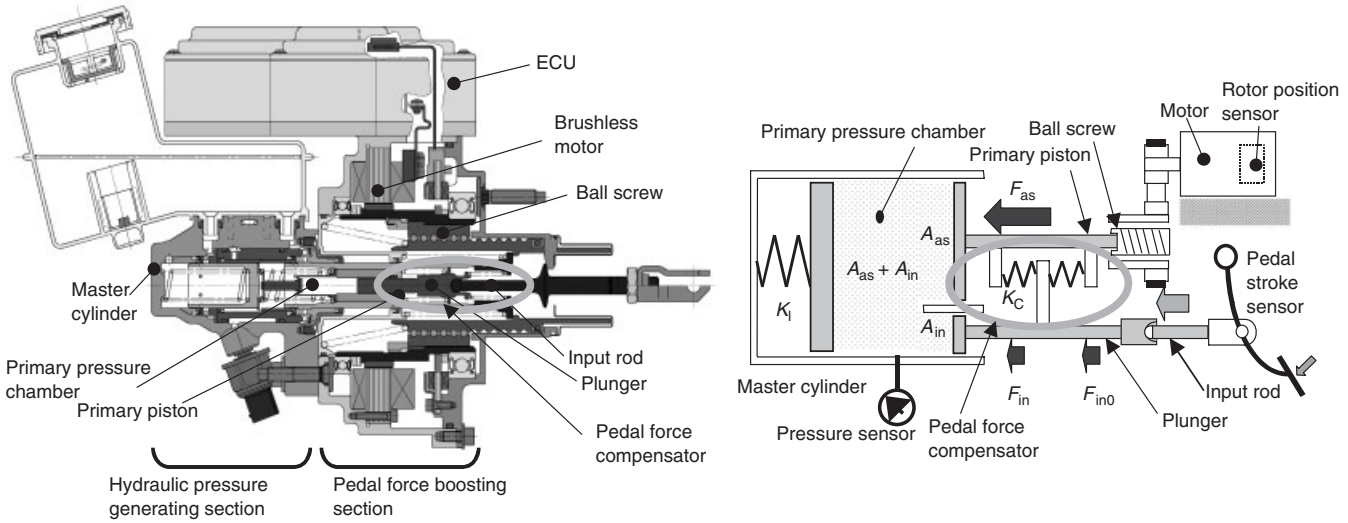

Figure 8. Direct boost using thrust of electric motor.

HEV braking system are greater when regenerative braking torque is used to provide some of the service braking force to further increase the amount of kinetic energy recovered.

3.2 Regenerative-friction brake coordination system

As described in Section 2, regenerative braking torque from electric motors has the following characteristics.

1. The generated braking torque fluctuates in accordance with the battery SOC and vehicle speed.
2. Sufficient braking performance cannot be achieved only from the braking torque generated by electric motors.
3. Regenerative braking requires the generation motors to be rotating. As the vehicle cannot generate power while stopped, regenerative braking cannot be used.
4. The wheels at which regenerative braking torque is applied differ depending on the drive system.

For these reasons, it is not realistic to achieve vehicle braking torque using only electric motors. Therefore, when using regenerative braking torque to provide some of the service braking force, the friction braking torque must be adjusted in accordance with the regenerative braking torque. The following section describes the methods of adjusting the friction braking torque.

3.2.1 Methods of adjusting friction braking torque

There are four methods of adjusting the friction braking torque, which are closely related to the methods of achieving the boost function described in Sections 3.1.1–3.1.2.

3.2.1.1 Wheel cylinder hydraulic pressure control using active vacuum booster. In this method, an active vacuum booster is driven in accordance with the required friction braking torque to adjust the hydraulic pressure inside the master cylinder. The friction braking torque is then adjusted by introducing the desired hydraulic pressure into the wheel cylinder (von Albrichsfeld and Karner, 2009) (Figure 9).

3.2.1.2 Wheel cylinder hydraulic pressure control using electric motor. In this method, the electric motor on the master cylinder is driven in accordance with the required friction braking torque to adjust the hydraulic pressure inside the master cylinder. The friction braking

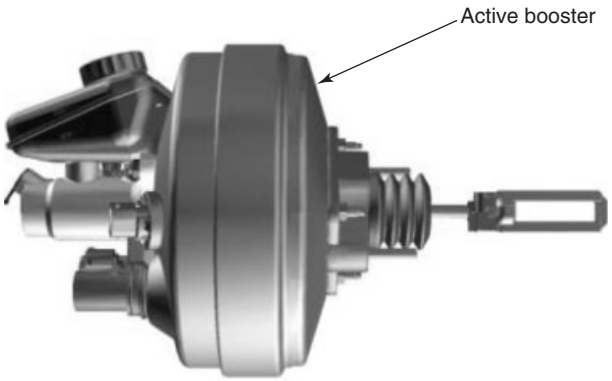

Figure 9. Adjusting friction braking torque by boost vacuum control.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto053
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

torque is then adjusted by introducing the desired hydraulic pressure into the wheel cylinder (Hano and Hakiai, 2011; Obata *et al*., 2011).

3.2.1.3 Wheel cylinder hydraulic pressure control using linear solenoid valve. In this method, a linear solenoid valve is driven in accordance with the required hydraulic pressure. The friction braking torque is then adjusted by directly introducing accumulated high pressure brake fluid into the wheel cylinder (Nakata *et al*., 2009) (Figure 10).

3.2.1.4 Direct friction braking torque control using electric motor. In this method, the friction braking torque is adjusted by an electric motor directly installed on the wheel cylinder, which is driven in accordance with the degree of required friction braking torque.

Another requirement for a regenerative-friction brake coordination system is a natural braking feel. The braking feel is enhanced by adjusting the friction braking torque in accordance with the action of regenerative braking system to achieve the vehicle deceleration intended by the driver. In addition, the brake pedal stroke and effort must not fluctuate depending on the state of regenerative braking torque generation or the friction braking torque adjustment. The following section describes how fluctuations in brake pedal stroke and effort are suppressed.

3.2.2 Suppression of fluctuations in brake pedal stroke and effort using pedal stroke simulator

The common approach to generate the targeted brake pedal feeling is to provide a separate pedal stroke simulator to make sure that the adjustment of the friction braking torque does not affect the brake pedal (Nakamura *et al*., 2002; Nakata *et al*., 2009). This separates the friction braking torque adjustment from the brake pedal feeling so that fluctuations in the pedal stroke and effort can be suppressed.

The brake pedal feeling in a conventional braking system is the result of the wheel cylinder in each wheel consuming brake fluid in accordance with hydraulic pressure. The role of the pedal stroke simulator is to realize this feeling without consuming brake fluid. The main method for accomplishing this is to adopt a pedal stroke simulator comprising springs and a piston that reproduces reaction force characteristics equivalent to a wheel cylinder (Figure 11).

3.2.3 Securing regenerative braking and vehicle stability

Sections 3.2.1 and 3.2.2 described how the regenerative braking torque and friction braking torque are controlled independently from the driver's brake pedal operation. However, further considerations are required depending on the drive system of the vehicle as this alters the wheels at

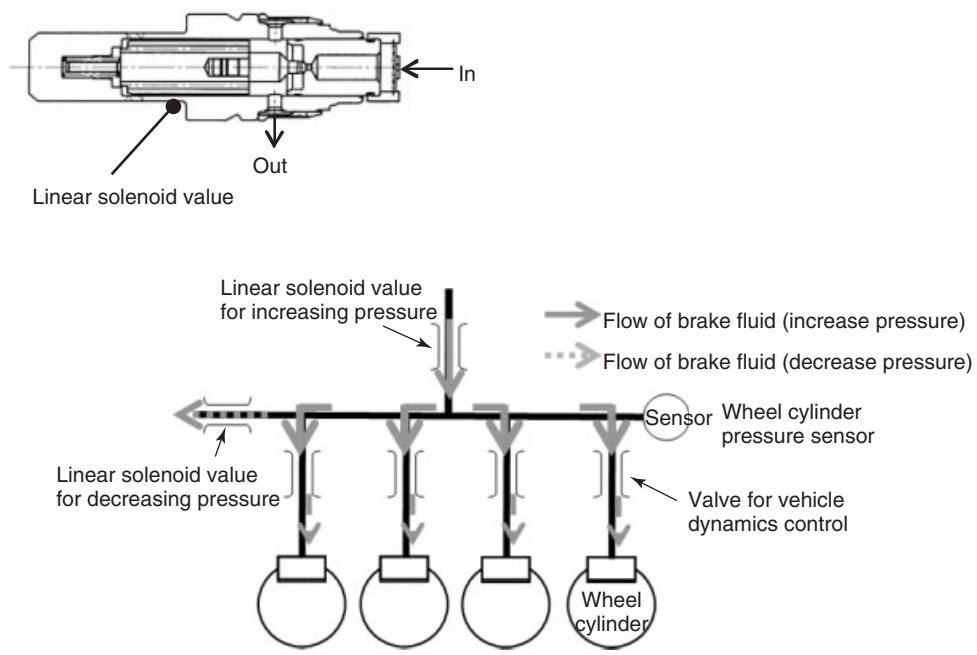

Figure 10. Adjusting friction braking torque by linear solenoid valve control.

DOI: 10.1002/9781118354179.auto053
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

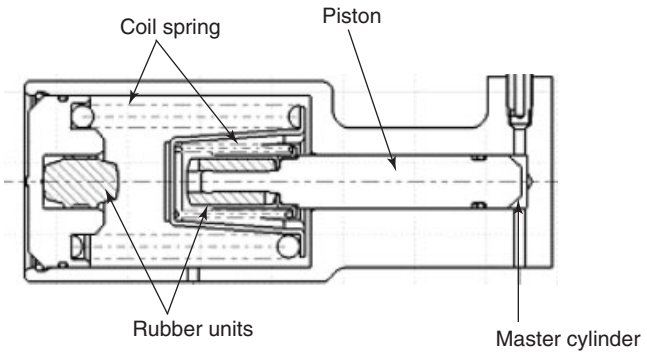

Figure 11. Example of pedal stroke simulator using springs and piston.

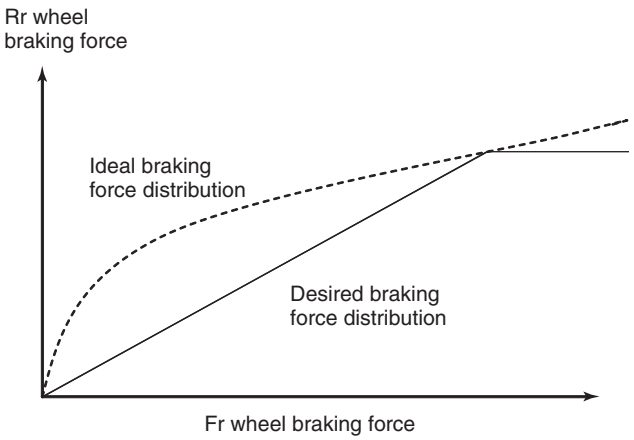

Figure 12. Front/rear braking force distribution.

which regenerative braking torque is applied (see point 4 in Section 3.2). This point is described in detail below.

Figure 12 shows an example of an ideal front/rear wheel braking force distribution. With conventional braking, the desired front/rear braking force distribution can be achieved by designing brake specifications for each wheel. However, regenerative braking torque can only be applied to the drive wheels (only the front wheels in a FWD vehicle and only the rear wheels in a RWD vehicle). Therefore, many vehicles with regenerative braking systems have a different front/rear braking force distribution from the desired distribution for a vehicle with conventional braking.

3.2.3.1 Braking systems capable of independently controlling braking force generated by front and rear friction braking. A braking system configuration that adjusts the wheel cylinder hydraulic pressure independently for each wheel or each braking circuit enables coordinated control between regenerative braking and friction braking with a free front/rear wheel braking force distribution. More specifically, the braking force distributions shown in examples (i) and (ii) in Figure 13 can be achieved even in a FWD vehicle where regenerative braking torque is applied to the front wheels only (Nakamura *et al*., 2002).

3.2.3.2 Braking systems that control braking force generated by friction braking at all four wheels simultaneously. This configuration performs coordinated control between regenerative braking and friction braking. More specifically, this configuration can achieve the braking force distributions shown in examples (iii) and (iv) in Figure 13. In practice, the braking force distribution is determined in consideration of the improvement in fuel efficiency due to the amount of regenerative braking and the vehicle characteristics on braking (Hano and Hakiai, 2011; Nakata *et al*., 2009; Obata *et al*., 2011).

3.3 Braking systems that can perform vehicle dynamic control function

The growing popularity of HEVs and EVs is also helping advance the growth of safety functions such as antilock brake systems (ABSs), traction control systems (TCSs), and electronic stability control (ESC) systems. The most common method of achieving these ABS, TCS, and ESC dynamic control functions is to install a conventional ESC unit inside the braking system (von Albrichsfeld and Karner, 2009; Fujiki *et al*., 2011; Hano and Hakiai, 2011; Obata *et al*., 2011).

These systems have been developed in compact and lightweight forms by reconfiguring the braking mechanism for achieving coordinated control between the components of the ESC unit and regenerative braking (Nakamura *et al*., 2002; Nakata *et al*., 2009).

3.4 Relevant regulations

Regulations for braking systems that include regenerative braking include FMVSS 125 (Federal Motor Vehicle Safety Standard) and ECE-R13H (Economic Commission for Europe). Various regulations also include references to regenerative braking, which require compliance as well. ECE-R13H divides regenerative braking systems into categories A and B according to the system characteristics. Category A applies when regenerative braking is applied independently of service braking and category B applies when regenerative braking is utilized to provide some of the service braking force.

4 REGENERATIVE BRAKING AND FRICTION BRAKING CONTROL

Sections 2 and 3 focused on the characteristics of regenerative braking and methods for adjusting braking force through braking systems that utilize regenerative braking and friction braking. This section examines the technologies for securing vehicle dynamic performance and improving fuel efficiency using regenerative braking and friction braking.

There are two categories of regenerative braking systems. With the first, regenerative braking force is applied independently of service braking. With the second, regenerative braking force is applied as part of service braking. In the first system, regenerative braking is performed by an accelerator pedal operation, shifting, or switch operation by the driver, that is, in the same way as engine braking in a gasoline-powered vehicle. In the second system, the vehicle coordinates the regenerative braking control with conventional service braking to generate the required braking force in accordance with the driver's brake pedal operation. The characteristics of these systems are described below.

4.1 Regenerative braking applied independently of service braking

The explanation in this section uses a method that generates braking force equivalent to engine braking in a conventional vehicle and then recovers the kinetic energy from this process (Figure 14). This method is characterized by the fact that the regenerative braking that recovers kinetic energy is isolated from the service braking. For example, the driver can trigger regenerative braking in this case by easing off the accelerator pedal, lifting off the pedal, or pressing a switch while driving (it depends on operation system of vehicle). This is similar to engine braking in

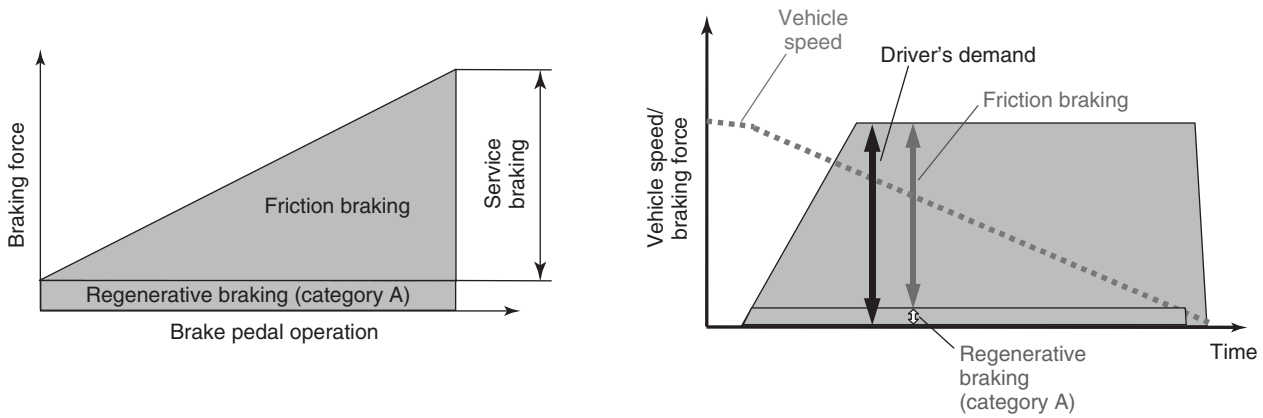

Figure 14. Illustration of regenerative braking applied independently of service braking.

DOI: 10.1002/9781118354179.auto053
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

conventional vehicles. Some HEVs also use technology to supplement braking force by a powertrain control such as engine braking to reduce changes in braking force caused by fluctuations in regenerative braking.

4.2 Regenerative braking applied as part of service braking

The explanation in this section uses a method that expands the application of regenerative braking as part of service braking to recover a larger amount of kinetic energy (Figure 15). More kinetic energy can be recovered by allowing regenerative braking to provide some of the service braking force generated by operating the brake pedal. In other words, this method optimizes the use of regenerative braking within the range of braking force demanded by the driver. Compared to the method described in Section 4.1, the larger amount of recovered kinetic energy allows fuel efficiency to be improved.

The required deceleration for service braking reaches approximately 1 G. However, there are various factors that limit the available regenerative braking force, such as the battery SOC, vehicle speed, and so on. Therefore, regenerative braking alone cannot generate the braking force required by the driver and friction braking must be used to compensate for any insufficiency. At the same time, the regenerative-friction braking coordination control must also achieve the same natural braking feel as a conventional gasoline vehicle, control friction braking independently of the driver's brake pedal effort, and accurately coordinate friction braking in accordance with the fluctuations in regenerative braking.

Figure 16 shows an example of regenerative-friction braking coordination control. As described in Section 2, regenerative braking is not available when the vehicle is not moving. For this reason, the following control is performed to improve fuel efficiency and secure the braking force demanded by the driver. In the initial period of braking, the driver's braking force demand is achieved

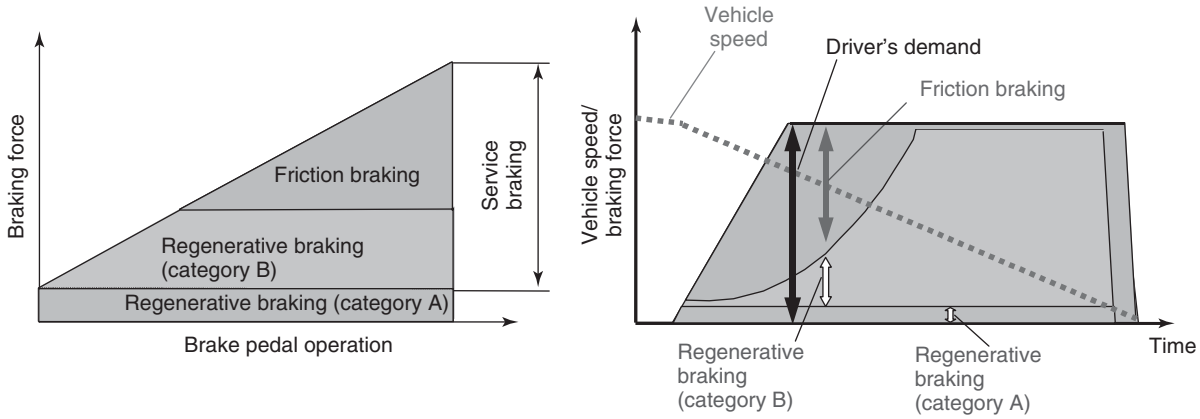

Figure 15. Illustration of regenerative braking applied as part of service braking.

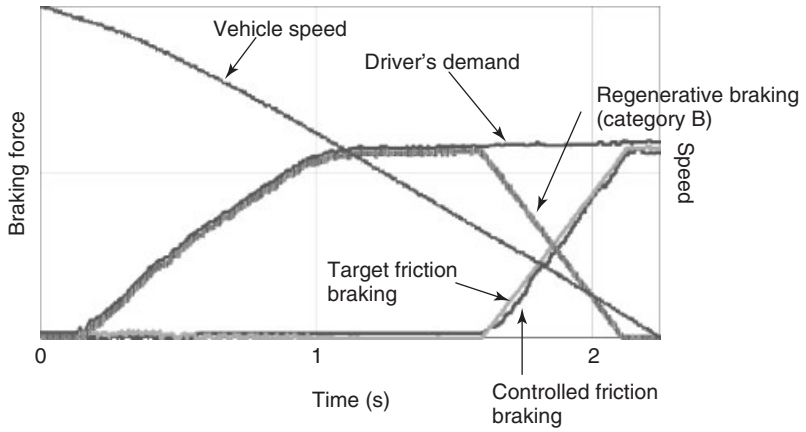

Figure 16. Illustration of regenerative-friction braking coordination control.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto053
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

mainly by regenerative braking alone to maximize the kinetic energy recovered during braking. Then, immediately before the vehicle stops, the distribution of braking force from friction braking is increased as regenerative braking is decreased.

Regenerative braking is also reduced in situations such as when the battery has a full charge or a failure has occurred, or when possible vehicle instability is detected. Consequently, the regenerative-friction braking coordination control must be highly accurate to constantly change the distribution between regenerative braking and friction braking. Technological development is advancing to reduce changes in the degree of deceleration while this control is performed (Nakata *et al*., 2009).

4.3 Front/rear braking force distribution depending on drive system

The front/rear braking force distribution is designed to maximize braking force on any road surface. It is generally understood that too much braking force distributed to the front or rear wheels will adversely affect vehicle stability.

It is preferable to increase the proportion of regenerative braking compared to the braking force from friction braking to recover as much energy as possible. However, as the drive system of the vehicle determines the wheels on which regenerative braking is applied, the use of regenerative braking alone to generate braking force will result in over-distribution of braking force to the front wheels in the case of a FWD vehicle or to the rear wheels in the case of a RWD vehicle. Consequently, it will not be possible to achieve the desired front/rear braking force distribution. In other words, regenerative braking has the potential to affect vehicle stability. Therefore, the application of regenerative braking must consider the front/rear braking force distribution as well as coordination with friction braking. The following sections describe the approaches to the front/rear braking force distribution in consideration of typical vehicle drive systems.

4.3.1 Front-wheel drive

In a FWD HEV or EV, the motor is only connected to the front wheels. Therefore, braking the vehicle using regenerative braking alone will result in a disproportionate distribution of braking force to the front wheels. Consequently, the application of regenerative braking in a FWD vehicle may have the following adverse effects on vehicle handling.

4.3.1.1 When regenerative braking is applied independently of service braking. Generally, the application of regenerative braking in this case creates a disproportionate distribution of braking force to the front wheels. When a situation that might affect vehicle handling occurs (e.g., when the front tire slip ratio is high), regenerative braking is reduced to secure vehicle stability.

4.3.1.2 When regenerative braking is applied as part of service braking. The front/rear braking force distribution is generally created by the following types of coordination between regenerative braking and friction braking (Hano and Hakiai, 2011; Nakamura *et al*., 2002).

4.3.1.2.1 Braking systems capable of independently controlling braking force generated by front and rear friction braking. The desired front/rear braking force distribution can be achieved by applying friction braking to the rear wheels while applying regenerative braking to the front wheels (line a in Figure 17). However, when the braking force demanded by the driver is divided between regenerative braking and friction braking, the application rate of regenerative braking will be reduced by the amount of friction braking application. For this reason, it is difficult to maximize energy recovery. As shown by line b in Figure 17, energy recovery can be increased by generating braking force using regenerative braking at the front wheels up to a certain braking force region. Then, once that region is exceeded, braking force is applied to the rear wheels as well by friction braking (Obata *et al*., 2011).

4.3.1.2.2 Braking systems that control braking force generated by friction braking at all four wheels simultaneously. When the braking force demanded by the driver is divided between regenerative braking and friction braking, braking force is generated by regenerative braking at the front wheels up to a certain braking force region (line c in Figure 17). Then, once that region is exceeded, braking force is applied to all four wheels

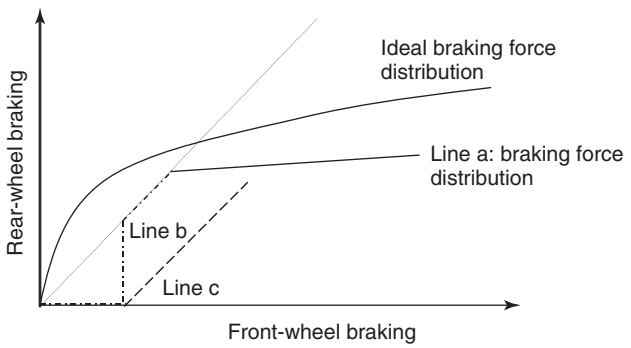

Figure 17. Front/rear braking force distribution.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

as well by friction braking. Alternatively, regenerative braking and friction braking may also be applied at the same time.

For both systems with or without coordinated control between regenerative braking and service braking, the front/rear braking force will be distributed more to the front wheels than in a conventional vehicle. Moreover, in comparison to a conventional vehicle, this may cause a vehicle with regenerative braking to have worse handling or increase the frequency of unexpected intervention of ABS at the front wheels. Consequently, as the front tire slip ratio is high, the general approach is to determine the regenerative braking force from the standpoints of both improved fuel efficiency and vehicle stability.

4.3.2 Rear-wheel drive

In a RWD HEV or EV, the motor is only connected to the rear wheels. Therefore, braking the vehicle using regenerative braking alone will result in a disproportionate distribution of braking force to the rear wheels. Consequently, the application of regenerative braking in a RWD vehicle may make the rear wheels more susceptible to skidding. In the same way as a FWD vehicle, the regenerative braking force and front/rear wheel braking force distribution must be determined in consideration of vehicle stability and dynamic performance.

4.3.3 All-wheel drive

4.3.3.1 Drive system with separate motors connected to the front and rear wheels. As a separate motor is attached to the front and rear wheels, the front/rear wheel braking force distribution can be determined freely by instructing regenerative braking separately to each motor. Therefore, the desired front/rear wheel braking force distribution can be achieved by using the motors to adjust the distribution of regenerative braking force at the front and rear wheels. Additionally, more energy can be recovered than in a FWD or RWD vehicle without disrupting the desired front/rear wheel braking force distribution.

4.3.3.2 Drive system with one motor connected to the front and rear wheels. In this system, the front/rear wheel regenerative braking force distribution is determined by the characteristics of the center differential gear or the like. Normally, as the front/rear wheel braking force distribution becomes weighted toward the front or rear wheels depending on the situation, the amount of energy recovery from regenerative braking and the use of friction braking are generally determined in consideration of vehicle stability and dynamic performance in the same way as a FWD or RWD vehicle.

4.4 Dynamic control and regenerative-friction braking coordination functions

4.4.1 Applications to driving assist systems

Cruise control is one example of a recently developed driving assist system that is starting to become more popular in HEVs and EVs. Regenerative braking is also starting to be applied to cruise control systems so that regenerative braking force can be generated during deceleration while these systems are in operation. In this situation, ways are being found to increase opportunities to recover energy and improve fuel efficiency even when driving assist systems are active.

4.4.2 Applications to safety functions

A growing number of vehicles are being provided with ABS and ESC functions to enhance safety performance. These functions require braking force to be adjusted independently at all four wheels. This makes it difficult to operate ABS and ESC functions using regenerative braking that can only generate braking force at the wheels to which the motors are connected.

Therefore, when ABS or ESC is in operation, the general approach is to reduce regenerative braking and supplement the braking force using friction braking. In this case, friction braking can be controlled as required using information from wheel speed sensors, accelerometers, and the like. This control can use conventional technology for adjusting braking force independently at all four wheels. However, as described in Section 4.2, the accuracy of the regenerative-friction braking coordination control technology must be enhanced to vary the distribution between regenerative braking and friction braking. Technological research has made progress in recent years to actively adopt regenerative braking in ABS and ESC functions by making use of the excellent response of regenerative braking and the ability to accurately identify output torque (Fujimoto, 2011; Hori, 2004; Murata, 2011; Okano *et al*., 2002).

Energy Management System of EVs

Masayuki Komatsu

Toyota Motor Corporation, Toyota, Japan

1 INTRODUCTION

Electric vehicles (EVs) are powered by rechargeable onboard batteries. Although conventional EV batteries are still chemical-based (e.g., lead storage batteries), alternative means have also been developed, including flywheel batteries that store mechanical energy and capacitors that store electrical energy. These are commonly known as *rechargeable electrical energy storage systems* (*RESSs*).

The main performance requirements for onboard EV batteries are (i) single charge driving range, (ii) a short charging time, (iii) state-of-charge (SOC) display accuracy, (iv) lifetime, and (v) safety of handling. Owing to these extensive battery requirements, energy management is a considerably more important design issue for an EV than for a gasoline or hybrid electric vehicle (HEV). Energy management in an EV is performed by the battery management system.

The most fundamental way to extend the single charge driving range is to increase the number of onboard batteries. In this case, the key point is to balance the trade-off relationship between the increased battery weight and the subsequent reduction in usability caused by lower dynamic performance (slower acceleration and the like) and longer charging time. For these reasons, manufacturers are working to increase the popularity of EVs by minimizing the effects on usability by enabling the battery to be switched over or by providing rapid-charging infrastructure, even when the EV has limited battery capacity. Therefore, in a broad sense, the method energy management adopted in an EV is not determined simply by the design of the vehicle and battery systems and also depends on the state of the social infrastructure. Research has also been started into the use of EVs themselves as a RESS to supply power to homes. However, at this stage, the establishment of technology for energy management is awaiting further research for practical application.

The main object of energy management is to calculate the battery SOC. As the design requirements for detecting, calculating, and managing the battery state differ depending on the type of battery and the configuration of the EV propulsion system, this chapter focuses on the configuration and outline of onboard EV systems.

2 EV SYSTEMS

Figure 1 shows the configuration of a general EV system. Its main components are the RESS (i.e., the battery system for storing electrical energy), the charging system, the electric propulsion system which treat high power, the auxiliary system that includes the temperature control unit, power steering, and the like, and the energy management unit that integrates and controls these systems. The flow of signals between these component systems are shown by the bold lines. The basic flow of energy is as follows. AC from

ISBN: 978-0-470-97402-5

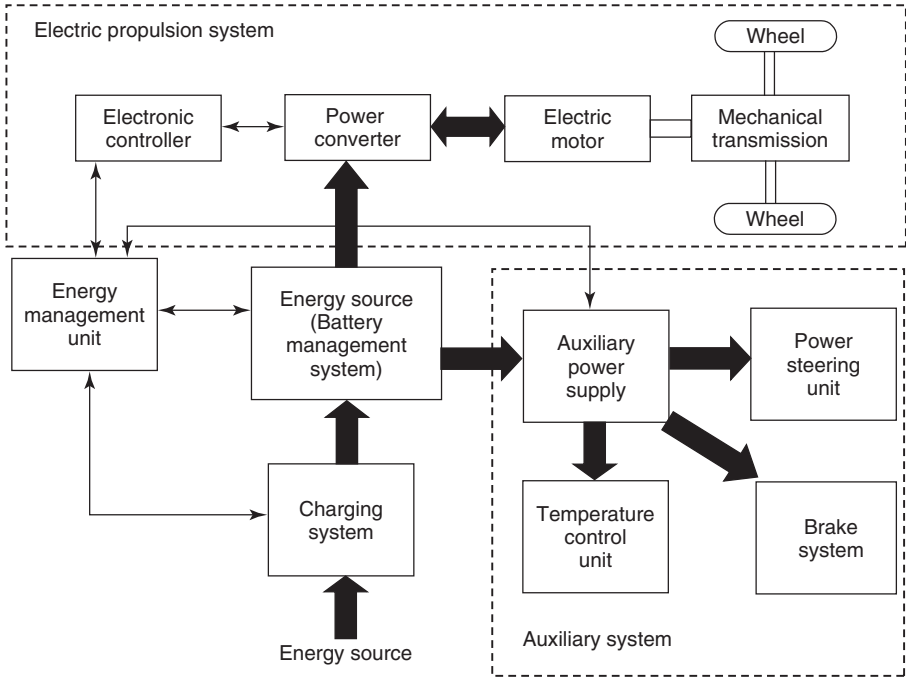

Figure 1. General EV system configuration. (Reproduced from Chan and Chau (2001). By permission of Oxford University Press (www.oup.com).)

an external energy source is passed through the charging system, converted to DC, and used to charge the RESS. The energy required to propel the vehicle is then supplied from the RESS to the electric propulsion system. In turn, kinetic energy generated when the vehicle brake is used to recharge the RESS as regenerated energy through the drive motor that acts as a generator. Furthermore, as the RESS supplies the energy required by the temperature control unit, power steering, and the like, reducing the power demand from the auxiliary system is a key part of extending the single charge driving range.

The energy management unit in Figure 1 functions as the vehicle control unit and battery management unit (BMU). However, the system design may combine the vehicle control unit with the motor system control unit. Other system configurations may place the vehicle control unit with the battery control or motor drive control units, or even by itself. In these systems, as the RESS is typically a lithium ion (Li-ion) or other rechargeable secondary battery, the following sections describe this type of battery system (Chan and Chau, 2001).

2.1 Energy management unit

The energy management unit functions as the vehicle control unit. It detects the driver's operations and the state of the component EV systems (i.e., the battery system, charging system, electric propulsion system, and auxiliary system including the temperature control unit) and manages the SOC of the battery system and the power used to propel the vehicle. The vehicle control unit may also be provided separately. Its configuration can be designed freely depending on the vehicle.

2.2 Rechargeable electrical energy storage system

The RESS is the source of propulsion energy. It recovers and stores the regenerative kinetic energy generated by the vehicle on braking and deceleration. Although some types of RESS use flywheel batteries or capacitors, most are rechargeable secondary batteries. Conventional lead-acid, nickel–cadmium, and nickel-metal hydride batteries have begun to be replaced by Li-ion batteries that have higher volumetric and gravimetric energy densities. The most important function of the RESS is to detect the state of the battery (i.e., the charge and discharge volumes, temperature, and the like) and to measure the SOC.

2.3 Charging system

The charging system supplies the power to be used by the EV from an external power source to the secondary battery.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

There are two basic types of charging system: one that converts commercially available AC to DC and the other that directly charges the battery with DC from a stationary charger. The former can use household power sources, whereas the latter is used in DC rapid charging systems.

The charging system consists of a connector on the power supply side called a *charging coupler* and an *inlet* on the vehicle side. The coupler may use a conductive or noncontact inductive electrical connection system. Both AC and DC conductive systems are available, and there are also differences in the number and layout of the conductive connecting pins. International efforts are being made to standardize both the charging system and the coupler. In addition, rather than charging the battery onboard the vehicle, methods have been developed in which the electrical system itself is removed, charged outside the vehicle, and replaced.

2.4 Electric propulsion system

This system converts power from the battery to power for driving the vehicle. It generally comprises a motor. The motor used may be categorized in accordance with the type of induction voltage applied to the input terminals, its excitation system, or its field system. Common examples include the DC motor, permanent magnet synchronous motor, induction motor, and switched reluctance (SR) motor. Typically, an AC motor is used with inverter control to increase the efficiency and controllability of the motor drive.

2.5 Auxiliary system

In conventional internal combustion engine (ICE) vehicles, the ICE provides the source of power and heat for the auxiliary units. As this is not available in an EV, all auxiliary units have to be powered by electricity. Typical examples of auxiliary units include the air conditioning, electronic power steering, power brake booster, and the like.

3 BATTERY SYSTEM MANAGEMENT

3.1 Configuration

In an EV or HEV, the battery management system refers to the battery used for driving the vehicle and its associated monitoring units. The main components of the battery management system are generally as follows:

- the battery pack;
- the battery assemblies;
- the battery monitoring system; and
- the battery cooling system.

The battery management system performs the following functions:

- storage of energy for driving the vehicle;
- control and maintenance of battery properties in the optimum state for driving; and
- maintenance of battery safety and reliability.

This section describes the battery monitoring system, which ensures the optimal function of the driving battery.

The main function of the battery monitoring system is to identify the state of the battery pack and to transmit control data based on this information. Figure 2 shows an example of a battery monitoring system for an EV that uses a Li-ion battery. This system measures various battery parameters in the battery modules inside the battery pack. It includes cell monitoring units (CMUs) that send this data to the BMU. The CMUs measure the voltage of each cell and the temperature inside the battery modules. At the same time, the BMU also collects information such as the current of the main high voltage circuits and the insulation resistance of the high voltage system from sensors installed inside the battery pack.

The BMU monitors the battery state based on this information. It then sends commands to maintain optimal battery function to the overall vehicle control unit, the battery cooling system controller, and the CMUs.

The specific primary functions of the battery monitoring system are as follows:

- battery protection;
- remaining power calculation;
- battery lifetime calculation; and
- fault diagnosis.

Of these, battery protection by monitoring the battery voltage and temperature and battery fault diagnosis are the most important functions. For this reason, the BMU at the core of the battery monitoring system is preinstalled with various control information in accordance with the chemical system of the battery (The Society of Automotive Engineers of Japan, 2011).

The following sections describe the main items related to the battery protection function.

3.1.1 Over-charging prevention function

Over-charging occurs when the upper limit voltage of a cell is exceeded and may be a cause of heat or smoke

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

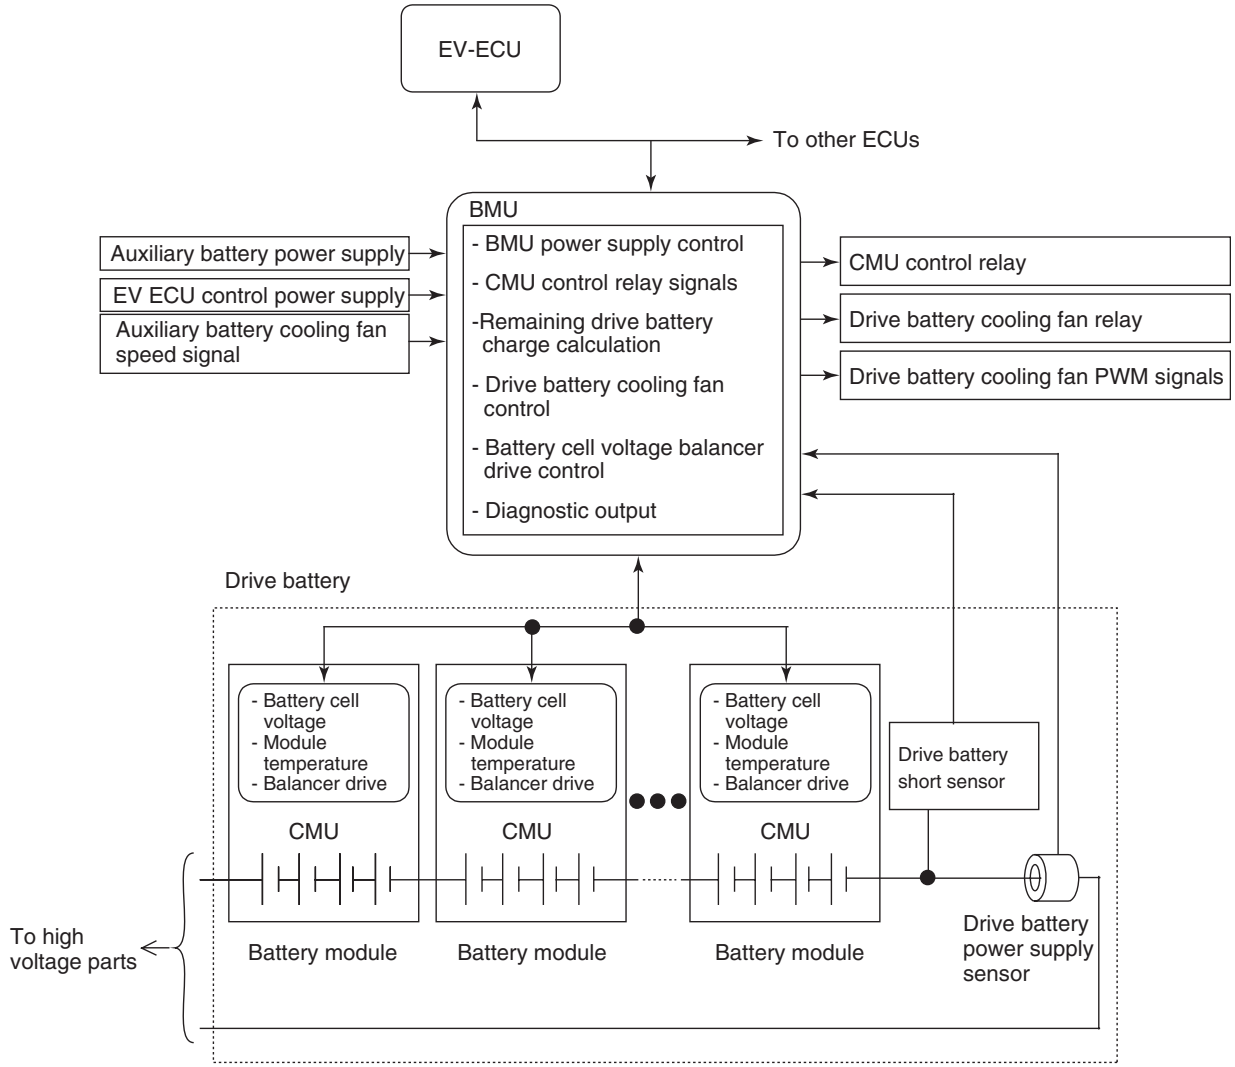

Figure 2. Diagram of battery monitoring system. (Reproduced with permission from Society of Automotive Engineers Japan (2011). © Society of Automotive Engineers Japan.)

generation in addition to battery performance deterioration. The voltage of each cell is monitored to prevent this, and the charge and regeneration currents are controlled to make sure that the upper limit voltage is not exceeded (Society of Automotive Engineers of Japan, 2011).

3.1.2 Over-discharging prevention function

The chemicals used in the cells have a particular lower limit voltage. Over-discharging occurs when the voltage falls below this level. Over-discharging causes irregular chemical reactions to occur inside the battery, which alters the internal composition of the battery and may prevent the battery from being used if allowed to continue. For this reason, the output current is controlled to prevent the cell voltage falling below its lower limit when the vehicle is being driven (Society of Automotive Engineers of Japan, 2011).

3.1.3 Voltage equalization function

As discussed earlier, an EV is generally propelled by a multiple number of cells that are connected in series. If the voltage of each cell is different, the cell with the lowest voltage will affect the performance of all the cells, and the battery pack will not function as designed. This is usually prevented by a voltage equalization circuit (a balancer circuit) provided in the CMU or BMU. Resistance absorption or power transfer type circuits are most common (Society of Automotive Engineers of Japan, 2011).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.1.4 Over-heating prevention function

This function prevents each cell from exceeding its recommended operating temperature range. Continuous driving or rapid charging at maximum power generates heat because of the internal resistance of the cells. Exceeding the upper limit temperature may affect battery capacity or output performance or lead to issues such as blistering of the battery. The CMUs measure and monitor the temperature of each cell or the battery modules in a typical unit. The upper limit temperature is protected by reducing the output or charging current and by using the battery cooling system to forcibly bring the temperature of the battery down (Society of Automotive Engineers of Japan, 2011).

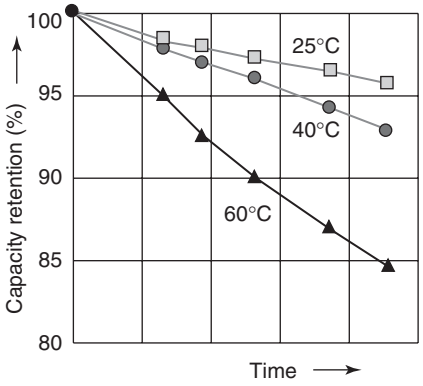

Figure 3. Example of battery deterioration temperature dependence test results. (Reproduced with permission from Society of Automotive Engineers Japan (2011). © Society of Automotive Engineers Japan.)

3.2 Battery cooling system

As mentioned earlier, the usage conditions of the battery may cause heat generation. In addition, the battery has a predetermined operating temperature range. Figure 3 shows the correlation between capacity reduction and temperature as a battery is used. When the cell temperature rises, the chemical substances inside the cells undergo changes, which clearly reduce the battery capacity. For this reason, an upper limit temperature is set and a battery cooling system is generally provided to ensure that this is not exceeded.

Figure 4 shows the configuration of a commonly adopted air cooling system. Air from the vehicle interior is blown onto the battery pack through cooling ducts. This air mainly flows through passages provided between each battery assembly and it is expelled through an outlet at the rear. In this configuration, the battery assemblies use this cooling air to expel heat to the rear. Some structures also include air passages between the cells in the battery assemblies to enable more efficient cooling.

The key points in designing a battery cooling system are the control timing to ensure that the cells do not exceed the upper limit temperature (e.g., the timing of input/output

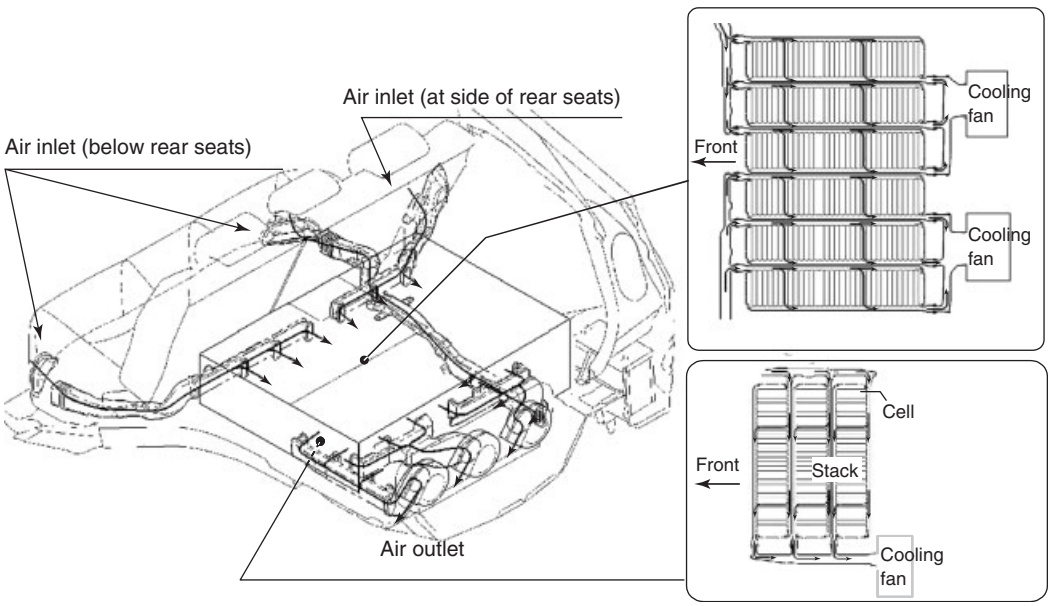

Figure 4. Example of air-cooling structure configuration inside battery pack. (Reproduced with permission from Onomura *et al*. (2010). © Toyota Motor Corporation, Japan.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

voltage reduction, cooling air introduction timing, and the like) and preventing temperature differences between the cells. As cell performance is strongly dependent on temperature, cooling may generate differences in cell voltage if it leads to the creation of different temperatures between the cells.

Consequently, cell temperature equalization is important. It relies on the basic battery pack structure related to the air distribution inside the pack (particularly the cooling air duct structure), the layout of the battery assemblies, the way that cooling air is supplied inside the battery assemblies, and the like (Society of Automotive Engineers of Japan, 2011).

3.3 Battery charge/discharge management

The battery charge/discharge state management technology plays the most important role in ensuring that the battery is used safely and in extending the charge/discharge lifetime. The characteristics of charge/discharge state estimation differs depending on the battery type, the control method of the battery management system, and the cooling method. The SOC is a critically important parameter in battery control, and its identification methods differ greatly depending on the battery. The characteristics of some typical batteries and their SOC management technologies are described later.

3.3.1 Lead-storage batteries

Lead batteries are comparatively stable with low energy density, high power density, and low self-discharge. The state of lead batteries (including the state of deterioration) is difficult to detect as it requires measurement of the specific gravity of the electrolyte. To counter this issue, technology was developed that estimates the battery SOC and deterioration from premeasured maps of the relationship between the open-circuit voltage and internal battery resistance (EV Handbook, 2001).

3.3.2 Nickel-metal hydride batteries

Nickel-metal hydride batteries have extremely well-balanced basic properties from the standpoint of energy density, power characteristics, regenerability, and lifetime, as well as from the standpoints of safety and recyclability. As the characteristics of nickel-metal hydride batteries change depending on the temperature, SOC is generally detected by measuring the temperature and voltage of the battery. SOC detection methods that also incorporate energy calculation have also been developed (EV Handbook, 2001).

3.3.3 Li-ion batteries

Li-ion batteries have the highest energy density, voltage, and long-term capacity retention characteristics of the various types of secondary batteries in practical use. Although the SOC of Li-ion batteries is generally calculated from the open-circuit voltage, voltage plateaus may be generated depending on the electrode material, which makes SOC estimation difficult. In these cases, the SOC is derived from fixed equivalent circuit parameters or the modeling of state variables (EV Handbook, 2001).

4 CHARGING SYSTEMS

Chargers and vehicle connection formats can be broadly categorized into direct-contact (conductive) and noncontact (inductive) types. Although ZEV rules in the United States include both types, conductive charging has been adopted for the creation of charging standards.

External large-capacity rapid chargers directly charge the vehicle battery with DC current by converting the supplied power to DC outside the vehicle. The most common proposed capacity for rapid charging is approximately 50 kW, in consideration of the ability of the battery to accept charge. Large-capacity household charging requires harmonization between the electrical specifications of the vehicle and the wiring of the building. Creating the necessary specifications for power supply, electrical distribution, and vehicle charging (i.e., the degree of electrical power reception by the vehicle) is an issue that transcends vehicle design and also includes the question of how far an EV can be made compatible with the power supply situation in each country.

In the latest developments related to inductive charging, feasibility studies are under way using large vehicles such as buses that drive over fixed routes. Inductive charging involves installing coils in the vehicle and infrastructure. In this way, charging takes place automatically and the required power is provided on the route of the vehicle. Verification tests are taking place and show promise for use with new forms of public transport such as trolley buses with no overhead cables.

In contrast, battery switching stations have also been suggested as an alternative to expanding the charging infrastructure. Shortening the time required to change the battery is a promising way of providing the same utility as rapidly charging a large-capacity battery. Feasibility studies carried out in Japan have discussed the difficulty of establishing these stations as a self-sustaining market depending on how customers perceive the added economic value of this service. However, as the reduction of CO_2

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

emissions and the adoption of alternative energies have emerged as pressing social issues, the number of battery switching stations may increase in certain local markets in accordance with the political needs of the country or region.

4.1 EV charging systems

Charging systems have been identified earlier as one of the key issues of EVs. The charging system of EVs is the same as that of plug-in hybrid electric vehicles (PHEVs). However, as the installed battery capacity of a PHEV is lower than that of an EV, it has a smaller need for large-capacity rapid charging. PHEVs are also designed to be mainly charged from normal charging sources (i.e., household outlets) from the standpoint of the battery life. On the basis of these characteristics and usability, normal charging is a significant merit from the standpoints of being able charge a vehicle easily using conventional existing household outlets.

Consequently, the specifications of chargers depend on the infrastructure available to normal households. In Japan, normal household outlets are rated at 100 V/15 A or 200 V/maximum 30 A. In addition, the maximum current under Japan's Meter-Rate Lighting B power supply contract for general households is 60 A. For this reason, charger output is likely to be several kilowatts. A small-output power charger like this is both compact and light, which means it can be used anywhere. Taking advantage of this fact, the charger can also be installed on the vehicle side. Figure 5 is a block diagram of a normal charging system featuring an in-vehicle charger. Usual charging configurations can be categorized into types that insulate or do not insulate the charging system through an electrical circuit by providing a transformer or the like between the charger side and the high voltage vehicle parts. The configuration in Figure 5 is the commonly used insulated type (Ishikawa, 2010).

Examples of the noninsulated type include the charger for Tesla Motor's Roadster EV, which was integrated with the main traction inverter circuit, and the charger for Toyota Motor Corporation's e-com EV, which was integrated with the circuits for the drive motor coil and traction inverter (Ishikawa *et al*., 1997).

In addition, Figure 6 shows some of the components of a charging system, such as the lid of the vehicle charging socket and the charging cable that includes a connector and charging circuit interruption device (CCID, that is, a ground fault breaker or the like).

The following sections describe the components in Figure 6 in more detail.

4.1.1 Charger

Normally, the charger is provided on the vehicle side. The charger charges the battery by converting external AC input to DC output through a high frequency transformer by semiconductor switching. Although the charging method depends on the battery characteristics, forced charging by constant power (CP) control (i.e., CP charging) or at a constant current/constant voltage (CC/CV charging) can also be performed by adopting a multistep CC charging method or the like. Figure 7 shows an example charging circuit configuration and its specifications and characteristics. Similar to a normal AC/DC converter, the circuit

consists of a filter, power factor corrector (PFC), bridge circuit, high frequency transformation circuit, and rectifying circuit.

4.1.2 Noise filter

A normal multilayer LC filter is provided to regulate harmonics and reduce line noise.

4.1.3 Vehicle charging socket lid and connector

The charging system is provided with a connector standardized for use in Japan, the United States, and Europe.

4.1.4 Charging circuit interruption device (ground fault breaker or the like)

Regulations in the United States require the use of a ground fault breaker and predetermined signal function (see SAE J1772) to guarantee safety when high voltages are applied.

4.2 Key points of normal charging systems

As mentioned earlier, the key point of a normal charging system is the extremely small power available. Assuming that the vehicle will be charged at a normal household, the available power will be 1.5 kVA for a 100 V system and a maximum of 6 kVA for a 200 V system, even in the case of commercial-use power sources. Consequently, ECUs and other auxiliary equipments consume a large proportion of the power during charging. For this reason, the total charging efficiency concept shown in Figure 8 becomes important. In specific terms, key issues are reducing the electricity consumption of auxiliary vehicle equipment during charging and improving the efficiency of the charger.

4.3 Public charging

Figure 5 shows the configuration of a normal household charging system (also referred to as *Mode 2 charging*). However, design of the charging system must also consider charging of the vehicle at public charging stations (Mode 3 charging). Figure 9 shows an example connection configuration and specifications of a public charging station. As the illustrated station complies with the requirements of SAE J1772, the charging system on the vehicle side can follow the same control sequence as that shown in Figure 5. However, it is also likely that some charging stations will not comply with this standard. For this reason,

the circumstances of the infrastructure, particularly Mode 3 public charging stations, must also be investigated when designing the vehicle side charging system.

5 AUXILIARY SYSTEM ENERGY MANAGEMENT

In the same way as conventional ICE vehicles, EVs also require a large number of auxiliary devices and systems to enhance the functionality of the vehicle and the comfort of the driver. Some of these systems, including the battery charger, BMS, regenerative brake system, and the like, are not required for ICE vehicles. In contrast, many are common between the two vehicle types, including the heating, ventilation, and air-conditioning (HVAC) system, auxiliary power supply, power steering system, navigation system, lighting, defroster, wipers, and radio. However, even when the purpose of the device is the same, its configuration often has to be designed especially for use in an EV.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto054
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

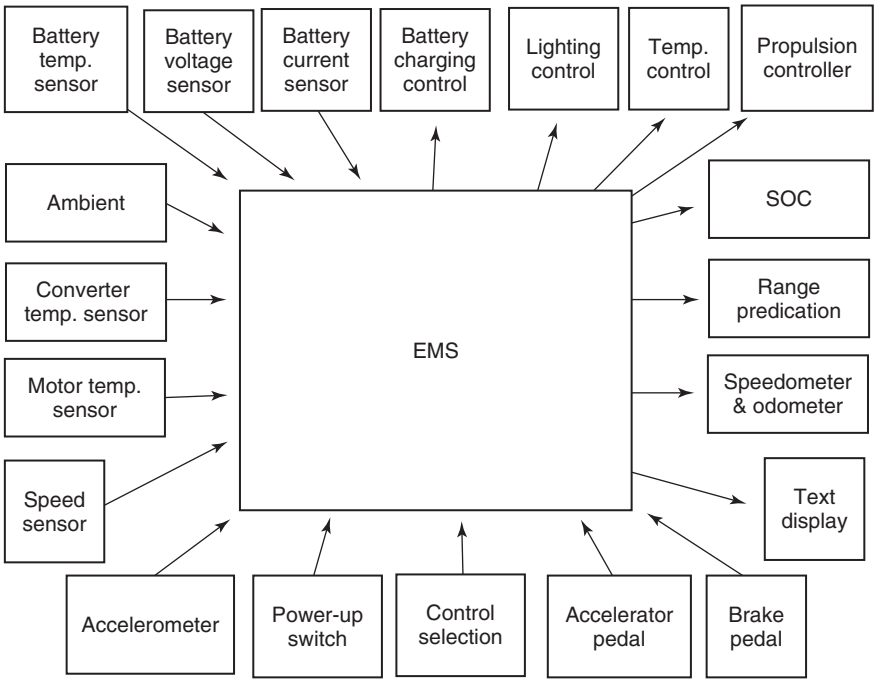

Figure 10. Energy management system. (Reproduced from Chan and Chau (2001). By permission of Oxford University Press (www.oup.com).)

As many auxiliary systems used in current EVs affect energy management, it is extremely important to improve their efficiency. The energy management system (EMS) plays a major role in systematically controlling the energy used by these systems.

As shown in Figure 10, the EMS is connected to the BMS, charging system, and the auxiliary device subsystems. It functions to efficiently manage the consumption of the limited available energy by identifying the state of these connected systems. The typical functions of the EMS are as follows (Chan and Chau, 2001).

- adjustment of power supplied to auxiliary systems;
- regulation of internal temperature control functions of EV components;
- display of available driving range; and
- limitation of energy used for interior HVAC.

Energy Management System of HEVs

Shinichi Abe
Toyota Motor Corporation, Toyota, Japan

1 INTRODUCTION

The basic configuration of a hybrid system can be categorized as either a series or a parallel type. A series-type HEV only uses the engine to generate electrical power. The generated electrical power is then used to drive electric motors that propel the vehicle. Surplus generated electrical power is stored in a secondary battery. The secondary battery provides additional power when the demand for power from the vehicle is large; for example, when the vehicle starts moving from a stop or when it is accelerating.

In a parallel type HEV, both the internal combustion engine (ICE) and the electric motor are mechanically coupled to the drive train. The ICE can provide mechanical power directly to the drive train. In addition, the electric motor can also provide mechanical power to the drive train using electrical power from a secondary battery. The ICE and electric motor can either work together or independently to provide mechanical power to the drive train.

The hybrid system in the Toyota Prius splits the power from the engine into two parts using a planetary gear set. A portion of the engine power is use to power a generator, whereas the rest of the engine power is use to directly propel the vehicle. This is sometimes called a *power split hybrid system*. This system is primarily known for its application in the Toyota Hybrid System (THS), but it can also be found in the two-mode hybrid system developed by the alliance between GM, Daimler, Chrysler, and BMW. This two-mode system features an extra planetary gear set compared to the THS, which gives it a wider control range for distributing mechanical and electrical power.

HEVs can also be classified as having *strong* or *mild* hybrid systems, depending on the functions of the system. Figure 1 illustrates the differences between a strong and a mild hybrid system.

Figure 2 shows the operating principle of a general strong hybrid system.

Energy management in an HEV refers to how the vehicle is controlled to optimize fuel efficiency while responding to the demands of the driver.

2 IMPROVEMENT IN FUEL EFFICIENCY THROUGH FULL HYBRIDIZATION

Full hybridization improves the fuel efficiency of a vehicle in the following four ways:

(a) At times of low engine efficiency when the engine is running at light loads (including when the engine is idling), full hybridization allows the engine to be

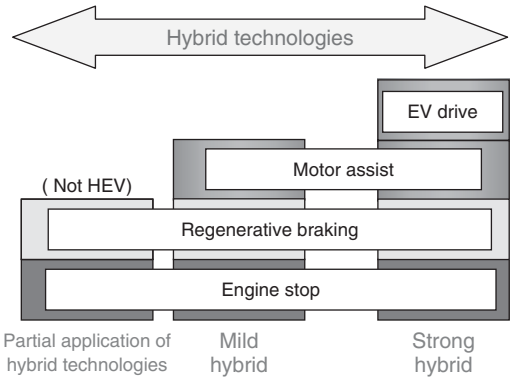

Figure 1. Classification of hybrid systems.

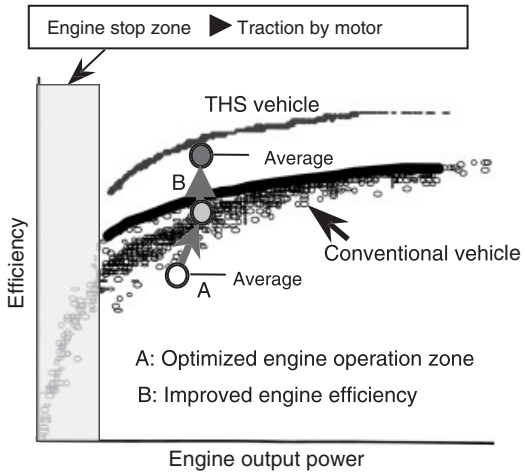

Figure 3. Efficiency improvement by full hybridization.

stopped and the vehicle to be operated as an electric vehicle (EV).

(b) Enhanced continuously variable transmission (CVT) functionality (i.e., the series/parallel hybrid configuration) and EV functionality [above-mentioned point (a)] enable the engine to be operated with optimum efficiency.

(c) A highly efficient engine that is sized for steady state operation can be used as power assist from the battery is available to meet peak power requirements. For example, full hybridization allows the adoption of an engine that uses a high expansion ratio cycle called the *Atkinson cycle*, which can be designed for optimum efficiency. It may also be possible to use a smaller engine depending on performance requirements.

(d) The electric motor can be operated as an electric generator, which converts the vehicle's kinetic energy to electric energy during braking. The electric energy is then stored in the battery to be reused later as kinetic energy. The vehicle's kinetic energy is usually dissipated as heat into the atmosphere by the mechanical friction service brakes.

The key point of a hybrid system is combining the above four merits to achieve optimal fuel efficiency. It is also critically important to use highly efficient and optimized individual components, such as the engine and motors. Figure 3 shows the differences in thermal efficiency between a vehicle with a conventional gasoline engine and one installed with the THS in the urban test cycle used in the United States.

2.1 Basic configuration of THS

Figure 4 shows the configuration of the THS. This system controls the distribution of power from the engine and the motor through a planetary gear set. The resultant driving force is composed of directly transmitted torque from the

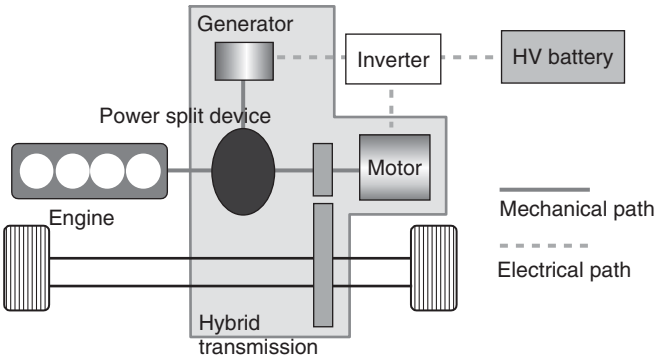

Figure 4. Configuration of THS.

engine and torque from the motor. The THS is also capable of stopping the engine and running the vehicle on motor power alone. Battery power also assists engine power under sharp acceleration.

2.2 Engine

A fuel-efficient engine is a prerequisite for maximizing system efficiency. High efficiency is the aim of an HEV, and the displacement of the engine can be selected freely within the limits of the required engine power and installation conditions. This allows friction losses to be reduced by adopting a high expansion ratio cycle with late closing of the intake valves and by lowering the maximum engine speed. The greater the displacement, the more it is possible to lower the maximum engine speed. Furthermore, friction losses can be reduced at the same power level by lowering the spring forces in the valve train and the piston ring tension. On the basis of these principles, Figure 5 shows the relationship between displacement and fuel efficiency. In high power regions, thermal efficiency increases in accordance with displacement. In contrast, in low power regions, thermal efficiency increases as displacement decreases. This demonstrates the fact that both indicated thermal efficiency and mechanical efficiency (i.e., friction losses) improve as displacement increases but that thermal efficiency improves as displacement decreases in low power regions because of the effect of pumping losses caused by the transition to partial load.

2.3 Relationship between planetary gear set, engine power, and axle output

Figure 6 shows the kinematic relationship between the three elements of a planetary gear set: the sun, carrier, and ring gears. It also illustrates the relationship between the torque split by the sun and ring gears with respect to the torque input through the carrier gear. The nomenclature is defined in Table 1.

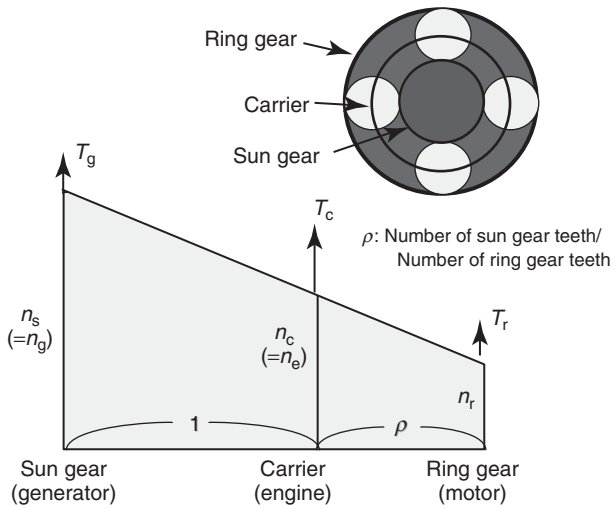

Figure 6. Colinear graph of planetary gear set.

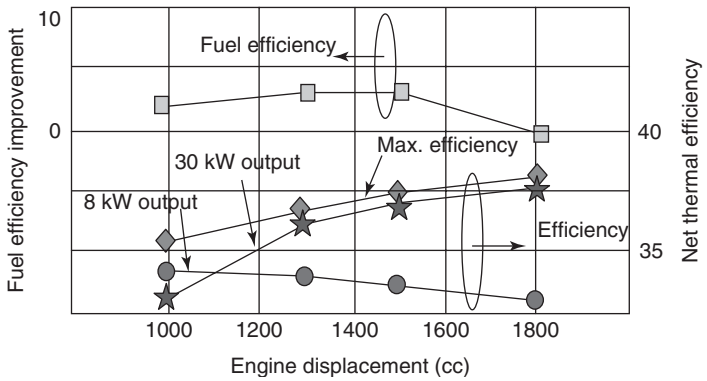

Figure 5. Engine displacement and fuel efficiency.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto055
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 1. Nomenclature.

Powertrain Component	Engine	Generator		Motor	Axle
Planet element	Carrier	Sun	Ring		
Speed	n_e	n_g	n_r	n_m	n_a
Torque	T_e or T_c	T_g	T_r	T_m	T_a

The planetary gear set has two degrees of rotational freedom and three inputs. Equation 1 describes the relationship between the rotational velocities of each element.

$$\rho \times n_g + n_r = (1+\rho) \times n_e \tag{1}$$

where ρ is the ratio of the number of sun gear teeth to the number of ring gear teeth.

Equations 2 and 3 describe the torque relationships between the three elements of the planetary gear set. These equations show that the input torque from the engine (coupled to the carrier) is split into two output torques: the generator (coupled to the sun gear) and the ring gear.

$$T_g = \frac{\rho}{1+\rho} \times T_e \tag{2}$$

$$T_r = \frac{1}{1+\rho} \times T_e \tag{3}$$

The output from the ring gear is directly transmitted to the axles via the reduction gear. The output from the sun gear is converted into electrical energy by the generator. This electrical energy is then supplied to the motor and converted into mechanical energy, which is mechanically coupled to the ring gear. The motor converts the electrically energy back into mechanical energy.

Equation 4 describes the total power at the axles as output from the generator is supplied to the motor. For simplicity, the conversion efficiency at the generator and motor and the efficiency of each gear are assumed to be 1.

$$n_a \times T_a = n_r \times T_r + n_m \times T_m \tag{4}$$

Equations 5 and 6 describe the right-hand side of Equation 4 in a different way using Equations 2 and 3.

$$n_r \times T_r = n_r \times \frac{1}{1+\rho} \times T_e \tag{5}$$

$$\begin{aligned} n_m \times T_m &= n_g \times T_g \\ &= n_g \times \frac{\rho}{1+\rho} \times T_e \end{aligned} \tag{6}$$

To summarize the above-mentioned explanation, Equation 4 becomes Equation 7 based on Equations 1, 5, and 6.

$$\begin{aligned} n_a \times T_a &= (1+\rho) \times n_e \times \frac{1}{1+\rho} \times T_e \\ &= n_e \times T_e \end{aligned} \tag{7}$$

As shown in Equation 7, power output from the engine is conserved and converted to power at the axles. In addition, Equation 1 can be rewritten as Equation 8 to describe the relationship between the generator rotational speed (n_g), the axle rotational speed (n_a), and the engine speed (n_e). Here, G_r is the gear reduction ratio, determined by dividing the rotational speed of the ring gear by the rotational speed of the axles.

$$G_r \times n_a = (1+\rho) \times n_e - \rho \times n_g \tag{8}$$

In other words, Equation 8 shows that the ratio between the rotational speed of the axles and the engine speed can be constantly varied by changing the rotational speed of the generator. Therefore, in conjunction with the power-saving relationship shown in Equation 7, the planetary gear system can be considered as having CVT functionality. As a result of this function, an efficient engine operating point can be selected regardless of the vehicle speed, thus reducing fuel consumption and improving efficiency.

2.4 HEV control strategy

The HEV control strategy for the engine, motor/generator, inverter, battery, and other main systems plays an extremely important role in maximizing fuel efficiency and reducing emissions, while achieving the excellent dynamic performance of HEVs.

2.4.1 HEV driving control

The purpose of the HEV driving control is to optimize fuel efficiency while simultaneously controlling the driving force and performing power and energy management.

The power required at the axles is calculated based on the information from the driver (i.e., the accelerator angle and shift position) and the vehicle speed. In addition, the required engine power is determined in consideration of the battery state of charge (SOC).

The engine speed cannot be controlled independently by the engine. However, as described in Equation 8, this system has CVT functionality that allows the engine speed to be controlled by the generator to achieve optimum fuel efficiency.

The vehicle must be able to produce the commanded drive force regardless of the engine operating point.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto055
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Therefore, it is necessary to estimate the output torque at the ring gear, which is split from the engine torque. In addition, the ring gear is mechanically coupled to the axles. Therefore, the ring gear torque is directly related to the drive force. Assuming steady state conditions, Equation 2 can be substituted into Equation 3 to give the estimated ring gear torque as a function of the generator torque.

$$T_r = \frac{T_g}{\rho} \tag{9}$$

The commanded drive force can be achieved by applying the appropriate amount of motor torque to the ring gear. The sum of the ring gear torque and the motor torque is the commanded drive force. Figure 7 illustrates the block diagram of driving control and Figure 8 illustrates the schematic diagram of the THS-II control.

2.4.2 *Engine control*

The following engine parameters are controlled by the engine ECU to generate the engine power commanded by the drive control algorithm: throttle position, ignition timing, and variable valve timing (VVT). The engine speed is controlled by the generator.

The opening and closing timing of the intake valves is optimized for efficiency and to suppress vibration when the engine starts and stops.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

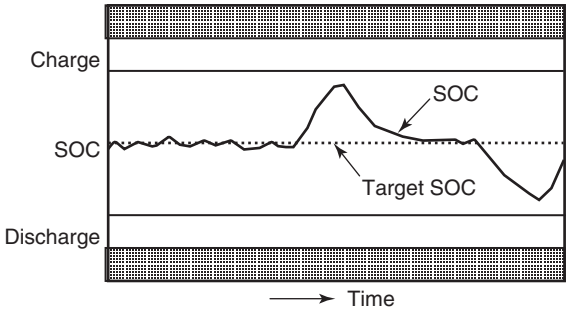

Figure 9. SOC control.

2.5 Battery control

Battery control involves calculating the available input and output power, and SOC at the current battery state using current, voltage, and temperature sensors. It also entails controlling the airflow of the battery cooling fan. The graph in Figure 9 illustrates that the target SOC is an average value during driving based on charge and discharge requests (Pch in the block diagram of driving control in Figure 7) from the battery.

2.6 Regenerative-hydraulic brake coordination system

The electronically controlled braking (ECB) system performs coordinated control between the hydraulic service brakes and regenerative brakes. The regenerative brakes improve fuel efficiency and HEV energy management using the electric motor as a generator to convert the vehicle's kinetic energy to electrical energy and storing it in the battery during braking. In a conventional vehicle, the kinetic energy is lost as heat during braking. Figure 7 illustrates the regenerative braking torque as "axle shaft torque." At the same time, increasing the maximum regenerated power by adopting a high power density battery improves regeneration efficiency. Figure 10 shows the distribution of hydraulic and regenerative braking in the THS (from 1997 to 2003) and THS II (from 2003) systems in response to braking demands. This improvement was completed by the refinement of the ECB system and the battery charge control. The use of regenerated energy has also been increased by improved aerodynamics and reducing various rotational losses, such as through brake friction and bearings. This increases fuel efficiency not only in low speed urban driving where there are many stops but also in higher speed suburban driving pattern and on the expressway.

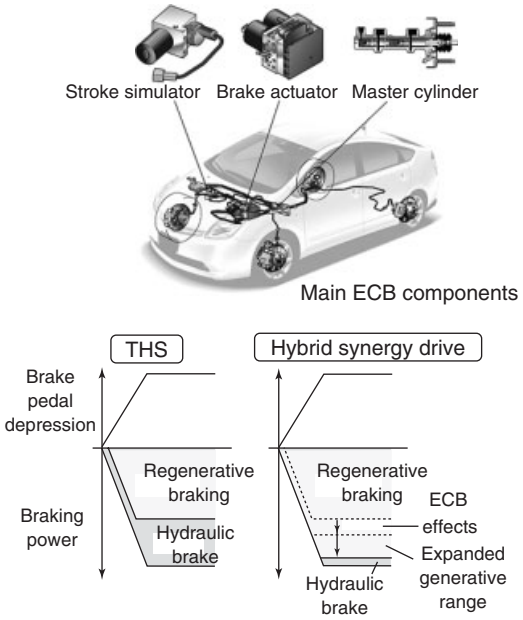

Figure 10. Improved regenerative braking.

3 ENERGY MANAGEMENT IN PARALLEL TYPE MILD HYBRID SYSTEM (IMA)

3.1 Purpose and aims of system

The integrated motor assist (IMA) system developed by Honda Motor Co., Ltd. is a parallel type hybrid system in which a motor provides assistance to the engine as the main source of driving power. A general hybrid system improves the efficiency of energy usage by recovering the vehicle's kinetic energy on deceleration and increasing the frequency that the engine operates in the most efficient operating regions. However, these gains are offset to some degree by a reduction in fuel efficiency due to the mass and volume of the system. The IMA system was developed with an emphasis on maintaining a balance between efficient energy usage and the mass and volume of the system. Its simple structure reduces mass and volume by directly connecting the motor to the engine crankshaft.

3.2 Engine

The engine in the IMA system can be characterized by two main points for improving fuel efficiency: reduced displacement and the adoption of a cylinder deactivation system. The following section describes these points in more detail.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto055

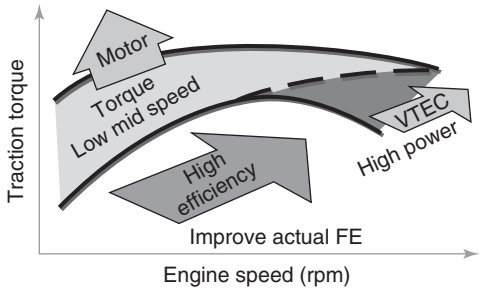

Figure 11. Dynamic performance of IMA system. (Reproduced with permission from Society of Automotive Engineers of Japan. © Society of Automotive Engineers of Japan.)

Improving fuel efficiency is the critical element for reducing engine displacement. However, the engine in a passenger vehicle is required to operate over a wide range of operating regions. In a vehicle installed with a conventional engine, this requirement is usually met by increasing displacement to ensure the necessary basic dynamic performance. Consequently, conventional vehicles generally have a substantial margin for driving power in low load regions in which actual operation is frequent, thereby deliberately reinforcing engine operation in relatively inefficient states. In contrast, reducing engine displacement to increase the engine operation frequency in high load regions, where engine efficiency is high, has an adverse effect on the dynamic performance of the vehicle. The IMA system increases engine efficiency in these frequently used low load regions by reducing engine displacement. At the same time, it ensures the required dynamic performance using the motor to assist the engine in low engine torque and speed regions. Figure 11 illustrates the dynamic performance of the IMA system.

3.3 Outline of IMA system operation

Figure 12 illustrates the basic energy management of the IMA system in the following five stages. (i) Normal engine start and engine start by the idling stop system are performed by the IMA motor. (ii) Acceleration after engine start is mainly performed by the engine, with motor assistance when required. (iii) When the vehicle is cruising in low load regions, the vehicle operates as an EV on motor power alone to avoid operating the engine in the inefficient regions. This stage represents highly efficient operation by the IMA system. When the vehicle is operating as an EV, the intake and the exhaust valves of the engine are closed to minimize pumping losses, and power from the motor is used to drive the vehicle efficiently. (iv) The vehicle is powered by the engine when cruising in high load regions. However, power is also generated by the motor in these regions, depending on the load region and the battery SOC (this operation is not described in Figure 12). (v) During deceleration, the motor acts as a generator to recover kinetic energy for charging the battery. In the same way as when the vehicle is operating as an EV, the intake and the exhaust valves of the engine are closed to minimize pumping losses and increase the amount of recovered energy. Finally, when the vehicle is stopped, the idling stop system ensures that the energy is not consumed needlessly.

In the IMA system, the engine and motor are directly coupled. However, a parallel type strong hybrid system is also being produced that allows the vehicle to be driven as an EV by providing a clutch to decouple the engine and motor. This ensures that the engine does not operate needlessly.

4 THERMAL ENERGY MANAGEMENT IN HEVS

Figure 13 shows the changes in fuel economy by season for the first-generation (1997) Japanese market Prius, second-generation (2000) Japanese market Prius, and an average conventional vehicle with an automatic transmission (AT). This data is normalized using the best month for fuel efficiency.

Figure 13 can be used to assess differences in fuel consumption between seasons. Both the conventional vehicle and the Prius models show a decline in fuel efficiency during the summer and winter months. The Prius shows a larger decline in fuel efficiency over the winter months than the conventional vehicle. The reasons for this are as follows: cold starts in cold weather require more energy to warm up the engine and catalyst, the heater uses more energy to warm up the vehicle's interior, and the duty cycle of the engine is higher to ensure that the required energy is available. A probable factor in the decline in fuel efficiency during the summer is higher energy consumption due to the use of air conditioning. Therefore, the efficiency of the hybrid system can be improved by focusing on the areas where such declines in fuel efficiency occur.

Figure 14 shows the energy distribution when the Prius is driven under the US urban test cycle in various heating conditions. With an outside temperature of 5°C, it can be seen that when the heater is turned on, more energy is used to heat the car than to drive the car.

4.1 Adoption of electrical air conditioning

As shown in Figure 15, the current Prius does not use a conventional engine-driven air conditioner compressor. Instead, it uses a high efficiency inverter-driven compressor

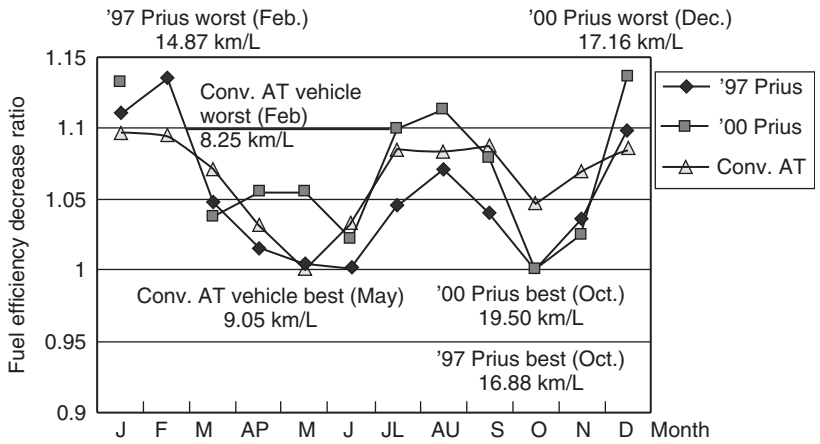

Figure 13. Fuel efficiency by season.

Electric air conditioning compressor

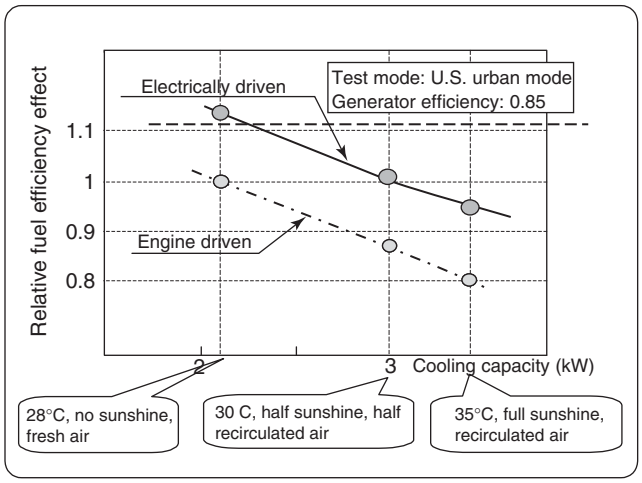

Figure 15. Fuel efficiency improvement by electric air conditioner compressor.

that takes advantage of the high voltage from the hybrid system battery. This contributes to improved air conditioning performance when the engine is stopped. In addition, it also improves fuel efficiency when the air conditioner is operating because the electrical system reduces the number of times the engine is required to start to drive the air conditioner compressor.

4.2 Engine thermal energy management

4.2.1 Electric water pump (EWP)

To further improve fuel efficiency, an enhanced engine cooling system is used. It consists of an electric water pump and exhaust heat recirculation device, which were specifically developed to improve fuel efficiency.

The flow rate of a conventional water pump is dependent on the engine speed. This uses excessive power even in conditions that require lower flow rates, such as in low temperatures or in low load, high engine speed conditions. However, using an electric water pump, the flow rate is no longer dependent on the engine speed. Now the flow rate can be varied and optimized according to the actual cooling demand.

Figure 16 shows a schematic drawing of a cooling system and compares the structure of a conventional water pump to the structure of an electric water pump. To achieve a size comparable to a conventional water pump, the electric water pump adopted a flattened compact motor design with an integrated motor driver. Unlike the conventional water pump, the impeller rotates about a center shaft, which is fixed to the water pump housing. This impeller is not powered by a traditional impeller shaft that passes through the housing to a pulley. Instead, the magnetic impeller is rotated by a rotating magnetic field situated in the water pump housing, which means that the water chamber is isolated from the outside. This eliminates the need for a mechanical seal and results in lower friction loss and no risk of water leakage.

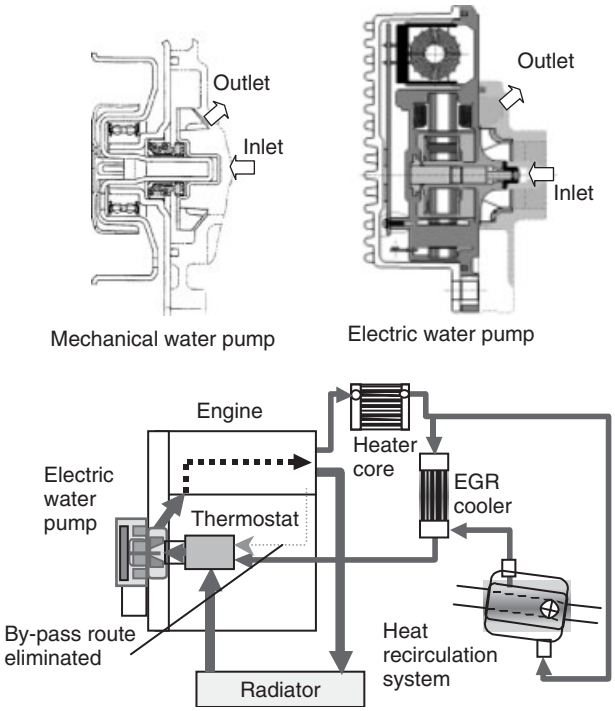

Figure 16. Cooling system.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

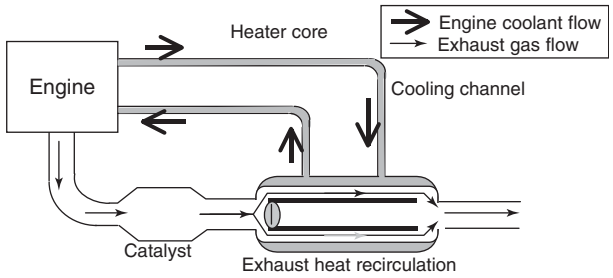

Figure 17. Exhaust heat recirculation system.

4.2.2 *Improving engine warm up*

The electric water pump is able to operate at a lower speed (lower flow rate) after a cold start-up, shortening the engine warm-up period.

Figure 17 shows a schematic drawing of the exhaust heat recirculation system. This was adopted to improve fuel efficiency in cold weather conditions. The warm-up performance of the engine and engine coolant is improved using the exhaust heat, which is normally wasted in conventional systems.

As a result, friction is reduced during the engine warm-up period. In addition, owing to the characteristics of the hybrid system, fuel efficiency is further improved by allowing the engine to stop earlier. Figure 18 shows the improvement in vehicle fuel efficiency during the winter. The fuel efficiency of the third-generation Prius, equipped with the EWP and the exhaust heat recirculation system, is 19% higher than the previous generation under the same test conditions.

5 PHEV SYSTEM CONFIGURATION

The various types of plug-in hybrid electric vehicles (PHEVs) can be categorized into two main types based on the way the vehicle uses its energy sources. The first is the all electric range (AER) type, which operates on battery power alone as long as it has remaining energy. When the battery is depleted of energy, the engine charges the battery. The second is the blended type, which "blends" power from both a battery and an ICE. The engine is not only used for charging the battery but also used to supplement the battery power when the requested drive force exceeds the available drive force from the battery power alone. Figure 19 shows an example for each configuration. Table 2 describes the characteristics of each type. Toyota's PHEV has a blended type system because of its lower cost and smaller size compared to an AER type with equal vehicle performance. Figure 20 shows the results from a Toyota PHEV demonstration project. The graph shows the percentage of users in the project versus the output power of the PHEV system. While the maximum output was rarely used, 30 kW or less was needed by the drivers 93% of the time. This demonstrates that a blended PHEV with a battery power of 30 kW can be driven on electricity alone 93% of the time, as long as battery energy remains. Furthermore, only small changes are required to the existing Toyota THS to upgrade to a blended type PHEV. This means that the

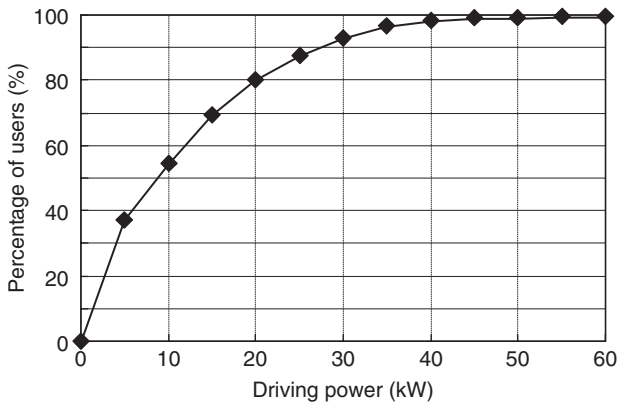

Figure 20. EV power usage.

benefits of driving a vehicle as an EV can be achieved at low cost with the THS.

6 FEATURES OF PHEVS

On average, the daily mileage of personal passenger vehicles is relatively short. PHEVs take advantage of this fact in their application of electrical energy. PHEVs have the advantages of both HEVs and EVs. The charging system of a PHEV differs from that of an HEV in the following manner: it has a larger energy capacity battery and it can use external electricity (e.g., household outlets) to charge the battery. PHEVs can operate as an EV over short distances. After the electrical energy in the battery is consumed, it operates as an HEV, propelled by both the engine and the motor, while consuming less fuel than conventional vehicles. In typical passenger vehicle usage, a PHEV can be driven almost fully as an EV during weekdays because trips are usually relatively short. In addition, it can be driven as an HEV after the energy in the battery is consumed for long distance trips that usually occur on weekends. This PHEV concept combines the advantage of an EV of using clean electrical energy with the advantages of an HEV, such as longer range, high fuel efficiency, and sufficient luggage space. In this way, a PHEV can be a substitute for a conventional vehicle.

Figure 21 shows a comparison of the battery SOC control strategies for HEVs and PHEVs. The left figure shows the SOC control strategy in an HEV. The SOC fluctuates in a small range but is controlled to maintain a set point

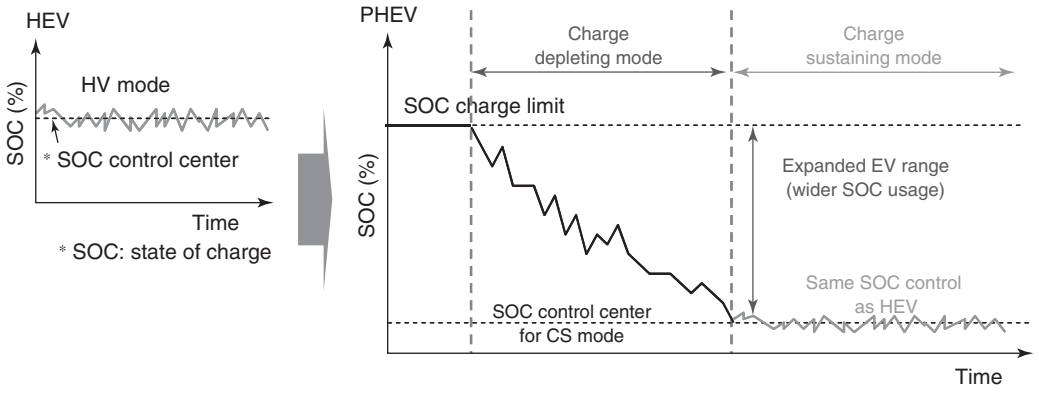

Figure 21. Comparison of HEV and PHEV operation.

or target SOC, because an HEV has no external charging system.

PHEVs have two driving modes: the first is charge depletion (CD) mode, which mainly uses the stored electrical energy that was externally supplied to the battery. After consuming the stored external electrical energy in the battery, the PHEV goes into charge-sustaining (CS) mode and operates like an HEV. In CD mode, the PHEV prioritizes EV operation, where energy is supplied from the battery. However, in the same manner as an HEV, it is still possible to start the engine when rapid acceleration is required. In CS mode, the PHEV operates like an HEV and it has the same characteristics of a long driving range and lower fuel consumption than a conventional vehicle. Accordingly, it is effective to design a PHEV based on an HEV, where the advantages of an EV and an HEV can be combined by simply expanding the capacity of the battery and adding battery charging control logic for SOC management.

Overview of Electric, Hybrid, and Fuel Cell Vehicles

C.C. Chan
The University of Hong Kong, Pokfulam, Hong Kong

1 INTRODUCTION

This chapter provides an overview of the state of the art of battery powered electric vehicles (BEVs), hybrid electric vehicles (HEVs), and fuel cell electric vehicles (FCVs) (Chan, 2007; Chan, Bouscayrol, and Chen, 2010; Chan and Chau, 2001; Yamada, Hanada, and Sasaki, 2006; Burke, 2002; Lai and Nelson, 2007; Eshani *et al*., 2005a; Gao, Mi, and Emadi, 2007) with focus on their technical features and commercial road map. This chapter begins with the distinct features of BEV, HEV, and FCV. As electric vehicle technology is the integration of automotive technology and electrical technology, system integration and optimization approach is essential, the overall design of electric vehicle system including its infrastructure and business model should be guided by proper engineering philosophy. Powertrain is the heart of electric vehicle; therefore, this chapter analyzes the architecture and functionality of various types of powertrains. Energy management is the key to achieve fuel economy and emission reduction; hence, this chapter explores the challenge of energy management, discusses the function and interaction of global control and local control, and suggests the possible types of appropriate control models.

The success of promotion of electric vehicles relies on the availability of good product, good infrastructure, and good business model as well as the integration of electric vehicles with smart grid and with information communication technology (ICT). Our goal is gradually to achieve four zeros: zero emission, zero gasoline, zero traffic accident, and zero traffic jams.

2 OVERVIEW OF BEV, HEV, AND FCV

2.1 Features of BEV, HEV, and FCV

Since the oil crisis in 1973, the world started paying attention to the balance of oil supply and consumption. The amount of fossil fuel resources is limited but the oil demand has increased significantly. The transportation sector is one of the largest energy sectors. In addition, it has the highest growth rate of oil consumption in recent decades. This growth has largely come from new demands for personal use vehicles powered by conventional internal combustion engine (ICE).

Some environmental problems, such as the greenhouse effect, the acid deposition, and the air pollution, are directly related to the vehicle emission. There have been increased tensions in part of the world because of the energy crisis.

Government agencies and organizations therefore have developed more stringent standards for the fuel consumption and emissions. BEVs look like ideal solutions to tackle

the energy crisis and global warming, as they have zero oil consumption and zero emission *in situ*. However, the high initial cost, short driving range, and long charging time have caused BEV only suitable for certain applications unless providing good infrastructure such as battery leasing or swapping, combination of slow charge, medium charge and quick charge, and integration with smart grid.

HEVs were developed to overcome the disadvantages of ICE vehicles and BEVs. An HEV combines a conventional propulsion system with an electric energy storage system and an electric machine (EM). It has a longer range than BEV. It shows improved fuel economy as compared with those of conventional ICE vehicles. The ICE can be stopped if the vehicle is at a stop. The electric drive system can optimize the efficiency of the ICE and thus reduce the oil consumption and emission. The kinetic energy can be recovered during braking and down slope driving. A certain range of silent operation with zero emission is possible when HEVs are driven in electric mode. In addition, this operating range may be extended if the battery can be recharged by connecting a plug to an electric power source, such as the electricity grid. This kind of HEV is called *plug-in hybrid electric vehicle* (*PHEV*). Furthermore, the onboard EMs of HEVs provide more flexibility and controllability to the vehicle control, such as antilock braking system (ABS) and vehicle stability control (VSC), and thus offer improved performance. Although HEVs can contribute to meeting the challenges in road transport regarding energy crisis and pollution, it is still somewhat difficult to be widely accepted by general public. Three main hurdles exist for vehicle buyers: the first one is their high purchase price; the second one is reliability and warranty related to the lack of electrician in the car shops; the third one is a lack of confidence in electric powered vehicle, concerning the introduction of high voltage, electromagnetic interference caused by high frequency high current switching and so on.

Fuel cell electric vehicles (FCVs) use fuel cell to generate electricity from hydrogen and air. The electricity is either used to drive the vehicle or stored in an energy storage device, such as battery pack or supercapacitors. They only emit water vapor, and they have the potential to have high efficiency. The major issues related to FCV are as follows: firstly, the high price and the life cycle problem of FCs; secondly, hydrogen onboard storage needs improvement of energy density; and thirdly, hydrogen distribution and refueling infrastructure needs to be constructed (International Energy Agency Implementing Agreement on Hybrid and Electric Vehicles, 2008).

Table 1 shows the comparison of the characteristics of EV, HEV, and FCV.

2.2 Engineering philosophy of EV, HEV, and FCV

The overall EV engineering philosophy essentially is the integration of automobile engineering and electrical engineering. Thus, system integration and optimization are major considerations to achieve good EV performances at affordable cost. As the characteristics of electric propulsion are fundamentally different from those of engine

Table 1. Characteristics of BEV, HEV, and FCV.

Types of vehicles	BEV	HEV	FCV
Propulsion	• Electric motor drives	• Electric motor drives • Internal combustion engines	• Electric motor drives
Energy storage subsystem (ESS)	• Battery • Ultracapacitor	• Battery • Ultracapacitor • ICE generating unit	• Fuel cells • Need battery/ultracapacitor to enhance power density.
Energy source and infrastructure	• Electric grid charging facilities	• Gasoline stations • Electric grid charging facilities (for plug-in hybrid)	• Hydrogen • Hydrogen production and transportation infrastructure
Characteristics	• Zero emission • High energy efficiency • Independence on crude oils • Relatively short range • High initial cost • Commercially available	• Very low emission • High fuel economy • Long driving range • Dependence on crude oil • Higher cost than ICE vehicles • Commercially available	• Zero or ultralow emission • High energy efficiency • Independence of crude oil (if not using gasoline to produce H_2) • High cost • Under development
Major issues	• Battery and battery management • Charging facilities • Cost	• Multiple energy sources control, optimization, and management. • Battery sizing and management	• Fuel cell cost, cycle life, and reliability • Hydrogen infrastructure

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

propulsion, a novel design approach is essential for EV engineering. Moreover, advanced energy sources and intelligent energy management are key factors to enable EVs competing with ICEVs (internal combustion engine vehicles). Of course, the overall cost effectiveness is the fundamental factor for the marketability of EVs.

The design approach of modern EVs should include state-of-the-art technologies from automobile engineering, electrical and electronic engineering, and chemical engineering, should adopt unique designs that particularly suitable for EVs, and should develop special manufacturing technology that particularly suitable for EVs. Every effort should be made to optimize the energy utilization of EVs.

The EV engineering philosophy is the marriage of automotive engineering and electrical engineering that includes motor, power electronic converter, controller, battery, or other energy storage device and energy management system. Marriage implies that the bride and the groom have fully understood the character of the partner and able to cope together harmoniously and best perform to achieve the required driveability at maximum energy efficiency and minimum emission.

The HEV engineering philosophy is $1+1>2$. This implies the added value gained from the integration of engine propulsion and motor propulsion, fully sizes the advantage and flexibility of electrical, electronic, and control technologies, not only to increase energy efficiency and reduce emission, but also become more intelligent, driving comfort, and safety. Just like mule is the hybrid of horse and moke, mule possesses the best DNA of horse and moke and hence more powerful and endurance. In HEV, the prime key technology is the control algorithm and optimization for energy management.

The FCV engineering philosophy is the integration of automotive engineering, electrical engineering, and fuel cell engineering. As fuel cell is a new kind of energy device that quite different with gasoline and batteries, every effort should ensure that the overall system of fuel cell is efficient, reliable, optimum, and last long at reasonable cost. Other high power density device such as lithium-ion battery or ultracapacitor may be used in conjunction with fuel cell to improve the starting performance of the vehicle. The electric propulsion system and fuel cell system must cope very well to achieve the required driveability at maximum energy efficiency and minimum emission.

In summary, the core of engineering philosophy is system integration and optimization. The principles of integrated system design can be summarized into the following six principles (Elliot and Deasley, 2007):

1. Debate, define, revise, and pursue the purpose/objective

   The system exists to deliver capability, and the end justifies the means. The statement of a requirement must define how it is to be tested. Requirements reflect the constraints of technology and budgets.

2. Think holistic

   The whole is more than the sum of the parts—and each part is more than a fraction of the whole.

3. Be creative

   See the wood before the trees.

4. Follow a disciplined procedure

   Divide and conquer, combine and rule.

5. Take account of the people

   To err is human; Ergonomics; Ethics and Trust.

6. Manage the project and the relationships

   All for one, one for all.

3 ARCHITECTURE OF POWERTRAINS

ICEVs are propelled by fuels and ICEs. BEVs are propelled by batteries and EMs. HEVs are propelled by the combination of the two powertrains. In which, the ICE provides the hybrid vehicle an extended driving range, whereas the EM increases efficiency and fuel economy by regenerating energy during braking and storing excess energy from the ICE during coasting. According to the way of how the two powertrains are integrated, generally, there are three basic architectures of HEVs, namely series hybrid, parallel hybrid, and series–parallel hybrid (Ehsani, Gao, and Miller, 2007; Gao and Ehsani, 2006; Miller, 2006).

Among these diverse architectures, a series–parallel hybrid vehicle with a planetary gear (Figure 1) has a "maximal" architecture, which can maximize the optimization. Therefore, this architecture is chosen as our base for discussion and comparison, and other architectures are derived from this basic architecture scheme. In these architectures, batteries are expressed by BAT, fuel tank by fuel, voltage source inverter by VSI, electric machine by EM, internal combustion engine by ICE, and Transmission by Trans respectively. Black lines mean electric coupling and orange lines mean mechanical coupling.

It is noted that the transmission could be a discrete gearbox with clutch, continuously variable transmission

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

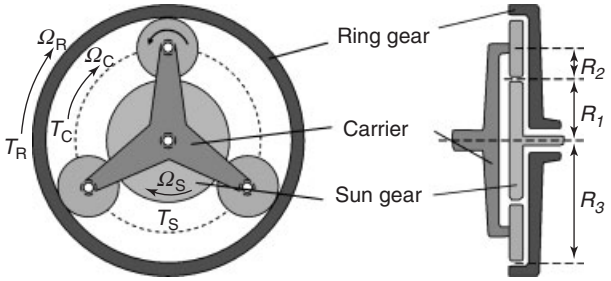

Figure 1. Planetary gear unit.

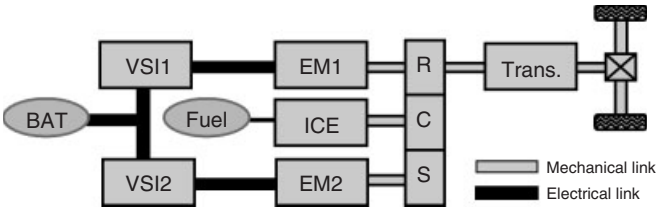

Figure 2. Series–parallel hybrid vehicle using a planetary gear unit.

(CVT), or fixed reduction gear. Series–parallel HEV in a series–parallel hybrid vehicle, a planetary gear (Figure 1) is used (Eshani, *et al*., 2005b; Syed *et al*., 2006). The electric machine 1 (EM1) and the transmission shaft (Trans.) are connected to the planetary set ring gear (R), whereas the ICE is connected to the carrier (C) and the EM2 is connected to the sun gear (S), respectively.

Thanks to the DC bus and the planetary gear, a series–parallel hybrid can operate as a series hybrid or a parallel hybrid, respectively. Because of the planetary gear, the ICE speed is the sum of the EM1 speed and the EM2 speed. The EM1 speed is proportional to the vehicle speed. At a given vehicle speed (or given the EM1 speed), the EM2 speed can be adjusted in order to adjust the ICE speed. The ICE can thus operate in an optimal region by controlling the EM2. Despite possessing these features of both the series and parallel HEVs, two machines and a planetary unit are necessary, which makes the drivetrain somewhat complicated and costly. Moreover, the control of this architecture is quite complex. This architecture (Figure 2) is depicted in such a way in order to deduce the other classical architectures.

3.1 Series HEV

From this series–parallel hybrid architecture, if the connection between the EM1 and the ICE is removed, a series hybrid vehicle is obtained. In this series hybrid vehicle (Figure 3), the energetic node among the power sources

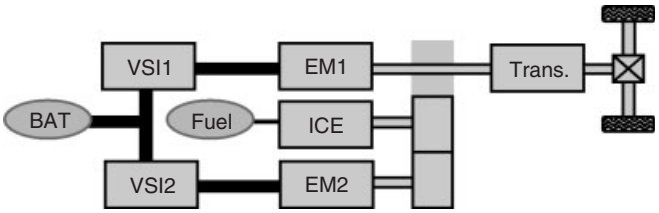

Figure 3. Series hybrid vehicle.

and transmission is occurred at the DC bus. Please note that Figures 2 and 3 are only schematic diagram, where the split path epicyclic cannot give true series operation.

In series HEV, the ICE mechanical output is first converted into electricity using EM2. The converted electricity either charges the battery or can bypass the battery to propel the wheels via EM1 and the transmission. Owing to the decoupling between the ICE and the driving wheels, it has the definite advantage of flexibility for locating the ICE generator set. Because of the same reason, the ICE can operate at its very narrow optimal region independently from the vehicle speed. Its control is simple because of a single torque source (EM1) for the transmission. Owing to the inherent high performance of torque–speed characteristic of the EM drive, multigear transmission and clutch would be unnecessary. However, such cascade structure leads to a relatively low efficiency and three machines (ICE, motor, and generator) are required. Another disadvantage is that all these propulsion devices need to be sized for the maximum sustained power, making series HEV expensive. On the other hand, when it is only needed to serve such as short trips commuting to work and shopping, a lower rating of the corresponding ICE generator set can be adopted.

More recently, EVT (electronic variable transmission) has been developed to replace the planetary gear. EVT is an electromechanical converter with two mechanical ports and one electrical port (consisting of two electrical machines and two inverters) (Hoeijmakers and Ferreira, 2006). An EVT (Cheng *et al*., 2007; Chen *et al*., 2008; Cheng *et al*., 2008) could be considered as a combination of two induction machines EM1 and EM2: the stator of EM2 rotates, and the rotor of EM2 is connected with the EM1 rotor. In order to reduce the system weight and size, the two machines can be integrated into a single machine, as a double-rotor induction machine (Hoeijmakers and Ferreira, 2006; Chau and Chan, 2007) or double-rotor permanent magnet machine (Chau, Chan, and Liu, 2007).

3.2 Parallel HEV

From the series–parallel hybrid architecture, if the EM2-based powertrain is removed, then a parallel hybrid vehicle

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

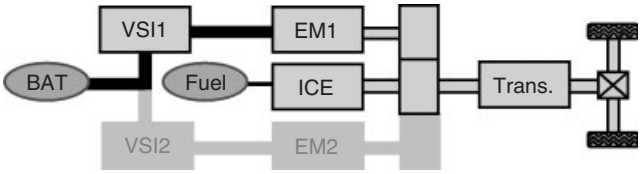

Figure 4. Parallel hybrid vehicle.

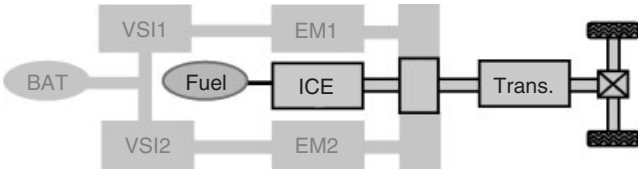

Figure 5. ICE vehicle.

is obtained (Figure 4). In a parallel hybrid drivetrain, the energetic node is occurred at a mechanical coupling. This mechanical coupling may be considered as one common shaft or connection of two shafts by gears, pulley-belt unit, and so on.

The propulsion power may be supplied by ICE alone, by EM1, or by both. EM1 can be used as a generator to charge the battery by regenerative braking or absorbing power from ICE when its output is greater than that required power to drive the wheels. Better than the series HEV, the parallel hybrid needs only two propulsion devices, the ICE and the EM. Moreover, smaller devices can be used to get the same dynamic performance. However, owing to the mechanical coupling between the ICE and the transmission, the ICE cannot always operate in its optimal region and hence clutches are necessary. Another drawback is the relatively complex control.

3.3 ICE vehicle

An ICE vehicle (Figure 5) is obtained when only the ICE-based drivetrain is remained from the series–parallel hybrid architecture. ICE vehicles have a long driving range and a short refueling time but are facing the challenge of the pressure of pollution problems and oil demand.

3.4 Battery powered electric vehicle

A BEV (Figure 6) is obtained when only the EM1-based drivetrain is kept. Because only batteries or electric energy-storage-based power sources drive the vehicle, zero emission can be achieved. However, its high initial cost, short driving range, and long charging (refueling) time have caused its limitation.

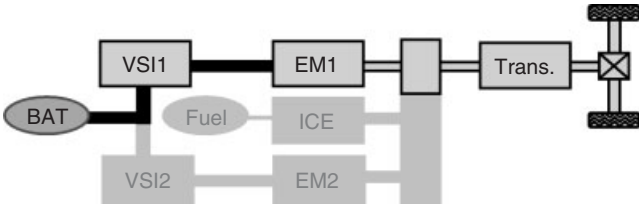

Figure 6. Battery powered electric vehicle.

3.5 Fuel cell vehicle

From the structural point of view, a fuel cell vehicle can be considered as BEV type. A fuel cell vehicle can also be equipped with a battery or a supercapacitor (Lai and Nelson, 2007). This fuel cell vehicle can be thus considered as series hybrid vehicle type with the fuel cell as an electrical generator from hydrogen (Hissel, Candusso, and Harel, 2007). The onboard fuel cell produces electricity, which is either used to provide power to the propulsion motor EM1 or stored in the battery or supercapacitor for future use.

3.6 Architecture versus functionality

Different functions can be achieved using the previous HEV architectures. They can be classified by their power ratio between the ICE and electrical machines. The more of using electrical power propulsion, the more of fuel economy improvement is gained.

3.6.1 Micro-hybrid (stop-and-go function)

In the case of micro-hybrid vehicle, a small power electrical machine is used as starter alternator (Sepe *et al.*, 2001). The ICE ensures the propulsion of the vehicle. The electrical machine helps the ICE to get a better operation point at the start-up. Because of the fast dynamics of EM, micro-hybrid HEVs ensure a "stop-and-go" mode: the ICE can be stopped when the vehicle is at standstill (e.g., at the traffic lights). A fuel economy improvement is estimated from 2% to 10% for urban drive cycles. Note that strictly speaking, micro-hybrid is not really a hybrid as the EM does not contribute to propulsion.

3.6.2 Mild hybrid (boost function)

In this case, the EM is used to boost the ICE during acceleration or braking by a supplementary torque. Of course, the stop-and-go function is also ensured. However, the electrical machine alone cannot propel the vehicle. A regenerative braking function is also achieved. A fuel economy improvement is estimated from 10% to 20%.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.6.3 *Full hybrid (electric traction)*

In this case, the EM is able to ensure the whole propulsion of the vehicle for a zero emission vehicle (ZEV) mode. This mode can be used in urban centre. The propulsion of the vehicle can also be made by the ICE or by the combination of ICE and the electrical machine. A fuel economy improvement is estimated from 20% to 50%.

3.6.4 *Plug-in hybrid (and range extender)*

In plug-in HEV, the battery can be externally charged using an electric plug. By this way, more energy can be extracted from the batteries and the electric grid; while the ICE is not required to maintain the SOC of the battery in a light range. In some cases, the plug-in vehicle can just be a BEV with a small power ICE in order to extend the driving range by charging the batteries from the fuel, ICE, and generator, such case is also called *range extender* The fuel economy of plug-in hybrid can be improved 100% if the ICE is not used to charge the battery (e.g., in urban drive cycles).

Architectures and HEV functionality have to be differentiated. However, some architectures are dedicated to some HEV's functions (Table 2). BEV and FCV are not considered in this table because they use only electric power and all the functions are ensured by electrical machines.

Figure 7 shows two ways of powertrain technology road map. One way is continuous improvement of ICE and another way is development of advanced motor drives. While HEV needs the combination of both. The key technologies of EVs are motor drives and batteries. Figure 8 shows the evolution of motor drives technology, and Figure 9 shows the evolution of batteries technology.

Table 2. Functionality versus architectures for HEVs (main industrial solutions).

	Micro-HEV	Mild-HEV	Full-HEV	Plug-in HEV
Series–parallel	—	x	x	x
Parallel	x	x	x	—
Series	—	—	x	x

Note that Figures 8 and 9 just show how things have developed in the past and should continue in likely more rapid developments. Such as special structure EMs with better materials that suit better the higher performance of electric vehicles; advanced power electronic devices with higher power density and higher reliability; and advanced lithium batteries with new materials for positive electrode, negative electrode, electrolyte, and separator. There are claims of revolutionary next generation battery technologies including lithium-air, lithium-sulfur, solid state, and aqueous lithium.

4 ENERGY MANAGEMENT OF BEVs, HEVs, AND FCVs

Energy management of BEVs, HEVs, and FCVs is a real challenge (Kessels, 2007). Firstly, they are composed of various multiphysical subsystems, which have their own control constraints. Secondly, the aim of BEVs, HEVs, and FCVs is to replace classical thermal vehicles. In order to achieve this goal, the same (or better) dynamical performance must be obtained and the best energy management is required to reduce fuel consumption and pollutant emissions.

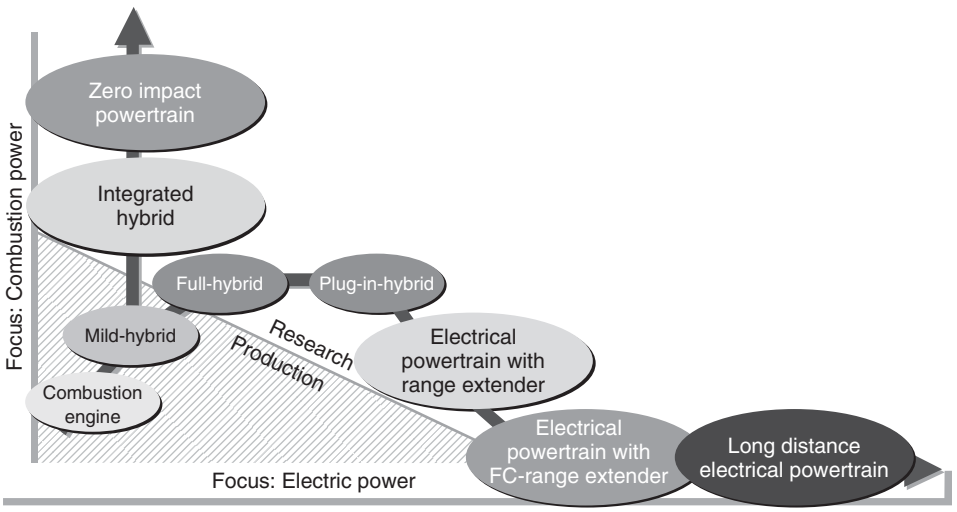

Figure 7. Two-way powertrain road map.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

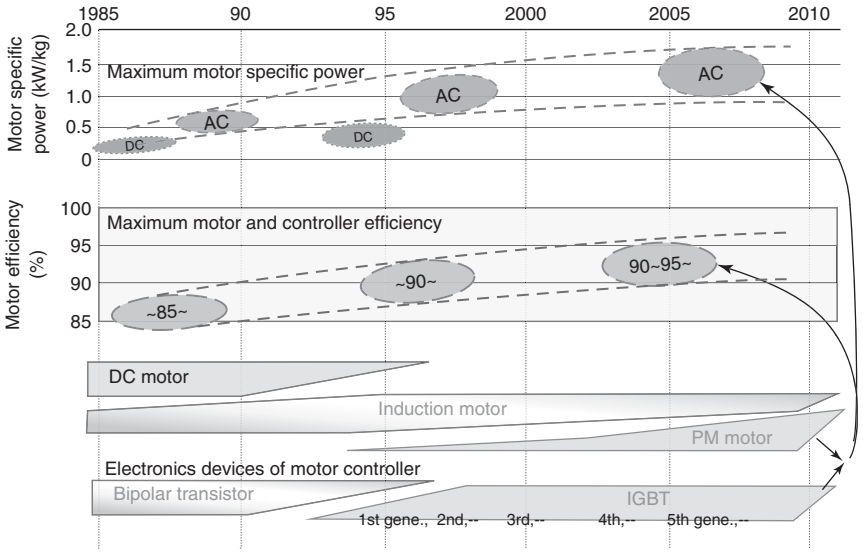

Figure 8. Evolution of motor drives technology.

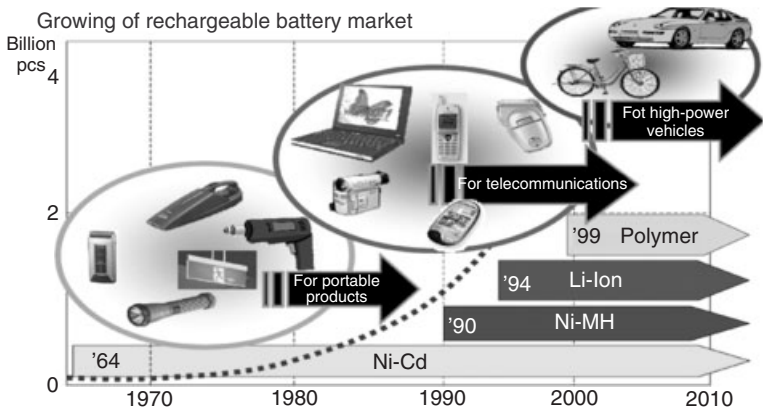

Figure 9. Evolution of battery technology.

It is essential to appreciate different control level (Moskowa, Munns, and Rubin, 1997). Because of the complexity of such systems, two control levels can be defined. The first one is associated with the local control of subsystems. The second control level is associated with the energy management of the whole system in order to coordinate all the subsystems.

Most of the papers on energy management of HEVs are only focused on the global control level. Nevertheless, appropriate local controls should be considered, and some constraints have to be considered on the subsystems.

1. *Local Control of Subsystems*. —The local control of subsystems is often neglected in study of energy management of HEVs. However, an efficient strategy cannot be achieved if the subsystems are not controlled in the best way. Most of the time the subsystems are considered as independent. From this assumption, classical controls of these devices are often used. However, from a systemic point of view, all the subsystems are interconnected. Their interactions have thus to be considered. Moreover, some associations of subsystem lead to modify their functional model (holistic approach). For example, when two electric motors and an IC engine are connected through a planetary gear, the three shafts have to be represented by a two dimension equivalent inertia (Bouscayrol, Hissel, and Trigui, 2008): only two independent rotation speeds have to be considered, in function of the three input torques.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Two specific speed controllers (and not three) are required to manage both speeds from the three torques. Moreover, the local control schemes have their own dynamics and limitations that impact on the global control.

2. *Global Control of the Whole System*. The global control has to co-ordinate the local subsystems in function of an energy management strategy. This supervision level generally leads to references for local control loops. For example, torque references of an electrical machine and ICE is often given from an energy management in parallel HEV. Because this global control has to manage the whole vehicle, it is often based on a simplified model. Backwards, noncausal, or steady-state models can be used to reduce the computation time.
3. *Local and Global Interactions*. Because this global control has to give reference to local control, its dynamics must be lower than the local closed-loop dynamics. This fact justifies the uses of quasi-static model to develop the global control. Moreover, limitations are often imposed during transient states (i.e., torque limitation). If the global control level does not consider limitations of local controls, the desired energy management cannot be achieved during these phases. It has been shown that, for systems with energy sharing, the energy nodes are a key issue (Bouscayrol, Hissel, and Trigui, 2008). The way to distribute energy is often multiple and several solutions can be used. These degrees of freedom have to be highlighted. In some works, this degree of freedom is used to connect the local controls and the energy management of vehicles (Guzzella and Amstuz, 1999; Bouscayrol *et al*., 2006; Won and Langari, 2005). In fact, the border of both control levels is not so obvious. The first step consists to define what can be considered in a local control and what can be considered in a global control.

In summary, energy management of HEVs, EVs, and FCVs using several energy sources are generally organized in two levels. The control of each subsystem has obviously to ensure to obtain the reference requested by the supervision level. Fast dynamics are required to respond quickly to the different power demand. The supervision of the whole system has to ensure the best energy management to reduce fuel consumption and pollutant emission. This global level has to distribute local references to the subsystem controls.

The decomposition between both control levels is not so obvious, when multiple subsystems strongly interact through energetic nodes. Functional causal descriptions can be very useful in these cases to analyze the constraints of the associations of local subsystems. Moreover, if one subsystem is in limitation, this information must be considered in the supervision level in order to distribute the power demand in a more appropriate way.

The controls of local subsystems are generally derived from expertise, such as ICE or electrical machine controls. For new components, such as fuel cell, inversion-based control is useful in order to exploit the subsystem in the best way. Dynamical causal models are thus required to develop these controls in real time.

The energy management (supervision) of the whole system has a lower dynamics than the controls of subsystems. Moreover, they have to consider the overall system from a global point of view.

5 COMMERCIALIZATION ROAD MAP

Cost reduction, reduction in size and weight, high performance, support of all stakeholders are the major issues for successful market penetration of EVs, HEVs, and FCVs. The support from government agencies, academic institutions, consumers, major components suppliers, and oil, gas, and electricity utilities is particularly critical. The key issues are as follows: What economical or other benefit that the users can get? What environmental benefit that the society can enjoy? Is it fun to drive without negative point as compared with conventional vehicles? Suitable legislative measures and incentives are essential in order to effectively reduce CO_2 and reduce dependence on oil. Levers that impact the penetration of electric and hybrid vehicles include fuel price, regulation and taxes, local legislation, purchase incentive, ownership intangibles such as green image and fun to drive, and public education.

The success of penetration of electric vehicles relies on availability of good product at reasonable cost; good infrastructure that is economy, efficient, and convenient; and innovative business model that can leverage the initial cost of batteries. The major criterion of the success of commercialization of electric vehicles lies on cost, usage convenience, energy consumption, and emission level. To reduce the cost, we should exploit the residual value of batteries. The roles of batteries is not only to provide energy and power while the vehicle is in driving mode but also to serve as energy storage to interact with the grid when the vehicle is not in driving mode. Thus, the electric power industry is in the position to exploit the value of the batteries during their service life and hence to globally optimize the usage of batteries. This needs the shake hand between two giant industries, namely automotive industry and electric power industry.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto061
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

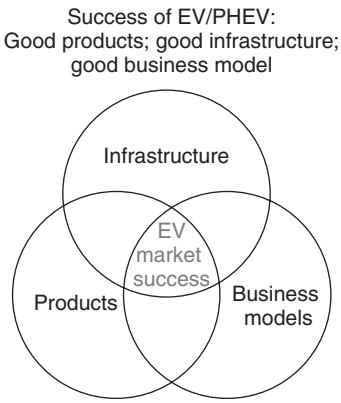

Figure 10. Three good factors.

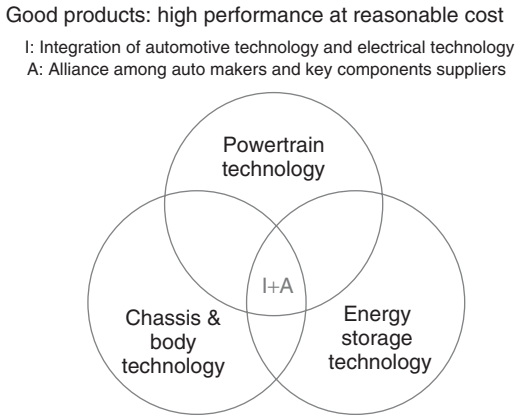

Figure 11. Good product approach.

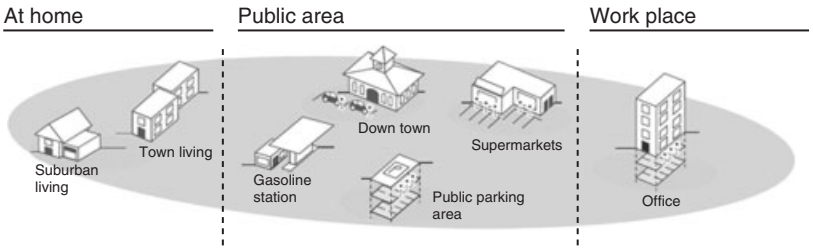
Figures 10–14 illustrate these concepts.

In order to maximize the added value of electric vehicles, the integration of electric vehicles with smart grid (Ota *et al*., 2010) and also with information and communication technology is essential. Figures 15 and 16 explain these advantages. The batteries of an EV have two roles: it acts as energy and power storage for EV, and it also acts as a spinning reserve of power grid. While the grid is strong, the grid will charge the batteries, but when the grid is weak, the batteries deliver power to the grid. Thus, it can achieve three advantages, namely 1 to enhance the stability and load factor of the grid; 2 to enhance the life of the batteries, as the batteries are properly charge and discharge by controlling the SOC of the batteries; and 3 to reduce the loss of wind power and solar power that connected to the grid at serious weather condition, as the batteries can serve as storage to accept the dynamic power of wind and solar.

Figure 17 shows the EV commercialization road map. It can be seen that the first step is driven by government. This is essential in order to gain experience and enhance the quality and reliability. It seems that the promotion in public transportation will have distinct advantages as it can reduce pollution in urban area, whereas the route of public transportation is fixed so that the batteries operation can be well designed according to the duty cycles of the buses. In addition, it seems that the promotion of mini battery electric vehicle will have distinct advantages as the required energy and power of batteries is relatively small. Moreover, the structure topology of mini-EVs can be optimized, such as using light materials and innovative body design.

Figure 18 shows the forecast of EV penetration. It is difficult to make accurate forecast, since now the development



Parking durations	14 h per day	2 h per day	7 h per day
Charging points	1 charging point per vehicle	< 0.5 charging point per vehicle	1 charging point per vehicle
Power & charging time requirements	Low power and normal charging (e.g., 3 kW, 10 h)	High power and quick charging (e.g., 22 kW, 2 h)	Low power and normal charging (e.g., 3 kW, 7 h)

Figure 12. Infrastructure.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

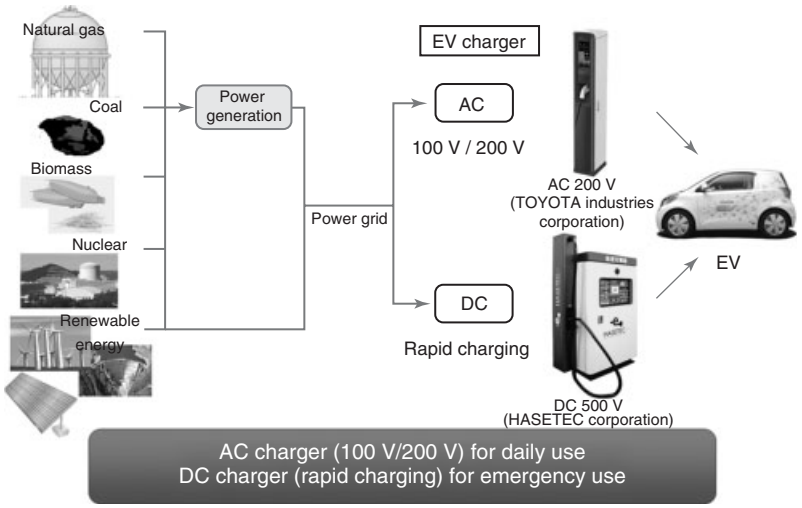

Figure 13. EV charger.

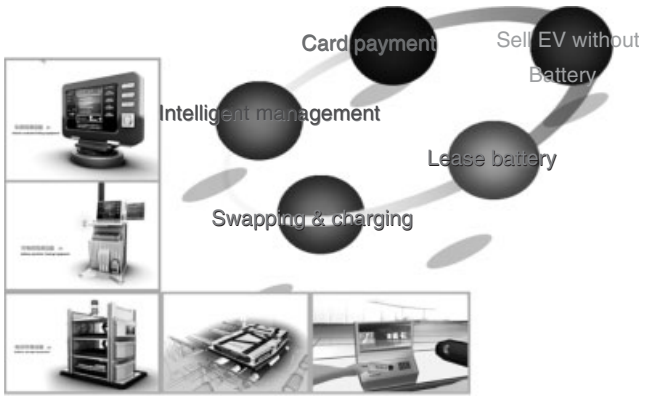

Figure 14. Possible business model.

of EV is in crucial and dynamic phase. Holistic approach of forecast is essential.

Electric vehicle industry is a disruptive industry and hence we should open mind, innovative design, and manufacturing as well as commercialization approach should be adopted. Figure 19 shows the distinct difference between traditional automotive industry and EV industry. It is expected that in addition to tradition automotive OEM, new EV manufacturers that only produce EV will appear. These new EV OEM will have no burden of ICE associated investment and hence will be able to create new value chain.

The standardization of electric vehicles and their infrastructure architectures will certainly enhance the safety, compatibility, and performance. Electric vehicle should be able to be charged safely everywhere. Figure 20 shows the related EV standards.

It is important that the company has proper commercialization road map. The company CEO should take lead in drawing the commercialization road map and the technical road map. This task should not just dedicated to the R&D department or sales department, as this is a major project, which will have major impact to the society and the company. In addition to have clear objectives, the senior management should also have holistic and creative thinking to oversee the progress of the project. The following is a success experience of a major automobile company in the development and commercialization of hybrid vehicles:

1. To have correct strategic plan, including near term, medium term, and long term.
2. To have sufficient funding to support the development plan.
3. To have innovative core technology, particularly innovative technology in integration of automotive technology and electric drive technology and energy storage technology.
4. To have correct technical road map. Understand the state of the art of technology, the trade-off among technology, cost, and market. Understand the different situation in the performance benefit versus cost characteristics in electric vehicles, hybrid vehicles, and fuel cell vehicles. A company may opt to produce whole spectrum of hybrids from micro to full hybrid for various types and sizes of vehicles. Another company may opt to focus on micro or mild hybrids for certain type and size of vehicles. A new OEM may focus only on the development of battery electric vehicles.

6 CONCLUSION

In a world where environmental protection and energy conservation are growing concerns, the development of electric, hybrid, and fuel cell vehicles has taken on an accelerated pace. The dream of having commercially viable electric and hybrid vehicles is becoming a reality. Electric and hybrid vehicles are now available in the market. This chapter provides timely systematic review on the state of the art of electric, hybrid, and fuel cell vehicles with focus on technical features, architecture, energy management, and commercialization road map. The success of penetration of electric vehicles relies on the availability of good product

Frost & Sullivan scenario	5,103	8,911	1,226,607	7%
Conservative scenario	5,103	7,550	520,953	4%

Figure 18. Forecast of EVs penetration.

at reasonable cost; good infrastructure that is economy, efficient, and convenient; and innovative business model that can leverage the initial cost of batteries. The integration of electric vehicles with smart grid and with information and communication technology is essential. The standardization of electric vehicles and their infrastructure architectures will certainly enhance the safety, compatibility, and performance. Electric vehicle should be able to be charged safely everywhere.

We are excited to be involved in the development of electric vehicles that will have impacts to the welfare of our future generation.

Rechargeable Battery Basics

Andrew Burke
University of California, Davis, CA, USA

1 INTRODUCTION

This chapter is concerned with various aspects of a basic understanding of rechargeable batteries for automotive applications, including cell construction and operation, testing/characterization, and battery performance in hybrid and electric vehicles (EVs). Emphasis is placed on lithium-ion batteries, but some consideration is also given to lead–acid and nickel metal hydride batteries. After summarizing the nomenclature and parameters to be used in subsequent sections, the first section of the chapter deals with basic concepts of cell design and testing for various battery chemistries. Next the performance—energy storage and power capability—of the batteries is considered including a discussion of installation in vehicles, battery charging, and battery management system (BMS) to mitigate safety issues with lithium batteries. The final sections of this chapter are concerned with battery life and cost. Both calendar and cycle life and factors that effect life for the various chemistries are considered. Battery cost estimates are given and life cycle and break-even fuel costs for vehicle applications are presented.

2 BATTERY NOMENCLATURE AND PARAMETERS

In this section, the general nomenclature to be used in subsequent sections of this chapter is discussed and the key parameters to be used to describe the batteries considered are introduced.

2.1 Nomenclature

2.1.1 Battery cell

The cell is the basic building block of the battery (Figure 1). It consists of two electrodes and a separator. The open-circuit voltage of the cell is uniquely set by the cell chemistry.

2.1.2 Battery pack

The battery pack is the combination of the cells connected in series and parallel to achieve the system voltage and energy storage (kWh) required by the vehicle.

2.1.3 Battery chemistry

Battery chemistry refers to the electrochemical reactions that occur in the cell. These reactions are dependent on the active materials used in the electrodes and the electrolyte used in the cell (Sections 3.1 and 3.2). The battery types are named to indicate their chemistry (e.g., lead–acid, nickel metal hydride, and lithium iron phosphate).

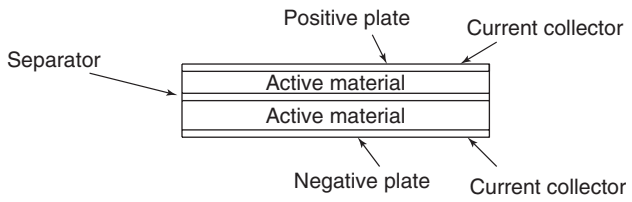

Figure 1. Basic cell geometry and construction.

2.1.4 *Performance characteristics*

The performance characteristics indicate the capability of the cells/pack to store electrical energy and provide electrical power for the vehicle. These characteristics are given in terms of the energy density (Wh/L) and power density (W/L) of the battery (Sections 4.1 and 4.2).

2.1.5 *Battery management*

Battery management refers to maintaining the cell voltages and temperatures during charging and discharging of the battery in specified ranges required for its safe and long life operation.

2.2 Battery parameters

2.2.1 *Cell parameters*

The key parameters describing the cell are the cell voltage V_{cell} and the ampere-hour capacity (Ah) of the cell. The cell voltage depends on the cell chemistry and the Ah capacity depends on the size of the cell. The energy (Wh) stored in the cell is given by $V_{\text{cell}} \times \text{Ah}$.

2.2.2 *Energy density*

The energy density of the cell or pack is determined by dividing the energy stored by the weight or volume of the cell or pack and is expressed as Wh/kg and Wh/L. The energy density is one of the key characteristics of the cells and pack that is determined from laboratory testing. The energy density is dependent on the discharge time of the test (Section 4.1).

2.2.3 *Power density*

The power density of the cell or pack is determined by dividing the maximum power that can be provided by the weight or volume of the cell or pack and is expressed as W/kg and W/L. The maximum power that can be provided depends markedly on the time period over which the power is sustained and the acceptable voltage drop (efficiency at which the power is provided) (Section 4.2).

2.2.4 *Charge and discharge rates (*n*C rate)*

The charge and discharge rate is often expressed as nC where n is defined as charge/discharge current divided by the Ah capacity of the cell ($n = I/\text{Ah}$). High power batteries can be discharged at nC rates >20C.

2.2.5 *Cycle life*

Cycle life for a battery is the number of times that a cell or pack can be cycled before a specified degradation in energy or power capacity occurs. This characteristic is determined from laboratory testing. The cycle life depends markedly on the temperature, the current or power profiles, and voltage limits of the tests. The calendar life of the battery depends on the calendar time over which the battery can be cycled before its performance degrades by a specified factor (Sections 5.1 and 5.2).

2.2.6 *Battery cost*

The battery cost is usually expressed as \$/kWh, which is simply the cost of the battery divided by the rated kWh energy storage capacity. For vehicle applications, the battery cost should be calculated for the complete pack with all accessory needed to operate it (Section 5.3).

3 BASIC CONCEPTS

3.1 Cell construction and operation

All batteries regardless of the detailed chemistry function in essentially the same way. As indicated in Figure 1, all batteries consist of positive and negative terminals/electrodes with a separator between the electrodes that conduct the ions exchanged and the blocks conduction of electrons that must pass through an external circuit. The electrodes and separator are porous and contain an electrolyte (usually a liquid or a gel), which has low resistivity for ion transport. The electrode materials are applied to a thin metallic foil or grid that collects/distributes the electrons to the electrodes from the positive and negative tabs of the cell. For the high power batteries used in vehicles, the electrodes are relatively thin being in the range of 100 μm.

The performance of the battery depends primarily on the materials used in the electrodes and the electrochemical reactions that occur between the ions in the electrolyte and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto062
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the solid material particles in the electrode. The mechanisms of these reactions and the ion transport in the porous electrodes are complex (Reddy, 2011; Yoshio, Brodd, and Kozawa, 2009; Nazri and Pistoia, 2003; Huggins, 2009), but the reactions in the electrodes can often be written in rather simple terms. For example, consider a nickel metal hydride cell in discharge, for which the electrochemical reactions are both electrodes are shown in Equations 1–3, where E_0 is the standard reduction potential. For charging, the reactions shown take place in the opposite direction.

Positive electrode:

$$\mathrm{NiOOH} + \mathrm{H_2O} + \mathrm{e} \rightarrow \mathrm{Ni(OH)_2} + \mathrm{OH^-}\ E_0 = 0.52\ \mathrm{V} \quad (1)$$

Negative electrode:

$$\mathrm{MH} + \mathrm{OH^-} \rightarrow \mathrm{M} + \mathrm{H_2O} + \mathrm{e}\ E_0 = -0.83\ \mathrm{V} \quad (2)$$

Total cell reaction:

$$\mathrm{MH} + \mathrm{NiOOH} \rightarrow \mathrm{M} + \mathrm{Ni(OH)_2} V_{\mathrm{cell}} = 1.35\ \mathrm{V} \quad (3)$$

MH is a mixed-metal oxide (Reddy, 2011; Linden and Reddy, 2002; Bennett and Sakai, 1994) that can store the hydrogen when the cell is charged. The electrolyte is 30% potassium hydroxide (KOH) in water. Note that the cell functions via the conduction (diffusion) of the hydroxide ion OH^- between the electrodes. In the case of the lithium batteries (Reddy, 2011; Yoshio, Brodd, and Kozawa, 2009; Nazri and Pistoia, 2003; Huggins, 2009), the Li^+ ion diffuses between the electrodes. Both battery chemistries are referred to as *swing* batteries; in both cases, the ion concentration in the electrolyte remains unchanged as the cell is charged/discharged. All the reactants are provided by the electrode materials and not the electrolyte. Experience has shown that "swing" batteries typically have long cycle life.

The voltages shown for each of the electrode reactions are the standard reduction potentials at 25°C (Reddy, 2011), which can be calculated from the differences in the free energy of the reactants and products of the reactions written in the "reduction" direction. The cell voltage is given by

$$V_{\mathrm{cell}} = (E_0)_+ - (E_0)_- \quad (4)$$

The theoretical charge transfer (Ah/g) in each half-reaction can be calculated from the following relationship:

$$\mathrm{Ah/g} = \frac{nF}{\mathrm{MW}}, F = 26.8\ \mathrm{Ah/mole} \quad (5)$$

where F is the Faraday constant, n the number of electrons involved in the half-reaction, and MW the molecular weight (gram) of the reactant.

Table 1. Electrochemical characteristics of various battery reactants.

Reactant	Valence	Standard Potential (V)	Charge Density (Ah/g)	Ah/cm^3
Hydrogen (H^+)	1	0.0	26.6	—
Lithium (Li^+)	1	−3.01	3.86	2.06
Manganese (Mn^{++})	2	−1.25	0.976	7.34
Iron (Fe^{++})	2	−0.44	0.960	7.54
Zinc (Zn^{++})	2	−0.76	0.82	5.82
Magnesium (Mg^{++})	2	−2.38	2.2	3.83
Lead (Pb^{++})	2	−0.13	0.259	2.94
Silver (Ag^+)	1	0.80	0.248	2.60
Copper (Cu^{++})	2	0.34	0.843	7.49
Nickel oxide (NiOOH)	1	0.45	0.29	2.16
Lead dioxide (PbO_2)	2	1.69	0.22	2.11
Manganese dioxide (MnO_2)	1	1.23	0.31	1.54
Lithium cobalt oxide ($LiCoO_2$)	0.5	−0.70	0.137	—

For a particular cell, the g/Ah for the total reaction (sum of the half-reactions) is given by

$$(\mathrm{g/Ah})_{\mathrm{cell}} = \left(\frac{\mathrm{MW}}{nF}\right)_- + \left(\frac{\mathrm{MW}}{nF}\right)_+ \quad (6)$$

The theoretical energy density of the cell is given by

$$(\mathrm{Wh/kg})_{\mathrm{theo.}} = V_{\mathrm{cell}}/(\mathrm{g/Ah})_{\mathrm{cell}} \times 1000 \quad (7)$$

For the nickel metal hydride cell cited above,

$$(\mathrm{Ah/g})_- = 0.45, (\mathrm{Ah/g})_+ = 0.292, (\mathrm{g/Ah})_{\mathrm{cell}} = 5.64$$

$$(\mathrm{Wh/kg})_{\mathrm{theo}} = 1000 \times 1.35/5.64 = 239$$

These theoretical calculations can be done for any electrochemical cell after the reactants and the electrolyte are postulated and their properties are known. The electrochemical properties of most reactants used in batteries are given in the study by Reddy (2011). Those for selected reactants are given in Table 1.

3.2 Battery chemistries

There are a number of battery types/chemistries being developed that can be used in vehicles. The chemistries of the various battery types are summarized in Table 2. The potential (theoretical limit) performance of each type is shown in Table 3 along with a practical performance to be

Table 3. Performance characteristics of battery chemistries for vehicle applications.

	Theoretical			Practical		
Battery Type	Maximum Voltage (V)	Charge Transfer (Ah/g)	Energy Density (Wh/kg)	Nominal Voltage (V)	Energy Density (Wh/kg)	(Wh/L)
Lead–acid	2.1	0.12	252	2.0	35	100
Nickel cadmium	1.35	0.181	244	1.2	40	90
Nickel metal hydride	1.35	0.178	240	1.2	80	220
Lithium–nickel cobalt	4.1	0.109	448	3.8	200	420
Lithium manganese	3.5	0.122	426	3.0	150	400
Lithium iron phosphate	3.65	0.111	405	3.4	115	255
Lithium titanate oxide	2.8	0.090	252	2.5	75	150
Lithium–sulfur	2.5	0.341	950	2.15	400	365
Sodium metal chloride	2.6	0.22	572	2.5	120	190
Zinc–air	1.6	0.82	1312	1.2	400	900
Magnesium–air	3.1	2.2	6820	1.4	800	1390
Lithium–air	3.4	3.68	13124	2.7	2500	3750

expected based on past experience in battery development. Experience has shown that in most cases, the operating voltage of the cell is reasonably close to the theoretical value, but the energy density (Wh/kg and Wh/L) is much less than the theoretical value by a factor at least 2–3. In the cases of the metal-air batteries, the reduction factor is much larger as the weight of the positive electrode is not included in the theoretical calculation because the active material (air) for the positive electrode comes from the environment and not the battery itself. Regardless, the practical energy densities of the metal-air batteries are projected to be much higher than the other battery chemistries. Those battery types are presently in an early stage of development and their future performance is very uncertain at the present time.

The cell theoretical performance values shown in Table 3 can be calculated using Equations 4–8 with pertinent inputs taken from the study by Reddy (2011). The practical performance values were taken from the study by Reddy (2011); Sion Power (2008), Lithium Sulfur Rechargeable Battery Data Sheet; and Burke and Miller (2009aa,b) based on test data for the batteries of various types and projections of future development of the battery technologies.

In the near term (5–10 years), the lithium batteries of various types are likely to be the technology used in most electric and hybrid vehicles. These batteries have relatively high energy and power densities and long cycle life as will be discussed in later sections of this chapter. In the long term (10–20 years), the metal-air batteries might be available for use in plug-in hybrid electric vehicles (PHEVs) making feasible long ranges (>150 miles).

3.3 Cell characterization and testing

Detailed data are needed concerning the performance of cells before they can be incorporated in the design of an electric or hybrid vehicle. The performance of cells can be characterized in terms of the following parameters:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto062
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(a) Charge stored (Ah) The *Peukert curve* (Ah vs discharge time) shows how the charge stored varies with the discharge time.
(b) Energy stored (Wh) The *Ragone curve* (Wh/kg vs W/kg) shows how the energy stored varies with discharge power *W*.
(c) Resistance (*R*) The *pulse power density* (W/kg or W/L) can be calculated from the measured resistance *R* and open-circuit voltage V_{oc} as a function of state of charge (SOC).

Determination of these parameters requires extensive testing of the cells. Detailed procedures for the testing have been developed by the United States Advanced Battery Consortium (USABC) and other organizations (Electric vehicle battery test procedures manual, 1996; Battery test manual for plug-in hybrid electric vehicles, 2008; FreedomCAR battery test manual for power-assist hybrid electric vehicles, 2003). These procedures require testing the cell over a range of charge and discharge currents and discharge powers at both steady and pulsed conditions. The series of tests for lithium cells should include at least the following:

(a) constant current at C/3, C/2, 1C, 2C;
(b) constant power at W/kg corresponding to C/3, C/2, C/1, 2C;
(c) pulse tests to determine the resistance at 2C, 4C, 6C; and
(d) charging at C/2, 1C, 2C, 3C, 4C.

When modules are available, similar tests should be performed on the modules. Examples of test data from this type of testing will be presented in the next section.

4 BATTERY PERFORMANCE

4.1 Performance data for lithium cells

Test data are available (Burke and Miller, 2009a, b) for most of the lithium cell types listed in Tables 2 and 3. A summary of test data are given in Table 4 for cells from a number of manufacturers. It is clear from Table 4 that there are significant differences in both the energy density and power capability of cells using the different lithium chemistries and both the Ah capacity and resistance of cells can vary over a wide range. The cell characteristics for the various lithium cell chemistries are summarized in Table 5.

Detailed test data similar that shown in Tables 6–8 are needed to characterize the performance of batteries for use in a vehicle. Such data are seldom available from the battery manufacture and almost never included on the spec sheets for the cells. A complete set of performance data is given in Table 6 for a Kokam 30 Ah cell. From this data, both the Peukert and Ragone curves for the cell can be plotted and the power capability calculated (Section 3.2). In addition, the open-circuit voltage and the resistance of the cell as a function of SOC can be determined for use in vehicle simulations.

Table 5. Characteristics of lithium-ion batteries using various chemistries.

Chemistry Anode/Cathode	Cell Voltage (V) Maximum/Nom.	Charge Transfer (Ah/g) Anode/Cathode	Energy Density (Wh/kg)	Cycle Life (Deep Cycle)	Thermal Stability
Graphite/$NiCoMnO_2$	4.2/3.6	0.36/0.18	100–170	2000–3000	Fairly stable
Graphite/Mn spinel	4.0/3.6	0.36/0.11	100–120	1000	Fairly stable
Graphite/$NiCoAlO_2$	4.2/3.6	0.36/0.18	100–150	2000–3000	Least stable
Graphite/iron phosphate	3.65/3.25	0.36/0.16	90–115	>3000	Stable
Lithium titanate/Mn spinel	2.8/2.4	0.18/0.11	60–75	>5000	Most stable

4.2 Power capability and cell design trade-offs

4.2.1 Power capability of batteries

In discussing the power capability of batteries (Burke and Miller, 2011), it is necessary to specify the time of the charge or discharge and the conditions under which the energy transfer takes place. By this is meant, the rate at which the energy stored in the device is transferred and at what SOC and/or voltage the transfer process is started and ended. The simplest process is a constant power discharge or charge of a device, which is customarily done to determine the energy density (Wh/kg or Wh/L). This test is usually started at full charge and is terminated at a specified cutoff or final voltage. These voltages are device chemistry dependent. In this test, the usable energy is measured for different power densities (W/kg) and the power density at which the usable energy begins to decrease markedly (e.g., has decreased by 20%) is determined. This power density is termed the $(W/kg)_{const.,\ max}$. It can be easily determined from constant power testing and there is little reason why the constant power capability should be unclear.

The definition and subsequent determination of the pulse power capability is not as straightforward as that of constant power capability. This is because the pulse power capability is highly dependent on the voltage drop permitted during the pulse and the duration (s) of the pulse. In general, the power capability is higher if a larger voltage drop is permitted and the duration of the pulse is shorter. The power capability of a battery is SOC dependent (lower at low SOCs). Hence, the test procedures should clearly state the SOC of the device and the voltage drop and duration of the pulse. Further the power capabilities of devices should be compared only for equivalent voltage drops/ranges, pulse times, and SOCs.

In general, there are two approaches to setting a limit to the power that can be taken from a battery (Burke and Miller, 2011). The first approach is to set a minimum voltage for a discharge pulse and a maximum voltage for a charge pulse that the device can experience during the pulse. This is the approach proposed by the United States Advanced Battery Consortium (USABC) (1996, 2003, 2008) in Electric vehicle battery test procedures manual, FreedomCAR battery test manual for power-assist hybrid electric vehicles, and Battery test manual for PHEVs. The initial voltage before the pulse is the open-circuit voltage (V_{oc}) at the stated SOC of the device. The maximum power then occurs at the current for which

$$V_{ch,max} - V_{oc} = I_{ch}R, \qquad P_{ch,max} = I_{ch}V_{ch,max}$$
$$V_{oc} - V_{disch,min} = I_{disch}R, P_{disch,max} = I_{disch}V_{disch,min}$$

R, which is the resistance of the device, varies with SOC and is determined from pulse tests of the device. The equations shown are the simple expressions for the ohmic voltage change due to the pulse current.

The second approach is concerned with the efficiency (EF) of the pulse or the fraction of the energy transferred from the device that is electrical energy rather than heat. In simplest terms using Ohm's law for a DC device,

$$P = VI, I = P/V, V = V_{oc} - IR$$

The efficiency is given by

$$\mathrm{EF} = P/(P + I^2R) = 1/(1 + IR/V) = V/V_{oc} \quad (8)$$

and the maximum power of the pulse becomes

$$P_{bat,max} = \mathrm{EF}(1 - \mathrm{EF})V_{oc}{}^2/R \quad (9)$$

The derivation of Equations 8–9 relating efficiency and maximum power to the voltage range of the pulse neglects the change in resistance during the pulse, but the equations show the direct relationship in principle between the power, open-circuit voltage, and resistance of the device. The efficiency at which the power capability is a maximum can be determined by differentiating Equation 9 with respect to EF. One finds that the power is a maximum for $EF = 1/2$ resulting in a maximum power of

$$P_{max,EF} = V_{oc}{}^2/4R \quad (10)$$

which is the well-known relationship for the matched impedance power of a device.

	50 A charge	2.0

Pulse Power Capability
Matched impedance power $P = V^2/4R = 16/4 \times 0.00155 = 2580$ W, 3280 W/kg
Power at specified pulse efficiency $P = \text{EF}\ (1-\text{EF})\ V^2/R$
95% $P = 0.95 \times 0.05 \times 16/0.00155 = 490$ W, 623 W/kg
90% $P = 0.9 \times 0.10 \times 16/0.00155 = 929$ W, 1180 W/kg
80% $P = 0.8 \times 0.20 \times 16/0.00155 = 1651$ W, 2099 W/kg

Equations 9–10 were used to calculate the power capability values given in Table 3 for the various batteries. As indicated in Table 9, the power capabilities (W/kg) projected for the various batteries vary greatly depending on the approach used to calculate the values. The matched impedance and the USABC max/min approaches clearly over estimate the power capability for most electric and hybrid vehicle applications. For hybrid applications in which a significant fraction of the energy is stored before it is used to power the vehicle, the efficient pulse EF = 95% is the appropriate value and for EVs, it seems reasonable to use the EF = 80% value.

4.2.2 Battery design trade-offs

The battery for an electric or hybrid vehicle must satisfy both an energy storage and power requirement for the vehicle to function properly. Unfortunately, batteries designed to optimize power having a low resistance will not be optimized for energy density because low resistance requires thin electrodes and large electrode area. These latter requirements also result in shorter cycle life and higher cost than for batteries optimized for high energy density. These design trade-offs are unavoidable and mean that complete knowledge of the battery design and performance are needed, including cycle life data, before the selection of the battery can be completed for a given vehicle application.

4.3 Battery pack design and testing

The electric driveline in most vehicles utilizes relatively high voltage −150 to 400 V in order to reduce the currents to reasonable levels. This means that the battery pack in the vehicle will consist of many cells in series. If large Ah cells are not available, the pack can also consist of a large number of cells in parallel or several strings of cells in series. In most cases, the cells are assembled into modules having a voltage many times the cell voltage. The module voltage can be in the range 12–75 V. Photographs of typical modules are shown in Figure 2. These modules would be tested using much the same procedures as outlined in the previous section for cells. The currents and powers for the testing would be based on the Ah and voltage ratings of the module. It is best to test the cells used in the module first because knowing the cell characteristics, one can predict the performance of the module with good confidence. If the measured characteristics (Ah, R, Wh, etc.) of the module do not follow directly from the cell characteristics either the module data are not correct or the connections of the cells in the module are faulty. It is also advisable to include interior

temperature measurements (Keyser and Smith, 2011) as part of the testing of modules. As discussed in a later section, thermal management of the modules and battery pack are critically important especially for lithium battery chemistries.

Before a battery pack is installed and tested in vehicles, it should be thoroughly tested in the laboratory. The test conditions for the pack should be determined from those to be experienced in the vehicle in which it will be installed. These conditions can be taken from simulation results of the vehicle operation. The battery pack should be tested using the same thermal management system (cooling), charger and charging algorithms, and battery management unit (BMU) as will be used when the battery pack is in the vehicle. The expected performance of the pack can be predicted with confidence from the test data for the cells and modules.

4.4 Battery charging

The proper charging of batteries (cells, modules, or pack) is dependent on information from the battery manufacturer.

(a) 70 V modules from EIG (b) 24 V, 50 Ah modules from Altairnano

Figure 2. (a,b) Photographs of lithium battery modules.

The key issue is the clamp (or maximum) voltage of the charge, which is dependent on the chemistry of the battery. The clamp voltage is close to the maximum voltage listed in Table 2 for each of the battery chemistries. In most cases, the battery is charged to the clamp voltage at a specified constant current and the current is then tapered to a specified fraction of the charge current. For example, a 20 Ah lithium iron phosphate cell could be charged at 20 A (1C rate) to 3.65 V and the current tapered to 1 A. For lithium batteries, regardless of the charging rate and battery age, the Ah put into the battery during charge (up to the clamp voltage and during taper) should be essentially equal to the Ah taken from the battery during the previous discharge. If this is not the case, either there is an error in the data or there are unwanted side reactions occurring in the cells. In either case, this is reason for concern.

When charging lithium modules or packs, it is advisable to track the voltages and temperatures of the individual cells and to maintain uniformity of the cells to a high degree. This should be accomplished by the BMU of the modules or pack if it is functioning properly. Part of the initial testing of the module or pack should be to establish that the BMS is functioning properly and to assess the magnitude of the variations between the cells. This will assure safe charging of the module or pack.

There is presently considerable interest in fast charging lithium batteries. By fast charging is meant replacing a significant fraction (at least 60–80%) of the Ah capacity of the battery in significantly <1 h. Laboratory testing of cells (Burke, 2009; Yvkoff, 2010) of lithium cells has indicated that with some cooling, charging rates up to 6C are possible for most of the lithium chemistries. The key issues are that the maximum voltage not be exceeded for any of the cells and that the interior temperature of the cells be limited to that specified by the battery manufacturer. Both of these conditions should be monitored by the BMS and the charge current reduced and/or charging terminated if one of the conditions is violated. Test results for the fast charging of the Altairnano Lithium Titanate cells are shown in Figures 3 and 4. The charging was done at the 6C rate with air cooling provided by a fan. Between the fast charges, the cells were discharged at the C/2 rate. As expected, the batteries heated

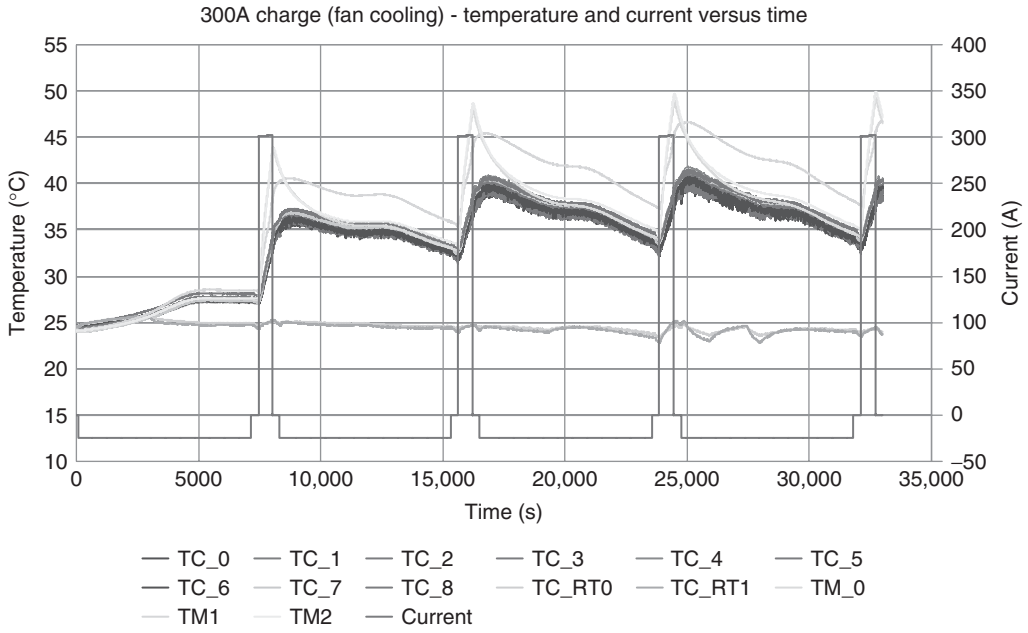

Figure 4. Fast charging (6C) of a 24 V module of the 50 Ah Altairnano cells.

up during the charging and cooled during the discharge reaching essentially a steady-state condition after about two cycles. For this cell, only small cooling is required to permit charging at 6C. The maximum temperatures measured on the exterior cell surface and the interior of the module were 45–50°C. In these fast charge tests, the batteries were completely charged and discharged.

4.5 Battery safety and management

There are safety concerns (Electrochemical Storage System Abuse Test Procedure Manual, 1999; Roth, 2004; Doughty, 2006; Orendorff, Roth, and Nagasubramanian, 2011; Keyser and Kim, 2011; Kim, Pesaran, and Smith, 2008) with all of the lithium battery chemistries. These concerns stem primarily with experience with cylindrical 18,650 cells in laptop computers. For this reason, lithium batteries have been used with caution in vehicle applications. The primary concerns are the possibility of thermal runaway because of an internal short in the battery caused by a manufacturing flaw (Orendorff, Roth, and Nagasubramanian, 2011; Keyser and Kim, 2011; Kim, Pesaran, and Smith, 2008) or abnormally high currents or temperature because of a failure of the battery control or a vehicle accident. These concerns have been addressed in two ways. First extensive abuse testing (Electrochemical Storage System Abuse Test Procedure Manual, 1999; Roth, 2004; Doughty, 2006) of lithium batteries has been done to show that thermal runaway does not occur even if the cells or modules are subject to acts of sudden compression, intrusion of sharp objects, dropping, fire, etc. Prevention of thermal runaway is dependent on both battery chemistry and design. The second approach to battery safety is to provide a BMU that monitors the cell/module voltages and temperatures and alerts the vehicle control system/computer if any of the cell voltages or temperatures is outside the normal range. Development of a BMU for use with their battery is common practice for battery manufacturers (Andrea, 2010; Pop *et al.*, 2008). As noted earlier, validation of the functioning of the BMU should be done during testing of the battery modules and packs.

5 BATTERY LIFE

5.1 Factors affecting calendar and cycle life

In evaluating battery technologies for hybrid and EVs, it is important to consider battery life as well as battery performance. The usable life of a battery is a key issue in evaluating the economic viability of a particular battery technology. End-of-service life is defined as the time (calendar time or number of cycles) over which the energy capacity decreases by about 20% or the resistance increases by about 50%. Estimating cycle life for a particular vehicle design and application is not a simple matter (Battery

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

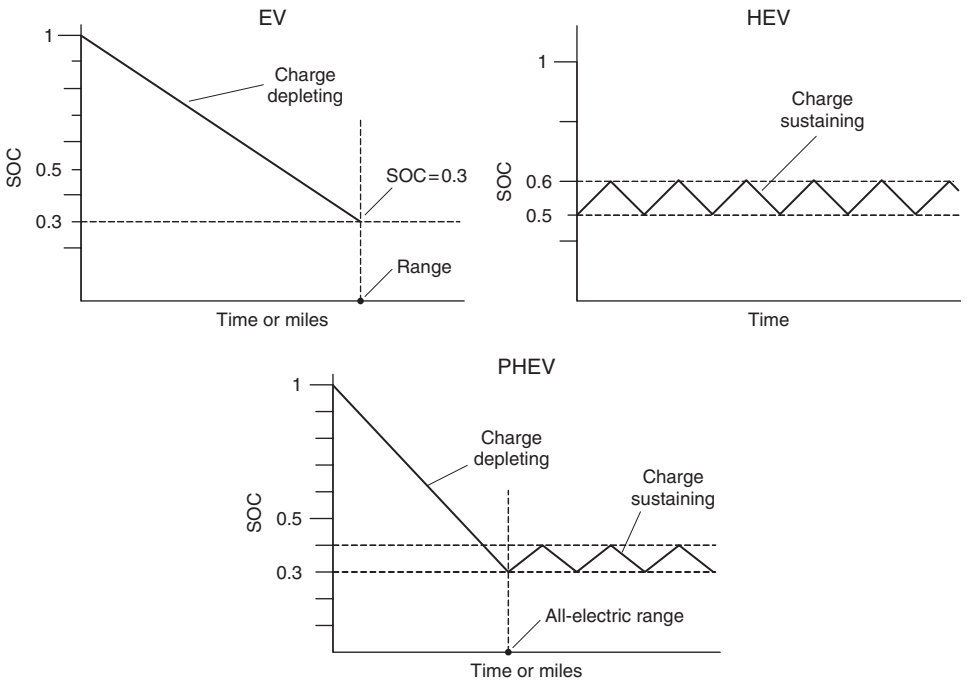

Figure 5. Battery state-of-charge history for EVs, HEVs, and PHEVs.

Technology Life Verification Test Manual, 2005). The cycle life depends on the rate of discharge, how the battery is recharged and the average depth of discharge before recharge, and the temperature of operation of the battery. The use of the battery in charge-sustaining hybrid electric vehicles (HEVs) and PHEVs and EVs is very different. As illustrated in Figure 5, the operating range of the battery's SOC in EV, HEV, and PHEV is different.

In the case of the hybrid vehicles, the battery experiences a very large number (300,000–500,000) shallow discharge cycles (about 5%) at an intermediate SOC (50–60%). The battery is charged and discharged at high rates requiring a high power design. It is never fully charged and the opportunities for cell equalization are limited. In the case of the plug-in vehicles, both plug-in hybrids and battery-powered EVs, the batteries experience deep discharge and long periods of charging from the wall plug. For plug-in hybrids, the energy stored in the battery is relatively small (<10 kWh in many vehicle designs) and the battery experiences its minimum SOC almost daily. In addition, the battery will experience long periods of shallow cycling near its minimum SOC when the plug-in hybrid is driven for long distances. Hence, life cycle testing of batteries for plug-in hybrid vehicles must include both deep and shallow cycling (Gaillac, 2008).

The batteries for EVs are sized to provide a relatively long vehicle range at least 75–100 miles in most cases and, as a result, will not be deep discharged nearly every day. The batteries are relatively large—store at least 25 kWh of energy—and experience high current pulses only during fast accelerations or quick decelerations (braking) of the vehicle. For most vehicle designs, the battery can be designed to maximize energy density and cycle life without power being a prime consideration. Except for fast charging, the EV batteries are expected to be charged in hours rather than minutes. For EVs, a battery cycle life of 1000–1500 deep discharge cycles is required, and for PHEVs, the cycle life is 2000–3000 cycles depending on the all-electric range of the vehicle. The calendar life of the batteries is intended to be at least 10 years. In order to reach this goal, the cell temperatures should be maintained below 50–55°C or even lower if specified by the battery manufacturer. This will require cooling of the battery pack in most cases.

In estimating the cycle life for a battery in a particular application, the depth of discharge before recharge and the fraction of the stored energy to be used are key factors. As shown in Figure 6, the cycle life increases rapidly if the usable depth of discharge of the cycles is <50%. Whether the battery is fully charged before each discharge cycle is also important. Both of these factors influence directly the usable energy and the effective energy density of the battery and the vehicle range for a given weight and cost of the battery.

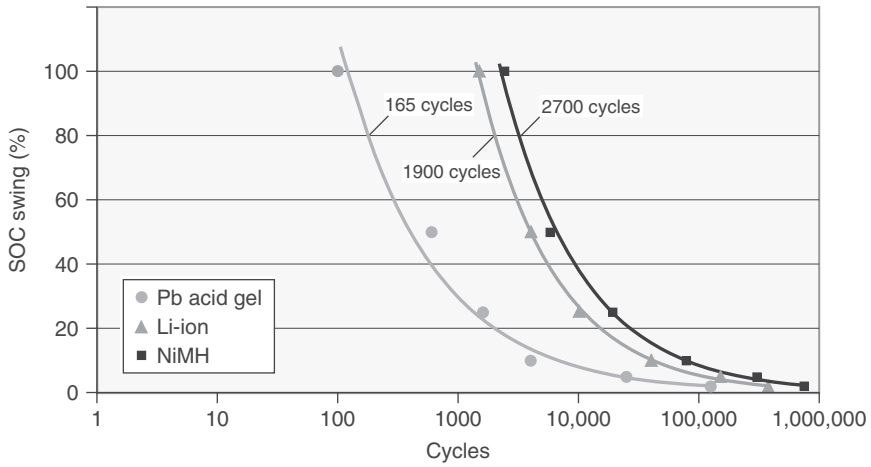

Figure 6. Cycle life correlations (Battery Technology Life Verification Test Manual, 2005) for various types of batteries.

5.2 Life cycle testing

Life cycle testing of batteries for vehicle applications is a long and complex process because of the diverse use and environmental conditions expected to be encountered by the battery during its lifetime. In addition, a vehicle battery pack consists of 100–200 cells in series with significant variability of the cells. These factors make both the planning of life cycle tests and analysis of data to estimate battery life with confidence difficult and expensive. As in the case of determining battery performance, life cycle testing is done first with cells and then with modules and packs. It is possible to do testing with large numbers of cells to get statistical data on cell degradation, but it is unlikely that equally large numbers of modules and packs can be tested. Another complication of life cycle testing is that one must select an appropriate test cycle (power vs time) and temperature environment for the testing.

Test procedures for testing batteries for HEVs, PHEVs, and EVs have been developed and published Electric vehicle battery test procedures manual, FreedomCAR battery test manual for power-assist hybrid electric vehicles, and Battery test manual for plug-in hybrid electric vehicles in the United States by the United States Advanced Battery Consortium (USABC) (1996, 2003, 2008). These procedures are intended to be followed by battery developers and National Laboratories and will yield a complete set of life cycle data. Study of the test procedures is informative, but little of the data from battery developers or National Laboratories will ever be published because it is proprietary to the battery developers. This is especially true for the advanced chemistry batteries—nickel metal hydride and lithium—of interest for vehicle applications.

In life cycle testing, the initial interest is in how the Ah capacity of the battery is degrading with calendar time and number of cycles and second how the resistance is increasing over the same period. The life of the battery is often defined as the number of cycles for which the Ah capacity decreases by 20% and/or the resistance increases by 50%. Often, the lithium cells are charged and discharged at the 1C rate. Test data (Shelburne, Manev, and Hanauer, 2009) for the Altairnano 11 Ah lithium titanate cell are shown in Figure 7. This confirms the expected long cycle life of the lithium titanate chemistry. Test data for the 20 Ah lithium manganese spinel chemistry are shown in Table 10. The data indicate that Ah capacity of two of the cells has decreased by 10% in 1100 cycles and the resistance of the cells has increased by 50–60%. Hence, the cell manufacturer has concluded the cell life of the cells is about 1000 cycles. It is not uncommon that the cell cycle life is determined by an increase in resistance and not the degradation in Ah capacity.

Life cycle testing of the Saft-Johnson Control lithium batteries used in the Daimler Chrysler Sprinter Van is reported in detail in the study by Gaillac (2008). The vehicle is a plug-in hybrid so the batteries were tested in both the charge-depleting mode (such as an EV) and the charge-sustaining mode (such as an HEV). The battery is discharged to a depth of discharge of 75% in the charge-depleting mode followed by testing in the charge-sustaining mode until the total cycle test time is 2.6 h corresponding to a vehicle range of 50 miles. The batteries are recharged at about the C/3 rate. The life cycle testing was done using three 21.6 V modules at room temperature (25°C) over a period of about 3 years. During that period, the test modules experienced 2100 cycles corresponding to 105,000 miles for the vehicle. Calibration testing of the modules at 240

% Capacity	90	91	94
Initial resistance (mΩ)	4.87	4.59	4.92
Resistance at 1100 cycles (mΩ)	7.87	6.94	7.56
% Increase of resistance	62	51	54

[a] Charge and discharge at 1°C at room temperature.

cycle intervals indicated that after the 2100 cycles, the C/1 and C/3 Ah capacities of the modules have decreased by 5% and 8%, respectively. The pulse power of the module has decreased by 7% over the same time period. During the testing, a BMS was used and the cell voltages were balanced if the BMS indicated that balancing was required after the charging and before the next discharge. These tests indicate that if the lithium batteries are maintained near room temperature and the cells are kept in good voltage balance, cycle life in excess of 2000 cycles can be expected with <10% degradation in capacity or pulse power for combined charge-depleting and charge-sustaining operation in a plug-in hybrid vehicle.

5.3 Battery cost considerations

The relative cost ($/kWh) of lithium-ion batteries of the different chemistries can be estimated using available computer programs. Projection of the cost of batteries requires inputs on the material costs as well as the costs of manufacturing equipment and processes. It is difficult to get good information on the costs of the various materials used in the electrodes of batteries. When such information is available, it is straightforward to estimate the differences in the electrode material costs for the different chemistries assuming ideal use of the materials in the electrodes. In terms of $/Wh, the following equation can be used:

$$(\$/\mathrm{Wh})_{\mathrm{materials}} = \{[((\$/\mathrm{gm}) + (\$/\mathrm{cm}^3)_{\mathrm{electrolyte}}/\rho/\varepsilon)/\mathrm{Ah/gm}]_{\mathrm{anode}} + [((\$/\mathrm{gm}) + (\$/\mathrm{cm}^3)_{\mathrm{electrolyte}}/\rho/\varepsilon)/\mathrm{Ah/gm}]_{\mathrm{cathode}}\}/V_{\mathrm{nom}} \quad (10)$$

The values for the Ah/gm and V_{oc} are given in Table 3. Calculated values for the electrode material costs ($/kWh) are shown in Table 11 for assumed unit costs of the various materials. The material unit costs used in the calculations are based on those used in a recent Argonne National Laboratory study (Nelson, 2008; Nelson, Santini, and Barnes, 2009). The results shown in Table 11 indicate that there is not a large difference in the electrode material costs of the various chemistries and also that electrode material costs should not dominate the total battery cost. Note that, in general, the higher cost lithium battery chemistries have the potential for longer cycle life which on a life cycle cost basis can compensate for the higher initial cost of those chemistries. This is especially true of the lithium titanate chemistry.

Researchers at Argonne National Laboratory (ANL) have developed a detailed lithium battery cost model (Nelson, 2008; Nelson, Santini, and Barnes, 2009) that is applicable to the various electrode chemistries. The model and results obtained at ANL are discussed in detail in the study by Nelson (2008); Nelson, Santini, and Barnes (2009); and Burke and Zhao (2010). Results obtained at UC Davis with the model for plug-in hybrid vehicle applications are summarized in Table 12 for the three electrode chemistries. The performance parameter values (Wh/kg and W/kg) for

[a]Unless noted otherwise, all values are the battery pack.

the battery pack given in the table are consistent with the cell test data presented previously in Table 4. The peak power in Table 12 corresponds to a pulse voltage of 80% of V_{oc}, which is an efficiency of 80%. The power densities (W/kg) for the modeled batteries are lower than those given in Table 8 because they are based on the pack weight not the weight of the cells.

Another aspect of the battery cost model that should be noted is that it accounts for the differences in the fraction of the stored energy expected to be available using the three chemistries—60% from NiCoAl, 65% from LiFe phosphate, and 85% from Li titanate oxide. This is the reason that the stored energy (kWh) is different for the three chemistries. This is also the reason that the battery costs for the different batteries are nearly the same even though the energy densities are quite different. Note also that on a $/kWh basis, the Lithium titanate batteries are significantly more expensive than the other two chemistries, but a significant part of the unit cost difference is negated by its higher energy use fraction. The battery costs ($/kWh) are sensitive to the unit material costs ($/kg), but it seems unlikely that the relative costs of the three chemistries will be much different than that shown in Table 12.

Vehicle cost and break-even gasoline price projections for mass marketed PHEVs and EVs in 2030 for mid-sized passenger cars are given in Burke and Zhao (2010); Ogden and Anderson (2011) for a range of battery costs. The results of the study are summarized in Table 13. Note that the lower end battery costs assumed in the study are consistent with the battery cost projections given in Table 12. The break-even gasoline price calculations were made assuming a 5-year payback period for the PHEV-20 and a 10-year period for the PHEV-40 and BEV-100. For the vehicles with the longer battery-only range, the cost calculations were done for the assumed life time of the battery. Note from Table 13 that the break-even gasoline prices are in a reasonable range when the battery costs approach those projected using the Argonne National Laboratory battery cost model. Hence, if the projected battery costs can be met in future years, it appears that both PHEVs and BEVs would have total ownership costs close to those of ICE vehicles in 2010. However, the results of the study discussed by Ogden and Anderson (2011) indicate

	—	—	300	9095	3.99

[a] Battery cost to the auto manufacturer.
[b] Battery cost in the show room.
[c] Difference in show room vehicle cost compared to a conventional ICE car.
[d] 5 years and 4% discount rate, 12,000 miles/yr.
[e] 10 years and 6% discount rate, 12,000 miles/yr.

that the PHEVs and BEVs would have higher ownership costs than advanced ICEs and HEVs unless the price of gasoline was >$7–8/gal.

6 SUMMARY AND CONCLUSIONS

This chapter discusses the basic concepts related to batteries for automotive applications including HEVs and EVs. Emphasis is placed on lithium-ion batteries, but some consideration is also given to lead–acid and nickel metal hydride batteries. The performance—energy storage and power capability—of the batteries is considered including a discussion of installation in vehicles, battery charging, and BMS to mitigate safety issues with lithium batteries. The construction and operation of cells are discussed in detail as well as the laboratory testing of the cells and modules. Test data for lithium batteries of several chemistries are given from which it can be seen that the performance of lithium batteries is now suitable for HEV and EV applications. Test data indicate that fast charging (>4C) of lithium batteries, especially lithium titanate oxide, is feasible if the proper charging infrastructure is available.
