Both calendar and cycle life and factors that effect life for the various chemistries are discussed. There is still considerable uncertainty concerning the cycle and calendar life of lithium batteries in vehicle applications, but the data shown indicate that long cycle life (at least 10 years) is a reasonable expectation. Cost estimates ($/kWh) are given for the various lithium battery chemistries based on a cost modeling program from Argonne National Laboratory. The projected future battery costs are in the range $300–$400/kWh. Using these cost estimates, it was found that the effective break-even gasoline prices for PHEVs and BEVs are $3–$4/gal when the battery cost is recovered over its 10-year life. Lithium battery safety is strongly dependent on the development of dependable BMU that monitor cell voltages and battery temperatures.

Power and Energy Requirements for Electric and Hybrid Vehicles

Andrew Burke
University of California, Davis, CA, USA

1 INTRODUCTION

This chapter is concerned with the assessment of the power and energy requirements for battery-powered electric vehicle (EV) and hybrid electric vehicle (HEV), including plug-in hybrid electric vehicles (PHEVs). Section 2 deals with the vehicle design parameters (weight, road load, and powertrain component powers) and their relationship to vehicle performance (range, speed, and acceleration). Section 3 is concerned with how the power and energy requirements are affected by the operating strategies of the vehicle powertrain especially in the case of plug-in hybrid vehicles. Section 4 includes vehicle simulation results for electric and hybrid vehicle designs that incorporate the design features discussed in the initial sections.

2 VEHICLE DESIGN AND PERFORMANCE PARAMETERS

2.1 Design parameters

The key vehicle design parameters are the curb weight, the aerodynamic drag coefficient and frontal area, and the tire rolling resistance. When these parameters are known, the road load can be calculated and the powertrain power requirements for specified acceleration and top speed performance for the vehicle can be determined. The force Equation 1 for the vehicle operation is the following:

$$W_v \frac{dV}{dt} = F_{wheels,powertrain} - F_{aero} - F_{tires} \quad (1)$$

where $F_{aero} = {}^1/_2\ \rho C_d A_f\ V^2, F_{tires} = W_v\ f_{rolling}$

The driving force on the vehicle applied through the tires on the road is due to the torque of the electric motor and/or the engine on the drive shaft of the vehicle. The energy required to power the vehicle is stored onboard the vehicle in the fuel tank and/or in the battery. The force required at the wheels by the vehicle for any driving pattern can be reduced by decreasing the vehicle weight and road load parameters (C_D and $f_{rolling}$). The energy required to provide the force at the wheels depends on the efficiencies at which the electric motor and/or engine are operating. The primary objective of the hybrid vehicle operating strategy is to significantly increase the average efficiency of engine operation for typical vehicle driving patterns.

The weight and frontal area of the vehicle are highly dependent on the size and class of the vehicle and its utilization. Typical curb weights and frontal areas for

Table 1. Light-duty vehicle road load parameters.

Vehicle Class	Weight (kg)		Drag Coefficient		Rolling Resistance	
	2010	2030	2010	2030	2010	2030
Cars						
Compact	1270	1025	0.27	0.22	0.008	0.006
Mid-size	1479	1188	0.30	0.22	0.008	0.006
Full	1660	1330	0.30	0.25	0.008	0.006
SUVs						
Small	1614	1361	0.40	0.35	0.009	0.007
Mid-size	2050	1740	0.40	0.35	0.009	0.007

various classes of light-duty vehicles in 2010 are given in Table 1. The curb weight can be reduced by utilizing lightweight materials (Mallick, 2010; SAE International, 2004; Husain, 2005) in the construction of the vehicle. Weight reductions of 10–20% seem likely in the next 10–20 years (Assessment of Fuel Economy Technologies for Light-duty Vehicles, 2010; Schafer *et al*., 2009). The drag coefficients of most automobiles are about 0.3 in 2010 and could be decreased to 0.25 or lower in future years (Hucho, 1998). Little change in the frontal area is expected because it is set primarily by seating comfort of the passengers in the vehicle. The rolling resistance of tires (Tire and Passenger Vehicle fuel Economy, 2006; Barrand and Bokar, 2008) has decreased in recent years being about 0.8% in 2010. It may be further reduced to 0.6% if that can be done without sacrifice in tire traction on slippery roads. These road load parameters and the expected ranges of values in future are shown in Table 1.

Reducing the energy use of a vehicle is dependent on increasing the efficiency of the operation of the powertrain as well as the reducing its weight and road load. This aspect of the design and operation of the vehicle is discussed in later sections of this chapter.

2.2 Performance parameters

The design of a vehicle is highly dependent on the performance requirements set for the vehicle. In the case of a conventional internal combustion engine (ICE) vehicle, its performance is expressed in terms of the acceleration characteristics, top speed, and fuel consumption (L/100 km or mpg). In the case of a battery-powered EV, its performance is expressed in terms of its acceleration characteristics, top speed, range (miles), and electricity consumption (Wh/km). Two types of hybrid vehicles are of interest—a charge-sustaining HEV that utilizes only liquid fuel and a PHEV that utilizes both a liquid fuel and wall-plug electricity. In the case of the HEV, the performance parameters are the same as for a conventional ICE vehicle. In the case of the PHEV, the performance parameters are a combination of those of the EV and the HEV. In that case, the electric range (miles) and electricity consumption (Wh/km) using the battery in the EV mode and fuel consumption as an HEV are of interest as well as the acceleration characteristics in both the electric and HEV modes of operation. The performance parameters for ICE, EV, HEV, and PHEV are summarized in Table 2.

Table 2. Summary of the performance parameters for the various vehicle designs.

Performance Parameter	ICE Vehicle	Electric Vehicle (EV)	Hybrid Vehicle (HEV)	Plug-in Hybrid (PHEV)

Fuel consumption (L/100 km or mpg)	×		×	×
All-electric range (km)		×		×
Energy consumption from battery (Wh/km)		×		×

3 VEHICLE/POWERTRAIN REQUIREMENTS

3.1 Requirements for electric vehicles (EVs)

The simplest of the vehicles with an electric driveline is the battery-powered vehicle (EV). The driveline (Figure 1) of this vehicle consists of an electric motor, power electronics, and a large energy storage battery. All the energy to operate the vehicle is provided by the battery, which is recharged from the wall-plug. The range of the vehicle is determined by the energy storage capacity (kWh) of the battery and the vehicle's energy consumption (Wh/km). The acceleration and top speed characteristics are dependent on the power rating (kW) of the electric motor. As indicated

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

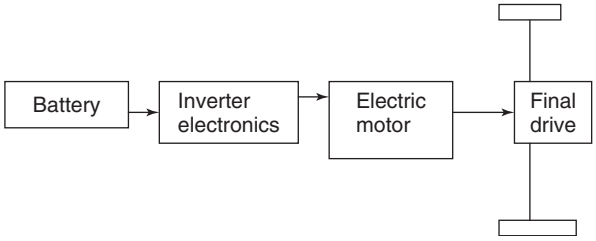

Figure 1. Battery electric vehicle driveline schematic.

in Table 3, battery electric vehicles have been designed and built in recent years by a number of auto companies. The size, functionality, electric motor power, acceleration, and range of these EVs vary greatly. Some of the vehicles are full-function vehicles intended for use on freeways at highway speeds, whereas others are intended for use on neighborhood streets at relatively low speeds.

The acceleration characteristics (acceleration times) are dependent primarily on the peak electric motor power. The acceleration times (simulation results) are given in Table 4 for a number of combinations of vehicle weight (kg) and motor power (kW). The low speed acceleration (0–48 kmph) is good for all the EVs, but the high speed acceleration (0–96 kmph) varies significantly with motor size. Good acceleration (0–96 kmph in <9 s) requires a power-to-weight ratio of 0.055–0.07 kW/kg.

Considerable care should be taken in the design of EVs to reduce their weight and road load compared to conventional ICE vehicles of the same size and type in order to attain maximum range for a reasonable size battery. The range of the vehicle is given by

$$\text{Range (km)} = (\text{kWh})_{\text{usable battery}} \times \frac{1000}{(\text{Wh/km})_{\text{veh}}}$$

Table 4. Relationship between electric motor power and acceleration characteristics for electric vehicles.

Vehicle Test Weight (kg)[a]	Peak Motor Power (kW)	Power-to-Weight Ratio (kW/kg)	Acceleration Time, 0–48 kmph (s)	Acceleration Time, 0–96 kmph (s)
1136	50	0.044	3.2	10.7
	60	0.053	2.9	9.1
	75	0.066	2.7	7.7

	100	0.061	2.8	7.9
	125	0.076	2.7	6.8

[a] For all the vehicles, $C_d = 0.25$, $A_f = 2.2\ m^2$, and $f_r = 0.007$.

where $(\text{Wh/km})_{\text{veh}}$ is the energy from the battery to operate the vehicle. The energy use of the vehicle depends on its weight, drag (C_DA), and rolling resistance coefficient (f_r) of the tires and the driving conditions (driving cycle). The range is dependent on the usable energy (kWh) from the battery—not the total energy stored. In most EVs, the fraction of the stored energy that can be used is only 60–80%. This is done to prolong the life of the battery.

Some of the trade-offs in energy use for light-duty vehicles are shown in Table 5 based on simulation results for the Federal City and Highway driving cycles. The battery storage requirement is given by

$$(\text{kWh})_{\text{bat}} = (\text{Range}) \times \frac{(\text{Wh/km})_{\text{battery}}}{(1000 \times \text{fr}_{\text{bat}})}$$

where fr_{bat} is the usable fraction of battery-stored energy.

	0.20	0.006	136	117	118	136	10.9

[a] All vehicles used a 75 kW AC induction motor, regenerative braking.
[b] The frontal area is 2 m^2.
[c] All vehicles used lithium-ion batteries, 150 Wh/kg, 20 kWh, 80% usable.

The corresponding battery weight is given by

$$(\text{Weight})_{\text{battery}} = (\text{kWh})_{\text{bat}} \times \frac{1000}{(\text{Wh/kg})_{\text{battery}}}$$

For light-duty vehicles, usable energy storage of 25–30 kWh is needed to attain a range of 150 miles depending on vehicle size and weight. This appears to be practical only for high energy density batteries such as lithium-ion or other chemistries having a usable energy density greater than 100 Wh/kg. Ranges in excess of 200 miles will require usable energy densities greater than 150 Wh/kg. The United States Advanced Battery Consortium (USABC) has set a minimum goal of 150 Wh/kg for long-term commercialization of EVs and a longer term goal of 200 Wh/kg (USABC) Goals for Advanced Batteries for EVs.

The power and energy requirements for various sizes of EVs (cars and sport utility vehicles (SUVs)) are given in Table 6 for vehicles having a range of 100 miles. The

DOI: 10.1002/9781118354179.auto063
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

power and energy requirements are strongly dependent on the vehicle type and size. The power required from the battery is the electric motor power divided by the efficiency of the motor/electronics. It will be assumed in this chapter that the electric drive efficiency is 90%.

3.2 Requirements for hybrid electric vehicles (HEVs)

There are several design approaches for HEVs. In all cases, the vehicle has the capability to generate electricity onboard the vehicle from liquid or gaseous fuel and an electric motor provides at least part of the torque to propel the vehicle. The electricity can be generated using either an engine/generator or a fuel cell. The vehicle is not designed to be plugged into the wall.

The engine can be connected directly to the wheels or only to the generator. The latter arrangement is referred to as a *series hybrid* and the former as a *parallel hybrid*. These powertrain arrangements are illustrated in Figure 2. The battery is charged off the engine or fuel cell and maintained in a relatively narrow range of state of charge (SOC). This hybrid vehicle is referred to as a *charge-sustaining hybrid* and all the energy to operate the vehicle is provided by the liquid or gaseous fuel. Refueling such a hybrid vehicle is not much different from a conventional ICE vehicle. The intent of the HEV design is to improve the efficiency of the engine operation and thus the fuel economy of the vehicle. All the HEVs offered for sale by the auto companies before 2011 are of the charge-sustaining type. As with EVs, the energy consumption of the HEV can be reduced by decreasing the vehicle weight, aerodynamic drag, and tire rolling resistance.

3.2.1 *Parallel hybrid drivelines*

The powertrain characteristics of selected hybrids are shown in Table 7. From the driver's point of view, these vehicles operate essentially the same as a conventional ICE vehicle but get much higher fuel economy. Markets for HEVs are growing as more models are becoming available from more auto companies (Hybrid vehicle sales data (current)). The power requirements and operating strategies of parallel and series hybrids are discussed in the following sections.

3.2.2 *Parallel hybrids*

A schematic for a single-shaft parallel hybrid powertrain is shown in Figure 2a. The key feature of the parallel configuration is that the engine is connected directly to the wheels of the vehicle and the total torque and power to the wheels is the sum of the outputs of the electric motor and the engine. Figure 2b shows the more complex planetary arrangement in which there are two electric machines—one primarily used as a traction motor to power the vehicle and the other as a generator to utilize part of the engine

output to generate electricity onboard the vehicle. This is the arrangement used by Toyota in the Prius. It has some of the characteristics of a series hybrid as it is possible to recharge the batteries even when the traction motor and engine are being used to provide torque to the wheels. In this more complex arrangement, the combination of the engine, traction motor, and generator act as a continuously variable, electromechanical transmission whose effective gear ratio depends on the ratios of the powers of the three components. The traction motor is also used as a generator to recover energy during braking of the vehicle.

In the simple parallel arrangement (Figure 2a), the engine output can be used to power the vehicle and to generate electricity using the traction motor as a generator to recharge the battery. A mechanical transmission is required for efficient operation of the engine even with the electric motor. The optimum choice of transmission for this single-shaft parallel hybrid is a continuously variable, mechanical unit (Frank, 2004; Bradley, Huff, and Frank, 2005) consisting of a variable geometry steel belt or linked chain operating between two adjustable pulleys (Figure 3). The continuously variable transmission and utilization of part of the engine output to recharge the battery permits the engine to operate most of the time at high efficiency resulting in a large improvement in the fuel consumption of the vehicle. The continuously variable transmission also results in regenerative braking energy recovery down to near zero vehicle speed. Both parallel arrangements (Figure 2b and 3) utilize in essence a continuously variable transmission. It is likely that the system efficiency gains from the planetary arrangement will be slightly greater than with the single-shaft CVT arrangement (Burke and Van Gelder, 2008), but it also seems likely that the cost of the planetary arrangement will be higher.

One of the key issues in designing a parallel hybrid is the size (kW) of the engine and the resultant peak power requirement of the electric motor(s). One approach is to minimize the power of the electric motor and to downsize

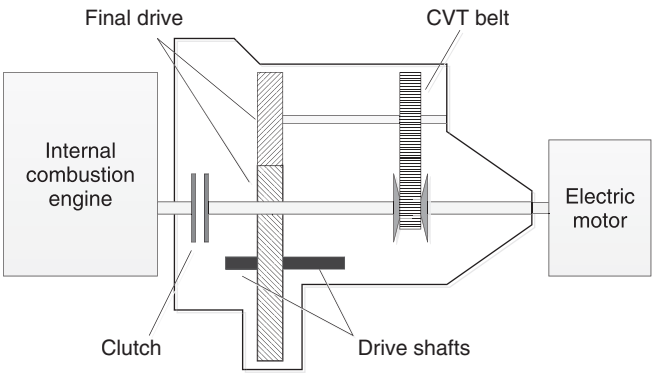

Figure 3. Schematic of a CVT in a hybrid driveline.

the engine only slightly. With this approach (Burke, 2009; Burke, Zhao, and Van Gelder, 2009), the power of the electric motor is selected such that the vehicle can be operated in the electric mode whenever operation of the engine would be inefficient. In this case, the peak power of the electric motor is only 15–20% of that of the engine and the vehicle is termed a *mild hybrid*. This approach also results in a relatively small, low cost energy storage unit that could utilize either batteries or ultracapacitors (Burke, Zhao, and Van Gelder, 2009). These single-shaft designs have been marketed by Honda (Table 5) and testing of the vehicles has shown that city cycle fuel economy improvements of 30–40% can be achieved using this approach.

Parallel hybrids can also be designed in which the engine is significantly downsized and a relatively large electric motor is used to augment the power of the engine. In this approach, which is termed a *full hybrid*, the electric motor and engine are of comparable size (kW) and the energy storage unit is significantly larger than for the "mild hybrid" in terms of both kilowatt-hours and power rating (kW). This approach is used by Toyota in the Prius (Table 5). The fuel economy improvement achieved with the "full

hybrid" approach will be somewhat larger than with the "mild hybrid" approach, but the incremental vehicle cost will also be significantly higher.

The battery used in the HEV whether in the single-shaft or in the planetary shaft designs is relatively small storing 0.75–1.2 kWh of energy. However, the power requirements for the battery depend on the size (kW) of the electric motor being used in the powertrain. Hence, the power requirement for a battery in the "full" hybrid (40–60 kW) is significantly greater than for the "mild" hybrid (10–20 kW). In both cases, the battery is maintained at an intermediate SOC (50–60%) in order that it can provide the high power in both discharge and charge. In addition, maintaining the battery in a narrow range of SOC results in long battery life of several hundred thousand shallow charge/discharges. The batteries used in HEVs must be high power batteries with power densities of 1000–1500 W/kg. The characteristics of a number of batteries (Burke and Miller, 2009; Burke and Miller, 2011) suitable for use in HEVs are given in Table 8.

3.2.3 Series hybrids

As shown in Figure 2c, the series hybrid is essentially an electric, battery-powered vehicle with an engine/generator onboard to generate electricity as the vehicle is driven. When the power output capacity of the engine/generator is equal to or greater than the average power required for a particular use (speed and grade) of the vehicle, the range of the vehicle for that use is set by the size of the fuel tank and not the battery. In most cases, the engine/generator rating is selected for range extension on some specified driving cycle. The advantage of the series hybrid is that the engine can be controlled to operate near its maximum efficiency independent of vehicle speed and power demand. The series approach is most suited for applications in which the peak electrical power demand is high compared to the average power demand and periods of high power demand are relatively short so that they can be met using energy from the battery. Otherwise, the power rating of the engine, generator, and electric motor have to be nearly the same, which results in the powertrain being heavy, large, and high cost.

The design of a series hybrid starts with the design of a battery-powered vehicle with a battery sized to a relatively short range. As for an EV, the electric motor is sized (kW) so that the vehicle has a specified acceleration performance (0–60 mph time). The engine/generator is sized to meet a specified maximum electrical output (kW), which is often set by maintaining the vehicle at a specified constant speed on a grade. The battery energy storage capacity (kWh) is determined from the range (km) requirement and the expected energy consumption (kWh/km) of the vehicle.

The series hybrid can be operated either as a charge-depleting hybrid such as an EV with the battery being charged from the wall-plug or as a charge-sustaining (HEV) hybrid using only a liquid fuel. In the latter case, the primary objective of the hybridization is to achieve a large improvement in fuel consumption. In the former case, the primary objective is range extension of an EV and the substitution of electrical energy for the liquid fuel. A combination of the two operating modes yields a PHEV like the GM volt.

3.3 Requirements for plug-in hybrid electric vehicles (PHEVs)

"Full hybrids" can be designed as either charge-sustaining (HEV) or PHEVs. All hybrids marketed by the auto companies before 2011 were HEVs, but some Toyota

Prius were converted to PHEVs by several small vehicle engineering companies (Duoba *et al*., 2009; Ghorbani, Bibeau, and Filizadeh, 2010). In order to convert an HEV to a PHEV, it is necessary to increase the onboard energy storage from 1–1.5 to 5–10 kWh. In addition, the system control software must be altered to permit the batteries to be depleted as the vehicle is operated as an EV over some range of speed and power demand. Provision must also be made to recharge the battery from the wall-plug. Several hundred Prius have been converted to PHEVs with good success in that their fuel economy on gasoline have been increased to about 100 mpg for city driving. The cost of the conversions was high being $10,000–$15,000 in 2007–2009.

In 2011, General Motors began marketing the *Volt*, which is a plug-in hybrid. The Volt has a 110 kW electric motor and a lithium-ion battery that stores 16 kWh. It operates as an EV before the battery is depleted and as series hybrid after the battery is depleted. The range of the ***Volt*** on battery-stored energy operating as an EV is about 64 km. The electrical power capability of the engine/generator on the Volt is 54 kW. Hence, the *Volt* is essentially an EV with a range of 64 km, but it has extended range on gasoline comparable to a conventional ICE vehicle for most driving conditions.

Most of the auto companies that have marketed HEVs are in the process of developing plug-in hybrids based on their parallel HEV designs. The main change from the HEV design is to increase the size (kWh) of the battery. The selection of the battery for plug-in vehicles can be a complicated process depending on several factors. In simplest terms, the battery should meet the energy storage (kWh) and peak power (kW) requirements of the vehicle in the all-electric mode of operation. In addition, the battery must satisfy cycle life requirements for both deep discharge in the charge-depleting all-electric mode and shallow cycling in the charge-sustaining mode of operation. The final considerations are concerned with the initial and life cycle costs of the battery.

The battery size and cost will vary markedly depending on the all-electric range (AER) of the vehicle and whether all-electric operation means that the engine is not used under any circumstances when the battery's SOC is greater than a minimum specified value. This control strategy would limit the vehicle acceleration that is possible using only the electric motor even though greater acceleration performance would be possible by turning on the engine. Another control strategy would minimize engine use when the battery SOC is high, but not forbid it, and only recharge the battery from regenerative braking until its SOC has reached the minimum specified value. In this approach, high power demand is met by a combination (blending) of the engine and electric motor torques. This approach results in a near maximum substitution of electricity for petroleum and at the same time offers the driver the maximum vehicle acceleration performance. The blended approach would also lead to a lower cost hybrid powertrain because the power of the electric driveline (motor and batteries) could be smaller than would be the case if AER meant no engine operation under any circumstances. After the batteries are discharged to the minimum SOC, the control strategy would be similar to that for a charge-sustaining hybrid with the intent of maximizing the engine operating efficiency and vehicle fuel economy.

In the case of PHEVs, there is much design flexibility in selecting the battery size and the electric motor and engine powers because the AER is a design variable and the power demand of the vehicle can be met by a combination (blending) of motor and engine output even while the battery is being depleted. Typical design combinations for AERs between 10 and 40 miles are shown in Table 9 for a mid-sized passenger car. The increasing weight and decreasing power density requirement of the battery with increasing all-electric (battery depletion) range of the vehicle is typical for plug-in hybrid designs. The battery in

a plug-in hybrid vehicle with a short AER (<50 km) will experience a deep discharge cycle almost every day and hence must be designed for more deep discharge cycles than the battery in a vehicle with a longer AER. It is clear from Table 9 that the requirements for batteries used in vehicles with short AER are more demanding than those in other hybrid vehicles. This will result in those batteries being more expensive on a $/kWh basis than batteries in vehicles with longer AER.

3.4 Summary of battery requirements for various electric drive vehicles

On the basis of the discussions of the previous sections, the battery requirements for mid-sized passenger cars and mid-sized SUVs are summarized in Table 10. It was assumed that lithium-ion batteries were used in all the vehicles but that the batteries were optimized for power and energy appropriate for the application. For example, the batteries used in the HEVs were optimized for power and had lower energy density than the batteries used in the EVs and PHEVs. It was also assumed that the PHEVs operated in a blended engine/electric mode for high power demands.

All the battery packs shown in Table 10 can be assembled using cell technology available in 2010 if the battery container and thermal management system designs yield packaging factors of 0.6–0.7.

Further development of lithium battery technology and technologies beyond lithium can be expected. Some of that development will be required to meet the battery pack goals set by the USABC and DOE for EVs and PHEVs (Snyder, 2012). These goals are summarized in Tables 11 and 12.

4 VEHICLE SIMULATION RESULTS

The previous sections have discussed in general terms various aspects of the design and operation of electric and hybrid vehicles. The discussions focused on the energy and power requirements and the trade-offs between those requirements, vehicle design parameters, and component performance characteristics. In this section, the results of detailed vehicle simulations are presented that show how vehicles meeting specified power and energy design requirements can be expected to perform on various driving cycles. Simulation results will be discussed separately for EVs and HEVs and PHEVs. The simulations were obtained using the Advisor computer program (Wipke *et al*., 1999; Gonder *et al*., 2009) as modified at the University of California-Davis.

4.1 Electric vehicle designs and performance

The design of EVs has been discussed in general terms in Section 3.1. The simulation of EV operation is quite simple because all the torque to the wheels is applied by the electric motor and all the energy to power the vehicle comes from the battery, which is charged from the wall-plug. The block diagram of the driveline schematic used in Advisor to simulate EVs is shown in Figure 4.

The input screen for the Advisor simulation is shown in Figure 5 and typical output graphics for a simulation are given in Figures 6 and 7. Outputs are shown for the FUDS and US06 driving cycles. The higher power demands and battery currents for the US06 driving cycle are clearly evident from the figures.

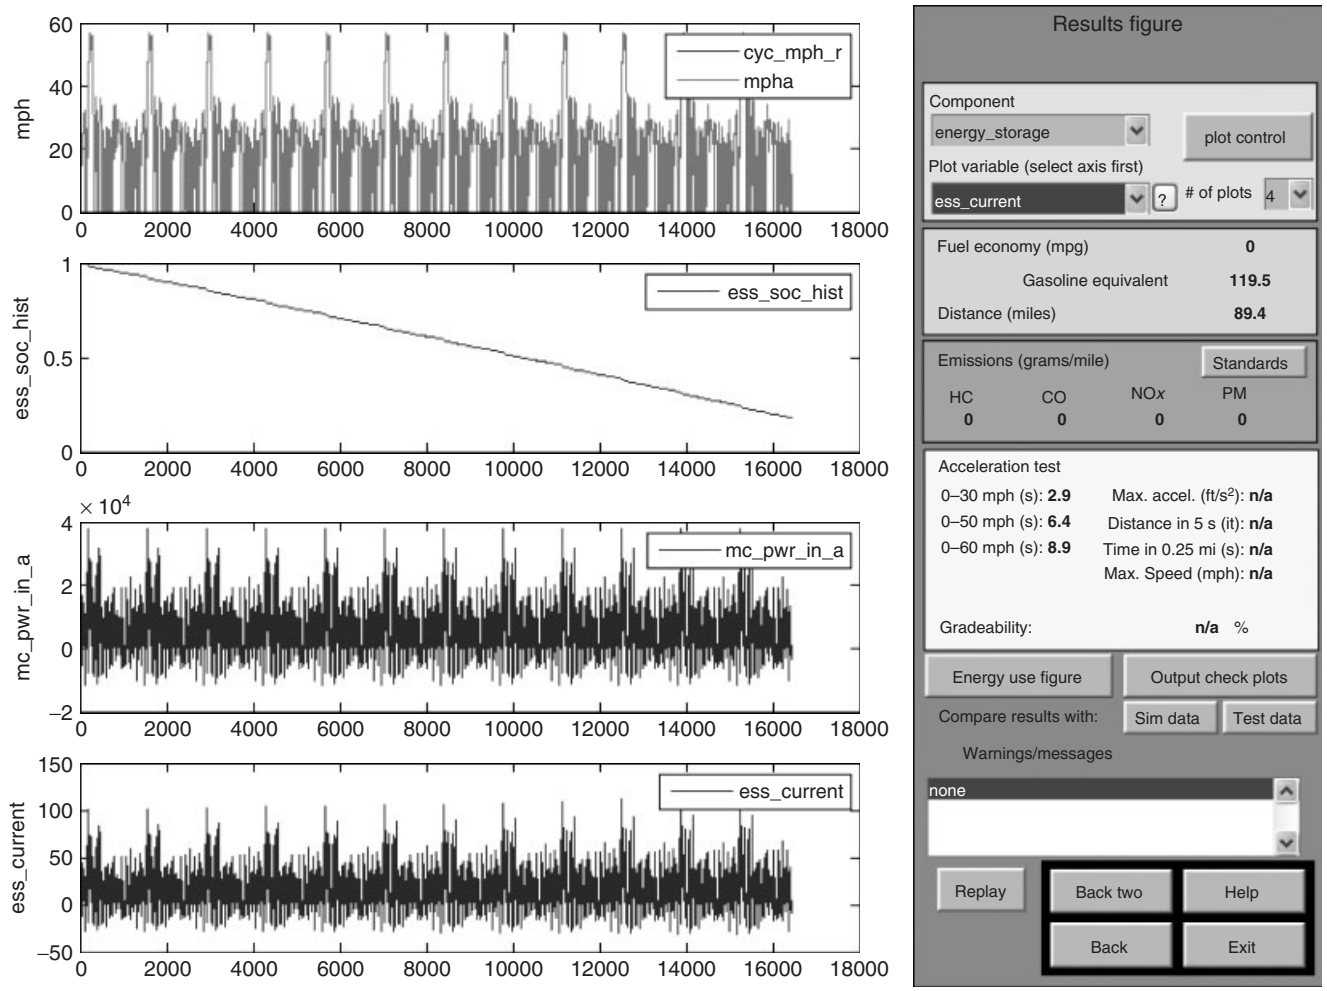

Figure 6. Output graphic for an electric vehicle simulation using Advisor—FUDS driving cycle.

Simulation results for various vehicle designs and driving cycles are summarized in Table 10. The results are given for the energy use (Wh/km) from the battery, range (km) using 80% of the energy stored in the battery, and the times (s) for 0–48 and 0–96 kmph accelerations. The influence of changes in vehicle weight, drag, rolling resistance, and peak motor power on the vehicle performance is evident in the table. The energy use and range of an EV are strongly dependent on the driving cycle and vehicle speed. Hence, specifying a single value for the range can lead to an inaccurate description of the EV range capability. The acceleration capability of an EV depends on the maximum power of the electric motor. As indicated in Table 10, the acceleration performance of the EV can be significantly increased with only a small decrease in vehicle range using the same battery.

Battery-powered EVs are recharged with electricity from the wall-plug. The energy use of the EVs is given as Wh/mi from the battery. The gasoline equivalent can be calculated from $(\text{gal/mi})_{\text{gas.equiv.}} = (\text{kWh/mi})/33.7$. The energy saved depends on the battery charging efficiency and the efficiency of the powerplant generating the electricity. For an EV using 245 Wh/mi from the wall-plug (90% charging efficiency), the gasoline energy equivalent saved is 75% from the wall-plug and 38% at a 40% efficient powerplant compared to the 2007 baseline ICE mid-sized car (34 mpg). Compared to a 2030 HEV (85 mpg), the gasoline equivalent saved is only 38% from the wall-plug and there are no savings at the powerplant until the efficiency of the powerplant exceeds about 60%. Hence, the energy saving potential of EVs can be expected to decrease markedly in

future as the efficiency of hybrid vehicles continue to increase.

4.2 Hybrid vehicle (HEV) designs and performance

The design of charge-sustaining HEVs has been discussed in general terms in Section 3.2. Detailed simulations of HEVs are discussed in this section. The Advisor program can be used to simulate the operation of hybrid vehicles (Burke, 2007; Burke and Miller, 2010). As indicated in Figure 8, the block diagram of the hybrid driveline in Advisor is considerably more complex than that of the EV (Figure 4).

The control strategy for the HEV driveline that is implemented via the block diagram is complex because its intent is to share the power demanded between the engine and the electric motor such that the engine operates only in the most efficient regions of the engine map. As will be discussed later in this section, this strategy leads to large improvements in the fuel economy of the HEVs compared to conventional ICE vehicles.

The Advisor vehicle simulation program has been utilized to calculate the fuel economy of a number of conventional ICE and HEV vehicles being marketed in 2010. The results of the simulations are summarized in Table 13. In nearly all the cases, the EPA dynamometer test data (U.S. Department of Energy and U.S. Environmental Protection Agency) and the simulation results are in good agreement. These comparisons serve to validate the Advisor program for evaluating HEV technologies.

Projections of fuel economy and fuel savings of HEVs have been made for future (Ogden and Anderson, 2011) using Advisor. The inputs used in the simulations are given in Table 14 and the results of the simulations are summarized in Table 15. A typical output graphic of the

calculations is shown in Figure 9. The large improvements in fuel economy shown in Table 14 are consistent with those found in previous studies by other groups (Assessment of Fuel Economy Technologies for Light-duty Vehicles, 2010; Plotkin and Singh, 2009; Kasseris and Heywood, 2007). These improvements are due largely to the efficient operation of the engine made possible by the addition of the electric motor to the driveline. As indicated in Figure 9, the engine is operated in an on/off mode and only consumes fuel when it is needed to power the vehicle and recharge the battery to maintain it in a narrow range of SOC. For the example simulation shown in Figure 9, the average engine efficiency was 37%. The fuel and energy savings are 60% and 29% compared with the 2007 ICE and 2030 ICE vehicle, respectively.

4.3 Plug-in hybrid vehicle (PHEV) designs and performance

The design of PHEVs has been discussed in general terms in Section 3.3. Detailed simulations of HEVs are discussed in this section. The Advisor program can be used to simulate the operation of PHEVs using essentially the same block diagram shown in Figure 8. In the case of the PHEVs, the vehicle operates when possible as an EV when the battery SOC is above a minimum specified

electric motor and the engine. This will be the case for most PHEVs for high power driving cycles such as the US06 even though the same vehicles could operate as EVs on the FUDS driving cycle. One of the key design parameters for the PHEVs is their AER. This is the driving distance for the vehicle when the battery becomes depleted to the minimum specified SOC. For driving distances shorter than AER, the vehicle will use mostly electricity from the battery and the fuel economy based on gasoline used will be very high (often in excess of 100 mpg). The characteristics of the batteries used in the Advisor simulations are given in Table 16. In all cases, lithium batteries were used.

Simulations of PHEVs have been performed using the Advisor program for a number of vehicle designs (Ogden and Anderson, 2011). The inputs for these designs are given in Table 17 for nominal AER values of 20 and 40 miles. The simulation results are summarized in Table 18. Results are given for operation of the vehicles in both the charge-depleting and charge-sustaining modes. For these designs, the vehicles are essentially EVs for driving distances shorter than the AER. The fuel economy in the charge-sustaining mode is essentially the same as an HEV (Table 15). For a specified driving range in excess of AER, the energy use (electricity and gasoline) can be calculated from the values given in Table 18. The acceleration characteristics of the PHEVs on the helectric motor only will be modest (0–96 kmph in about 10 s) based on a power-to-weight ratio of 0.04 kW/kg but will be very good using both the electric motor and engine (blended operation) with a power-to-weight ratio of 0.092 kW/kg.

The split between electricity and gasoline for PHEV vehicle will depend on its usage pattern (average miles driven per day and number of long trips taken). Assuming for the PHEV-20 and PHEV-40 mid-sized car that 20% and 65% of the total annual kilometers (miles) (city plus highway), respectively, are driven on electricity, one can calculate the wall-plug electricity and gasoline used and the total energy (gasoline plus energy needed to generate the electricity) savings. Assuming 24,000 annual kilometers (15,000 miles), a battery charger efficiency of 90%, and a powerplant efficiency of 40%, one can calculate the gasoline (fuel) and energy savings of the two PHEVs. The results for the PHEVs are given in Table 19 compared with similar results for other advanced technologies using different baselines for the comparisons. In terms of saving energy, there is not much difference between the various hybrid technologies. However, the energy savings with the BEV-100 are much less than with the hybrids regardless of the baseline used. The energy savings with the EV would be greater for a more efficient powerplant than the 40% plant assumed in the calculations. Clearly, the PHEV-40 and the BEV-100 result in more fuel (gasoline) savings because of the substitution of electricity to power them for most or all of their operation.

5 SUMMARY AND CONCLUSIONS

In this chapter, the power and energy requirements (both electricity and gasoline) for battery-powered EVs and HEVs, including PHEVs, are assessed. The influence of the vehicle design parameters (engine and motor power, weight, frontal area, drag coefficient, and tire rolling resistance) on vehicle performance (range, speed, and acceleration) is determined based on simulations of several classes of vehicles. The battery must be sized to meet the energy storage (kWh) and power (kW) requirements of the vehicles. It was found that lithium batteries of various chemistries are available that satisfy the requirements for both HEVs and PHEVs.

The power and energy requirements were calculated for both parallel and series powertrain arrangements using the Advisor vehicle simulation computer program. The simulations were performed for several driving cycles (FUDS, Highway, and the US06) for vehicle and component characteristics expected to be appropriate for 2015–2045. The simulation results indicated that large reductions in fuel consumption and energy use can be expected in the future with the various advanced technologies (Table 19). The magnitudes of the reductions depend on the baseline used. The energy savings (gasoline plus electricity including powerplant efficiency) are about 60% for all the hybrid technologies considered using the 2007 ICE vehicle baseline and about 30% using the 2030 ICE baseline. The energy savings (electricity) for the EV are smaller than for the hybrids especially compared with the advanced ICE and HEV technologies. The primary advantage of the EV is the substitution of electricity for a liquid fuel.

SYMBOLS AND PARAMETERS

C_d	drag coefficient of the vehicle
A_f	frontal area of the vehicle (m^2)
$f_{rolling}$	rolling resistance of the tires (kg/kg)
W_V	inertia weight of the vehicle (kg)
L/100 km	fuel consumption in terms of liters per 100 km
mpg	fuel consumption in terms of miles per gallon

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Wh/km	electrical energy from the battery per kilometer
$(kWh)_{usable}$	usable energy (kWh) from the battery
Wh/kg	energy density of the battery
W/kg	power density of the battery
Ah	Amp-hour capacity of a cell in the battery
Driving cycles (FUDS, Highway, and US06)	The *velocity versus time* profiles used in the vehicle simulations that are intended to model driving in the real world. These same driving cycles are used in the United States to test vehicles for emissions and fuel economy.

NOMENCLATURE

ICE	Conventional vehicle with engine and transmission
EV	Electric vehicle (battery powered)
HEV	Hybrid electric vehicle (charge sustaining with electric motor and engine)
PHEV	Plug-in hybrid electric vehicle with a rechargeable battery
PHEV-XX	PHEV vehicle with an all-electric range of XX miles
Parallel hybrid	Hybrid vehicle in which both the electric motor and engine apply a torque to the vehicle drive shaft
Series hybrid	Hybrid vehicle in which the electric motor is connected to the wheels and the engine drives a generator to produce electricity
Single-shaft hybrid	Hybrid vehicle in which the electric motor and engine are on the same shaft with or without a clutch to decouple the engine from the shaft
Planetary shaft hybrid	Hybrid vehicle in which the electric motor, generator, and engine is connected using a planetary gear arrangement (Toyota Prius)
CVT	Continuously variable transmission (mechanical component)
All	electric range—the range for a PHEV in which the vehicle is operated in the charge-depleting mode and the fuel usage is minimal
Advisor	The vehicle simulation computer program used to simulate the operation of the ICE, EV, HEV, and PHEV vehicles

Advanced Batteries for Vehicle Applications

Andrew F. Burke
University of California, Davis, CA, USA

1 INTRODUCTION

This chapter is concerned with the research and development on advanced batteries for plug-in electric vehicles (PEVs) in the next 10–20 years. The PEVs include both electric vehicles (EVs) and plug-in hybrid electric vehicles (PHEVs). The primary motivation for the development of the advanced batteries is to permit the design of electric vehicles having ranges comparable to conventional internal combustion engine (ICE) vehicles—300–500 miles. By advanced batteries are meant cell chemistries having energy densities significantly higher than those presently available, hopefully leading to the batteries needed for 300–500-mile range electric cars. This chapter is not concerned with batteries for charge sustaining HEVs. These vehicles require batteries with high power capability, and energy density is a secondary concern. For this reason, it is unlikely that any of the battery technologies considered in this chapter will be appropriate for HEVs. Present lithium battery technologies seem to be adequate for the HEV application as all the auto manufacturers that are presently marketing HEVs have begun to use lithium batteries in place of the nickel metal hydride batteries used in their earlier designs.

Early research is underway and laboratory cells are being prepared for most of the chemistries considered in this chapter, but in nearly all cases, it is anticipated that many years of R & D will be needed before the most advanced batteries could be marketed for use in vehicles. Most of the research is presently concerned with new lithium chemistry formulations and metal–air in electrodes and small cells. It is expected that some of the new lithium chemistries will be the first of the advanced battery technologies to be marketed in the next 5–10 years. The metal–air batteries are much further in the future and likely will be required to approach the 300–500-mile range goal.

The first sections of the chapter will deal with defining the requirements for the advanced batteries if they are to be used in long-range electric vehicles and a review of the chemistries that are likely to lead to high energy density, rechargeable batteries suitable for use in these vehicles. In the next sections, the present status of research on advanced batteries is discussed and available data for the various chemistries presented. In the final section, computer simulation results are given for vehicles using projected advanced batteries. These simulations include combinations of the advanced batteries with ultracapacitors or high power lithium batteries that would be needed if the advanced batteries do not have sufficiently high power capability to meet vehicle acceleration and braking requirements.

2 BATTERY REQUIREMENTS FOR FUTURE ELECTRIC AND PLUG-IN HYBRID VEHICLE DEVELOPMENT

Using lithium batteries available in 2012, the range of PEVs is limited to 75–100 miles in order that the weight and volume of the battery pack does not significantly affect the utility/functionality of the vehicle. For example, the Nissan Leaf utilizing lithium batteries has a useful range of about 75 miles with a battery pack weighing about 300 kg and a volume of about 300 L. The battery stores 24 kWh with about 80% useable on a regular basis. The energy consumption of the Leaf is about 250 Wh/mi. The energy densities of the cells in the Leaf battery are 140 Wh/kg and 300 Wh/L. In order to achieve a range of 300 miles, a vehicle such as the Leaf would need to store about 100 kWh and require cells with energy densities of 600 Wh/kg and 1200 Wh/L to maintain the same size battery pack. The maximum power requirement of the battery in the Leaf is 100 kW assuming a 90-kW electric motor with an efficiency of 90%. For a 300-mile vehicle, the power requirement for the cells would be 600 W/kg, which is the same as the battery in the Leaf. This is a modest power requirement for the lithium chemistries, but may not be easily met with the metal–air chemistries.

As shown in Table 1, the vehicle energy and power requirements can be reduced if the vehicle weight and road load characteristics are improved. For example, if the vehicle energy consumption is reduced to 180 Wh/mi, the battery pack energy storage requirement for a 300-mile range Leaf-type EV becomes 72 kWh and the power requirement is 80 kW. The corresponding cell performance requirements are 433 Wh/kg, 880 Wh/L, and 480 W/kg for the same size battery as in the 2011 Leaf.

It seems clear that to achieve 300-mile range in a mid-size passenger car will require a significant reduction in the energy consumption (Wh/mi) of the vehicle and large increases in the energy density of the battery. Reasonable design targets for the advanced batteries are 500–600 Wh/kg and 1100–1400 Wh/L for energy density and 500–600 W/kg for power density. Successful development of these batteries would permit the design of electric vehicles with ranges comparable to conventional ICE vehicles. However, the refueling (recharge) time for the batteries would be much longer than filling the gasoline tank of the conventional vehicle. The power density (W/kg and W/L) of the advanced batteries must be sufficiently high to permit the desired acceleration performance of the vehicle without the need to size the battery based on power requirements. High energy density batteries can be used to either extend the range of the EV or reduce the size and cost of the battery for the same range. In either case, the development of high energy density batteries will improve the prospect for marketing electric vehicles.

Table 1. Performance characteristics of battery-powered electric vehicles of various weight, drag, and tire rolling resistance.

The advanced batteries can also be used in PHEVs, permitting the design of vehicles with all-electric ranges of 50–75 miles, which would satisfy the needs of most drivers on most days. The result would be vehicles that would use gasoline only for long trips and electricity for a large fraction (until 75%) of the total miles per year. The size (weight and volume) of the battery would be reduced proportional to the increase in the energy density of the battery. For example, in the case of the General Motor's Volt, the weight of the cells in the battery using 300 Wh/kg cells would be 75 kg for an all-electric range of 75 miles if 80% of the stored energy (22.5 kWh) was useable. This weight compares with 110 kg for 40 miles using the cells available in 2011. The power density of the advanced batteries used in the 75-mile range PHEVs would need to be about 1500 W/kg to meet the 115-kW power requirement of the Volt. Hence, the power density of batteries to be used in PHEVs must be higher than those used in EVs.

If the power capability of the advanced battery is not sufficient to meet the acceleration requirements of either the EV or the PHEV, it would be necessary to combine the advanced battery with an ultracapacitor or high power lithium battery. These high power energy storage units are similar to those used in HEVs (charge sustaining hybrids) and should be readily available for use with the advanced batteries.

The previous paragraphs have been concerned with determining the performance requirements of the advanced battery cells. The advanced batteries must also meet essentially the same cycle and calendar life and safety requirements as the lower performance batteries presently available. That is at least a 10-year life in the vehicle application and safe operation with minimal concern for dangerous failure modes such thermal runaway. If the EV using the advanced batteries is to be cost competitive with a conventional engine-powered vehicle, the battery unit cost ($/kWh) must be at least a factor 3–4 less than present lithium batteries. This will be possible only if the advanced batteries have a weight-based cost ($/kg) equal to or less than present lithium batteries. This will preclude the use expensive materials in the advanced batteries.

3 BATTERY CHEMISTRIES BEING DEVELOPED

3.1 Introduction

There are a number of battery types/chemistries being developed that could be used in vehicles. The potential (theoretical limit) performance of the various chemistries is shown in Table 2 along with a practical performance to be expected based on battery developments as of 2012. Experience has shown that in most cases, the operating voltage of the cell is reasonably close to the theoretical value, but the energy density (Wh/kg and Wh/L) are much less than the theoretical value by a factor at least 2–3. Table 2 indicates the chemistries that are the prime candidates for the development of advanced batteries. These candidates are lithium–sulfur, zinc–air, magnesium–air, and lithium–air. In addition, various combinations of lithium chemistries show promise of considerably higher energy density than that in presently available cells even if it is not likely they can approach the 500–600 Wh/kg needed for the 300-mile range EVs.

The metal–air chemistries have the highest theoretical potential, but the reduction factors to practical designs are larger than that for the other chemistries because the weight of the positive air electrode is not included in the theoretical calculations. The active material (air) for the positive electrode comes from the environment and

Table 2. Performance characteristics of various battery chemistries.

Battery Type	Theoretical			Practical (2011)		
	Maximum Voltage (V)	Charge Capacity (Ah/g)	Energy Density (Wh/kg)	Nominal Voltage (V)	Energy Density (Wh/kg)	Energy Density (Wh/L)
Lead–acid	2.1	0.12	252	2.0	35	100

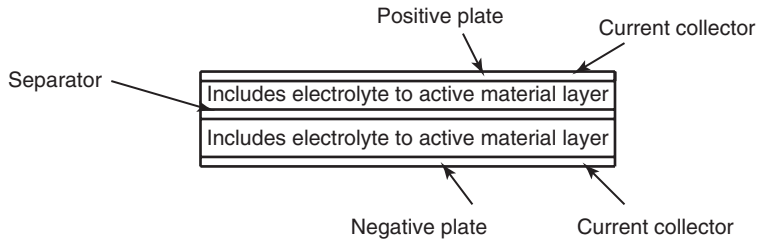

Figure 1. Cell schematic.

not from the battery itself. Regardless, the practical energy densities of the metal–air batteries are projected to be much higher than that of the other battery chemistries. Those battery types are presently in an early stage of development and their future performance is uncertain.

The steady improvement in the energy density of batteries for PEVs over the last 40 years (1970–2010) is evident in Table 2. In the 1970s, most of the EVs available used lead–acid batteries and had a useable range of <80 km (50 miles) and acceleration capability less than that required to follow the Federal Urban Driving Schedule (FUDS). The energy density of the lead–acid batteries (on a cell basis) was about 30 Wh/kg. The next generation of electric vehicles in the 1990s used nickel metal hydride batteries that had an energy density of 70–80 Wh/kg and a usable range of 120–160 km (80–100 miles). These electric vehicles had sufficient power to follow the FUDS driving cycle. The present generation (2010 and beyond) of electric vehicles use lithium-ion batteries and can have ranges of 160–240 km (100–150 miles). The lithium batteries have an energy density of 150–200 Wh/kg. The present generation of electric vehicles has excellent acceleration characteristics that can exceed that of conventional ICE vehicles. To a significant extent, both the range and acceleration characteristics of the EVs being marketed in 2012 are limited not by the performance of available batteries but by their high cost (>500$/kWh). Hence, the information in Table 2 show the steady progress in battery technology for EVs since 1970, and the projected development of the advanced batteries would only continue that trend, leading to longer-range vehicles.

3.2 Development of near-term advanced lithium-ion batteries

By near-term batteries are meant advanced batteries that are likely to being marketed for vehicle applications in 5–10 years. The chemistry of these batteries will evolve from the presently available lithium batteries and likely have energy densities <300 Wh/kg for cells.

There is much research (Yoshio, Brodd, and Kozawa, 2009; Reddy, 2011a; Schalkwijk and Scrosati, 2002; Thackeray *et al*., 2007; Marom *et al*., 2011) currently underway to increase the energy density of lithium-ion batteries. The research is being done in three areas: (i) increase the specific charge capacity (mAh/g) of the cathode (positive electrode), (ii) increase the specific charge capacity of the anode (negative electrode), and (iii) increase the cell voltage. The performance of the cells must be improved maintaining high cycle life and sufficient power capability for vehicle applications.

A schematic of a cell is shown in Figure 1. The specific charge capacity of the electrodes depends primarily on the materials used and the cell voltage depends primarily on the electrolyte utilized. Hence, the research cited above (Yoshio, Brodd, and Kozawa, 2009; Reddy, 2011a; Schalkwijk and Scrosati, 2002; Thackeray *et al*., 2007; Marom *et al*., 2011) is concerned with the electrochemistry of electrode materials and organic electrolytes for reversible intercalation of lithium ions in those materials. The objectives of the research are to find materials that have significantly higher mAh/g capacity than graphite currently used in the anode and the combinations of metal oxides used in the cathodes in presently available lithium batteries. The cell voltage depends both on the characteristics of the electrolytes and their compatibility with the electrode materials. Presently, cell voltages for lithium batteries vary between 3 and 4 V. Present research is targeting cells with voltages up to 5 V.

A summary of the characteristics of advanced electrode materials being studied is given in Table 3. For each electrode, the general approach is to prepare material composites that have specific charge capacities (mAh/g) that are significantly higher than that in the present baseline. In the case of the anode, the composites consist of mixtures of graphite/carbon and silicones. For the cathodes, the composites consist of layered atomic structures of various metal oxides—Mn, Ni, Co, and Al. As indicated in Table 3, present lithium cells utilize materials that have charge capacity values of 100–150 mAh/g, and advanced materials having charge capacities up to 250 mAh/g are being tested

Electrolytes				
EC–EMC		1.16		103
PC-DEC (propylene carbonate-diethyl carbonate)		1.09		137

in the laboratory. In the case of the anodes, most cells presently use graphites having specific charge capacities of 330–350 mAh/g. As indicated above, the most promising of the new anode materials appear to be mixtures of carbon and silicone (Si/C). Research to date seems to indicate that mass fractions of silcone of 25–40% are possible consistent with reasonable cycle life. In that case, the mAh/g of the anodes would be in the range of 800–1000 (Table 3).

The key considerations in developing an electrolyte for lithium batteries are the following: (i) the extent to which it forms an SEI (solid electrolyte interface) layer on the anode and cathode materials and whether that layer is stable for several thousand charge/discharge cycles, ii) the voltage at which the cell using the advanced electrode materials is stable, (iii) high solubility of the lithium salts and high conductivity of the lithium ion, and (iv) stable cell operation at high temperatures (until at least 65–70°C). Most lithium cells having graphite anodes use 50 : 50 mixtures of EC–EMC and 1 mol LiPF6 as the lithium salt. The ionic conductivity of the electrolyte is about 10 mS/cm and the maximum cell voltage is 4.0–4.2 V. Considerable research effort (Zhang, Zhang, and Amine, 2011a; Horino *et al*., 2010; Smart *et al*., 2011; Hassoun *et al*., 2010) is underway to increase the cell voltage to 4.4–4.6 V and later to 4.8–5.0 V. Much of this research is directed to the development of additives that will increase the stability of the SEI layer at the higher voltages.

It is not a simple matter to translate the electrode material properties into projected values for the energy density and power characteristics of the advanced lithium cells. Most of the available references (Yoshio, Brodd, and Kozawa, 2009; Reddy, 2011a; Schalkwijk and Scrosati, 2002; Thackeray *et al*., 2007; Marom *et al*., 2011; Zhang, Zhang, and Amine, 2011a; Horino *et al*., 2010; Smart *et al*., 2011; Hassoun *et al*., 2010) deal with the characteristics of the electrodes alone. However, the presentations shown in Nelson *et al*. (2002) and Barnett (2011) compare the performance of cells using the advanced materials to a baseline cell using graphite and LCO. Further comparisons can be made by estimating the energy density and resistance of the cells for the various material combinations as follows.

The charge stored in the electrodes can be calculated from the mAh/g characteristic of the material and its density (ρ), porosity (ε), and thickness (δ).

$$(\text{mAh})_+ = (\text{mAh/g})_+ \rho_+ \delta_+ (1 - \varepsilon_+)$$

$$(\text{mAh})_- = (\text{mAh/g})_- \rho_- \delta_- (1 - \varepsilon_-)$$

The weight of the electrodes is given by

$$W_+ = 2.7\, t_+ + \rho_+ \delta_+ (1 - \varepsilon_+) + \rho_+ \delta_+ \varepsilon_+ \rho_{\text{electrolyte}}$$

$$W_- = 8.9\, t_- + \rho_- \delta_- (1 - \varepsilon_-) + \rho_- \delta_- \varepsilon_- \rho_{\text{electrolyte}}$$

t_+ and t_- are the thicknesses of the current collectors, which are copper foil for the negative and aluminum for the positive electrodes, respectively. $\rho_{\text{electrolyte}}$ is the density of the electrolyte.

The thicknesses of the negative and positive electrodes are related by the relative charge storage capacities of the electrodes.

$$\text{NPR} = (\text{mAh})_-/(\text{mAh})_+, \text{NPR} = \text{negative–positive ratio}$$

In most cases, NPR is slightly >1 meaning that the cell charge capacity is limited by that of the positive electrode. This is done to prevent overcharging of the negative electrode (plating of lithium). Hence, in the analysis, the thickness of the positive electrode will be specified and the thickness of the negative will be calculated. Hence, the energy storage (Wh) of the cell is given by

$$\text{Wh} = (\text{mAh})_+ V_{\text{cell, av}}/1000$$

$$V_{\text{cell, av}} = V_{\text{cell, av+}} - V_{\text{cell, av–}}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto064
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and the energy density

$$\text{Wh/kg} = [(\text{mAh})_{+} V_{\text{cell, av}}]/(W_{-} + W_{+}) \quad (1)$$

The cell resistance is difficult to estimate in a simple way, because it includes the ionic resistance of the porous electrodes, the contact resistances and the effective resistances of the current collection, the electronic resistance of the electrode material, and the solid diffusion resistance of the lithium ions into the nanoparticles of the electrode material. It is possible to calculate rather simply the ionic resistance of the electrolyte in the porous electrodes ($R_{\text{electrolyte}}$) and the electronic resistance of the electrode material ($R_{\text{elec.mat}}$), but estimating the other resistances is complex and requires detailed models of the cell.

$$R_{\text{electrolyte}} = \left[\left(\delta_{+}\varepsilon_{+}{}^{-1.5} + \delta_{-}\varepsilon_{-}{}^{-1.5}\right)/2 + \delta_{\text{sep}}\varepsilon_{\text{sep}}{}^{-1.5}\right] \kappa_{\text{electrolyte}}$$

$$R_{\text{elec.mat}} = \left[\delta_{+}\kappa_{\text{elec.mat}+}\left(1-\varepsilon_{+}\right)^{-1.5} + \delta_{-}\kappa_{\text{elec.mat}-}\left(1-\varepsilon_{-}\right)^{-1.5}\right]/2$$

The total resistance is given by

$$R_{\text{cell}} = R_{\text{electrolyte}} + R_{\text{elec.mat}} + R_{\text{contact}} + R_{\text{collect}} + R_{\text{particlediffus}}$$

An estimation of an upper bound for the power capability of the cell can be made using only the resistance R_{mat} of the electrode materials

$$R_{\text{mat}} = R_{\text{electrolyte}} + R_{\text{elec.mat}}$$

The pulse power capability of the cell can be calculated from the relationship

$$P = \text{EF}\ (1 - \text{EF})\ V^{2}{}_{\text{cell, av}}/R_{\text{mat}} \quad (2)$$

where EF is the efficiency of the pulse (Burke and Miller, 2011).

The above equations were incorporated into a spreadsheet model in which the material characteristics could be easily varied. The model combined with the material characteristics shown in Table 3 was then used to estimate the energy density and power capability of cells using the various material technologies. The following assumptions were made concerning the thickness of the various cell components:

Electrodes $\delta_{+} = 30$, 50, and 75 μ, $\varepsilon = 0.25$
Separator $\delta_{\text{sep}} = 20\,\mu$, $\varepsilon_{\text{sep}} = 0.40$

Current collector foil 25 μ (active material coating on both sides).

The results of the cell calculations for energy density and power capability are shown in Table 4. The values shown in the table do not include packaging weight and volume.

The first results in Table 4 are for lithium cells presently available (2010) and represent the baseline for the cells using the advanced materials. Values are given for cathode thicknesses of 30, 50, and 75 μ. Depending on the cathode material and the electrode thickness, the baseline cells have energy densities of 150–250 Wh/kg and 350–650 Wh/L. These cell performance values are consistent with test data (Burke and Miller, 2009a, b).

If graphite anodes are combined with layered–layered composite metal oxide cathodes, significant increases in energy densities are projected—240–320 Wh/kg and 500–710 Wh/L. The comparisons with the baseline cells should be made at the same electrode thickness. The results indicate that the cells with the composite layered cathodes are likely to have lower power capability than the baseline cells.

The next set of results shown in Table 4 is for the silicone–carbon anodes combined with cathodes using the various materials. The results indicate that the use of the silicone–carbon anodes results in very little change in cell performance for all the electrode thicknesses and cathode materials compared to the corresponding performance using a graphite anode. There also seems to be very small change in the power potential using the silicone–carbon anodes. These surprising comparisons likely are owing to the higher voltage of the silicone–carbon anodes compared to the voltage of the graphite anodes.

One of the research targets of present research is to increase the voltage of the cathode. In the last set of results in Table 4, the cathode voltage was increased by 0.5 V. The benefit of increasing the cathode and thus the cell voltage is shown in the results for all the combinations of anode and cathode materials. For example, for a cell having a 50-μ thick cathode, the energy densities using graphite and a layered-composite cathode are 334 Wh/kg and 710 Wh/L compared to 289 Wh/kg and 620 Wh/L at the lower voltage. The power potential using the higher cathode voltage is also significantly higher.

The projected cell results using the various chemistries indicate that the largest improvements in cell performance will result from significant increases in cathode charge capacity mAh/g and increases in the cathode voltage. Using silicone–carbon anodes is not projected to have a significant improvement in cell performance compared to using graphite in the anode. Large differences in cell performance and power capability result from changes in the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto064
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

electrode thicknesses, and comparisons in cell performance for different electrode chemistries should be done at the same electrode thickness.

3.3 Metal–air battery potential and development

In this section, the design of metal–air batteries is discussed. As indicated in Table 2, the theoretical potential energy density of metal–air batteries is much greater than that of lithium batteries. For this reason, there is much interest in the development of these battery chemistries for vehicle applications. As discussed in Reddy (2011b), Kowalczk, Read, and Salomom (2007), (Dahn), Lee *et al*. (2011), Girishkumar *et al*. (2010), Kraytsberg and Ein-Eli (2011), Zhang *et al*. (2011b), metal–air battery technology is in a very early stage of development especially for chemistries suitable for vehicle applications that require electrically rechargeable and high power cells. More R & D has been done on primary (non-rechargeable) metal–air cells, especially Zn–air, but research is now underway on rechargeable cells, especially Li–air.

A cell schematic is shown in Figure 1. In the case of the metal–air cell, the negative (anode) electrode is the metal (lithium or zinc) and the positive (cathode) is an air electrode consisting of porous carbon with an added catalyst. The reactant (oxygen) at the cathode is taken from the ambient air and thus it does not add to the weight of the cell. This is one of the reasons that the metal–air batteries have such high theoretical energy densities. As discussed later, one of the reasons that development of the metal–air batteries has been so difficult for vehicles applications is that they require a bidirectional air cathode that must be capable of reasonable high rates for both charge and discharge of the cell. The development of the air electrode is much less difficult if it must function only in the discharge direction (chemical reduction of oxygen) as in a hydrogen fuel cell.

For vehicle applications, the most attractive metals are lithium (Li), zinc (Zn), and magnesium (Mg). A summary of selected characteristics (Reddy, 2011b) of these metals for metal–air cells are given in Table 5. Lithium is the most attractive of the metals, but all of them have good potential for developing high energy density batteries. In the case of lithium, neglecting the weight and volume of the air cathode, the energy densities (13124 Wh/kg and 7008 Wh/L) are comparable to those of gasoline (12,222 Wh/kg and 9533 Wh/L). However, as discussed in later paragraphs, the practical potential energy density of lithium–air batteries is much less than that of liquid fuels.

It is of interest to develop a simple method of evaluating the practical potential of metal–air batteries, which includes the weight and performance of the air cathode. This can be

Table 4. Performance characteristics of advanced lithium-ion batteries using various electrode technologies.

Cell Technology	Energy Density (Wh/kg)[a]	Wh/L	Power Density (kW/L)[b]
Anode/cathode

SiliconeC 1050 Ah/g/layered–layered 245 Ah/g, $\Delta V = 0.5$ V	300/373/425	650/830/970	35/18/10

[a] a/b/c correspond to cathode electrode thicknesses of 30, 50, and 75 μ.
[b] The power density corresponds to ionic and electronic resistance of the electrode material only and does not include resistance to particles. The power density shown is for an 85% efficient pulse (Equation 1).

Table 5. Summary of the characteristics of the metals in a metal–air cell.

Metal	Atomic Weight (g)	Density (g/cm^3)	Charge Density (Ah/g)	Charge Density (Ah/cm^3)	Valence Change	Cell Voltage with Air Electrode (V)	Theoretical Energy Density (kWh/kg)
Lithium	7	0.534	3.86	2.06	1	3.4	13
Magnesium	24	1.74	2.2	3.83	2	3.1	6.8
Zinc	65	7.1	0.82	5.82	2	1.6	1.3

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto064
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

done using an approach similar to that discussed previously for lithium-ion cells.

The energy stored (Wh/cm^2) in the cell is that resulting from the electrochemical oxidation of the metal at the anode and can be calculated from the charge capacity of the metal and the voltage of the cell. Hence,

$$(\text{Wh/cm}^2)_{\text{theo.}} = V_{\text{cell}}(\text{Ah/g})_-\rho_-\delta_-(1-\varepsilon_-) \qquad (3)$$

and the usable energy is given by

$$(\text{Wh/cm}^2) = \text{UL}_{\text{factor}}(\text{Wh/cm}^2)_{\text{theo}}$$

where $\text{UL}_{\text{factor}}$ is the fraction of the metal in the anode that is utilized. The theoretical capacity of the cell is the capacity if all the metal in the anode could be utilized in the discharge. However, only a fraction (50–80%) can be utilized due to pore blockage in the porous metal electrode.

An important parameter for any battery for vehicle applications is its power-to-energy ratio (N_{per}), which can be defined as

$$N_{\text{per}} = P/E = \text{W/cm}^2/(\text{Wh/cm}^2)$$

W/cm^2 can be expressed as

$$(\text{W/cm}^2)_{\text{cell}} = (\text{A/cm}^2)\,(V_- + V_+) = N_{\text{per}}(\text{Wh/cm}^2) \quad (4)$$

Since the A/cm^2 is equal for the negative and positive electrodes, we can express the A/cm^2 for the cell in terms of the value for the air cathode. Hence,

$$(\text{A/cm}^2) = (\text{A/g})_+\rho_+\delta_+(1-\varepsilon_+) \qquad (5)$$

Now using Equations (3) and (4),

$$(\text{A/g})_+\rho_+\delta_+(1-\varepsilon_+) = N_{\text{per}}(\text{Wh/cm}^2)/(V_- + V_+)$$

Using Equation (2) and solving for the ratio of the electrode thicknesses,

$$\delta_+/\delta_- = (N_{\text{per}})\left(\frac{\rho_-(\text{Ah/g})_-\text{UL}_{\text{factor}}}{[\rho_+(\text{A/g})_+]}\right)\frac{(1-\varepsilon_-)}{(1-\varepsilon_+)} \qquad (6)$$

$(\text{A/g})_+$ is the current density at the air cathode and strongly influences the overpotential $(V_{\text{ovp}})_+$ at the cathode. The voltage at the cathode V_+ is given by

$$V_+ = (V_{\text{equil}})_+ + (V_{\text{ovp}})$$

The open-circuit voltage is given by

$$V_{\text{oc}} = (V_{\text{eq}})_- + (V_{\text{eq.}})_+$$

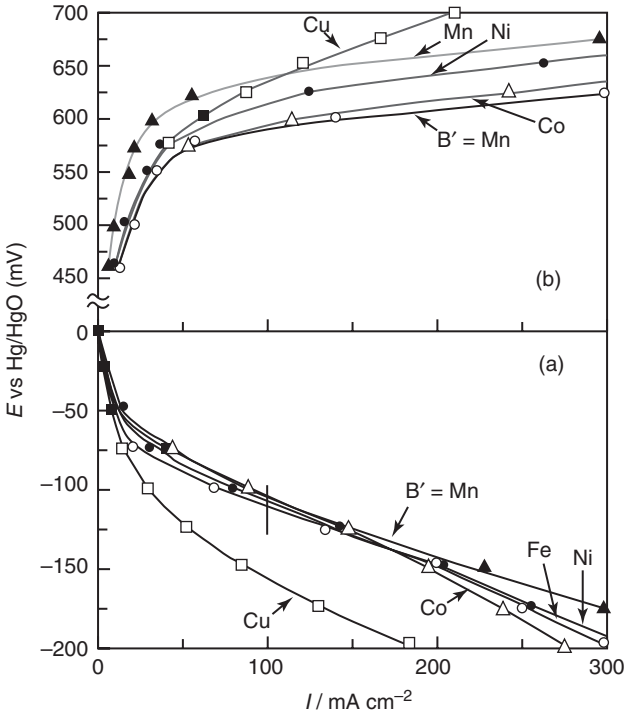

Figure 2. Overvoltage data for the air cathode. (Reproduced from Burke and Miller (2011). © Elsevier.)

The overpotential at the cathode is negative for discharge currents and positive for charging currents for the cell. The magnitude of the overpotential for the air electrode can be large (hundreds of millivolts) for both discharge and charge currents, but particularly large for charge currents. Research (Martin *et al*., 2009; Neburchilov *et al*., 2010; Yuasa *et al*., 2011; Wei *et al*., 2000) is presently being done to decrease the overvoltage using catalysts to permit higher values of A/g in the air cathode electrode (Figure 2).

The energy density of the cell requires calculation of the cell weight and volume. The weight of the cell is given by

$$(\text{Wt/cm}^2)_{\text{cell}} = (\text{Wt/cm}^2)_- + (\text{Wt/cm}^2)_+ + (\text{Wt/cm}^2)_{\text{sep}} + (\text{Wt/cm}^2)_{\text{electrolyte}}$$

The weights of the electrodes depend on their thickness and effective density including porosity. Hence,

$$(\text{Wt/cm}^2)_{\text{cell}} = \delta_-\rho_{\text{metal}}(1-\varepsilon_-) + \delta_+\rho_{+\text{C\&cat}}(1-\varepsilon_+) + \delta_{\text{sep}}\rho_{\text{sep}} + \delta_-\rho_{\text{electrol.}}\varepsilon_- + \delta_+\rho_{\text{electrol.}}\varepsilon_+ + \delta_{\text{sep}}\rho_{\text{electrol.}}\varepsilon_{\text{sep}} + \delta_{\text{cc}}\rho_{\text{cc}} \qquad (7)$$

where ε is the porosity of the various cell components.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto064
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The thickness of the cell is simply

$$\delta_{\text{cell}} = \delta_{-} + \delta_{+} + \delta_{\text{sep}} + \delta_{\text{cc}} \tag{8}$$

The energy stored in the cell is given by

$$(\text{Wh/cm}^2) = V_{\text{cell}}(\text{Ah/g})_{-}\delta_{-}\rho_{\text{metal}}(1-\varepsilon_{-})\ \text{UL}_{\text{f canactor}} \tag{9}$$

The energy densities are given by

$$(\text{Wh/kg}) = (\text{Wh/cm}^2)/(\text{Wt/cm}^2)_{\text{cell}} \tag{10}$$

$$(\text{Wh/L}) = (\text{Wh/cm}^2)/\delta_{\text{cell}}$$

In calculating the cell energy densities for a specific metal–air chemistry, the key design parameters are $N_{\text{per.}}$, $\text{UL}_{\text{factor}}$, δ_{-}, component porosities ε, and the A/g, the current density at the air cathode. The discharge time of the cell at the maximum steady power is simply $1/N_{\text{per.}}$

The steady power capability of the cell is given by either

$$(\text{W/cm}^2) = N_{\text{per}}(\text{Wh/cm}^2)$$

or

$$(\text{W/cm}^2) = V_{\text{cell}}(\text{A/g})_{+}\delta_{+}\rho_{+}(1-\varepsilon_{+}) \tag{11}$$

The power densities are given by

$$(\text{W/kg}) = (\text{W/cm}^2)/\text{Wt/cm}^2$$

$$(\text{W/L}) = (\text{W/cm}^2)/\delta_{\text{cell}}$$

The steady power capability of the cell is proportional to A/g at the air cathode. The pulse power of the cell will be dependent on the resistance of the cell for short pulses of 5–10 s.

$$P = \text{EF}(1-\text{EF})\ V^2/R_{\text{cell}} \tag{12}$$

where EF is the efficiency of the pulse.

The voltage drop across the cell is the sum of the voltage drops across the anode and cathode electrodes and the separator. Hence,

$$V_{\text{oc}} - V = (\text{Ovp})_{\text{anode}} + \left[\left(\delta_{+}\varepsilon_{+}{}^{-1.5} + \delta_{-}\varepsilon_{-}{}^{-1.5}\right)/2 + \delta_{\text{sep}}\varepsilon_{\text{sep}}{}^{-1.5}\right]\kappa_{\text{electrolyte}}\left(\frac{\text{A}}{\text{cm}^2}\right) + (\text{Ovp})_{\text{aircathode}} \tag{13}$$

The effective resistance R_{cell} is given by

$$R_{\text{cell}} = V_{\text{oc}} - V\,/\text{A/cm}^2(\text{Ohm}-\text{cm}^2)$$

$$V_{\text{cell}} = V_{\text{oc}} - R_{\text{cell}}(\text{A/cm}^2) \tag{14}$$

Overpotential data for both discharge and charge currents are show in Figure 2 for various catalysts (Martin *et al.*, 2009). The V_{cell} used in Equations (8) and (10) for the energy and power densities should include the cell resistance given in Equation (13).

This model can be used to project the performance characteristics of metal–air batteries. This will be done for Zn–air and Li–air batteries in the following sections. A summary of the input parameters for the metal–air cell calculations is given in Table 6.

3.4 Zn–air batteries

As indicated in Table 5, the potential energy density of the Zn–air battery is quite high (1300 Wh/kg), but the practical energy density is much lower. In this section, the previously discussed modeling equations are used to estimate the energy density and power capability that can be expected in practical designs. The electrochemistry of the electrodes in the Zn–air battery is quite complex, but it can be simplified as follows:

Zn anode:

$$\text{Zn} + 4\text{OH}^{-} \rightarrow \text{Zn(OH)}_4{}^{-2} + 2\text{e} \qquad V_{\text{eq.}} = 1.22 \tag{15}$$

$$\text{Zn(OH)}_4{}^{-2} \rightarrow \text{ZnO} + \text{H}_2\text{O} + 2\text{OH}^{-}$$

Air cathode:

$$1/2\text{O}_2 + \text{H}_2\text{O} \rightarrow 2\text{OH}^{-} \qquad V_{\text{eq.}} = 0.40 \tag{16}$$

Overall reaction:

$$\text{Zn} + {}^{1}/_{2}\,\text{O}_2 \rightarrow \text{ZnO} \qquad V_{\text{eq.}} = 1.62 \tag{17}$$

The electrolyte used in the Zn–air cell is KOH. The cell geometry is illustrated in Figure 1. The reactions shown are for the discharge of the cell. The reactions proceed in the reverse directions for charging the cell. Note that the oxygen reacted at the air electrode is taken from the ambient air. The construction and functioning of the air electrode (cathode) is complex (Reddy, 2011a; Schalkwijk and Scrosati, 2002; Thackeray *et al.*, 2007; Marom *et al.*, 2011; Zhang, Zhang, and Amine, 2011a; Horino *et al.*, 2010; Smart *et al.*, 2011; Hassoun *et al.*, 2010; Nelson *et al.*, 2002; Barnett, 2011; Burke and Miller, 2011; Burke and Miller, 2009a, b; Reddy, 2011b; Kowalczk, Read, and Salomom, 2007; Dahn; Lee *et al.*, 2011; Girishkumar *et al.*, 2010; Kraytsberg and Ein-Eli, 2011; Zhang *et al.*, 2011b; Martin *et al.*, 2009; Neburchilov *et al.*, 2010; Yuasa *et al.*, 2011; Wei *et al.*, 2000). It is particularly difficult to develop the bidirectional air electrode needed for vehicle

applications in which high power in charging is required for regenerative braking and battery recharging in an hour or less is desirable. High power air electrodes operating in the discharge direction have been developed for use in fuel cell applications.

Equations (1–14) can be used to prepare an EXCEL spreadsheet to analyze the cell energy density and power capability. The primary design inputs are the following:

Cell power-to-energy ratio N_{per}
Thickness of the air cathode δ_+
Current density of the air cathode A/g
Utilization factor of the anode UL_{factor}

Note that $1/N_{per}$ is the discharge time of the cell at the current density A/g. The voltages of the anode and cathode depend on the equilibrium voltage $V_{eq.}$ and the overpotentials η of electrodes. The voltage at an electrode is given by

$$V_{electrode} = V_{equil.} - \eta$$

The overpotentials depend on the current density and can be obtained from detailed modeling of the electrodes (White, 2005; Mao and White, 1992) or from test data (Martin *et al*., 2009; Neburchilov *et al*., 2010; Yuasa *et al*., 2011; Wei *et al*., 2000). There is considerable uncertainty concerning the characteristics of the air cathode because the overpotential depends critically on the catalyst being used. The electrode inputs used in the present analysis are given in Table 6.

For a given set of design inputs and electrode current A/g, the ratio of the electrode thicknesses and then the thickness of the anode (metal electrode) can be calculated from Equation (6). The current density (A/cm^2) and energy stored (Wh/cm^2) follow from Equations (5) and (9). The weight of the active materials in the cell and its thickness are given by Equations (7) and (8). The Wh/kg and Wh/L follow from Equation (10). The steady power density (W/kg and W/L) are calculated using Equation (10). The cell voltage, resistance, and the pulse power characteristics of the cell can be calculated using Equations (12–14) for various current densities (A/cm^2). These calculations will include charging currents (oxygen evolution) and will be an indication of the ability of the cell for regenerative braking and recharge. The charging efficiency is given by

$$EF_{charging} = (V - V_{oc})_{charging}/V_{oc}$$

The spreadsheet model was utilized to obtain the results shown in Table 7 for number of combinations of input parameters. The cell design parameters that varied in the calculations were the thickness and current density (A/g) of the air cathode and the discharge time ($1/N_{per}$) of the cell. Discharge times of 3, 5, and 10 h were considered. These are short discharge times for zinc–air batteries, but reasonable for batteries intended for vehicle applications. The results in Table 7 indicate that cells with energy densities in the range of 500–600 Wh/kg

[a] $UL_{factor} = 0.65$.

and 2100–2400 Wh/L (not including packaging) could be possible for zinc–air batteries. The power capability of the cells is relatively low being in the range of 200–300 W/kg for cells with a discharge time of 3–5 h. The calculations indicate that an air cathode thickness of about 0.15 mm seems to result in reasonable anode thicknesses. A zinc utilization of 65–70% was assumed in the calculations based on the detailed modeling results given in White (2005) and Mao and White (1992).

3.5 Lithium–air batteries

As indicated in Table 5, the theoretical energy density of lithium–air batteries is the highest of the various metal–air chemistries. For that reason, there is considerable research underway (Girishkumar *et al*., 2010; Kraytsberg and Ein-Eli, 2011; Zhang *et al*., 2011b) to understand the science needed to develop lithium–air batteries for vehicle applications. The lithium–air cell utilizes lithium metal at the anode and a bifunctional air cathode. Uniform deposition of the lithium at the anode during recharge is critical to the safe and long cycle life operation of the cell. Cells can incorporate either an aqueous or an organic electrolyte.

The electrochemistry of the battery is relatively simple. In the case of cells using an organic (nonaqueous) electrolyte, the reactions for cell discharge are

Anode:

$$Li \rightarrow Li^+ + e$$

Cathode:

$$O_2 + 2Li^+ + 2e \rightarrow Li_2O_2 \qquad V_{eq.} = 3.1$$

$$O_2 + 4Li^+ + 4e \rightarrow 2Li_2O \qquad V_{eq.} = 2.91$$

The dominate reaction yields Li_2O_2, which is not soluble in the organic electrolyte. The reaction to form Li_2O_2 takes place in a porous carbon electrode with a catalyst and can be reversible at low rates. The open-circuit voltage of this cell is about 3 V. A thin protective layer is applied to the anode to prevent the formation of a barrier layer that impedes diffusion of the lithium ions. This and other challenges seem to have led to minimal work to develop rechargeable lithium–air cells using organic electrolytes. The reactions in charging are the reverse of those shown for discharge. It is important that the reaction rates are reasonably fast in both directions.

In the case of lithium–air cells using aqueous electrolytes, the reactions are

Anode:

$$Li \rightarrow Li^+ + e \qquad V_{eq.} = 3.04 \qquad (15)$$

Cathode:

$$O_2 + 2H_2O + 4e \rightarrow 4OH^- \qquad V_{eq.} = 0.40 \qquad (16)$$

$$4Li^+ + 4OH^- \rightarrow LiOH$$

Overall reaction:

$$4Li + O_2 + 2\,H_2O \rightarrow 4\,LiOH \qquad V_{eq.} = 3.44 \qquad (17)$$

The LiOH is soluble in the aqueous electrolyte and thus does not clog the pores of the air cathode. The cathode reaction is reversible, so it is possible to develop electrically rechargeable cells.

Since lithium reacts vigorously in water, it is necessary to apply a protective film on the lithium metal anode. In addition, a buffer layer is needed between the lithium foil and the protective film to minimize the formation of dendrites during recharging of the cell. The protective film is a lithium-conducting glass ceramic and the buffer layer can be a solid material or a polymer electrolyte. With these protective layers, the lithium metal anode can be stable in

[a] ULfactor = 0.5, $\delta_{sep} = 150\,\mu$

the aqueous electrolyte. However, the protective layers do have high ionic resistance, which must be greatly reduced in order for the lithium–air cells to have power capability suitable for vehicle applications. Hence, it can be expected that lithium–air batteries would have high energy density (a theoretical value of 2450 Wh/kg including oxygen), but relatively low power capability. The open-circuit voltage of the cell using an aqueous electrolyte is 3.84 V. The cell is stable at that high voltage because about 3 V occurs at the buffer layer leaving only about 0.8 V at the air cathode with the aqueous electrolyte.

Most lithium–air cells developed to date have not been electrically rechargeable (i.e., primary cells). However, it is possible that rechargeable cells can be developed. As discussed in connection with the zinc–air cells, bifunctional air electrodes with aqueous electrolytes have been the subject of active research for many years. The recharge rates (mA/cm^2) at the air cathode are dependent on the use of catalysts. Progress in the development of catalysts that will permit increased recharge rates is being made. Owing to the voltage drops at the anode protective layers and the air cathode, it seems likely that the charge efficiency will be low even for recharge times of many hours.

The projected performance of lithium–air cells using an aqueous electrolyte can be made using Equations (1–14) that were applied previously to develop a spreadsheet model for the Zn–air cells. A major difference between the two chemistries is the need for an anode protective layer in the case of the lithium–air cell. Input parameters for the lithium–air calculations are included in Table 6. In the case of the protective layer, it is assumed that further development of that technology will result in lower resistance (reduced Ohm-cm) and thinner layers than is presently possible. Otherwise, the power capability of the cells will not be suitable for vehicle applications. A summary of calculated characteristics of the lithium–air cells is given in Table 8.

Although the calculated cell performance does not include cell packaging, the results shown in Table 8 indicate that the water-stable lithium–air cells show good promise for vehicle applications with energy densities >2500 Wh/kg and 1500 Wh/L for packaged cells. The power capabilities seem reasonable and are sufficiently high that the lithium–air cells combined with high power lithium-ion batteries or ultracapacitors should meet the power requirements for vehicles.

4 TEST DATA AND THE STATUS OF ADVANCED BATTERIES OF VARIOUS BATTERY CHEMISTRIES

The design and performance of advanced batteries have been discussed in the previous section. The energy densities of the batteries have been projected based on available information on the electrode materials and electrolytes. In this section, test data are presented for lithium and metal–air cells. Unfortunately, the data available are very limited especially for the most advanced chemistries.

4.1 Lithium batteries

Test data are available for cells using the various lithium chemistries that have been commercialized. Test results (Burke and Miller, 2009a, b) are summarized in Table 9. The energy densities of the cells vary significantly between the various chemistries, the sizes (Ah), and power capabilities. The maximum energy density of the commercially available cells using graphite in the anode is 150–170 Wh/kg, which is somewhat lower than the

projections given in Table 4, because the projection values do not include packaging of the cells. In addition, most of the available cells have been designed to provide high power. The power values (W/kg) given in Table 8 can be achieved in lithium batteries for both discharge and charge pulses. As indicated in Table 10, lithium batteries can be fast charged in 10–15 min. Hence, in all respects, available lithium batteries have power capabilities suitable for vehicle applications.

There is essentially no test data available for packaged lithium cells using the advanced layered–layered nano-metal clusters media (NMC) composites in the cathode and silicone–carbon anodes. A summary (Barnett, 2011) of data for some laboratory cells using the advanced materials is shown in Figure 3. The data indicate the wide range of specific capacity (mAh/g) and voltages for the various chemistries.

4.2 Metal–air batteries

Modeling results for the metal–air batteries are given in Tables 7 and 8. The cell projections were done assuming electrically rechargeable cells even when the bifunctional air cathode technology for reasonable recharge times has not yet been developed. For this reason, most of the commercial metal–air cells are not rechargeable (i.e., primary cells). Nevertheless, several examples of those cells will be given to indicate the present status of the metal–air battery technology.

4.3 Zinc–air

Zinc–air coin cells for hearing aids are manufactured in very large quantity around the world. These small cells (150–300 mAh) have an energy density of about 400 Wh/kg and maximum power rating of about 5–8 mW/g. They are not rechargeable and have very low power and thus the technology is not suitable for vehicle applications.

There has been considerable R & D to develop larger cells for use in cell phones and vehicles of various sizes from passenger cars to buses. Some of the development has been recent (Revolt portable battery-Technology Brief, n.d.) and others in the more distant past (Goldstein and Koretz, 1994; Schimpf, 1995; Cheiky, Danczyk, Wehrey, 1990) as an effort to develop advanced batteries for electric vehicles. However, these efforts have not yet resulted in commercial products.

Revolt Technology in Switzerland is developing a rechargeable cell for cell phones (Revolt portable battery-Technology Brief, n.d.). A photograph of a 10-Ah, 1.2-V cell is shown in Figure 4. The cell shown has energy densities of 450 Wh/kg and 1040 Wh/L. The power capability of the cell is about 200 W/kg, which is much lower (about a factor of 10) than required for vehicle applications.

Figure 4. A 10-Ah rechargeable, Zn–air cell Revolt technology.

As discussed in (Goldstein and Koretz, 1994; Schimpf, 1995; Cheiky, Danczyk, Wehrey, 1990), large Zn–air batteries have been assembled for testing in electric passenger cars, vans, and buses. Both mechanically rechargeable and electrically rechargeable systems were developed. The mechanically recharge units (battery switching) by *Electric Fuel* in Israel were large (110 kWh) and had an energy density of 230 Wh/kg and 230 Wh/L. The batteries were relatively low power with a power density of 100 W/kg. There was considerable in-vehicle testing of *Electric Fuel* batteries in vans and buses (Goldstein and Koretz, 1994). Electrically rechargeable cells were developed by AER Energy Resources Energy Resources (Schimpf, 1995) and Dreisbach Electromotive (DEMI) (Cheiky, Danczyk, Wehrey, 1990) in the 1990s. These batteries had energy densities of 180 Wh/kg and 150 Wh/L and pulse power of about 200 W/kg. Hence, the rechargeable Zn–air batteries of the 1990s had much lower energy density and power than the present lithium-ion batteries. It is uncertain (Table 7) whether the more recent developments in Zn–air batteries will result in batteries of high enough energy density and power capability for vehicle applications.

4.4 Lithium–air

In recent years, there have been many claims that lithium–air batteries can be the answer to the marketing of electric cars with ranges comparable to gasoline-fueled vehicles. In a recent news release (IBM, 2012), IBM claims a breakthrough that will permit the development of lithium–air batteries for a 500-mile range electric vehicle by 2020. This will require batteries with an energy density of about 2000 Wh/kg and adequate power capability to maintain the vehicle at 70–75 mph. In addition, the battery will require a recharge capability of several hours and a low cost and long calendar and cycle life of 10–15 years. As discussed earlier in this section, this will require technical breakthroughs in the areas of a low resistance protective film for the lithium metal anode and large advances in the performance of the bifunctional air cathode. Present technology in those areas is very much inadequate for the development of lithium–air batteries for vehicle applications.

The present status of lithium–air battery technology is given in Reddy (2011b), Girishkumar *et al*. (2010),

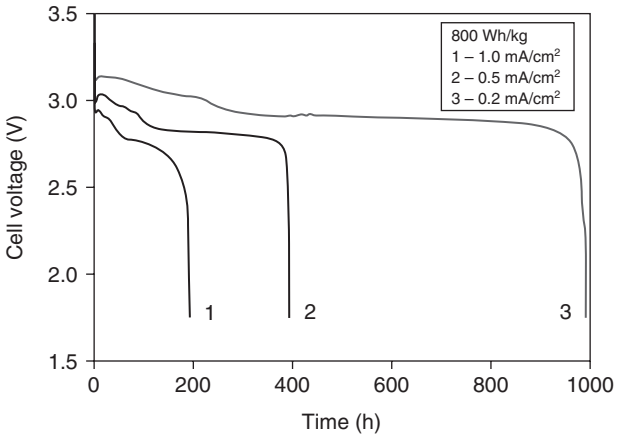

Figure 5. Lithium–air cell and discharge curves. (Reproduced with permission from T.B. Reddy, Linden's Handbook of Batteries (Reddy, 2011b) © The McGraw-Hill Companies, Inc.)

Kraytsberg and Ein-Eli (2011), Zhang *et al*. (2011b). An example of the present technology shown in Figure 5 is taken from Reddy (2011b). The energy density of the cell can be very high, but the discharge times are very long. Practical batteries for oceanic applications are being tested by *Polyplus* (Polyplus, 2009), but those batteries are not rechargeable and have discharge times of many months.

Projections of the performance of lithium–air batteries that could be suitable for vehicle applications are given in Table 8. These projections require technologies that do not presently exist, but much R & D is being done on lithium–air cell technologies that could result in advances making possible lithium–air batteries for vehicles.

5 VEHICLE CALCULATIONS USING ADVANCED BATTERIES

In this section, the application of the advanced batteries in PEVs will be considered.

5.1 Electric vehicles

The design parameter of primary interest for EVs is the range (miles). Using the high energy density advanced batteries, it is reasonable to consider ranges up to 300–500 miles. The battery for the EV is sized by the energy storage requirement (kWh), which depends on the energy use (Wh/mi) of the vehicle and the fraction of the energy stored that can be used on a regular basis. The battery pack weight and volume are design inputs and the required cell performance parameters (Wh/kg and Wh/L) depend on the packaging factors relating to cell and pack weight and volume. As discussed in Section 2, the vehicle energy use depends on vehicle weight and road load parameters and is in the range of 200–250 Wh/mi for most EV designs. The cell/battery packaging factors are highly dependent on battery pack design and are expected to improve markedly in future years from the present low values in the Leaf and Volt. It seems reasonable to assume values of 0.75 and 0.5 for the weight and volume packaging factors, respectively. Calculations of the resultant cell energy and power density requirements are shown in Table 11.

Comparison of these cell requirements with the cell performance projections for advanced lithium chemistries in Table 4 indicate that for well-designed battery packs and vehicles with reduced weight and road load, the advanced lithium chemistries may satisfy the cell requirements for up to 300-mile range, but not 400–500-mile range. The power density requirements are well within the capability of the advanced lithium batteries.

It appears that the metal–air batteries would be needed to extend the range of the electric vehicles beyond about 300 miles. The projected energy density of the zinc–air and Li–air batteries are given in Tables 7 and 8. The energy density of the metal–air batteries seems to be adequate for the long-range EVs, but there are questions concerning the adequacy of their power capability. It is likely necessary to combine a high power battery or ultracapacitor with the metal–air battery to meet the power requirements of the vehicles.

Table 11. Cell performance requirements for various range EVs.

Range (miles)	Energy Stored (kWh)	Pack Weight (kg)	Pack Volume (L)	Cell Weight (kg)	Cell Volume L	Cell Energy Density (Wh/kg)	Cell Energy Density (Wh/L)	Power (kW)	Cell Power Density (W/kg)
100	25	250	200	188	100	133	250	80	320
200	50	250	200	188	100	266	500	80	320
300	75	300	250	225	125	333	600	75	250
400	100	300	250	225	125	444	800	75	250
500	125	300	250	225	125	555	1000	75	250

Vehicle energy use 200 Wh/mi, usable energy fraction 0.8, weight packaging factor 0.75, volume packaging factor 0.5.

5.2 Plug-in hybrid vehicles

At the present time, PHEVs such as the Volt are limited to about a 40-mile electric range in order to fit the battery into the vehicle without compromising its functionality. With the higher energy density of the advanced batteries, PHEVs will be possible with electric ranges of 50–75 miles. For 75-mile range, the battery pack would need to store about 19 kWh. If the energy densities of the cells are 300 Wh/kg and 650 Wh/L with the same packaging factors used in Table 11, the cell weight and volume for a 75-mile PHEV would be 63 kg and 29 L resulting in a battery pack weight and volume of 84 kg and 58 L. Hence, the battery pack in the PHEV would be much smaller than that in an electric vehicle. Assuming the same power rated electric drive in the PHEV as in the EV, the power requirements of the cells would be 1190 Wkg and 2586 W/L. These are high power requirements that may not be able to be met with the advanced lithium cells even using thin electrodes. If they cannot be met, the advanced battery can be combined with an ultracapacitor to provide the maximum power for acceleration and regenerative braking.

5.3 Combinations of advanced batteries and ultracapacitors

Computer simulations of PHEVs using the advanced batteries are presented in Burke and Miller (2010) and King *et al*. (2003). Simulation results are given for vehicle operation using the batteries alone and in combination with ultracapacitors. In a PHEV, if the batteries are power limited, the additional power is provided by the engine even when the vehicle is operating in the battery charge depletion mode. This type of operation is called the *blended* mode of operation. In the case of batteries combined with ultracapacitors, the ultracapacitors provide the peak power and the batteries provide the average power over the driving cycle. In addition, the ultracapacitors accept all the charge during regenerative braking. Results are given in Table 12 for a PHEV using a zinc–air battery and carbon/carbon ultracapacitors on various driving cycles.

All the simulations were performed using the following vehicle inputs:

$C_D = 0.27$, $A_F = 2.2$ m^2, $f_r = 0.008$, test weight = 1650 kg (approx.)
Engine: Honda 1.3L, iVTEC engine map, scaled to 90 kW
Electric motor: Honda hybrid Civic AC PM 2006 efficiency map, scaled to 70 kW
DC/DC inverter: constant efficiency 0.96
Transmission: 5-speed manual (3.11, 2.11, 1.55, 1.0, 0.71, FD = 3.95), automatically shifted.

The characteristics of the battery and ultracapacitors are as follows:

Zinc–air batteries:
Zn–air 32 kg 60 Ah cells 180 in series 9.5 kWh useable
385 Wh/kg 156 W/kg, 95% effic., 616 W/kg, 75% effic.

Carbon/carbon ultracapacitors:
Symmetric C/C 20 kg 1350 F cells 110 in series
100 Wh usable
5.5 Wh/kg 2320 W/kg, 95% effic., 11.6 kW/kg, 75% effic.

The nominal energy storage unit voltage was 240 V (approximately) with the maximum currents limited to about 300 A even in the cases of the batteries alone. In all cases, the batteries were depleted to 30% state of charge (SOC) from 100% SOC in the charge depleting mode of operation.

Note that the zinc–air battery is power limited with a peak power density for efficient pulses of only 156 W/kg.

The carbon/carbon ultracapacitor has a high power density of over 2 kW/kg for both discharge and charge pulses.

Simulations were made for the FUDS, Federal Highway, and ES06 driving cycles. For each of the driving cycles, runs were made for selected numbers of cycles to represent driving in the charge depleting and charge sustaining modes of operation. The all-electric range and energy use (Wh/mi) were determined for the charge depleting mode, and the fuel economy (mpg) was determined for all cases/modes in which the engine was operating.

The simulation results in Table 12 show the advantages of using ultracapacitors in combination with batteries especially ones with limited power capability. With the batteries in combination with the ultracapacitors, the PHEV was able to operate in the all-electric mode until the battery SOC was equal to 30% on the FUDS and Federal Highway driving cycles. In all cases for the ES06 driving cycle, the vehicle had blended operation (engine and electric drive both needed) in the charge depleting mode. The use of the ultracapacitors with the batteries permits all-electric operation of the vehicle over a wide range of driving conditions and more use of electrical energy (higher Wh/mi) for all the driving cycles. Even when the engine is needed in the charge depleting mode, the fuel economy (mpg) is higher by 50–100% using the ultracapacitors. The fuel economy in the charge sustaining mode is also higher for all the driving cycles using the ultracapacitors by about 30%. The acceleration times of the vehicle were lower using the ultracapacitors than for the batteries alone. With the ultracapacitors, the acceleration times were 2.7 s for 0–30 mph and 6.9 s for 0–60 mph. For the batteries alone, the acceleration times were 3.1 s for 0–30 mph and 8.6 s for 0–60 mph. Hence, in all respects, vehicle performance was improved using the ultracapacitors with the zinc–air battery.

The current and voltage responses of the battery with and without the ultracapacitors are shown in Figure 6 for the FUDS driving cycle. The effects of the load leveling of the power demand from the battery using the ultracapacitors are evident in the figure. Both the average currents and the peak currents from the batteries are lower by a factor of 2–3 using the ultracapacitors. The minimum voltages of the battery are significantly higher using the capacitors, and the voltage dynamics (fluctuations) are dramatically reduced. Hence, the stress on the battery and resultant heating are much reduced. The simulation results in Figure 6 also show that the ultracapacitors are utilized over a wide voltage range, indicating that a large fraction of their usable energy storage (100 Wh) is being used to load level the batteries. This is only possible using a DC/DC converter between the battery and the DC-bus. The use of the ultracapacitors will permit the use of the advanced batteries in PHEVs even when their power capability is limited.

6 SUMMARY AND CONCLUSIONS

This chapter was concerned with the research and development on advanced batteries for PEVs in the next 10–20 years. The primary motivation for the development of the advanced batteries is to permit the design of electric vehicles having ranges comparable to conventional ICE vehicles—300–500 miles. By advanced batteries are meant cell chemistries having energy densities significantly higher than those presently available. These chemistries include (i) lithium-ion cells using layered–layered composites of metal oxides in the cathode, mixtures of carbon and silicone in the anode, and advanced electrolytes permitting cell voltages of 4.5–5 V and (ii) metal–air cells utilizing zinc or lithium in the anode and an air cathode. Research is underway and laboratory cells are being prepared for most of these chemistries, but in nearly all cases, it is anticipated that many years of R & D will be needed before the most advanced batteries could be marketed for use in vehicles. It is expected that some of the new lithium chemistries will be the first of the advanced battery technologies to be marketed in the next 5–10 years. The metal–air batteries are much further in the future and likely will be required to approach the 300–500-mile range goal.

Spreadsheet models of cells using the various chemistries were developed to calculate their energy densities and power capability. In the case of the advanced lithium-ion chemistries, it was found that the largest improvements in cell performance will result from significant increases in cathode charge capacity mAh/g and increases in the cathode voltage. Using silicone–carbon anodes is not projected to have a significant improvement in cell performance compared to using graphite in the anode. For example, for a cell having a 50-μ thick cathode, the energy densities using graphite and a layered-composite cathode are projected to be 334 Wh/kg and 710 Wh/L at a cell voltage of 4.5 V compared to 289 Wh/kg and 620 Wh/L at the lower voltage of 4 V. The power potential using the higher cathode voltage is also significantly higher. Large differences in cell performance and power capability result from changes in the electrode thicknesses, and comparisons in cell performance for different electrode chemistries should be done at the same electrode thickness. The model results for the advanced lithium-ion cells indicate that energy densities of 350–400 Wh/kg and 750–800 Wh/kg (unpackaged) are possible at power capabilities suitable for vehicle applications. With improvements in plug-in vehicle design (lower weight and energy consumption-Wh/mi), the advanced lithium batteries could be used in 250–300-mile range vehicles.

Zinc–air and lithium–air cells were also modeled to project their performance. Both metal–air systems were modeled using an aqueous electrolyte (KOH) and a carbon/catalyst air cathode. In the case of the lithium–air cell, a ceramic protective film was used on the anode to make the cell water-stable. In the case of the zinc–air cells, the projected energy densities were 500–600 Wh/kg and 2000–2400 Wh/L (unpackaged) depending on the discharge time and air cathode current density assumed. The power capability of the Zn–air cells was relatively low in the range of 150–300 Wh/kg. The projected energy densities of the lithium–air cells were 2000–3000 Wh/kg and 2000–2500 Wh/L (unpackaged) depending on the resistance (Ohm-cm^2) assumed for the anode protective film and the current density of the air cathode. In all cases for the lithium–air calculations, it was assumed that large reductions in the present high resistance of the anode protective film would occur in the future. The power capability of the lithium–air cells with the improved protective film was 1000–1500 W/kg, which was much higher than that for the Zn–air cells. The higher power capability of the Li–air cells is primarily due to their higher cell voltage.

It appears that the metal–air batteries would be needed to extend the range of the electric vehicles beyond about 300 miles. The energy density of the metal–air batteries seems to be adequate for the long-range EVs, but there are questions concerning the adequacy of their power capability. It is likely necessary to combine a high power battery or ultracapacitor with the metal–air battery to meet the power requirements of the vehicles.

NOMENCLATURE AND ABBREVIATIONS

AER	all-electric range
ICE	Conventional vehicle with engine and transmission
EV	Electric vehicle (battery-powered)
HEV	Hybrid-electric vehicle (charge sustaining with electric motor and engine)
LMO	Lithium Manganese Oxide
NMC	Nickel Manganese Cobalt
PHEV	Plug-in hybrid electric vehicle with a rechargeable battery
PHEV-XX	PHEV vehicle with an all-electric range of XX miles
C_d	drag coefficient of the vehicle
A_f	frontal area of the vehicle (m^2)
$f_{rolling}$	rolling resistance of the tires (kg/kg)
W_V	inertia weight of the vehicle (kg)
L/100 km	fuel economy in terms of liters per 100 km
mpg	fuel economy in terms of miles per gallon
Wh/mi	electrical energy from the battery
$(kWh)_{useable}$	useable energy (kWh) from the battery
Wh/kg	energy density of the battery
W/kg	power density of the battery
Ah	Amp-hour capacity of a cell in the battery

Battery Safety for Lithium Batteries in Vehicle Applications

Andrew Burke
University of California, Davis, CA, USA

1 INTRODUCTION

There are safety concerns with all of the lithium battery chemistries. These concerns stem primarily from failures experienced with cylindrical 18650 $LiCoO_2$ cells in laptop computers. For this reason, lithium batteries have been used with caution in vehicle applications. The primary concern is the possibility of thermal runaway due to an internal short in the battery caused by a manufacturing flaw or abnormally high currents or temperatures due to a failure of the battery control unit or in the case of a vehicle accident. This concern has been addressed in two ways. First, extensive abuse testing of lithium batteries has been done to show that thermal runaway does not occur even if the cells or modules are subject to sudden compression, intrusion of sharp objects, dropping, fire, and so on. The second approach to battery safety is to provide a battery management system (BMS) that monitors the cell/module voltages and temperatures and alerts the vehicle control system/computer if any of the cell voltages or temperatures is outside a specified normal range. Development of a BMS unit for use with their battery is common practice for battery manufacturers. All of these aspects of lithium battery safety are discussed in this article.

2 SAFETY CONCERNS FOR LITHIUM BATTERIES

The concern for safety is especially significant for lithium batteries because of their high energy density and capability to store large quantities of energy and the fact that they use organic electrolytes that are highly flammable and toxic. Battery failures can result from operation of the batteries outside of normal operating conditions due to a failure of the battery control and monitoring systems or due to a vehicle accident that could subject the battery to abnormal physical conditions such as crushing or metal penetration. These types of battery failures are addressed in abuse testing of the cells/batteries as discussed in Sections 3 and 5 of the chapter. A second type of battery failure, often referred to as *field failures*, can occur suddenly with little warning during what appears to be normal operation of the battery. These failures usually result from internal "shorts" in a cell due to flaws in the manufacture of the cell. This type of failure is considered in Sections 4 and 6. Primarily because of safety concerns, all lithium batteries are equipped with

Table 1. Relative thermal stability and safety of various lithium battery chemistries.

Lithium Cell Chemistry	Temperature of the Onset of Self-heating (°C)[a]	Heat Release Tendencies	Relative Thermal Stability[b]	Relative Safety Concerns[b]
$LiCoO_2$	185	High	6	6
$LiNi_xCo_yAl_zO_2$	195	High	5	5
$LiNi_xCoyMn_zO_2$	210	Medium	4	4
$LiMn_2O_4$	200	Low	3	3
$LiFePO_4$	225	Low	2	2
$Li_4Ti_5O_{12}/LiMn_2O_4$	200	Low	1	1

[a] Significant self-heating resulting in temperature rise of 1°C/min.
[b] 1 (best)–6 (worst).

Table 2. Summary of abuse testing categories and tests.

Mechanical abuse
- Mechanical shock
- Vibration
- Drop test
- Penetration (nail)
- Immersion (water)
- Crush

Thermal abuse
- Radiant heat (simulated fire)
- Thermal stability (maximum temp.)
- Accelerating rate calorimetry (ramp)
- Overheat/thermal runaway

Electrical abuse
- Short circuit
- Overcharge
- Overdischarge

Table 3. Example of core abuse tests performed on most cells.

Overcharge
- Low rate at 1C, high rate at 3–4C
- Overvoltage of 0.5–1.0 V
- Test for heat and gas generation and possible thermal runaway

Short circuit
- Hard short (1 mΩ)
- Intermediate short (equal to unit impedance)

Thermal stability
- Controlled ramp rate up to 200–250°C
- Test of onset of thermal runaway reactions
- Test flammability of vent gases

Controlled crush and penetration
- 50% max. deformation (load max < 1000x battery weight)
- Nail penetration test at several rates

an extensive battery management and monitoring system, which is intended to mitigate safety issues and, if possible, issue a warning to the vehicle operator of an impending failure. In most cases, the battery monitoring is done on a cell basis. BMSs are discussed in Section 7.

The safety concerns for various lithium battery chemistries are discussed in detail in the next sections. Detailed consideration is given to the analysis of the relative thermal stability of the different chemistries in Section 5. The conclusions of these considerations are summarized in Table 1. Since there are wide variations in the tendencies of the different chemistries to experience thermal events, including runaway, it is necessary to understand the differences and the reasons for them. Approaches for investigating these differences are discussed in the following sections.

3 ABUSE TESTING OF BATTERIES

Abuse testing of lithium batteries is well documented in the literature and the procedures used in the testing are also specified in detail (Battery Safety, 2011; Mikolajczak *et al*., 2011; Roth, 2009; Roth, Wunsch, and Orendorff). Abuse testing is done in several categories: (i) mechanical, (ii) thermal, and (iii) electrical. As shown in Table 2, there are a number of tests done in each category. In most cases, the test conditions would not be encountered in normal operation of the battery, but might be encountered due to a malfunction of the battery control system or in the event of a vehicle accident on the road. One of the objectives of the abuse testing is to determine the extent of the abuse that a particular battery can tolerate. Therefore, the abuse testing is often done to induce battery failure and destruction with the intent of comparing the tolerance of various lithium battery chemistries and mechanical designs.

An example of a core set of abuse tests is given in Table 3. The testing is usually done with the cell/battery at full charge. These tests are customarily performed by the developer to demonstrate the safety of their cells. Testing at extreme conditions to determine the safety limits of specific cell chemistries and designs is usually done at DOE

Table 4. Summary of hazard level designations for abuse testing.

Hazard Level	Description	Classification Criteria, Effect
0	No effect	No effect, no loss of functionality
1	Passive protection activated	No defect, no leakage, no venting, no fire or flame, no rupture, no explosion, no exothermic reaction or thermal runaway. Cell reversibly damaged. Repair of protection device needed
2	Defect/damage	No leakage, no venting, no fire or flame, no rupture, no explosion, no exothermic reaction or thermal runaway. Cell irreversibly damaged, repair needed.
3	Leakage $\Delta m < 50\%$	No venting, no fire or flame, no rupture, no explosion, weight loss <50% of electrolyte weight. (electrolyte = solvent + salt)
4	Venting $\Delta m \geq 50\%$	No fire or flame, no rupture, no explosion, weight loss $\geq$ 50% of electrolyte weight.
5	Fire or flame	No rupture, no explosion, that is, no flying parts
6	Rupture	No explosion, but flying parts, ejection of parts of the active mass
7	Explosion	Explosion, that is, disintegration of the cell

Descriptions adapted from EUCAR and SAND2005-3123.

Figure 1. Battery failure testing at Sandia National Laboratory. (Reproduced from Roth, Winsch, and Orendirff, Sandia National Laboratory.)

National Laboratories such as Sandia National Laboratory (Roth, 2009; Roth, Wunsch, and Orendorff).

The response of the battery/cells to the abuse testing is often rated on a qualitative basis as indicated in Table 4. A response of "hazard level" of 1–4 is preferred, but levels up to 5 are probably acceptable. As shown in Figure 1, abuse testing can result in catastrophic disassembly of the cells without a fire or explosion (Level 6 hazard).

Most abuse testing reported in the literature at the present time (2012) has been done on relatively new cells, but in the future, abuse testing is needed on aged cells and full battery packs. It seems likely that full battery pack abuse testing has been done by battery and/or vehicle developers, but those results are not available in the literature.

4 SUDDEN FAILURE MODES OF LITHIUM BATTERIES

In vehicle applications, safety concerns are related to sudden failure of the batteries that can endanger the vehicle operator and/or lead to destruction of the vehicle. These failures are usually caused by a thermal runaway condition (a rapid increase in temperature and pressure) inside the battery, which can result in disassembly of the battery or a fire. Under some conditions, the thermal runaway can occur in a few seconds with little prior warning that something was wrong. Under more normal conditions, the BMS would alert the vehicle controller that the battery temperature was increasing out of the normal, allowable range, and action

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

would be taken to limit the temperature increase before thermal runaway occurred.

Present thinking is that sudden battery failures could be the result of internal shorts in a cell in the battery pack. The likely scenario (Barnett and Siriramulu, 2011; Barnett *et al*., 2009) is that there are "soft shorts" in the cells which normally result only in localized nonuniform distributions of current in the cells, but not large enough variations to result in localized high temperatures that can lead to thermal runaway conditions. In rare occasions, the "soft shorts" can lead to "hard shorts" and localized high currents and resultant heating that can lead to thermal runaway conditions. This occurrence is a very rare event (occurring in only one in several million cells from high quality battery manufacturers), but nevertheless, cells should be designed to avoid the possibility of thermal runaway. The analysis and testing for thermal runaway and how the possibility of it can be minimized or even eliminated are discussed in Sections 5 and 6.

A "soft short" in a cell is simply a small area (a few square millimeter) for which the resistance (Ω-cm^2) is significantly less than the average for the cell. The result will be that the current (A/cm^2) will be higher through that region of the cell and I^2R heating will result in the temperature being higher than elsewhere in the cell, Over time, this can lead to further degradation of the cell in that region and even a total failure of the separator, leading to direct contact of the positive and negative electrodes. This results in a "hard short", very high currents, very high local heating and temperature rise, and possible total failure of the cell and battery. The initial "soft short" could be the result of a significant nonuniformity in the cell electrode coating during manufacturing or a defect in the separator material. The most likely direct cause of a "hard short" is the presence of a very small metal particle that inadvertently got into the cell during manufacturing or assembly. Such a particle could cause a direct contact between the two electrodes as the cell ages in the vehicle. Overdischarge of the cell could lead to the deposition of copper from the anode current collector, which would also lead to a "hard short". Once a "hard short" is encountered, the cell temperature will increase very rapidly (in seconds) and there is little that can be done to prevent total failure of the battery.

5 ANALYSIS AND TESTING FOR THERMAL RUNAWAY

5.1 Thermodynamic and cell heating considerations

Determination of the change in temperature of a cell under conditions of rapid heating and resultant chemical change inside the cell requires complex modeling (Fang, Kwon, and Wang, 2010; Chen, Wang, and Wan, 2006; Kim, Pesaran, Spotnitz, 2007), but the essence of what is occurring can be expressed in the rather simple equation below:

$$\sum \mathrm{i}\,(m_{\mathrm{i}}C_{\mathrm{Pi}})\mathrm{d}T = (\,I^2R + \sum \mathrm{i}\,(\mathrm{mdot}_{\mathrm{i}}(H_{\mathrm{Ri}}))\mathrm{d}t - IT\,\mathrm{d}S + Q_{\mathrm{heating}} - Q_{\mathrm{loss}} \qquad (1)$$

Subscript "i" refers to the constituent components of the cell (Figure 2). Each of the components has a mass and specific heat ($m_{\mathrm{i}}C_{\mathrm{Pi}}$) associated with it as well as a heat release due to chemical reaction ($\mathrm{mdot}_{\mathrm{i}}$ (H_{Ri})). The heat release term depends on the kinetics of the reaction (mdot), which is highly temperature-dependent. It is this dependency and the magnitude of the heat of reaction that strongly affects the tendency of particular lithium battery chemistries to

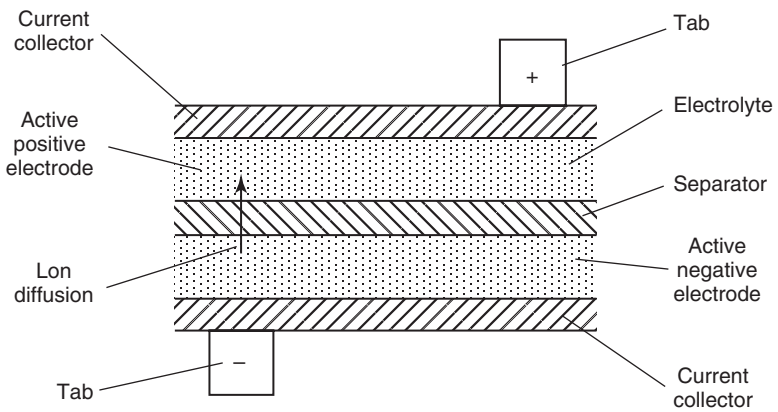

Figure 2. Schematic of the cell components.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto065

experience thermal runaway. $Q_{heating}$ and Q_{loss} are the heating and cooling rates provided to the cell from external sources.

It is of interest to evaluate Equation 1 for the simple case of a hard short in which only the resistant heating is considered. The maximum power discharge condition (matched impedance) corresponds to 50% efficiency for which one-half of the electrochemical energy in the cell is dissipated in heat. If the cell is insulated, an estimate of the temperature increase due to a hard short (very high current) will be the following:

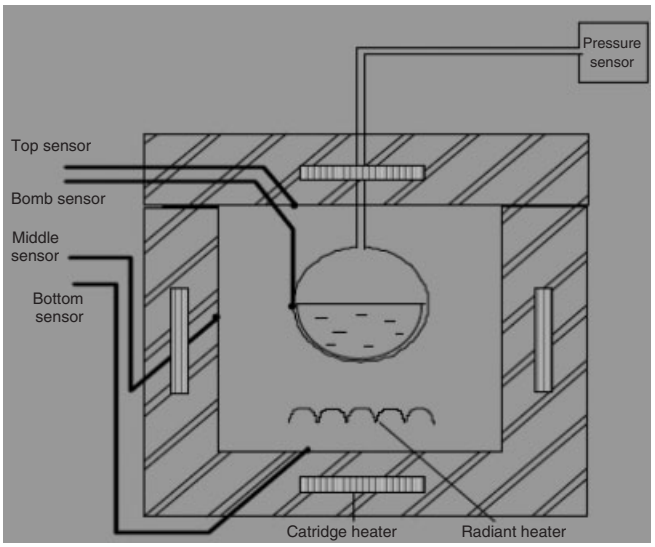
$$\Delta T = {}^1/_2\ (3.6)\ (\text{Wh/kg})/C_p, C_p = 1.1\ \text{kJ/kg}\ ^\circ\text{C}$$

Energy Density (Wh/kg)	ΔT (°C)
100	164
150	245
175	278
200	328

The temperature increase is strongly dependent on the energy density (Wh/kg) of the cell, indicating that the potential for thermal runaway is greater for the higher performance lithium chemistries. The actual increase will be much greater than shown in the table due to the heat release from the chemical reaction (H_{Ri}) at the high temperatures.

Equation 1 considers the total volume and mass of the cell and assumes uniform heating. Thus, the equation determines an average temperature and not the distribution within the cell or the effects of nonuniform heating as would be the case for internal shorts or the penetration of foreign objects. Uniform heating would be appropriate to evaluate the cell response to overcharging or an external short. There has been considerable research (Barnett, 2011; Smith *et al*., 2010; Kim, Pesaran, and Smith, 2008; Keyser, Kim, and Pesaran, 2010) concerned with modeling the response of lithium cells to localized heating. These analyses are complex and require the adaptation of multidimensional, time-dependent finite-element numerical methods to the cell. In addition, they require detailed descriptions of the cell construction and material properties and extensive thermochemical data to model the high temperature chemistry that occurs in the cell. These calculations indicate that localized heating (internal shorts) can lead to thermal runaway conditions in a few seconds under certain conditions of cell design, discharge current, and cooling. These computer results will be discussed later in Section 6.

Much of the available information relative to lithium battery safety is based on testing of cells in a special test apparatus known as an *accelerating rate calorimeter* (*ARC*),



Test chamber with cell

Figure 3. An accelerating rate calorimeter. (Reproduced by permission of Thermal Hazard Technology (2012).)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto065
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

which permits the heating of cells in a systematic way in a controlled, adiabatic environment until the cell undergoes exothermic reactions (often leading to thermal runaway and cell rupture). ARC testing and the information/conclusions gained from that testing are discussed in the next several sections.

5.2 Accelerating rate calorimetry (ARC) testing

Under normal battery operating conditions, the anode, cathode, and electrolyte materials in the battery are stable and the heat generated is due primarily to resistance heating (I^2R). The magnitude of this heating is significant, but the battery temperature can be controlled to 50–60°C by cooling without great difficulty. However, if the battery experiences much higher heating rates than I^2R and the battery temperature increases to much higher values (>100°C), the anode and cathode materials become unstable and begin to react with the electrolyte which itself begins to decompose. These reactions can be exothermic, leading to large increases in internal heating and resultant increases in the cell temperature. The ARC is designed to systematically increase the temperature of the cells and contains the cell fragments and gases if/when it ruptures (Figure 3). The ARC chamber (Thermal Hazard Technology) is constructed of steel and has the capability of controlling its surface temperatures to track the surface temperature of the test cell as it is heated and experiences exothermic reactions. In this way, the cell test is done under adiabatic conditions. The temperature and internal pressure of the cell is recorded during the test and the rate of temperature rise (°C/minute) is determined as a function of test time.

The standard procedure for most of the ARC testing is to gradually increase the cell temperature in steps using the heat-wait-seek approach. After the heat step, the temperature is maintained constant (wait) for 30–35 min, seeking whether the cell will enter into the exothermic mode in which the temperature of cell continues to increase without external heating. This test (Thermal Hazard Technology, 2012) is illustrated in Figure 4 for a 18650 $LiCoO_2$ cell. Note that in this test, thermal runaway started at about 105°C and took place over a period of about 20 min to a maximum temperature greater than 300°C.

Test results (Thermal Hazard Technology, 2012) for an overcharge test of the 18650 cell are shown in Figure 5. The overcharge was done to a voltage of 5 V at a constant current of about 1C. The cell became self-heating in 40 min at a temperature of about 50°C after the start of the overcharge test. The thermal runaway started at about 65 min at a temperature of 100°C. Onset of thermal runaway from the overcharge occurred relatively slowly and seemed to be controllable by cooling and termination of the overcharge.

External short (Figure 6) and nail penetration (Figure 7) tests (Thermal Hazard Technology, 2012) can also be performed in the ARC. In the case of the external short, thermal runaway started about 15 min after the "short" event at about 150°C and took place over about 3 min to a maximum temperature of 450°C. In the case of the nail penetration test, thermal runaway started about 180 min after the "nail" event at about 150°C and took place over about 5 min to a maximum temperature of 450°C. Especially, in the case of the nail penetration, the thermal runaway took place long after the heating event and an initial finding might be that neither test resulted in thermal runaway. However, the thermal runaway event was similar in both cases. All the test results shown (Figures 4–7) are for the 18650 cell. Unfortunately, corresponding data

for other lithium battery chemistries do not seem to be available.

5.3 Thermal runaway sequences for lithium batteries

Test data for several thermal runaway events for 18650 $LiCoO_2$ cells are shown in Figures 4–7. In the case of the events with local heating (external short and nail penetration), the time in which the temperature rises rapidly to a maximum of 450–500°C is 3–5 min. This period is preceded by a longer time in which the temperature rises more slowly, but nevertheless, self-heating (exothermic reactions) is taking place in the cell. It is of interest to understand what is happening chemically in the cell during the complete thermal runaway event. In general terms, as shown in Figure 8, this is presently reasonably well understood for the lithium batteries. The initial step in the self-heating of the battery is the decomposition of the SEI layer and reaction of the anode material (graphite) with the electrolyte. This occurs in the temperature range of 80–120°C. The next steps involve reactions of the cathode materials (composite metal oxides) with the electrolyte and the evolution of oxygen from the cathode. This occurs at temperatures near 150 °C and signals the onset of the rapid rise in the temperature and in most cases ends in a rupture of the cell and venting of gases. Figure 8 shows how the rate of temperature rise (°C/min) changes rapidly from the initial to final phases of the self-heating of the cell. To avoid thermal runaway, it appears necessary to limit the cell temperature to <100°C even when self-heating becomes evident by adequate cooling of the cell. The details of the chemistry and associated temperatures at which the different steps occur vary with the lithium battery chemistry of interest as discussed in the next section.

5.4 Comparisons of the thermal runaway tendencies of lithium batteries of various chemistries

Most of the thermal stability and abuse testing of lithium batteries has been done with 18650 cells of the $LiCoO_2$ chemistry. These cells are used in battery packs for laptop computers and other consumer electronics and are available in very large quantities. Some testing has been done of other lithium battery chemistries. ARC data (Roth, 2009; Roth, Wunsch, and Orendorff; Doughty, 2012) are shown in Figure 9 for several battery chemistries. The data show that there are large differences in the tendencies of the various chemistries to experience thermal runaway. The $LiCoO_2$ and Li NiCoAl composite cathode chemistries exhibit much higher tendencies for thermal runaway than the other chemistries containing Mn and phosphate. Not shown is the lithium titanate oxide cell which is the most thermally stable of all the lithium cell chemistries (Takami *et al*., 2009; House, 2007).

Thermal stability and abuse studies of the $LiFePO_4$ cells are given in Deveney *et al*. (2007). Temperature data for 10-Ah and 25-Ah cells are shown in Figures 10 and 11 for several types of tests. In Figure 10, test results are shown for short circuit and overcharge events for 10-Ah cells. In both cases, the maximum temperature reached in the cell was 100°C and no venting was experienced. In the case of the short circuit test (0.63 mΩ), the initial current was very high, the time to peak temperature was about 60 s, and no thermal runaway was exhibited. In the case of the overcharge test, the overcharge current was 2C and the voltage was limited to about 4.5 V. The internal cell temperature reached 100°C in about 250 s and then decreased after venting (no smoke, no fire).

Abuse test results for a larger 25-Ah $LiFePO_4$ cell are shown in Figure 11 for overcharge to 5 V and a nail penetration. In both tests, the cells vented. There was smoke, but no flame. It is interesting to note that 1C overcharge to 5 V resulted in thermal runaway to 310°C, but 2C overcharge to 4.5 V resulted in a temperature of only 100°C and no venting. The nail penetration test resulted in heating over several minutes and maximum temperatures of only 100–120°C with venting, but no thermal runaway. The results shown in Figures 9–11 indicate that $LiFePO_4$ batteries seem to be resistant to thermal runaway except in cases of marked abuse.

6 ANALYSIS OF "SOFT SHORT" BATTERY SAFETY ISSUES

Most of the thermal runaway events discussed in the previous sections concerned abuse conditions that could result from battery mismanagement or vehicle accidents. These events in most cases were preceded by periods of exothermic heating of the battery lasting many minutes. It seems reasonable to assume that these events could be avoided with the appropriate BMS and cooling strategy. In addition, these events would be the result of a vehicle accident or human error in the management of the battery.

This section is concerned with battery failures resulting from the large localized heating caused by the development of hard shots interior to a cell. These shorts would be unknown to the battery user and occur very infrequently. Hence, totally avoiding the occurrence of these shorts is likely not to be possible. What is then needed is a cell design and chemistry that will not result in thermal runaway even should a hard short occur. Much of the research

concerning the recognition and consequences of "shorts" in batteries is thus directed toward understanding how the thermal runaway develops and how to design runaway proof cells. This research is considered in the next section.

6.1 Modeling of soft/hard short transitions and failures

Most of the research involving shorts and cell safety has involved computer modeling of the cells (Barnett and Siriramulu, 2011; Barnett *et al*., 2009; Barnett, 2011; Smith *et al*., 2010; Kim, Pesaran, and Smith, 2008; Keyser, Kim, and Pesaran, 2010). The models involve the solution of the three-dimensional, time-dependent partial differential equations (Fang, Kwon, and Wang, 2010; Chen, Wang, and Wan, 2006; Kim, Pesaran, Spotnitz, 2007) using the finite-element approach. It is critical to include the high temperature thermodynamics and kinetics of the chemical reactions between materials in the anode, cathode, and electrolyte in the cell. Details of the model are illustrated in Figure 12. A key element of the model is how to specify the characteristics of the "short" in terms of its size (mm), energy release (% of cell energy), and power (W). Some combinations of these parameters lead to thermal runaway and others do not. A typical model result leading to thermal runaway in a cylindrical $LiCoO_2$ cell is shown in Figure 13. Note that the average internal temperature of the cell is higher than on the external surfaces and the temperature increase occurs at an earlier time.

In this case, the time to thermal runaway to 500°C is about 10 s although internally the exothermic heating and average temperature increase was more gradual. Hence, it appears that thermal runaway due to internal shorts can occur over a very short time.

As noted previously, there are combinations of parameters for which thermal runaway does not result from the presence of a "short" in the cell. This is shown in Figure 14 for various values of energy and power when the short is initiated (Barnett, 2011). For small values of the relative energy, the power of the short can be quite large (>100 W) and there will not be thermal runaway. Hence, there is a wide region for all cells that should be thermal-runaway-free.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

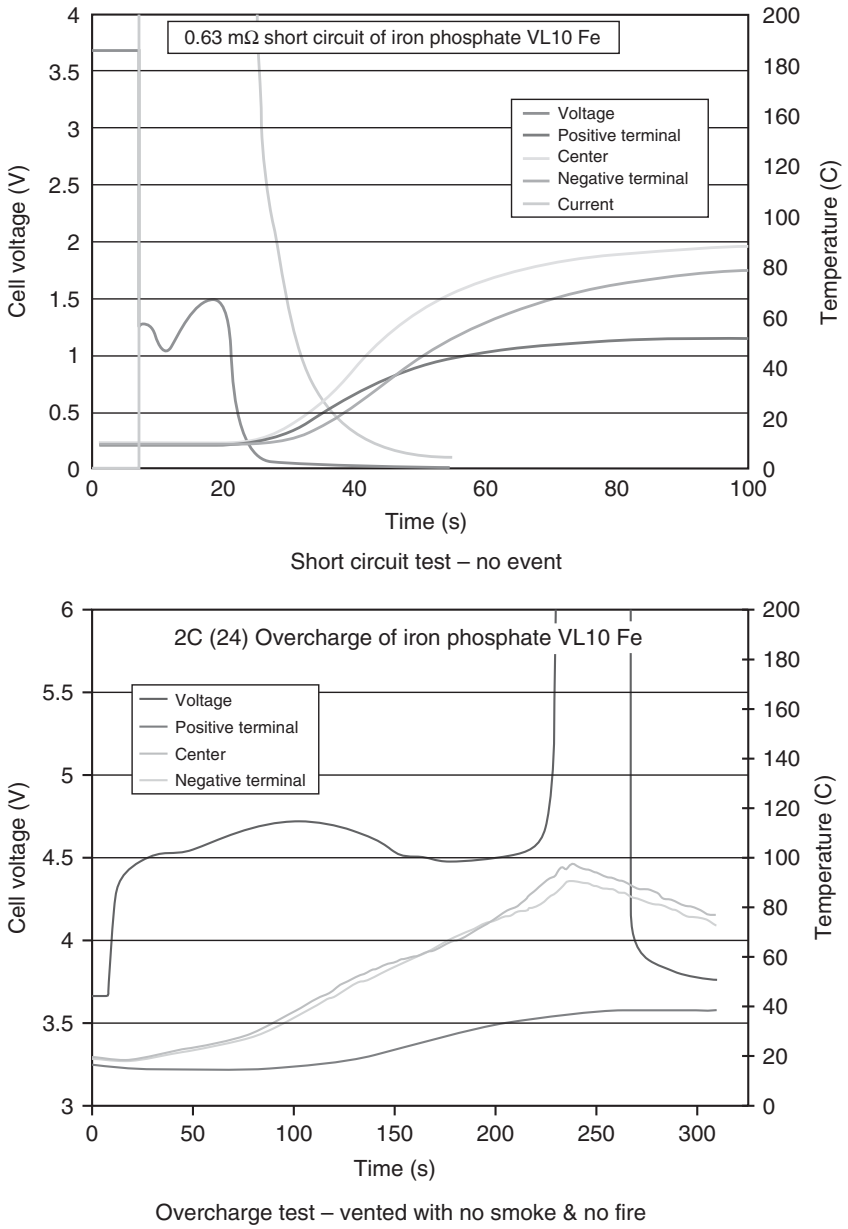

Figure 10. Short circuit and overcharge tests of the Saft 10-Ah $LiFePO_4$ cell. (Reproduced from Deveney *et al*. (2007). © Saft.)

Calculations have also been made (Barnett, 2011) comparing the response of cylindrical and prismatic cells to the occurrence of "shorts". As shown in Figure 15, it was found that for the same relative energy, the threshold power for thermal runaway was much higher for a prismatic cell than for a cylindrical cell of the same size (Ah). This is due to the higher heat loss from the prismatic cell. It is also evident from Figure 15 that for both types of cells, there is a sharp sensitivity to the initiating power—only a very small difference in power can have a large influence on whether thermal runaway occurs. In both cases, there is an extended period of exothermic heating and then a sudden temperature rise to runaway.

The model results presently available (2012) are incomplete, especially concerning the effects of lithium battery chemistry on the response of cells to soft/hard shorts. The results are also not conclusive regarding how to design thermal-runaway-free cells, but they seem to indicate that providing adequate cooling of the interior of the cells is important.

7 BATTERY MANAGEMENT SYSTEMS TO MITIGATE SAFETY ISSUES

It is well recognized that providing an appropriate BMS is key to safe operation of lithium batteries. All BMSs monitor the voltages and temperatures of the cells and warn the vehicle controller when a cell condition is outside safe ranges. This monitoring function of the BMS should permit the battery to avoid abusive conditions during normal operation of the vehicle. Operation of the battery disconnect contactors by the BMS should also avoid abusive conditions in the event of a vehicle accident.

Utilizing the BMS to warn of the presence of soft/hard shorts or conditions that indicate "shorts" may have occurred is much less developed than the straightforward monitoring function. There has been considerable work

(Mikolajczak *et al*., 2010; Schaffhauser, 2012; Darcy and Smith, 2010; Sanyo; Texas Instruments) concerned with (i) identifying indicators (Mikolajczak *et al*., 2010; Schaffhauser, 2012; Darcy and Smith, 2010) pointing to the presence or impending occurrence of "shorts" and (ii) development (Sanyo; Texas Instruments) of chips and printed circuit boards (PCBs) that implement in hardware and software the various approaches to possible battery failure detection. Most of this work has been done in connection with lithium-ion cells and units used in laptop computers. However, this work should be valuable for lithium battery applications in vehicles.

One approach to detecting the presence of "micro-shorts" in cells or battery packs is to analysis their voltage–current behavior during charging and rest periods. For example, it has been found (Mikolajczak *et al*., 2010) that cell behavior that indicated incipient faults include elevated self-discharge during rest periods, extended taper-current times, and charge capacity significantly higher than discharge capacity. In these cases, the batteries should be inspected and tested carefully to identify the source of the problem before continuing to use them.

Most of the thinking regarding detection of "shorts" during the normal use of the battery is concerned with

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

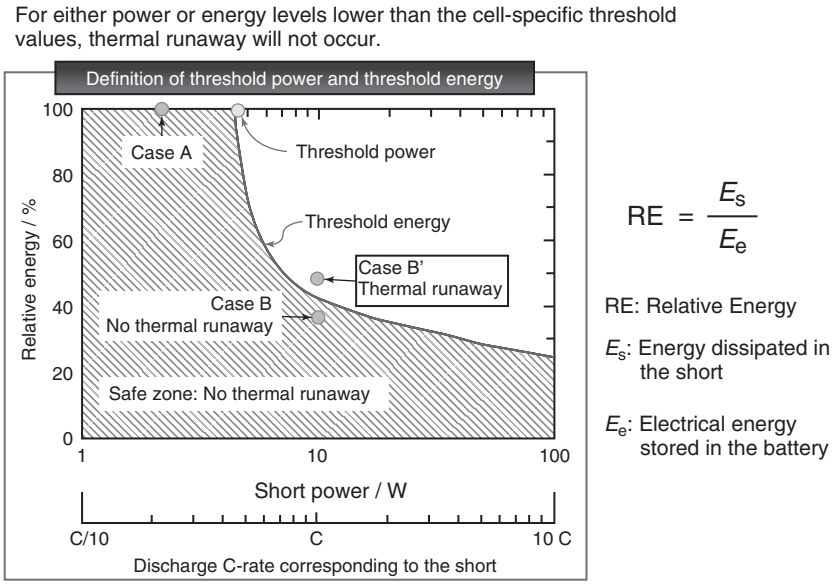

Figure 14. Combinations of relative energy and power (Barnett and Siriramulu, 2011) for which the cell will be free of thermal runaway. (Reproduced from Barnett (2011). © the Knowledge Foundation.)

detecting sudden changes in cell resistance or impedance and/or changes in temperature either at the surface of the cells or at the negative or positive terminals (Figure 13). These approaches can be combined with the monitoring function of the BMS. One approach (Schaffhauser, 2012) for detecting these changes is to apply a small current at specific frequencies to the cells which can indicate changes in the temperature of the SEI layer on the anode (Figure 8). If the onset of the exothermic heating of the cell can be detected and then mitigated, thermal runaway can be avoided even if soft/hard shorts are being developed. Some of the mitigation steps could be isolating the section of the pack affected from the other parts of the pack, increased cooling to the affected cells, and reduction of the peak currents/powers demanded of the pack or if it can be done safely as in a hybrid, open all contactors to disconnect the battery from the powertrain with continued cooling.

Unfortunately, there is little information/data in the literature showing that thermal runaway has been avoided in particular cases using any of the approaches and detectors discussed. All the electric vehicles being sold with lithium-ion batteries (Leaf, Volt, EVFocus, and EVFit) have BMS units to protect the batteries, but these units seem to only monitor the cells and report any abnormal voltages and temperatures to the vehicle controller, which alerts the driver and reduces the maximum power demanded from the battery. In addition, in nearly all cases, the energy used from the batteries is limited to 60–70% of the total stored in the batteries. This is done by not fully charging the battery and terminating the discharge before the battery is fully discharged. Most of the damage and stress to the cells occurs near full charge and full discharge, and these conditions are avoided by limiting the useable energy from the battery. In the future, when better instrumentation for diagnosing potential serious battery problems becomes available, it is likely that vehicle manufacturers will utilize a greater fraction of the total energy stored in the battery.

8 SUMMARY AND CONCLUSIONS

In this article, various aspects of the safety of lithium-ion batteries of different chemistries have been reviewed based on information available in the literature as of early 2013. The primary safety concern is the possibility of encountering a thermal runaway condition unexpectedly during otherwise normal operation of the batteries. This concern has been evaluated both through study of the abuse testing of cells and computer modeling of cell response to soft/hard shorts.

The abuse testing has shown that thermal runaway can be induced for all cells and chemistries under extreme conditions, but there are significant differences in the tendencies of the different chemistries to experience thermal runaway. The most informative testing has been done using ARC in which the cell temperature can be tracked under known conditions (heat input and heat loss). These tests indicate that thermal runaway in almost all cases

DOI: 10.1002/9781118354179.auto065
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

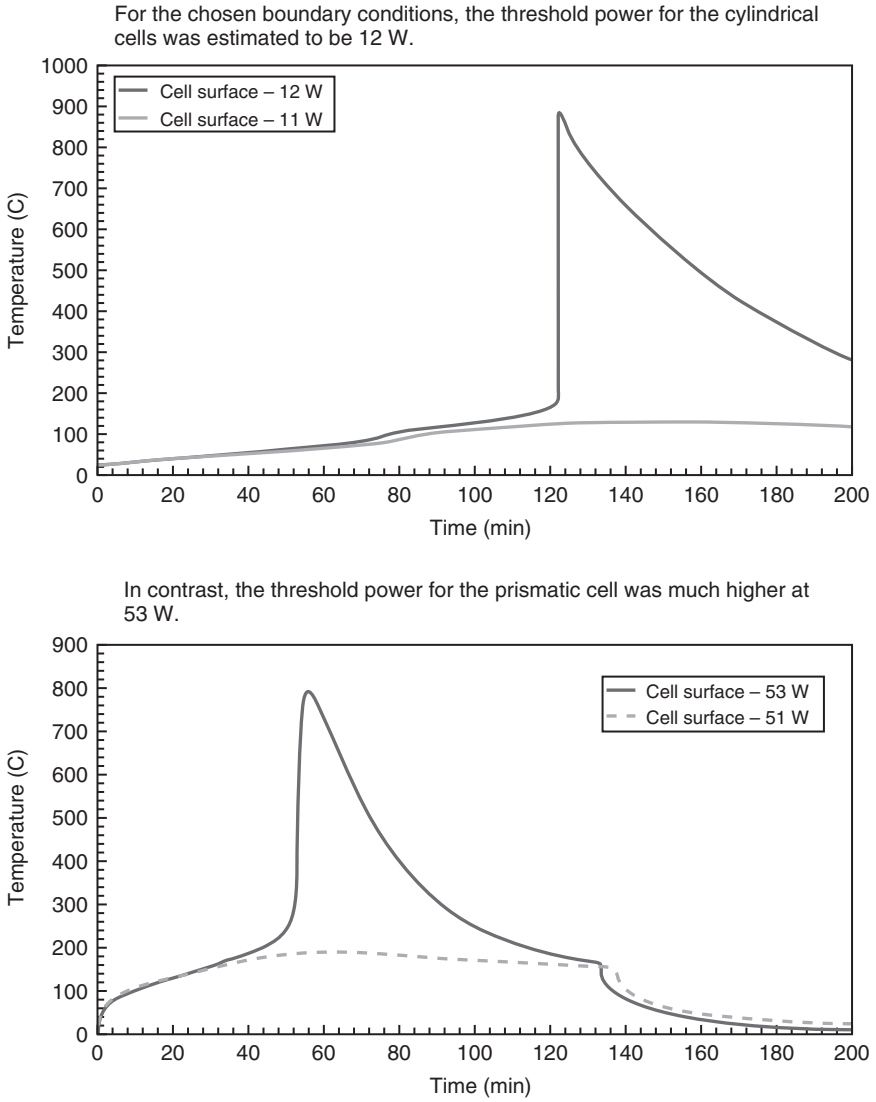

Figure 15. Thermal runaway characteristics of cylindrical and prismatic cells. (Reproduced from Barnett (2011). © the Knowledge Foundation.)

is preceded by a relatively long period (many minutes) of exothermic heating of cell. The temperature increase during the thermal runaway event is very rapid, lasting only seconds reaching temperatures of over 500°C in some cases. Under many conditions, the period of exothermic heating does not lead to thermal runaway. In these cases, the heat loss during the exothermic heating period results in a maximum temperature of <150°C and an uneventful failure of the cell with venting but no fire or explosion. Thermal runaway is most likely with $LiCoO_2$ cells and least likely with cells using Fe PO_4 and Mn oxide cathodes and/or lithium titanate oxide anodes. Thermal runaway is due primarily to the reaction of the electrolyte with the electrode materials at elevated temperatures and subsequent combustion of the electrolyte with the resultant products of the reactions. Any steps to reduce heat generation from these reactions and to increase the heat loss from the cell will minimize the possibility of thermal runaway.

Most of the studies of the response of cells to internal shorts have involved computer simulations. These studies have shown that for all chemistries, there are combinations of the geometry and energy release through the "short" and heat loss from the cell, which will lead to thermal runaway. Even in the case of shorts, the simulations indicate a relatively long period of exothermic heating (gradual temperature increase) before a sudden thermal runaway event. Adequate heat loss (cooling) during the exothermic heating time is critical for mitigating thermal

runaway. Hence, designing the cells for good heat loss and/or cooling and monitoring the temperature of the cells via a BMS so it becomes known quickly if/when the temperature (probably of a terminal) exceeds a specified value (probably 85–90°C) will greatly reduce the probability of thermal runaway due to internal shorts for lithium battery chemistries.

Fuel Cell Powered Vehicles

Hengbing Zhao and Andrew Burke

University of California, Davis, CA, USA

1 INTRODUCTION

Fuel cell vehicles (FCVs) utilize a fuel cell with hydrogen as the fuel to produce electricity that is used by an electric motor to power the vehicle. The fuel cell system consists of a hydrogen storage tank, fuel and air supply circuits, the fuel cell stack, and water and thermal management subsystems. Owing to the highly transient operating conditions in automotive applications, hybridization using batteries or ultracapacitors is often adopted to reduce electrical stresses on the fuel cell and improve its life.

Section 2 of this chapter deals with FCV powertrain arrangements and several other system aspects such as onboard hydrogen storage and refueling. In Section 3, the fuel cell system architecture and operating principles are introduced, and various operating modes and optimum performances of a fuel cell system are discussed based on an optimum operating approach. Section 4 explores different power splitting strategies between the fuel cell and electrical energy storage (batteries or ultracapacitors) and the effect on the fuel economy of FCVs over various driving cycles. The fuel economy of FCVs is then compared with that of vehicles utilizing other advanced driveline technologies.

2 THE FUEL CELL VEHICLE DRIVELINE AND ITS OPERATION

2.1 Powertrain arrangements

In automotive applications, fuel cell systems must be able to adapt to challenging operating conditions such as frequent start-up and shutdown and rapidly varying power demand. These conditions are easier to cope with if the fuel cell system is hybridized using batteries or ultracapacitors. In addition to mitigating the stress on the fuel cell via load leveling or power assist, the energy storage permits the capture of regenerative braking energy, which benefits vehicle fuel economy and can potentially permit downsizing the fuel cell system. Designers have a number of choices (Gao, 2005; Zhao and Burke, 2010a, 2010b; Thounthonga, Raël, and Davat, 2009; Uzunoglu and Alam, 2007; Lin *et al*., 2006; Bauman and Kazerani, 2008; Garcia-Arregui, Turpin, and Astier, 2007; Jeon, 2005; Schaltz, Khaligh, and Rasmussen, 2008; An, Lee, and Kim, 2008; Zhao, Burke, and Miller, 2011; Emadi *et al*., 2005; Lai and Nelson, 2007; Jeong and Oh, 2002; Ohkawa, 2004; Zolot, Markel, and Pesaran, 2004) to hybridize the fuel cell. These alternatives include the physical arrangement of the power sources, selection of the energy storage technology and devices, and the control strategy for splitting power between two power sources. Hence, there are several practical arrangements of the power sources (Figure 1). Each arrangement has its advantages and disadvantages relative to operating conditions, control complexity, development cost, vehicle performance, and fuel economy potential.

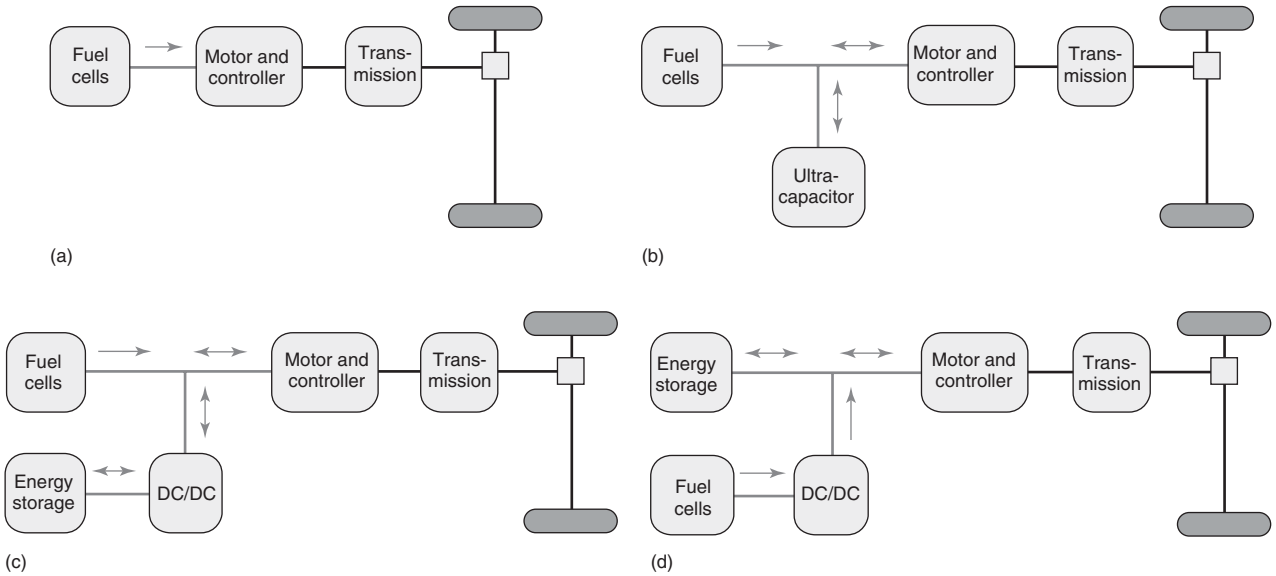

Figure 1. Powertrain configurations for fuel cell vehicles.

(a) *A direct hydrogen FCV without electrical energy storage*. This configuration is the simplest. No DC/DC converter is employed to control the DC-link voltage resulting in the fuel cell stack voltage being equal to the DC-link voltage. Because the dependency of fuel cell output current on the hydrogen and airflow rates limits its response to load transients, this configuration requires a higher power fuel cell stack and fast hydrogen and air supply systems to satisfy the large variations in load power. The DC-link voltage can experience large swings because of the slow response of the air supply system. This configuration will be used as the baseline for comparing different powertrain configurations (Zolot, Markel, and Pesaran, 2004; Zhao and Burke, 2009a).

(b) *FCVs with supercapacitors directly connected to fuel cells*. The supercapacitors are directly connected in parallel with the DC-link (fuel cell stack). In this case, the voltage of the ultracapacitor unit and fuel cell is equal. The relatively soft voltage–current characteristics of fuel cell allow supercapacitors to operate over a fairly wide range of voltages and to self-regulate the DC-link voltage fluctuation. The supercapacitors will absorb the excess power from the stack and the regenerative braking energy and provide a fraction of transient power for vehicle acceleration. A diode is utilized between the fuel cell and DC-link to prevent current from flowing into the fuel cell during regenerative braking of the vehicle. This configuration is the simplest of the hybridized powertrain arrangements (Zhao and Burke, 2010a; Garcia-Arregui, Turpin, and Astier, 2007; Lai and Nelson, 2007).

(c) *FCVs with electrical energy storage (supercapacitors or batteries) coupled in parallel with fuel cell stack through a DC/DC converter*. The fuel cell voltage is the DC-link voltage. The transient power provided by the energy storage is regulated by the DC/DC converter. The introduction of the DC/DC converter will maximize the utilization of supercapacitors or batteries during acceleration and cruise and regenerative braking. This configuration permits controlling the transient power from the fuel cell by applying different power split strategies such as power assist or load leveling to mitigate the stress on the fuel cell stack (Gao, 2005; Zhao and Burke, 2010b; Emadi *et al*., 2005; Lai and Nelson, 2007; Ohkawa, 2004). The state of charge (SOC) of supercapacitors or batteries can also be controlled within appropriate ranges.

(d) *FCVs with the fuel cell coupled with energy storage unit such as supercapacitors or batteries through a DC/DC converter*. The energy storage voltage is the DC-link voltage. The power provided by the fuel cell passes through the DC/DC converter (Zhao and Burke, 2010b; Emadi *et al*., 2005; Jeong and Oh, 2002; Zolot, Markel, and Pesaran, 2004). The converter regulates the fuel cell power to avoid large fluctuation of the DC-link voltage. The SOC of the battery or supercapacitor is also a factor that is determining the fuel cell output power.

Over the years, one of the auto companies developing FCVs has adopted most of these arrangements. The present Honda FCX Clarity, Toyota FCHV, and GM Fuel Cell Equinox Vehicles use the powertrain arrangement shown in Figure 1c. The energy storage is connected to the fuel cell via a DC/DC converter and acts as a power assist or load leveling unit. Ford developed the first research prototype pure FCV without hybridization (Figure 1a) in 1999. Ford's latest HySeries Drive uses powertrain configuration shown in Figure 1d, with a hydrogen fuel cell that operates as an onboard charger. Fiat developed in 2001 an APU (the first generation, Seicento Phase I) using the powertrain architecture shown in Figure 1d. The fuel cell acts as a battery charger, in order to extend the range of the vehicle. In 2003, Fiat presented a Seicento Elettra (the second generation) with a hybrid configuration shown in Figure 1c where the battery acts as a load leveling unit. The third prototype Panda Hydrogen uses the pure fuel cell powertrain architecture without the assistance of a battery or an ultracapacitor because of the improvement in fuel cell performance and cost.

2.2 Onboard hydrogen storage

Most FCVs operate on gaseous hydrogen from a hydrogen tank and oxygen from ambient air. The lower heating value of hydrogen is 121 MJ/kg and that of gasoline is 121.7 MJ/gal. Therefore, 1 kg of hydrogen has the same energy content as 1 gallon of gasoline. Hence, it is easy to relate the mpkgH of hydrogen in an FCV to the equivalent miles per gallon of gasoline. For a specified range RH_2 of the FCV, the weight of hydrogen to be stored is simply

$$WH_2 = RH_2/\text{mpkgH}$$

Hence, for a desired range of 300 miles in an FCV having a fuel economy of 80 mpkgH,

$$WH_2 = 3.75\ \text{kgH}_2$$

Hydrogen has good energy density by weight, but poor energy density by volume (MJ/L). As a result, it is not easy to store 3–5 kg of hydrogen onboard a mid-size passenger car. Hydrogen can be stored using different approaches to reduce storage volume in automotive applications (Broom, 2011; Burke and Gardiner, 2005). These approaches can be classified into two groups: physical storage (gas, liquid, or absorption) and chemical storage (hydrides). Hydrogen can be stored at high pressure in cylindrical tanks wound from carbon filaments. Compressed hydrogen at 350 bar (5000 psi) and 700 bar (10,000 psi) is a well-developed approach being used for by most car manufacturers in their FCVs—Honda, Toyota, Nissan, Daimler, and GM. The present technology for compressed gas hydrogen storage is 66 L/kg at 350 bar and 40 L/kg at 700 bar (Gardiner and Cunningham, 2001). Hence, storing 3.75 kgH_2 would require 250 L at 350 bar and 150 L at 700 bar. Hydrogen can also be stored as a liquid at cryogenic temperatures—at about 20°K. The volume required to store hydrogen as a liquid is 20–25 L/kgH_2 resulting in 75–95 L to store 3.75 kgH_2 (Gardiner and Cunningham, 2001). Storing hydrogen as a cryogenic liquid is presently the most volume efficient method, but the cryogenic systems are much less convenient than the compressed gas systems for vehicle applications. Only BMW has adopted liquid storage of hydrogen in their prototype vehicles.

Hydrogen can also be stored using gas absorption on materials with a large specific surface area such as activated carbon (Gardiner, 2004; Sevilla, Foulston, and Mokaya, 2010). Chemical storage in the form of metal hydrides in which the hydrogen is chemically bonded in covalent and ionic compounds at controlled temperature and pressure are also being studied (Young *et al*., 2004; Mori *et al*., 2005). In these cases, the hydrogen is released by heating the host material. The hydrides have good volume storage characteristics (15–20 L/kgH), but can be heavy (50–60 kg/kgH in the case of low temperature hydrides). High temperature hydrides (>300°C) can have reasonable good weight characteristics (15 kg/kgH).

A comparison of various hydrogen storage approaches for FCVs is shown in Table 1. Liquid hydrogen shows the highest system gravimetric and volumetric capacities. However, current liquid hydrogen systems use more than

DOE goals for hydrogen storage (2015/ultimate)	1800/2500	1300/2300

30% of the energy in the hydrogen for liquefaction and cannot meet the DOE long-term targets for volumetric capacity. Also shown in the table are the DOE system development goals (Dillich, 2009; DOE report, 2009) for weight and volume. If the ultimate targets are met, the system volume to store 3.75 kgH would be 53.6 L with a weight of 50 kg. Comparisons of energy storage in hydrogen with various battery chemistries and liquid gasoline are shown in Table 2. Note that energy densities for storage in hydrogen are at least one order of magnitude higher than for lithium batteries. However, compared to gasoline, energy storage in hydrogen is only 0.25–0.30 as good as gasoline even if the DOE ultimate goals are met. As the fuel economy of FCVs is expected to be about twice that of conventional ICE vehicles, the short fall in energy storage would only be about a factor of two in hydrogen-fueled FCVs.

2.3 Fuel cell assembly and operation

2.3.1 Introduction

A fuel cell is a device that converts chemical energy from a fuel directly into electricity via controlled electrochemical reactions at two separate electrodes (Mench, 2008; Srinivasan, 2006; Spiegel, 2008). Fuel cells are usually named based on the electrolyte material between the two electrodes. Two types of fuel cells of particular interest for vehicles are the following: polymer electrolyte membrane fuel cell (PEMFC) and solid oxide fuel cell (SOFC). The SOFC utilizes a ceramic, solid oxide electrolyte and operates at a high temperature—around 1000°C. High temperature operation removes the requirement for a precious metal catalyst in the electrodes and enables the use of a variety of fuels, but results in a slow start-up and critical thermal insulation and sealing issues. Efforts are being made for developing lower temperature SOFC to deal with high temperature-related issues. The PEMFC utilizes a polymer electrolyte membrane and operates at relatively low temperatures—around 80°C. The low temperature operation of PEMFCs requires precious metal catalyst—platinum and also pure hydrogen as a fuel. However, the low temperature operation allows PEMFCs to start quickly and makes them suitable for use in vehicles, especially light-duty vehicles. Research is being done to develop non-noble catalysts to deal with cost and CO poisoning issues and also higher temperature membranes that function over 100°C to improve electrochemical kinetics and simplify water and thermal management. In this chapter, only PEMFCs are considered for the FCV application.

2.3.2 The assembly and operation of PEMFCs

All types of fuel cells have essentially the same structure and arrangement of internal components. Figure 2 shows a schematic of a generic PEMFC. An anode with fuel flow channels, anode gas diffusion layer (GDL), electrolyte, cathode GDL, and a cathode with airflow channels and coolant flow channels. Anode and cathode plates are made of thermal and electrical conductive materials such as graphite, composites, or metals with machined or stamped flow channels. They are designed to accomplish many functions, such as supplying reactants, removing heat and by-product—water, and collecting current and carrying current from cell to cell. The porous GDLs are made of electrically conductive carbon paper or carbon cloth to ensure that reactants are uniformly diffused over the active

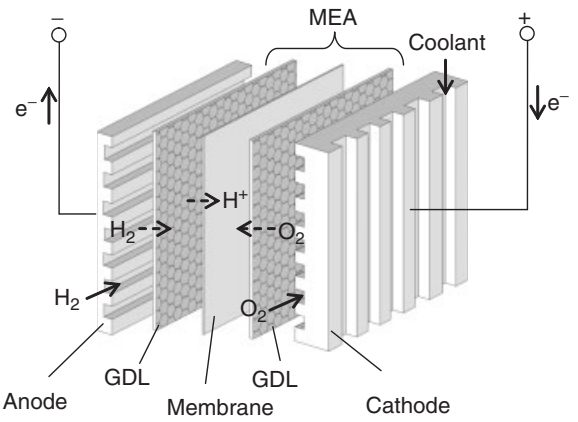

Figure 2. Schematic of a generic fuel cell.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto066
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

area of fuel cell electrodes. The GDLs are typically treated with the hydrophobic material—PTFE (Teflon) to ensure that the diffusion pores are not clogged with condensed by-product—water. The membrane of the PEMFC is a type of chemically resistant and durable polymer. The most commonly used membrane is Nafion. It performs as a separator and selectively transports cations—protons (H^+)—across the cell from the anode to the cathode. A thin catalyst layer—a mixture of platinum or platinum alloys, carbon black, and PTFE particles—is applied to the membrane on the anode and cathode sides according to the assembly process (Litster and McLean, 2004). This is the active electrode layer where the electrochemical reaction occurs. The anode GDL, membrane, and the cathode GDL are assembled through hot pressing to form the membrane electrode assembly (MEA).

Hydrogen is delivered to the anode catalyst layer through the anode flow field plate and the anode GDL and split into H^+ and electrons through the electrochemical oxidation reaction. The electrons flow through the anode GDL and the anode plates to the external circuit, whereas the H^+ ions diffuse (conduct) through the polymer electrolyte membrane to the cathode electrode. At the cathode electrode catalyst layer, the oxygen through the cathode flow field plate and the cathode GDL reacts with the H^+ ions that have permeated through the membrane and the electrons from the external circuit (via the adjacent anode plate) through the electrochemical reduction reaction. The products of the fuel cell are by-product water, waste heat, and electricity. The cells in the fuel cell are arranged in a bipolar manner with the electron current flowing from anode to cathode and finally into the external circuit.

A single cell produces less than 1.0 V. Multiple cells are stacked in series into a fuel cell stack to achieve a higher voltage for automotive applications. The output current of a fuel cell stack is proportional to the active area of the individual cells, and the stack voltage depends on the number of the cells in series. The electrical power that can be generated by a fuel cell stack is limited by its electrical resistance, which is dependent on the reaction kinetics and the rates of diffusion of the reactants in the membrane and the electrodes. For example, high pressure and high air stoichiometry improve the kinetics and reactant diffusion in the catalyst layers and enhance removing condensed water from the active area of the cathode, but high pressure and high airflow result in high parasitic losses and reduced system efficiency. Therefore, optimal operation of the fuel cell system is needed to achieve high vehicle fuel economy.

2.3.3 Start-up from subfreezing temperature

The presence of water in the fuel cell stack is one of the major challenges in the operation of FCVs in cold climates. Water is formed at the cathode of the fuel cell as a by-product and needs to be removed to avoid flooding in the cathode GDL. At the same time, the PEM needs to be well hydrated to maintain its high performance. The inherent presence of water creates a problem when FCVs are parked in a subfreezing weather environment. Rapid start-up of a fuel cell in a subfreezing environment is critical to the marketing of FCVs. FCVs require that the stack reaches 90% rated power in less than 30 s at temperatures as low as -20°C. Properly managing the start-up at subfreezing temperatures is necessary for avoiding fuel cell damage.

Different start-up and shutdown approaches have been proposed or adopted to address the rapid start-up in a subfreezing environment (Pesaran, Kim, and Gonder, 2005). The proposed solutions can be categorized into three main strategies: dry gas purge, keep-warm, and thaw and heat at start-up. The dry gas purging process before fuel cell shutdown can minimize residual water in the membrane, porous electrodes, and GDLs. The keep-warm uses thermal insulation to delay the fuel cell cool-down and freezing following system turn-off. Using insulation can delay freezing up to several days, but cannot eliminate freezing. Periodically heating the fuel cell via embedded electric heaters or heated air supply may be used to maintain fuel cell temperature above 0°C for long-term storage in a subfreezing environment. The thaw and heat method uses electric heaters to warm up the fuel cell directly or via the air supply circuit before the vehicle is driven. However, freeze/thaw cycles create a durability issue for the fuel cell system such as increased MEA internal resistance because of internal ice expansion and require a long warm-up period. Appropriate combinations of the dry gas purging and the thermal management in the fuel cell are likely the best approach to solve the rapid start-up issue.

2.4 Hydrogen refueling

Currently, prototype FCVs store compressed hydrogen in carbon-fiber-reinforced composite tanks or as liquid hydrogen in a cryogenic tank. These vehicles can achieve ranges up to about 400 miles. They require hydrogen refueling stations that provide pressurized hydrogen gas at high pressure (up to 5000–10,000 psig) and/or liquefied hydrogen at low temperature (-253°C). Hence, a new infrastructure (facilities and systems) must be constructed for producing and delivering hydrogen. During the early

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto066
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Table 3. Comparison of various hydrogen refueling alternatives.

Hydrogen Refueling Methods	Overall Energy Conversion Efficiency[a]	Cost of Hydrogen[b]
Bulk liquid hydrogen is produced from natural gas from an existing central reformer, transported to a refueling station by truck, stored as a cryogenic liquid, and dispensed to the vehicle as a liquid or converted to a compressed gas before dispensing to the vehicle	—	$2.3–2.4/kg
Bulk gaseous hydrogen is produced from natural gas from an existing central reformer, transported to the refueling station by existing pipeline, compressed on-site and stored as a compressed gas at 500 psi, and dispensed to the vehicle as a gas	—	~$3.2/kg
Natural gas is transported to the refueling station by existing pipeline, hydrogen is produced by steam methane reforming or partial oxidation process, compressed and stored at 5000 psi, and dispensed to the vehicle as a gas	67% for methane reforming 69% for partial oxidation process	~$4.7/kg for methane reforming ~$4.4/kg for partial oxidation process
Gaseous hydrogen generated at the refueling station by electrolysis using grid electricity, stored as a compressed gas at 5000 psi, and dispensed to the vehicle as a gas	80%	~$3.7/kg

[a]Efficiency is based on the higher heating value.
[b]On the basis of the value of the US dollar in 2001.

adoption of the FCVs, it seems likely that hydrogen refueling facilities/stations will be provided in clusters around some pilot cities (Yang and Ogden, 2010; Ogden and Yang, 2005). FCVs can also be refueled through mobile refueler. Hydrogen can be produced on-site at the stations from water with an electrolyzer or from natural gas with a reformer, then compressed and stored for dispensing to the vehicle. Hydrogen can also be delivered to the station as a high pressure gas or a cryogenic liquid by a tank truck from a central production site for storage and later dispensing to the FCVs.

Schoenung and Weinert analyzed and compared all hydrogen refueling station alternatives in terms of overall energy conversion efficiency and cost (Schoenung, 2001; Weinert and Lipman, 2006). Various hydrogen refueling approaches and associated energy conversion efficiency assuming 100% utilization of the facility are summarized in Table 3. Schoenung calculated the cost of hydrogen dispensed from the annual operating costs divided by the total GJ of hydrogen delivered per year. The cost of hydrogen is then converted to the cost per kilogram using the lower heating value of hydrogen (120 MJ/kg).

3 THE FUEL CELL SYSTEM AND OPTIMAL OPERATION

3.1 Fuel cell system

The fuel cell stack is the key element of a fuel cell system. However, without auxiliary components such as the air compressor, humidifier, and pressure and flow regulators, the stack itself would not function properly. Fuel cell system configurations vary considerably in different applications. A direct hydrogen fuel cell system, as shown in Figure 3, typically involves the following four major auxiliary subsystems: air supply and control, fuel supply and control, water management, and thermal management subsystems. The air supply subsystem consists of several interacting components—namely, an air compressor and expander, supply and return manifolds, and back pressure control valve (Cunningham, 2001; Chen and Peng, 2005). The fuel supply subsystem consists of a high pressure fuel tank, pressure regulator, supply manifold, hydrogen recirculation pump, and purge control valve. The water management subsystem includes air/fuel humidifiers or vapor injector and vapor condenser. The thermal management consists of the cooling loop for the stack and temperature control for humidifiers and a radiator (Badrinarayanan *et al*., 2001).

Water and thermal management are two of the critical issues in the operation of PEMFCs. The proton (H^+) conductivity of the Nafion membrane (Xu, Kunz, and Fenton, 2006) requires its humidification. The humidity of inlet air stream should be maintained at a high level (>60% RH at 80°C). Temperatures above 80°C will dry the membrane and result in high membrane resistance. High pressure and high flow rate of air will benefit the disposal of the condensed water in the cathode GDL. These subsystems interact and careful attention to these interactions is required. Optimal air and fuel supply and water and thermal management will improve the performance and life of the fuel cell stack and increase efficiency of the fuel cell system.

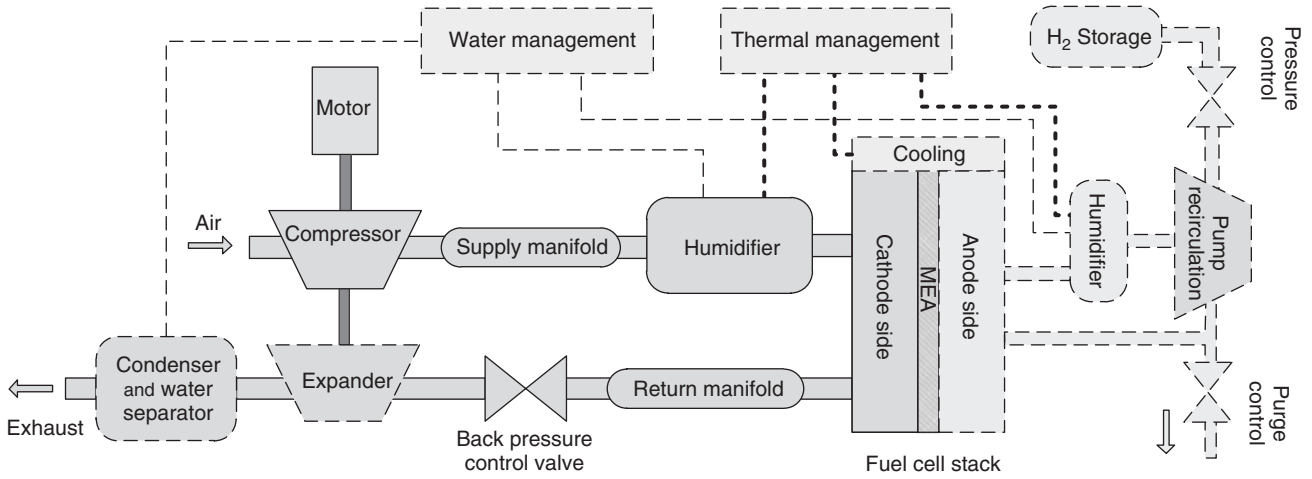

Figure 3. Schematic of a fuel cell system in a fuel cell vehicle.

3.2 Optimal operation

The fuel cell stack can deliver electricity at high efficiency (up to about 60%). However, the operation of the on-board auxiliaries significantly affects the performance and efficiency of the fuel cell system. PEMFC systems can consume up to 20% of the stack output to provide power to auxiliaries such as compressors, heaters, and pumps. The air supply system accounts for about 80% of the parasitic losses and has a dominant impact on the system efficiency and response time. The optimization of the fuel cell system operation is concerned with the analysis of various air supply configurations and their operation to maximize the net system power and system efficiency (Li and Liu, 2009; Sundström and Stefanopoulou, 2007).

There are many considerations for optimizing the operation of a fuel cell system. First, the fuel cell performance is sensitive to the mass flow of the reactants, which depends on the fuel cell stack design and operating conditions. The number of cells, the active area of the cell, and flow field design including the channel shape, dimensions and spacing, and the maximum allowable pressure drop are key stack design parameters. Secondly, in terms of operating conditions, temperature, relative humidity, operating pressure, and the air mass flow are the four key external variables that have a major impact on the performance of the stack. They determine the oxygen partial pressure at the cathode catalyst layer, which determines the resultant cathode overpotential as a function of stack current. Finally, the selection of the main auxiliary device—the compressor—accounts for most of the parasitic losses and determines the two key operating variables—pressure and mass flow.

The compressor that pressurizes and delivers air into the fuel cell has a direct effect on the system efficiency. High pressure operation of the fuel cell can give high power density and better water management, but it results high parasitic losses. There are a variety of compressors available for FCV applications. The turbo compressor and the twin-screw compressor are two well-suitable options for high pressure operation because of their low weight and small size. Kulp (2001) found that the turbocharger is more efficient than the twin-screw compressor, especially at low mass flows. However, a neutral water balance was more difficult to maintain with a turbocharger than in a twin-screw setup. In the present analysis, a twin-screw compressor is used. Pressure ratio (outlet pressure/inlet pressure) and mass flow rate are the two main parameters needed to match the fuel cell requirements.

The pressure drop across the stack depends on the humid air mass flow, stack back pressure, and channel flow field plate design following the Darcy–Weisbach Law. The optimum operating conditions can be determined as follows. The humid air flow rate is calculated from the back pressure, the dry air mass flow rate, and the interpolated pressure drop consistent with the maximum allowable pressure drop (0.4 atm in the present analysis). The optimum pressure drop across the stack can then be determined. For every triplet, the current density (J), the dry air mass flow ($\dot{m}$), the back pressure (P_r), and the net output power of $P_{net}(J, \dot{m}, P_r)$ can be calculated. All the values of $P_{net}(J, \dot{m}, P_r) > 0$ that fall within the safe operational region of the compressor are then scanned to find the one with max $P_{net}(J, \dot{m}, P_r)$.

$$P_{net}(J, \dot{m}_{optimal}, P_{r,optimal}) = \max[P_{net}(J, \dot{m}, P_r)] \quad (1)$$

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

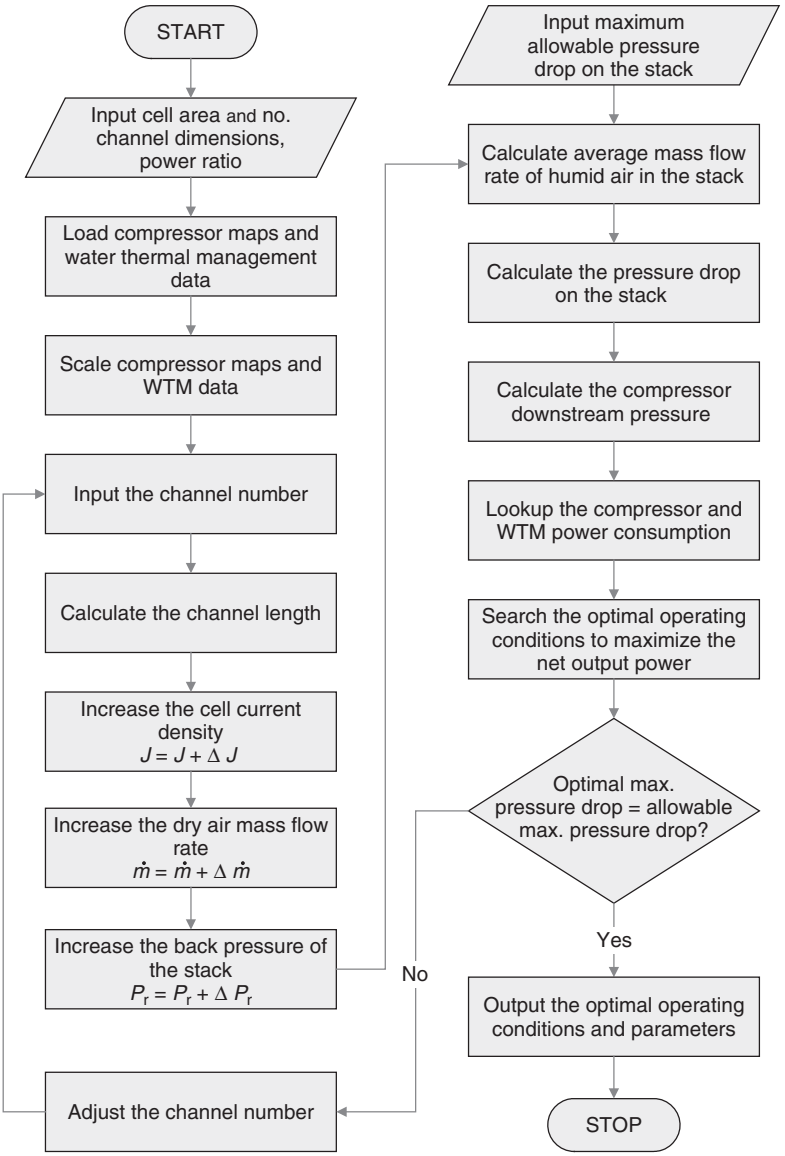

Figure 4. Flowchart of optimization of the fuel cell stack design and operating conditions.

In other words, the optimal mass flow $\dot{m}_{\text{optimal}}$ and back pressure $P_{\text{r,optimal}}$ will yield the maximum net power for each J value. The optimization process is shown in Figure 4 (Zhao and Burke, 2009b).

In the optimization process, the maximum pressure drop is obtained from the optimal results and compared with the input allowable pressure drop. If the maximum pressure drop in the stack matches the allowable pressure drop, the selected channel number is acceptable and the optimum operating conditions are also acceptable. Otherwise, the channel number is varied and the model is run until the maximum optimum pressure drop in the stack is acceptable (less than the allowable pressure drop). The above optimization of fuel cell system operation only gives an approximate calculation. For detailed analysis, commercial computational fluid dynamic (CFD) software programs such as CFD−ACE+, CFX, Flow-3D, and Fluent are usually employed to analyze the microfluidic flow in the diffusion layer of fuel cells and verify the cell and stack design.

3.3 Comparison of fuel cell operation modes

In a fuel cell system, a pressure control valve or regulator is used to control the back pressure. The back pressure can be kept constant at varied gas flow conditions (fixed back pressure operation) or can be varied with the change

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto066
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

of the load (optimal varying back pressure operation). For both cases, the pressure difference across the membrane is minimized to reduce the stress on the membrane electrode assembly and the airflow or air stoichiometry ratio (SR) is optimized by avoiding operation of the compressor at low mass flow rate.

It is of interest to compare fixed and varying pressure operation of the system. Hence, the optimization approach was used to optimize the air SR for fixed back pressure operation and the SR and back pressure for optimal varying back pressure operation. For this analysis, a fuel cell system having 440 cells with the active area of 510 cm^2 and employing a twin-screw compressor is optimized. The fuel cell system was first optimized for varying SR and back pressure operation mode. Then the same system was optimized at the fixed back pressures of 2.0, 1.5, and 1.1 atm (Zhao and Burke, 2009b). A plot of system efficiency versus system net power is shown in Figure 5. The optimal polarization curves, the compressor responses, and the pressure drop across the stack for different operating modes are shown in Figures 6–8, respectively.

The comparisons of the results for the different operating modes indicate the following:

- The fuel cell system with optimal varying back pressure can achieve higher system efficiency over the full load range (Figure 5) and can produce more power than the fuel cell system operating at constant back pressures.
- For the same fuel cell system with different operating modes, lower constant back pressure operation has higher pressure drop across the stack than other operating modes because of higher ratio of water vapor partial pressure to dry air partial pressure (Figure 8).
- At low power demand, the fuel cell system operating at low pressure and at optimal back pressure has higher system efficiency than the fuel cell system operating at high pressure because of relatively low parasitic losses.
- At high power demand, the high pressure operating mode and the optimal varying back pressure operation mode can achieve higher system efficiency compared to the low pressure operation because of the high oxygen

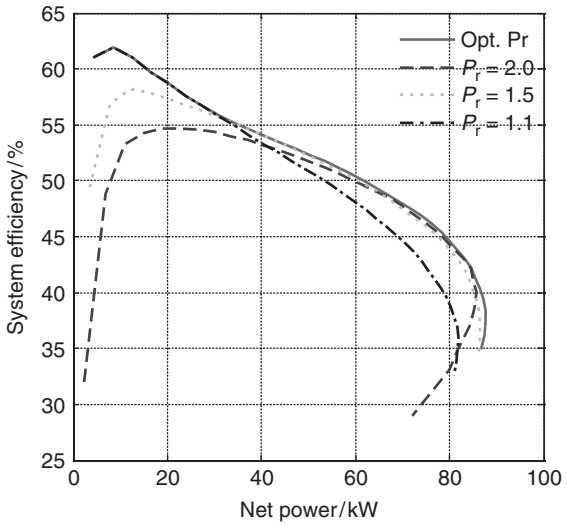

Figure 5. Comparison of the optimal system efficiency for different operating modes: optimal varying back pressure operation and fixed back pressure of 2.0, 1.5, and 1.1 atm.

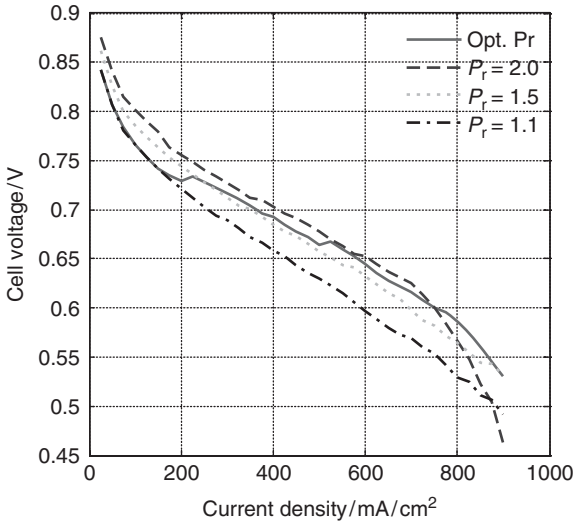

Figure 6. Optimal fuel cell polarization curves for different operating modes.

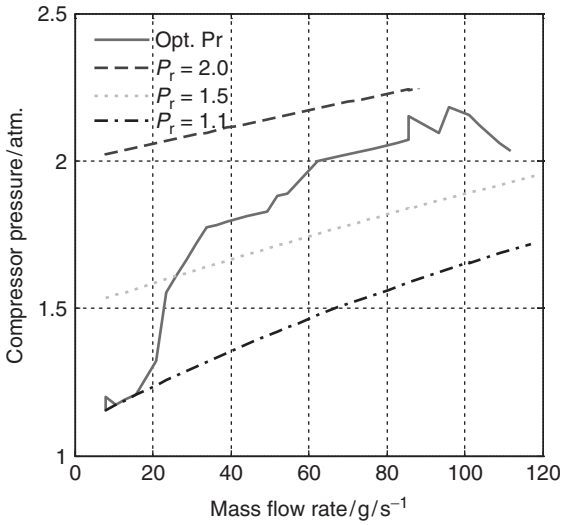

Figure 7. Optimal compressor quasi-steady responses for different operating modes.

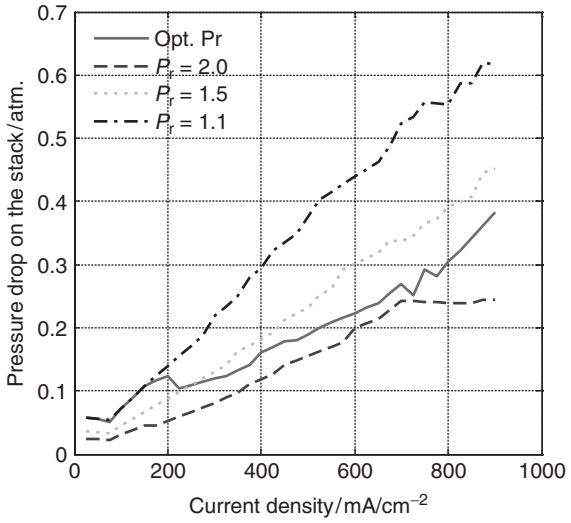

Figure 8. Pressure drop across the stack versus current density.

partial pressure at the catalyst layer and low pressure loss on the stack.

- At medium load demand, there is no apparent difference in the system efficiency for the different operation modes. However, low pressure operation requires a much larger humidifier than high pressure operation.
- The optimal operation can achieve higher efficiency over wide load change. However, coordinated control of the compressor and the back pressure valve can be complicated and is needed to avoid large transient voltage drops during rapid changes in power demand.

4 FUEL CELL VEHICLE CONTROL STRATEGY AND SIMULATION

4.1 Vehicle power splitting strategy

As discussed in the previous section, optimal operation of a fuel cell system varies the back pressure and air supply SR according to the change of the power demand. Coordinated control of the mass flow and pressure of the cathode and anode sides of the stack is required. This is the main drawback of the optimal operation of the fuel cell system for automotive applications. These rapid changes in the operating conditions of the fuel cell stack can have a major impact on the lifetime of the fuel cell stack because of the mechanical and thermal stresses on the MEA and the stack accessory components. Hybridization of the vehicle power train is an effective approach to mitigate the stress on the fuel cell stack by shifting most of the dynamic power demand to a second power source such as batteries and/or ultracapacitors. Another advantage of hybridization of an FCV is the ability to recover energy while decelerating through regenerative braking. In the hybrid configuration, the total power demand from the vehicle is satisfied by splitting the power between the fuel cell stack and the second power source, usually a battery pack. The power split strategy has a significant effect on the dynamics of the power demands of the fuel cell stack and the battery pack. The primary factors of interest for different power split strategies are impacts on the sizing of the power sources, durability of the fuel cell stack and battery, and vehicle fuel economy.

The fuel cell operation (power, voltage, current vs time) and hydrogen consumption (fuel economy) are closely related to the strategy utilized to split power between the fuel cell and the energy storage as the vehicle is operated over various driving cycles. The general objective of any control strategy is to operate the fuel cell system only in its high efficiency region, avoiding operation in the very low power and very high power regions. Power-assisted control and load leveling control strategies can be used in hybrid FCVs (Zhao and Burke, 2010a). Power-assisted control splits the power/current demand of the traction motor i_{motor} based on the fuel cell voltage V_{fc} and the energy storage SOC. The current command for the energy storage device i_{ess} is expressed in Equation 2 with the fuel cell providing the remaining current (Equation 3).

$$i_{\text{ess}} = f_{\text{fc}}(V_{\text{fc}}) \cdot f_{\text{ess}}(\text{SOC}) \cdot i_{\text{motor}} \tag{2}$$

$$i_{\text{fc}} = i_{\text{motor}} - i_{\text{ess}} \tag{3}$$

where f_{fc} and f_{ess} are factors related to fuel cell voltage and energy storage device SOC, respectively. If the fuel cell voltage remains relatively high, it will provide most of the current to the motor. When the fuel cell voltage becomes low, the energy storage device will provide a large fraction of the current demanded by the motor. Figure 9 shows an example of the splitting factors of f_{fc} and f_{ess} used in a fuel cell-battery hybrid vehicle with power-assisted control.

For load leveling control, the fuel cell provides relatively steady power and the energy storage device provides transient power. The fuel cell current command i_{fc} is calculated by averaging the traction motor current i_{motor} over a specified time period such as 60 s.

$$i_{\text{fc}} = i_{\text{av,60s}} \tag{4}$$

$$i_{\text{ess}} = i_{\text{motor}} - i_{\text{av,60s}} \tag{5}$$

The implementation of the control strategy for power split is shown in Figure 10. Both control strategies maintain

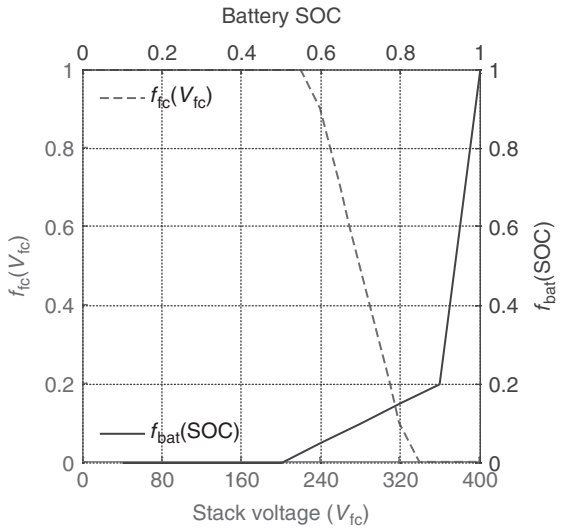

Figure 9. Power split factors for power-assisted control.

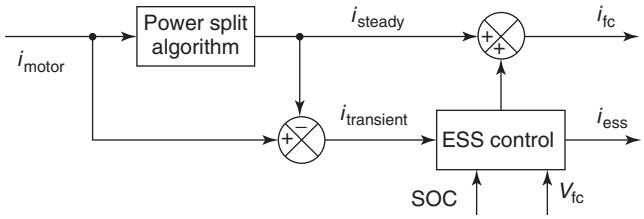

Figure 10. Schematic of power split control.

the SOC of the battery or supercapacitor within a specified range. Compared to the power-assisted control, load leveling control permits the fuel cell to operate within a relatively narrow high efficiency region. This mitigates the stress on the fuel cell and maximizes fuel cell life by utilizing the energy stored in the battery or supercapacitor to meet high power transients. However, a significant fraction of the transient power passes through the DC/DC converter for leveling the fuel cell current, which introduces significant losses in the power electronics.

For FCVs with supercapacitors coupled directly in parallel with the fuel cell, no DC/DC converter is employed. The voltages of the supercapacitor unit and fuel cell are equal. The current of the supercapacitors is governed by the differential Equation 6.

$$\frac{dV}{dt} = \frac{i_{cap}}{C} + R_{cap}\frac{di_{cap}}{dt}, V = V_{cap} = V_{fc} \qquad (6)$$

This arrangement avoids the losses in the DC/DC and takes maximum advantage of the high efficiency of the supercapacitors.

4.2 Fuel cell vehicle simulation

4.2.1 Vehicle simulation inputs

Simulations of the operation of fuel cell hybrid vehicles using various drive train arrangements and energy storage technologies (Li-ion batteries and supercapacitors) were performed using the UCD FCV simulation program (Zhao and Burke, 2010a, 2009a, 2009b). Simulations were performed using both the power-assisted and load leveling control strategies. In addition to the choice of drive train arrangements and energy storage technologies, the simulations have been run with different size energy storage units (kWh or Wh). In the simulations, the battery SOC is maintained between 0.6 and 0.8. In addition, the regenerative braking currents are limited to protect the batteries from over voltage. The minimum voltage of the supercapacitor is set at 50% of its rated voltage, which limits the maximum usable energy to 75% of the total energy stored in the capacitor. The supercapacitor SOC $= 1 - \left[\frac{(V_{rated} - V)}{(V_{rated}/2)}\right]$ is controlled to be between 0.95 and 0.2. Test data for the carbon/carbon supercapacitors (Burke and Miller, 2009a) and the lithium batteries (Burke and Miller, 2009b) are used to model the energy storage units.

Simulations were performed for mid-size passenger vehicles without energy storage, with supercapacitors directly connected in parallel with the fuel cell, with the fuel cell connected to supercapacitor DC-link via a DC/DC converter, and with supercapacitors and Li-ion batteries

coupled with the fuel cell through a DC/DC converter. All the drive trains were simulated in the same vehicle having the road load characteristics shown in Table 4. The fuel cell system generated a net output power of 87.6 kW. The total vehicle mass was adjusted to reflect the type and capacity of the energy storage unit and was recalculated based on the specific energy of energy storage units. The rated traction motor power was 75 kW for all cases. An empirical efficiency map of a bidirectional DC/DC converter, indexed by the input/output voltage ratio and the output power, was employed in the simulations. The energy storage current is limited by the maximum charging/discharging current, which is calculated based on the open circuit voltage, the maximum/minimum voltage, and the internal resistance of the energy storage.

4.2.2 *Fuel cell vehicle simulation results*

Energy storage is utilized in the fuel cell driveline both to improve the fuel economy of the vehicle and to increase the life of the fuel stack by reducing the peak currents and current transients that it experiences. First, consider the improvements in fuel economy projected using the various driveline arrangements with lithium batteries and ultracapacitors. Detailed simulation results for the various drivelines for the FUDS and US06 cycles are given in Table 5. The fuel economy results are summarized in Table 6.

Table 5. Comparisons of energy consumptions and efficiencies of fuel cell vehicles using different drivelines with energy storage.

	US06	50.7/—	

The effect of the control strategy on fuel economy improvement is of particular interest. In all cases, the improvement is calculated relative to the driveline without energy storage, in which case the fuel cell is load following and there is no energy recovery during braking of the vehicle. In general, the power-assisted strategy results in larger improvements in fuel economy than the load leveling strategy. This is due to the higher losses in the energy storage and the DC/DC in the case of the load leveling strategy that requires a greater fraction of the energy to pass through energy storage. However, the load leveling strategy mitigates to a larger extent current transients in the fuel cell stack. As shown in Table 6, the improvements in fuel economy using energy storage are modest in magnitude being in most cases less than 15%. The fuel economy improvements are slightly less for the US06 cycle than for the FUDS. The largest improvements projected are using ultracapacitors directly connected to the fuel cell bus without DC/DC electronics. In this case, the improvements are 18–25%. The simulation results indicate that the best approaches are to use ultracapacitors without DC/DC electronics or batteries with power-assisted control strategy. An ultracapacitor unit storing 100–120 Wh of usable energy or a lithium battery storing 1.5 kWh seems to be good energy storage solutions for FCVs. The influences of energy storage unit capacity on the fuel economy improvement for ultracapacitors and batteries are shown in Figures 11 and 12.

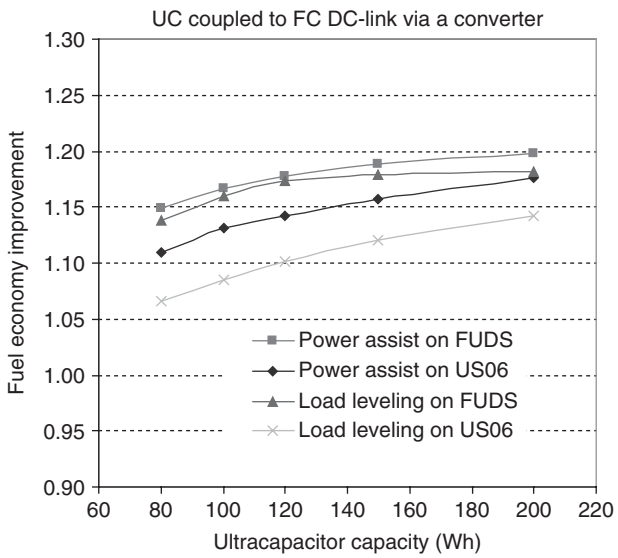

Figure 11. Fuel economy improvements of fuel cell vehicles utilizing ultracapacitors for different control strategies.

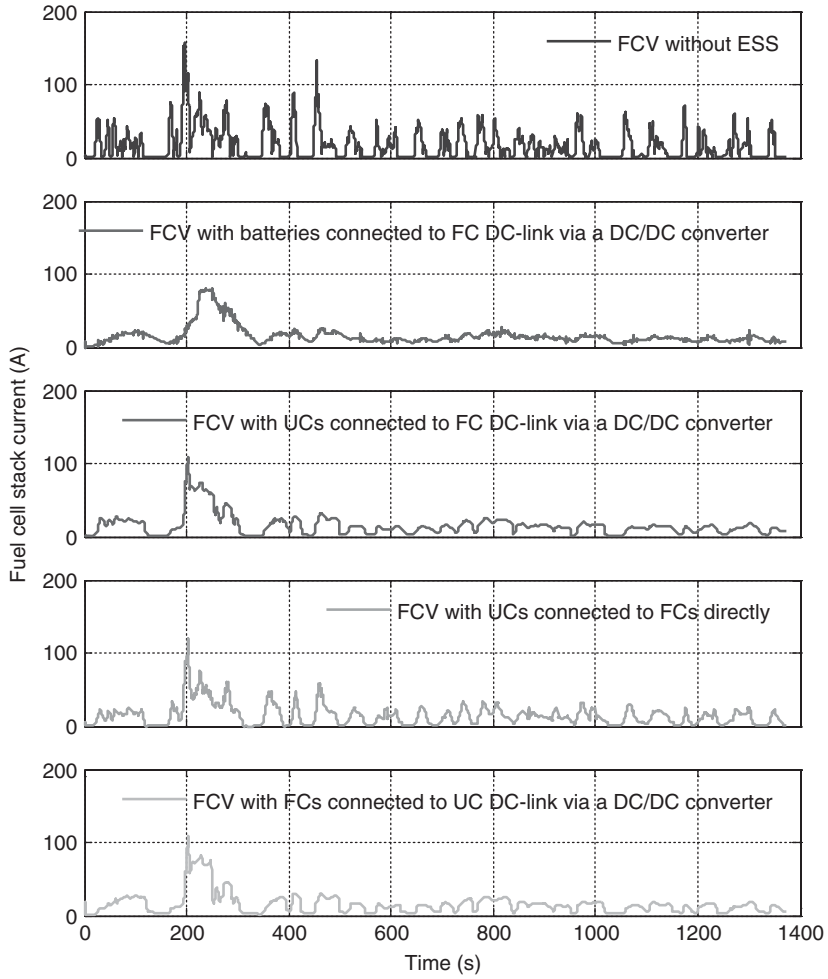

Figure 13. Comparison of the current transients for various driveline arrangements on the FUDS.

Comparisons of the simulation results for the fuel stack and energy storage unit currents using the different drive train configurations are shown in Figures 13 and 14. The results indicate that the use of energy storage in all cases significantly reduce the maximum current and the current transient dynamics and thus mitigates the stress on the fuel cell stack. However, the reduction of the current transients is significantly greater using the load leveling control strategy (Figure 14). Connecting the ultracapacitors directly across the fuel cell results in only slightly higher transients than with the load leveling strategy (Figure 13).

4.3 Comparison of the fuel economy of fuel cell vehicles with other advanced technology vehicles

As one of the future vehicle technologies, it is of interest to compare the fuel economy of FCVs with that of other advanced technology vehicles being developed to reduce fuel use and greenhouse gas emissions from passenger cars in years ahead. Computer simulations of the operation of mid-size passenger cars were performed for fuel cell-battery hybrid vehicles, hybrid electric vehicles (HEVs), and advanced conventional internal combustion engine (ICE) vehicles in future years—2015, 2030, and 2045—to project how much each technology would reduce energy consumption (Burke and Zhao, 2010; Ogden and Anderson, 2011).

The FCVs (FCHEV) used for comparison with the other vehicle technologies are fuel cell-battery hybrids with the lithium-ion battery connected to the fuel cell bus by a DC/DC converter. The converter controls the output power of the battery such that the output power of the fuel cell is load leveled. The engines used in the simulations of HEVs and conventional ICEs are spark-ignition engines. The engine efficiencies are increased in the simulations for

future years based on expected significant improvements in engine technology (Kasseris and Heywood, 2009). The batteries used in the simulations of HEVs and FCHEVs are scaled from lithium titanate oxide batteries (Burke and Miller, 2009b) (Table 7). The vehicle characteristics—curb weight, drag coefficient, frontal area, and tire rolling resistance—are the same as assumed by DOE (Plotkin and Singh, 2005). A summary of the vehicle and powertrain characteristics used in the simulations is given in Table 8.

Simulations of the fuel cell-battery hybrid vehicles were performed for the FUDS, HWY, and US06 driving cycles for the years of 2015, 2030, and 2045, respectively. The simulation results for the fuel economy are given in Table 9. Also shown in the table are the FCV fuel economy projections of DOE (Plotkin and Singh, 2005).

The projected fuel economy and fuel savings for the different driving cycles are plotted in Figures 15 and 16. The simulation results indicate that large improvements in the fuel economy of mid-size fuel cell-hybrid passenger cars can be expected in 2015–2030. Further improvements are projected for 2045. Compared to a mid-size 2007 baseline passenger car, these improvements are 60% (2015) to 70% (2045) for fuel savings. The simulation results published

by the DOE (Plotkin and Singh, 2005) are also plotted in Figures 15 and 16. The UCD and DOE projections for fuel cell-battery hybrids are in good agreement over the complete time period of the simulations with the agreement being closest in the 2030–2045 time periods.

Studies directed toward projecting the performance of advanced ICE vehicles and HEVs were also performed in

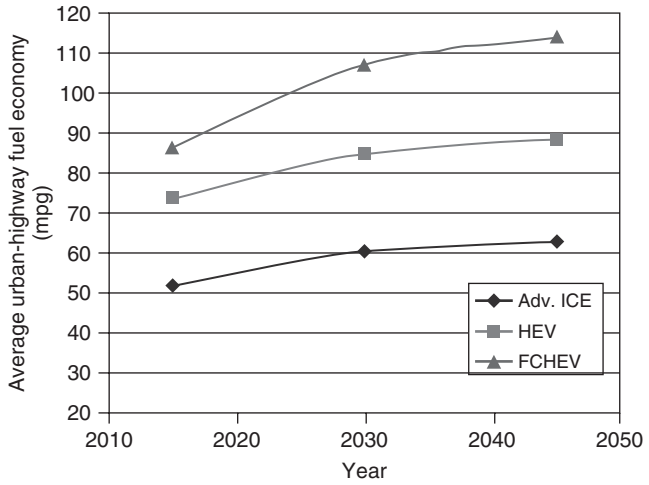

Figure 17. Comparisons of the fuel economies of future advanced vehicle technologies.

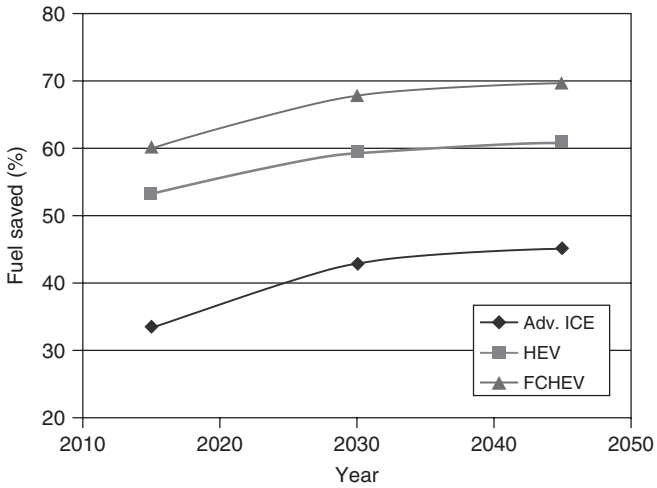

Figure 18. Comparison of fuel savings of future vehicle technologies.

(Burke and Zhao, 2010; Ogden and Anderson, 2011). The projected fuel economies and fuel savings for advanced ICEs, HEVs, and hybrid FCVs are plotted in Figures 17 and 18, respectively. The simulations show that FCVs achieve about twice the fuel economy of the improved conventional engine/transmission ICE vehicles, but only about 33% better fuel economy compared to the HEV vehicles. However, the resultant difference in the fuel savings of the FCVs compared to the hybrids is only 16%. This savings does not include consideration of the differences in the efficiencies of producing gasoline from petroleum and hydrogen from natural gas or coal.

All-Wheel Drive Hybrid System

Eiji Sato

Toyota Motor Corporation, Toyota, Japan

1 INTRODUCTION

All-wheel drive (AWD) systems may be implements in hybrid vehicles with a number of alternative configurations that may extend to individual wheel control. Some aspects of these are considered in EV Powertrain Configurations and Basic Consideration.

One type of AWD hybrid electric vehicle (HEV) takes a combination approach in which a rear-wheel motor system is added to a front-wheel drive (FWD) hybrid system. As this combined hybrid system does not require a propeller shaft to mechanically connect the front and rear wheels, it is relatively easy to secure the space to install the rear-wheel motor system, and its installation results in only a small increase in weight. The rapid response of the rear-wheel motor in this system also allows refined front- and rear-wheel driving force control, in accordance with the driving conditions, and four-wheel regeneration. As a result, this improves fuel efficiency while enhancing dynamic performance on low friction road surfaces. In addition, installing drive motors for the front and rear wheels increases the overall driving force and allows the load to be evenly divided between the front and the rear wheels. Consequently, this system is particularly suitable for heavy vehicles such as minivans and sport utility vehicles (SUVs).

Using the current Lexus RX400h as a specific example, this chapter describes the configuration of the hybrid system used in an AWD HEV, its component technology, and its control principles.

2 BACKGROUND

Toyota Motor Corporation launched the Estima Hybrid as an AWD HEV that combines a rear-wheel motor system with an FWD hybrid system in Japan in 2001 (Figure 1). This vehicle is an AWD hybrid minivan without a propeller shaft. The front wheels are powered by a parallel hybrid system that combines a mechanical continuously variable transmission (CVT) with a single motor, and the rear wheels are powered by a motor drive system that is mechanically independent from the front wheels (Sasaki, 2005).

In 2004, Toyota launched the Lexus RX400h hybrid SUV (Figure 2) and Highlander Hybrid. These vehicles were equipped with a similar but higher power rear-wheel system than in the Estima Hybrid but combined with the Toyota Hybrid System II (THS II) at the front. The THS II is a power split two-motor type hybrid system that uses a planetary gear set. It should also be noted that the RX400h was also produced with an FWD version without the rear-wheel motor (Sadakata and Ikuta, 2005).

3 SYSTEM OUTLINE

3.1 System configuration

Figure 3 shows the configuration of the AWD hybrid system. The front-wheel system is the THS II used in the Prius and other vehicles. Engine power is divided into two by the power split device, with a portion used to directly drive the front wheels and the remainder converted into electrical power by the generator. This power is then used to operate the motor in combination with power from the battery. In addition, the vehicle can be driven using the battery and motor even when the engine is stopped. A motor speed reduction device and a motor for driving the rear wheels were added to optimize this system for use in an SUV.

Table 1 lists the main specifications of each component in the AWD hybrid system and shows a comparison with the specifications of the components in the Prius.

3.2 Front-wheel unit

Figure 4 shows a cross-sectional view of the front-wheel hybrid system transmission for an SUV, and Table 2 shows its main specifications. This hybrid transmission includes a motor speed reduction device and a compound gear. The motor speed reduction device multiplies the output torque without increasing the length of the transmission.

The compound gear, which integrates two planetary ring gears, a counter (or transfer) gear and a parking gear, is laid out to the outside of the motor speed reduction gear and power split device. The use of this compound gear eliminates the chain in the previous hybrid system and

makes the system more compact by reducing the number of axes from four to three.

Figure 5 shows a schematic view of the front-wheel system. From the right side (engine side) of the figure, the first axis includes a damper with a torque limiter, a generator, two planetary gears, and a motor. The planetary gear on the right acts as the power split device that divides the force from the engine into driving force for the vehicle and force to drive the generator. The planetary gear on the left acts as the motor speed reduction device. The compound gear, which integrates the two ring gears, counter gear, and parking gear, is laid out to the outside of these two planetary gears. Driving force is transmitted to the counter-driven gear and drive pinion gear on the second axis and the ring gear and differential on the third axis.

3.3 Rear-wheel unit

In the rear transaxle, the distance between the input shaft from the motor and the output shaft to the side gear was shortened significantly. This results in a lightweight and compact three-shaft counter gear single-speed transaxle that can be integrated with the motor (Figure 6).

The rear-wheel unit in the Lexus RX400h uses an AC synchronous brushless motor based on that used in the Estima Hybrid. However, the operating voltage was increased to 650 V, which enabled a substantial increase in power by adjusting the number of coil turns in accordance with the voltage (Figure 7). As a result, coordinated control between the front-wheel and rear-wheel drive motors in accordance with the driving conditions creates rear-wheel driving force suitable for an SUV when the vehicle starts to move, while accelerating, and when climbing hills.

Figure 6. Rear-wheel unit. (Reproduced with permission from Sadakata and Ikuta (2005). © Toyota Motor Corporation.)

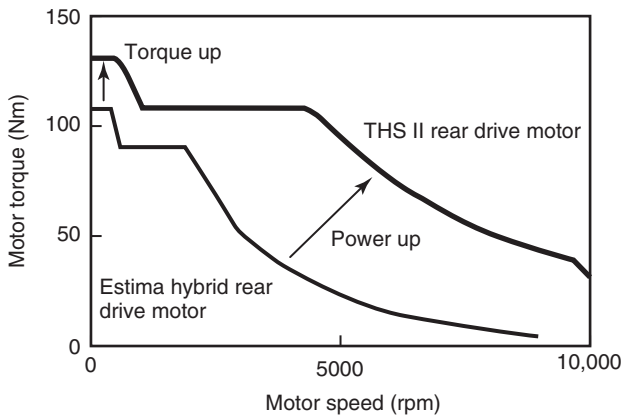

Figure 7. Rear drive motor torque profile. (Reproduced with permission from Kimura (2005). © Toyota Motor Corporation.)

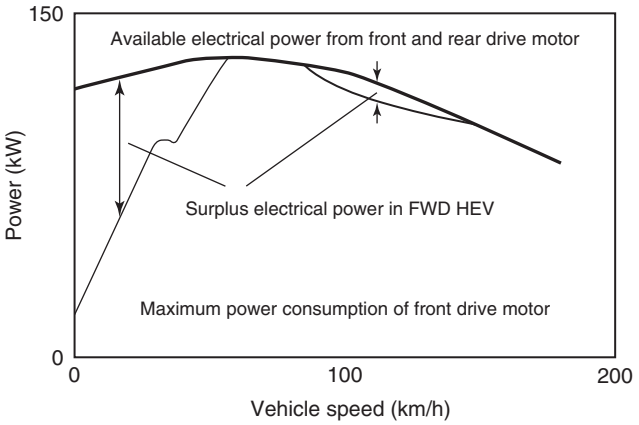

Figure 8. Surplus power in FWD HEV. (Reproduced with permission from Kimura (2005). © Toyota Motor Corporation.)

In an FWD HEV, surplus battery and generator power may occur in low speed regions. In the AWD HEV system, this surplus power can be converted to driving force by the rear-wheel motor (Figure 8). Although an FWD vehicle conventionally has superior dynamic performance than an AWD vehicle because of lower vehicle weight and other reasons, the conversion of surplus power by the rear-wheel motor gives the AWD HEV better dynamic performance than an FWD HEV, despite the weight increase caused by installing the rear-wheel unit.

3.4 Power control unit (PCU)

The THS II in the Prius contains a boost circuit that is capable of variable control up to a maximum of 500 V (Kikuchi and Matsubara, 2005). The boost circuit in the SUV hybrid system power control unit (PCU) is capable of variable control up to 650 V in accordance with the driving conditions. The increased motor size and the boosting voltage enabled a SUV hybrid system with a maximum motor output of 123 kW, which is approximately 2.4 times greater than the Prius THS II (maximum 50 kW). In addition, the PCU was designed to be compact enough for installation at the front of the vehicle, even while integrating the traction inverter for the rear-wheel motor, which has a maximum power of 50 kW (Figure 9).

Figure 10 shows the configuration of the primary circuit of the PCU. The inverters for the generator, front-wheel motor, and rear-wheel motor are voltage type inverters. These inverters drive the generator, front-wheel motor, and rear-wheel motor by the operation of switching devices using voltage boosted by the boost converter. The output from the generator and motor inverters is controlled by the three-phase voltage type pulse width modulation (PWM)

method. Voltage is applied to the generator and motor as sine wave or rectangular wave output depending on the rotational speed.

The PCU is water cooled. The generator and motor inverters are integrated at the top surface of the cooling circuit. The configuration can be made compatible with an FWD HEV by removing the rear-wheel motor inverter (Figure 11).

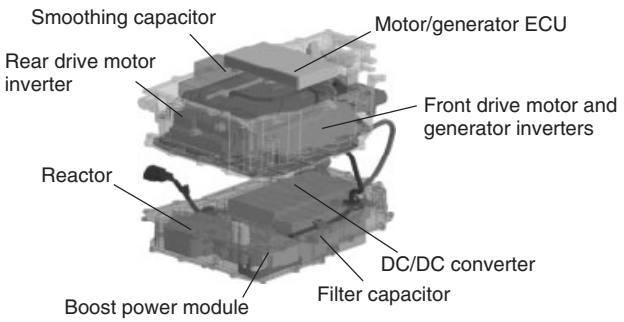

Figure 11. Configuration of PCU. (Reproduced with permission from Kikuchi and Matsubara (2005). © Toyota Motor Corporation.)

3.5 Battery

The AWD HEV system uses the same nickel-metal hybrid batteries as in the Prius. The number of cells was increased to 240 to adjust to the weight of an SUV. Instantaneous power is 45 kW with a 10 s rated value of 36 kW. The cells were also reduced in size to allow installation in a three-row SUV. Figure 12 shows how the batteries are installed under the second row of seats without affecting the internal space of the SUV. The main relay, the resistor to prevent inrush current, and the current sensor were integrated inside the battery pack, enabling a compact design.

4 CONTROL

4.1 Driving force distribution to front and rear wheels

The front-wheel unit is designed to generate sufficient performance for an FWD HEV (Kimura, 2005). In contrast, the power of the rear-wheel unit is restricted for packaging reasons. However, as the rear-wheel motor has power of 50 kW and 130 Nm, a 50 : 50 front-rear torque distribution is possible at an acceleration level of approximately 50% (Figure 13).

In this electrical AWD system, the front-wheel and rear-wheel units are installed with independent motors. Changes in the front-/rear-wheel driving force distribution ratio are implemented by changing the torque of the front- and rear-wheel motors. The distribution ratio can be changed rapidly as the driving force of the front and rear wheels is adjusted directly without intervention from hydraulics or other controls used in conventional AWD systems (Figure 14). This improves both fuel efficiency and vehicle stability.

4.2 Outline of AWD control

In consideration of driving force transfer efficiency, the AWD HEV system mostly operates the vehicle as an FWD HEV. AWD operation is only applied when necessary. As the rear-wheel unit is powered by electricity alone, constant output of driving force would require power generation by the front-wheel unit.

The reason for adopting FWD as the basic mode of operation is as follows: compared with FWD operation, AWD operation in this system reduces the torque of the front-wheel motor. This amount of torque is then added to the torque from the rear-wheel motor to enable AWD operation. This is preferable from the standpoints of overall driving force and the balance of the battery. If full-time AWD operation was adopted instead, the torque of the front-wheel motor would need to be increased to the negative side to drive the rear-wheel motor. The resulting power exchange between the front and rear-wheel motors would increase the losses of the electrical system and affect efficiency.

As described earlier, as the operation mode can be switched rapidly between FWD and AWD, vehicle stability can be guaranteed even when AWD is only engaged when necessary. AWD for vehicle stability is required when

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto067
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the vehicle starts to move, when the wheels begin to slip, or when turning left or right. AWD operation is also adopted for regeneration of kinetic energy during deceleration.

4.3 System operation

4.3.1 When vehicle starts to move

The engine is stopped when the vehicle is not moving. When the vehicle starts to move, AWD operation is selected and the front- and rear-wheel motors are driven by power from the battery (Figure 15).

4.3.2 Normal driving

During normal driving, the driving force from the engine is divided into two paths by the power split device (Figure 16). One path is used to directly drive the wheels. The other is used to drive the generator to generate power, which is then used to drive the motors.

4.3.3 Wide open throttle

When the driver accelerates the vehicle at wide open throttle, battery power is supplied to supplement the power from the engine (Figure 17). Maximum vehicle power is achieved by driving both the front- and rear-wheel motors.

4.3.4 Light load

When driving in conditions that may force the engine to operate in a low efficiency area, such as driving at low vehicle speeds or down a gradual hill, the engine is stopped and the vehicle is driven by the front-wheel motor (Figure 18). However, the engine is not stopped in

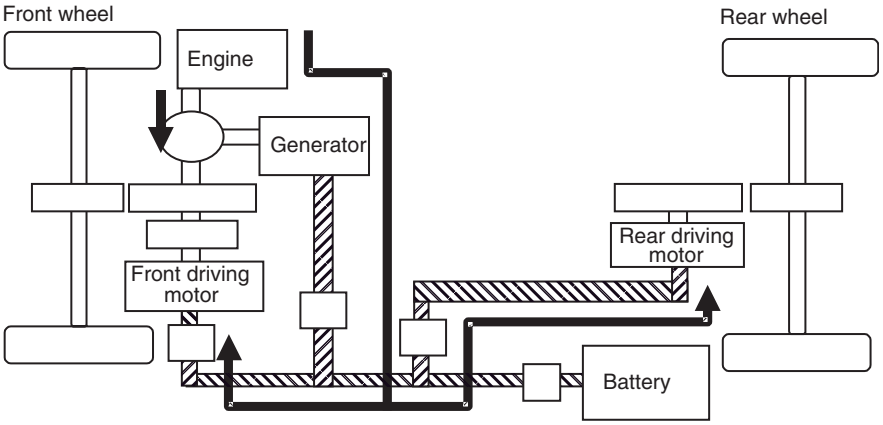

Figure 21. System operation (when front wheels slip). (Reproduced by permission of Toyota Motor Corporation.)

light-load regions if the battery charge is low or the engine coolant temperature is too low.

4.3.5 Deceleration and braking

When decelerating and braking, the wheels are driven by the front- and rear-wheel motors, which are operated as generators (Figure 19). The braking energy of the vehicle is regenerated into electrical power and used to charge the battery.

4.3.6 When charging

The system control maintains the battery charge at a constant level. If the amount of charge falls below a threshold level, the battery is charged using engine power through the generator (Figure 20).

4.3.7 When front wheels slip

When the system detects that the front wheels are slipping, a portion of the power from the generator is used to drive the rear-wheel motor (Figure 21). This reduces the driving force of the front wheels and generates driving force at the rear wheels. If the available power from the generator is not sufficient, the battery provides the necessary adjustment.

Engine Management Systems

John Lahti
John Deere Power Systems, Waterloo, IA, USA

1 INTRODUCTION

This chapter provides an overview of the engine control strategies that are commonly used for diesel and spark ignition engines. Models are now routinely used within the electronic control unit (ECU) to predict parameters that are not measured. The models may also be used for calculating the required actuator positions. These models and their use in the control structure are described. Strategies are explained for modeling and controlling the airflow, exhaust gas recirculation (EGR), variable geometry turbocharger (VGT) vane position, fuel injection, and spark advance. Model fidelity is discussed and a new individual cylinder engine model is introduced.

Engine control strategies for diesel and spark ignition engines are slightly different because of the different combustion strategies, but for the most part the engine models that are used for controlling the engine are the same. The main control differences are in the way the fuel is delivered, how combustion is initiated, and the strategy for regulating the air to fuel ratio. With spark ignition engines, the torque is regulated primarily with the air throttle, while the fuel is normally delivered at a rate that results in a stoichiometric mixture in the cylinder for combustion. Diesel engines regulate torque by directly controlling the fuel injection mass, with the engine running lean most of the time. The fuel injection mass may be limited to prevent smoke when there is insufficient air for complete combustion. Engine models may be used in the controller to predict some of the control parameters. The models of engine flow, throttle flow, EGR, as well as the turbocharger models are the same for both engine types. In both applications, EGR is used to reduce emissions of nitrogen oxides (NO_x). The same models can be used with each engine type to predict the concentration of air in the manifolds and in the cylinder.

2 ENGINE MANAGEMENT SYSTEM COMPONENTS

Engine controls were originally implemented using mechanical devices such as the carburetor, mechanical diesel fuel injector, distributor with centrifugal or vacuum advance, and thermal bimetal actuators. Although these devices provided acceptable performance in many applications and were relatively inexpensive, they could not provide the level of control needed to meet the emission regulations of today. Many of the control functions performed by these devices are now done electronically using sensors and actuators. The sensors provide information about the operating condition of the engine while the actuators are used to regulate its operation. The ECU

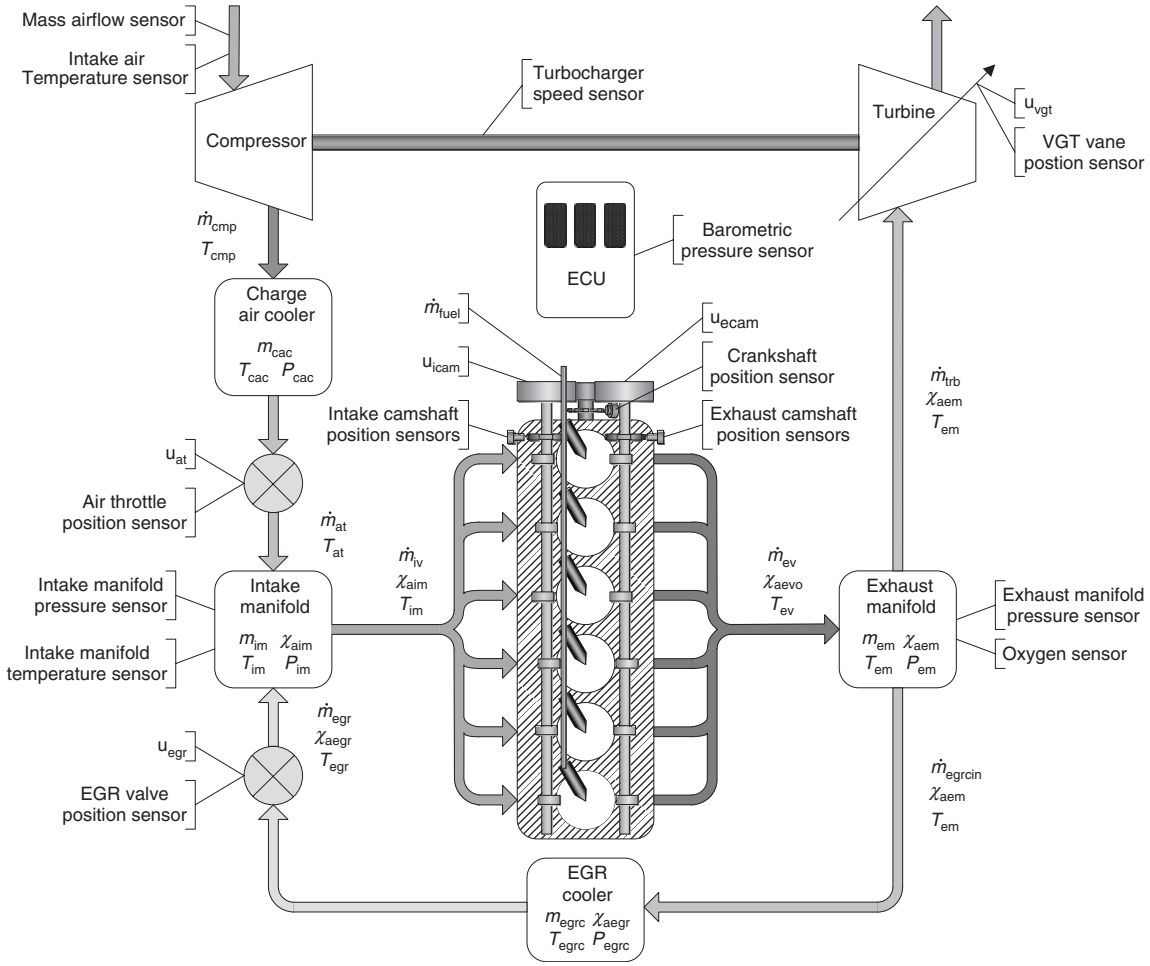

Figure 1. Engine components and model parameters.

processes information from the sensors and determines the desired position for each actuator.

Some of the components that make up the engine control system are shown in Figure 1. Also shown are model parameters described later.

2.1 Sensors

Some sensors interpret inputs from the driver of the vehicle. Examples of these include the accelerator pedal position, transmission range selector, and brake pedal switch.

Other sensors provide information about the operating condition of the engine. These include the coolant temperature sensor, intake air temperature sensor, and barometric pressure sensor. These signals change at a slow rate, allowing the sampling to occur at a slower rate than other sensors.

Some sensors provide information about the current state of the engine and may be used for feed forward and feedback control. These include the crankshaft position sensor, which is used for ignition and fuel injection timing as well as for calculating the engine speed. The camshaft position sensor along with the crankshaft position sensor determines where each cylinder is within the engine cycle. It may also be used to control camshaft phasing if the engine is equipped with variable valve actuation. The manifold air pressure sensor and mass airflow (MAF) sensor are used in the airflow calculations that determine the amount of fuel to inject and what spark advance is required. Oxygen sensors in the exhaust system provide feedback to the engine controller indicating whether the engine is running rich or lean.

2.2 Actuators

Actuators are devices that regulate operation of the engine. Examples of actuators include the fuel injector, air throttle,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

EGR valve, VGT turbine vanes, and ignition system. Actuators that have position control normally have a position sensor that is used with a feedback controller to maintain the desired position.

2.3 Controller

One of the factors contributing to widespread use of electronic engine controls has been emission regulations. Electronic controls make it possible to more accurately control the air to fuel ratio, spark advance, fuel injection timing, and EGR flow rate. Electronic controls can also improve performance, drivability, fuel economy, and integration with other vehicle systems.

Figure 1 shows some of the common sensors and actuators on an engine. The air throttle, EGR valve, and VGT vane are controlled using actuator commands: u_{at}, u_{egr}, and u_{vgt}, respectively. The intake and exhaust camshaft phasing are controlled using commands u_{icam} and u_{ecam}. Engines with electronic fuel injection regulate the fuel rate by controlling the duration of the fuel injector for each cylinder.

3 ENGINE CONTROL STRATEGIES

The block diagram for a typical engine control system is shown in Figure 2. The actuator controls are shown as just one block in this figure but the actuator control may have its own sensor and feedback controller. Proportional-integral-derivative (PID) controllers are commonly used for actuator position control. The actuator controller is within the control loop of the setpoint controller, which requires special consideration when selecting the controller gains. The actuator controls need to be fast enough during transient conditions to prevent the setpoint controller from making adjustments to the actuator setpoint because the actuator position and the corresponding engine response have not yet been achieved. To prevent dynamic interactions between these control loops the actuator control should ideally be more than 10 times faster than the setpoint control. A factor as low as 5 may be acceptable in certain cases.

The feed forward calculation shown in Figure 2 is a calculation of the required actuator position using the given setpoint command and known system parameters. Feed forward control allows the system to respond quicker under transient conditions because the required actuator position is calculated at each time step with essentially no lag. The feedback controller is different in that it is designed to remove control system error over a period with a certain time constant. Using the combination of feed forward and feedback control allows the system to respond quickly to changes in the setpoint command while still having the ability to correct for system changes or errors in the feed forward calculation. When the feed forward calculation is done correctly, the output of the feedback controller will be small.

The feed forward term can be obtained from tables, empirical models, or physics-based models. In some cases, the steady state position for the actuator is determined for each operating condition and those values are then placed in tables that are used to determine the feed forward term. This approach gets the actuator close to the required steady state position fast but it does not provide compensation for the system dynamic so the control under transient conditions is not as good as it could be. Empirical and physics-based models that more accurately account for the system dynamics can provide better transient response.

The main difference between empirical models and physics-based models is that empirical models generally require engine data for calibration whereas physics-based models are based mostly on first principles, allowing them to be calibrated with parameters such as component sizes and fluid properties.

An example of a physics-based model is the compressible gas flow equation for an orifice (Equation 1). This equation is commonly used for modeling airflow through the throttle. The parameter ψ is a function of the pressure ratio across

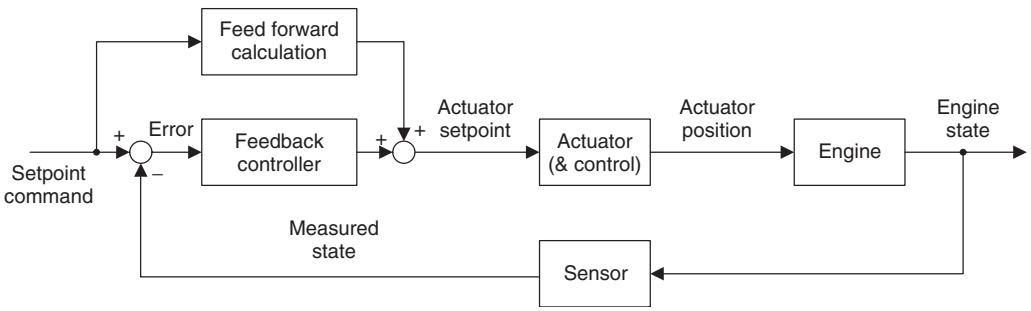

Figure 2. Engine control using sensor feedback.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

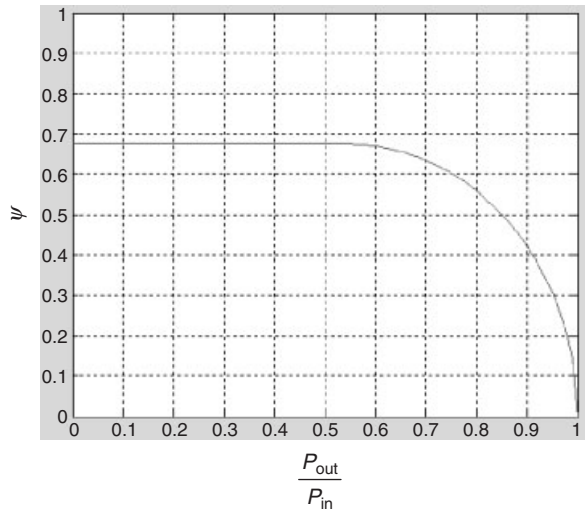

Figure 3. Parameter ψ for air throttle compressible gas flow equation.

the throttle and the ratio of specific heats for the fluid (Guzzella & Onder, 2010). Within the ECU, the parameter ψ is typically stored in a table covering a range of pressure ratios. The table lookup in this case is more efficient in terms of ECU throughput than the equation for ψ. A plot of ψ versus pressure ratio is shown for air in Figure 3. This model considers the throttle opening area, upstream air properties, and pressure ratio across the throttle. The effective area ($C_d \cdot A$) is typically calibrated using data from a flow bench and a table in the ECU with throttle position as the input.

$$\dot{m} = C_d \cdot A \left(\frac{P_{in}}{\sqrt{R_{in} \cdot T_{in}}} \right) \cdot \psi \tag{1}$$

$$\psi = \sqrt{k \cdot \left(\frac{2}{k+1} \right)^{\frac{k+1}{k-1}}}, \quad \text{for } P_{out} < P_{cr}$$

$$\psi = \left(\frac{P_{out}}{P_{in}} \right)^{\frac{1}{k}} \cdot \sqrt{\frac{2k}{k-1} \cdot \left(1 - \left(\frac{P_{out}}{P_{in}} \right)^{\frac{k-1}{k}} \right)}, \quad \text{for } P_{out} \geq P_{cr}$$

$$P_{cr} = \left(\frac{2}{k+1} \right)^{\frac{k}{k-1}} P_{in}$$

An example of an empirical model is the "speed–density" calculation for engine airflow using volumetric efficiency (VE) tables (Equation 2). This is a mean value model of the engine that does not account for the discrete events of each cylinder or the delays associated with the combustion cycle. The model does account for changes in manifold pressure, manifold temperature, and engine speed, making it a reasonably good method for predicting flow to the engine cylinders. This model is discussed in more detail in Section 3.1.1.

Models such as these can be used in a feed forward calculation to determine what manifold pressure is required to achieve the desired airflow to the cylinders or what throttle position is required to achieve a given airflow through the throttle.

In some cases, the desired control parameter does not have a sensor to provide a feedback signal. It may be impractical to have certain sensors because of cost or reliability. For example, it is not practical to measure the flow at the intake valve or to measure the mass fraction of air within the cylinder. If such parameters are important for controlling the engine, a model may be used to estimate these parameters so that the feedback controller can use them. Such a model is called an *observer* (Figure 4). The observer receives the same inputs as the real engine so dynamically it responds similar to the engine. The states of the model are compared to the measured states on the real engine allowing corrections to be made to the model, reducing the parameter estimation error.

In addition to providing state information to the feedback controller, information from the observer model and the model parameters may also be used in the feed forward calculation.

The following discussion describes how an observer model can be used to improve the engine airflow estimate that is used for controlling the air to fuel ratio and setting the spark advance.

3.1 Engine airflow

A mean value engine model is a model of the engine that does not consider the effects of individual cylinders. It assumes the flow through the engine is continuous as it would be in a gas turbine. When such a model is used for control purposes, the mass of air, fuel, or exhaust gas within each cylinder is calculated by evaluating the total mass going through the engine in one cycle and dividing by the number of cylinders.

3.1.1 Speed–density–flow

The speed–density model calculates flow to the engine cylinders using engine speed, the density of the fluid in the intake manifold, the displacement of the engine, and the VE (Equation 2). VE is the ratio of the actual flow to the theoretical flow that would be achieved if flow

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

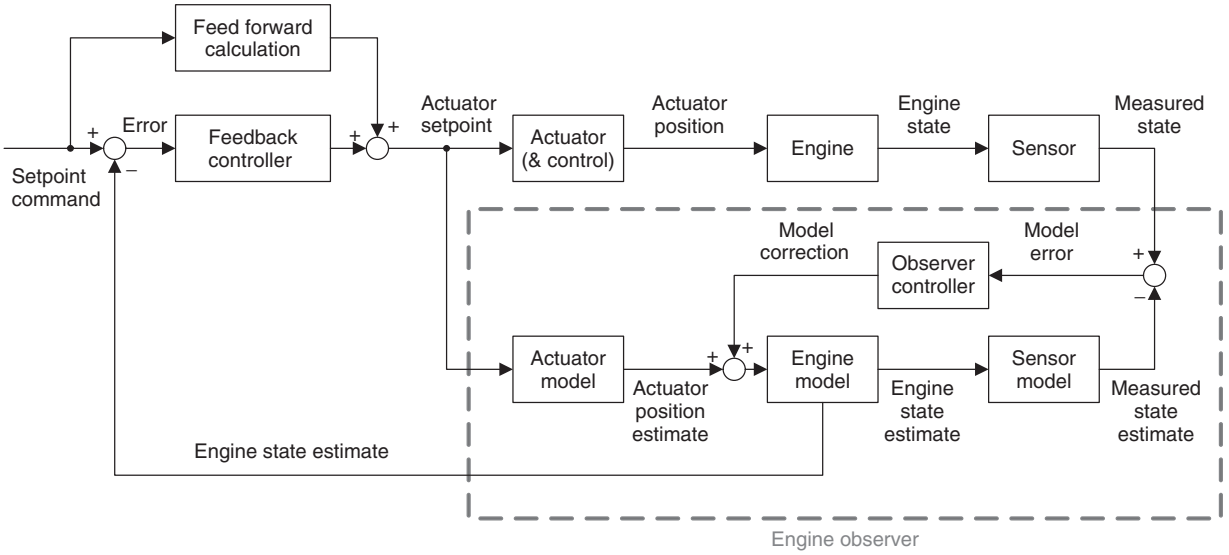

Figure 4. Observer-based engine control.

equivalent to the displaced volume of the engine at the intake manifold fluid density were achieved during each engine cycle. Sometimes, VE is specified with respect to the density of air at atmospheric conditions but this method is seldom used for control purposes. By setting Equation 2 equal to the measured mass flow from an engine test, it is possible to solve for the VE. The VE is sometimes calibrated using a table with axes of engine speed and intake manifold pressure. Turbocharged applications may require a more complex empirical model to accurately predict the VE.

$$\dot{m}_{\mathrm{iv}} = \left(\frac{N_{\mathrm{e}}}{120}\right) \cdot \rho_{\mathrm{im}} \cdot V_{\mathrm{disp}} \cdot \mathrm{VE} \tag{2}$$

This flow estimate includes both air and EGR entering the cylinder. During operation of the engine, the ECU calculates the mass entering each cylinder using the intake manifold fluid density, cylinder displacement, and VE as shown by Equation 3.

$$m_{\mathrm{cyl,in}} = \rho_{\mathrm{i}} \left(\frac{V_{\mathrm{disp}}}{n_{\mathrm{cyl}}}\right) \cdot \mathrm{VE} \tag{3}$$

The total mass in the cylinder at the time when the intake valve closes is equal to the mass that entered through the intake valve plus the residual mass that remained in the cylinder from the previous engine cycle (Equation 4).

$$m_{\mathrm{cyl,ivc}} = m_{\mathrm{cyl,in}} + m_{\mathrm{cyl,res}} \tag{4}$$

A separate model provides the estimate of $m_{\mathrm{cyc,res}}$. The residual mass will be affected by engine speed, manifold pressures, fuel rate, and valve timing.

The speed–density method provides reasonably good estimates of flow to the cylinder under steady state operation but there are several sources of error under transient conditions:

1. The mass of residual exhaust gas retained within the cylinder may change from one cycle to the next, making the VE under transient conditions different than the steady state value. When the intake manifold pressure is increasing the speed–density–flow estimate will be too low because the residual mass has not yet increased to the steady state value, which may cause the spark advance to be set too high resulting in engine knock.
2. The wave dynamics within the intake manifold will be changing under transient conditions and the pressure near the intake valve at the time when the valve closes may be different than it was during the steady state condition, resulting in a different VE.
3. On a port fuel injected engine, the fuel has to be injected before the intake stroke. The manifold pressure may change between the time at which the fuel was injected to the time when the intake valve closes, causing an error in the air to fuel ratio. The flow estimate will be too low when the intake manifold pressure is increasing and it will be too high when the intake manifold pressure is decreasing. The speed–density–flow estimate will cause the engine to run lean on tip-ins and rich on

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

tip-outs. This flow estimate tends to lag behind the true flow to the cylinders.

Some of the limitations listed here can be addressed by adding ad hoc features to the control software that make corrections under certain conditions. For example, when a tip-in is detected the spark advance can be reduced by several degrees to prevent knock. Alternately, to improve fuel control extra fuel can be added with a tip-in, or removed with a tip-out. Calibration of these corrections for all operating conditions can be very time consuming.

The speed–density–flow estimation can be improved by using predicted manifold pressure instead of a measured value that may have to be filtered. The method of using predicted manifold pressure is discussed more in Section 3.1.3.

3.1.2 Measured mass airflow

A MAF sensor measures flow in the air intake duct between the air cleaner and the throttle, or before the compressor on turbocharged engines. Under steady state conditions, this flow (plus the EGR flow rate) should match the speed–density–flow estimate. Under conditions where the intake manifold pressure is changing, the mass contained within the intake manifold will also be changing. For the case with no EGR flow, when the intake manifold pressure is increasing the measured MAF will be higher than the actual airflow into the cylinders. Likewise, when the intake manifold pressure is decreasing the measured MAF will be lower than the actual airflow into the cylinders. These characteristics are opposite to those of the speed–density calculation. The measured MAF tends to lead the true cylinder airflow.

The measured MAF would not provide very good fuel control under transient conditions if used directly. The real benefit to using a MAF sensor is that corrections can be made to the VE, improving the airflow estimate under steady state conditions. The speed–density model provides an estimate of flow to the cylinder while the VE is corrected with the MAF reading. This model-based approach to cylinder air charge estimation is described more in the following section.

3.1.3 Model-based cylinder air charge estimation

One way to improve the estimate of air entering the cylinder is to use a model-based approach. By constructing an observer model of the engine, it is possible to predict the rate of change in intake manifold pressure. The rate of change in manifold pressure can then be used to predict the pressure in the manifold at the time when the intake valve closes. The modeled version of the intake manifold pressure will have less variation than the measured value and will not require filtering. This approach can overcome the lag associated with the speed–density–flow estimate and provide a much more accurate estimate of cylinder air charge for the fuel injection calculations.

The observer model can also estimate the concentration of air and exhaust gas within the cylinder, allowing spark advance and other control parameters to be set for the expected state of the cylinder. This approach improves control under transient conditions.

3.2 Exhaust gas recirculation

EGR significantly increases the complexity of the models needed to predict the mass of air entering the cylinder and the composition of the mixture within the cylinder. Modeling airflow, EGR flow, and residual exhaust gas within the cylinder allows the air per cylinder and exhaust gas concentration to be calculated. This information can then be used to deliver the correct amount of fuel and to set the spark advance.

Diesel engines regulate the exhaust gas concentration for controlling NO_x. Since diesel engines commonly run lean, the calculation of residual and recirculated exhaust gas must consider the concentration of excess air retained in the exhaust gas.

In order to control the mass of air per cylinder and exhaust gas concentration, an estimate of these parameters is needed. The next section describes an engine model that can be used as an observer within the ECU to provide this information.

3.2.1 Exhaust gas recirculation model

The model described in this section includes airflow, exhaust flow, and EGR flow. This is a mean value engine model with lumped parameter manifold models. Lumped parameter means that the concentration of air and exhaust gas is assumed to be evenly distributed within each manifold. The pressure and temperature within the manifold is also assumed to be uniform. Manifold models are based on the principal of conservation of mass. Manifold pressure can be calculated using the ideal gas law with manifold fluid mass and estimated or measured manifold temperature as inputs.

The equations that follow are for an engine with direct fuel injection. The equations will be slightly different for an engine with port fuel injection.

The rate of change in intake manifold mass is equal to the MAF through the throttle, plus the EGR mass flow,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

minus the mass flow entering the engine through the intake valves (Equation 5).

$$\frac{dm_{im}}{dt} = \dot{m}_{at} + \dot{m}_{egr} - \dot{m}_{iv} \tag{5}$$

The rate of change in air mass within the intake manifold is equal to the MAF through the throttle, plus the EGR mass flow times the mass fraction of air contained in the EGR, minus the mass flow entering the engine through the intake valves times the mass fraction of air in the intake manifold (Equation 6).

$$\frac{dm_{aim}}{dt} = \dot{m}_{at} + \dot{m}_{egr}\chi_{aegr} - \dot{m}_{iv} \cdot \chi_{aim} \tag{6}$$

The mass fraction of air contained in the intake manifold is equal to the mass of air in the intake manifold divided by the total mass of air and exhaust gas in the intake manifold (Equation 7).

$$\chi_{aim} = \frac{m_{aim}}{m_{im}} \tag{7}$$

The rate of change in exhaust manifold mass is equal to the mass flow leaving the engine through the exhaust valves, minus the EGR mass flow, minus the mass flow through the turbine (Equation 8).

$$\frac{dm_{em}}{dt} = \dot{m}_{ev} - \dot{m}_{egr} - \dot{m}_{trb} \tag{8}$$

The rate of change in air mass within the exhaust manifold is equal to the mass flow leaving the engine through the exhaust valves times the mass fraction of air in the exhaust gas when the exhaust valve opens, minus the mass flow to the EGR cooler times the mass fraction of air in exhaust manifold, minus the mass flow through the turbine times the mass fraction of air in the exhaust manifold (Equation 9).

$$\frac{dm_{aem}}{dt} = \dot{m}_{ev} \cdot \chi_{aevo} - \dot{m}_{egrcin} \cdot \chi_{aem} - \dot{m}_{trb} \cdot \chi_{aem} \tag{9}$$

The mass fraction of air contained in the exhaust manifold is equal to the mass of air in the exhaust manifold divided by the total mass of air and exhaust gas in the exhaust manifold (Equation 7).

$$\chi_{aem} = \frac{m_{aem}}{m_{em}} \tag{10}$$

The mass flow in the cylinder at the time when the intake valve closes is equal to the mass flow that enters the cylinder through the intake valve plus the residual mass (Equation 11). Mass flow rates are used here because this is a mean value model. In a real engine, these would be discrete masses for each cylinder event.

$$\dot{m}_{ivc} = \dot{m}_{iv} + \dot{m}_{res} \tag{11}$$

The exhaust gas residual mass fraction is defined as the mass of residual exhaust gas divided by the total mass in the cylinder at the time when the intake valve closes (Equation 12). Engine speed, manifold pressures, fuel rate, and valve timing all affect the residual mass fraction.

$$x_r = \frac{m_{res}}{m_{iv} + m_{res}} \tag{12}$$

Equation 12 can be rearranged and the residual mass can be expressed as a flow rate as shown in Equation 13. Expressing the residual mass as a mass flow allows it to be used in the mean value model.

$$\dot{m}_{res} = \dot{m}_{iv}\left(\frac{x_r}{1 - x_r}\right) \tag{13}$$

The mass flow in the cylinder at the time when the exhaust valve opens is equal to the mass flow in the cylinder at the time when the intake valve closes plus the fuel mass flow rate (Equation 14). Mass flow rates are used here because this is a mean value model. In a real engine, these would be discrete masses.

$$\dot{m}_{evo} = \dot{m}_{ivc} + \dot{m}_{fuel} \tag{14}$$

The mass flow through the exhaust valve is equal to the mass flow in the cylinder at the time when the exhaust valve opens minus the residual flow (Equation 15).

$$\dot{m}_{ev} = \dot{m}_{evo} - \dot{m}_{res} \tag{15}$$

The MAF in the cylinder at the time when the intake valve closes is equal to the mass flow through the intake valve times the mass fraction of air within the intake manifold, plus the residual mass flow rate times the mass fraction of air in the cylinder at the time when the exhaust valve opens (Equation 16).

$$\dot{m}_{aivc} = \dot{m}_{iv} \cdot \chi_{aim} + \dot{m}_{res} \cdot \chi_{aevo} \tag{16}$$

The mass fraction of air in the cylinder at the time when the intake valve closes is equal to the mass of air in the cylinder at the time when the intake valve closes divided by the total mass in the cylinder when the intake valve closes (Equation 17).

$$\chi_{aivc} = \frac{\dot{m}_{aivc}}{\dot{m}_{ivc}} \tag{17}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The MAF in the cylinder at the time when the exhaust valve opens is equal to the MAF in the cylinder at the time when the intake valve closes minus the fuel mass flow times the stoichiometric air to fuel ratio (Equation 18). For modeling purposes, the fuel is assumed to react with a stoichiometric amount of air in the cylinder. This assumption only applies when the engine is running lean. If the engine is running rich, there will be no remaining air in the exhaust gas.

$$\dot{m}_{\text{aevo}} = \dot{m}_{\text{aivc}} - \dot{m}_{\text{fuel}} \cdot \text{AFR}_{\text{stoich}} \tag{18}$$

The mass fraction of air in the cylinder at the time when the exhaust valve opens is equal to the mass of air in the cylinder at the time when the exhaust valve opens divided by the total mass in the cylinder when the exhaust valve opens (Equation 19).

$$\chi_{\text{aevo}} = \frac{\dot{m}_{\text{aevo}}}{\dot{m}_{\text{evo}}} \tag{19}$$

The equations presented up to this point can be shown in block diagram form as illustrated in Figures 5 and 6. Figure 5 is a model of the total mass flow through the engine. Figure 6 is a model of airflow and air concentration. The orifice equation for throttle airflow was shown in Equation 1. The speed–density calculation was shown in Equation 2.

The EGR valve and cooler could be modeled as an orifice and a volume, or with an empirical model in a different form. The mass fraction of air in the recirculated exhaust gas could be modeled using a transport delay instead of a volume with uniform mixture distribution. The hardware configuration and desired level of model fidelity will determine which model is the best for the application.

The mass of air and exhaust gas entering the cylinder from the intake manifold depends on the pressure in the manifold and the composition of the mixture within the intake manifold. Cross coupling exists between the pressure and concentration terms. To achieve the same mass of

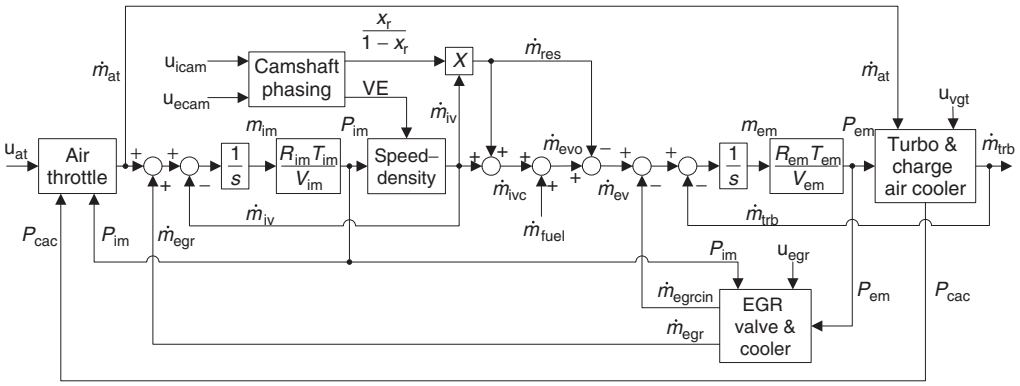

Figure 5. Engine mass flow model.

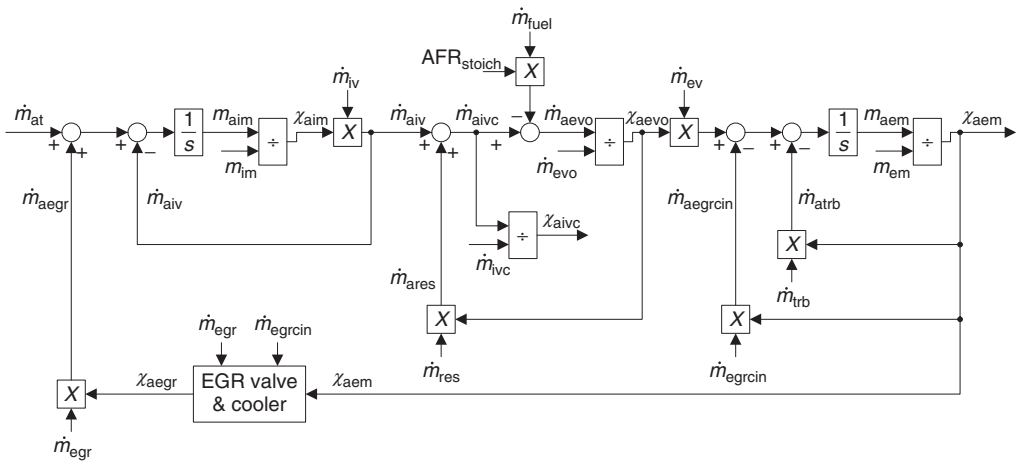

Figure 6. Engine air mass concentration model.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

air in the cylinder with a higher concentration of exhaust gas requires higher intake manifold pressure. In general, opening the EGR valve, closing the turbocharger vanes (higher back pressure), or closing the air throttle (lower intake manifold pressure) will provide more recirculated exhaust gas to the intake manifold, whereas closing the EGR valve or opening the air throttle will provide more air to the intake manifold. Depending on the operating range of the turbocharger, closing the vanes may increase both fresh airflow and EGR flow.

Certain actuators are better at providing fast response under transient conditions while others may be used to guide the system to an efficient operating point. For example, the air throttle provides the fastest air response but in many cases it is desirable to have the throttle opened all the way to minimize pumping losses. Likewise, the EGR valve can provide fast response for controlling the EGR rate but adjusting the VGT vanes also affects the EGR rate and there will be an optimum setpoint for each actuator under steady state conditions.

Different manufacturers have different strategies for controlling these actuators and the details are mostly proprietary. Some research papers have been published on this topic while additional work is still ongoing to determine the best approach. PID controls may provide acceptable performance in certain applications where the control response does not have to be very fast. The controls for these actuators are cross-coupled and very nonlinear, which can limit the gains used in a PID controller. Some researchers have proposed methods for decoupling the system, and others have proposed the use of sliding mode control to better handle the nonlinear characteristic of the system.

Multivariable control is an option that could provide very good control but is more difficult to implement. It uses optimization cost functions to provide a response that uses all the actuators in a way that can be calibrated to provide a response that is considered ideal or "optimal." The cost functions penalize factors such as excessive actuator movement, slow response, or control overshoot. Multivariable control works best with linear systems and the engine system is very nonlinear. One of the steps to implementing multivariable control is to create a model in state variable form, which may require the creation of several linear operating point models of the system. Another challenge is the proper handling of system constraints such as actuator limits, limits on manifold pressure, or turbocharger speed.

3.3 Fuel injection

On diesel engines, the driver demand torque (or governor torque) is primarily controlled with fuel. The other engine actuators respond as needed to provide the correct amount of air and EGR for the mass of fuel that is to be injected into the cylinder. Diesel engines typically run lean so the mass of air in the cylinder is not of much concern until operating at high loads where there may not be sufficient air in the cylinder to prevent smoke. Under a transient smoke-limited operating condition, the fuel injection mass may be limited until the other actuators can make adjustments to provide sufficient air to the cylinder.

With spark ignition engines, the driver demand torque is primarily controlled with the air throttle. The fuel injection quantity depends on the mass of air that is expected to be in the cylinder. A stoichiometric air to fuel ratio is normally maintained so that low levels of both hydrocarbons and NOx can be achieved. In addition, a stoichiometric air to fuel ratio allows the three-way catalytic converter to be most efficient at reducing emissions.

The rest of this section focuses on fuel injection controls for spark ignition engines.

3.3.1 Port fuel injection

Switching from carburetors to throttle body fuel injection offered the ability to accurately control the amount of fuel delivered to the engine. The real challenge was calculating how much fuel was required under transient conditions. A speed–density type model could predict the airflow to the engine cylinders with reasonably good accuracy but the changing intake manifold pressure affected the evaporation rate of the fuel and the resulting air to fuel ratio for the mixture entering the cylinders. One solution was to inject extra fuel with a throttle "tip-in" similar to the accelerator pump on a carburetor. Likewise, less than the normal amount of fuel could be injected when a throttle "tip-out" was detected. This ad hoc solution was difficult to calibrate for all operating conditions and did not provide very accurate control.

Aquino (Aquino, 1981) proposed a "wall-wetting" model of the intake manifold that accounted for the mass of liquid fuel within the manifold and the rate at which that fuel evaporated (Figure 7). By inverting this model, the fuel injection quantity can be adjusted to compensate for the liquid fuel accumulation and evaporation that occurs within the manifold.

The wall-wetting model was initially developed for throttle body fuel injection systems and then later applied to engines with port fuel injection. Although each port had independent fuel films that could be modeled separately it was common to continue using a single mean value wall-wetting model.

The following equations are used to model the wall-wetting process. The mass flow of injected fuel entering the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

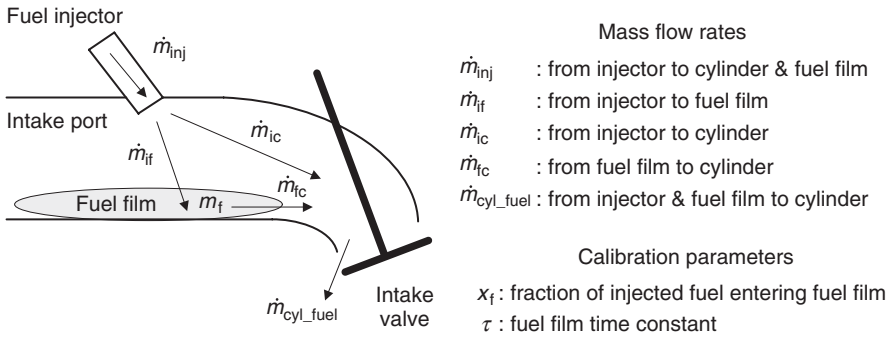

Figure 7. Port fuel injection wall-wetting model.

fuel film is equal to the mass flow of injected fuel times a factor x_f called the *impact factor* (Equation 20). The impact factor is the fraction of injected fuel entering the fuel film.

$$\dot{m}_{if} = x_f \cdot \dot{m}_{inj} \tag{20}$$

The mass flow of injected fuel not entering the fuel film is equal to the mass flow of injected fuel times one minus the impact factor (Equation 21).

$$\dot{m}_{ic} = (1 - x_f) \cdot \dot{m}_{inj} \tag{21}$$

The fuel film is assumed to evaporate with a time constant of τ (Equation 22). Fuel evaporating from the fuel film is assumed to enter the cylinder.

$$\dot{m}_{fc} = \frac{m_f}{\tau} \tag{22}$$

The change in mass of the fuel film is equal to the mass flow entering the film from the injector minus the mass flow that is evaporating and entering the cylinder (Equation 23).

$$\frac{dm_f}{dt} = \dot{m}_{if} - \dot{m}_{fc} \tag{23}$$

Figure 8 shows these equations in block diagram form. This model has the fuel injection mass flow as the input and the fuel mass flow entering the cylinder as the output.

This model can be inverted as shown in Figure 9 to have the mass flow entering the cylinder as the input and the mass of injected fuel as the output. The model in this form

can be used in the feed forward calculation to determine the amount of fuel to inject. This model will cause more fuel to be injected during a tip-in, when less fuel is evaporating from the fuel film, and less fuel to be injected during a tip-out, when more fuel is evaporating from the film.

3.3.2 Gasoline direct injection

The wall-wetting model is not required for engines with direct fuel injection because all the fuel stays in the cylinder until combustion. Gasoline direct injection normally occurs early in the engine cycle before the intake valve closes. This provides more time for fuel atomization before combustion, reducing hydrocarbon emissions. In addition, the cooling effect of the injected fuel allows more air to enter the cylinder, which allows higher peak torque and power to be achieved.

3.3.3 Closed loop air to fuel ratio control

To achieve a high level of conversion efficiency with the catalytic converter the air to fuel ratio has to be controlled very close to the stoichiometric ratio. Engine to engine variation, variation in fuels, and purging of the evaporative emission canister can cause the engine to run rich or lean of stoichiometry. Closed loop control can be used to correct for these fueling errors. The closed loop fuel controller uses an oxygen sensor for feedback (Figure 10). The oxygen sensor is installed in the exhaust manifold or exhaust pipe and provides a signal that is related to the oxygen concentration in the exhaust.

The oxygen sensor is constructed from a ceramic material called *zirconium oxide*. The sensor is in the shape of a thimble that protrudes into the exhaust stream. The inner and outer surfaces of the sensor are coated with porous layers of platinum, which act as the electrodes. When there is a difference in oxygen concentration between the inner and outer surfaces of the sensor, oxygen ions pass through the ceramic material with reactions occurring at the platinum electrodes generating an electric potential that can be measured as a voltage.

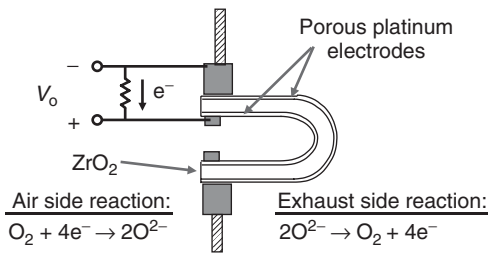

Figure 10. Oxygen sensor.

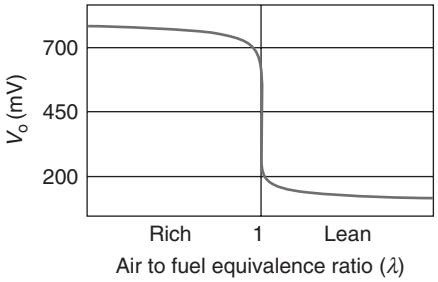

Figure 11. Oxygen sensor response curve.

The sensor voltage is related to the oxygen partial pressure at each electrode. The voltage can be approximated using the Nernst equation:

$$V_o = \frac{R \cdot F}{4F} \cdot \ln\left(\frac{P_{O_2\,\mathrm{ref}}}{P_{O_2\,\mathrm{exh}}}\right) \tag{24}$$

where R is the gas constant, T is the temperature, P is the partial pressure, and F is the Faraday constant. A typical response curve is shown in Figure 11. As the engine switches from running lean to rich, the oxygen sensor voltage increases significantly. The sensor operates as a switch, indicating whether the engine is currently operating rich or lean.

The sensor temperature has to be above a certain value for the reactions to occur at the platinum electrodes, generating the sensor output voltage. The minimum operating temperature for the sensor is about 300°C. Some sensors use an electric heating element to warm up the sensor so that it can be used for control sooner after a cold start.

The sensor is normally used with a proportion integral (PI) controller to adjust the mass of fuel that is injected. Figure 12 shows two examples: control with just integral control and control with a PI controller. With integral control, the fuel injection mass is adjusted up or down at each fuel injection event depending on the output of the sensor. When the oxygen sensor indicates that the engine is running lean, the integrator will increase the fuel injection mass until the oxygen sensor indicates that the engine is running rich; then, the fuel injection mass will start decreasing.

There is a delay between the time when fuel is injected and the time its effect is detected at the sensor. Part of this delay is associated with the engine cycle time and part is due to the transport delay for the exhaust gas to travel from the exhaust valve to the location of the sensor. The transport delay causes the air to fuel ratio at the engine to overshoot the setpoint and affects the period of the rich–lean cycling. The cycle time can be reduced by using a PI controller. Since a certain amount of overshoot is expected because

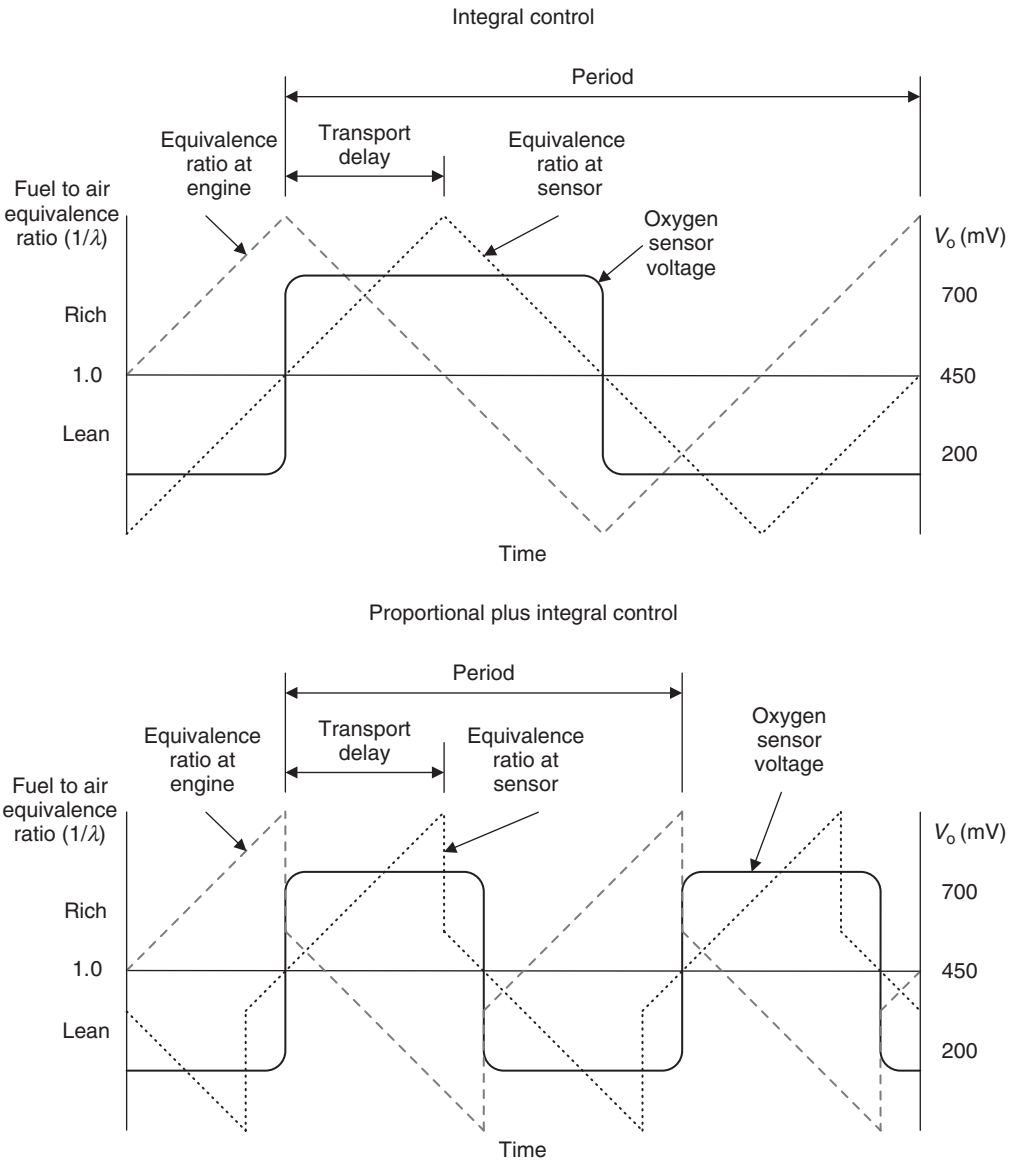

Figure 12. Air to fuel ratio control.

of the transport delay, the proportional term can be used to quickly change the fuel injection mass when a rich-to-lean or lean-to-rich transition occurs at the sensor. Figure 12 shows a reduction in the period of the rich–lean cycling with the PI controller.

3.4 Spark advance

Spark advance is normally set to a value that provides the maximum torque with the minimum amount of spark advance. This is called the *minimum spark advance for best torque* (MBT). Under some conditions with regular grade fuel the spark advance may have to be set lower to prevent engine knock. Knock occurs when the combustion mixture auto-ignites, making a knocking sound rather than burning as a flame front that propagates from the spark plug to the edge of the piston. Combustion may start off as a flame front and then auto-ignite once a certain temperature and pressure is achieved. Reducing the spark advance lowers the pressure during combustion, reducing the tendency to knock. The spark advance for the engine is normally calibrated using tables that are sometimes called maps. The base spark advance is normally set to the minimum of the MBT spark advance and the knock-limited spark advance.

The base spark advance table normally has engine speed as one axis and some indication of engine load on the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

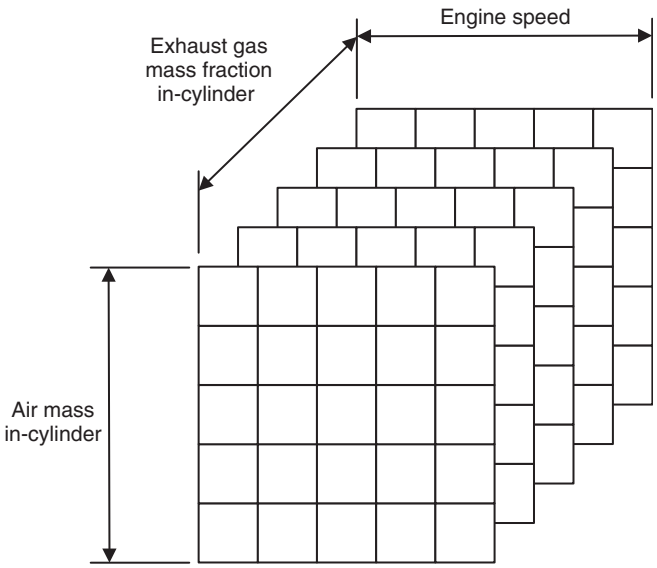

Figure 13. In-cylinder parameter-based spark advance table.

other axis. If only measured parameters are available the throttle position or intake manifold pressure are sometimes used as the second axis. If an engine airflow observer is implemented in the ECU, then the mass of air per cylinder could be used for the second axis.

The combustion burn rate is affected by the mass fraction of exhaust gas contained in the cylinder. If an estimate of exhaust gas mass fraction is available it could be used as a third table axis as shown in Figure 13.

The use of in-cylinder parameters for setting the spark advance provides good control under transient conditions because the advance is set using factors that ultimately affect the combustion process.

The spark advance may also be adjusted for non-standard operating conditions such as when the engine is colder or hotter than normal. These adjustments can be made using additional tables that adjust the spark advance based on coolant temperature or the estimated in-cylinder temperature.

Using only actuator positions or sensor measurements as inputs to spark advance tables would require many tables to cover all operating conditions and would not provide the level of transient control that is possible with in-cylinder estimated parameters.

4 INDIVIDUAL CYLINDER MODELS

As can be seen from what has been described up to this point, the mean value engine model can provide a lot of useful information for controlling the engine when implemented as an observer in the ECU. There are still some sources of error that may need to be addressed if more accurate control is required for advanced combustion strategies such as homogeneous charge compression ignition (HCCI). These limitations are as follows:

1. The real engine operates in discrete cylinder events with delays associated with the engine cycle that are not properly captured by the mean value model. This can cause errors in the residual cylinder mass and composition calculations.
2. The model does not account for the wave dynamics in the intake manifold that can significantly change the flow entering the cylinder under transient conditions from that of the flow predicted by the speed–density method using VE tables.
3. Engines with variable valvetrain systems offer a wide range of valve-opening strategies, making it difficult to accurately model all possible operating conditions with VE tables.

These limitations can be overcome by using a higher fidelity model that includes individual cylinders and by modeling the wave dynamics of the intake and exhaust manifolds. Such a model provides more information but requires more processing capacity from the ECU. This approach eliminates the need for VE tables.

A project at the University of Wisconsin–Madison created a real-time combustion and compressible gas flow model that could be used in an ECU as an observer (Lahti, 2004). The following discussion provides an overview of that model.

The wave dynamics were modeled using a process called the *method of characteristics*. The governing equations are the continuity equation and the momentum equation. Through a process or variable transformations the state of the fluid in the manifold runners can be defined using parameters called *Riemann variables*. One Riemann variable defines the right moving characteristic and the other defines the left moving characteristic. For isentropic flow, the Riemann variables remain constant as they propagate through the manifold runner. This modeling technique makes it possible to predict the state of the fluid at the valve and to predict the flow through the valve when the cylinder pressure is known. The reader is referred to Benson (Benson, 1982) for more details on the wave modeling techniques.

The method of characteristics was originally developed for solving wave problems on a drafting board. Later it was implemented as a computer program. Other wave analysis methods may provide more accuracy but the software code may not run fast enough to be used in a real-time

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

application. This method was found to work well when the isentropic flow assumption was not violated. If the valve timing was such that hot cylinder gases entered the intake runner during part of the intake event, the model would not accurately represent the wave dynamics at that point. If such a valve-opening strategy were required, a slightly more complex model could be implemented to more accurately model those effects.

An individual cylinder model was developed to calculate the temperature and pressure in the cylinder throughout the engine cycle. This information was used with the wave dynamics model to determine the flow through the valves.

The states of the cylinder were modeled using the first law of thermodynamics, conservation of mass, and the ideal gas law. The first law equation for the cylinder is

$$\dot{Q}_{cv} - \dot{W}_{cv} + \dot{m}_{iv} \cdot h_{Si} - \dot{m}_{ev} \cdot h_{Se} = \frac{d(mu_S)cv}{dt} \tag{25}$$

This right side of the equation can be rewritten as

$$\frac{d(mu_S)cv}{dt} = (\dot{m}_{iv} - \dot{m}_{ev}) \cdot u_S + m_{cyl} \cdot C_v \cdot \frac{dT_{cyl}}{dt} \tag{26}$$

It is now possible to solve for the rate of temperature change:

$$\frac{dT_{cyl}}{dt} = \frac{\dot{Q}_{comb} + \dot{Q}_{wall} - \dot{W}_{cv} + \dot{m}_{iv} \cdot h_{Si} - \dot{m}_{ev} \cdot h_{Se} - (\dot{m}_{iv} - \dot{m}_{ev}) \cdot u_S}{m_{cyl} \cdot C_v} \tag{27}$$

The temperature at each time step is calculated as

$$T_{cyl}(t + \Delta t) = T_{cyl}(t) + \frac{dT_{cyl}(t)}{dt} \Delta t \tag{28}$$

The cylinder mass is updated using the mass flow rates at the valves

$$m_{cyl}(t + \Delta t) = m_{cyl}(t) + (\dot{m}_{iv} - \dot{m}_{ev}) \cdot \Delta t \tag{29}$$

The pressure at the new time step is calculated using the ideal gas law:

$$P_{cyl}(t + \Delta t) = \frac{m_{cyl}(t + \Delta t) \cdot R_{cyl}(t + \Delta t) \cdot T_{cyl}(t + \Delta t)}{V_{cyl}(t + \Delta t)} \tag{30}$$

This model was evaluated using a single cylinder spark ignition research engine. Figure 14 shows the measured and estimated cylinder pressures through one engine cycle. During this test, the model was running in real time using a dSPACE rapid prototype control system. The measured and estimated cylinder pressures were nearly the same throughout the cycle. Similar results were obtained for different combinations of valve timing, valve lift, airflow, and engine speed.

The combustion heat release was modeled using a mathematical function called a *Weibe function*. Weibe functions are commonly used to model the mass fraction of fuel that has burned as a function of crank angle. The calibration parameters for the Weibe function were stored in tables

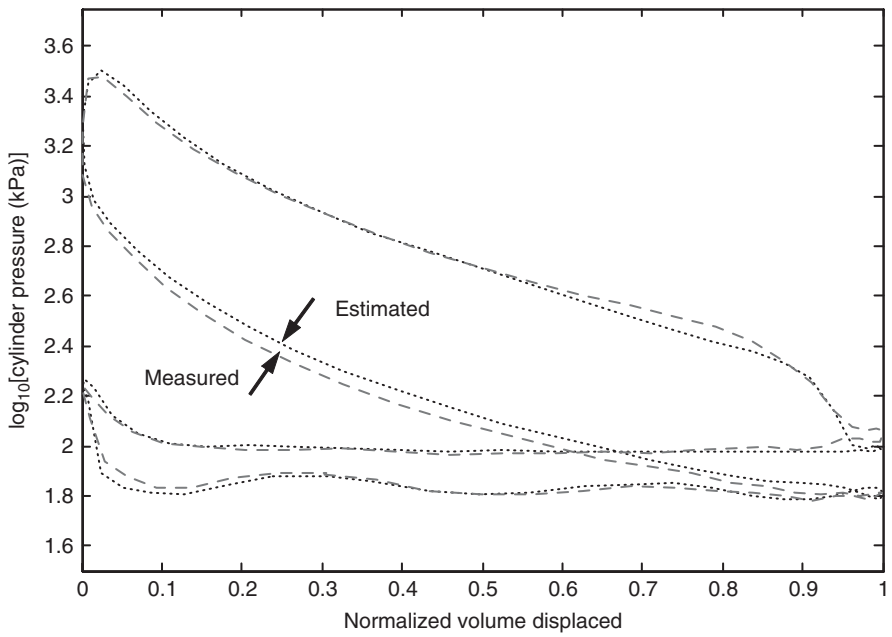

Figure 14. Real-time individual cylinder model data.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068

of the form shown in Figure 13 to be consistent with the strategy used for the spark timing. More complex models could be implemented to define the heat release for applications using premixed, partially premixed, or multiple direct inject combustion strategies.

With the individual cylinder models, each cylinder event is a transient event. The cylinder pressures and temperatures are continually changing. There is intermittent flow through the valves, and the mass within the cylinder keeps changing. This is much different than the mean value model where the flow is continuous and the engine cycles are assumed to occur with no delay.

One of the challenges to implementing HCCI in a production application is controlling the process under transient conditions. Current engine control strategies using mean value models are not able to provide information about the state of the engine with sufficient accuracy to control the process. The individual cylinder models offer an alternative that accurately represents many of the factors that affect when combustion begins. Information from the models could be used for controlling the trapped residual mass and EGR flow as a way of regulating the HCCI process.

A patent for the engine control technology described in this section is held by the University of Wisconsin Alumni Research Foundation (WARF) at the University of Wisconsin–Madison (Lahti & Moskwa, 2006).

5 CONCLUSION

In many cases, the engine parameters that need to be controlled are difficult or impractical to measure. It may be possible to model the important parameters using the actuator and sensor information that is available. Such a model is called *an observer*. There are several advantages to using observers: they provide the desired state feedback information without adding sensors, the modeled response does not require filtering like a sensed parameter, the model information can be used for feed forward calculations to provide better control response, and the observer can be used for diagnostics to detect changes in engine operation.

The mean value engine model may provide sufficient information for controlling the engine in some applications. As with any model, assumptions are made and those assumptions can be a source of error under certain conditions. The mean value model assumes continuous flow through the engine with no delays. This assumption may be acceptable for some applications but not for others.

The level of model fidelity for an application may vary depending on the requirements. Increasing model fidelity has many control advantages but the model must be capable of running in real time within the ECU, which has limited processing capacity. As processor capacity increases, in the future it may be possible to implement higher fidelity models such as the individual cylinder model, and models of the manifold wave dynamics. These higher fidelity models allow better control under transient conditions, which may resolve some of the implementation problems associated with alternative combustion strategies.

NOMENCLATURE

The variables listed below are used in the equations that follow.

Δt	controller time step
ρ_{im}	intake manifold fluid density
τ	wall wetting time constant
χ_{aegr}	mass fraction of air in EGR
χ_{aem}	mass fraction of air in exhaust manifold
χ_{aevo}	mass fraction of air when exhaust valve opens
χ_{aim}	mass fraction of air in intake manifold
χ_{aivc}	mass fraction of air when intake valve closes
ψ	compressible gas flow parameter
A	orifice area
$\text{AFR}_{\text{stoich}}$	stoichiometric air to fuel ratio
C_{d}	discharge coefficient
C_{p}	specific heat at constant pressure
C_{v}	specific heat at constant volume
ECU	engine control unit
EGR	exhaust gas recirculation
H	enthalpy
H_{s}	sensible enthalpy
k	ratio of specific heats
m_{aem}	mass of air in exhaust manifold
m_{aim}	mass of air in intake manifold
m_{cac}	mass in charge air cooler
m_{cyc}	mass in cylinder
$m_{\text{cyl,in}}$	mass that entered the cylinder from intake valve
$m_{\text{cyl,ivc}}$	mass in cylinder when intake valve closes
$m_{\text{cyl,res}}$	residual mass in cylinder
m_{egrc}	mass in EGR cooler
m_{em}	mass in exhaust manifold
m_{f}	wall-wetting model fuel film mass
m_{im}	mass in intake manifold
$\dot{m}$	mass flow through orifice
$\dot{m}_{\text{aevo}}$	mass flow of air (mean value model) when exhaust valve opens
$\dot{m}_{\text{aivc}}$	mass flow of air (mean value model) when intake valve closes

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto068

$\dot{m}_{at}$	mass airflow through throttle
$\dot{m}_{egr}$	mass flow of EGR
$\dot{m}_{egrcin}$	mass flow into the EGR cooler
$\dot{m}_{ev}$	mass flow through exhaust valve
$\dot{m}_{evo}$	mass flow when the exhaust valve opens
$\dot{m}_{fc}$	mass flow of fuel from film to cylinder
$\dot{m}_{fuel}$	mass flow of fuel to engine
$\dot{m}_{ic}$	mass flow of injected fuel entering cylinder
$\dot{m}_{if}$	mass flow of injected fuel entering fuel film
$\dot{m}_{inj}$	mass flow of injected fuel
$\dot{m}_{iv}$	mass flow through intake valve
$\dot{m}_{ivc}$	mass flow when intake valve closes
$\dot{m}_{res}$	mass flow of residual mass in cylinder
$\dot{m}_{trb}$	mass flow to turbine or exhaust pipe
MAF	mass airflow
n_{cyl}	number of cylinders
N_e	engine speed (rpm)
NO_x	nitrogen oxides
P_{cac}	pressure in charge air cooler
P_{cyl}	pressure in cylinder
P_{cr}	critical pressure
P_{egrc}	pressure in EGR cooler
P_{em}	pressure in exhaust manifold
PI	proportional-integral controller
PID	proportional-integral-derivative controller
P_{im}	pressure in intake manifold
P_{in}	orifice inlet pressure
P_{out}	orifice outlet pressure
$\dot{Q}_{comb}$	combustion heat release rate
$\dot{Q}_{cv}$	control volume heat transfer rate
$\dot{Q}_{wall}$	rate of heat transfer to the cylinder walls
R	gas constant
R_{in}	gas constant of flow entering orifice
T	time
T_{cac}	temperature in charge air cooler
T_{cyl}	temperature in cylinder
T_{egrc}	temperature in EGR cooler
T_{em}	temperature in exhaust manifold
T_{im}	temperature in intake manifold
T_{in}	temperature of flow entering orifice
U	internal energy
u_{at}	actuator command for air throttle position
u_{egr}	actuator command for EGR valve position
u_{ecam}	actuator command for exhaust camshaft position
u_{icam}	actuator command for intake camshaft position
u_{vgt}	actuator command for VGT vane position
U_S	sensible energy
V_{cyl}	volume of cylinder
V_{disp}	engine displacement
VE	volumetric efficiency
VGT	variable geometry turbocharger
$\dot{W}_{cv}$	rate of work done by the control volume
X_f	mass fraction of injected fuel entering fuel film
X_r	exhaust gas residual mass fraction

Turbocharging

Syed Shahed

3E Technology LLC, Rancho Palos Verdes, CA, USA

1 INTRODUCTION: TURBOCHARGING HISTORY AND PERSPECTIVE

The first turbocharger powered by engine exhaust was developed by Alfred J. Buchi, Chief Engineer, Sulzer Brothers Research Department, and was patented[1] in 1905. He did propose a turbocharged diesel engine in 1915 but early application was to aircraft gasoline engines. The primary purpose of boosting the intake pressure to an internal combustion engine is to increase power. The power developed by an engine is a function of the amount of fuel burnt, which is a function of the amount of air available and effectively utilized (near 100% in premixed gasoline engines, about 60–70% in diesel engines). The volume of air required is 9000 (for gasoline) to 20,000 (for diesel) times the volume of fuel. Hence, the power developed by an engine is limited by the amount of air available. Turbocharging greatly increases the amount of air an engine is able to breathe, and hence is greatly effective in increasing the power density (power/displacement). The impact of boost pressure on power density at high altitude is obvious. Hence, the first application of turbocharging was to gasoline engines used in aircraft. In 1920, the LaPere biplane achieved a record altitude for the time—33,113 ft.

Turbocharging was applied to diesel engines by Elliott Company for large marine, industrial, and locomotive applications. The Cummins turbocharged diesel engine[2] achieved the pole position at the Indianapolis 500 in 1952. Simultaneously, the 1950s saw the application of turbocharging to off-road diesel engines in construction equipment (Caterpillar) largely for power density and smoke control. Application to on-road truck engines (Cummins, Volvo) followed soon after.

The 1970s saw a great acceleration of turbocharging and charge-cooling for all heavy-duty diesel engines, not only for power density but also for emissions control and improved efficiency. The 1990s saw a great acceleration of turbocharged diesel engines for passenger car applications in Europe driven largely by the need for fuel economy. Today, all heavy-duty equipment and vehicles use turbocharged diesel engines. Turbo-diesel passenger cars are around 50% of all cars in Europe and rapidly increasing in the United States. Turbocharging is such an essential part of diesel engines that today there are no serious diesel engine applications without turbocharging.

Application of turbocharging to gasoline engines for passenger car applications is attracting increasing attention.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

The reason (as in early application) is increased power density, but this time not for high altitude but for engine downsizing and "de-throttling" at part load. This effect is discussed in greater detail in Section 2.

2 BENEFITS OF TURBOCHARGING—DIESEL AND GASOLINE ENGINES

As has already been noted, the benefits of turbocharging diesel engines are so overwhelming that there are no significant naturally aspirated diesel engines. Therefore, in discussing benefits of turbocharging in diesel engines, a comparison between turbocharged and naturally aspirated diesel engines is not important. Also, the benefits of turbocharged diesel engines in heavy-duty trucks and equipment is so well established that a discussion of turbocharged versus naturally aspirated diesel engines or gasoline engines is not relevant. However, turbo-diesel application in passenger vehicles, while well established in Europe, is still in its starting phase in the United States. Therefore, such a comparison is of much interest. Figure 1 shows this comparison for 2011 model year US vehicles. All vehicles are certified to meet the US Environmental Protection Agency (EPA) Tier II Bin 5 emission regulations. The data are taken from EPA fuel economy Web site and manufacturer Web sites. This is not a back-to-back comparison in the same vehicle and there may be other technology differences that contribute to the difference, but the overall picture is very effective, showing a 30–50% advantage in fuel consumption for turbo-diesel vehicles.

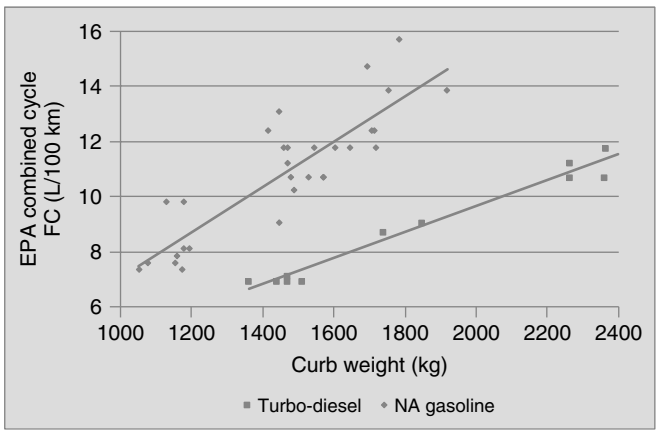

Figure 1. Fuel economy comparison between turbo-diesel and naturally aspirated gasoline US 2011 model year passenger vehicles.

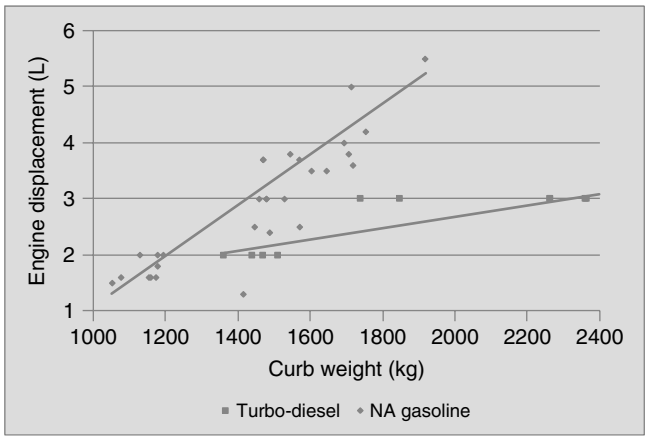

Figure 2. US 2011 model year turbo-diesel and naturally aspirated gasoline engine displacement in comparable vehicles.

One other significant factor needs to be pointed out. Figure 2 shows the engine displacement for exactly the same vehicles as in Figure 1. It is seen that turbo diesel engines are 30–50% smaller in displacement. This should have an impact on cost and somewhat mitigate the added cost of emissions control equipment. The same observation can be made about vehicle curb weight.

The reasons for fuel economy benefits are related to the high throttling losses in gasoline engines compared to turbo-diesel engines and to the differences in compression ratio (as well as energy content of a liter of each fuel). Smaller displacement diesel engines can be used partly because turbocharging increases power density but mostly because turbo-diesel engines have higher low speed torque and a small engine gives good drivability compared to a large, naturally aspirated gasoline engine.

Similar benefits can be shown in vehicles certified for European emissions regulations, and, as has already been observed, turbo-diesel penetration in European passenger vehicles is very high.

Turbocharging and downsizing is on the increase in gasoline engines also. Figures 3 and 4 show, respectively, the fuel consumption and displacement comparison of model year 2011 US passenger vehicles with naturally aspirated and turbocharged engine options. It is seen that downsized turbo gasoline engines give about 20% benefit in fuel consumption and enable about 50% reduction in engine displacement.

The fuel consumption benefit shown in Figure 3 is the result of using smaller engines, as shown in Figure 4. At light loads, gasoline engines are throttled. Throttling losses are a major factor in the poor fuel economy of

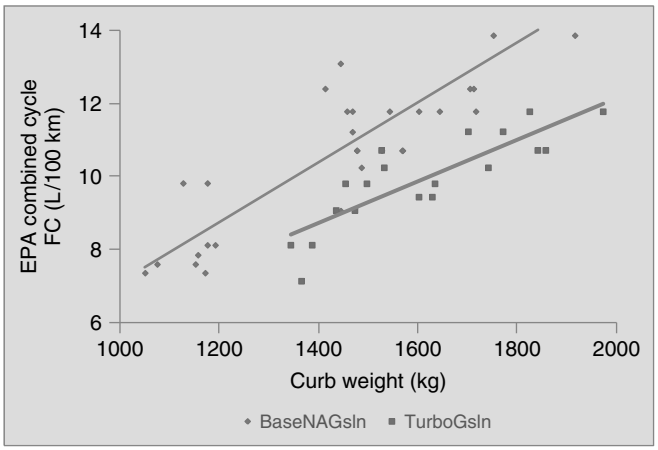

Figure 3. Fuel consumption in US model year 2011 vehicles—naturally aspirated and turbocharged gasoline engines.

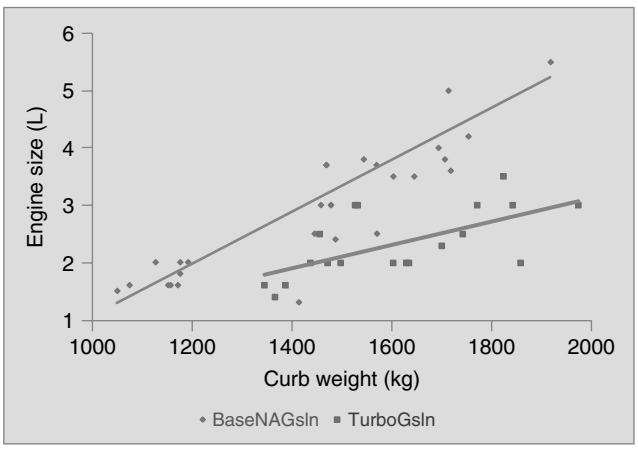

Figure 4. Engine displacement in US model year 2011 vehicles—naturally aspirated and turbocharged gasoline engines.

gasoline engines. If the engine displacement is large, greater throttling and greater throttling losses are involved. For smaller engines, less throttling is required for the same load, hence throttling losses are correspondingly lower. A detailed discussion of the mechanisms of these effects can be found in Walzer (2001). The benefits shown in Figure 3 are a major factor driving the growth of turbocharged, downsized gasoline engines in passenger vehicles.

Requirements placed on turbochargers for diesel engine and gasoline engine applications are different, and differences in design and materials result from this. However, the basic fluid mechanics and thermodynamics are the same. These aspects are discussed in the following sections.

3 TURBOCHARGERS—BASIC STRUCTURE AND FUNCTIONALITY

In this and the following sections, turbocharger designs and design methodology are discussed. The discussion is primarily from an engine design and development point of view, not from a detailed turbocharger design point of view. Turbocharger design is a highly specialized field involving a deep understanding of fluid mechanics and stresses in high speed rotating machinery. Requirements placed on turbochargers, turbo–engine interactions, design responses, design methodology, and advanced concepts are discussed. This is by no means a stand-alone turbocharger design manual.

The basic functionality of a turbocharger is illustrated in Figure 5.[3] Exhaust gas from the engine is made to pass through a turbine wheel, causing the wheel to rotate at a high speed. A compressor wheel is connected to the turbine on the same shaft and rotates at the same high speed inducting fresh air, imparting momentum and high velocity to this air. High velocity discharge air is slowed down aerodynamically in a diffuser/housing, and kinetic energy converted to high pressure/density. The inefficiencies of the compression and recovery processes increase the temperature of air, which is cooled in a charge cooler before being supplied to the engine.

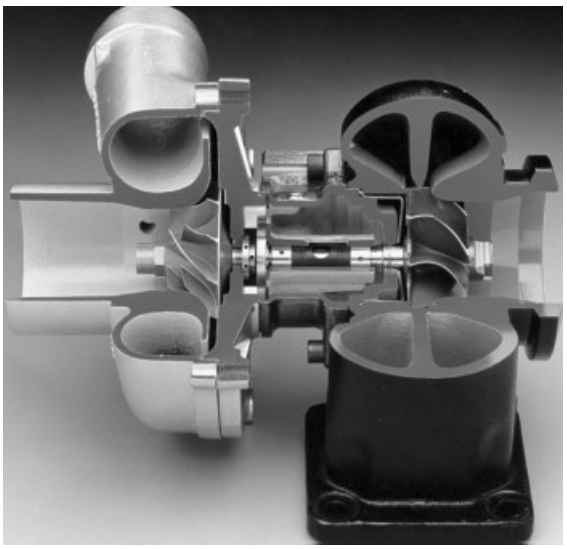

Figure 6. Cut-away illustration of a basic turbocharger. (Reproduced by permission of Honeywell Turbo Technologies.)

Figure 6 shows a cut-away view of a basic turbocharger to illustrate its design and componentry.

Figure 6 shows a turbine housing on the right-hand side (to be attached to the engine exhaust manifold) guiding the exhaust flow to the turbine wheel radially (design variations with axial flow and mixed flow are also used but are not discussed here). The center housing carries bearings (journal and thrust) for the shaft attached to the back of the turbine wheel and the compressor wheel on the left-hand side. The intake to the compressor is attached to the air filter and the discharge to the engine intake manifold usually with a charge cooler in between, as shown in Figure 5.

Power is developed by the turbine as a result of momentum transfer from the exhaust gases to the turbine wheel. Under steady-state conditions, this power is exactly equal to the power consumed by the compressor plus losses in the center housing. During acceleration, the turbine is required to develop greater power to accelerate the rotating mass to the new higher speed (and power) condition. The turbocharger has to "pick itself up by its bootstraps" during this process. A slight increase in fueling results in higher exhaust temperature, which slightly accelerates the turbocharger, resulting in increased airflow, which enables more fuel to be burnt resulting in higher speeds, and so on. The ability of the turbocharger to respond quickly to changes in demand is an important design consideration.

3.1 Compressor wheel and housing design

A primary requirement of the compressor wheel is to deliver the full range of flow that the engine requires. This implies not only mass flow rate but also the intake manifold pressure (density) required by the engine at all operating conditions. The efficiency with which the compressor is able to do this has an impact on the power demanded by it. This power is supplied by the turbine, which imposes a backpressure on the engine depending on its efficiency.

Compressor aero performance design objectives are met by the detailed design of blade shape at the inducer, in the body (including the hub), and at the exducer, as well as the aero design of the diffuser and housing. Centrifugal stresses are the most usual limiting factor, although air exit temperatures can impose a limit if pressures are high and the material softening temperature (as for aluminum) is reached. Conventional compressor wheel designs have a through hole at the center for the shaft to pass through. A nut at the free end secures the compressor wheel to the shaft.

Fatigue life is an important design consideration for both turbine and compressor wheels. High cycle fatigue failure is most usually associated with the high frequency vibrations of the blades. Design details associated with pressure fluctuations around the rotational path, blade geometry, and material properties are independent design parameters generally used to get satisfactory high cycle fatigue life. Low cycle fatigue failure is most usually associated with the centrifugal stress level and the frequency of changes in stress as in start/stop or slowing down/speeding up. Blade and hub geometry (e.g., blending radii at the blade/hub interface), material properties, and manufacturing processes all play a significant role in obtaining acceptable low cycle fatigue life.

Blade/hub geometry details can yield only small refinements in low cycle fatigue life because of the maturity of designs. Greater improvements are possible with major design changes[3] such as "boreless" compressor wheels (Figure 7), forged and machined wheels, counter gravity "pouring" of molten aluminum to minimize oxide inclusion (which can be crack initiation sites), and use of high strength material (e.g., titanium).

Prediction of fatigue life is a highly empirical process, with each manufacturer using a historic (and confidential) database of failure rate versus duty cycle. Design, material, and process changes are evaluated against this database to obtain fatigue life predictions such as shown in Figure 8 (Arnold, 2004).

3.2 Turbine wheel and housing design considerations

Design considerations include size/flow capacity, inertia/response, thermomechanical durability, aerodynamic

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

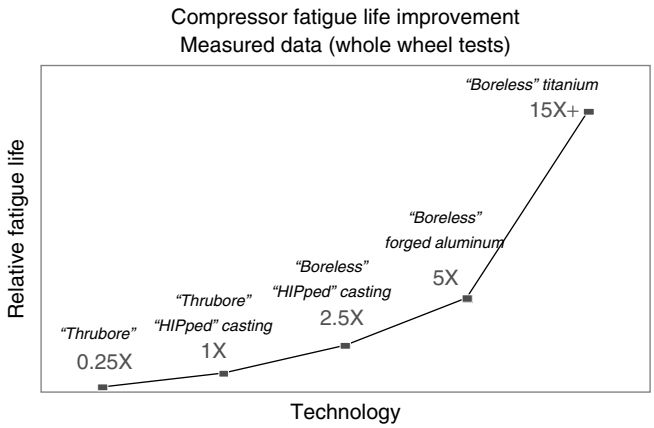

Figure 8. Improvements in fatigue life of a compressor wheel resulting from design, material, and process changes.

performance, and a host of other parameters, including cost. The turbine wheel has to be large enough (high inertia) to have enough flow capacity to handle the engine exhaust flow rate without choking and without imposing an unduly high backpressure on the engine. At the same time, it has to withstand high exhaust temperatures. Therefore, it is made of high nickel alloys, which tend to have high density, so much so that turbine wheels generally comprise more than 70% of the rotating inertia of a turbocharger. This sets up a design trade-off between the flow capacity and the response. The material, size (diameter), number of blades, blade thickness, back disk profile, and hub profile all require detailed design consideration of the trade-off between aerodynamic performance, inertia, thermomechanical integrity, and noise/vibration. This is done using highly specialized 3-D rotating flow and stress analysis computer codes in an iterative process for trade-off and design validation.

A primary requirement of turbine wheel design is that it should deliver the power required by the compressor without imposing high backpressure on the engine, that is, at a high efficiency. This is achieved by the geometry of the blades and details of the flow path. 3-D rotating flow computer codes are used to achieve aero design objectives.

The turbine housing has to withstand similar high temperatures as the turbine wheel. In addition, it has high temperature gradients because of direct exposure to the ambient on the outside. In general, the turbine housing has a center divider (shown in Figure 6) to preserve exhaust pulse energy of each cylinder. This sets up a design requirement to handle high thermal gradients/stresses in the center divider area. Sophisticated finite element analyses are done to choose the right material and the right detailed geometry to prevent turbine housing cracking.

Turbochargers rotate at very high speeds, with compressor wheel tip speeds reaching 550 m/s (somewhat lower for turbine tip speeds because turbine wheels are typically slightly smaller in diameter). A wheel burst and escape of high velocity pieces is a serious concern. Therefore, turbine (and compressor) housings have to be designed to contain wheel bursts, that is, not allow any broken parts to escape.

Centrifugal stresses are an important consideration in turbocharger wheel design because of its high rotational speed. A hole drilled through the center of a rotating disk doubles the centrifugal stresses. Turbine wheels are generally designed without a hole through the center. The shaft is welded to the back of the wheel (current practice is electron-beam welding versus earlier practice of friction welding). High speed balancing of the shaft–wheel assembly (as well as of the complete rotating assembly) is a highly specialized manufacturing process design and control technology. It has a healthy component of experience and empiricism and is usually treated as a "trade secret."

3.3 Center housing design considerations

The center housing carries the rotating assembly (turbine and compressor wheels and the shaft). Major design requirements for the center housing are to provide bearing capacities (rotational and thrust), damping to help reduce vibrations induced by high speeds and imbalance, cooling, and sealing. Each of these is considered in the paragraphs that follow.

Balancing of the rotating assembly is a critical design and manufacturing process requirement because of the high rotational speeds of the turbocharger and of the need to control shaft motion (displacement from the nominal

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

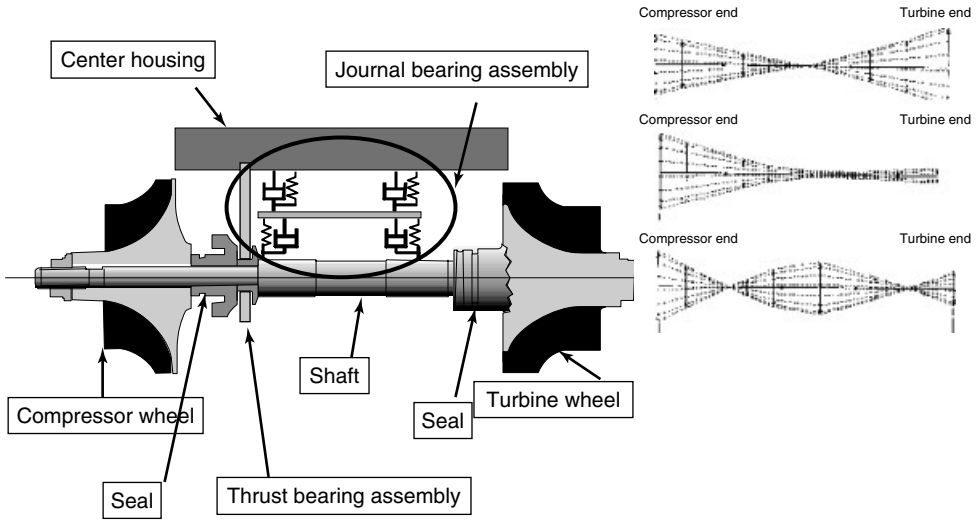

Figure 9. Modes of bending of the rotating assembly and the role of oil film damping in controlling shaft motion. (Reproduced by permission of Honeywell Turbo Technologies.)

geometric center of rotation). Shaft motion can set up local pressure cycles in the rotational path (causing high frequency vibrations in the blades) and cause noise and vibration and possible interference between the wheel and housing. The clearance between the wheel and housing represents an aerodynamic loss. Minimizing this loss requires that shaft motion be controlled at all rotational speeds. Residual imbalance (due to manufacturing tolerances, e.g., shaft–turbine wheel joining, compressor wheel assembly), flexibility of the shaft, and overhung loads of the compressor and turbine wheels all play a significant role in the satisfactory performance of the rotating assembly. Damping provided by bearings can mitigate shaft motion. High speed bearings have two hydrodynamic oil films: one between the shaft and the inner diameter (ID) of the bearing, and the other between the outer diameter (OD) of the bearing and the housing, as shown in Figure 9. Bearings can be free to rotate in the housing (fully floating) or pegged to not rotate but nevertheless gyrate at high speed to create a film between the OD and the housing. These oil films play a critical role in providing the necessary damping.

The net thrust load along the axis can be in either direction depending on the engine/turbo operating conditions. A thrust bearing and collar on the shaft and housing are designed to pick up oil, create a dynamic oil film, and provide enough load capacity to prevent metal-to-metal contact. The thrust bearing is placed near the compressor side because it is cooler. A careful look at Figures 6 and 9 show the placement of the thrust bearing and collar.

Proper sealing at the points where the shaft penetrates through the center housing is a significant design consideration to prevent oil from leaking out into the exhaust or intake flow path as well as to prevent gases from leaking into the center housing. A steel ring is usually used on the turbine side and the dynamic centrifugal separator (with or without deflectors) on the compressor side to provide an effective oil seal. The center housing runs at crank-case pressure (oil drains into the crank case), and aerodynamic design at the back of the wheels can be used to always maintain a slightly higher pressure on the air and exhaust sides to prevent oil from leaking into the gas path.

The oil drain from the center housing to the crank case is a sometimes neglected part of the design and can cause serious issues if oil does not drain freely.

Oil flow rate plays a critical role in carrying heat away from the center housing. Most often, a critical condition for cooling is not when the engine/turbo is running at high speeds and loads but during "hot shut down" when heat is still getting transferred from the hot turbine housing to the center housing and oil is not flowing. Sometimes, this can lead to coking of the oil in the bearings. Often, a heat shield is designed to present a resistance to the heat flow path from the turbine housing to the bearings. A careful look at Figure 2 on the right-hand side shows the placement of the heat shield.

Sometimes the center housing is cooled by providing coolant flow.

4 TURBOCHARGER PERFORMANCE

The parameters most usually used to measure the performance of a turbocharger are the following:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- The ability of the compressor to supply air (flow rate and intake density/pressure) needed by the engine;
- Useful flow range of the compressor covering the full range of engine requirements;
- Compressor efficiency over the operating range;
- The capacity of the turbine to flow all exhaust without imposing a high backpressure on the engine;
- The efficiency of the turbine over the operating range (the losses in the center housing due to bearing and seal friction are conventionally included in turbine efficiency calculation);
- A host of thermomechanical attributes such as low noise and vibration, acceptable life (low cycle and high cycle fatigue included), no leaks, ability to withstand thermal stresses, fast response, and so on, in addition to cost targets.

Thermomechanical attributes have been discussed earlier. Performance attributes are discussed using example performance maps of compressors and turbines with engine maps superimposed on them. It is worth recalling the definition of some of the terms used in performance maps.

Total versus static temperature and pressure: high fluid velocities are involved in both compressors and turbines. Total and static properties are defined as

$$P_{\text{tot}} = P_{\text{stat}} + \rho \frac{V^2}{2}$$

$$T_{\text{tot}} = T_{\text{stat}} + \rho \frac{V^2}{2} C_{\text{p}}$$

Corrected flow: actual flow corrected to standard temperature and pressure conditions. The correction is derived using dimensional analysis but it is important to remember that corrected flow is *not* a dimensionless parameter.

$$\dot{\text{m}}_{\text{corrected}} = \frac{\dot{\text{m}}\sqrt{T_0/T_{\text{standard}}}}{p_0/p_{\text{standard}}}$$

It should also be noted that inlet temperature and pressure are relatively close to standard temperature and pressure for a compressor. Hence, the corrected flow is relatively close to the actual flow. However, for a turbine both inlet temperature (~800–1000°C) and pressure (2–4 bar) are considerably different from standard temperature and pressure. Hence, the corrected flow can be a factor of 2 or more different from actual flow.

The use of corrected flow enables comparison of different turbochargers.

Corrected speed: actual speed corrected to standard temperature and pressure conditions. The correction is derived using dimensional analysis but it is important to remember that corrected speed is *not* a dimensionless parameter.

$$N_{\text{corrected}} = \frac{N_{\text{actual}}}{(\sqrt{T_0/T_{\text{standard}}})}$$

Efficiency: on the compressor and turbine side takes into account aerodynamic losses in the wheel itself as well as in the entry and exit sections and housings. Mechanical losses are usually included with turbine efficiency calculation.

For the compressor side

$$\frac{\Delta E_{\text{ideal}}}{\Delta E_{\text{actual}}} = \frac{C_p \times (T_{06,\,\text{ideal}} - T_{00})}{C_p \times (T_{06} - T_{00})} = \frac{T_{00}(PR_{T-T}^{\gamma-1/\gamma} - 1)}{(T_{06} - T_{00})}$$

and for the turbine side

$$\frac{\Delta E\,(\text{Actual energy extracted})^*}{\Delta E_{\text{ideal}}(\text{Ideal energy extracted})} = \frac{C_{\text{p}} \times (T_{00} - T_{04,\text{actual}})}{C_{\text{p}} \times (T_{00} - T_{4,\text{ideal}})}$$
$$= \frac{C_{\text{p}} \times (T_{00} - T_{04,\text{actual}})}{C_{\text{p}} \times T_{00} \times (1 - 1/PR_{T-S}^{\gamma-1/\gamma})}$$

Surge: the engine represents a restriction to compressor discharge. Under certain conditions, the compressor flow rate can be higher than the engine is able to accept. Under such conditions, flow separation can occur between the blades of the compressor wheel, resulting in reverse flow, noise, and possible damage to the wheel. When compressor discharge pressure is "relieved" by reverse flow, normal flow is reestablished, pressure builds up, and reverse flow can begin again. This repeated flow reversal phenomenon is termed *surge*.

Choke: can occur both on the compressor and turbine sides. Under both conditions, the maximum aerodynamic flow capacity has been reached and wheel is unable to handle (or supply) more flow regardless of the discharge condition.

4.1 Compressor performance

Figure 10 shows a typical heavy-duty diesel engine compressor map (Arnold, 2004). The compressor corrected flow is plotted on the *x*-axis and the compressor pressure ratio on the *y*-axis. Compressor characteristics are shown in dark gray, and engine operating lines superimposed on the same map are shown in light gray.

First, consider compressor speed lines. At a given (constant) compressor speed, as the flow increases (exit restriction is reduced), the pressure ratio drops. This continues as the exit flow restriction is reduced to a point where choking occurs and the flow can no longer increase

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

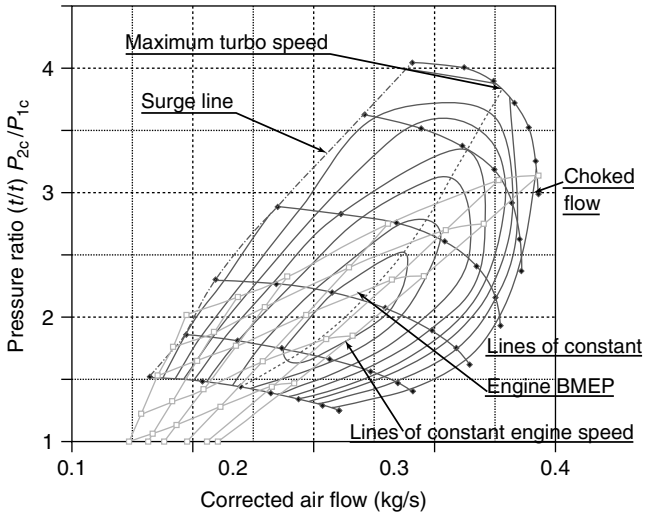

Figure 10. Representative heavy-duty diesel engine compressor map with engine operating conditions superimposed in light gray.

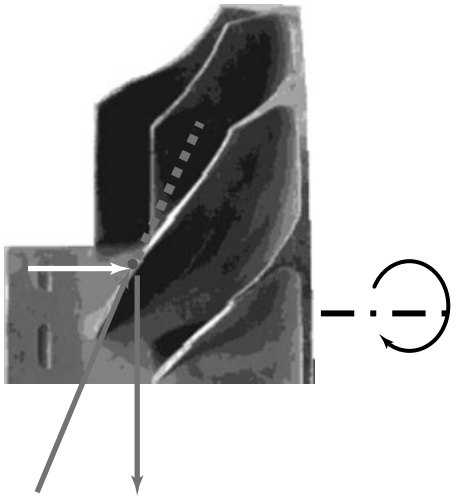

Figure 11. Illustration of inlet axial velocity, blade tip velocity, resultant velocity, angle of incidence, and blade angle at the compressor inlet.

(is no longer a function of discharge conditions). This is seen toward the right of the compressor map, where the pressure ratio drops nearly vertically without any further increase in the flow rate. Choke flow line is shown as the rightmost efficiency contour in Figure 10. At this line, the compressor efficiency is generally considered to be at its lowest acceptable value.

Next, consider the process as the exit restriction is increased, that is, the flow rate reduces and pressure ratio increases (along the same constant speed line). This can continue to a point where flow separation occurs in the compressor blades, resulting in reverse flow and surge, as described in the previous section. Surge line is shown as the leftmost efficiency contour in Figure 10. Operating the engine at conditions to the left of the surge line can result in damage to the turbocharger. Blade geometry is designed to give a wide usable flow range from surge to choke so that the engine operating map can be fitted within the usable flow range. The useful flow range can also be extended by providing a recirculation path or a "ported shroud" around the compressor intake.

Consider compressor efficiency. Compressor blade tip velocity is determined by the local radius and rotational speed of the compressor wheel. The incoming flow comes axially at compressor inlet (Figure 2). The angle of incidence is the resultant of the axial velocity and the blade tip velocity at that point. If the angle of incidence matches the blade angle, flow glides smoothly into the wheel and the efficiency is high. Figure 11 is an illustration of the velocity vectors at the inlet of the compressor wheel. Efficiency drops off on either side (flow rate, inlet velocity) because of the mismatch between the angle of incidence and the (fixed) blade angle. The high efficiency ridge, shown as the dotted line in Figure 10, represents the best match between the angle of incidence and the blade angle. On either side of the ridge, as the flow falls or increases, the resultant incidence angle is not exactly equal to the blade angle, resulting in flow vortices and aerodynamic losses. Therefore, efficiency drops off on both sides of the high efficiency ridge. Compressor wheel blade angle is designed to give the best compromise of efficiency over the engine operating map and the expected duty cycle.

Consider the peak pressure ratio capability of the compressor. This is determined largely by the speed at which the wheel can rotate without getting overstressed. Usually, the peak pressure ratio of the compressor is considerably higher than the operating pressure at full load so that the operating points of interest (depending on the duty cycle) may fall in the best efficiency region of the compressor.

In Figure 10, the engine operating lines are shown in light gray. The top light gray line is the full load line and is determined by the air–fuel ratio the engine requires (a requirement dictated by the combustion system and engine efficiency and emissions targets). It is seen from the figure that the full load–full speed point is at choke and the full load–idle speed point is at surge, using up the full useful flow range of the compressor without any margin of safety. The compressor designer has some flexibility in increasing the useful range at the expense of peak pressure ratio capability by changing the geometry of compressor

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

blades (the backward curvature). Below the full load line, operating lines at part loads are shown. Constant engine speed lines are also shown: rated speed line to the right, and idle speed line to the left.

Thus, compressor performance characteristics, that is, the flow capacity, flow range, efficiency, pressure ratio, and wheel speed, are all shown on the compressor map. The process of matching (discussed in Section 5) is used to evaluate the performance of the compressor on the engine.

4.2 Turbine performance

Figure 12 shows a turbine map suitable for the same heavy-duty diesel engine as used for the compressor map (Arnold, 2004).

Consider turbine flow characteristics. The top set of curves show the flow rate versus expansion ratio at various constant turbine speeds. It is seen that all speed lines collapse into essentially a single flow versus expansion ratio curve. It is also seen that at an expansion ratio of ~2.8 turbine flow capacity is reached as a result of choking. For higher flow rates, a larger diameter turbine (or a turbine with radically different flow characteristics) would be required.

The bottom set of curves show the efficiency versus expansion ratio for each speed. Only a small range of expansion ratios is shown. The efficiency curves as shown are generally referred to as the *eye brow curves*. A pictorial representation (dashed line) of efficiency over a wider range of expansion ratio (at a constant speed) is shown. In most datasets, only a narrow range (pictorially an "eye brow") is shown because usually the engine flow and turbine speed are self-adjusting so that the operating point falls near peak efficiency for that speed. Efficiency drops off on either side of the peak because the incidence angle changes, resulting in aerodynamic losses.

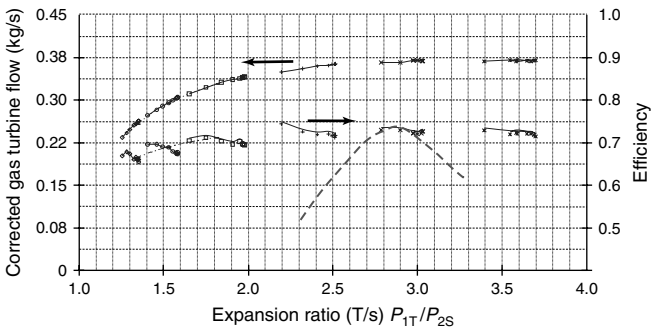

Figure 12. Illustrative turbine operating characteristics of a heavy-duty diesel engine turbocharger.

The calculation of turbine power is discussed in Section 5.

Turbine peak efficiency is seen to be around 72%. It is usually less for smaller turbines because the clearance area is a larger proportion of the total flow area.

5 ENGINE/TURBOCHARGER MATCHING BASICS

The purpose of "matching" is to select compressor and turbine size and performance characteristics that best match the needs and performance targets of the engine/vehicle/equipment. This is necessarily an iterative process, with the number of iterations considerably reduced by appropriate simulations. Further, there is some leeway in tweaking some design parameters of the turbocharger (such as *A*/*R* ratio, trim) to fine-tune the match.

Engine simulation, design targets, and candidate compressor and turbine maps are used as the starting point. It is best to start with engine airflow requirements.

Engine airflow requirement is calculated using power rating, brake specific fuel consumption (BSFC) target, and target air–fuel ratio (the effect of exhaust gas recirculation (EGR) is discussed later) set by the expected combustion system performance and emissions targets. Thus,

$$\text{Fuel rate (g/h)} = \text{BSFC (g/kWh)} \times \text{Power (kW)}$$

$$\text{Air mass flow rate (g/h)} = \text{Fuel rate (g/h)} \times \text{AFR}$$

Volume flow rate is set by engine displacement, speed, and target volumetric efficiency. Thus,

$$\text{Air volume flow rate (L/h)} = \eta_{\text{vol}} \times V_{\text{displ}}\ \text{(L)} \times \frac{n}{2}\ \text{(L/min)} \times 60\ \text{(min/h)}$$

The mass flow rate and the volume flow rate readily give the intake air density and, together with the intake manifold temperature (dependent on charge cooler, EGR rate, EGR cooler), the required intake manifold pressure can be calculated. Thus,

$$\text{Air density } (\rho) = \frac{\text{Mass flow rate}}{\text{Volume flow rate}}$$

$$\text{Intake manifold pressure (kPa)} = \rho RT$$

Knowing the engine airflow requirement and the compressor pressure ratio required to enable this airflow, compressor power requirement can be calculated. Thus,

$$\text{Power (kW)} = \frac{[m_{\text{a}} \times C_{\text{p}} \times T_{int} \times (P_{\text{out}}/P_{\text{in}})^{(\gamma-1)/\gamma}]}{\eta_{\text{c}}}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Note that the compressor efficiency is needed to calculate the power. The efficiency can be obtained by plotting the operating point on the compressor map and reading the corresponding efficiency. This process also yields the compressor speed.

The turbine has to supply the power required by the compressor. The power developed by the turbine is given by

$$\text{Power (kW)} = \eta_{\text{tm}} \times m_{(\text{a+f})} \times C_{\text{p}} \times T_{\text{exh}} \times \left[1 - \left(\frac{P_{\text{out}}}{P_{\text{in}}}\right)^{(\gamma-1)/\gamma}\right]$$

In the above equation, T_{exh} is the engine exhaust temperature, which is obtained by simulation or estimated using similarity with other engines. P_{out} is turbine outlet pressure and set by the exhaust system. There are two unknowns in this equation: η_{tm} and P_{in}, that is, turbine efficiency and engine exhaust pressure. An iterative solution using turbine performance map and turbine speed (equal to compressor speed because they are on the same shaft) readily yields these two values.

The engine operating point can be plotted on the compressor map and on the turbine map. It is not enough to plot just one operating point. This calculation has to be repeated preferably over a range of load and speed conditions and checked to see if the operating points fall within the operating range of the compressor, with efficiency requirements in mind. Figure 10 is such a representative plot. Note that the best compressor efficiency is around 50% engine speed and 50% load. Perhaps in this match, a case can be made that the engine duty cycle is such that the engine seldom runs at full load–full speed or at full load–idle speed. This match has no "surge margin" or "altitude capability." At higher altitudes, in order to maintain the air–fuel ratio, the pressure ratio requirement increases (because of decreasing intake air density), pushing the engine operating points into surge beyond the usable flow range of the compressor. If that is a major design requirement, a different compressor will have to be selected for this engine. Turbocharger manufacturers usually have a wide range of turbochargers with different performance characteristics available to choose from (and match).

Engine flow is plotted on the turbine map in a similar manner and shown in Figure 13 (Arnold, 2004). In this figure, the turbine flow curves for all turbine speeds are collapsed into a single curve and turbine efficiency lines are not shown. The engine flow operating line at full load is also shown.

A significant feature to note is the difference between the turbine wheel flow characteristic and the engine flow. The turbine wheel has to be sized to handle the flow at full load–rated speed. This implies that the turbine is too large for lower speed conditions and turbocharger inertia has an impact on turbo response. Wastegate turbines, variable geometry turbines, and multistage turbocharging to mitigate this problem are discussed in the following sections.

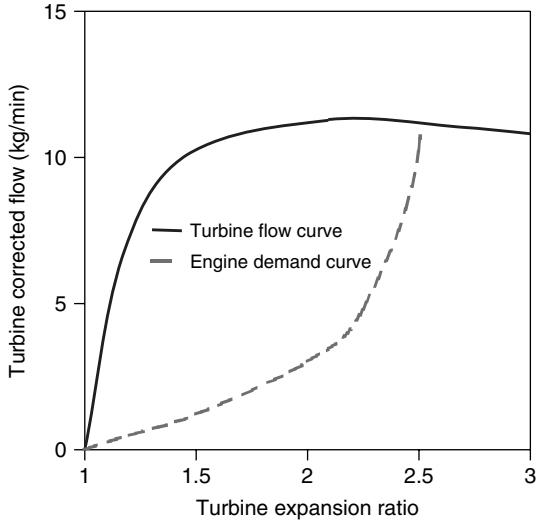

Figure 13. Illustrative simplified flow map of a heavy-duty diesel engine turbine. Engine full-load operating line is also shown.

6 ADVANCED ENGINE REQUIREMENTS AND TURBO TECHNOLOGIES

Some of the requirements and technologies described below can no longer be considered "advanced" but are grouped together for convenience.

6.1 Wastegate turbocharger

In the previous sections, we have considered the basic free-floating turbocharger. As discussed in Section 5, the basic match results in a turbine large enough for full flow conditions but too large at low engine flow conditions. This can result in a response issue.

To get around this issue, the turbine is intentionally designed to be too small for full flow conditions, and under such conditions a "wastegate" valve is opened to (partially) bypass the turbine. This prevents overspeeding the turbo and/or inducing too high a backpressure on the engine. It also "wastes" the exhaust energy. But this might be a net benefit under duty cycle conditions that require frequent accelerations and infrequent operation at full load–full speed (as in a passenger car). A picture of a cut-away turbine housing focusing on the wastegate valve is shown

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

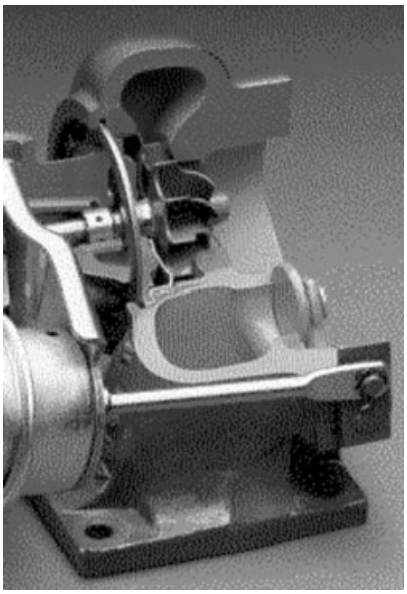

Figure 14. Illustration of a wastegate turbocharger. (Reproduced by permission of Honeywell Turbo Technologies.)

in Figure 14. In this rendering, the wastegate valve is actuated with a pneumatic actuator using compressor outlet pressure.

6.2 Variable-geometry turbocharging

Instead of using a small turbine and wastegate, a full-sized turbine wheel is retained and the issue of response is addressed by using a variable-geometry inlet in the turbine. Figure 15 is a collection of photographs of cutaways of a light-duty diesel engine turbocharger showing how one specific variable-geometry mechanism works (Petitjean *et al*., 2004).

Under low flow conditions, the vanes are closed (top right inset) to increase the velocity of exhaust gases coming at the turbine wheel. This keeps the turbo speed up and helps with low engine speed torque and response. Under high flow conditions, the vanes are open (bottom right inset). The turbine wheel size is adequate to handle full flow, thus the backpressure on the engine is not excessive (nor is the flow bypassed through a wastegate, saving fuel). The actuator shown in the main picture is a pneumatic actuator that can be intelligently controlled. An electric actuator shown in the inset enables greater flexibility.

Heavy-duty diesel engines and the forces involved, together with the possible use of the variable-geometry mechanism in synergy with engine braking, require a design capable of withstanding higher pressures and higher pressure fluctuations. Figure 16 shows a heavy-duty diesel engine variable-geometry turbo mechanism where vanes are supported on both sides rather than cantilevered as shown in Figure 15. Details of the moving vane mechanism are shown in the inset to the left. Also, the pneumatic actuator works using the vehicle's pneumatic pressure system because the force required to move the vanes is high. Hydraulic actuation using engine oil is an alternative.

Figure 17 shows the performance characteristics of a variable-geometry turbine. Turbine flow characteristic at vane fully open position is shown as the top dark gray curve. Each successive dark gray curve under it is the turbine flow characteristic with the vanes progressively

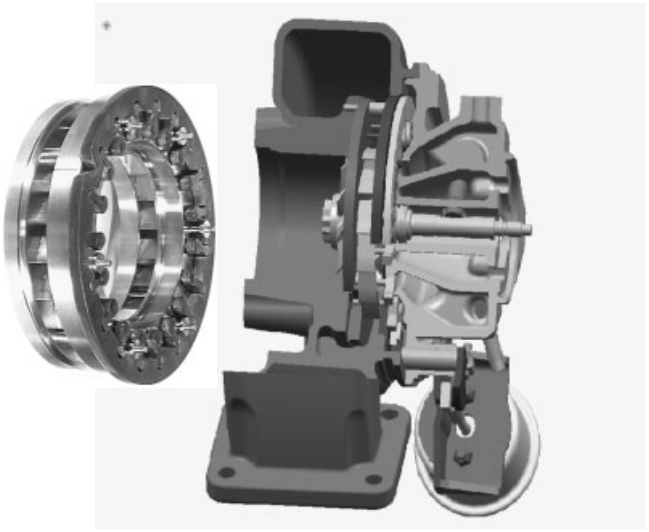

Figure 16. Illustrative view of a heavy-duty diesel engine variable-geometry turbocharger. (Reproduced by permission of Honeywell Turbo Technologies.)

closed. It is seen that, by appropriately choosing the vane position for the load (and speed) condition of the engine, a better match between the turbine flow characteristics and the engine flow requirements can be made.

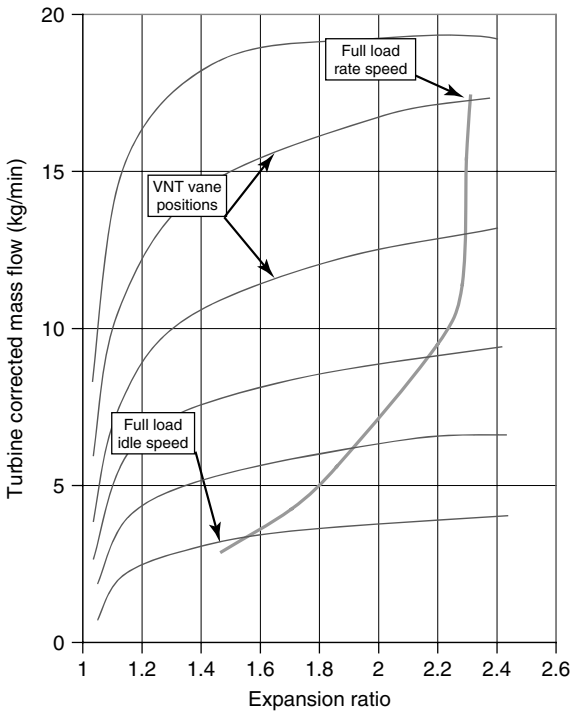

Figure 17. Turbine flow characteristics with various vane positions. Also shown is the full-load engine flow curve (light gray).

6.3 Exhaust gas recirculation (diesel engines)

EGR is necessary to control the engine nitric oxide (NO*x*) emissions. EGR presents problems both on the compressor and turbine sides. High pressure (short) loop (HPL)-EGR is discussed first. A schematic of a representative HPL-EGR arrangement is shown in Figure 18 (Arnold, 2004).

In a well-designed and well-matched turbocharger, the exhaust pressure is lower than the intake pressure over a large part of the engine load–speed range, giving a net positive pumping work contribution. Thus, driving the EGR involves increasing the backpressure on the engine and undoing the pumping work benefit of turbocharging. At the same time, in order to maintain the same combustion system performance (particulate emissions), the oxygen/fuel ratio has to be maintained at or near the pre-EGR levels. The inert constituents of the EGR (nitrogen, carbon dioxide, water vapor) proportionately use up space in the cylinder which fresh air would have occupied. Therefore, the intake manifold pressure (density) has to be increased to supply the needed air. In addition, because the EGR temperatures are high, the pressure has to be further increased to compensate for the lower density.

A variable-geometry turbine can be used to increase the backpressure to drive EGR and at the same time increase turbo speed and drive more fresh airflow. On the compressor side, the increase in intake manifold pressure (therefore compressor pressure ratio) tends to drive the engine operating curve more toward the surge line. The compressor has to be rematched to avoid surge. Another possible problem could be (if pressure ratio increases too high) that the compressor outlet temperatures may be high enough to soften aluminum. In some applications, titanium compressor wheels are being used, as well a precooler upstream of the aluminum charge air cooler. Figure 18 illustrates this.

A low pressure (long) loop (LPL)-EGR system presents a different set of challenges. EGR is usually drawn from downstream of the diesel particulate filter (DPF) and fed to the intake of the compressor. In addition to high pressure requirements, this increases the temperature even more because the compressor inlet temperature is increased, and then goes through a compression process further increasing its temperature. In spite of the efficiency of the DPF, there is enough particulate level in the EGR stream (and it accumulates on the walls over time), so that this presents a severe fouling challenge both to the compressor wheel and to the charge air cooler. Further, even with low sulfur fuel, acid condensation and corrosion remain serious issues to be considered. Compressor wheels coated with a corrosion-resistant material are usually considered.

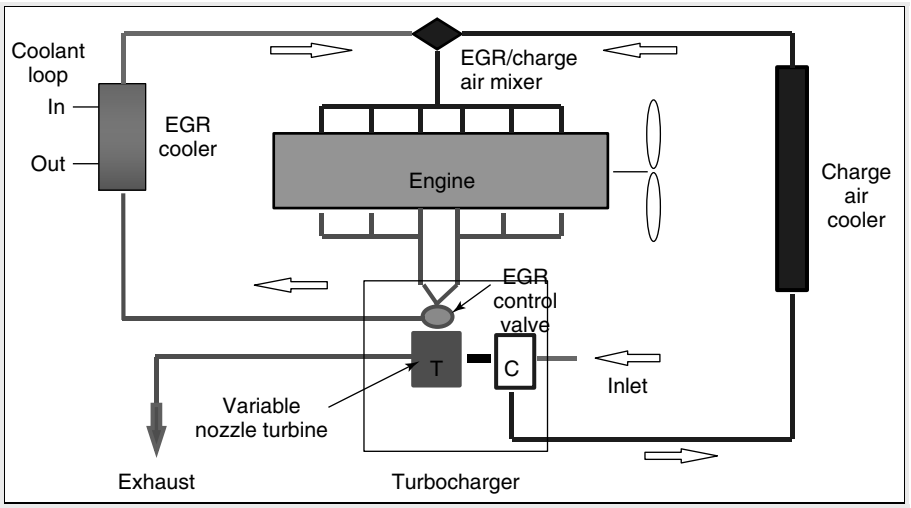

Figure 18. Illustration of a high pressure loop EGR system with variable geometry turbocharging.

6.4 Multistage and sequential turbocharging

High EGR rates increase the intake manifold pressure needed, as discussed earlier. Figure 19 shows the average peak compressor pressure ratios used between 1980 and 2004 in heavy-duty diesel engines in the United States (Arnold, 2004). The gradual, linear increase in compressor pressure ratio between 1980 and 2002 is a reflection of engine development and increase in power rating of the same basic engine (more air, more fuel, and more power). The step increase in 2002 reflects the implementation of EGR systems to meet the stringent (at the time) new NO*x* emissions regulations.

While the illustration in Figure 19 uses a heavy-duty diesel engine database, the same trend applies to light-duty diesel engines. Even as the need for compressor ratio is increasing, the sensitivity to response from the air handling system is also increasing. Multistage turbocharging is being implemented to meet these needs. As the name implies, two turbochargers are used. In the series and series-sequential configuration, the high pressure turbocharger is smaller in size (because it handles less volume flow because of higher pressures). This makes the system more responsive. Also, the multiplication effect of the compression ratio in the two stages gives the possibility of very high overall compressor pressure ratios without getting into surge.

Figure 20 shows a series turbocharging system (Mattes, 2007) with bypass valves on both turbines and on one

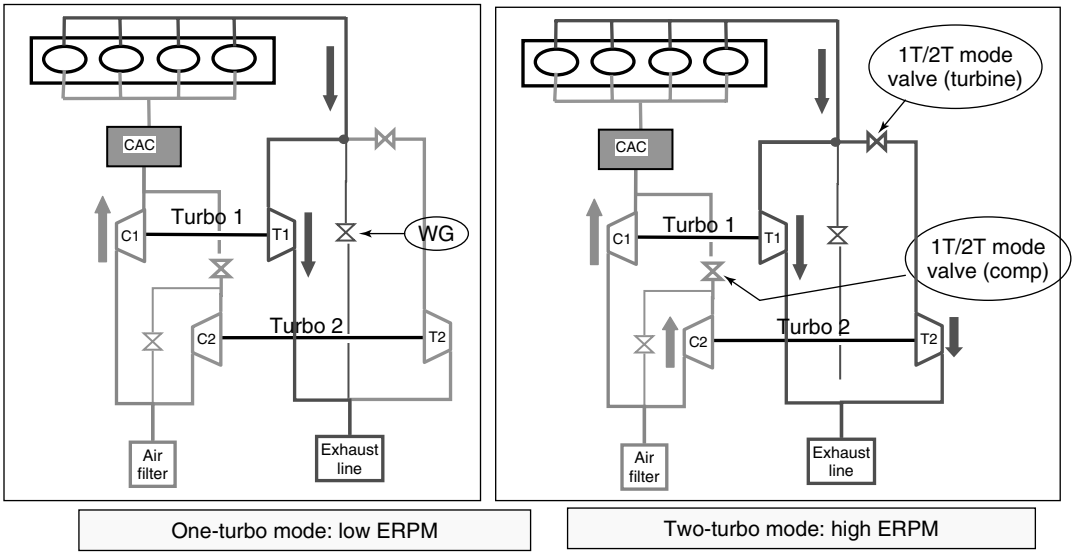

Figure 21. Parallel sequential turbocharging.

compressor, which enables the turbochargers to be used sequentially or together depending upon the load–speed conditions.

Figure 21 shows a parallel-sequential configuration (Portalier *et al*., 2006). In this version, both turbos (two-turbo mode) are used under high flow conditions and a single turbo (one-turbo mode) is used under low flow conditions. Both turbos may be (but do not have to be) of the same size. Figure 22 shows a picture of the production configuration.[4]

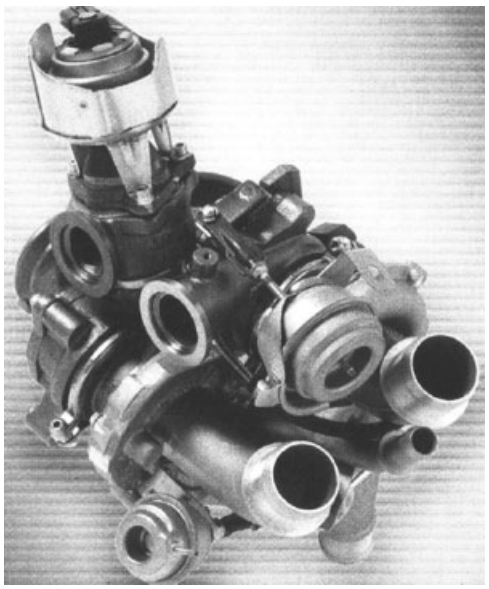

Figure 22. Production implementation of parallel sequential turbocharging.

6.5 Single-sequential turbocharging

Figures 23 illustrates a rather innovative implementation of series multistage compression on a compact single axis design (Arnold, 2007).

Back-to-back compressor wheels are designed, and the discharge from the front compressor wheel is supplied to the rear wheel, resulting in the second stage of compression. Figure 24 shows the impact of this design change on the compressor flow map. It is seen that, in a compact, single-axis machine, very high compressor ratios and a wide useful flow range is obtained.

A slightly different implementation of the same basic idea (back-to-back compressor wheels) is shown in Figure 25. In this implementation, the two compressor wheels are used in a parallel flow mode. This enables

a reduction in the compressor wheel and turbine wheel diameters for the same airflow, thereby greatly reducing inertia and improving response.

Note that there are two fresh air inlets, one for the front compressor and one for the rear. Both compressors discharge into the same outlet. By suitably matching the aero characteristics of the two compressors, both high pressure ratio and wide flow range can be obtained, as shown in Figure 26.

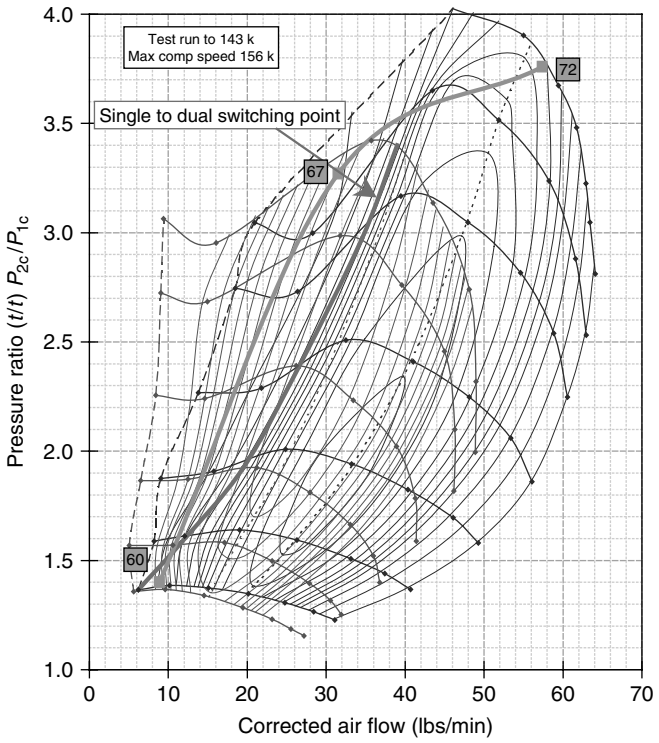

Figure 26. Performance map of parallel flow compressor designed on a single shaft.

6.6 Gasoline engine turbocharging

The benefits of gasoline engine downsizing and turbocharging (as also of turbocharged diesel engines) have already been discussed in Section 2. The discussion here is limited to the turbocharger itself. There are several major issues with gasoline turbocharging.

- The need for a wide flow range because of the typically much wider speed range of gasoline engines;
- Much higher (than diesel engines) exhaust temperatures;
- Heightened sensitivity to response due to passenger car applications.

Fortunately, there are mitigating factors also. First, the pressure ratios required are not very high, usually limited by engine knock considerations and, second, the airflow rate required for the same amount of fuel is not very high because of stoichiometric (rather than lean) mixture ratios.

In the 1980s, considerable effort was put into developing ceramic turbine wheels, which addressed both temperature and response issues. These were put into production for a limited time but ultimately did not achieve major applications because of "foreign object damage." The flow range issue was addressed by using wastegate turbochargers.

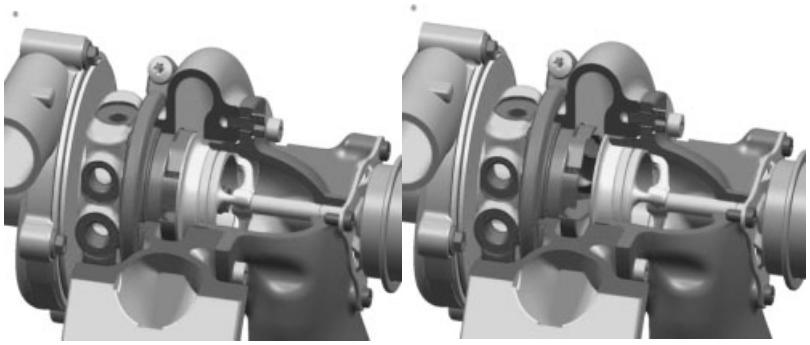

Figure 27. Illustrative variable-geometry implementation for gasoline engine turbocharging. (Reproduced by permission of Honeywell Turbo Technologies.)

More recent developments include the design of variable-geometry turbocharging with sliding vanes rather than moving vanes to handle higher thermal distortions associated with higher exhaust temperatures (Petitjean *et al*., 2004).

Figure 27 shows one such design, with the two sides illustrating low flow and high flow positions. Note that all the vanes are fixed on the disk behind the turbine wheel. The slider slides in and out, controlling the flow area into the turbine (and hence the velocity of the incoming exhaust).

Figure 28 shows a moving-vane design adapted especially for high temperature gasoline engine applications with the use of high temperature austenitic steel. Note the use of additional disks on the pivoted and free sides of the moving vanes, all mounted on the same package, to keep the effects of thermal distortion under control.[5]

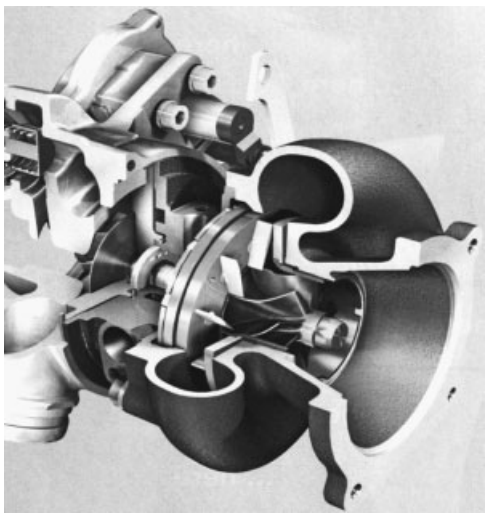

Figure 28. Moving-vane variable-geometry mechanism implemented on a production gasoline engine.

7 SUMMARY

The first patent for a turbocharger design was issued in 1905, and turbocharging has seen significant and continuous improvements since then. The first application of turbocharging was for reciprocating gasoline aircraft engines and has proceeded to on highway and off-highway heavy-duty diesel engines, light-duty passenger car diesel engines, and now to passenger car gasoline engines, thus covering all reciprocating engines. Turbocharging is increasingly recognized as a critical part of engine/vehicle performance, emissions, and fuel economy.

In heavy-duty diesel engines, turbocharging has increased power density, enabled emissions reduction through charge-cooling and EGR, and improved fuel economy. In light-duty diesel engines, turbocharging has given similar improvements and 30–50% better fuel economy compared to equivalent gasoline engines. Turbocharging is so significant to diesel engines that there are no important diesel engines without turbocharging.

In light-duty passenger-vehicle gasoline engines, turbocharging has enabled engine downsizing and reduced throttling over the drive cycle. This has improved fuel economy by about 20% while enabling 40–50% downsizing of engines.

Fatigue life, size/weight/inertia, high temperature capabilities, noise, and oil leakage are important mechanical design considerations. Performance/aerodynamic design considerations include efficiency, wide flow range, and flow and pressure capability. Material, manufacturing process, and detailed blade and hub design all play a significant role in determining both the performance and mechanical design capabilities of a turbocharger. Detailed geometric design features of turbine and compressor wheels are rapidly reaching a highly mature stage. Further improvements are expected at a system level with variable-geometry and multistage turbocharging.

DOI: 10.1002/9781118354179.auto069
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Turbochargers have to be carefully matched to meet specific engine requirements such that the engine operating lines lie well within the useful flow range of the compressor and the turbine is able to supply the power needed by the turbocharger as well as handle engine exhaust flow without imposing a high backpressure on the engine. EGR and DPFs impose additional requirements on turbocharger matching and design.

Variable-geometry turbochargers are available for light- and heavy-duty diesel engines and gasoline engines. Variable-geometry turbocharging improves response and fuel economy.

Increasingly, the stringent requirements imposed by the need for high rates of EGR, faster response, and high lowspeed torque drive the need for multi-stage turbocharging. Parallel, series, and sequential turbocharging, as well as multistage turbocharging packaged on a single shaft giving a compact design, have been designed, developed, and brought to production.

Turbocharging has become an increasingly significant and integral part of engine design for all classes of diesel and gasoline engines, and also for alternate fuel engines.

Bearings and Bearing Design for Transmissions

Reinhart Malik, Ernst Masur, and Andreas Schick

Schaeffler AG, Herzogenaurach, Germany

1 INTRODUCTION

The primary aim in modern transmission manufacturing is to achieve greater efficiency. This applies both to the considerable influence of the transmission on the overall energy efficiency of a vehicle and to the costs. The transmission is one of the most valuable systems in a vehicle. Over the last few years, vehicle and transmission manufacturers have responded to the need for efficiency with, among other things, strong diversification in the design variants described in detail in the previous chapters. The torque density of vehicle transmissions—that is, the maximum torque transferred in relation to the overall installed size—has increased significantly as modern engines offer more torque at low speeds (thanks also to the trend for turbocharging), whereas the mounting space available for the transmission is shrinking.

However, what all transmissions have in common, despite the different design variants and the individual models, is that the engine speed is transmitted to the output speed via rotating shafts. Engine development gives rise to ever-increasing torques that lead to high loads on the moving parts. Therefore, the bearings installed in the transmission have a decisive influence on the service life of the transmission.

Owing to the conditions present in the transmission, bearings are to some extent subject to specific loads that do not occur in this form in other applications. For example, frequently changing axial and radial loads occur simultaneously in the transmission, and dynamic loads prevail. This applies even for normal operation due to the forces that arise on the gear wheel mesh. Shaft deflection also occurs, as well as impact loads due to uneven roads.

The trend for light construction means that transmission housings are often made from light metal (aluminum and, increasingly, magnesium). These materials demonstrate relatively high coefficients of thermal expansion giving thermal distortion that has to be compensated. The temperature range within which a vehicle transmission has to operate without any problems ranges from -40 to $+60\,^{\circ}\mathrm{C}$ external temperature, whereby the temperature of the transmission oil can be considerably higher.

The transmission oil itself is usually used to lubricate the bearings. As the transmission oil is no longer changed over the entire life of passenger cars today, oil contamination and oil ageing represent significant challenges for bearing developers. The fact that transmission oils with low viscosity are increasingly being used only compounds the issue. Despite this, the development of a load-bearing lubricating film must be guaranteed at all usage temperatures.

Due to the friction that arises, the bearing points also contribute directly to the overall efficiency of the transmission and thus to the fuel consumption of the vehicle. A modern rolling bearing may reach an efficiency level of over 99%, but the multiplication of many small

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

losses at individual bearing points results in a measurable influence on the CO_2 emissions of the overall vehicle.

2 FROM THE COMPONENT TO THE SYSTEM: BEARING APPLICATIONS IN TRANSMISSIONS

There is not and cannot be one typical transmission bearing. In industrial practice, every bearing planned for transmissions produced in high quantities is designed specifically for the individual use case. The best design solution is selected for each bearing point, meaning that one individual transmission can contain more than two dozen different types of bearing construction (Figure 1).

The bearings installed in a transmission are primarily rolling bearings in which a rolling element runs between an inner and an outer ring. The main components of a rolling bearing (Figure 2) are:

- The *rolling elements*, generally designed as balls or rollers.

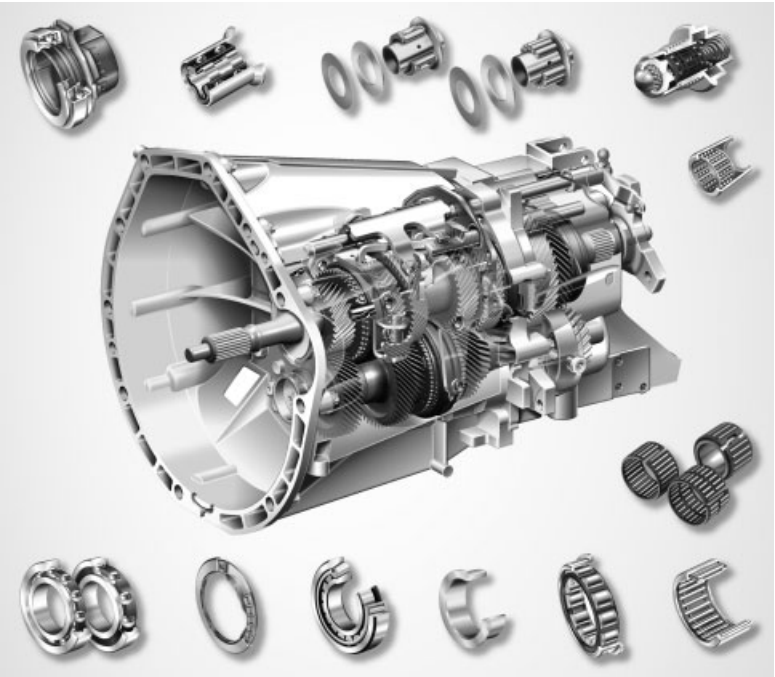

Figure 1. Types of bearing construction in a typical manual transmission. (Reproduced with permission from Schaeffler Group.)

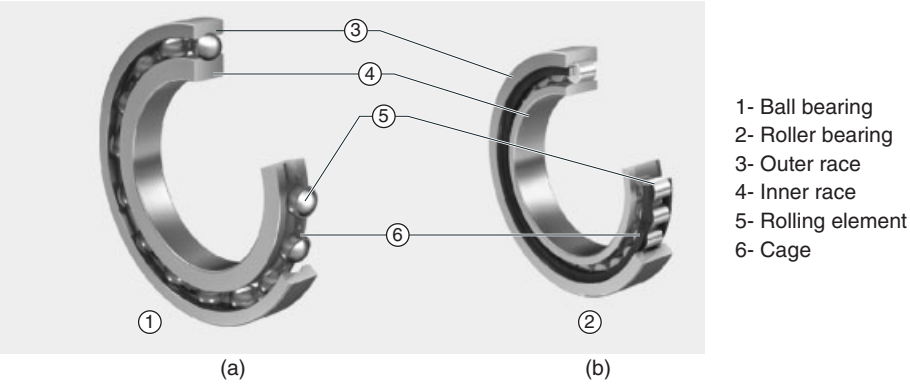

Figure 2. Main components of rolling bearings as ball bearings (a) or roller bearings (b). (Reproduced with permission from Schaeffler Group.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto073
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- The *tracks* on which the rolling element runs. Generally, the tracks consist of an inner and an outer ring. However, in some cases, the component or shaft to be supported is itself used as the track.
- The *cage*, used to protect the rolling elements against mutual contact and slipping.
- The *seal*, if the rolling bearing is to be protected against penetrating media.
- The *lubricant*, if the rolling bearing is lubricated with grease. In vehicle transmissions, lubrication is provided almost exclusively by the transmission oil.

The diversity of design variants for rolling bearings reflects the multitude of applications in transmissions. These applications differ particularly with regard to the possible occurrence of axial and radial forces. As it is the design of the rolling element that varies most strongly, it makes sense to look at the bearings based on the respective design variants and, in this context, to consider the respective transmission applications. Figure 3 shows an overview of the types of rolling elements used most frequently in transmissions.

2.1 Ball bearings

As the name indicates, ball bearings use balls as rolling elements. Ball bearings were used in automotive engineering long before the car was invented, for example, in bicycles. Industrial mass production began with the invention of the ball mill by Friedrich Fischer in 1883. Fischer, who founded the company FAG Kugelfischer, designed a grinding machine that, for the first time, enabled a large number of steel balls to be produced with identical dimensions. Transmission manufacturing today uses primarily deep groove ball bearings and angular contact ball bearings; they differ in particular in the arrangement of the running surfaces.

2.1.1 *Deep groove ball bearings*

The deep groove ball bearing is the classic ball bearing *per se*. Here, the balls run in a groove in the outer ring and one in the inner ring. Deep groove ball bearings are suitable for applications in which primarily radial forces occur. The absorption of axial forces is limited to approximately 10% of the maximum radial force absorption (Figure 4). If the axial forces are too high, this reduces the life of the bearing considerably.

Deep groove ball bearings are suitable as locating bearings for guiding the shaft, for example. Due to their small contact surfaces, they produce relatively low friction, but this very fact also limits their absolute load capacity. This means that deep groove ball bearings are primarily used as the main bearing in smaller transmissions with input torques of up to 250 Nm. One factor that determines the average dynamic load capacity and thus the service life of a bearing is the material used. The standard steel used is 100Cr6, but higher quality heat-treated materials are also widely used.

For transmission applications, deep groove ball bearings are being increasingly designed with an integrated elastomer seal for the cage in order to protect the running surfaces against contamination, for example, small particles in the transmission oil. The grease enclosed in the bearing provides the lubrication. These bearings are known as *clean bearings.* The synthetic rubber NBR (nitrile butadiene rubber) has proven its value as a sealing material. In individual cases, a similar effect can be achieved by providing a closed bearing housing with small oil bores on the inner ring.

Rolling elements		Bearing type
	Steel ball	Ball bearings
	Cylindrical rollers	Cylindrical roller bearings
	Needle rollers	Needle roller bearings, needle roller and cage assemblies
	Tapered rollers	Tapered roller bearings

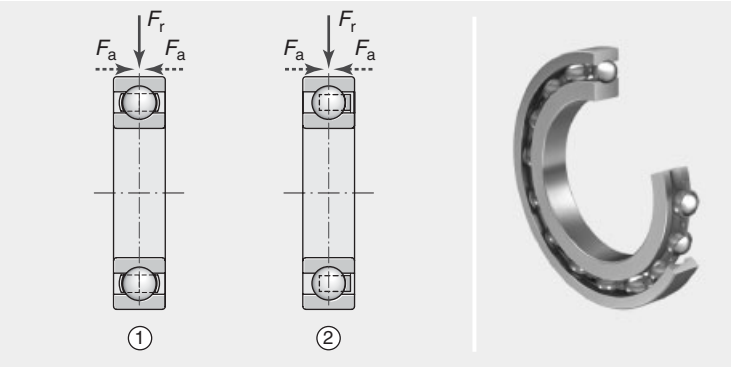

Figure 4. Structure of a deep groove ball bearing. (Reproduced with permission from Schaeffler Group.)

When a ball bearing is designed as a locating bearing, the environment and the intended assembly sequence must be considered so as to ensure that the bearing housing and assembly flange are coordinated optimally. This can be achieved, for example, by including the retainer as part of the assembly in the delivery scope of the bearing manufacturer and thus reducing the assembly time at the transmission manufacturer.

2.1.2 Angular contact ball bearings

The angular contact ball bearing is a type of ball bearing in which the running surfaces of the inner and outer ring are diagonally offset to the bearing axis. This means that greater axial forces (but only in one direction) can be absorbed in addition to the radial forces (Figure 5). With identical dimensions, more balls can be used, which leads to an increase in the load capacity.

A radial load can only be applied to an individual angular contact ball bearing if a minimum axial load is present at the same time. This means that angular contact ball bearings are often installed in pairs and mirror-inverted. The load capacity of the bearing can also be increased by a double row design, provided there is sufficient space for this. Here, we must differentiate between a tandem ball bearing, where both ball sets are of identical size (Figure 6), and a tandem bearing that consists of one large, higher load capacity ball set and one smaller, supporting ball set (Figure 7).

In transmissions, angular contact ball bearings are generally used for medium sized load situations in which a deep groove ball bearing is no longer sufficient, but the use of a tapered roller bearing is not yet necessary. The level of friction that occurs is between that for a deep groove ball bearing and that for a tapered roller bearing.

The combination of an angular contact ball bearing on one side of the shaft in conjunction with a tapered roller bearing on the other side is possible in principle if the forces occurring are known precisely. This type of design would be implemented in a rear-axle differential, for example.

If the lubrication fails, angular contact ball bearings have relatively good emergency properties. If there is insufficient lubricant, they do not allow the shaft to seize up quickly—a situation that could occur above all due to a lack of sliding

Figure 7. Tandem angular contact ball bearing for applications in rear-axle transmissions. (Reproduced with permission from Schaeffler Group.)

friction. One disadvantage of angular contact ball bearings compared with roller bearings is the greater sensitivity to external dirt effects, which is the result of highly loaded point-type contact.

2.2 Roller bearings

In a ball bearing, the rolling elements have a point-type contact to the running surfaces, whereas in a roller bearing, the contact is linear. This increases the static load capacity considerably, and the axial load capacity of a radial bearing can also be increased specifically by the design. The greatest disadvantage of almost all roller bearings is the inherently higher friction. In many cases, the ball bearing is also the more cost-effective design. The design variants needle roller and cage assembly and drawn-cup roller bearings are an exception.

2.2.1 Cylindrical roller bearings

Cylindrical roller bearings can be designed as radial or axial bearings in accordance with their main loading direction. To a limited extent, axial forces can also be transferred by a radial bearing via the design of the end retainer in the outer and inner ring. Both design variants can be found in vehicle transmissions. Radial cylindrical roller bearings (Figure 8) are typically used in the non-locating bearing arrangement of the pinion shaft in transmissions—that is, shafts that have an output drive shaft. As cylindrical roller

DOI: 10.1002/9781118354179.auto073
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

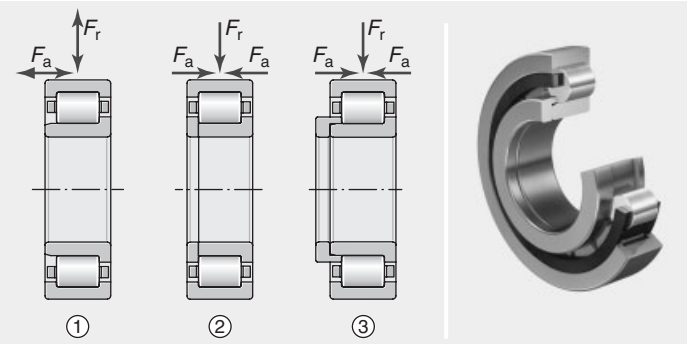

Figure 8. Radial cylindrical roller bearing. (Reproduced with permission from Schaeffler Group.)

bearings are relatively rigid, they are often used in light metal housings.

2.2.1.1 Radial and axial needle roller bearings. Needle roller bearings are used where low section height is advantageous. They are a type of cylindrical roller bearing in which the ratio of length to diameter of the rolling element is greater than 2.5 : 1 (Figure 9). In practice, the design variants are clearly differentiated and irrelevant for individual design cases.

In automatic transmissions, most bearings are axial needle roller bearings (Figure 10). This is because the forces that occur in planetary gear trains cancel each other out to a large extent and only the axial forces that occur due to the helical gearing of the sun gear/ring wheel pairing have to be supported by the bearing. In the radial direction, the bearing

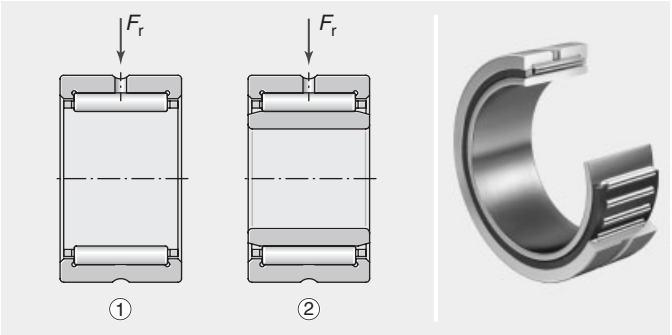

Figure 9. Structure of a radial needle roller bearing. (Reproduced with permission from Schaeffler Group.)

DOI: 10.1002/9781118354179.auto073
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

in automatic transmissions primarily takes on management functions. Additional functions can be assigned to the thin-walled discs of the bearing, such as oil throttle points or fixtures that counteract faulty assembly.

2.2.1.2 Needle roller and cage assemblies. Needle roller and cage assemblies have no outer and inner ring—the rolling elements run directly on the surrounding components. The rolling elements can be very small in relation to the bearing diameter. If needle-shaped rolling elements are run in a cage, they take up very little space, which is why they were used increasingly in transmission manufacturing in the 1950s. They have almost completely eliminated the plain bearings formerly used.

Needle roller and cage assemblies are used for the bearing arrangement in constant mesh gears (Figure 11). In the design, it is very important to consider the ambient conditions: to cool the synchronizer, sufficient oil supply must be ensured in all circumstances by designing the cage correspondingly (e.g., with grooves). When speed gears are not engaged, the bearing load is very uneven due to the vibrations that occur. This leads in particular to high loads on the cage. Suitable design measures must be used to protect the cage against fractures. When speed gears are engaged, the static loads are very high as there is no relative movement between the speed gear and the shaft. With the right design of the clearance between the cage and the shaft, it is possible that the rollers do undergo a slight relative movement, thus preventing damage.

The planet gears of automatic transmissions also have needle roller and cage assemblies as bearings. Here, "crank pin cages" that can absorb very high acceleration forces are used. The name comes from the manufacturing of two-wheeled vehicles where these bearings were first used. They are therefore optimized for minimal friction. In comparison with earlier bearing designs, the friction reduction is up to 2 kW for the entire automatic transmission. When designing the crank pin cages, it is important to note that centrifugal forces of up to 7500 g are at work in the planet gears (Figure 12). In combination with the gear wheel meshes—in particular for torque steps—these centrifugal forces bring strong fluctuating loads into the bearing. The life is therefore influenced more by the ambient conditions, in particular the safeguarding of good lubrication, than by static loads (Hertzian contact pressure).

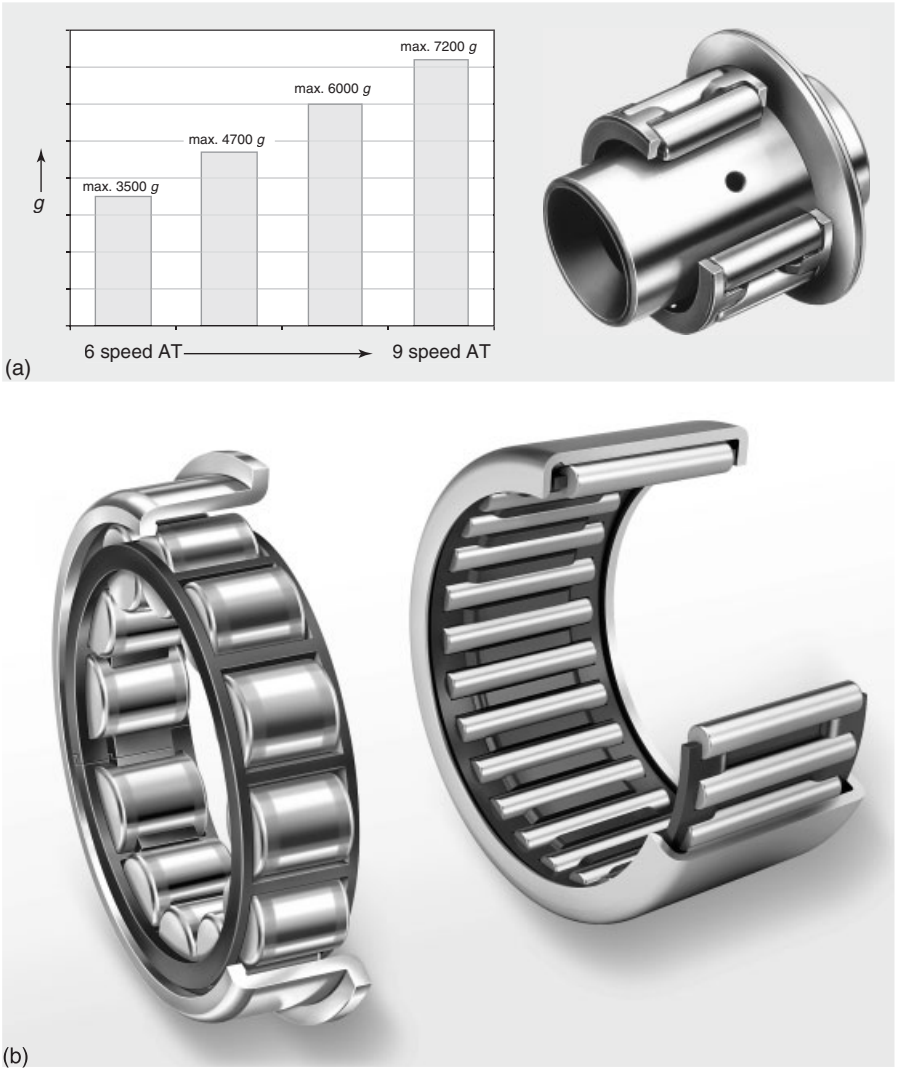

Figure 12. (a) Centrifugal forces on planetary bearings in automatic transmissions. (Reproduced with permission from Schaeffler Group.). (b) Drawn-cup roller bearings. (Reproduced with permission from Schaeffler Group.)

To achieve an optimum service life, the trend is toward developing bearings and planet gear sets together and supplying them directly to transmission manufacturers as an assembled component. The advantage is not only in the shorter assembly time but also in the optimized design with regard to oil supply.

2.2.1.3 Drawn-cup roller bearings. Drawn-cup roller bearings are not manufactured by mechanical processing (turning, hardening, grinding, and honing). Instead, they are formed by deep drawing and therefore offer considerable cost advantages, provided large quantities that justify the higher tooling costs can be achieved. However, in high volume production, maximum precision and process stability must be ensured, as mechanical post-processing is not feasible. The manufacturing process is important even at the material selection stage. Low carbon steels that achieve the required strength through case hardening after processing are generally used.

In particular, drawn-cup roller bearings are used for the non-locating bearing arrangement in a locating and non-locating bearing system. What makes them so useful is the excellent ratio of required space to load capacity. Thus, in comparison with a cylindrical roller bearing, either a considerable amount of space can be saved or the load capacity can be considerably increased while keeping the dimensions the same. The fact that, as a drawn part, the outer ring of drawn-cup roller bearings is relatively thin is generally an advantage but must be considered with regard to maximum pressure. This is particularly true if

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto073
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

aluminum or magnesium is used for the drawn-cup rather than steel.

2.2.2 *Tapered roller bearings*

In a tapered roller bearing, tapered rolling elements run on an inner ring that has a conical track and an inner ring shoulder (Figure 13). The higher level absorbs the axial forces and the lower level is the actual track.

Tapered roller bearings can also only absorb axial forces in one direction. Therefore, in transmissions, they are installed almost without exception in pairs and mirror-inverted. The important thing in the design of tapered roller bearings is that axial and radial forces must not be considered independently of one another. If a radial load is applied to this type of bearing at a certain contact angle, backpressure forces with an axial load component arise within the bearing. This vector must be absorbed by the counter bearing in addition to the axial forces working externally.

Tapered roller bearings are used in automotive engineering primarily where very high loads occur and high bearing arrangement rigidity is required, for example, in trucks but also in passenger cars with high engine power. Typical uses cases are differential transmissions (Figure 14) or bearing arrangements in the output shaft. The friction of tapered roller bearings is inherently higher due to the larger contact surfaces. This is why ball bearings are preferred as long as they can control the forces that occur.

As tapered roller bearings require more lubrication than ball bearings, particular importance must be attributed to this aspect during component design. Specific oil bores are often implemented in the housing and the shaft. Oil feed devices such as distributor plates or drip trays are optional.

A high degree of integration of components is also becoming increasingly important in tapered roller bearings. For example, double row design variants in which the rolling elements run in a common outer ring are used successfully.

2.3 Other types of bearings in transmissions

For manual transmissions, a shift rod bearing arrangement is required. This can be implemented via a ball cage that can execute a longitudinal movement. The bearings in the transmission are often assigned further functions, for example, a contact that switches on the rear light when reverse gear is engaged. In automated manual and dual clutch transmissions, the contact signal is also an input parameter for the transmission control system. The trend for gearshift mechanisms is also toward pre-assembled complete units that include the shift rod, the shift forks, the detents, the bearings, and the assembly aid.

As described, rolling bearings have largely eliminated the plain bearings previously used in transmissions. Bushes are still used for radial loads and thrust washers for axial loads in some cases, in particular in automatic transmissions (Figure 15).

3 BEARING DESIGN FOR TRANSMISSIONS

Transmission bearings are designed specifically for the respective transmission and the installation location; "catalogue bearings" are virtually unknown. It is therefore beneficial if the transmission manufacturer—in some cases, the vehicle manufacturer themselves—works together with the bearing supplier from an early design stage. If the two parties define the space required for the bearing arrangement together, technically optimum solutions that also offer high efficiency are possible, for example, by planning the assembly flange as part of the bearing housing.

The process of bearing development should always begin with a precise analysis of the entire transmission. In addition to the design conditions and the forces and torques at work, the oil supply in the transmission must also be considered. Only then should a specific

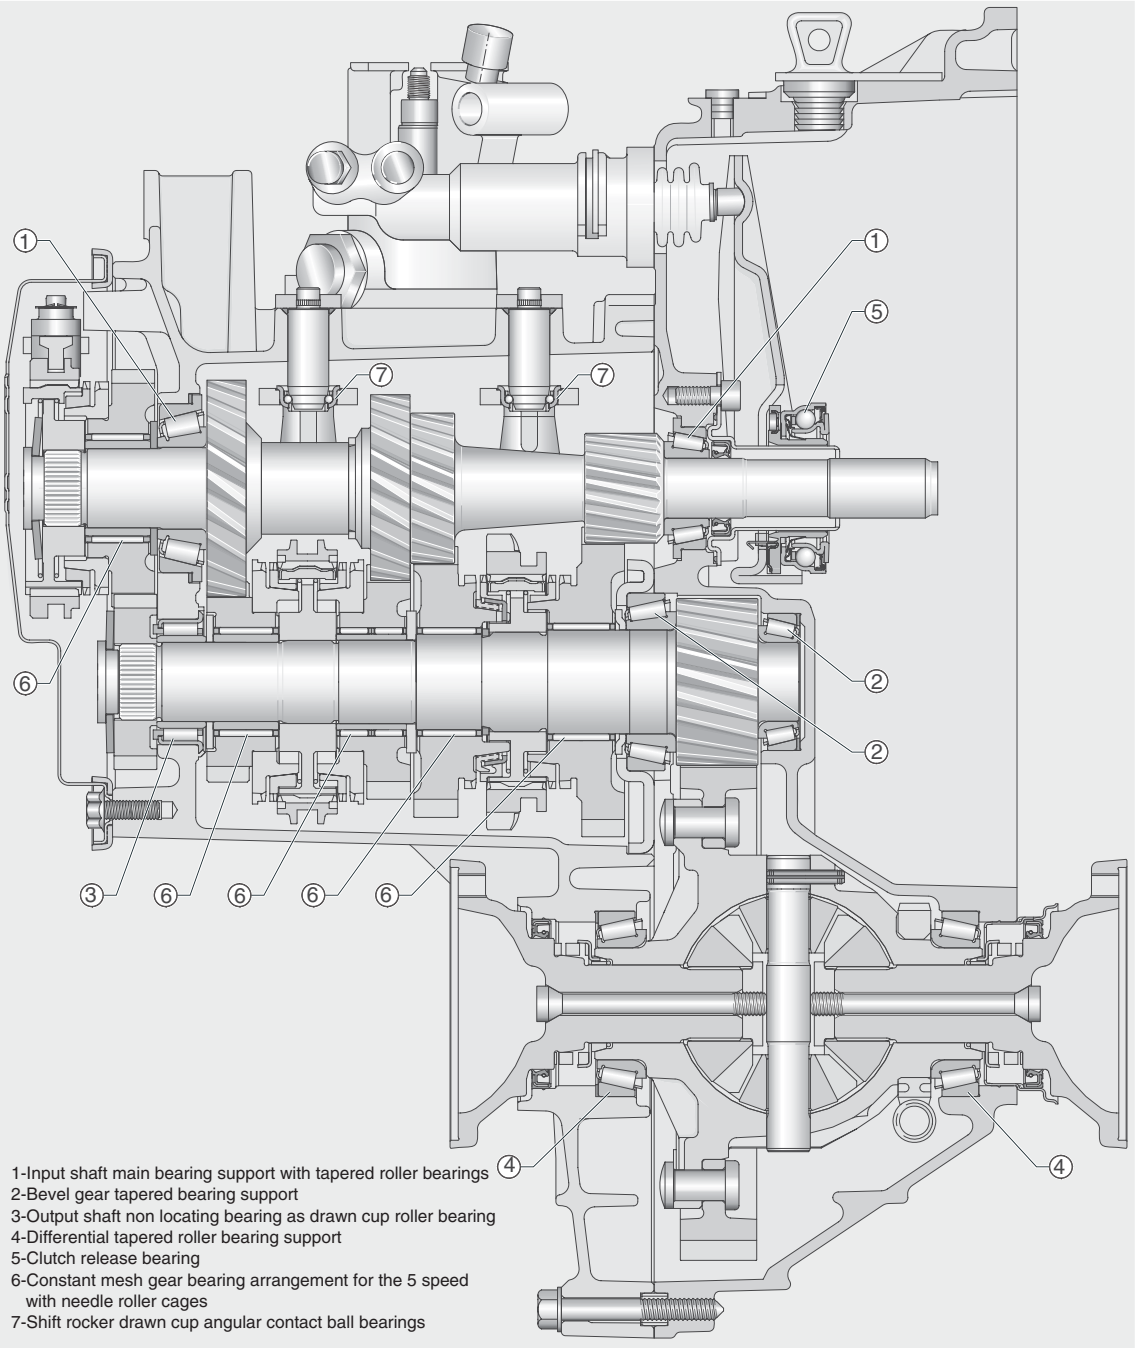

Figure 14. Installation positions of different bearings in a front-drive manual transmission. (Reproduced with permission from Schaeffler Group.)

bearing concept and its design implementation be selected. Therefore, it is not possible to assign specific bearing construction types to applications generally. Figure 16 illustrates this using the example of a bearing arrangement for a main shaft. The first variant, a locating and non-locating bearing arrangement system, has the lowest friction. In contrast, the adjusted bearing arrangement is extremely rigid and requires the least space. Alternatively, a floating bearing arrangement shows no definite axial fixture and causes the least difficulties with regard to axial positioning of, for example, shifting devices.

3.1 Service life

The most important design criterion of every bearing is its service life. The service life is the life during which no component failure occurs under typical load conditions and defined cases of misuse. In automotive manufacturing, the service life is generally 300,000 km for passenger cars, which corresponds to a usage time of approximately 5000 h. As the transmission components are not constantly subject to full load during the service life, this results in typical lives of between 500 h for passenger cars and 6000 h for heavy trucks (Naunheimer, Bertsche, and Lechner 2007).

The basis for the durability calculation is the fatigue theory developed by Lundberg and Palmgren (1947). According to this theory, the dynamic load rating C is decisive for bearing fatigue; C is defined as the load of unchanging size and direction at which a sufficiently high quantity of identical bearings achieves a nominal life of one million revolutions.

This calculation has since been considerably extended, and the following parameters are included in the extended calculation method:

- The extent of the bearing load
- Material fatigue limits
- Degree of surface separation by the lubricant
- Cleanliness in the lubricating gap
- Lubricant properties
- Inner load distribution and friction in the bearing

Beyond these parameters, modern simulation tools such as the BEARINX program from Schaeffler also consider the influence of heat treatments and surface coatings as

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

well as the influence of the overall system—for example, the bending of transmission shafts under load. In reality, loads occur that are not reflected by DIN ISO 281 for the durability calculation. Therefore, the power flow in the entire transmission, including the gearings, must be modeled. The load spectrum used for the calculation differs considerably depending on the vehicle manufacturer.

Nowadays, the calculation also enables the property of the lubricating film to be calculated for every load point: for example, the friction state (mixed friction, hydrodynamic friction, etc.) of the bearing is always known. The direction of flow of the oil and the temperature of the oil must also be analyzed. This makes it possible to adjust the bearing geometry such that a load-bearing lubricating film is built up under all operating conditions.

Although the calculation was previously used to verify a bearing arrangement created by a design engineer, the procedure today is almost reversed; initially, based on calculations, a set of rolling elements is optimized in a simulated transmission environment to the extent that it fulfills the service life demands (without being excessively large); then the entire bearing and, if applicable, additional peripherals such as the assembly aids mentioned, are designed. The bearing developer generally selects the rolling element set used for the calculation from an existing library of bearings already implemented and then optimizes it step-by-step.

Important options for optimizing the life include changing the geometry—provided this is possible within the mounting space—and adjusting the material, including the heat treatment. Other methods for increasing the strength are case hardening and strength peening. The standard basic material for transmission rolling bearings is still steel type 100Cr6 (carbon content 0.9%, chrome content 1.35%). Steels with higher chrome and magnesium content are also used. The life of the bearing can also be increased up to ten times by selecting the ideal heat treatment (i.e., aligned to use).

Maximum surface hardness is not, however, the key to the longest service life. This is because under some circumstances, the rolling elements can roll over dirt particles transported with the transmission oil more easily in a softer surface compared to a very hard surface that, in an identical operation, could cause permanent damage.

To achieve the required service life in practice, knowledge of the typical damage patterns is also necessary (Section 4).

3.2 Friction

In light of the increasingly stringent CO_2 limits, minimal frictional losses are becoming even more important for the entire powertrain. After the frictional losses in the gearing, the losses through the rolling bearing are important. Various studies have demonstrated that simply by optimizing the bearings, the overall friction in a manual transmission can be reduced by up to 2% and in a rear-axle differential by up to 4%.

Using modern simulation tools, the friction of a rolling bearing can be predicted to a precision of 10–15%. In turn, the accuracy of the calculation for the entire transmission depends on how well the environmental influences, such as oil churning losses, are considered.

In this encyclopedia, the friction optimization of transmission bearings is addressed in a separate chapter (see Chapter "Rolling Bearings and Bearing Design for Transmissions" in this encyclopedia). The chapter also discusses the surface coating as an option for low friction rolling bearings.

3.3 Acoustics

The use of guide bearings can reduce the relative movement of a shaft to the transmission housing, thereby improving the acoustic properties of the powertrain. One example is the use of polygon bearings that pretension a shaft against the housing, that is, they eliminate the shaft clearance.

The definition of the bearing points has a considerable influence on the vibration behavior of the shaft under dynamically changing loads. Therefore, the bearing points should not be defined considering only the aspects strength and the mounting space.

4 BEARING DAMAGE AND PREVENTING DAMAGE

In principle, bearing damage must be avoided by making the bearings of the correct size and using a suitable design construction. However, due to the objectives of light construction and downsizing, as well as the economic pressure in the automotive industry, the classic engineer virtue "if in doubt, a little bit more" is no longer an option. If, however, bearings are to be adapted precisely to the loads present, it is important to be aware of any potential damage that may occur and to plan suitable countermeasures during development.

Just like any other machine element, a transmission rolling bearing changes over the course of its use. Therefore, there must be a differentiation between normal signs of use and damage that can lead to restricted function or even failure of the component. Some typical types of damage for transmission bearings are discussed below.

4.1 Fatigue damage

"Natural" bearing damage is the material fatigue that occurs at some point for every bearing. However, if the design is correct, it occurs only after the end of the service life. Fatigue is caused by alternating shearing stresses near to the surface of the structure of a bearing material. An inner ring raceway is more affected than the rolling element or the outer ring raceway. Fine cracks appear and gradually multiply.

As this type of damage during the service life can be eliminated at the outset by choosing an appropriate design, fatigue-related wear on the surface is particularly important in practice. It arises when the maximum shearing stress shifts as a result of fluctuating load at the surface. In some circumstances, very low expansion plastic deformations can occur there (<0.1 mm). If this damage occurs frequently, it is visible to the naked eye and is called *gray staining* due to its appearance (Figure 17).

If gray staining occurs, the first thing to check is whether the optimum type of bearing construction was selected for the loads occurring in the axial and radial direction. Switching to a different type of bearing construction may resolve the situation. Triggers for this type of surface damage can also be individual particles in the lubricant, which are pressed into the material by the rolling element, causing a plastic deformation. Therefore, the formation of the lubricating film must also be analyzed.

4.2 Wear damage

Wear damage comprises all damage patterns where the surface gradually changes. There is a differentiation between abrasive and adhesive wear. Adhesive wear arises through the direct atomic contact between the sliding contact surfaces, whereas abrasive wear is caused by frictional forces that arise on the running surface.

A frequent form of wear damage for transmissions is riffling in constant mesh gears (Figure 18). It arises because the bearing that is not moved relative to the shaft is subject to high loads. Due to the lack of speed, sufficient lubricating film cannot be built up, meaning that there is direct metallic contact. As the needles of the speed gear bearing always come to rest at the same point on the outer ring, longitudinal grooves occur—known as riffling. A design idea can provide help here; the very small rolling movements of

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the needles are used to move the entire cage slightly on the shaft, creating even, uniform wear over the entire surface.

4.3 Corrosion damage

Even though every transmission is in principle protected against oxidation by the lubricant, specifically through the additives used in the lubricant, corrosion damage can still occur from time to time. The cause is usually contact corrosion, which occurs when a material pairing is unevenly coated with lubricant over a constant period. This type of damage is particularly relevant in the transmission area of vehicles that are stationary for long periods, because they are only used on a seasonal basis (combine harvesters, ski run snowplow, etc.). Special surface coatings can be used to resolve this problem.

4.4 Bearing overload

Extreme load spectrums that were not considered in the bearing design can lead to premature fatigue and then to bearing fracture. One example of this is the constant rally use of a road vehicle. Repeated load impacts through extreme contraction of the shafts in the transmission can lead to a fracture in this type of situation; thin-walled bearings such as roller sleeves are particularly at risk here. Bearing fractures can also be caused by primary damage at the transmission shafts or the planet gear sets of an automatic transmission. As a result, the load on the bearing is so uneven that the bearing deforms and eventually breaks (Figure 19).

In modern automotive development, individual misuse tests are performed as standard, for example, driving over a curb at high speed. These tests are reflected in the load spectrums used for the bearing design. Any further damage occurring must be analyzed in each individual case and the relevance for the actual operation of the vehicle must be considered.

4.5 Temperature failures

Overall, temperature failures in transmission bearings are very rare. However, if they do occur, for example, during extreme load tests (e.g., repeated journeys over high mountain passes), they usually indicate insufficient lubrication. A self-reinforcing effect can occur because an increased oil temperature leads to a decrease in the oil viscosity. However, the thinner the oil, the more difficult it is for the load-bearing lubricating film to form—and therefore, the greater the waste heat arising from the mixed friction.

Bearing cages that are, in the case of transmission rolling bearings, often made from colored metals or plastics suffer particularly from excessive temperatures. If the local temperature exceeds the permitted value for a long period, the cage can become permanently deformed or even melt completely in extreme cases.

4.6 Special features in hybrid vehicles

In hybrid vehicles, the electric motor is often installed directly in the bell housing of the automatic transmission or in the direct vicinity of the differential. This led to the

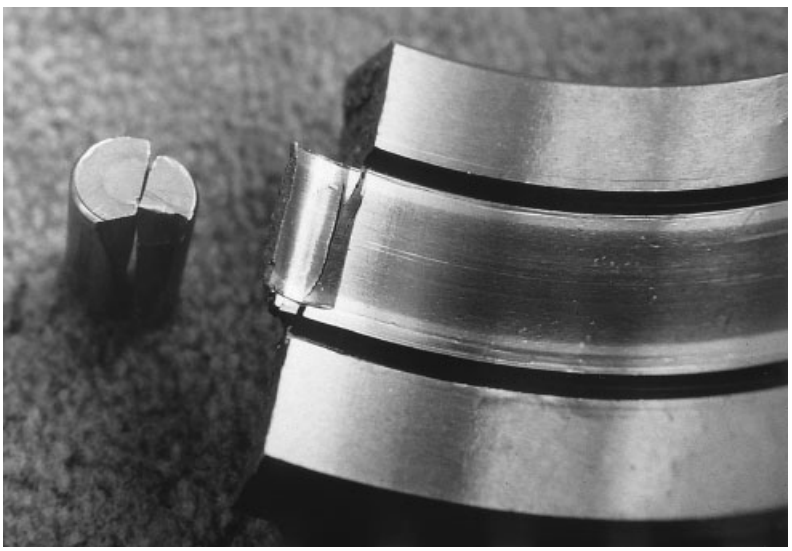

Figure 19. Forced fracture on the bearing of a planet gear. (Reproduced with permission from Schaeffler Group.)

DOI: 10.1002/9781118354179.auto073
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

fear that the magnetic fields occurring could influence the bearing function—for example, metallic particles in the transmission oil could move in the direction of the field and, under some circumstances, could also be deflected to the bearing surfaces. In existing hybrid vehicles, this issue has been considered to some extent in the oil conduit in the transmission. No increased damaged has been observed in the field so far.

5 SUMMARY

The requirements concerning the design of transmission bearings are constantly increasing. The classic criterion of a sufficient service life is supplemented by lower frictional losses and—thanks to the competitive pressure in the automotive industry—a cost-optimized design. This leads increasingly to modules that perform further functions in addition to pure bearing arrangement.

Using modern calculation tools, it is possible to optimize the entire shaft/bearing system of a transmission numerically first. This approach enables different types of bearing construction as well as materials and after-treatment methods for the respective installation location to be varied very quickly and conflicting goals to be resolved. It is therefore impossible to provide hard and fast rules for individual applications.

With proper design and by using modern methods, it is not difficult to reflect the required service life. However, engineers must still have knowledge of typical damage patterns, particularly when new technologies are being tested.

1 INTRODUCTION

There is hardly any system; mechanism, device, or machine that does not incorporate load bearing surfaces. These are the interfaces formed by contact of a pair of solids, often limiting the performance of the system as a whole. The same is true of the natural world itself. For example, the load that a species can carry is often a measure of its skeletal structure and the limiting joint stresses. The working efficiency of species is not only a function of their respiratory and circulatory system but also their joints' friction. Therefore, similar to the natural world, machines have performance constraints in terms of load and speed. These are two key parameters that need to be considered in the operational performance of all machines. The geometrical, mechanical, and physical properties of contacting surfaces determine their performance, thus the machine which they are a part. The subject that deals with the fundamentals of load bearing surfaces is called *contact mechanics*. This chapter intends to familiarize the reader with the fundamental aspects of the subject. Two aspects are of interest; firstly the behavior of the contacting bodies under normal load and secondly their interactions in relative motion.

2 CONTACTING SOLIDS UNDER NORMAL LOAD

The subject of contact mechanics was initiated with the works of Pascal (1653), where the pressure generated between a pair of solid smooth surfaces with an interfacial area A under a normal applied load W can be determined as $p_m = \frac{W}{A}$. This is the mean (as opposed to the maximum) pressure that is generated between a pair of solids in contact. The contact area A is the footprint area (impression) that one of the solids, considered as a rigid body, would make on the other having an effective stiffness of the pair. The footprint shape and area are functions of the geometry of the solid surfaces.

The deformation behavior of contacting solids varies according to the applied load and their mechanical properties. Broadly, this can be classified into two categories. One category is concerned with the global deformation of solids, where significant changes in the shape of solids occur. These various shapes of the solids under load are known as *mode shapes*. Depending on loading and compliance of the solids, there may be many such mode shapes. In all cases, the extent of deformation can be comparable to the geometrical dimensions of the solids themselves. The other category is concerned with the localized deformation of the solids in the region of their contact, being far smaller than the overall geometrical dimensions of the solids themselves. The difference between these forms of elastic deformation, global versus local, is the extent of elastic deformation

strain (Rahnejat, 2010). Therefore, with localized contact deformation, there is no appreciable change in the shape of the loaded contacting solids themselves (i.e., very small strains). This chapter is devoted to the contact mechanics of solids with localized deformation.

There are certain salient features for localized deformation of solids in contact or impact. These were noted by Hertz (1881). In Pascal's equation, the contact of solids is considered to be over a flat region. This implies that surfaces with infinite radii of curvature are idealized. In practice, the contact occurs over a finite region. In other words, all surfaces have finite radii of curvature, however large these may be. Hertz (1881) noted that localized deformation occurs, when elastic deflection of solid surfaces in contact, δ, is far smaller than the footprint contact dimensions, which are in turn far smaller than the radii of curvature of the surfaces at the point of contact. Thus, for an assumed circular footprint contact of radius a, made by an equivalent rigid spherical indenter of radius R, pressed onto an elastic plane of large dimensions $\delta \ll a \ll R$. For example, a sphere of several millimeter radius loaded onto a compliant surface yields a circular contact footprint radius of a few tenths of a millimeter, causing a deflection of several tenths to a few micrometers.

As in dynamics problems where a simple model is a mass–spring system, in contact mechanics, one strives to make a basic model, comprising an ellipsoidal rigid solid loaded against an elastic surface of assumed infinite dimensions termed an *elastic half-space* or a *semi-infinite elastic solid*. This is assumed in order to reduce the effects often associated with defined boundaries. The radius of the rigid solid should consider the radii of contact of the actual physical surfaces and their elastic properties should incorporate those of the same surfaces as well.

Figure 1 shows the different contact configurations. Figure 1a is that of a pair of closely conforming solids (i.e., radii R_1 and R_2 are very similar in size). This type of contact is referred to as *conforming*, good examples of which are journal bearings, where $\frac{R_1}{\Delta R} > 100$, $c = \Delta R = R_2 - R_1$ is the nominal clearance and R_1 is the journal radius. R_2 is the radius of the bearing bushing or shell. Figure 1b shows the partially conforming (or counterformal) contact of two solid surfaces. A good example is that of a ball bearing or a roller bearing (end view) in its raceway groove. The degree of conformity R_1/R_2 is no longer near unity (as in Figure 1a). Typically, for the contact of rolling elements to raceway grooves, this ratio is between 0.8 and 0.9, whereas for journal bearings, it is usually in excess of 0.99. This small difference in conformity makes a significant change in the mechanics of contact. Figure 1c shows the extreme case of a counterformal contact with zero degree of conformity (R_2 being very large). The area of contact becomes infinitesimally small. This is an idealized case, used for modeling purposes. In practice, counterforming contacts are showed by Figure 1d.

The contact area is determined by the degree of conformity. The angle φ in Figure 1 shows the extent of contact. In the case of journal bearings this could extend to the value of π. Therefore, a large contact area would result, whose dimensions are comparable with the radii of the contacting solids. Thus, the use of Hertzian theory is inadmissible. For the partially conforming contacts and those with a counterforming nature, one may consider the Hertzian theory. For example, for a roller in a raceway groove, the small value of φ yields a thin rectangular strip footprint, whose width is a function of the applied load and whose length is approximately that of a right cylindrical roller, except for its relieved axial end extremities. These forms of contact, usually with high loads and small contact area, are termed *concentrated contacts*. The footprint shape is a function of the applied load, elastic properties of contacting solids, and their radii of curvature. These are known as the *principal radii of contact*, which are usually given in the planes zx and zy in Figure 2 for an equivalent ellipsoidal solid representing the contact of a ball–inner race in a ball bearing.

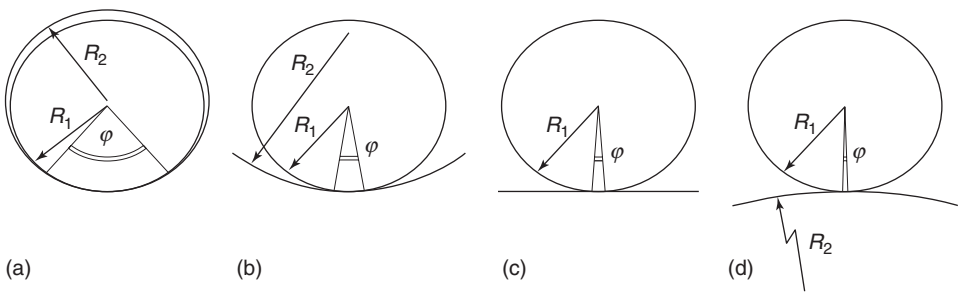

Figure 1. (a–d) Various contact configurations.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto075
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

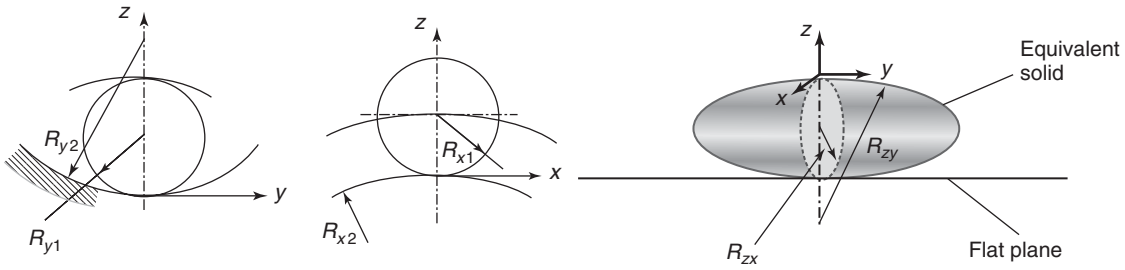

Figure 2. Actual geometry and the equivalent ellipsoidal solid.

The radii for the equivalent ellipsoidal solid, contacting a semi-infinite elastic plane, are obtained as:

$$\frac{1}{R_{zx}} = \frac{1}{R_{x1}} + \frac{1}{R_{x2}} \quad \text{and} \quad \frac{1}{R_{zy}} = \frac{1}{R_{y1}} - \frac{1}{R_{y2}} \tag{1}$$

Note that a concave surface is represented by a negative radius of curvature, in this case the groove radius R_{y2}. For the counterforming contact, the equivalent radius, $R_{zx} < R_{x1} < R_{x2}$, thus it is referred to as the *reduced radius*. For the partially conforming surfaces, $R_{zy} > R_{y2} > R_{y1}$, hence the equivalent radius is referred to as the *increased radius*. It is clear that for case (c) in Figure 1, the radii of curvature $R_{x2} = R_{y2} \to \infty$ (very large) and the ellipsoidal solid becomes a sphere. As the ellipsoidal solid is considered to be rigid, the elastic modulus of the semi-infinite elastic plane is adjusted accordingly and is referred to as the *equivalent* or *effective elastic modulus*:

$$\frac{1}{E^*} = \frac{1-\upsilon_1^2}{E_1} + \frac{1-\upsilon_2^2}{E_2} \tag{2}$$

If both the solids are made of the same material, Equation 2 simplifies to $E^* = \frac{E}{1-\upsilon^2}$. This is known as the *plane strain elastic modulus*. The contact stresses are considered to be compressive $\sigma_z(x,y) = -p(x,y)$, where x, y is the small flattened contact region (for a circular footprint x and $y \le a$). Outside the contacting region (x and $y > a$), $p = 0$. The contact of an ellipsoidal solid with a semi-infinite elastic half-space is an elliptical footprint, with an aspect ratio (Figure 3):

$$e_p^* = \frac{b}{a} \approx \left(\frac{R_{zy}}{R_{zx}}\right)^{\frac{2}{3}} \tag{3}$$

In ball bearings, the direction of ball rolling is along the minor axis of this contact ellipse. Also note that for a circular point contact $R_{zx} = R_{zy} = R_{x1} = R_{y1} = R$ (radius of a sphere) and thus $e_p^* = 1$ (a circular contact footprint of radius a). The contact of a crowned roller with its inner

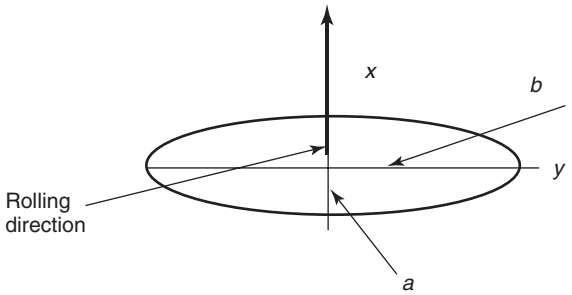

Figure 3. An elliptical footprint.

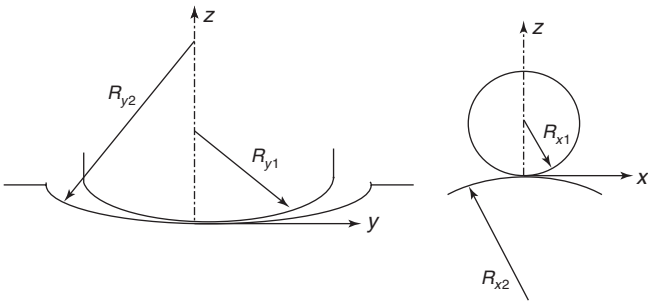

Figure 4. Roller–race contact geometry.

raceway groove (Figure 4) can also be represented by an ellipsoidal solid against a semi-infinite elastic flat plane as in Figure 1. The ellipsoidal solid would usually be long and slender (i.e., $R_{zy} \gg R_{zx}$). Therefore, the elliptical aspect ratio would be quite large, normally with a value in excess of 10. In fact, the contact footprint of a roller of any axial profile (crown barreled as in Figure 4, crowned at the edges or with small dub-off radii at its extremities) with a flat would usually be a dog bone or dumbbell shape because of sharp generated pressures at its rather abrupt axial edge profile (Johns and Gohar, 1981).

Disregarding the spread in the footprint shape at its extremities, the contact of a pair of loaded rollers (such

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto075
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

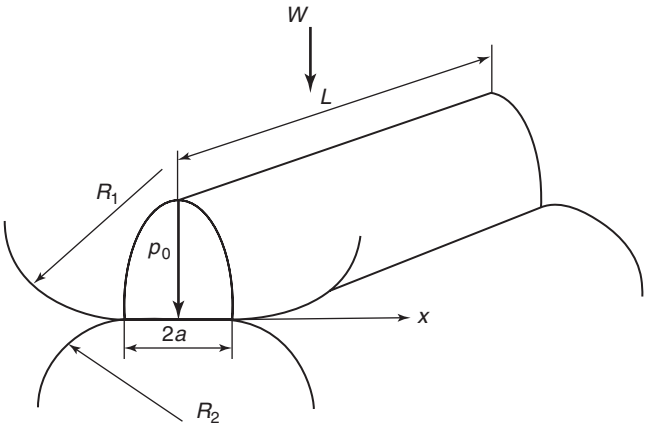

Figure 5. Elastic line contact of cylinders.

as a roller against the inner race, ignoring any roller axial profile) yields a thin rectangular footprint of width $2a$ and length L (nearly the length of the roller itself) as shown in Figure 5. As $a \ll L$, the contact footprint is often referred to as a *line contact*, where an analytic solution for generated pressures and contact deflection was found by Hertz (1881) along the contact width $2a$, considering the pressure distribution to be uniform along the length of contact (Figure 5). For a two-dimensional solution, considering the actual length of the contact, a numerical finite difference or finite element technique is required. The solution is referred to as *finite line contact* (Johns and Gohar, 1981; Rahnejat *et al*., 2009).

A narrow band pressure distribution is generated because of the applied load W, locally flattening the surfaces and forming a thin rectangular contact footprint. Using purely dimensional considerations, the contact half-width may be obtained in the form:

$$a = k\left(\frac{WR}{LE^*}\right)^n \tag{4}$$

where the term in the bracket has the dimension $\frac{FL}{L^F/L^2} = L^2$, with $F \equiv$ force, $L \equiv$ length.

Hence, in order to make the right-hand side of Equation 4 dimensionally compatible with its left-hand side, $n = 1/2$. Hertz (1881) showed that dimensionally, an elliptical pressure distribution is required over the footprint band for long line contacts, and an ellipsoid is needed over a circular footprint for contacting spherical surfaces. In the general case of a point contact with differing principal radii of curvature along orthogonal axes, such as a ball in an annular groove (a ball-race contact is an example), one requires an ellipsoidal pressure distribution over an elliptical footprint. The localized small deflection δ is as the result of the generated pressures. Table 1 provides a summary of classical Hertzian contact mechanics for cases of elastic line, general elliptical point, and the special case of circular point contacts. Note that the mean pressure p_m is the Pascal pressure and for a circular point contact $R_{zx} = R_{zy} = R$.

Hertzian theory applies to an assortment of load bearing surfaces encountered in the various automobile systems, particularly in the engine and drivetrain systems. This is because many of the conjunctions (a word used to describe contact of surfaces with a lubricant film usually present) are subject to high loads applied to infinitesimal contact areas of counterforming or partially conforming solids of revolution. In other words, they are regarded as concentrated contacts. Typical concentrated contacts include cam–tappet pair (Kushwaha, Rahnejat, and Jin, 2000), teeth of an engaged helical gear pair of the transmission (De la Cruz, Theodossiades, and Rahnejat, 2010), and those of hypoid gears of the differential (Litvin *et al*., 2002). The instantaneous contact of the cam against a flat tappet or a roller may be considered as an equivalent cylinder with the instantaneous radius of cam at the point of contact (Gohar and Rahnejat, 2008). This varies according to the cam lift profile. The length of the contact is that of the cam width. The profile of the cam width and that of the tappet are considered to be flat. Therefore, at any instant of time, the

Table 1. Relationships for Hertzian contacts.

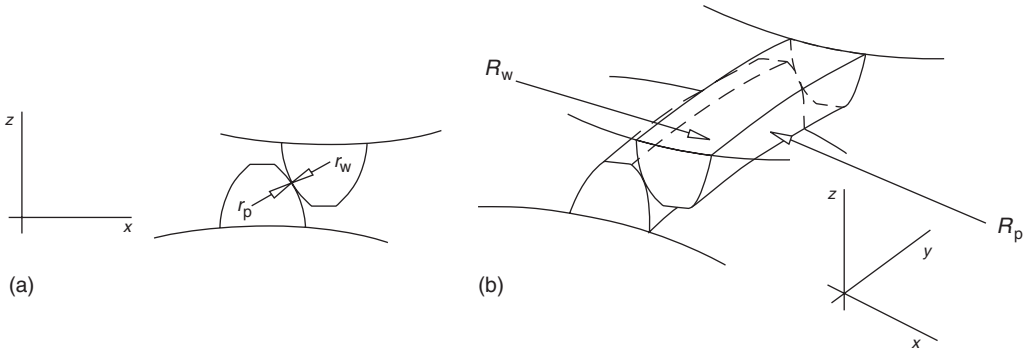

Figure 6. (a, b) Teeth pair contact.

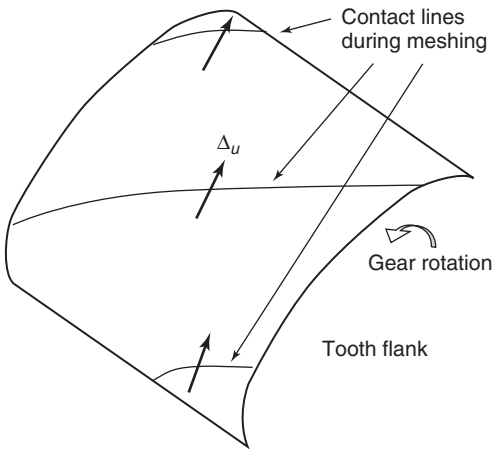

Figure 7. Procession of contact line during a meshing cycle.

contact footprint is a thin rectangular strip similar to the example in Figure 5.

Figure 6 shows typical contact of a gearing teeth pair. Clearly, as in the previous example in Figure 2, at any instant of time, an equivalent ellipsoidal solid can be determined according to the principal radii of teeth pair in the region of contact. For spur and helical gears, the transverse principal radii of contact in the *zy*-plane are very large, so can be ignored. This yields a slanted thin rectangular contact strip across the tooth flank as the instantaneous contact footprint. The contact line is shown in Figure 7, where the sliding motion (Δu is the relative sliding velocity between a pair of contacting teeth flanks) occurs along the interface and at an angle to the thin strip (De la Cruz *et al*., 2012).

In general, all forms of bevel gears have curved surfaces in the *zy*-plane of contact and in the *zx*-plane. Therefore, the hypoid gear pair of the differential can be represented by an instantaneous equivalent ellipsoidal solid; R_{zx}, R_{zy} contacting a semi-infinite elastic half-space of effective elastic counterface modulus E^*. The footprint shape is clearly a slanted ellipse with lubricant entrainment into it at an angle. If one fixes the direction of sliding (lubricant entrainment), the ellipse appears to precess about the contact normal as shown in Figure 8 for a pair of differential hypoid gear teeth through a meshing cycle (Mohammadpour, Theodossiades, and Rahnejat, 2012).

The Hertzian pressure distribution is for dry contact of solids of revolution in a concentrated contact. Figure 9a shows a typical ellipsoidal pressure distribution for an elliptical point contact footprint. For the line contact condition, a typical pressure distribution is shown in Figure 9b. For a finite line contact of a roller against a flat plane, there are pressure peaks at the sharp edges of the contact as shown in Figure 9c (Johns and Gohar, 1981). These pressure spikes are reduced where edges of the roller bearings are provided with a small relief radius, referred to as a *dub-off*. The contact line in Figure 7 is in fact similar to the footprint in Figure 9c.

3 ELASTOHYDRODYNAMICS

The concentrated contacts described in engine and drivetrains are usually lubricated conjunctions. Grubin (1949) proposed the mechanism of elastohydrodynamic (EHD) lubrication, based on his work with Ertel (Figure 10). He postulated that as a film of lubricant is entrained into the contact of a pair of elastic solid surfaces in concentrated contact and in relative motion, its viscosity is increased significantly because of the generated pressures that closely follow the pressure profile predicted by the Hertzian theory. An almost parallel thin lubricant film h_0 is formed in the flattened Hertzian contact footprint. The lubricant becomes almost incompressible, acting similar to an amorphous solid. As the lubricant film flows toward the contact exit, its viscosity reduces to comply with the principle of continuity of flow. The localized reduction in

viscosity reduces the lubricant load carrying capacity, thus diminishes the gap (minimum film thickness, $h_{\min}$) and increases the pressure, which is exhibited by a pressure spike (pip) near the contact exit.

The main interests in prediction of film thickness and the corresponding pressure distribution are to ascertain friction, wear, and fatigue behavior of the contact. These are the limiting performance parameters for any conjunction. Unlike Hertzian theory, prediction of pressure distribution and film thickness (Figure 10) requires numerical analysis. This is usually carried out by finite difference methods (Jalali-Vahid *et al.*, 2001; Dowson, Ehret, and Taylor, 1999). Some film thickness equations have been obtained from the results of many simulation studies. The following are a representative sample:

For line contact (Dowson and Higginson, 1966):

$$h^*_{\min} = 1.6G^{*0.6}U^{*0.7}W^{*-0.13} \tag{5}$$

For finite line contact (Mostofi and Gohar, 1983):

$$h^*_0 = 1.67G^{*0.421}U^{*0.541}W^{*0.059} \tag{6}$$

For elliptical point contact (Hamrock and Dowson, 1977):

$$h^*_{\min} = 3.63U^{*0.68}G^{*0.49}W^{*-0.073}(1 - e^{-0.68e^*_p})$$

where:

$$U^* = \frac{u\eta}{E^*R}, \quad W^* = \frac{W}{E^*RL} \text{ (line contact)},$$

$$W^* = \frac{W}{E^*R^2_{zx}} \text{ (point contact)},$$

$$G^* = E^*\alpha, \quad e^*_p = \frac{a}{b}, \quad \text{and} \quad h^* = \frac{h}{R_{zx}}$$

Wear and fatigue are adequately covered by Gohar and Rahnejat (2008). The remainder of this chapter is devoted to friction.

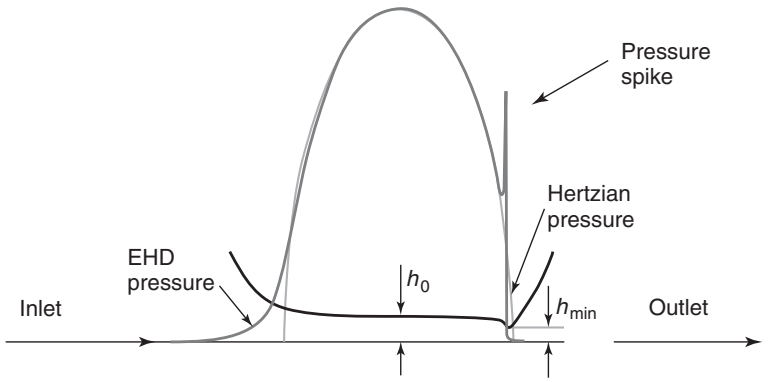

Figure 10. Elastohydrodynamic conjunction.

4 FRICTION

Study of friction originates from the work of Amontons (1699). Friction is defined as the resistance to the tangential relative movement of a pair of surfaces in contact. As real surfaces are rough, then Amontons noted that friction is as the result of interaction of rough topography of the surfaces. Therefore, it is clear that for dry surfaces, friction is independent of the nominal (apparent) area of contact, as the interacting roughness peaks only account for a small proportion of the apparent contact area. Under the application of load, a pair of opposing asperities in contact cold weld together. These junctions need to be broken for any ensuing relative motion, the resistance to which is termed *adhesive friction*. In addition, asperities on the harder surface can elastically deform (flatten) or plastically plow through their counterparts on the softer counterface. This mechanism of friction is termed *plow* or *deformation friction*. The described mechanisms lead to dry or boundary friction, F, which is directly proportional to the applied load W. This was shown by Amontons (1699): $F = \mu W$, where the coefficient of proportionality is known as the *coefficient of friction* μ, which is a function of the material of the counterfaces, typical asperity geometry and distribution on the surfaces (Greenwood and Tripp, 1971).

Friction can be viewed as an energy sink. It is a major source of inefficiency in almost all machines and mechanisms. Therefore, except for the few cases where friction is an essential feature of a system, such as for locomotion, traction, and braking, its reduction is a primary design aim and is becoming progressively more important because of the diminishing traditional sources of energy.

The main principle of lubrication is to separate the contacting surfaces with a film of fluid of low shear strength and avoid shearing and deformation of asperities on solid surfaces with much higher shear strengths. Unlike for the rough surfaces, viscous friction arising from shear of a lubricant film is directly proportional to the area covered by the lubricant. In practice, as in nature itself, almost all wetted conjunctions are subject to a mixed regime of lubrication. This means that thinness of a lubricant film enables interaction of some surface asperities. Therefore, friction occurs as the result of viscous shear of a fluid film as well as some boundary interactions.

Depending on the geometry of the conjunction, film thickness can be predicted by an equation such as Equation 5 or 6. This is compared with the root mean square (RMS) of composite surface roughness (average roughness of the two counterface surfaces: ψ_1, ψ_2) to ascertain the likely degree of boundary interactions. If the RMS surface roughness is $\psi = \sqrt{\psi_1^2 + \psi_2^2}$, then Stribeck (1907) defined an oil film parameter as $\lambda = {}^{h}/_{\psi}$. The regime of lubrication and an idea of the likely coefficient of friction are indicated by the Stribeck graph (Figure 11). Note that $\lambda > 3$ indicates a fluid film regime of lubrication, where insignificant boundary interactions would be expected. The coefficient of friction, μ, would normally be in the range 0.005–0.01, meaning that less than 1% of the input energy would be lost because of friction. At the other extreme, the lubricant film would be so thin as to allow significant direct contact of surfaces (boundary lubrication). The coefficient of friction would depend on the surface roughness and the shear strength of the counterface materials. For steel-on-steel contacts, the coefficient of friction would be in the range 0.2–0.3. It is clear that significant frictional power loss would ensue.

Viscous shear of a film of lubricant of dynamic viscosity η subjected to relative sliding motion of contact surfaces at velocity Δu and conjunctional pressure gradient ${}^{dp}/_{dx}$ is:

$$\tau = \pm \frac{h}{2}\frac{dp}{dx} + \frac{\eta \Delta u}{h} \tag{7}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto075
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

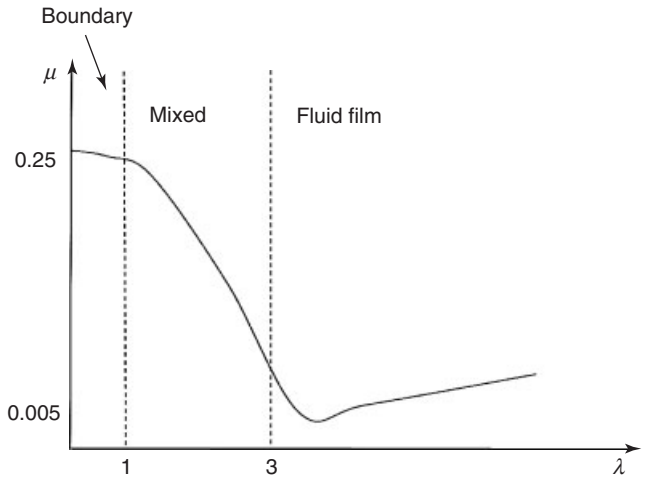

Figure 11. Stribeck graph for regimes of lubrication.

The first term in Equation 7 is often quite small compared with the latter in the flat region of the EHD film, as h is diminutive (a few tenths of micrometers) and the pressure gradient is only significant in the inlet wedge of the contact. Therefore, viscous friction is obtained as:

$$F_{\mathrm{v}} = \tau(A - A_{\mathrm{a}}) \tag{8}$$

where $A_{\mathrm{a}} = \pi^2(\zeta\kappa\psi)^2 A F_2(\lambda)$ is the area of asperity summits in contact in mixed regime of lubrication. $\zeta\kappa\psi$ is the roughness parameter (see Notations); a measure of surface topography assumed as a Gaussian distribution described by $F_2(\lambda)$ as a function of the oil film parameter, λ (Greenwood and Tripp, 1971).

Boundary friction occurs over the summit of opposing asperity pairs, where high load intensity (over a diminutive area) is assumed to induce non-Newtonian shear behavior of the lubricant at the limiting Eyring shear stress, τ_0. For most engine oils: $\tau_0 = 2{-}3$ MPa, for transmission fluids: $\tau_0 = 4{-}5$ MPa, and for differential oils: $\tau_0 = 5{-}7$ MPa. Boundary friction is obtained as:

$$F_{\mathrm{b}} = \tau_{\mathrm{o}} A_{\mathrm{a}} + \xi W_{\mathrm{a}} \tag{9}$$

where ξ is the pressure-induced coefficient of boundary shear strength of the softer of the counterfaces. For steel-on-steel contact: $\xi = 0.17$. The share of load carried by the asperities is

$$W_{\mathrm{a}} = \frac{8\sqrt{2}}{15}\pi(\zeta\kappa\psi)^2\sqrt{\frac{\psi}{\kappa}}E^* A F_{5/2}(\lambda) \tag{10}$$

Therefore, the total friction can be obtained as:

$$F_{\mathrm{T}} = F_{\mathrm{b}} + F_{\mathrm{v}} \tag{11}$$

The coefficient of friction is found from the same relationship originally noted by Amontons (1699). Referring back to Figure 11, various analyses have shown that typically: $\mu = 0.005$ (Fluid film lubrication) $- 0.09$ (mixed lubrication) for ball and rolling element bearings as well as cam–follower pairs and $\mu = 0.005$ (Fluid film lubrication) $- 0.15$ (boundary lubrication) for piston rings.

This chapter has provided an introduction to the important subject of contact mechanics, with emphasis put on concentrated counterformal or partially conforming contacts. Interested readers should refer to more in-depth texts such as Rahnejat (2010), Gohar and Rahnejat (2008), and Johnson (1985).

NOTATIONS

A	Apparent (nominal) contact area
A_{a}	Asperity contact area
a, b	Hertzian contact radii
E	Young's modulus of elasticity
E^*	Equivalent plane strain modulus of elasticity
e_p^*	Ellipticity ratio
F	Friction
F_{b}	Boundary friction
F_{T}	Total (mixed regime of lubrication) friction
F_{v}	Viscous friction
h	Film thickness
h_0	Central contact film thickness
h_{min}	Minimum (exit) film thickness
L	Contact length
p_{m}	Mean contact pressure
p_0	Maximum contact pressure
$R_{zx,zy}$	Equivalent radii of curvature in zx and zy planes of contact
$R_{x1,2}$	Principal radii of contacting solids in the zx-plane
$R_{y1,2}$	Principal radii of contacting solids in the zy-plane
u	Speed of lubricant entraining motion
W	Contact load
W_{a}	Load share of contacting asperities
α	Lubricant pressure viscosity coefficient
Δu	Sliding speed
δ	Contact deflection
η	Lubricant dynamic viscosity
κ	Average asperity summit (tip) radius
λ	Stribeck's oil film parameter
μ	Coefficient of friction
φ	Extent of contact
σ	Normal direct stress
τ	Shear stress
τ_0	Eyring shear stress

Synchronizers—Gear Change Process, Loads, Timing, Shift Effort, Thermal Loads, Materials and Tolerances

Syed T. Razzacki

Retired, Chrysler LLC, Auburn Hills, MI, USA

1 INTRODUCTION

In a manual, synchromesh transmission, friction clutches called *synchronizers* are used to synchronize the rotational speed of the transmission output shaft and the gear to be engaged to actualize and secure smooth and noiseless gear transition. The size and location of synchronizers in transmissions varies for passenger cars and trucks. Increasing trend toward higher engine power and higher engine speeds due to multivalves per cylinder in pass cars and larger engines in trucks necessitate higher shift efforts. Regardless, the driver still demands smooth shiftability. These conflicting expectations require greater efficiency from the synchronizer design. In order to meet these conflicting expectations larger size synchronizers as well as multicone synchronizers are selectively inserted between the tall ratio gears to efficaciously sustain greater loads and provide slick gear change.

In sizing and locating the synchronizers, it is important to ensure minimizing the effect of system inertia and relative speeds of the rotating components. It must be recognized that synchronizer endures incessant punishment, more so than any other transmission components, and is expected to continue to work flawlessly for the life of the vehicle. Additionally, characteristically different driving habits ranging from silky smooth to sportive neck-snapping shifts affect the synchronizer design parameters for performance.

2 GEAR CHANGE PROCESS

Engine develops maximum power at high speed and it is desirable to have greater power available for excellent acceleration. A device called *transmission* was developed carrying a series of gears on two parallel shafts with ratios varying in descending order. It is attached to the engine that lets the engine run at the speed of maximum power at any vehicle road speed.

2.1 Early concept transmission

In 1895, M. Emile Levassar designed a three-speed transmission for use in Panhard et Levassar automobile. It had no mechanism for smoother gear change. Considerable skill was required to change gears without damaging the gear teeth as the selected gear was moved axially along a splined main shaft to engage with a countershaft (or lay shaft) gear, which was already turning resulting in clash. Hence, these transmissions were called *clash* (or *crash*) *boxes* and were very inefficient from performance standpoint.

2.2 Constant mesh

The concept of constant mesh gears was introduced later with sliding dog teeth to engage the gears. The constant mesh gears are always rotating as a driving and driven set. Sliding dog teeth improved the gear change process as a skillful driver with coordinated hand and foot movement could achieve clash-free shift.

2.3 Synchromesh

Again the gears are in constant mesh; rotating as a driving and driven pair except here the synchronizers are inserted between the speed gears, hence synchromesh. The gears rotate freely all the time, an intended gear, engaged through the synchronizer, can only transmit the torque. The synchronizer acts as a friction clutch to bring the relative speed of the transmission gear, engine, clutch disk, and the output shaft instantaneously to zero and aligns teeth for smooth gear change. Hence, synchronizer provides essential mechanism for ease of gear change.

3 SYNCHRONIZER COMPONENTS: DESIGN FEATURES AND FUNCTIONALITY

The synchronizer assembly is selected and designed to meet the load requirements of a specific application. Single cone, double cone, and triple cone synchronizers are used in the modern transmissions with medium to high torque engines. Typically, a synchronizer assembly, inserted between two speed gear wheels, slidingly engages either one intended. Synchronizer assembly comprises the following components, and respective design features are briefly described.

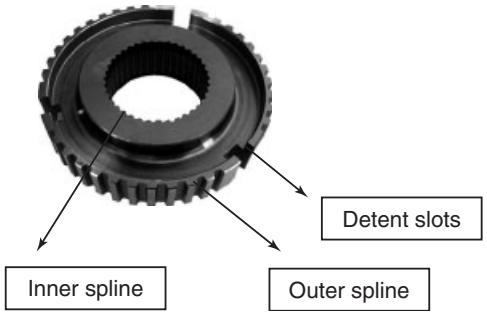

Figure 1. Synchronizer hub.

3.1 Hub

Hub has inner and outer splines; it is rotationally connected to the output shaft, spline fitted with internal splines. Three equally spaced slots are designed on the OD for housing the detent assemblies (Figure 1).

3.2 Sleeve

Sleeve has inner splines, slidingly fitted to the external splines of the hub, and travels on synchronization to lock with the clutching teeth of the intended gear. It has three annular grooves on the internal splines, equally spaced, for housing the three detents. An annular recess around the outer surface is provided for shift fork legs that instrumentally slide the sleeve to left or right when activated by the external applied force at the gearshift lever for consequent gear engagement. Traditionally, three splines at each of the three strut pockets are back tapered for a suck in engagement feel as well as anti-jump-out mechanism (Figure 2).

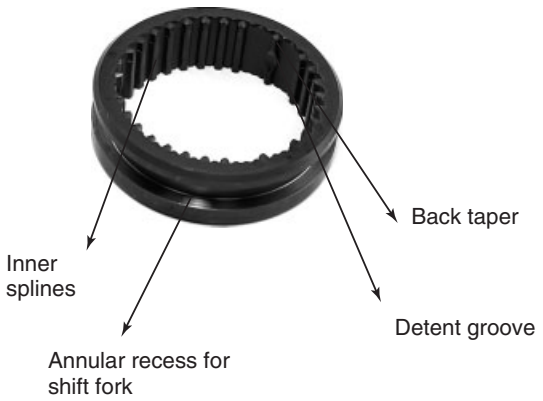

Figure 2. Synchronizer sleeve.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

3.3 Strut detents

Three strut detent assemblies per synchronizer are designed; the detent strut bumps or balls are nested in the three annular grooves of the sleeve in neutral position. These are primary energizing elements and provide initial indexing load for the friction (blocker) ring and set it ready for oncoming sleeve.

3.4 Friction (blocker, or baulk) ring

Bronze friction rings with oil wiping threads, used in the earlier design and still in vogue, having three equally spaced slots for the strut detent to push on. Various design and manufacturing developments have occurred to tackle the higher loads. Powder metal rings are being used coated with different robust friction materials for adequate and stable coefficient of friction at specified shift force. Friction material durability and efficiency are also significant considerations (Figure 3).

3.5 Friction cone

Friction cone could be integral part of the gear or separate slottedly locked in the gear. It generates cone torque required for synchronization when the friction ring surrounds it in full contact. The surface finish, roundness, and straightness are essential design requirements to ensure achieving the cone torque intended by design.

3.6 Gear locking (clutching) teeth

The sleeve traverses from initial stage, pushing the friction ring, which generates the friction torque and subsequently cone torque when synchronization is complete, and sleeve passes freely through the blocker ring and is sucked in by the gear locking teeth to engage the gear. The chamfer angle of the clutching teeth is designed 1° or 2° less than that of the sleeve pointing angle for easy engagement.

3.7 Spline chamfer angle

Sleeve spline and friction ring teeth pointing chamfer angles are designed the same. It is desirable to design clutching teeth chamfer 1° or 2° less than the sleeve chamfer angle to urge the sleeve in for gear lockup. The sleeve and blocker ring chamfers contact to generate index torque, whereas sleeve and clutching teeth chamfers contact to index the gear for engagement.

4 SIGNIFICANT PARAMETERS AND DERIVATIONS

Smooth, noiseless, and flawless gear change are the design objectives of the synchronizer. In order to achieve these objectives, synchronizer torque analysis will be conducted by addressing certain significant physical parameters.

4.1 Breakthrough load (BTL) and proximity

Also known as *push through load*, breakthrough load (BTL) effectively sets the blocker ring into block position. The BTL starts to build as soon as the force applied at the shift lever initiates sleeve movement via shift fork and stays on until the sleeve tooth chamfer contacts the blocker ring tooth chamfer. Looking at the graph in Figure 4, the following observations can be made:

- axial distance from sleeve tooth pointing to the blocker ring tooth pointing contact is called *proximity;*
- BTL drop-off short of proximity will unload blocker ring too soon and inhibit oil wiping process resulting in gear clash;

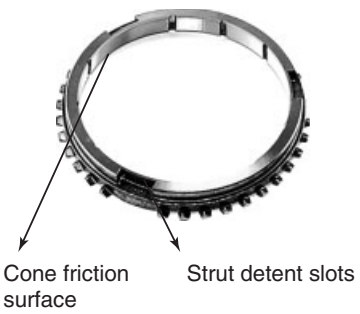

Figure 3. Synchronizer friction ring.

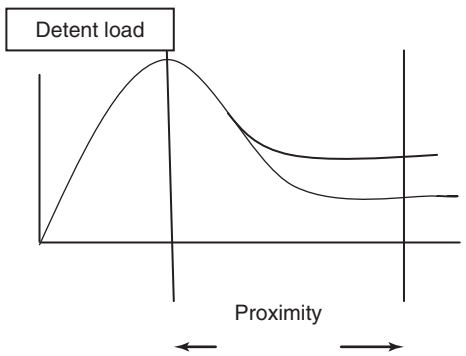

Figure 4. Detent load versus proximity.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

- BTL prolonging beyond proximity will cause ring sticking; and

BTL is a function of detent spring rate, strut bump or ball height, coefficient of friction between detent ball and the sleeve, and the ramp angle of the annular groove in the sleeve.

4.2 Ball detent analysis

Ball detent used extensively in modern synchronizers is the subject of calculations later. Mathematically analyzing the forces on one of the three ball detents, BTL can be calculated from the following derivations.

As shown in Figure 5, taking sum of forces on the sleeve in x- and y-direction

$$\begin{aligned} F_A &= N_S \sin\theta + f_S \cos\theta \\ f_S &= \mu N_S \\ F_A &= N_S(\sin\theta + \mu\cos\theta) \end{aligned} \tag{1}$$

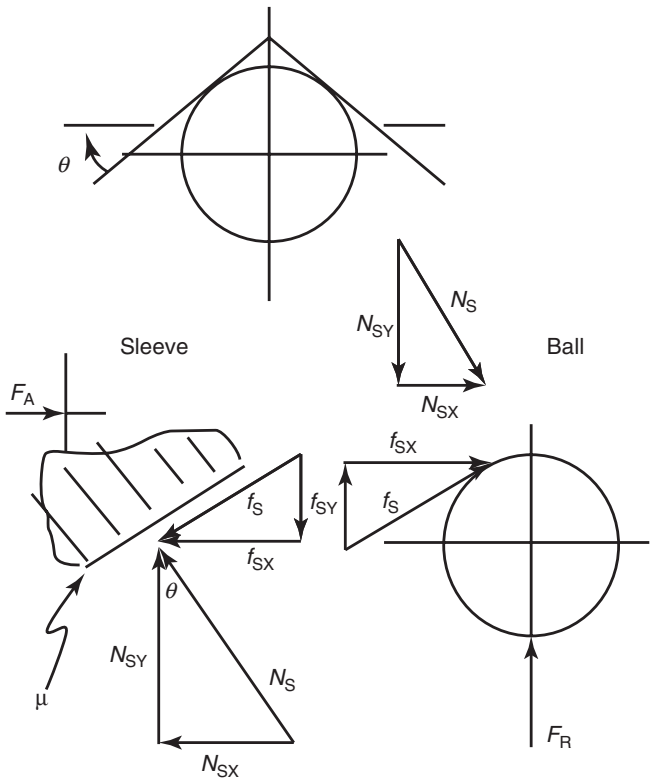

Figure 5. BTL—free body diagram. (Reproduced from Razzacki, 2004. Copyright © SAE International. Reprinted with permission.)

taking sum of forces on ball

$$\begin{aligned} F_A &= N_S \sin\theta + f_S \cos\theta \\ &= N_S \sin\theta + \mu N_S \cos\theta \\ F_R + f_S \sin\theta &= N_S \cos\theta \\ F_R &= N_S(\cos\theta - \mu\sin\theta) \end{aligned} \tag{2}$$

Substituting for N_s from Equation 1 in Equation 2,

$$\begin{aligned} F_R &= F_A \frac{\cos\theta - \mu\sin\theta}{\sin\theta + \mu\cos\theta} \\ F_A &= F_R \frac{\sin\theta + \mu\cos\theta}{\cos\theta - \mu\sin\theta} \\ &= F_R \frac{\mu + \tan\theta}{1 - \mu\tan\theta} \\ \text{BTL} &= 3 \times F_A \\ &= 3 \times F_R \frac{\mu + \tan\theta}{1 - \mu\tan\theta} \end{aligned} \tag{3}$$

By magnitude, the BTL should be smaller than the axial force applied at the sleeve groove, and too low could create clash condition. From experience 9–11 lbf (around 45N), BTL is sufficient to start ring indexing.

4.3 Cone torque

The chamfer of the oncoming sleeve tooth contacts with the blocker ring tooth chamfer and in the process pushes the inner conical surface of the blocker ring axially on to the external conical surface of the gear. Consequently, the lubricant oil is wiped out and friction force is developed in the direction of the cone angle generating cone torque for synchronization. The cone torque is primarily a function of the axial force applied to the sleeve, the cone angle, the surface coefficient of friction, and active cone diameter. Cone torque is calculated from the following equation, refer Figure 6:

$$T_C = \frac{F \times \mu_C \times R}{\sin\alpha} \tag{4}$$

The cone torque is countered by the index torque. The cone torque must be greater in magnitude to overcome the index torque to successfully complete synchronization,

$$T_C \geq T_I \tag{5}$$

4.4 Index torque

When the synchronizer ring is indexed and the sleeve has traversed the proximity distance, the sleeve pointing

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

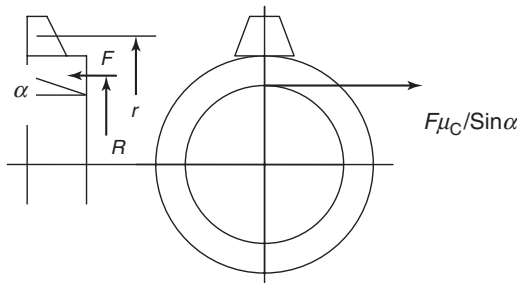

Figure 6. Cone torque—free body diagram. (Reproduced from Razzacki (2004). Copyright © SAE International. Reprinted with permission.)

contacts the blocker ring pointing and a friction force is generated between the two chamfer surfaces. This friction force is in the direction of pointing angle resulting in what is known as *index torque*. The index torque is a function of axial force applied to the sleeve, the tooth pointing chamfer angle, the pitch diameter of the blocking teeth, and surface coefficient of friction between the tooth chamfer surfaces of sleeve and blocker ring. The index torque is calculated from the following derivations (refer Figure 7):

$$T_I = F_I \times r$$

Summation of forces in *x*-direction on sleeve:

$$F_I = N_S \cos\beta - f_S \sin\beta = N_S(\cos\beta - \mu_p \sin\beta)$$

Summation of forces in *y*-direction on sleeve:

$$F = N_S(\sin\beta + \mu_p \cos\beta)$$

$$N_S = \frac{F}{\sin\beta + \mu_p \cos\beta}$$

$$F_I = F\frac{\cos\beta - \mu_p \sin\beta}{\sin + \mu_p \cos\beta}$$

$$T_I = F \times r\frac{\cos\beta - \mu_p \sin\beta}{\sin\beta + \mu_p \cos\beta}$$

$$= F \times r\frac{1 - \mu_p \tan\beta}{\mu_p + \tan\beta} \quad (6)$$

In the inequality 5, substituting for T_C from Equation 4 and for T_I from Equation 6 gives

$$\frac{F \times \mu_C \times R}{\sin\alpha} \geq F \times r \times \frac{1 - \mu_p \tan\beta}{\mu_p + \tan\beta} \quad (7)$$

Inequality 7 can be simplified to

$$\tan\beta \geq \frac{\frac{r}{R} - \mu_p \frac{\mu_C}{\sin\alpha}}{\frac{\mu_C}{\sin\alpha} + \mu_p \frac{r}{R}} \quad (8)$$

It can be observed that the inequality above has four interdependent significant synchronizer parameters. Treating this as equation nomograms have been developed to help size, select, and verify the parameters of synchronizer for a given application. The nomograms are shown in Figures 8 and 9a and b and explained in Section 4.6.

4.5 (Hat type) strut detent analysis

The strut detent arrangement in the initial stage of synchronizers design consisted of a hat type strut actuated with two circular springs, one on each side. This configuration is still conveniently and suitably useful and design analysis for this scheme of strut design is explored below.

4.5.1 Free body diagrams

The three figures in this section show detail of various forces acting to develop the analysis. Figure 10 shows the interface between sleeve pointing and ring pointing in a radial sense. Figure 11 shows a circumferential view of the strut contact with the ring, and Figure 12 shows the

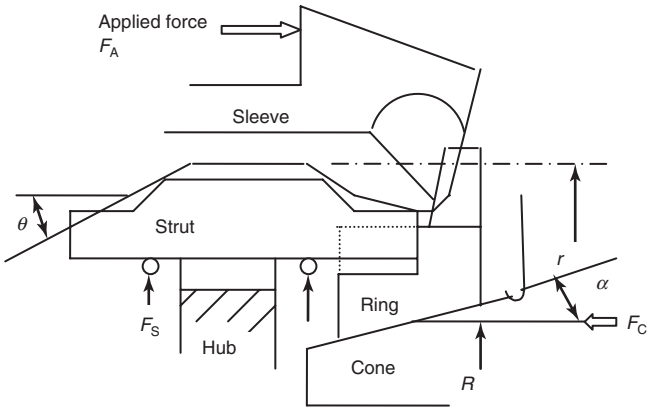

Figure 11. Sleeve loading the strut to index the blocker ring.

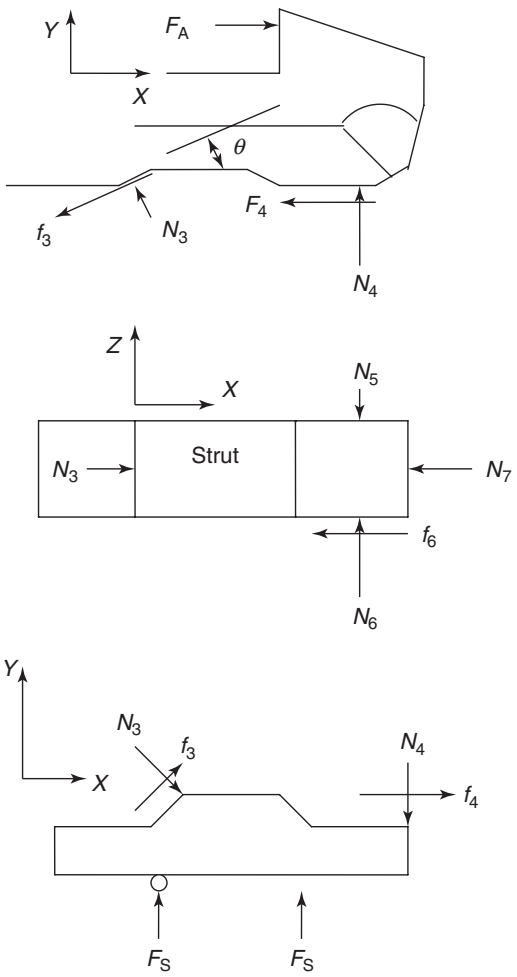

Figure 12. Sleeve and strut free body diagrams.

appropriate free body diagrams

$$T_C = \frac{F_C \times \mu_C \times R}{\sin \alpha}$$

$T_S = T_C - T_I$ where T_S is torque reaction on strut.

4.5.2 *Free body diagram equilibrium equations*

$$f_1 = \mu_{SH} N_1$$
$$f_2 = \mu_2 N_2$$
$$f_3 = \mu_3 N_3$$
$$f_4 = \mu_4 N_4$$
$$f_5 = 0$$

(No sliding after BTL developed)

$$f_6 = \mu_6 N_6$$

4.5.3 *Summation of forces on sleeve*

Summation in x-direction:

$$\begin{aligned} F_A &= f_1 + f_2 \cos\beta + N_2 \sin\beta \\ &\quad + f_3 \cos\theta + N_3 \sin\theta + f_4 \\ F_A &= \mu_{SH} N_1 + N_2(\sin\beta + \mu_2 \cos\beta) \\ &\quad + N_3(\sin\theta + \mu_3 \cos\theta) + \mu_4 N_4 \end{aligned} \tag{9}$$

Summation in z-direction:

$$\begin{aligned} N_2 \cos\beta &= N_1 + f_2 \sin\beta = N_1 + \mu_2 N_2 \sin\beta \\ N_1 &= N_2(\cos\beta - \mu_2 \sin\beta) \end{aligned} \tag{10}$$

4.5.4 *Summation of forces on strut*

Summation in x-direction:

$$\begin{aligned} N_3 \sin\theta + f_3 \cos\theta + f_4 &= f_6 + f_7 \\ N_3(\sin\theta + \mu_3 \cos\theta) + \mu_4 N_4 &= \mu_6 N_6 + N_7 \end{aligned} \tag{11}$$

where $N_7 \geq 0$

Summation in z-direction:

$$N_5 = N_6$$

Summation in y-direction:

Let F_{ST} = total radial strut load

$K = \frac{N_4}{F_{ST}}$ = Percent of strut load, strut not in detent

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$F_{ST} + f_3 \sin\theta = N_3 \cos\theta + N_4$$
$$N_3(\cos\theta - \mu_3 \sin\theta) = F_{ST}(1-K)$$
$$N_3 = \frac{F_{ST}(1-K)}{\cos\theta - \mu_3 \sin\theta} \quad (12)$$

4.5.5 *Summation of forces and torques on ring*

Summation of forces in x-direction:

$$F_C = N_2 \sin\beta + f_2 \cos\beta + N_7$$
$$F_C = N_2(\sin\beta + \mu_2 \cos\beta) + N_7$$
$$= \text{resultant axial load on cone} \quad (13)$$

Summation of torques:

$$T_C = T_S + T_I = \frac{\mu_C F_C R}{\sin\alpha}$$
$$F_I = N_2 \cos\beta - f_2 \sin\beta$$
$$F_I = N_2(\cos\beta - \mu_2 \sin\beta)$$
$$T_I = R_P N_2(\cos\beta - \mu_2 \sin\beta) \quad (14)$$

where T_I is the index torque.

4.5.6 *Breakthrough load (BTL)*

$$\text{BTL} = N_3(\sin\theta + \mu_3 \cos\theta) + \mu_4 N_4 \quad (15)$$

Substituting Equation 12 in Equation 15:

$$\text{BTL} = \frac{F_{ST}(1-K)}{\cos\theta - \mu_3 \sin\theta}(\sin\theta + \mu_3 \cos\theta) + \mu_4 K F_{ST}$$
$$\text{BTL} = F_{ST}\left[\mu_4 K + \frac{(1-K)(\mu_3 + \tan\theta)}{1 - \mu_3 \tan\theta}\right] \quad (16)$$

Solving for normal forces: substituting Equations 10 and 12 in Equation 9

$$F_A = N_2[(\mu_{SH} + \mu_2)\cos\beta + (1 - \mu_{SH1}\mu_2)\sin\beta] + F_{ST}\left[\mu_4 K + \frac{(1-K)(\sin\theta + \mu_3 \cos\theta)}{\cos\theta - \mu_3 \sin\theta}\right]$$

Substituting for N_2 from above equation in Equation 14 for index torque:

$$T_I = R_P\left[\frac{1 - \mu_2 \tan\beta}{\mu_{SH} + \mu_2 + (1 - \mu_1\mu_2)\tan\beta}\right]\left[F_A - F_{ST}\left(\mu_4 K + \frac{(1-K)(\mu_3 + \tan\theta)}{1 - \mu_3 \tan\theta}\right)\right] \quad (17)$$

4.6 The nomograms

The nomogram in Figure 8 depicts the relationship of pointing chamfer angle with the size of the synchronizer, cone coefficient of friction, and cone angle for a given μ_p. This relationship resulted from the necessary condition in (inequality) 5 and the algorithms derived from it in (inequality) 8, and it can be observed that smaller the size to cone friction ratio smaller the pointing chamfer angle for a given μ_p and together would result in clash. On the other hand, bigger the ratio bigger the pointing chamfer angle and the combination would result in hard shift. Again, from computations based on inequalities 5 and 8, plotted in the nomogram in Figure 8, it is clear that for a given μ_p, size to coefficient of friction ratio above 2.5 could result in hard shift and below 1.5 in clash and comfortable shiftability between the two.

Figure 11a and b shows the graphical representation of the same relationship as in Figure 8 except here all four parameters are separately charted. These charts elicit that, for a given μ_p, greater the r/R ratio greater the pointing angle resulting in hard shift, whereas smaller the r/R ratio smaller the pointing angle resulting in clash. Any of the three nomograms can be used conveniently as desired.

4.7 System drag consideration

Excessive losses in the transmission including clutch drag, frictional, and fluid churning losses adversely affect the synchronization process. The system drag assists up shift by slowing the gear train and resists speeding up the gear train during downshift. It is hence understood that the index torque should be designed to compensate for the total drag. Applying the basic principle of synchronizer design, the synchronization torque must be greater than the index torque at every instant during the synchronization event. Therefore, synchronizer design, be it for conventional manual transmission, or the modern dual clutch (DCT) transmission, specially the wet clutch DCT, must satisfy the following two criteria.

1. Cone torque (T_C) must be greater than index torque (T_I) at every point during synchronization event to prevent clash or grating noise, that is, $T_C > T_I$.
2. Index torque must be high and able to shift in cold conditions to overcome the total system drag (T_D) to insure gear shiftability, that is, $T_I > T_D$.

The above-mentioned two requirements establish the boundary limits for index torque as follows. The index torque derivation shows that it is inversely proportional

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to sleeve/ring pointing angle, and higher index torque can be obtained by designing steeper pointing chamfer angle. Imperatively at the same time attention must be paid to maintain synchronization torque always greater than index torque by tweaking the cone coefficient of friction up as needed, which might warrant larger cone angle as well.

Total drag torque (T_D) is sum of clutch drag, fluid churning, and system friction losses:

$$T_D = T_d + T_C + T_f \tag{18}$$

Clutch drag torque is an uncertain quantity and its directional values should be calculated from existing empirical formulae, such as

$$T_d = 6.6 \times 10^{-13} \frac{\eta \times \Delta n \times F_N \times R_F^3 \times b}{l_F} \tag{19}$$

Subsequently, laboratory tests should be conducted to measure clutch drag torque at various speeds and temperatures for correlation with calculated values and most importantly to assist in selecting adequate pointing angle and cone coefficient of friction in the initial stage of design.

Torque due to fluid churning (T_{Ch}) is a function of drive pinion speed and a constant k dependent on viscosity, quantity, and temperature of oil:

$$T_{Ch} = k \times N_i \tag{20}$$

Torque due to frictional losses (T_f) consists of bearing friction, shift and clutch actuation mechanism bending and deflection, and all other system friction in the transmission.

The objectives of fuel economy and associated smooth shifting are largely dependent on clutch drag and transmission system efficiency: lower the drag higher the efficiency and higher the fuel economy and smoother the gear transition.

4.8 Synchronizer location and sizing

In a synchromesh, all gears are turning hence the inertia of all gears must be overcome in order to make a gear selection. It is advantageous to locate the 1/2 synchronizers on the intermediate shaft, whereas the other synchronizers on the input shaft as a best compromise from the stand point of reflected inertias and relative speeds of the rotating components. Vehicle size, engine power output, and number of transmission ratios and steps are required for synchronizer analysis. Synchronization torque and synchronization time relationship is crucial in sizing the synchronizer. Given synchronization time, which is dependent upon initial velocity of the output synchronizer and gear ratio step, its relationship to synchronization torque can be derived by solving differential equation of motion for both input side and output side. In a dual clutch transmission, ratio steps for skip shift would be higher and should be considered for upshifts and downshifts. The solution to the differential equation at the completion of synchronization is

$$t = \frac{\omega I_C (n-1)}{T_C \pm T_D} \tag{21}$$

Synchronization torque requirements can be calculated for a given synchronization time with known gear ratios and steps. The total drag that slows the input must be factored in the calculations as it assists the upshift and resists the downshift.

Next important factor in sizing the synchronizer is the total energy dissipation and rate of energy dissipation and can be calculated as follows: Total energy

$$E = \pm \frac{T_C \omega (n-1)}{2} \times t \tag{22}$$

Rate of energy dissipation

$$\frac{E}{t} = \pm \frac{T_C \omega (n-1)}{2} \tag{23}$$

Rate of energy dissipation per unit area of synchronizer cone is used to size the cone width and cone mean radius as indicated in Equation 24:

$$E/t/A = \frac{T_C \omega (n-1)}{4\pi R_r W_C} \tag{24}$$

4.9 Synchronization time (t)

200 ms is typically used in layshaft transmissions. Following observations can be made from the calculations above:

- Synchronization time is directly proportional to speed differential and inertia and inversely proportional to synchronization torque, hence higher the axial apply force shorter the synchronization time.
- Energy dissipation is directly proportional to synchronization torque, which is proportional to axial force, hence higher the axial force higher the energy dissipation. Assuming synchronization torque constant through the shift, the speed differential becomes overriding factor. As an example, a family of curves was generated for specific application graphically representing energy dissipation per unit area for miscellaneous shifts and axial apply forces (Figure 13).

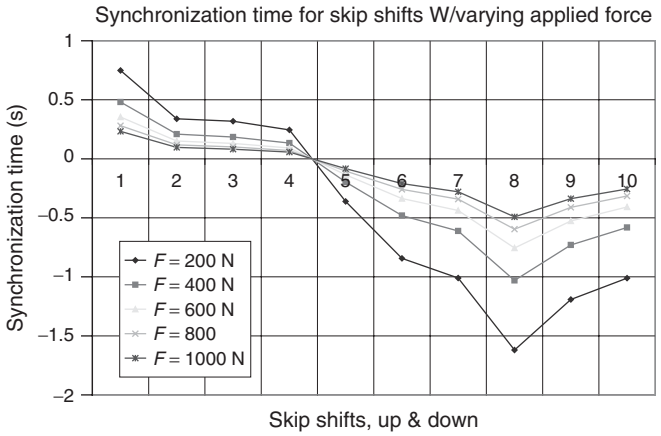

Figure 14. Synchronization time for misc shifts at various axial forces. (Reproduced from Razzacki and Hottenstein, 2007. Copyright © SAE International. Reprinted with permission.)

- For a known drag torque value, the axial force can be determined from synchronization torque/time relationship for upshifts, downshifts, and skip shifts. As an example, a family of curves was generated for a specific application graphically representing synchronization time for miscellaneous shifts for various values of axial apply force (Figure 14).
- Based on calculated synchronization torque, the synchronizer diameter and width can be established to package axially and radially for a specific application.
- Multiple friction surfaces may have to be incorporated especially in positions with higher numerical gear ratios to suitably adjust to higher synchronization torque requirements and packaging constraints.

Figures 13 and 14 assist in recommending appropriate axial apply force based on compliance of synchronization time and energy dissipation criterions.

5 DESIGN PROCESS

An important feature of the synchronizer is the aspect ratio, which is the relationship between its diameter and the width. A wide synchronizer sleeve slides smoothly to meet the blocker ring and clutching teeth squarely. A favorable aspect ratio allows maintaining tighter clearances for ease of operation.

Heavier vehicles and high power engines effectively require greater shift time and effort. Increased synchronizing moment is required to mitigate the consequent events. Aspect ratio adequately selected in a synchronizer having single cone friction surface, with relatively high coefficient of friction, would sufficiently meet the demand. Theoretically, a multicone synchronizer with multiple friction surfaces would boost the synchronizing moment by a factor of root mean square of the sum of inner and outer cone radii as shown in the equation below. Hence, the effort required to synchronize the angular velocities of input and outputs as well as the engagement time are significantly reduced.

$$T_C = \frac{F \times \mu_C}{\sin\alpha}\sqrt{(R_I^2 + R_O^2)}$$

It is generally assumed that the cone torque multiplies by a factor of number of friction surfaces. However, the measure of each friction surface radius, intermediate and inner, is smaller from the one above it. Plus the clearance between each friction surface. These factors do not support the above assumption.

A typical dual cone synchronizer assembly is shown in Figure 15.

After selecting any of the arrangements described above, and the physical parameters of the synchronizer namely sleeve and blocker ring pointing chamfer angle, cone angle, cone coefficient of friction, and the size, the most critical step is to design, dimension, and tolerance the synchronizer components. The intended objective of the design process should be to dimension and tolerance the individual components in a manner such that along with the selected parameters the functional objectives are achieved satisfactorily. The process consists of charting the synchronization events and iteratively dimensioning, stacking, and tolerancing for the best results. Hat type strut is used through the process of dimensioning and tolerancing. The synchronization episode has been broken up into following six distinct events as shown in Figure 16. Each event is descriptively explained in the ensuing sections.

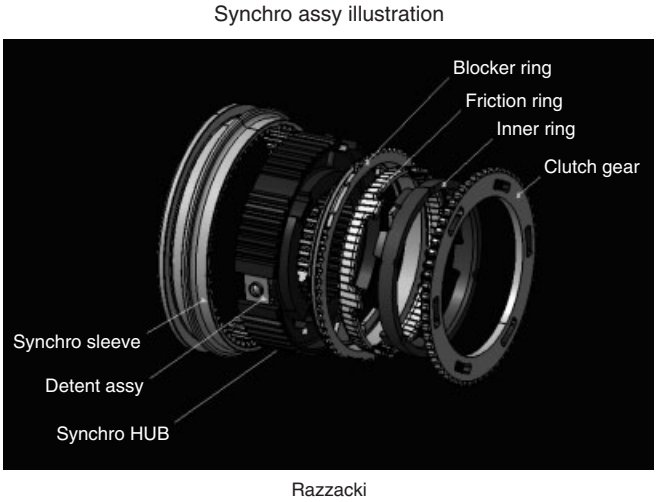

Figure 15. Dual cone synchronizer assembly.

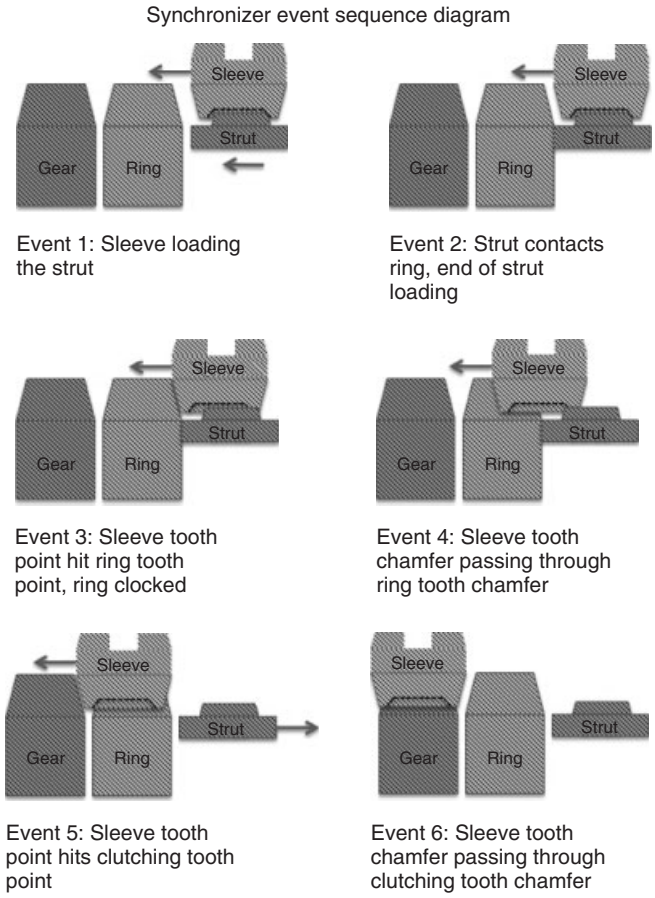

Figure 16. Synchronizer event sequence diagram.

5.1 Event I: strut contacts blocker ring

This is the starting point of the blocker ring energizing system, and the mechanism moves the blocker ring up to the gear cone prior to contact between the indexing teeth on the sleeve and the teeth on the blocker ring. The strut loading starts to generate BTL. What is also called *zero (0) point* will be the first contact of the strut on the ring. The zero point implies maximum strut length, maximum ring lug thickness, and maximum gage point offset. On the other extreme, the last contact point implies minimum strut length, minimum ring lug thickness, and minimum gage point offset. Hence, the total differences are as follows:

$$\text{Max} - \text{min strut length} = (L_{\text{ST max}} - L_{\text{ST min}})$$
$$\text{Max} - \text{min ring thickness} = (L_{\text{Rmax}} - L_{\text{Rmin}})$$
$$\text{Max} - \text{min gage point} = (G_{\text{max}} - G_{\text{min}})$$

Taking first contact point as zero point, the last contact will occur at a distance

$$(L_{\text{ST max}} - L_{\text{ST min}}) + (L_{\text{Rmax}} - L_{\text{Rmin}}) + (G_{\text{max}} - G_{\text{min}}) \quad (25)$$

The event is pictorially illustrated in Figure 17. The strut loading starts at the point of first contact, and earlier the loading begins the better.

The components involved in this event are sleeve, detent strut/ball, and detent spring.

5.2 Event II: end of strut loading, strut out of detent

This is the end of strut loading. The strut snaps back and the sleeve moves on toward the blocking ring. It is to be noted here that the detent load is a function of the ramp angle of the sleeve annulus groove and significantly influences the magnitude of BTL.

Detent profile is critical in achieving desirable BTL. As the desirable BTL has been calculated in Section 4.1, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

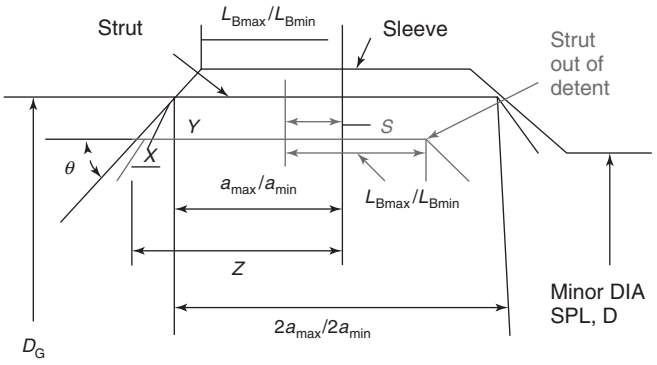

Figure 18. Strut detent profile. (Reproduced from Razzacki, 2004. Copyright © SAE International. Reprinted with permission.)

task at hand is to dimension the detent profile accordingly as shown in Figure 18.

Computing X & Y:

$$X = \frac{Y}{\tan\theta}$$

$$Y_{max} = \frac{D_G - D_{min}}{2}$$

$$Y_{min} = \frac{D_G - D_{max}}{2}$$

For X to be minimum ramp angle and minor diameter should be maximum, or Y minimum, hence

$$X_{min} = \frac{Y_{min}}{\tan\theta_{max}} = \frac{D_G - D_{max}}{2\tan\theta_{max}} \tag{26}$$

For X to be maximum ramp angle and minor diameter should be minimum, or Y maximum, hence

$$X_{max} = \frac{Y_{max}}{\tan\theta_{min}} = \frac{D_G - D_{min}}{2\tan\theta_{min}} \tag{27}$$

Computing groove width Z: for Z to be minimum gage dimension a and X should be minimum,

$$Z_{min} = a_{min} + X_{min} \tag{28}$$

For Z to be maximum gage dimension a and X should be maximum,

$$Z_{max} = a_{max} + X_{max} \tag{29}$$

The distance strut out of detent S can be found as follows:

$$S_{max} = Z_{max} - L_{B\,min} \tag{30}$$

$$S_{min} = Z_{min} - L_{B\,max} \tag{31}$$

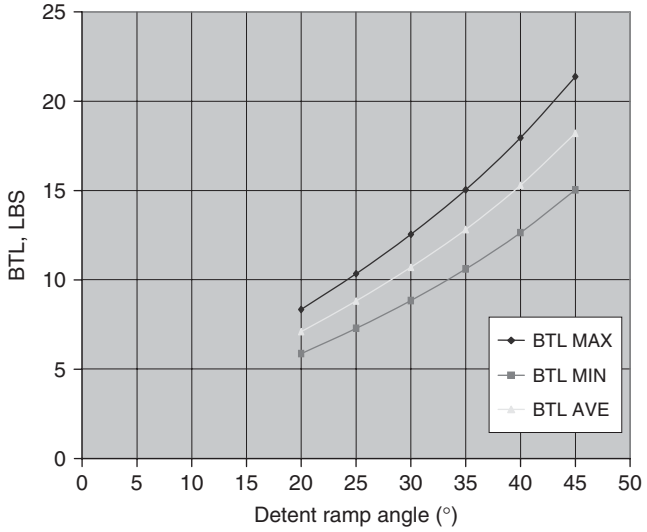

Figure 19. BTL versus sleeve groove ramp angle. (Reproduced from Razzacki, 2004. Copyright © SAE International. Reprinted with permission.)

Equations 24 through 30 can be used to design the detent profile for reasonable detent load to achieve the desired BTL. The sleeve groove ramp angle contributes significantly to the detent load and the BTL as such and it is illustrated in Figure 19. It can be observed that a ramp angle of 30° for a given application will yield the desired BTL.

The components involved in this event include sleeve, strut/ball, and detent spring.

5.3 Event III: sleeve point hits ring point, ring clocked

In this event for the sleeve point to hit the ring point the soonest, the gap between them should be the minimum. The minimum gap is obtained with maximum ring width, maximum strut, and maximum gage point offset at "0" point condition. Similarly, the maximum gap can be obtained with minimum ring width, minimum strut, and minimum gage point offset. Referring to Figure 20, the gap between sleeve tooth pointing and ring tooth pointing is called *proximity* =

$$(L_R + L_{ST} + L_B) - L_{SL} \tag{32}$$

The gap between the sleeve tooth pointing and ring tooth pointing is shown in Figure 20, Section A-A.

If sleeve and ring teeth have rake angle, then using trigonometry L_R will increase by a fraction and L_{SL} will diminish by a fraction affecting the proximity by a fraction too.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

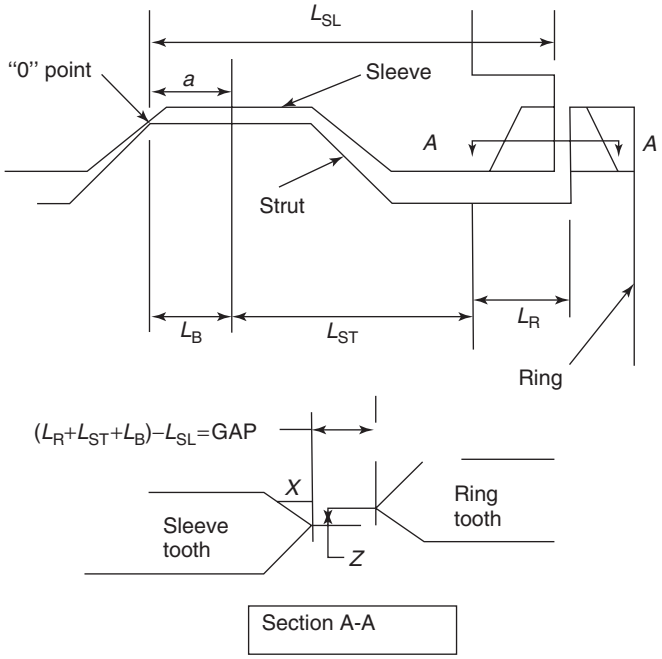

Figure 20. Proximity dimensioning. (Reproduced from Razzacki, 2004. Copyright © SAE International. Reprinted with permission.)

During this event, as soon as the sleeve pointing contacts the ring pointing the blocker ring starts to clock and indexes with the oncoming sleeve. The clocking angle is a function of the widths of the lug integral to the ring and slot width in the hub. The lug and the slot widths should be dimensioned adequately and minimum maximum clocking angles should be calculated to insure that it is not too low allowing not enough time for BTL to develop and not too high when the ring would take too much time to set for the oncoming sleeve.

The clocking angle is calculated by applying trigonometry using the lug and slot widths and the radius at the lug as shown in Figure 21. Maximum clocking is obtained from maximum slot width, minimum lug width, and minimum radius.

$$\sin\alpha_{SLOT} = \frac{W_S}{2 \times r_S},$$

$$\alpha_{SLOT} = \sin^{-1}\frac{W_S}{2 \times r_S} \tag{33}$$

$$\sin\beta_{LUG} = \frac{W_L}{2 \times r_S}$$

$$\beta_{LUG} = \sin^{-1}\frac{W_L}{2 \times r_S} \tag{34}$$

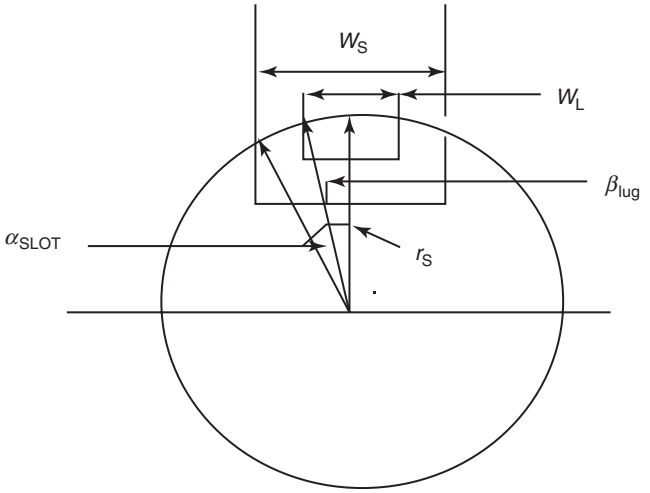

Figure 21. Clocking angle. (Reproduced from Razzacki, 2004. Copyright © SAE International. Reprinted with permission.)

Clocking angle

$$\psi = \alpha_{SLOT} - \beta_{LUG} \tag{35}$$

From experience, the clocking angle should be less than 4 but greater than 3° ($4>\psi>3$), and the lug and slot width should be dimensioned accordingly.

In Figure 20, Section A-A, the dimension Z between the tooth points is an arc. Angle between the center of a sleeve tooth and the center of a space is

$$\frac{360}{N+N} = \frac{180}{N}$$

$$AL(180/N) = \frac{180}{N} \times r_R \tag{36}$$

$$AL(\psi) = \psi \times r_R \tag{37}$$

In Equations 36 and 37, the angles $(180/N)$ and ψ are in radians.

For x to be small, the pointing angle should be maximum,

$$\tan\beta = \frac{z}{x}$$

$$z = AL\left(\frac{180}{N}\right) - AL(\psi) \tag{38}$$

Components involved in this event are sleeve, blocking ring, reaction cone, and friction ring.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

5.4 Event IV: sleeve chamfer through ring chamfer

Given the pressure angle, the ring tooth thickness and the circular space width of sleeve spline can be calculated. Obtaining four values, maximum and minimum for each, they can be compared to determine the combination of tolerances at which the ring teeth thickness to sleeve space widths would have positive or negative clearance. The combination of tolerances can be selected that provide desirable fit and feasible manufacturability.

5.4.1 Ring tooth width calculation

Using the ring outer diameter (D_t) and tooth width at the pitch diameter (t_{DP}), two minimum and two maximum values of ring tooth width can be calculated (refer Figure 22).

The ring tooth width can be calculated by applying Equation 39 available in any gear design book:

$$\frac{t_t}{D_t} = \frac{t_{DP}}{D_P} + \text{INV}\varphi - \text{INV}\varphi_t,$$

or

$$t_t = D_t\left(\frac{t_{DP}}{D_P} + \text{INV}\varphi - \text{INV}\varphi_t\right) \tag{39}$$

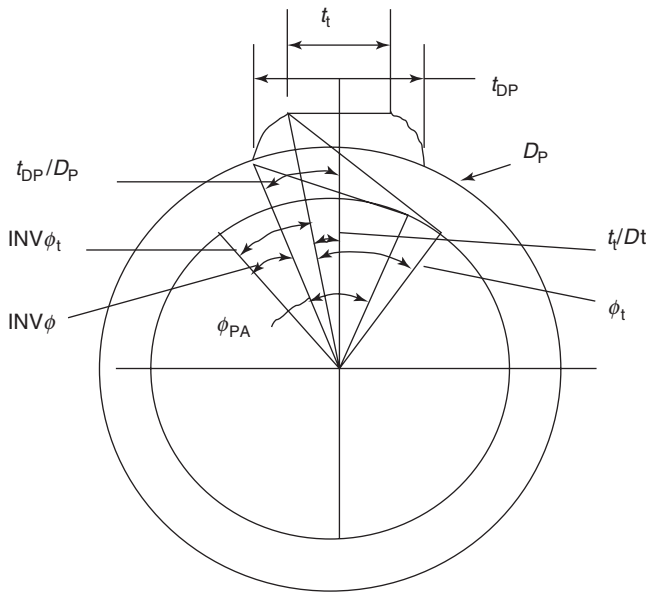

Figure 22. Ring tooth width illustration. (Reproduced from Razzacki (2004). Copyright © SAE International. Reprinted with permission.)

5.4.2 Sleeve spline circular space width calculation

Again, using Equation 39, the sleeve spline space width that would yield four values, two maximums and two minimums can be calculated. Comparing the values of ring tooth width with the sleeve spline space width, the combination of tolerances can be assessed that yield positive running clearance.

5.4.3 Sleeve tooth width calculation

Having calculated sleeve tooth space width, the tooth width can be calculated as follows:

$$t_{(\text{tooth+space})} = 1 \text{ tooth} + 1 \text{ space} = \frac{\pi D_t}{N_T} \tag{40}$$

The sleeve space width is determined in Section 5.4.2. Hence, the sleeve tooth width can be computed as follows:

$$t_S = t_{(\text{tooth+space})} - t_{\text{space}} \tag{41}$$

5.4.4 Total sleeve travel from "0" point through ring chamfer

Finally, it is possible to determine the distance traveled by the sleeve pointing chamfer from zero point to the ring pointing chamfer (Figure 23).

From Figure 23,

$$\begin{aligned}\tan\beta &= \frac{t_R}{2 \times a_R} \\ &= \frac{t_S}{2 \times a_S} \\ &= \frac{t_R + t_S}{2(a_R + a_S)}\end{aligned} \tag{42}$$

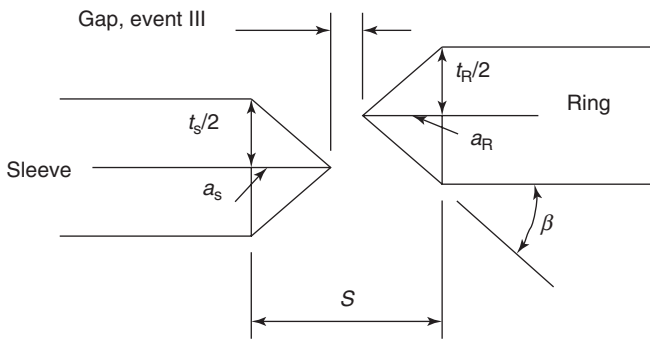

Figure 23. Sleeve chamfer through ring chamfer. (Reproduced from Razzacki (2004). Copyright © SAE International. Reprinted with permission.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

or

$$a_R + a_S = \frac{t_R + t_S}{2 \times \tan \beta}$$

Total travel

$$S = \text{GAP} + a_S + a_R$$
$$= \text{GAP} + \frac{t_R + t_S}{2 \times \tan \beta} \quad (43)$$

Hence, for minimum distance traveled by sleeve in event IV,

$$S_{\min} = \text{GAP}_{\min} + a_{R\min} + a_{S\min} \quad (44)$$

For $S_{\min}$ use from event III the minimum GAP and from event IV, the values of t_R and t_S for conditions assigned for minimum values. Similarly, for $S_{\max}$ use from event III the maximum GAP and from event IV, the values t_R and t_S for conditions assigned for maximum values.

5.5 Event V: sleeve tooth point contacts clutching tooth point

Here again, it is possible to stack up dimensions to calculate the distance traveled by sleeve from zero point to meet the clutching tooth point (Figure 24), see the illustration in Figure 20.

The distance sleeve pointing has to travel from zero point to meet the clutch tooth pointing can be computed by stacking up the GAP in event III along with the ring and clutching tooth dimensions as follows:

$$P = \delta + G + L_{RW} + L_{ST} + L_B - L_{SL}$$
$$P = \delta + G + W_{RT} + \text{GAP} \quad (45)$$

For $P_{\min}$, the dimension L_{SL} maximum and all other dimensions minimum will be required. For $P_{\max}$, the dimension L_{SL} minimum and all other dimensions maximum will be required.

5.6 Event VI: sleeve tooth chamfer through gear clutching tooth chamfer

Clutching teeth chamfers traditionally are cut, whereas the modern gear forging technology is producing as-forged clutching teeth with rounded chamfers for smooth operation. Such forgings are called *monoblocks*.

This is the final event when the sleeve travels from the zero position, and its chamfer passes the gear clutching tooth chamfer to complete the gear engagement. During this event, the blocker ring is completely unloaded and freely gets back to zero position marking the end of cone

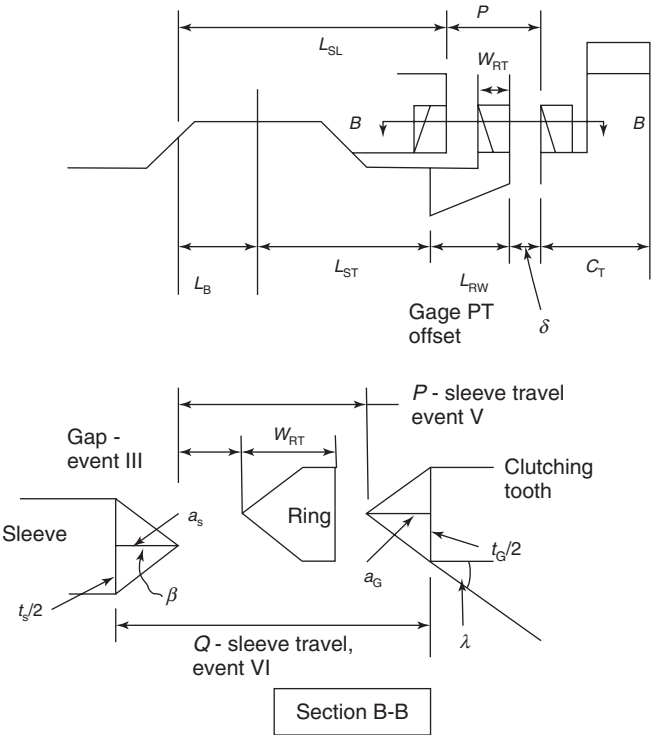

Figure 24. Distance P, sleeve tooth pointing to clutching tooth pointing. (Reproduced from Razzacki (2004). Copyright © SAE International. Reprinted with permission.)

torque. The total distance traveled by sleeve pointing from zero position to go past the gear clutching tooth chamfer can be computed as follows: refer to Figure 20, Section B-B,

$$Q = P + a_S + a_G \quad (46)$$
$$\tan \beta = \frac{t_S}{2 \times a_S},$$

or

$$a_S = \frac{t_S}{2 \times \tan \beta} \quad (47)$$
$$\tan \lambda = \frac{t_G}{2 \times a_G},$$

or

$$a_G = \frac{t_G}{2 \times \tan \lambda} \quad (48)$$

Substituting values from Equations 47 and 48 in Equation 46

$$Q = P + \frac{t_S}{2 \times \tan \beta} + \frac{t_G}{2 \times \tan \lambda} \quad (49)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

6 FRICTION AND RING MATERIAL COMPATIBILITY WITH LUBRICANT OIL

Engines with greater torque and power are being used in modern vehicles including passenger cars, trucks, and tractors. And, yet the comfort of lower shift effort and smoother gear transition is imperatively demanded. High dynamic coefficient of friction is required to meet this demand, which can be secured by boundary lubrication, that is, the cone and blocking ring surfaces are separated with a boundary layer. The friction elements are designed with mechanisms to wipe out the oil film from cone surfaces to prevent hydrodynamic pressure from developing. Furthermore, selection of optimized friction material and lubricant for wear is essential factor as the comportment of friction and ring material is contingent upon the lubricant oil. It is necessary to engineer the lubricant with adequate additives such as extreme pressure, friction modifiers, and detergents/dispersants to enhance thermal stability. Hence, it is earnestly recommended that tests be conducted to establish oil compatibility for the friction and ring materials.

6.1 Friction material

The selection of friction materials is application specific and is made with keen consideration for wear and friction. Some of the friction materials being currently utilized are listed in the following:

- *Copper forging alloys*, such as aluminum bronze, are selected for synchronizer ring based on composition, strength, and stability as required. Friction rings are forged or cast. Fine pitch internal threads are cut and finished along with fine flats on top of the threads as oil wiping mechanism to generate synchronization torque. Grooves are machined along the width of the internal threaded cone of the ring to allow rapid removal of the wiped oil and subsequent quick development of cone torque.
- *Paper lining* used as friction element that provides adequate coefficient of friction and is capable of dissipating kinetic energy to the amount of 3150 kJ/m^2. However, its wear rate is high and resistance to thermal degradation is low.
- *Sintered Friction Lining*, which is a complex mixture of metallic and nonmetallic powders, provides high thermal capacity. It is capable of high load level and maintains low surface temperature.
- *Woven carbon fiber* has high unit loading capacity and is used in automotive and truck applications. Its high energy capability allows smaller synchro system. It provides stable coefficient of friction in that the static and dynamic coefficients of friction are relatively same.

6.2 Friction ring material

Copper forgings were largely used in the early transmissions and are still in vogue in some low power applications. However, the modern casting technology advances that allow maintaining tighter tolerances have made cast ring prevalent in current transmissions.

7 PERFORMANCE FAILURE CONDITIONS

Accurate design and meticulous manufacture of synchronizer components are key factors in accomplishing the objectives of flawless gearshift. Some of the failure conditions will be enumerated here along with reasons thereof.

7.1 Clash

Clash is the most annoyingly common performance failure in a transmission. Insufficient cone torque due to partially energized synchro ring causes clash. There are a host of factors stemming from defective design and/or fallacious manufacturing and quality of the components that result in clash. Listed below are some of the reasons for clash.

7.1.1 Clash due to ring-related problems

- Worn or yielded ring
- Worn or too wide thread flats on bronze rings
- Poor ring to cone conformity: roundness, flatness, run out, etc
- Sticking rings
- Ring blocking teeth worn or broken
- Incorrect ring clocking

7.1.2 Clash due to mismachined parts

- Sleeve detent groove
- Fork groove in sleeve
- Hub to sleeve spline backlash and tilt excessive
- Fork pads mismachined or worn
- Fork pads deflection excessive or uneven

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

7.1.3 Clash due to inadequate strut snap back

- Excessive shift linkage friction
- Excessive strut clearance due to ring wear
- Mismachined sleeve strut groove
- BTL too low

7.1.4 Clash due to incorrect torque ratio

- Low or poor cone microfinish specs
- High oil viscosity causing cold clash
- Improper lubricant additives
- Incorrect ring or sleeve pointing angles
- Ring or sleeve pointing off center
- Incorrect proximity

7.1.5 Clash due to clutch drag and related problems

- Clutch housing misaligned
- Bushing lube inadequate

7.1.6 Clash due to high index torque

Index torque higher than the cone torque will always cause clash. Since index torque is a function of sleeve pointing angle, it is determinatively critical to design so that the index torque remains lower than the cone torque throughout the synchronization event. Hence, sleeve pointing angle and cone angle must be selected to maintain $T_C > T_I$.

7.2 Double bump

During the synchronization process, immediately after the cone torque has peaked and prior to completion of the event, a sensation of another smaller peak is felt, which is defined as double bump (Figure 25).

Following are the reasons for double bump:

- BTL too high
- Coefficient of friction too high

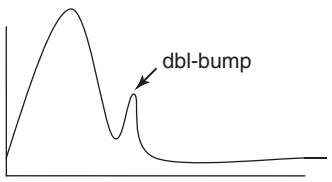

Figure 25. Cone torque versus sleeve travel.

- Cone angle too low
- Sleeve pointing angle too high

7.3 Gear jump out

The sliding sleeve splines engage with the gear clutching teeth that transmit the power. Transmission lugging could distress the hard parts to the extent to cause jump out. Listed below are some of the reasons for jump out:

- Insufficient or worn out back taper
- Broken or worn out fork pads
- Worn out fork sleeve groove
- Worn gear clutching teeth due to lugging

7.4 Hard shift and block out

Hard shift and block out occurs either due to intemperate harsh shifting or due to improper design of synchronizer components.

Breakneck power shift in a flash forcing the sleeve to crash through and not letting the blocker ring to index or the synchronizer torque to develop.

Hard shift and clash consideration in the design phase would reduce the possibility of block out. Pointing angle, cone angle, shift time, and shift effort relationship should be maintained as depicted in Figures 9a and b. Furthermore, blocker ring chamfer angle damage or gear clutching tooth chamfer angle damage would also result in block out.

Excessive clutch drag, windage, and oil churning could cause block out as well.

NOMENCLATURE

A	Unit area
AL	Arc length
a	½ detent groove width at gage point
a_R	X-coordinate of ring pointing angle
a_S	X-coordinate of sleeve pointing angle
a_G	X-component of gear clutching tooth pointing
BTL	Break through load
b	Width friction lining
C_T	Gear back face to clutching tooth front face
D	Minor diameter sleeve splines
D_G	Gage diameter sleeve detent ramp
D_P	Pitch diameter ring/sleeve tooth
D_t	Outer diameter ring tooth
E	Total energy
F	Axial force sleeve groove

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto077
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

F_A	Axial load to overcome detent spring reaction
F_N	Number of friction surfaces
F_R	Reaction force, detent spring
F_S	Spring actuating force
F_{ST}	Total radial strut load
F_I	Indexing force
f_1	Frictional force, hub spline to sleeve spline
f_2	Frictional force, sleeve pointing to ring pointing
f_3	Frictional force, strut ramp to sleeve pocket ramp
f_4	Frictional force at sleeve contact at strut edge
f_5	=0 (no sliding after N_7 developed)
f_6	Frictional force, strut contacts one side of ring pocket
f_R	Friction force, ring
f_S	Friction force, sleeve
G	Gage point offset
K	Percent detent load, strut not in detent
L_B	½ strut bump length
L_R	Ring lug width, axial
L_{RW}	Total ring width
L_{SL}	Length, sleeve front face to rear gage point
L_{ST}	½ strut length
l_f	Clearance per friction surface
N	Number of ring teeth/sleeve spaces
N_R	Normal force, ring
N_S	Normal force, sleeve
N_T	Number of sleeve teeth
N_1	Normal force, hub spline to sleeve spline
N_2	Normal force, sleeve pointing to ring pointing
N_3	Normal force, strut ramp to sleeve pocket ramp
N_4	Normal force, sleeve contact at strut edge
N_5	Normal force, strut contact at one side of ring pocket
N_6	Normal force, strut contact one side of ring pocket
N_7	Normal force, strut contact at other side of strut pocket
ΔN	Rubbing speed, rpm
n	Gear step
P	Sleeve tooth point to clutching tooth point from zero point
Q	Sleeve tooth chamfer to clutching tooth chamfer from zero point
R	½ cone gage dia
R_F	Radius, friction surfaces
R_r	Overall ratio reduction
r	½ pitch diameter sleeve/ring tooth
r_R	Ring radius
r_S	Radius at slot for ring lug in sleeve
S	Sleeve tooth point to ring tooth point from "0"
T_C	Cone torque
T_D	Total system drag
T_d	Clutch drag torque
T_f	Torque due to frictional losses
T_I	Index torque
T_S	Torque reaction on strut
T_{Ch}	Torque due to fluid churning
t	Synchronization time
t_G	Gear clutching tooth width
t_R	Ring tooth width
t_S	Sleeve tooth width
t_t	ring tooth width at ring OD
t_{DP}	Ring tooth width at pitch dia
W_C	Combined vehicle weight
W_L	Ring lug width
W_S	Hub slot width
W_{RT}	Ring tooth thickness, axial
X	X-component of sleeve ramp angle
Y	Y-component of sleeve ramp angle
Z	½ sleeve detent groove width
α	Cone angle
α_{SLOT}	Angle at any side of hub slot
β	Pointing angle, sleeve/ring
γ	Angle at any side of lug
δ	Distance, cone gage point to front of clutching tooth
θ	Sleeve detent ramp angle
λ	Clutching tooth pointing angle
η	Dynamic viscosity
μ	Coefficient of friction, detent strut/ball to sleeve
μ_C	Coefficient of friction, cone surface
μ_l	Locking Coefficient, $\sin\alpha$
μ_p	Coefficient of friction, sleeve to ring pointing
μ_{SH}	Coefficient of friction, sleeve spline to hub spline
ψ	Ring clocking angle
φ_{PA}	Pressure angle, ring/sleeve
φ_t	Transverse pressure angle
ω	Initial velocity of output side of synchronizer

Automatic Transmissions—Gear Train Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manufacturing, Assembly

Takashi Shibayama
JATCO Ltd., Fuji City, Japan

1 INTRODUCTION

In order to understand the basic structure and the basic operating principle of the automatic transmissions (ATs), the following topics are described.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto081

1.1 Typical layout and structure of a step AT

Figure 1a shows a typical step AT installation layout for a front wheel drive vehicle and its typical structure. Engine output torque is transmitted to the torque converter. The shifting mechanism is built with several clutches, brakes, and planetary gear sets. Through the reduction gears and differential gear box, transmission output torque is transmitted to the drive shaft. The torque converter also contains a lockup clutch system by which converter slipping losses can be eliminated during cruising conditions. In general, the automatic transmissions have the mechanical parking mechanism, which serves to mechanically lock the transmission output shaft. Hence, a parking gear is added on the output shaft as is shown in the figure. An oil pump is driven by the hub of the torque converter outer cover. Figure 1b shows a typical step AT installation layout for a rear wheel drive vehicle and its typical structure. The basic layout and structure is similar to that of a step AT for a front wheel drive vehicle, except it does not have a differential gear box drive as with front drive designs. In addition, the rotating axis is straight as shown in the figure. Its output torque is transmitted to the in-line propeller shaft. In step AT development, the parking system is important. Designers have to pay attention to obtain good park performance and good shift lever operation feeling. Figure 2 shows a typical parking system. Shift operation force and feeling is adjusted by shaping of manual plate and detent spring characteristics. The details of an AT are

explained in this chapter, using a typical 5-speed AT for a rear wheel drive vehicle as an example.

2 BASIC PRINCIPLE OF SHIFTING BY USING A PLANETARY GEAR SET

The first step is to study the shifting principle of a planetary gear set. It is very fundamental but very important to understand the shifting mechanism of a step AT. In Figure 3, a typical planetary gear set and its actual parts are shown (Society of Automotive Engineers, 1962).

The important elements are the sun gear, the carrier, and the ring (or annulus) gear and the symbols S, C, and R are used for those elements.

S, sun gear
C, carrier
R, ring gear

Figure 3. A typical planetary gear set and the shifting principle. (Reproduced by permission of Jatco, Ltd.)

In Figure 3, there is an important table that shows the possible shifting combinations obtained by one planetary gear set.

A planetary gear set can make several kinds of shifts. As in Figure 3, speed reduction, speed increase, or reverse function can be obtained by connecting its elements to input, output, or stationary elements. The obtained function depends on which element is connected to input, output, or stationary elements. Here, the gear ratio can be calculated from following fundamental formula (Society of Automotive Engineers, 1973).

$$(N_R - N_C) = -\alpha(N_S - N_C)$$

where

N_R = rotational speed of ring gear
N_C = rotational speed of carrier
N_S = rotational speed of sun gear

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto081

Ex. $\alpha = 0.5$

	Gear element: Sun (S)	Carrier (C)	Ring (R)	Toruque flow	Function of gear set	Gear ratio output speed/ input speed	Lever expression (○ Input ● Output ▲ Stop; S C R)
①	Input	Output	Stop		Widely speed reduction	$\frac{\alpha}{1+\alpha}$ = 0.33 When $\alpha = 0.5$	②	Input	Stop	Output		Reverse and speed reduction	$-\alpha$ = –0.5 When $\alpha = 0.5$	③	Stop	Input	Output		Speed increase	$1+\alpha$ = 1.5 When $\alpha = 0.5$	④	Output	Input	Stop		Widely speed increase	$\frac{1+\alpha}{\alpha}$ = 3.0 When $\alpha = 0.5$	⑤	Output	Stop	Input		Reverse and speed increase	$-\frac{1}{\alpha}$ = –2.0 When $\alpha = 0.5$	⑥	Stop	Output	Input		Speed reduction	$\frac{1}{1+\alpha}$ = 0.67 When $\alpha = 0.5$	⑦	Any two element of the three element are engaged each other				Direct connection	1	
α : Z_S / Z_R Z_S : Tooth number of sun gear

Z_R : Tooth number of ring gear

Figure 4. Possible shifting function obtained by one planetary gear set. (Reproduced by permission of Jatco, Ltd.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto081
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$\alpha = Z_S/Z_R$$

Z_S = tooth number of sun gear
Z_R = tooth number of ring gear

For example, if carrier is stopped, $N_C = 0$. Then,

$$N_R = -\alpha N_S$$

In this case, the reverse function is realized. In the same way, several functions can be provided. In the figure, detailed function and possible speed ratios are described.

In Figure 4, the lever expression is introduced. The expression is very popular in the step AT industry to determine ratios. The vertical axis indicates the rotating speed of each element and horizontal axis indicates speed ratio obtained by tooth ratio of ring gear and sun gear.

By utilizing this lever expression, it is easier to understand how speed reduction or speed increase can be obtained by visualizing mechanical leverage. Input, output, and stationary elements can be visualized by this expression.

3 GEAR TRAIN COMBINATION FOR MULTIPLE STEP SHIFTING

In actual step ATs, several planetary gear sets are combined to obtain multiple steps shifting. Here, in this encyclopedia, a typical conventional 5-step AT with three planetary gear sets will be described to comprehend such a Gear Train Combination Shifting System (Yamaguchi and Sugihara, 2002, pp. 16–22).

Figure 5 shows a stick diagram and connection of the rotating members. To facilitate shifting function, some ring gear or sun gear or carrier should be braked or stopped. This is accomplished by brakes as indicated in the figure, for example, Fr/B (Front Brake) and R/B (Reverse Brake).This gear train combination is actually adopted in the JATCO RF507E model, which is in mass production. Rectangles indicate elements of the planetary gear, sun gear, carrier, and ring gear. White circles indicate multiple wet plate clutches. Moreover, there are three one-way mechanical clutches in this system that can transmit torque in only one direction. Such one-way clutches are often adopted because they are very useful to provide a smooth shift feeling. Using a one-way clutch, connecting or disconnecting is automatically achieved during shifting.

Figure 5 also indicates the detail connection table to make a 5-speed AT with reverse range. Because the one-way clutches can only transmit torque in one direction, bypass clutches are connected to obtain the other direction torque transmitting capacity when desired. Bypass clutches are engaged to transmit engine braking torque when it is necessary, for example during desending mountains.

In Figure 6, a detailed connection and lever expression of this typical 5-speed AT with reverse range is described, and in Figure 7, torque flow of this 5-speed AT is described.

4 COMPONENTS FOR PROVIDING THE SHIFTING FUNCTION

Figure 8 shows clutches and brakes that are used for providing shifting function and other power transmitting components. Multiple wet plate clutches, band brake, drum, one-way clutch, torque converter, gear sets, and shafts. Detailed explanation of multiple plate clutches is described in previous Chapter 2.8 (see Clutch Wet). In addition, torque converter is described in previous Chapter 2.9 (see Automotive Torque Converters). One-way clutches can only transmit torque in one direction. A band brake is often used for step ATs, which has a unique characteristic of torque transmitting capacity as shown in the figure. The band brake has a different capacity according to the drum rotation direction.

Up to this chapter, basic principles and mechanisms have been explained using the example of a conventional 5-speed AT. Recently, 6-, 7-, and 8-speed ATs have become popular, and the number of gears and the clutches tend to increase to provide such multiple steps ATs; therefore, the cost, the size, and the weight also tend to increase. So, the study of gear combination has become very important.

For the development of a step AT, many requirements must be considered: for example, reducing the numbers of clutches/brakes or numbers of parts, easy handling in assembly, or simplify the shift control. Recently, ZF made big progress in the gear train combination by computer-aided development.

As is shown in Figure 9, ZF adapted a very smart gear train combination for its 8-speed AT (SAE paper 2009-01-0510). This gear train combination has very limited number of shift elements, three multi-disc clutches and two multi-disc brakes. There are only two open clutches or brakes causing slip losses so the losses become minimal. During shifting, the system only requires to open one clutch/brake and close another clutch/brake, which makes the control system simple. With those points and others, this newly developed ZF 8-speed AT gear train is a very advanced system. Because aspeed has already been developed.

5 HYDRAULIC SYSTEM

As is described in Sections 2–4, shifting operation is done by hydraulic actuators of clutches and brakes. In addition, there are other important roles provided by the hydraulics. Figure 10a indicates the basic concept of utilizing hydraulic benefits. Indeed, hydraulics have many benefits: actuation, power supply, cooling, lubrication, shift feeling adjustment, cleaning, and so on. (Stebar *et al*., 1990, pp. 827–840).

Oil is delivered to each device through control valves after flow has been generated by the oil pump.

Usually, there are several of these devices. The whole oil circuit tends to become a little bit complex as is shown in Figure 10b, which is a typical oil circuit of a step AT. Using such an oil circuit, oil flow is switched or delivered

objective devices. Sometimes, orifices are provided in the separator to restrict oil flow to adjust actuating timing.

6 CENTRIFUGAL BALANCE SYSTEM

In rotating wet clutch systems, avoiding influence of centrifugal pressure is very important. Figure 12a explains centrifugal pressure effect. Although clutch pressure is released, oil remains in the clutch apply chamber. This oil in the clutch apply chamber has a mass and therefore provides a force when the clutch is rotated. This centrifugal pressure can apply the clutch "unintentionally" at higher rotational speeds and therefore must be counteracted.

If the clutch rotating speed is low enough, the piston return spring force is large enough to overcome the centrifugal apply force due to rotation of the clutch. However as the clutch rotating speed becomes high, clutch apply force by centrifugal pressure exceeds the return spring force. Figure 12b shows such a case. The clutch piston is stroked against the return springs and provides an apply force to the friction material. Drag torque and excess heating are generated on the friction material surfaces. This condition must be avoided for reliability and durability.

To avoid this issue, a balancing or canceling system is usually adopted in the wet clutch assembly. There are two ways to make a balance chamber or to make an oil removal system.

Figure 12c indicates the preferred way to make a cancel chamber. In this system, as is indicated in the figure, the balance or cancel chamber is added to provide an equal and opposite centrifugal force to cancel the applying force by the centrifugal pressure in clutch apply chamber. This system is often adopted in recent newly developed ATs because the cancel performance is reliable, but this system requires another oil seal and another oil supplying circuit.

Another approach is to make an oil removal system. Figure 12d indicates one example, which is utilizing a check ball valve. Usually, the check ball is made of steel. This steel ball receives two forces: one is centrifugal force originated by its own weight and the other force is flow force originated by clutch oil pressure. As is shown in Figure 12d, if clutch rotating speed is low, centrifugal force is small, so the steel ball acts as an oil seal. Conversely, if clutch rotating speed becomes high, centrifugal force becomes large and the steel ball moves toward outer diameter along the sloped surface in the steel ball cylinder.

Actually, the steel ball position depends on clutch rotating speed and pressure at the clutch apply inlet hole. In this way, seal or drain is switched according to the solid line and dashed line in the figure. Flow force changes according to flow rate around the steel ball, so, there is some hysteresis between the solid line and dashed line. This ball system was very popular in the past but time lag during oil filling and other sensitivities brought pretty much difficulty into development, so, this system tends to be replaced by the balance system.

7 COOLING AND LUBRICATION

Cooling and lubrication are very important in AT development. Figure 13a explains a typical circuit for cooling and lubrication.

The largest heat generator is the torque converter. Therefore, usually output flow from the torque converter is

usually sent directly to the oil cooler, which provides the required ATF (automatic transmission fluid) cooling. From the cooler, this cooled oil is sent back to the transmission where it enters the lubrication circuit, where it is used to lubricate and cool various parts such as bearings, bushings, gears, and clutch friction material. Usually, the shafts have holes for lubrication oil flow, and sometimes, additional pipes for routing lubrication flow are used.

Oil flow rate is adjusted by oil hole diameter or number of oil holes on the shafts.

(b) Typical oil circuit of step AT

Figure 10. (*Continued*)

After lubrication, the oil comes back into oil pan and is drawn up by the pump to begin its journey through the transmission circuits once again.

Figure 13b indicates a typical cooling system for a rear wheel drive AT. In the radiator lower tank, a heat exchanger is installed. This heat exchanger provides ATF cooling using engine coolant and cool air. As is shown in the figure, hot ATF comes from AT and cooled ATF returns back to transmission.

Cool air also cools the transmission case directly.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

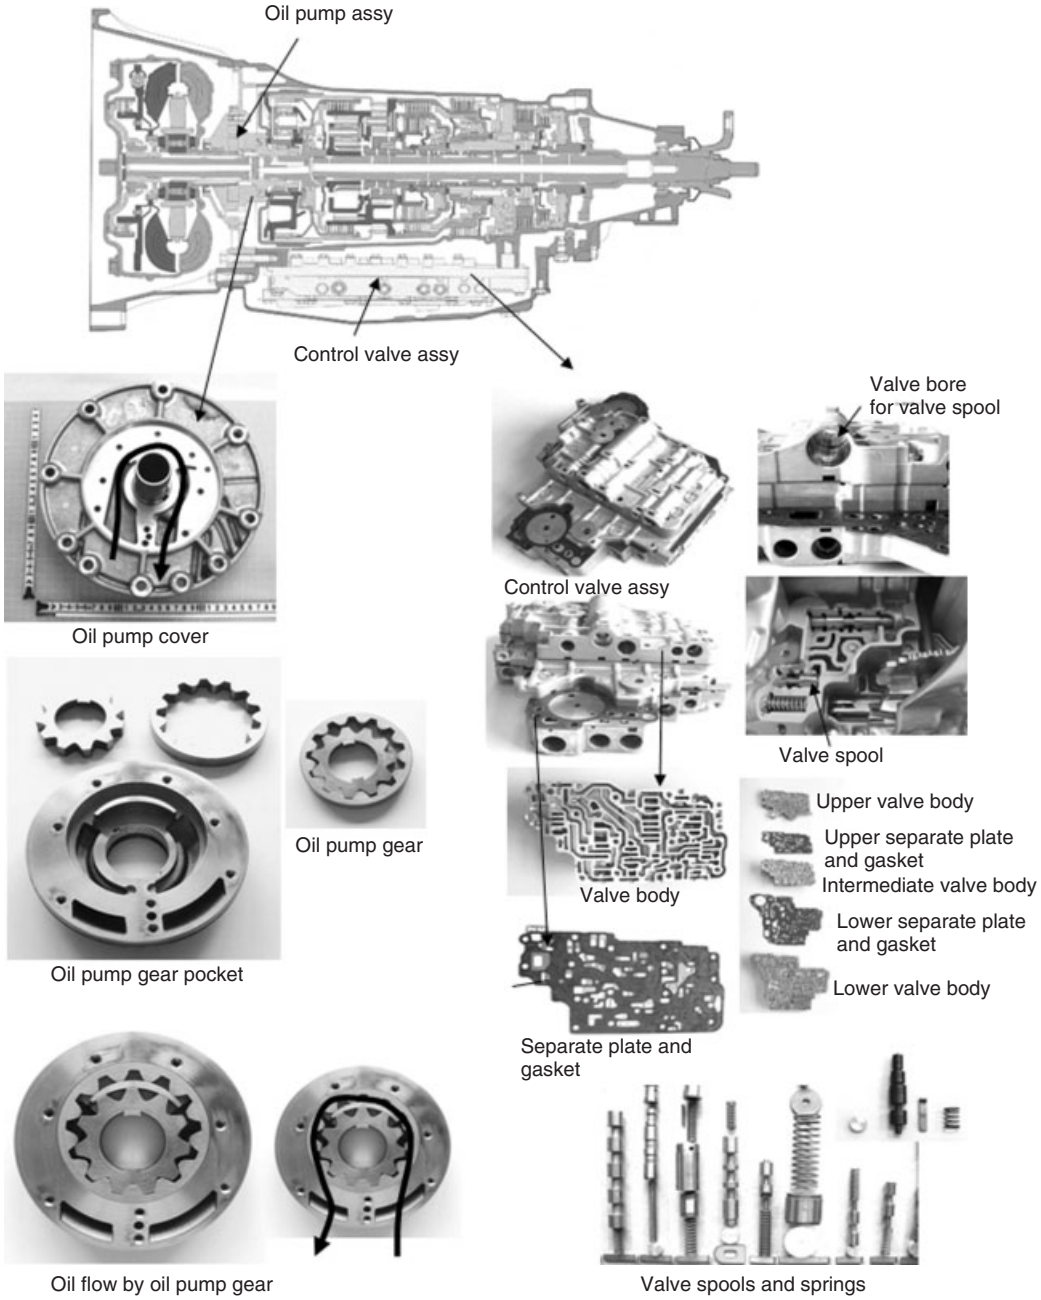

Figure 11. Actual components and parts for hydraulic system. (Reproduced by permission of Jatco, Ltd.)

Sometimes, for severe use vehicles such as heavy-duty trucks or taxis, an additional cooler (or radiator) that uses cool air for cooling is adopted.

Figure 13c indicates another cooling system. An independent oil cooler can be used that is attached on the transmission case by bolts.

This system has more flexibility for various vehicle installations but tends to have less cooling capacity than the radiator system described earlier. Therefore, sometimes, both a radiator in tank cooler and an independent attached cooler are adopted.

8 PACKAGING AND ASSEMBLING

For packaging and assembling, the designer and engineer investigate several issues.

Figure 14 indicates such issues. The figure shows an example of lineup and common parts strategy. Among several family models, some parts or components are shared. Using such a strategy, cost, and developing speed is improved.

In this example, the PTO (power take off) gear layout is also investigated for commercial vehicles. Such investigations are also important to make the lineup simpler (Shinohara *et al.*, 1989).

Figure 15 shows other examples of assembly issues. Here, work ease and cycle time for assembly are investigated by computer simulation. Recently, such simulation has become very important to establish a good mass production factory line, because such

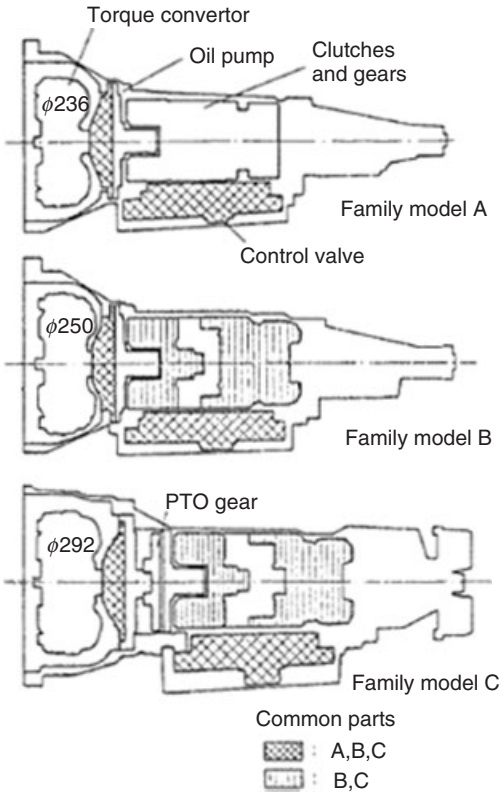

Figure 14. An example of lineup and common parts strategy. (Reproduced by permission of Jatco, Ltd.)

simulation can reduce or eliminate actual modification during production preparation (Takatori *et al*., 2009, pp. 25–42).

Three-dimensional simulation technology makes it possible to investigate such issues during the early preparation stages.

9 MANUFACTURING

For manufacturing, designers and engineers have to investigate various things and in this area; technology and innovation are also making great progress day by day (Martin and Redinger, 1993, pp. 579–602).

Figure 16a shows one example of a pressure die casting simulation. In pressure die casting, molten aluminum flow is very important. If flow is not adequate, as is shown in the figure, an unfilled area will create a void. Such void can cause oil leak or some weakness issue for the case.

To predict and avoid such unfilled areas in early development stages is very important to reduce large amounts of time and financial loss. Figure 16a includes another computer-aided engineering (CAE) system example for die design. Die design can be semiautomatically done aided by computer. Tooling design and lead time can also be improved using CAE. Figure 16b shows a tooling simulation example (Takagi, Ito, and Makino, 2008).

The Variable Pulley CVT

J.G.L.M. van Spijk[1] and A. Englisch[2]

[1]*Bosch Transmission Technology B.V., Tilburg, The Netherlands*
[2]*LuK GmbH & Co. KG, Bühl, Germany*

1 INTRODUCTION

Leonardo da Vinci was already aware of the importance of continuously variable transmissions (CVTs) in making driving power available to the load with the right transformation. (Figure 1) Centuries later, the Dutch inventor and car manufacturer Mr. Hub van Doorne (DAF) took the challenge to design a CVT that was suitable to be produced in automotive mass production. The rubber V-belt pulley variator proved to be a success in the market, but attracted a specific segment of people who had problems with manual gear shifting and who were looking for a cost-effective automatic transmission. The urge to overcome the resulting image and also to respond to the need for ever higher power density motivated the development of an alternative for the rubber V-belt. This resulted, on the one hand, in the mass-produced steel push belt, directly from Mr. van Doorne's initiative; on the other hand, in the chain that now is offered in mass production as well. In this chapter, the pulley variator system is described, for both push belt and chain. The system description concentrates on the most specific items for CVT, which are the variator part and its controls.

2 CONSTRUCTION AND OPERATION

Figure 2 shows a state-of-the-art front wheel drive CVT. The structure of this CVT consists of a torque converter (TC), an oil pump, a drive–neutral–reverse (DNR) device, a variator (consisting of a primary pulley set, a push belt or chain, and a secondary pulley set), a set of reduction gears, a differential, a parking mechanism, a hydraulic control unit, and a transmission control unit (TCU).

2.1 Most characteristic components of the CVT

The most characteristic components of the CVT include the following:

- Launch device.
- A torque convertor, which is the most commonly used device in a modern CVT. This device provides good performance and controllability during drive-off situations, in comparison to a wet-plate clutch, which is beneficial for its dimensions and cost.
- Forward, neutral, and reverse mechanism, usually realized with a planetary gear set, to be able to switch among Drive, Neutral, and Reverse.

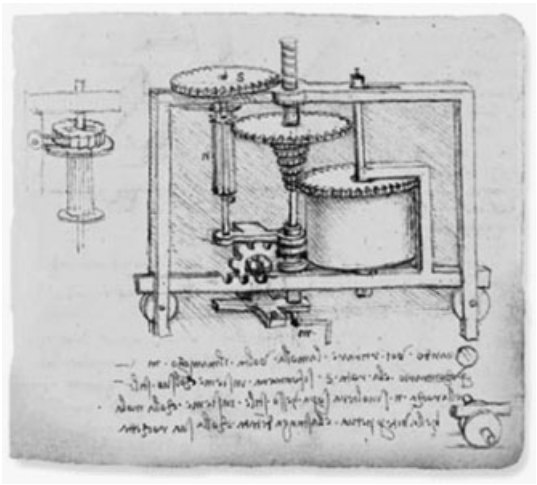

Figure 1. Da Vinci's CVT.

- A variator, which consists of a driving and a driven pulley. Each pulley comprises two conical sheaves that face each other. One of these sheaves is axially movable by a controlled pressure. A push belt/chain runs in the V-groove between the two sheaves.
- A final drive and differential. The final drive ratio reduces the variator output speed to vehicle wheel speed. The differential divides the torque over the driven wheels.
- Hydraulic/electric actuation, controlled by a TCU. This unit controls the transmission behavior.
- A pump. The pump generates hydraulic energy for actuation, lubrication, and cooling.

2.2 Transmission architecture

The main components of a CVT can be arranged in several layouts. The choice for a specific layout depends on the requirements of packaging, comfort, cost price, efficiency, and so on. Figures 3–7 show a number of possible layouts with their major advantages and disadvantages. These figures are simplified in order to emphasize the differences within component arrangement.

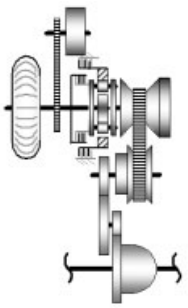
DOI: 10.1002/9781118354179.auto083
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

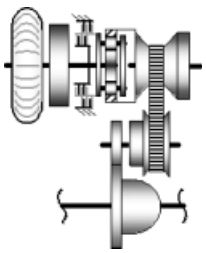


Features:
Torque converter, chain driven pump, DNR-set, variator, final drive, differential.
Remark: most common CVT-layout
Advantages:
* Compact pump; easy to change pump type/supplier
* Suits most FWD cars
Disadvantages:
* Extra pump drive component, cost
Production examples:
Jatco CVT0, CVT2, Honda 30mm-CVT, Hyundai CVT

Figure 3. Schematic architecture corresponding to Figure 2. (Reproduced by permission of Bosch Transmission Technology B.V.)

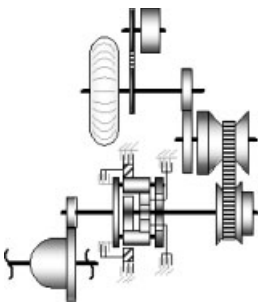
Features:
Clutches of DNR-set act as launch element, pump is mounted on end of primary side
Advantages:
* Cost, weight, & packaging (no torque converter and separate pump drive)
Disadvantages:
* Launch performance
* Comfort
Production example:
Punch VT2

Figure 4. CVT with wet-plate starting clutch. (Reproduced by permission of Bosch Transmission Technology B.V.)



Specific features:
DNR-set reduces speed & reverses direction of rotation in forward mode; no intermediate shaft
Advantages:
* Less components, from 4 to 3 shafts
* Packaging & weight
* Lower input speed for variator
Disadvantages:
* Increased input torque for variator
* Lower wheel torque in Reverse
* Efficiency loss in DNR
Production example:
Daihatsu D18C

Figure 5. Three-shaft layout. (Reproduced by permission of Bosch Transmission Technology B.V.)



Specific features:
Input reduction, 2-stage DNR-set on secondary side
Advantages:
* Large transmission ratio coverage
* Primary length
* Efficiency
Disadvantages:
* Cost
Production examples:
Jatco CVT7

Figure 6. Two-step CVT. (Reproduced by permission of Bosch Transmission Technology B.V.)

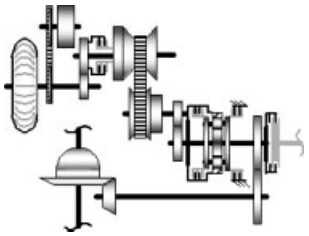
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5



Specific features:
Input reduction, clutch, output reduction, DNR-set on secondary side, clutch rear wheel.
Advantages:
* This layout suits most rear-wheel-drive vehicles
* Easy start/stop option (because of primary clutch)
* Option to switch rear-wheel-drive modus on/off
Disadvantages:
* Transmission length (primary side)
* Transmission weight
* DNR-set has to transfer higher torque
* Efficiency at high speed
Production examples:
Subaru Lineartronic

3 VARIATOR

3.1 Torque and clamping

Assuming the widely used architecture with a push belt as presented in Figure 2, positive driving torque comes from the engine, supplies the required torque to the pump, passes via the TC and DNR, and drives the variator from the primary pulley set. Here, half of the torque is transmitted to the moveable sheave and the other half to the fixed sheave on the shaft and both come together in the push belt (Figure 8).

The torque transfer between the push belt and firstly the primary and thereafter the secondary pulley sets is made possible by hydraulic actuation. The required clamping force is calculated according to the formula:

$$F_{\mathrm{ax,sec}} = \frac{T\,\mathrm{sec}^{*}\cos(\lambda)^{*}S_{\mathrm{f}}}{2^{*}\mu^{*}R_{\mathrm{sec}}} \tag{1}$$

where

μ = friction coefficient between push belt and pulley
R_{sec} = running radius on secondary pulley set
λ = pulley angle
S_{f} = safety factor on clamping force
T_{sec} = torque at secondary shaft.

The controlled oil pressure (p_{sec}) on the secondary cylinder area (A_{sec}) and the centrifugal effect of the oil on the cylinder ($f_{\mathrm{c,sec}}$) together with the spring force (F_{spring}) result in the clamping force secondary ($F_{\mathrm{ax,sec}}$):

$$F_{\mathrm{ax,sec}} = p_{\mathrm{sec}}{}^{*}A_{\mathrm{sec}} + \omega_{\mathrm{sec}}{}^{2*}f_{\mathrm{c,sec}} + F_{\mathrm{spring}} \tag{2}$$

The function of the compression spring is to pretension the push belt under the condition of no engine running and no oil pressure during towing or transport.

From the condition that the clamping force is secured by Equation 1, the variator will stay in a given ratio by control of the clamping force on the cylinder of the primary pulley ($F_{\mathrm{ax,prim}}$). For a stationary condition of ratio, the necessary $F_{\mathrm{ax,prim}}$ is determined by the KpKs value according to the formula:

$$\mathrm{KpKs} = \frac{F_{\mathrm{ax,prim}}}{F_{\mathrm{ax,sec}}} \tag{3}$$

Example with typical KpKs values as a function of safety and ratio (Figure 9).

To be able to shift from Low to OD ratio, the $F_{\mathrm{ax,prim}}$ has to be higher than $F_{\mathrm{ax,sec}}$ * KpKs and vice versa. The radial shaft load generated by clamping the push belt has to be supported by the variator system. The force is estimated by the formula:

$$F_{\mathrm{shaft}} = \frac{4^{*}F_{\mathrm{ax,sec}}{}^{*}\tan\lambda^{*}\sin\left(\frac{\alpha}{2}\right)}{\alpha} \tag{4}$$

where

α = wrapped angle.

This results in the variator loading conditions, which can serve as an input for the calculation of the bearing loads.

3.2 Stiffness

The variator accommodates the mechanical stops for the low and overdrive ratios. The stops prevent the outer ring of the push belt running out of the outer diameter of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto083
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

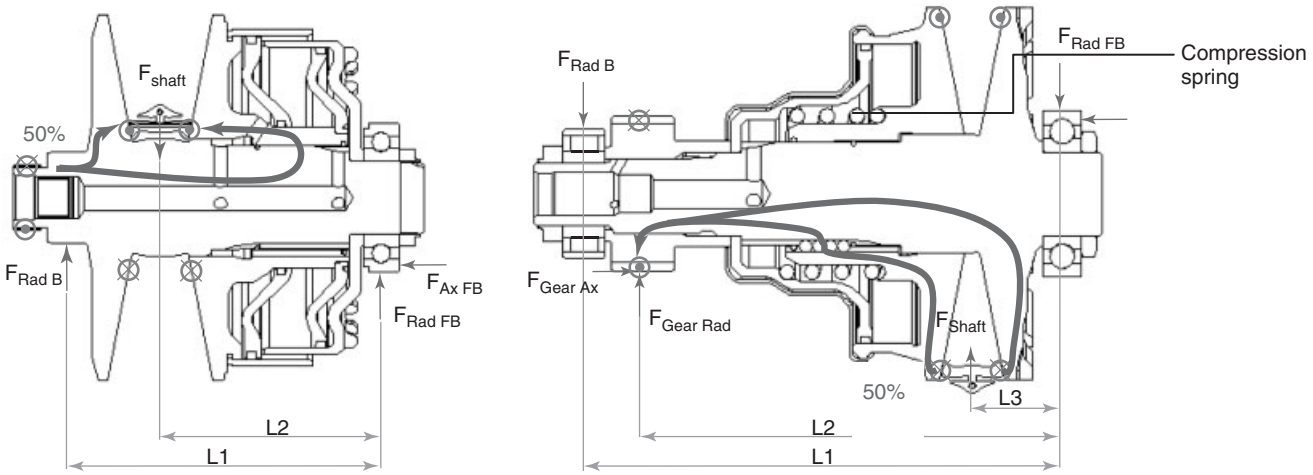

Figure 8. Primary and secondary pulley sets. (Reproduced by permission of Bosch Transmission Technology B.V.)

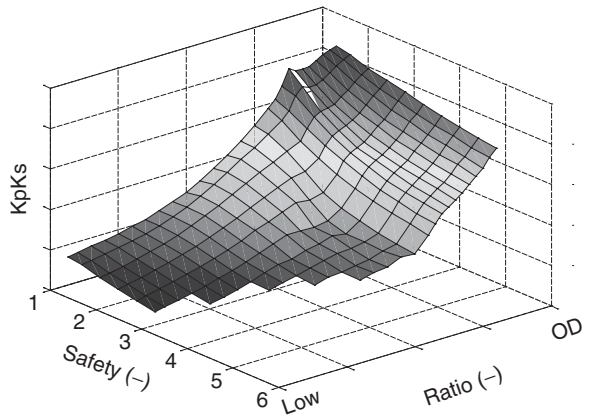

Figure 9. KpKs mapping. (Reproduced by permission of Bosch Transmission Technology B.V.)

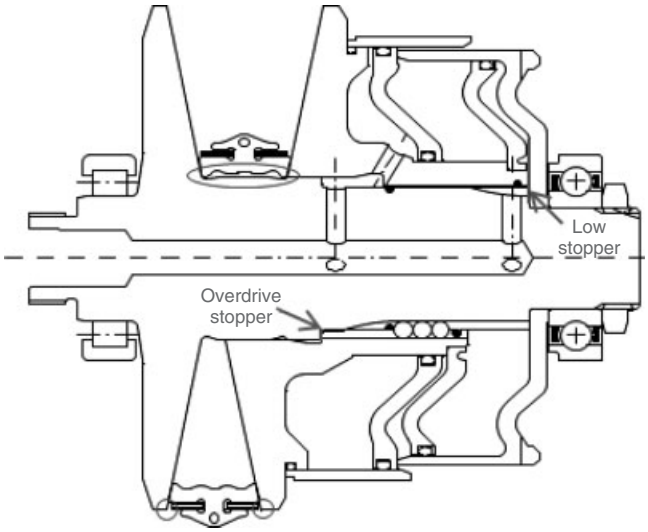

Figure 10. Primary pulley cross section. (Reproduced by permission of Bosch Transmission Technology B.V.)

pulleys, and toward the shaft center, it prevents the push belt element from running onto the shaft.

In practice, different designs are applied: both stops on one pulley set (primary), as shown in Figure 10, or a stop between movable pulley shaft and plunger on each pulley set (with a stepless pulley design).

A variator design, which is capable of transmitting the torque with high efficiency, ensures that the total axial deformation of the sheaves does not exceed a certain value. Axial deformation of the sheaves results in undesirable radial sag and consequently spiral running of the pushbelt/chain around the pulley. The radial component of this running (slip) does not contribute to the torque transmission and results in the loss of efficiency (Figure 11).

The torque is transmitted from the shaft with the fixed sheave to the moveable sheave by a design feature that gives low backlash, high tangential stiffness, and low sliding force. Typically, a so-called ball groove design is applied, in which at three positions around the shaft, half circular grooves are in the shaft and the inside of the moving sheave, in which balls are positioned with a tight tangential fit. Lower cost solutions as a single roller in just one groove are also applied (Figure 12).

3.3 Materials for pulley sets

The combined demands of high bending and torsional loads and tribological robustness of the contact require a material that combines ductility and a hard surface,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto083
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

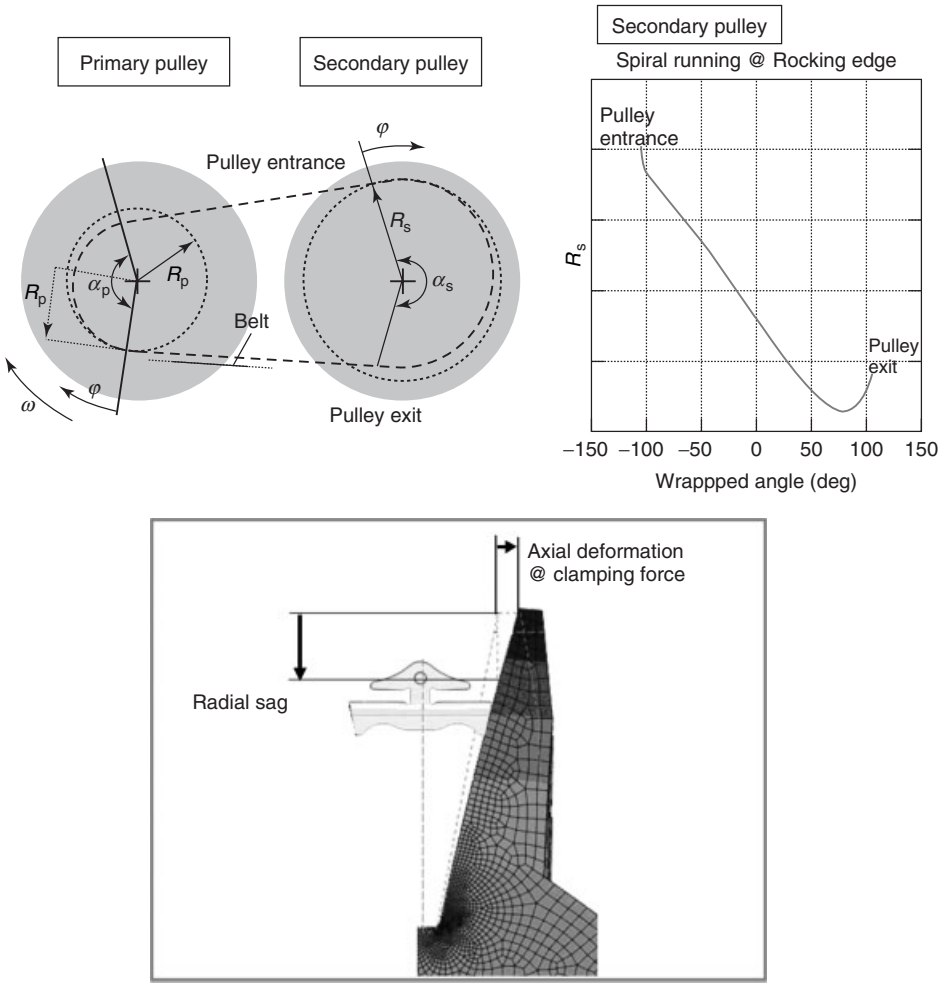

Figure 11. Radial sag—cause of spiral running. (Reproduced by permission of Bosch Transmission Technology B.V.)

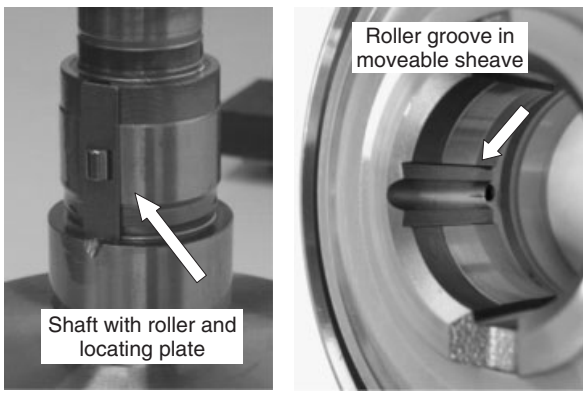

Figure 12. Sheave guiding by single roller. (Reproduced by permission of Bosch Transmission Technology B.V.)

which can be found in case hardening steels. The pulley material is a compromise among formability, machinability, heat treatability, strength, and cost. Typical materials are 20MnCrS5 and 20CrMoS5.

3.4 Tribology

The contact between push belt and pulley is lubricated and cooled by dedicated CVT oil. Together with the right setting of surface hardness and texture, this lubrication and cooling function limits wear and overheating of variator parts. Bosch performs oil validation testing, according to the so-called CVT fluid test (Brandsma *et al*., 2003). The fact that oil is also used in other contacts in the CVT, such as clutches and gears, as well as to perform hydraulic power transfer and control functions, makes dedicated CVT oil necessary.

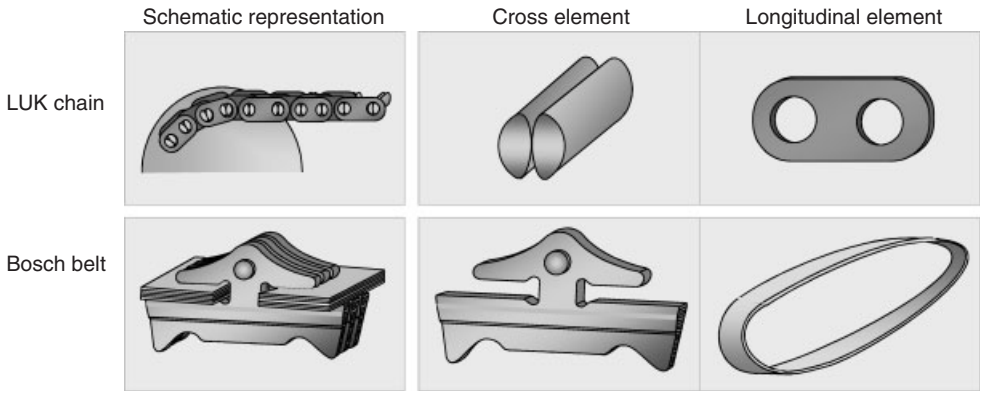

Figure 13. Components of chain and belt. (Reproduced by permission of Bosch Transmission Technology B.V.)

4 DIFFERENCE IN PRINCIPLE BETWEEN BELT AND CHAIN

The main function of the medium between the two pulleys, whether it is a chain or a belt, is to transmit power, by means of torque and speed, from one pulley to the other. The way in which this is realized, however, is different for the chain and the belt. For a better understanding, the transfer of torque is explained stepwise.

The first step is the transfer of torque from the driving pulley into the medium, which must be able to receive this torque from the driving pulley. The chain receives this torque via pins and the belt via elements (Figure 13, cross element). The transfer is, in both cases, enabled by a contact force between the pin or element and the pulley, which by friction creates a tangentional force. At stationary conditions, the sum of the tangentional forces of the pins or elements at their contact radius is in balance with the driving torque. So far, there is no distinguishing difference between the belt and the chain. The difference between the two products occurs in the second step, namely, the transfer of the received torque toward the driven pulley.

To get a picture of the second step, the layout of the two products must be examined a little closer. First is the chain. The sets of pins in the chain do not have direct contact with each other, but are attached to each other by the so-called links. It is the function of these links to transfer the received torque, by means of force, from one set of pins toward the next set, and so on, until the pins that are in contact with the driven pulley. Therefore, the function of these links is to transfer the torque from one set of pins to the other, by means of pulling force. Finally, the pins that make contact with the driven pulley transfer their pulling force into torque at the sheave similar to the pins on the driving side, namely by friction between the two contacts areas.

Next is the process for the belt. The elements in the driving pulley have absorbed the torque and feel a tangentional force. The elements transfer this force to their neighbors with whom they are in direct contact. In this way, they directly transfer the received torque by pushing the neighboring elements toward the driven pulley. The function of the loops in the push belt is just to keep the elements together under the radial forces inside the wrapped angle in the pulleys and guide them from one pulley to the other. Again, like the chain, the elements that are in contact with the driven pulley transfer their torque by friction between the two contact areas.

To be complete, it must be added that the loops do have a limited function in the transfer of torque. This can be understood by imagining the radial force of the elements in the wrapped angles, which is supported by the rings. The rings do have a relative speed to the elements, and this combination creates a positive or negative driving torque, depending on the speed ratio of the belt.

With this, the functions of the different parts of the belt and chain are described and it is understood how torque is transferred between the two pulleys. With this, it is made clear why the mediums transferring the torque have these typical different names, (pull) chain and (push) belt.

5 PUSH BELT DESIGN

5.1 Construction

The metal push belt consists of two sets of loops and a number of wedge-shaped steel elements (Figure 14). The compression type belt is designated as a push belt as the compressed elements act as a solid column to transfer torque from one pulley set to the other. The thin steel loops are the main structure of the belt. The loops are fitted

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto083
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

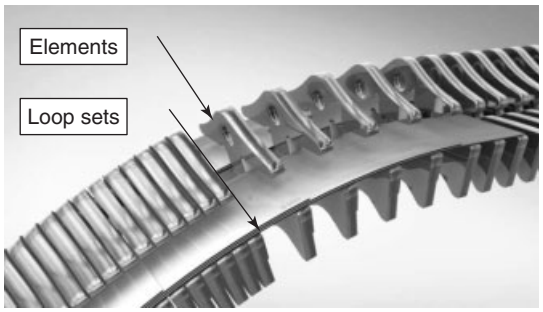

Figure 14. Push belt. (Reproduced by permission of Bosch Transmission Technology B.V.)

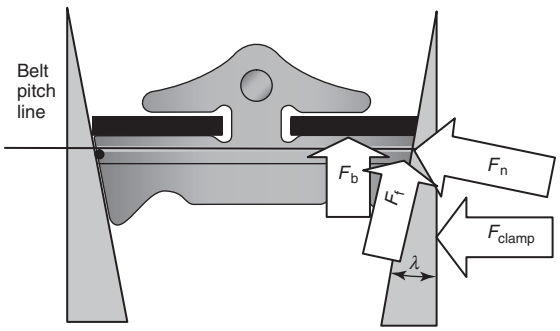

Figure 15. Loads on variator section. (Reproduced by permission of Bosch Transmission Technology B.V.)

closely together to form a nested set with no play. There are two loop sets, one on each side of the belt assembly. Each loop is approximately 0.2 mm thick, and a loop set typically consists of 6, 9, 10, or 12 loops. The loop sets give the push belt assembly high tensile strength with maximum flexibility. A special profile on the inner side of each loop optimizes the lubrication area and minimizes the friction losses between the sliding loops. This design, combined with the selected material, results in a compact system with a high power density and fatigue strength. The steel belt operates in a lubricated condition.

5.2 Belt length and pitch definition

The optimal length of a push belt is determined for each specific transmission layout. The design length of a push belt can vary continuously, as this belt length depends on the diameter of the loop sets and not on the thickness of the elements. Once the diameter of the loops has been determined, a quantity of elements with slightly different thickness is selected to "fill" the belt. The official product code (<element type/width>/<number of loops in each loop set>/<thickness of elements>/<inner diameter of the innermost loop>: e.g., 24/9/1.5/208.8) identifies the diameter of the innermost loop and not the diameter of the belt itself (which is defined by pitch line on the segments). Running radii are always defined on the pitch line height.

5.3 Maximum flank angle

In some applications, the belt needs to change ratio at standstill. In that case, it is not allowed to have a self-locking effect between the element flank angle and the pulley angle (λ). Therefore,

$$\lambda > \arctan(F_f{}^* F_n^{-1}) \tag{5}$$

And because $\mu = F_f{}^* F_n^{-1}$

$$\lambda > \arctan(\mu) \tag{6}$$

(Figure 15)

5.4 Maximal push force

The push force through the elements may never exceed the tensile force in the loop sets. If the push force would exceed the tensile force, the stack of elements would buckle. The tensile force is indirectly applied to the loop sets by the clamping force (F_{clamp}) on the pulleys and the pulley angle λ.

$$F_b = F_{clamp}{}^* \tan(\lambda) \tag{7}$$

5.5 Alignment sensitivity

The alignment is the axial distance of the primary (fixed) shaft running surface relative to the secondary (fixed) shaft running surface. In straight running condition, this distance is exactly the belt width at the pitch line. The fixed running surfaces of the two pulleys are diagonal to each other; with changing ratio, the alignment changes.

As shown in Figure 16, at two ratios the pushbelt runs in a straight line. For proper functioning, the alignment in the transmission should be set as indicated by the belt supplier.

5.6 Belt efficiency

The efficiency of a push belt variator depends on a number of parameters. It varies with ratio, torque, and speed. However, the applied clamping force also has a strong influence. With variation in the safety factor, as explained in formula 1, the clamping force varies.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto083
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

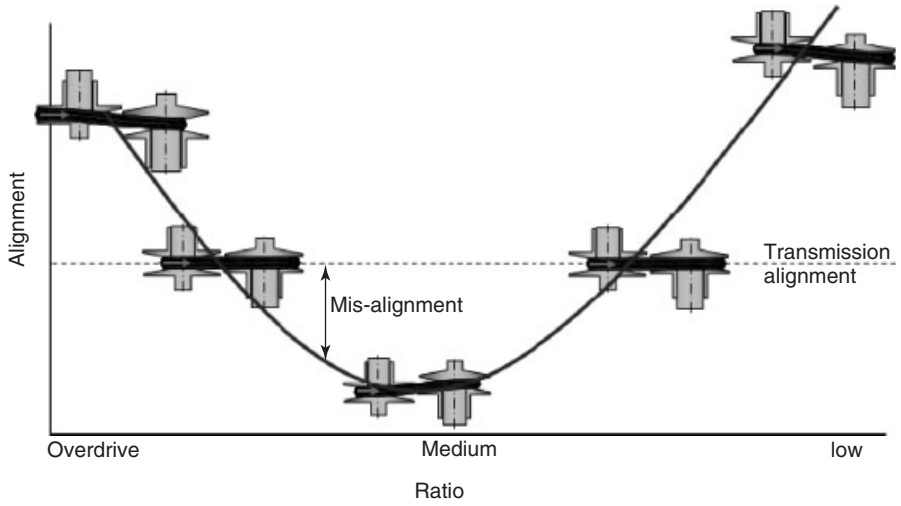

Figure 16. Alignment as function of ratio. (Reproduced by permission of Bosch Transmission Technology B.V.)

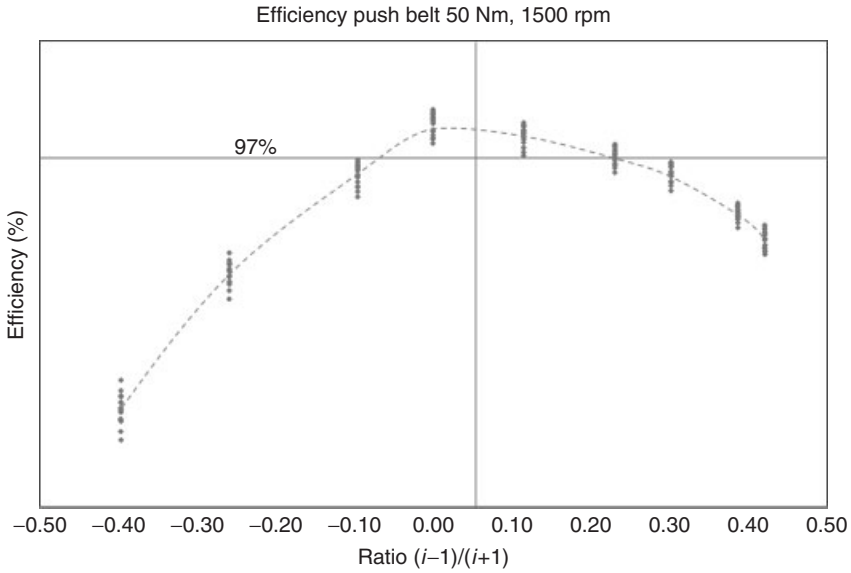

Figure 17. Belt efficiency diagram. (Reproduced by permission of Bosch Transmission Technology B.V.)

The example that is given for the push belt shows measured results at the given speed and load condition, with a safety factor of 1.3 (Figure 17).

5.7 Belt torque capacity

A push belt uses push force to transmit torque. Because steel can withstand more push force than tensile force, this enables a maximal power density. The contact surface with the pulley is also maximal and has a continuous character, which leads to low noise levels. The belt capacity is mainly determined by stress levels in the loops. These stress levels are a combination of tensile and bending stresses experienced by the belt. Stress is affected by rotational speed, ratio coverage, torque level, distance between primary and secondary pulleys, belt length, belt clamping safety factor, loop material, and belt dimensions. A variety of belt sizes, varying in width and number of loops within the loop set, is available for various applications. Typically, the wider the belt and the more rings in each set are, the higher will

Table 1. Torque capacity production belts.

	Number of loops in each loop set			
	6	9	10	12
24 mm phase 6		150 Nm		180 Nm
24 mm phase 7	150 Nm	215 Nm		
30 mm phase 6				350 Nm
30 mm phase 7			350 Nm	
28 mm				410 Nm

be the belt capacity. Table 1 shows some typical torque capacities for push belt configurations. Actual torque capacities depend on the application at hand.

The improvement from phase 6 to phase 7 is an improvement in the purity of band material.

6 CHAIN DESIGN

The chain consists of rocker pins and link plates. The rolling contact between the rocker pins causes a significant reduction in frictional losses. Beside the functional properties (efficiency and overall ratio), it benefits from its modularity. Owing to the construction of link plates and rocker pins, the chain can be matched to the loads and geometrical boundary conditions of the specific application.

The initial applications of the LuK CVT chain were mainly found in the moderate and upper torque range and were covered without exception by the chain type 08 (Figure 18). The number 08 reflects the average pitch distance in millimeters. In the course of discussions on increasing the power density of the subassemblies, the further development of "small" chains (07 and 06) was driven forward and a high performance capacity was identified.

The chain pattern, as shown in Figure 19, can be designed for optimized load distribution. Depending on the arrangement of the link plates, it is possible to reduce the bending of the rocker pins or the load on the outer links. The chain does not require specific alignment measures.

The acoustic behavior, which is impelled by the polygonic effect of the chain, can be improved on the one hand by the chain pattern and on the other using a guide rail. Chain pattern means, in this case, the arrangement of short and long links. If all the links would have the same pitch length, it causes a single tone, which might be easily perceived in a vehicle. By a "randomized" arrangement of the short and long links, this single tone can be eliminated.

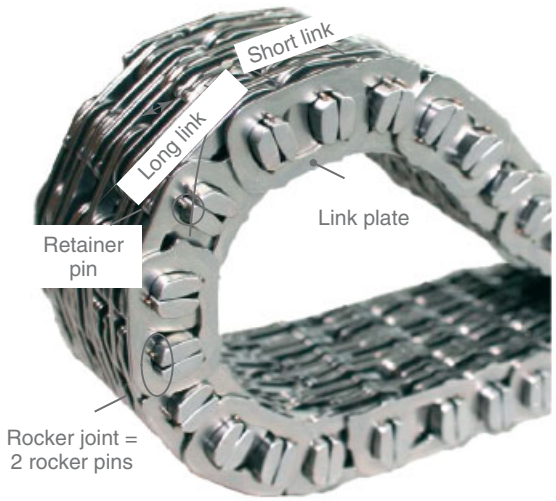

Figure 18. Chain design. (Reproduced by permission of LuK GmbH & Co. oHG.)

The function of the guide rail is to suppress oscillation effects of the free chain section and is in contact with the outside profile of the links during operation (Figure 20).

The specification of an absolute value for the chain's own efficiency is very difficult, as the exact configuration of the adjacent structure (pulley set, etc.) must be considered. However, a measurement of the efficiency profile of chain type 06 (Figure 21) shows the typical efficiency characteristic of a chain variator.

6.1 Chain types

The chain type 07 represents, in simplified terms, a scaling down of the type 08 with additional detailed optimizations. Figure 22 shows the geometrical and performance opportunities for the different chain types.

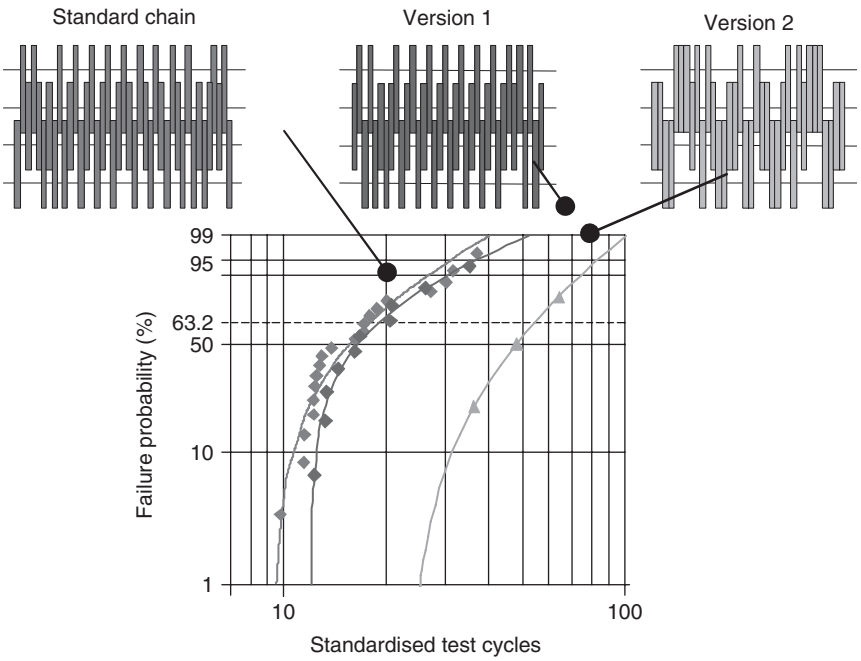

Figure 19. Chain pattern. (Reproduced by permission of LuK GmbH & Co. oHG.)

Figure 20. Guide rail. (Reproduced by permission of LuK GmbH & Co. oHG.)

As described in the preceding section, a reduction in the size of the chain type (transition from 08 to 07) brings a series of possible advantages. In order to answer the question as to what extent the size of the chain can be sensibly reduced further, an even smaller version of chain type 06 was designed and assessed using simulations and tests. As the individual parts become smaller, their strength decreases first. On the other hand, this leads to effects that can have a positive influence on the loading of the chain. Where a smaller chain pitch is present, for example, the frictional force between the chain and the pulley set is split between a larger number of rocker joints.

This leads to more uniform load distribution. Once all these conditions are considered, the chain type reduced in size by 10% (transition from 07 to 06) can be expected to show the performance capacity shown in Figures 22 and 23. In terms of chain width, it achieves approximately the performance capacity of chain type 07. This chain offers applications in passenger cars with low or moderate torque values and even in the two-wheel sector. A motivation in reducing the size of the chain is the possibility of influencing acoustic characteristics. The chain 06 offers a reduced weight and a lower chain pitch, which gives a reduction in the excitation level because of polygonal running. Furthermore, the smaller pitch changes the excitation frequencies.

7 OIL PUMP AND HYDRAULICS

7.1 General hydraulic control

Hydraulic control is normally used for CVT control because of the high power density and the flexibility in the actuation. The components in a CVT require a specific oil flow and oil pressure to function correctly. A pump generates the required hydraulic power, a flow at a certain pressure. The pump flow is pressurized and guided toward the different components by numerous valves, both passively and actively controlled.

7.2 Pump requirements

Depending on application and calibration, one of the following conditions (Figure 24) determines the pump size (cc/rev):

- Dynamic variator shifting conditions (Figure 24):

– Emergency stop from overdrive toward underdrive at low engine speed
– Kick-down starting from a low engine speed
– Programmed step-mode shift at low engine speeds.

Coordinated power train control concepts based on drive torque control in some cases lead to more gradual engine speed and ratio transients, occasionally bringing some relief to these requirements.

- Clutch/brake engagement.

Usually, the shifting variator imposes the critical demands in terms of pressure and flow. However, with ever-decreasing idle speed, the idle/launch condition also becomes decisive for the sizing of the engine-driven pump. The pump is driven by the engine, which operates over a large speed range. This speed range directly results in a changing pump flow. To prevent unnecessary large flows into the hydraulic system, pump flow control can be applied. The reduced maximal flow makes it possible to use smaller valves and can reduce parasitic pumping losses.

7.3 Pump choice

Currently, most CVT pumps are gear or gerotor type pumps based on designs from stepped automatic transmissions. Recently, vane type pumps have been introduced into CVT from the field of power steering technology (Van Der Sluis, 2003).

Typically, leak-tightness of gear and gerotor type pumps is defined by the tolerances of parts that define the critical radial clearance inside the pump. Closer tolerances mean better efficiency but also more expensive parts for which the risk of degrading efficiency due to wear increases. In order to apply these pump types for higher pressure applications such as CVT, cost increasing measures such as radial pressure compensation, additional seals, or complex rotor profiles are required.

In vane pump designs, the discussed leakage is avoided. Centrifugal force on the vanes results in a sealing contact between vane and body, as shown in Figure 25. This increases volumetric efficiency very effectively.

7.4 Pump system

A further advantage of a vane type of pump as shown in Figure 25 is that it basically consists of two independent pumps gathered around a single shaft. This offers the possibility to create flow control by disconnecting one of the pumps from the hydraulic system.

7.5 Typical CVT-related hydraulics properties

The control strategy of a CVT influences transmission efficiency in two ways:

- By the power requirement for the actuation of the variator.
- By the internal losses, which are functions of the applied actuation forces.

Compared to other transmission types, the CVT variator actuation requires relatively high oil pressures and large oil flows, which results in a CVT-typical pump specification.

In Section 3.1, the calculation of the required clamping force (1) has been explained.

Typically, the maximal pump pressure in a CVT varies between 30 and 70 bar.

7.6 Hydraulic variator control layouts

The main and most specific hydraulic function in a CVT is the variator control function. Generally, secondary pulley control is used to control the desired clamping force and primary pulley control for the desired ratio. To have robust clamping force control, the secondary pulley is controlled using pressure control. Primary pulley control can be chosen between flow and pressure controls. There are two principal types of CVT variator control systems (Figure 26).

7.6.1 Dependent control system

The primary pressure is derived from the secondary pressure through a 3/3 directional valve that controls transmission ratio. This simple and low cost circuit has the following features.

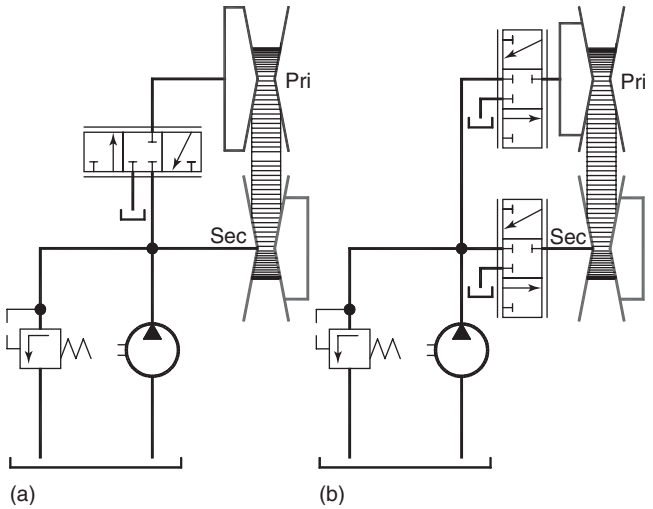

Figure 26. Variator control, dependent (a) versus independent (b) control. (Reproduced by permission of Bosch Transmission Technology B.V.)

- The variator pulley cylinder surface ratio A_{pri}/A_{sec} is set to the maximum KpKs that is required to keep the variator in overdrive plus an additional factor to enable dynamic variator shifting. Fast shifting toward underdrive, during which the secondary pulley cylinder is filled, is most critical in relation to variator slip.
- There is no distinction between the secondary pulley pressure and the pump pressure.
- The minimum secondary pressure is limited by other system pressures, and therefore no extreme low secondary pulley pressure (slip control) (Noll *et al*., 2009) is possible.

7.6.2 *Independent control system*

The circuit contains one 3/3 valve per cylinder fed by a line pressure control valve. The maximum cylinder pressure switches between the primary and the secondary cylinders. This circuit has the following features.

- The cylinder surface ratio A_{pri}/A_{sec} can be chosen to meet the most frequently occurring KpKs ratio. In this way, primary and secondary pressures lie close to each other most of the time. Moreover, for this circuit, the secondary cylinder surface area is an important parameter to determine pump size. For cost reasons, it can also be decided to use equal cylinder surface areas.
- The pump has to provide all shift flow to give ratio change.
- The secondary cylinder pressure can be reduced to ambient pressure and the pressure in the primary cylinder, when possible.
  As this setup can reduce pulley actuation force to a minimum, this offers the best potential for an "ideal" clamping strategy.
- The line pressure usually is controlled slightly above the maximum of secondary and primary pressures. As primary pressure can rise above secondary pressure, pump pressure will be high more often. Both effects negatively influence the efficiency of the hydraulic system.
  This negative effect can be solved when the hydraulic control is designed in such way that line pressure is directly connected to the highest of primary or secondary pressure. This system is called *SMART* (Van der Sluis *et al*., 2006).

7.7 Global hydraulic scheme layout

Current CVT designs contain several control functions that have to be supplied with pressurized oil. The hydraulic layout can be designed according to a specific priority level (for a typical complete diagram, see Figure 27):

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Priority 1: ——— Variator control functions, including solenoid actuation

Priority 2: – – – Auxiliary control for clutch/brake and TC controls

Priority 3: ------ Lubrication control.

In critical flow conditions, pressures will break down in reversed priority level.

This way, the most vital functions, namely variator control and solenoid supply, remain operational as long as possible.

7.8 Control actuators

As shown in Figure 27, typically five main functions (four in case of dependent control) are active/pilot controlled. Different types of solenoids can be used. The solenoids types do differ, that is, oil usage/leakage, accuracy, cost, and noise/vibration/harshness.

7.8.1 Different types of pilot control actuators

- Bleed type solenoid (pressure controlled by bleeding oil)
- Spool type solenoid (3/3 pressure control valve)
- On/off solenoids, controlled by pulse width modulation.

7.8.2 Other types of control

- Direct pressure/flow control (without pilot pressure)
- Stepper motor control (e.g., primary control with mechanical ratio feedback)
- Electromagnets applying direct force to hydraulic valves.

8 CVT ASSEMBLY

In general, the assembly of components in a CVT transmission is comparable to other transmission types. For a CVT, the variator—the combination of pulleys and push belt/chain—is the specific transmission part. Each pulley subassembly comprises two conical sheaves that face each other. One of these sheaves is axially moveable by a controlled pressure. Each pulley has for this reason a pressure chamber.

The contact surfaces on which push belt/chain is clamped contribute to an efficient torque transfer and generate the friction force. Special requirements for the material properties and roughness requirements have to be met.

For proper functioning of the variator, the alignment in the transmission should be set to the value given by the supplier. To keep the tolerance of the alignment value, special attention has to be given to the positioning of both the pulley parts in the transmission during assembly. With normal production spread, shimming on one of the pulleys is often needed to guarantee the alignment value.

During the complete assembly of the transmission, special attention is required to leakage checking of (sub) components. As the variator is hydraulically controlled to generate the required clamping force, any leakage in the system will lead to a less efficient transmission. To control the involved hydraulic components, there is a functional check, generally performed in the production line (Jatco Technical Review No. 11):

1. Performance of the oil pump in delivering the required pressure.
2. Performance of the control valves in regulating the pressure.
3. Absence of any leakage in the oil passages in the transmission from the oil pump to the hydraulically actuated devices.
4. Reliable assembly of pressure-related parts.

A final complete functional transmission check is performed at the end of line testing.

Traction Drive CVT

Hirohisa Tanaka
Yokohama National University, Yokohama, Japan

1 INTRODUCTION

The history of the traction drive in detail was given by Heilich III and Schube (1983) in the book of Traction Drives. This chapter gives a brief overview of the history of traction drive continuously variable transmissions (CVTs) applied to automobile transmissions. The GM Research started researching toroidal CVTs in 1928. About the same time as GM developments, the Austin Company in the United Kingdom had launched a similar design under license, and this was produced in small number for several models in 1934. It demonstrated the considerable smoothness and drivability advantages of a CVT, but suffered from reliability problems and was withdrawn from production after 2 years (Gott, 1991).

Their scientific research works were opened in the GM's symposium on the Rolling Contact Phenomena in 1962. Figure 1 shows a research traction test machine for evaluating the performance and durability of fluid and steel materials by Hewko *et al*. in GM (1962).

In 1958, Perbury Engineering in the United Kingdom developed the same type of full-toroidal variator for a small passenger car with a hydromechanical torque control system (Fellows and Greenwood, 1991). Comparing to the full-toroidal CVT, a half-toroidal CVT has a feature of low spin of the elliptical contact, which reduces heat generation and gives a steep traction curve in the microslip region. In 1958, C.E. Kraus invented an equal torque transmission mechanism of multiple rolling elements of the half-toroidal variator by supporting tangential force through oil hydraulic pressure line (Kraus, 1972). This was applied to a small car, but was not commercially sold on the issues of durability of both traction steel materials and thrust ball bearings, and of another reason on the supporting mechanism of multiple rolling elements.

An important component is the traction fluid; Monsanto and Sun Oil provided traction fluid called *Santotrac* in 1968. This oil has high traction characteristics in the range of room temperature; however, it cannot bear high shear traction at the high temperatures for automobile use. Figure 2 shows temperature toughness of a newly developed traction fluid with alicyclic compound, Fluid 2, compared to a fluid with aromatic compound, Fluid 1, at a microslip of 4% test (Tsubouchi *et al*., 1990).

The former has a high stiffness of molecular bonds, as schematically shown in Figure 3.

On the tribological researches, the concept of elastohydrodynamic lubrication principle was proposed by Ertel and Grubin in 1939, and Dowson and Higginson succeeded to obtain spike pressure at the outlet of the contact numerically in 1959 (Hamrock and Dowson, 1981). Their analyses were useful for estimating the thin-film thickness in the elliptical contact. An innovative proposal on the traction force estimation using thermal elastic–plastic fluid model was made

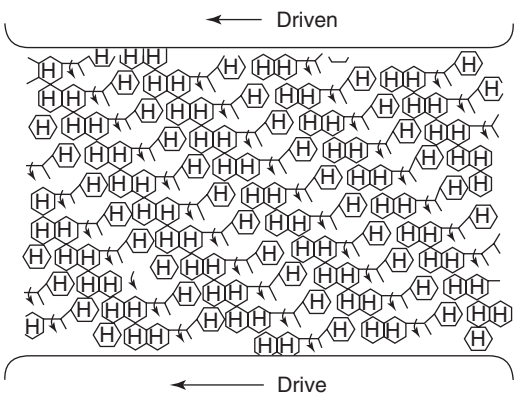

Figure 3. Molecular bonding model of traction fluid. (Reproduced from Tsubouchi, 1990. © Elsevier.)

by Tevaawerk (1980), which made it possible to calculate the efficiency of traction drives theoretically.

The traction drive CVT transmits tangential force F_t through glass-transitioned fluid by applying a contact force F_c between two rolling elements with a microslip as shown in Figure 4.

This microslip is usually called *creep*, $\mathrm{Cr} = (u_1 - u_2)/u_1$, and it is empirically known that the traction coefficient, $\mu_t = F_t/F_c$, increases with Cr in the microslip region and decreases after the saturation peak shown in Figure 5 because of temperature increase by gross slip. The working point is usually within the linear range of $\mathrm{Cr} = 1 \sim 2\,\%$ in Figure 5 and under a maximum traction coefficient of $\mu_t = 0.08$.

The rolling elements are pressurized by loading mechanism over the maximum Hertzian pressure of $P_{max} = 1.5$ GPa at a fluid temperature of $T_\theta = 75^\circ$C.

For designing a CVT, prediction of life is also important. In 1947, Lundberg and Palmgren proposed a stress-volume concept for subsurface-oriented failure of rolling bearings.

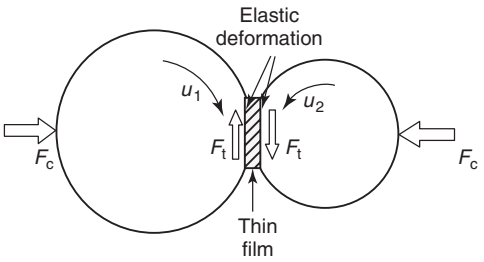

Figure 4. Traction drive image; F_c: contact force and F_t: traction force.

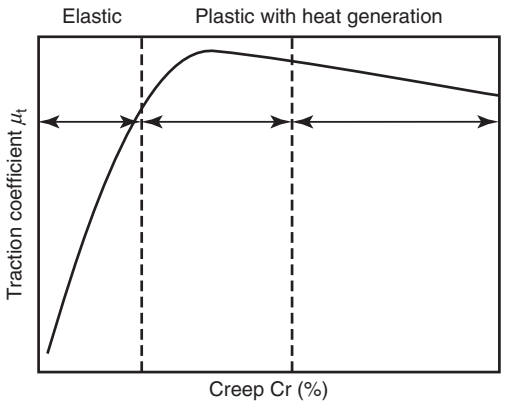

Figure 5. Typical traction curve: relation between creep Cr and traction coefficients μ_t.

Traction drive and ball bearing are definitely different on the tangential force action, but this formulation is simple and makes it possible to estimate the first-order rolling fatigue life (Coy, Loewenthal, and Zaretsky, 1976). Palmgren (1964) made also a database on the loss of several types of bearings. On the research of flaking, Suh (1973) gave many hints for heat treatment and purification of the steel materials.

In Japan, R&D of traction drive CVT for automobile use were started in 1979 and a 3L gasoline turbo passenger car came onto the market in 1999. A chronology of traction drive CVT history is shown in Table 1.

2 FILM THICKNESS, SHEAR MODEL, AND SPIN

2.1 Hertzian pressure in elliptical contact of toroidal variator

The toroidal variator transmits the traction force through the elastically deformed elliptical contact patches as shown in Figure 6 for the half-toroidal variator.

The size of this elliptical contact is calculated using the Hertzian theory (1881). Brewe and Hamrock (1977) proposed a simplified expression on the ellipticity parameter K and elliptic integral of the second kind ξ using equivalent radii R_x (rolling direction) and R_y:

$$\xi \simeq 1.0003 + 0.5968\left(\frac{R_x}{R_y}\right)$$

$$\text{and } K = \frac{a}{b} \simeq 1.0339\left(\frac{R_y}{R_x}\right)^{0.636} \quad (1)$$

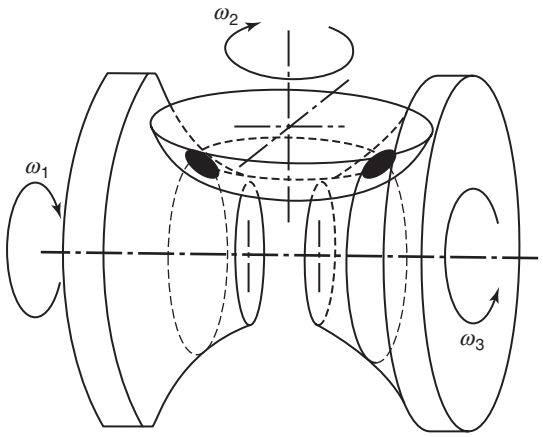

Figure 6. Elliptical contact patches of a half-toroidal variator. (From Tanaka, 2000. Reproduced by permission of Corona Publishing Co. Ltd.)

As an example of a half-toroidal variator in Figure 7, geometrical parameters are

$$r_{ax} = \frac{r_1}{\cos\varphi} = \frac{r_0(1 + k_0 - \cos\varphi)}{\cos\varphi},$$
$$r_{ay} = -r_0,\ r_{bx} = r_0,\ r_{by} = f_0 r_0 \tag{2}$$

where $k_0 = e_0/r_0$, $f_0 = R_{22}/r_0$, r_0 is the cavity radius and φ the tilting angle.

Then, the equivalent radii at inner (subscript i) and outer (subscript o) conjunctions are expressed by

$$R_{xi} = \frac{r_0(1 + k_0 - \cos\varphi)}{(1 + k_0)},\ R_{yi} = \frac{f_0 r_0}{(1 - f_0)},$$
$$R_{xo} = \frac{r_0[1 + k_0 - \cos(2\theta_0 - \varphi)]}{(1 + k_0)},\ R_{yo} = \frac{f_0 r_0}{(1 - f_0)} \tag{3}$$

where θ_0 is the half-cone angle of the power roller at the contact patch.

2.2 Film thickness and traction image

Höglund (1984) succeeded in visualizing the film thickness between a rolling steel ball and a sapphire disk lubricated by traction fluid. The schematic contour line of film thickness is shown in Figure 8. It can be seen that the flat area of central film thickness in the center and minimum film thickness at both edges.

Hamrock and Dowson (1981) expressed this central film thickness H_c using nondimensional parameters of speed U, material G, ellipticity K, and load W.

Figure 9 is an image of traction force transmission through the thin film and Figure 10 is a measured example

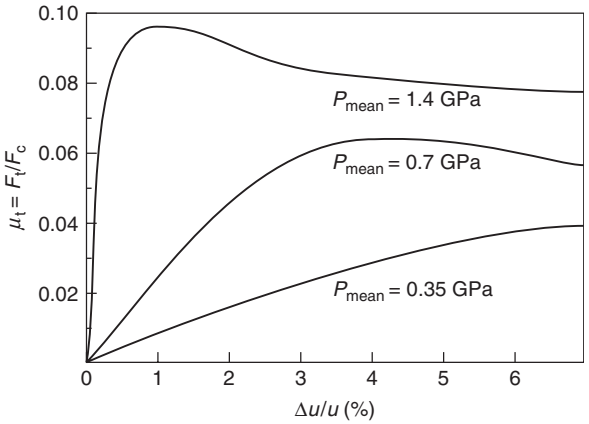

Figure 10. Example of traction curve measurement of the Santotrac 50 fluid, $u = 24$ m/s and $T_\theta = 75^\circ$C. (Reproduced with permission from Kraus, 1972. © C.E. Kraus.)

of a traction curve (Kraus, 1972). In these examples, it should be noted that the contact patch should be pressurized over 1.4 GPa for traction drive.

2.3 Shear model

The traction curve is important to predict a margin before gross slip. The curve is a relationship between microslip and traction coefficient. The traction coefficient is calculated theoretically by including microslip and spin on the elliptical contact. The shear stress is separated into an elastic region and a plastic region with heat generation (Tevaarwerk and Johnson, 1979). The shear stress of the thin film increases with creep linearly in the elastic region, but saturates at a lower value of limiting shear stress as shown in Figure 11.

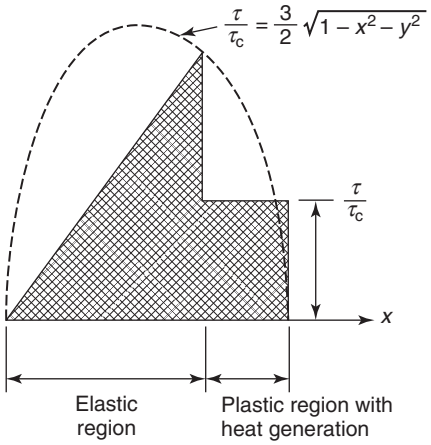

Figure 11. Elastoplastic shear stress model. (Adapted with permission from Tevaarwerk and Johnson 1979. © ASME.)

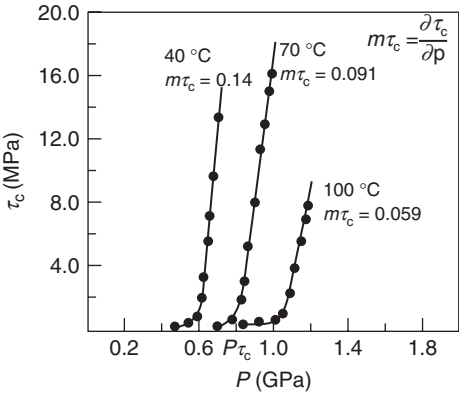

Figure 12. Measurement of limiting shear stress τ_c against pressure P for three temperatures of the Santotrac 50 fluid. (Reproduced from Höglund, 1984. © Luleå University of Technology.)

The grade of deterioration is calculated by iteration between the heat transfer mechanism of the rolling element and the limiting shear stress decrease of the traction fluid. An example of the glass-transition pressure and limiting shear stress of traction fluid as measured by Höglund is shown in Figure 12.

2.4 Spin

There are three major shearing motions in the elliptical contact. Creep in the rolling direction is the main component for traction force generation; sideslip perpendicular to the rolling direction plays an important role of generating the tilting force of the rolling element for speed ratio change; and spin normal to the elliptical surface decreases limiting shear stress of traction fluid because of heat generation. The spin occurs in the geometrical layout, as shown in Figure 13, by the pitch line of the contact not crossing the intersection of the rotating axes of the two rotating elements.

The film motion with spin is expressed schematically in Figure 14.

The equivalent traction force with spin is transmitted at an offset point of force pole from the elliptical contact center by f_p (Mägi, 1974).

3 FULL- AND HALF-TOROIDAL VARIATORS

3.1 Geometry

Full- and half-toroidal variators are characterized by the geometrical configuration of cone angle of the roller. In Figure 15, the cone angle of the full toroidal is $2\theta_0 = 180^\circ$,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

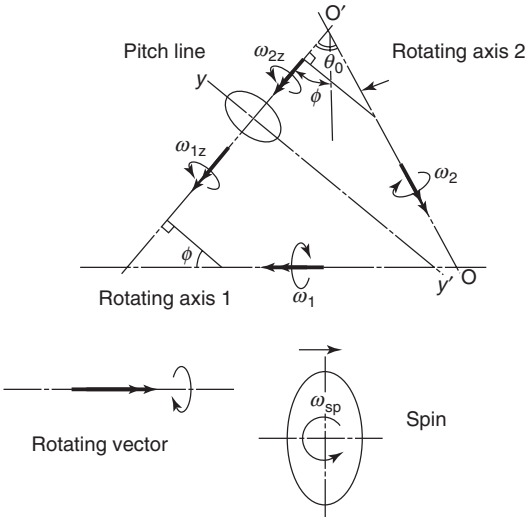

Figure 13. Spin: rotating motion of ellipsoid; the pitch line of the contact not crossing the intersection of the rotating axes of the two rotating elements.

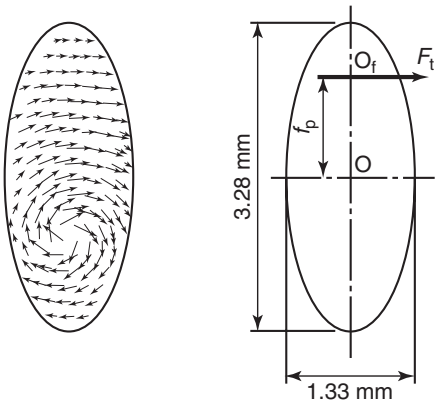

Figure 14. Schematic shearing model with spin and force pole O_f.

and, on the other hand, the half toroidal is smaller than 180°.

The choice of cone angle affects on the transmission efficiency because of spin and thrust forces on the rollers. The full toroidal has the advantage of no thrust force, but the disadvantage of high spin on the traction contact because the rolling axis of the roller is parallel to the pitch line of the elliptical contact at all tilting angles of the roller. On the other hand, the half toroidal has the advantage of small spin on the elliptical contact, but the disadvantage of supporting high speed and large thrust force of the roller. These mean that the full toroidal has issues on speed transmission efficiency, whereas the half toroidal has issues on torque transmission efficiency (Tanaka *et al.*, 1995).

3.2 Comparison of axial loading force and traction curves

It is significant to compare both toroidal variators on the traction curve and loading force by changing the cone angle. As an example, by fixing the speed ratio range of $e_s = 0.5:1$ to $2:1$, disk radius of $r_0 = 40$ mm, transmitted torque of $T_1 = 340$ Nm, a working traction coefficient of $\mu_t = 0.05$, and the same contacting size of disk radii of r_1 and r_3 in Figure 16. The loading force is compared and shown in Figure 17, where it can be seen that the

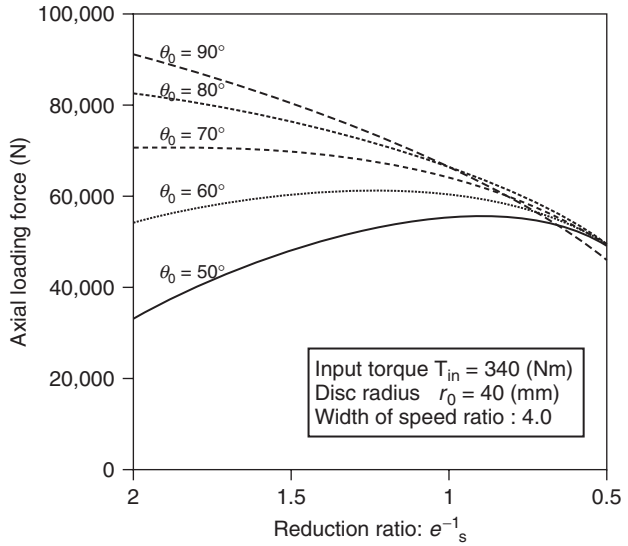

Figure 17. Axial loading force comparison by changing cone angles for transmitting torque of $T_1 = 340$ Nm at a traction coefficient of $\mu_t = 0.05$ in whole reduction speed ratio range; full toroidal ($\theta_0 = 90^\circ$) and half toroidal ($\theta_0 < 90^\circ$). (From Imanishi, Machida and Tanaka, 1996. Reproduced by permission of Takashi Imanishi.)

full-toroidal variator, $\theta_0 = 90^\circ$, needs double the loading force at maximum reduction ($1/e_s = 2$) against maximum speed increase ($1/e_s = 0.5$). The full toroidal cannot use mechanical loading, but only use a hydraulic loading system as shown in Figure 15b. On the other hand, the design of half-cone angle of $\theta_0 = 60^\circ$ keeps it to be almost constant in whole speed ratio range, which makes it possible to use a torque proportional cam loading system as shown in Figure 15a (Imanishi, Machida, and Tanaka, 1996).

The effect of cone angles on the traction curves are also shown in Figure 18. These are calculation examples at a working condition of speed ratio $e_s = 1$, input torque $T_1 = 340$ Nm, input rotational speed $N_1 = 4000$ rpm, cavity radius $r_0 = 40$ mm, and temperature $T_\theta = 75^\circ$C. The traction

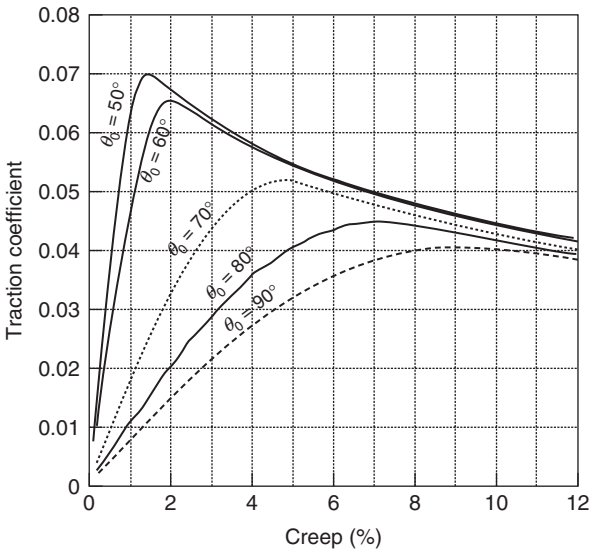

Figure 18. Effect of half-cone angles θ_0 on the traction curves; calculation at $e_s = 1$, input torque of $T_1 = 340$ Nm, input rotational speed of $N_1 = 4000$ rpm, cavity radius of $r_0 = 40$ mm, and temperature $T_\theta = 75^\circ$C. (From Imanishi, Machida and Tanaka, 1996. Reproduced by permission of Takashi Imanishi.)

curve of the half-toroidal variator is steep compared to the full toroidal because of low spin on the elliptical contact, which makes it possible to select a working point with higher traction coefficient.

4 ENDURANCE TEST OF TRACTION DRIVE DISKS

Rolling fatigue occurs usually on the driven elements because of the large tensile forces acting on the traction surface. Heat treatment giving compressive residual stress in the surface is one useful measure for elongating the life. It is well known that there are two types of flaking. One is subsurface flaking, due to reciprocal shear stress in the material, and the other is surface flaking, due to large tangential force transmission. In both cases, the original point of flaking is the place where harmful non-ferrous hard inclusions exist such as Al_2O_3 or $CaO \cdot Al_2O_3$. After removing these inclusions, surface flaking occurs because of the decrease of viscosity of traction fluid or the depletion of compressive residual stress of the steel by cyclic strong shearing. Figure 19 shows endurance test results of four half-size toroidal variators of 9–73.5 kW capacity (Machida, Aihara, and Tanaka, 1991).

In the figure, the black circles denote occurrence of flaking due to the decrease of viscosity of traction fluid by severe shearing in early developmental stage. Figure 20

is a sound disk photo after 10^8 running of 73 kW power transmission at $P_{max} = 2.15$ GPa.

Figure 21 is a photo of the center of running track magnified 500 times (Machida, Aihara, and Tanaka, 1991), in which straight lines of the grinding pattern of 0.2 μm in roughness still remain. This means that the traction film separates both rolling elements.

5 SPEED RATIO CONTROL SYSTEM

The variator changes its speed ratio by controlling the tilting angle of the rollers as shown in Figure 22.

The tilting force is induced by giving sideslip on the elliptical contact. The sideslip is another microslip perpendicular to the rolling direction. Figure 23 shows that the offset x of

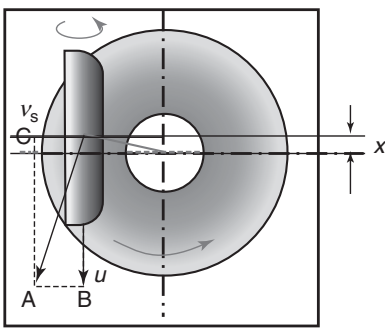

Figure 23. Sideslip (v_s) generation by giving offset (x) to the roller. (From Tanaka, 2000. Reproduced by permission of Corona Publishing Co. Ltd.)

DOI: 10.1002/9781118354179.auto084
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

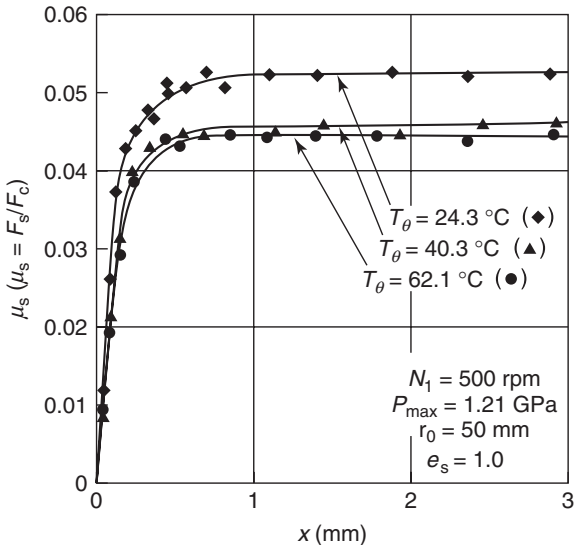

Figure 24. Measurement of nondimensional sideslip force at one contact. (From Tanaka, 2000. Reproduced by permission of Corona Publishing Co. Ltd.)

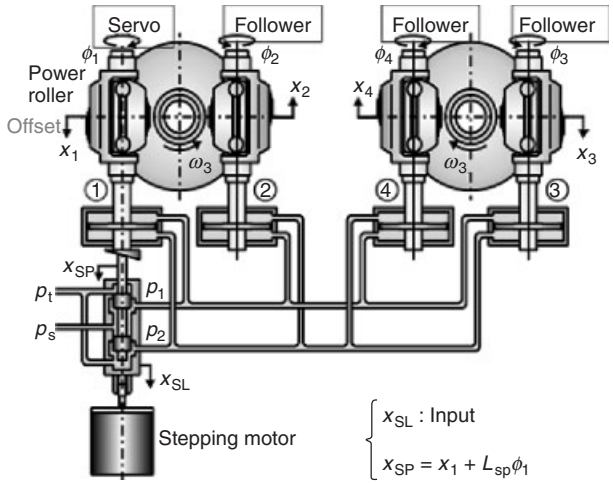

Figure 25. Speed ratio control system of a half-toroidal variator with four rollers; equal traction force transmission is achieved using hydraulically supporting pistons, and the servomechanism has two feedback loops of offset and tilting angle through a precise cam with gain L_{sp}. (From Tanaka, 2000. Reproduced by permission of Corona Publishing Co. Ltd.)

the rolling center gives rise to the sideslip. The sideslip v_s (direction C) is caused by the difference of rolling directions between the disk (direction A) and the roller (direction B).

Figure 24 is a measured example of the relation between the offset and the nondimensional sideslip force μ_s normalized by contact force. It can be seen that the offset x is adequate to be 0.5 mm at a maximum to prevent the decrease of traction force (Tanaka, 2000).

The control principle of half toroidal and full toroidal is different. The half toroidal controls the speed ratio of the variator, whereas the full toroidal controls torque in relation to the loading pressure. The half-toroidal rollers are supported by a hydraulic piston with offset and tilting angle control servomechanism as shown in Figure 25.

On the other hand, the full-toroidal rollers are supported by hydraulic pistons with caster angle without the need for a tilting angle control servomechanism as in Figure 26 (Fucks, Hasuda, and James, 2004) and hence, give speed ratio automatically.

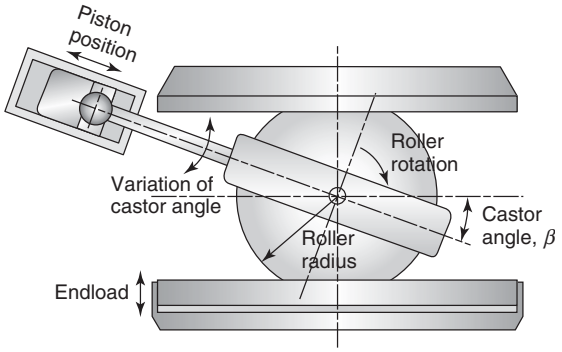

Figure 26. Torque control system of a full-toroidal variator; the roller supported by a hydraulic piston with caster angle. (Reproduced from Fucks, Hasuda and James, 2004. © R. Fucks, Y. Hasuda and I. James.)

6 ACTUAL TRANSMISSION DESIGN

A half-toroidal CVT was mounted in a 3L gasoline turbo passenger car in 1999 and remained in series production for several years. The transmission layout and the cross-sectional view are shown in Figures 27 and 28.

There are two toroidal cavities with two roller assemblies in each transferring drive from the end disks to central output disks. The input to the transmission is provided by

a torque converter that acts as a starting device, as well as increasing the ratio range. The CVT has two hydromechanical speed ratio control mechanisms for forward and reverse drives. Official data on the fuel economy at a Japanese 10–15 mode measurement is 9.7 km/L, which is 8% higher than the same model with 4AT.

NOMENCLATURE

Cr	creep, $\mathrm{Cr} = (u_1 - u_2)/u_1$
e_s	speed increase ratio ($e^{-1}{}_s$: reduction ratio)
F_c	contact force
F_t	tangential force
r_0	cavity radius
v_s	sideslip (microslip perpendicular to the rolling direction)
x	offset of the rolling center of the roller for generating sideslip
θ_0	half-cone angle
μ_s	nondimensional sideslip force normalized by contact force
μ_t	traction coefficient, $\mu_t = F_t/F_c$
τ_c	limiting shear stress of traction fluid
φ	tilting angle of roller
ω_{sp}	spin (rotating motion of ellipsoid)

Torque Transfer with AWD Systems

John A. Barlage, Todd L. Perttola, Larry Pritchard, and Tom Foster

BorgWarner, Inc, Auburn Hills, MI, USA

1 INTRODUCTION

Historically, AWD (all-wheel drive) was offered almost exclusively in pickup trucks and sport utility vehicles (SUVs), which were purchased primarily for their cargo loads and all-terrain capabilities (such as traction and mobility). In recent years, the demand for AWD systems has expanded. Drivers of passenger cars and crossover utility vehicles (CUVs) are demanding the technology for both traction and enhanced vehicle stability and handling. As the applications of AWD become more widespread, the technology becomes more complex, as is demonstrated in the following sections.

1.1 RWD-based AWD

In order to adapt a rear-wheel drive (RWD) vehicle to AWD, a transfer case is required to transfer power from the transmission to the front secondary drive axle. The transfer case is mounted between the transmission and the rear axle. The function of the transfer case is to transfer and manage torque from the transmission to both the front and the rear axles. A chain or geartrain (usually helical gears) is used to drive the front axle. Some transfer cases have some type of torque management device to control the torque distribution to the front and rear axles.

1.2 FWD-based AWD

In front-wheel drive (FWD) vehicles, the engine is typically mounted transversely or what is more commonly known as an *east–west* powertrain layout. In order to adapt the vehicle to AWD, a power transfer unit (PTU) is mounted to the differential case of the transaxle. This unit takes rotational motion from the transaxle and turns it 90° to drive a longitudinal propshaft that is attached to a secondary axle through a torque-coupling device.

2 TRANSFER CASES FOR RWD-BASED AWD

This section provides an in-depth analysis of the functional characteristics and construction of various transfer case types, used for RWD-based AWD. The transfer case is usually mounted directly to the back of the transmission and manages the torque distribution to the front and rear axles (Figure 1).

2.1 Part-Time AWD

Part-time AWD usually has a number of different operating ranges (high, low, and neutral) and modes (two-wheel and four-wheel) and is typically used in truck/SUV applications. The driver may select two-high (2H), four-high (4H), four-low (4L), and neutral.

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

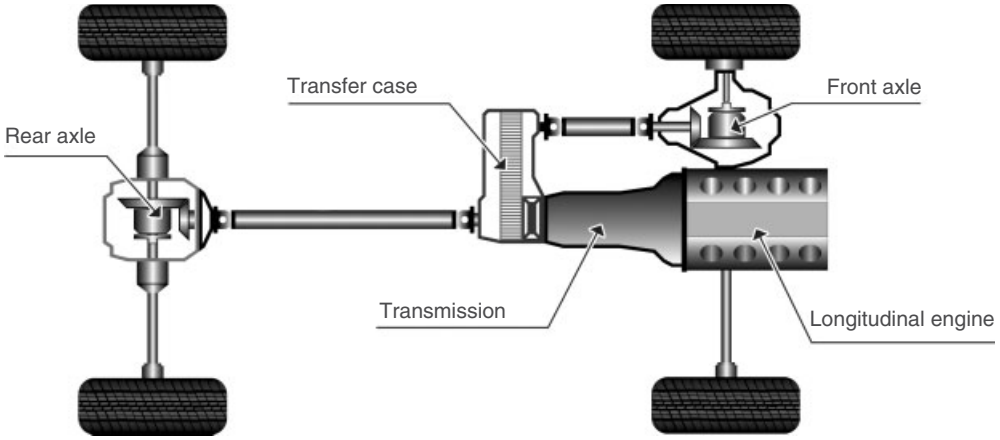

Figure 1. Typical RWD-based AWD architecture. (Reproduced by permission of BorgWarner, Inc.)

Two-high is normally used when driving on paved, dry roads. In 2H, only one axle (one set of wheels) is being driven (two-wheel drive). Four-high is used when additional traction is required, such as driving on ice or snow-covered roads or when operating off-road where the terrain is relatively flat without significant irregularities. In 4H, both axles (driving all four wheels) are mechanically connected and driven. The 4L mode operates similarly to 4H, but with a reduced gear ratio that multiplies the input torque.

Figure 2 shows the typical components of a part-time AWD transfer case. The operating modes of this type of transfer case are 2H, 4H, and 4L. Some systems will also have a neutral mode.

The 2H mode, used on paved, dry roads, provides power to only the rear axle and therefore the maximum efficiency to propel the vehicle. Auxiliary axle disconnect systems are often used when operating in 2H to stop all or part of the front axle from rotating to improve fuel economy and

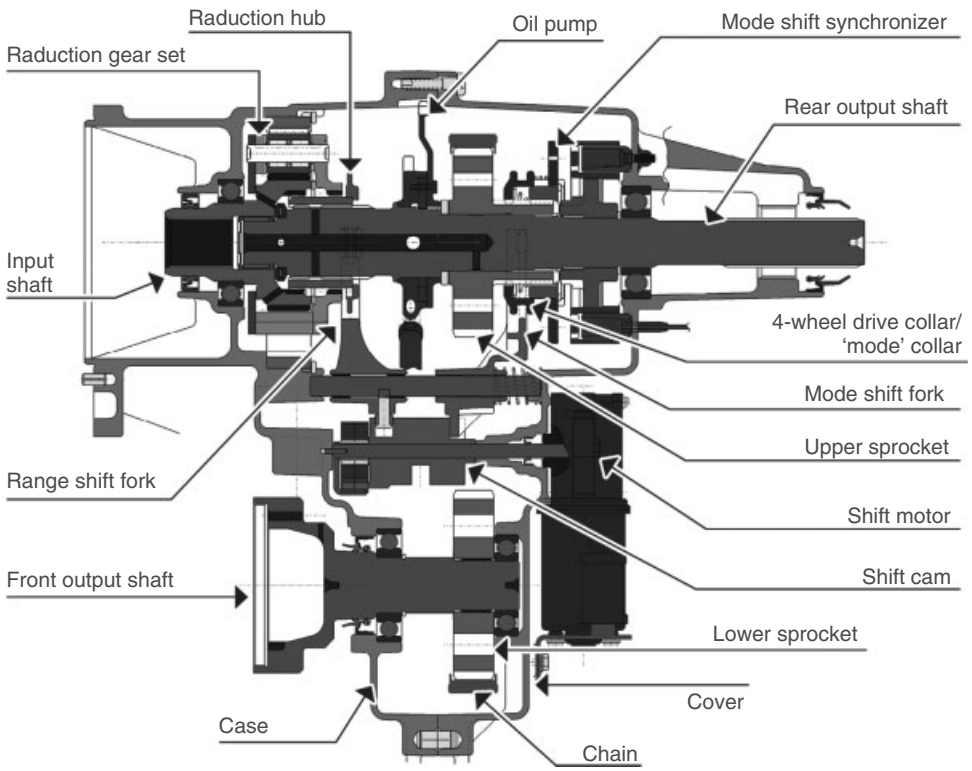

Figure 2. Typical transfer case components. (Reproduced by permission of BorgWarner, Inc.)

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

reduce noise, vibration, and harshness (NVH). In 2H, the front and rear wheels can rotate at different speeds because the front and rear axles are not locked together.

In 2H, power goes from the transmission straight through to the rear driveline (propshaft and axle). The input shaft and rear output shaft are connected together with a sliding dog clutch (reduction hub). Most components that drive the front wheels in 4L or 4H are disconnected to maximize fuel economy.

In 4H, the front and rear drivelines (propshafts and axles) are mechanically coupled together through some type of dog clutch arrangement and rotate at the same speed. There is no gear reduction in the transfer case in 4H. The torque at each propshaft is determined by the road or surface conditions, but the speed of front and rear propshafts remains equal. The input shaft and the rear output shaft are connected together with a reduction hub, whereas the rear output shaft and upper sprocket are connected together through a lock-up collar. Torque from the transmission drives the transfer case input shaft, which in turn drives the rear output shaft and upper sprocket. The front output shaft is driven by a chain that connects the upper and lower sprockets.

Four-low operation is similar to 4H in that the front and rear axles are locked together. However, the 4L mode also provides a gear reduction that multiplies the input torque before it is transmitted to the outputs. The additional torque is helpful in situations where maximum tractive effort is required, such as deep sand, deep mud, or when ascending steep grades. The additional gear reduction also increases the engine braking capability, allowing the driver to use the throttle instead of the brakes for ground speed control when descending steep grades.

The reduction hub is slid rearward connecting the rear output shaft to the planetary carrier. The rear output shaft and upper sprocket are connected together by the lock-up collar. Power from the transmission drives the transfer case input shaft and planetary sun gear (as they are splined together). Rotating the sun gear causes the planetary carrier to rotate in the same direction, but at a reduced speed as the planetary ring gear is fixed to the case. The rear output shaft and upper sprockets also rotate at this reduced speed because the output shaft is connected to the carrier by the reduction hub and the upper sprocket to the output shaft by the lock-up collar. The front output shaft is driven by a chain that connects the upper and lower sprockets.

In neutral, the power flow from the transmission to the transfer case outputs is interrupted. The vehicle can be towed in neutral without removing the propshafts. Care must be taken in the system design to ensure proper lubrication to the rotating transfer case components during towing, because the transfer case is equipped with a positive displacement lubrication system driven by the rotation of the mainshaft.

The reduction hub is positioned such that it is not connected to the input shaft or the planetary carrier. Power from the transmission is disconnected from the mainshaft. Rotational input from the wheels is isolated from the transmission.

2.1.1 Shifting from 2H to 4H while driving

Some part-time systems have a feature that allows the driver to shift from two-wheel to four-wheel drive while driving down the road at speed. This feature is commonly referred to as *shift-on-the-fly* (*SOF*). In SOF systems, a synchronizing device is employed to synchronize (match) the speeds of the front and rear output shafts, so the drive collar or dog clutch that connects the upper sprocket and mainshaft can be engaged smoothly. A variety of synchronization devices are used including mechanical cone-type synchronizers (similar to those used in manual transmissions) and electromagnetic clutches (such as those used in a number of BorgWarner's transfer cases). Additional details on synchronizers can be found in Synchronisers—Gear Change Process, Loads, Timing, Shift Effort, Thermal Loads, Materials and Tolerances.

Cone type is the most prevalent form of synchronizer used in transfer cases. Most manual transmission synchronizers are of the single cone design. However, in instances where there are particularly high synchronization torque demands, such as when shifting a transfer case from high to low range (high speed differential and transmission inertia) or mode shifting at high speeds, double or triple cone synchronizers—or unusually large-diameter single synchronizers—are required. Using intermediate rings increases the number of friction surfaces, resulting in increased frictional force, frictional torque, and heat dissipation.

Key components of a double-cone synchronizer are shown in Figure 3 and include the shift sleeve, synchronizer hub, struts, blocker rings, and gear cones.

Internal splines on the sleeve with angular-pointed ends mesh with the matching angular-pointed ends of the drive dogs on the drive gears at the completion of the shift. The sleeve has a circumferential groove that engages the shift fork, which then moves the sleeve axially. Notches in the internal teeth locate the pre-synchronization components (struts and springs).

The hub is attached to the output shaft (mainshaft) through internal splines with external splines that allow the sleeve to slide on it. Three notches on the circumference at each end of the hub engage corresponding lugs on the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

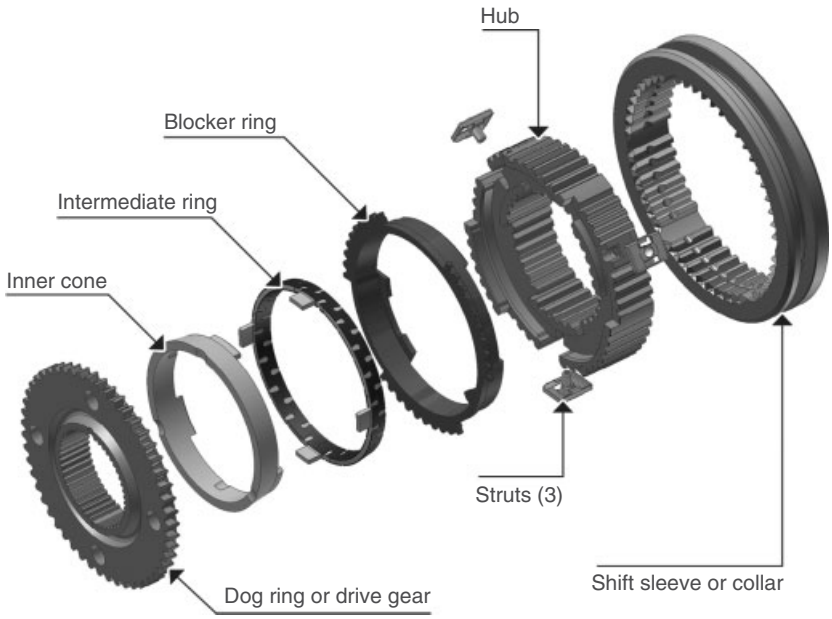

Figure 3. Components of a double-cone synchronizer. (Reproduced by permission of BorgWarner, Inc.)

blocker rings to prevent them from rotating. The hub has three axial slots for the pre-synchronization components.

The blocker rings were traditionally made from a special brass or bronze alloy. Modern production methods use organic or inorganic friction materials that are bonded to a steel or powdered metal core. The blocker rings have a cone-shaped surface on the inside diameter and "roof-shaped" teeth and lugs, which engage slots in the hub, on the outside diameter. The internal cone surface interfaces to an external cone surface on the drive gear. The blocker ring's cone surfaces have thread or groove patterns and axial grooves to allow faster displacement of the lubricant from the cone interface. The faster the lubricant can be displaced, the earlier the frictional torque increases, thus reducing the slip phase and resultant heat build-up.

Three radially movable struts are located on the circumference of the hub and spring loaded against three adjacent detent notches in the inside diameter of the shift sleeve. The struts can be ball bearings or roller bearings; or can be formed from sheet metal, powdered metal, or other processes.

The final element is the synchronizer cone, which is either machined onto the drive gear or is a separate steel piece welded onto the gear. The cone has "roof-shaped" clutching teeth machined at the outside diameter of the cone that mesh with the internal teeth in the sleeve when the shift is completed. In manual transmissions, the drive gear is supported on the mainshaft with roller or needle bearings. In transfer cases, the drive gear is integral with the upper sprocket.

During a shift, the shift fork slides the sleeve axially into position with the blocker ring. Owing to the chamfered sides on the detent notches inside the collar, the struts are compressed toward the center axis of the shift hub. The struts press the blocker ring axially against the cone on the drive gear. This action produces a frictional torque that causes the blocker ring to rotate slightly (limited by the hub groove width). The chamfered teeth on the sleeve contact the blocker ring teeth preventing premature axial movement of the sleeve. As the axial force from the shift fork increases, the resulting frictional torque brings the speed of the hub and drive gear (or sprocket) together, thus synchronizing them. When the speeds are equal, the frictional torque is eliminated. Because the shift force continues to act on the blocker ring teeth, the sleeve rotates the blocker ring and drive gear, allowing the teeth on the sleeve to slip into the blocker ring gaps and then mesh with the clutching teeth on the drive gear completing the shift. Operation of multiple-cone synchronizers is similar to the single cone design, except the intermediate cups and cones float between the main cones.

2.1.2 *BorgWarner electromagnetic synchronizer*

BorgWarner uses electromagnetic synchronizers in part-time transfer cases to facilitate the 2H to 4H shift while driving at road speeds. An electromagnetic synchronizer

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

consists of a stationary electromagnetic coil with a rotor or coil housing rotating around it and an armature placed in front of the rotor as shown in Figure 4.

The electromagnetic coil is an annular steel housing filled with insulated copper wire wrapped around the center axis. When voltage is passed through the wire, the resulting current generates an attracting magnet field.

The rotor is the component that rotates around the electromagnetic coil in close proximity to the outside diameter, inside diameter, and face of the coil. When the coil is energized, the rotor becomes part of the magnetic circuit. This part is usually attached to the mainshaft (rear output shaft). The armature is a flat plate usually attached to the upper sprocket via a collar.

When front axle synchronization is desired, the electronic control unit (ECU) energizes the magnetic coil with full available vehicle voltage (12 to 16 V). The shift system moves the armature, either touching it to or placing it in close axial proximity to the rotor. A magnetic flux circuit is created when the armature and rotor are touching each other. This is accomplished when the magnetic field generated by the coil flows through the rotor into the armature and back to the coil. This magnetic field causes an attractive force between the armature and the rotor.

The attractive force and the differential speed between the rotor and the armature causes a frictional torque to be imparted to the armature and thus to the upper sprocket. The upper sprocket translates the rotational force to the chain, then to the lower sprocket, and then to the front output shaft of the transfer case. The front propshaft and front axle assembly are attached to the front output shaft of the transfer case and are brought up to the same rotational speed as the rotor, thus the front driveline is rotating at the same speed as the rear driveline. The coil is shut off based on a prescribed time delay for synchronization or by input of front and rear driveline speed sensors.

2.2 Full-Time AWD

A typical full-time AWD system is always engaged and delivers power to all four wheels at all times. The power delivery is facilitated by an inter-axle or center differential in the transfer case. Full-time systems have a fixed torque split between the front and the rear axles. For example, the front to rear torque split for the BorgWarner 44–84 transfer case used in the Hummer H2 is 40 : 60, which means 40% of the input torque is distributed to the front axle and 60% to the rear axle.

The epicyclic (planetary) type is used as a center differential in the majority of full-time AWD applications, although the bevel gear type is still used in a few applications. Figure 5 depicts a typical full-time single speed transfer case (BorgWarner 44–79, used in the Cadillac STS) with an open-center differential. This center differential is an example of a transfer case using no ring gear and two sun gears. Power from the transmission flows to the planetary differential carrier. Power is then split between the front and the rear sun gears with the power going through one differential sun gear to the rear output shaft and the other sun gear to the front output drive sprocket, chain, then driven sprocket and front output shaft.

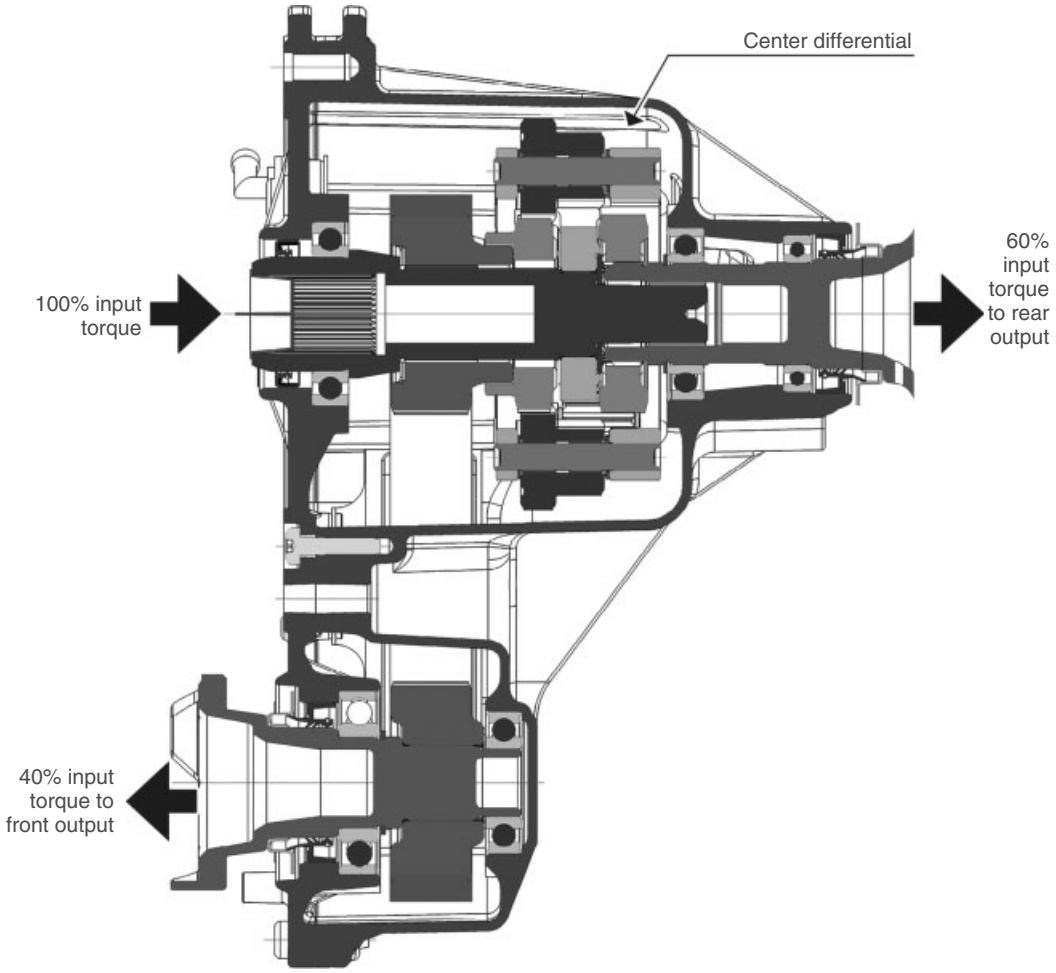

Figure 5. BorgWarner model 44–79 transfer case with open center differential. (Reproduced by permission of BorgWarner, Inc.)

For maximum traction, torque through the center differential must be controlled to ultimately distribute power to the tires with the greatest traction. Torque control, also known as *modulation*, can be done passively or actively with a torque biasing device or with brake-based traction control (TC) systems.

2.3 On-Demand AWD

An on-demand transfer case is directly connected to the rear (primary) axle and only distributes torque to the front (secondary) axle as required. Of the various AWD systems, on-demand systems are the most compatible with anti-lock braking systems (ABSs) and TC systems. In an on-demand AWD system, torque to the secondary axle is modulated by a torque management device; typically a wet clutch module within the transfer case.

Torque can also be directed to the secondary axle to improve vehicle handling on slippery or dry pavement. As the torque management device engages and disengages very quickly, a vehicle equipped with an on-demand transfer case can be driven on dry pavement without encountering the torque wind-up condition associated with a part-time system in the 4H or 4L mode.

Figure 6 shows a typical on-demand transfer case (BorgWarner 44–12, used in the Ford Explorer) in the on-demand (automatic) mode. When the automatic mode is selected, the electromagnetic clutch is engaged to synchronize the front and rear drivelines. The clutch is brought to a minimum current level that stages the components for any subsequent clutch increase and delivers approximately 35–70 Nm of torque to the front driveline. This torque level is too low to cause any torque wind-up problems during tight cornering maneuvers. The control system then monitors the speed difference between the front and the rear output shafts and increases the torque to the front output shaft if rear wheel slippage (speed difference between the front and the rear

output shafts) is sensed. In addition to output speed difference, the level of torque delivered can be determined from other vehicle parameters such as speed, throttle position, and accelerometer outputs. Once wheel slip is eliminated, torque to the front driveline is reduced to the staging level.

The BorgWarner 44–12 transfer case also has 4L and 4H operating modes. In these modes, maximum current is applied to the clutch resulting in a full lock condition similar to a part-time system. Power flow in 4L and 4H is the same as in a part-time transfer case. A variety of different torque management devices is used in on-demand transfer cases ranging from passive types to electronically controlled types.

3 POWER TRANSFER UNITS FOR FWD-BASED AWD

The term PTU is used to describe the automotive gearbox that is added to an FWD vehicle in order to facilitate the AWD architecture. The main difference between a PTU and a transfer case is that the PTU contains a right-angle gear system. This right-angle gear system is necessary because a PTU is mounted to a transverse (east–west) oriented transaxle, whereas a transfer case is mounted to a longitudinal (north–south) transmission.

Similarly to the transfer case, the PTU transfers power from the primary axle or wheels to the secondary (or auxiliary) axle. PTUs are most common on FWD-based AWD systems that typically incorporate the transverse (or east–west) powertrain layout. The PTU in FWD-based AWD vehicles is the focus of this section. There are, however, rear engine AWD vehicles that incorporate a PTU to deliver power to the front (auxiliary) axle.

There are two main types of AWD systems that utilize PTUs, which are full-time and on-demand. The main focus of this section is the PTU required for an on-demand system. We cover full-time PTUs later in the section. The primary shaft of the PTU is usually located on the output axis of the transaxle and is splined to the transaxle differential housing.

Figure 7 shows the typical packaging confines of a PTU. The halfshaft interconnecting linkshaft must pass through the primary PTU shaft. As a result, the primary shaft is hollow. This is one of the main sizing constraints of the PTU. The linkshaft must have a sufficient diameter to meet the torque requirements and duty cycle to drive the front wheel. The other typical sizing constraint for the PTU is the engine block and oil pan packaging envelope. With the size of the pass-through hole for the linkshaft and the engine and oil pan clearance defined, the inside and outside boundaries of the PTU are defined in the critical area of the primary shaft.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

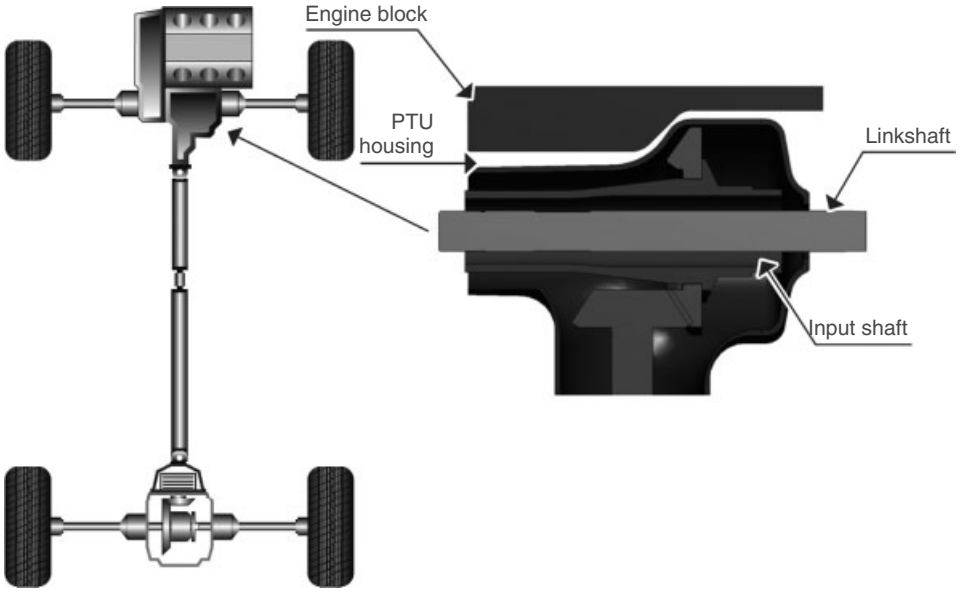

Figure 7. PTU integration to a transaxle. (Reproduced by permission of GKN Driveline.)

The two types of right-angle drive systems typically used are spiral bevel and hypoid gear systems.

The main difference between the spiral bevel and the hypoid gear systems is that the hypoid gear system has an offset. This is the difference between the centerline of the pinion and the centerline of the ring gear. Additional details on hypoid gears can be found in the chapter Basic Open Differentials.

The offset in the hypoid gear increases the contact ratio of the gear system, thus reducing NVH and providing more overall torque carrying capacity. The offset also creates more sliding at the ring/pinion interface. This sliding generates heat, pressure, and, without the correct lubrication, extreme wear. This resulting wear is the reason for extreme pressure additives in gear oil. This sliding also allows for lapping during the manufacturing process. Lapping refines the gear interface by rotating the gear members together under load with an abrasive fluid in the interface until an optimum contact pattern is established. The pinion offset is typically around 15–20% of ring gear outside diameter.

If there is not adequate space remaining to package a right-angle gearset in the PTU that meets the AWD system duty cycle, then one or more parallel axis gearsets are employed to facilitate locating the ring gear farther away from the confined area. These additional gearsets now change the single stage (hypoid set only) PTU to a two- or three-stage PTU.

In addition to creating packaging flexibility for the hypoid, adding the second or third stage of gearing may also reduce the torque requirement of the hypoid gearset. This is assuming that the parallel axis gear arrangement is a speed-increasing and torque-reducing arrangement. This gear arrangement may conversely be a speed-reducing and torque-increasing arrangement. Although not desirable, this arrangement may be required for some package environments. The consequence of adding multiple gear stages for improved packaging and torque optimization is that parasitic losses such as gear mesh losses, bearing and seal spin losses, oil churning, and increased mass will reduce the overall PTU efficiency and increase NVH.

The other main PTU packaging concerns are in the areas of the steering rack, exhaust, floor pan, and engine cradle cross members. All of these areas complicate the exact placement of the output shaft of the PTU. The other major issue with PTU placement is that the area behind the engine block intended for the PTU has minimal airflow. As a result of the gear sliding from the hypoids and other losses, heat is generated, which must be transferred to the lubricant and housing. In some extreme cases, liquid coolers have been added to help this situation. Most PTUs are not force cooled (primarily owing to cost and integration issues), so addressing the generated heat is yet another challenge during the design and development process.

Other noteworthy PTU design features that make it different from other gearboxes include the use of gear oil with extreme pressure modifiers similar to rear axle oil and a shaft-to-shaft seal between the hollow input shaft and the linkshaft to keep the transmission fluid separate from the PTU oil.

4 COUPLINGS FOR ON-DEMAND AWD

In this section, we cover couplings employed to manage the torque transfer between the front and the rear axles of AWD drivelines. On-demand AWD can be applied to either an FWD-based or an RWD-based AWD architecture. These are shown in Figure 8. In an FWD-based on-demand AWD driveline, the front axle is the primary driven axle and the function of the coupling is to transfer torque to the rear axle (secondary axle). In an RWD-based on-demand AWD driveline, the rear axle is the primary driven axle and the function of the coupling is to transfer torque to the front axle (secondary axle). The following coupling technologies can be applied in either of these architectures: dog clutch, passive, or active couplings.

4.1 Dog clutch for truck and SUVs

The simplest form of inter-axle control is the dog clutch arrangement used in part-time AWD systems. This type of clutch transmits power by engaging metal teeth or splines. It only allows direct mechanical engagement or disengagement without slippage or progressive torque transmission. Dog clutches are manually engaged using a lever or cable arrangement or electrically engaged by some type of electric motor/gear system.

Although the dog clutch is a very effective device for off-road traction, its use is fairly limited because of negative drivability issues when driving on-road. Because the system does not allow for speed differentiation between the front and the rear axles, driving on pavement can result in severe tire scrubbing and tight-corner binding. In addition, undesirable handling behaviors may occur during cornering. Dog clutch systems are only used on a part-time basis under extreme on- or off-road conditions, whereas on-road, these systems are typically disengaged. Dog clutch systems are typically offered on RWD-based pickup truck and SUV applications.

4.2 Passive and active on-demand AWD coupling control systems

Torque management technologies can be further categorized by the type of control system used (passive or active). Passive systems do not have an external control system to sense external variables. The operating characteristics of the passive systems are fixed and cannot be changed during operation to achieve a different set of operating characteristics. For example, the operating characteristics of a viscous coupling are determined by the number and diameter of the plates, viscosity of the fluid, percentage fill of fluid, and so on. The application of passive systems is sometimes limited because these systems can potentially interfere with the operation of other systems such as ABSs and electronic stability systems.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Active systems, on the other hand, use an external control system consisting of sensors to detect numerous variables (input speed, output speeds, and yaw velocity) and an ECU to process the signals that are sent to the actuation mechanism. Active systems are very versatile and can be integrated with other systems such as anti-lock braking, TC, stability control, and chassis control for improved vehicle-level performance. The system's capability is only limited by the number of sensors used and the control algorithm employed. Active systems can also be designed to be adaptive to compensate for hardware changes such as a degradation in the performance of the torque management device (clutch wear).

4.3 Speed-sensing passive couplers

On-demand passive couplers are self-actuated based on the speed difference across the device. They are also referred to as *speed-sensing*. Passive couplers generate a locking torque in response to the speed difference acting across the unit. There are typically three different methods to create a passive-type coupler:

1. Fluid friction
2. Hydraulic pump clutch actuation
3. Hydraulic resistance

4.3.1 Fluid friction type

The most common type of coupling using fluid friction is the viscous coupling. The coupling consists of a sealed housing with alternating inner and outer plates and is filled with a specific quantity of silicone fluid. One set of plates is connected to the housing of the coupling, which is then connected to the rear axle. Another set of plates is connected to the inner hub of the coupling, which is then connected to the front axle.

There are two operating modes in a viscous coupling, which are the viscous mode and the hump mode. The viscous mode is based on transmission of shearing forces in fluids. If the opposing surfaces of an inner plate and an outer plate move relative to one another in a fluid, a shear stress is produced in the fluid filling the gap. In a viscous coupling, this relative motion of the surfaces is achieved through a difference in the speed of rotation of the inner and the outer plates.

The silicone fluids used for viscous couplings are clear, nontoxic, and usually have a nominal viscosity between 5000 and 300,000 centistokes. The length of the molecule chains determines the flow properties—the longer the molecule is, the greater will be the viscosity of the fluid; the higher the nominal viscosity of the fluid is, the greater will be the torque that can be transmitted. The performance characteristics of the viscous couplings can be easily tuned to the vehicle in which it is to be used. The width of the gap between the inner and the outer plates also affects the torque transmission curve. The smaller the gap is, the greater will be the velocity gradient and the greater will be the transmitted torque at a given speed difference.

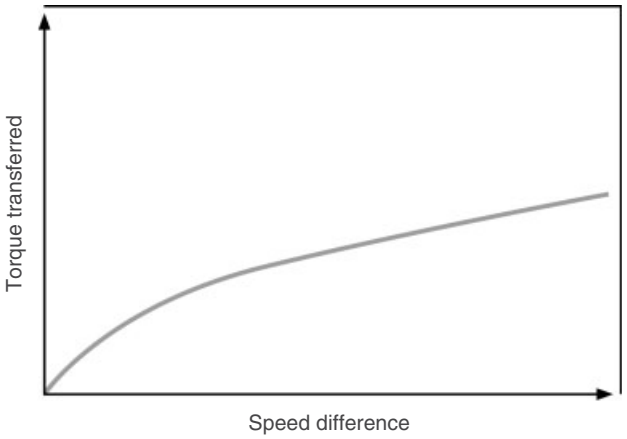

Figure 9. Generic viscous mode torque characteristic. (Reproduced by permission of BorgWarner, Inc.)

If a speed difference is present between the front and the rear axles, the outer housing rotates at a different speed than the inner shaft and the plates shear the viscous fluid. With increasing speed difference, there is an increase in torque transfer. The torque characteristic of this type of torque transfer device is said to be degressive. Figure 9 shows a typical speed-difference versus torque transferred. As the figure illustrates, the torque transferred at low speed differences is relatively high and increases quickly. As the speed difference increases, the rate of torque-transferred increase goes down. The physical properties of silicone fluid provide for significantly greater viscosity stable behavior across a wide range of operating temperatures as compared to using a mineral-based fluid.

The viscous coupling normally operates in the viscous mode, where torque transfer is accomplished by viscous shear (as described earlier). Under extreme driving conditions, the coupling will experience high speed difference and the fluid will begin to increase in temperature. The relatively large coefficient of thermal expansion of the silicone fluid causes the fluid inside the viscous coupling to expand considerably as the temperature increases. After several seconds of high speed difference, the fluid is expanded to such an extent that it fills all the available space inside the coupling, causing pressure to increase rapidly. This increase in pressure amplifies the throttling

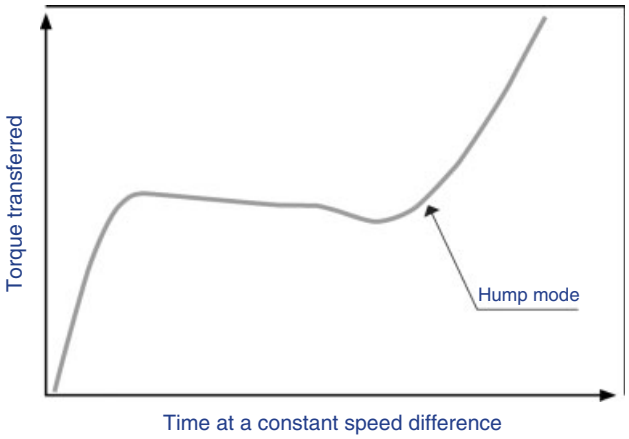

Figure 10. Generic hump mode torque characteristic. (Reproduced by permission of BorgWarner, Inc.)

effect between the plates, forcing the plates together and causing metal-to-metal friction to occur. The result is a substantial increase in torque transmission known as *self-induced torque amplification*, or *hump mode* (Figure 10), so named because of the hump-like shape of the torque curve. This torque amplification feature not only serves to protect the coupling against overheating but also provides additional traction in excess of axle skid torque.

The point where the hump mode is activated can be adjusted by varying the ratio of air and viscous fluid in the coupling. These adjustments allow the hump mode to be tuned so that it only engages under extreme driving conditions, or not at all (depending on the desired action).

Because this is a passive device, the final torque characteristic tuning selected must cover both winter and summer driving conditions as well as minimize tight corner binding. To ensure compatibility with certain ABSs, in the case of an FWD-based AWD vehicle, a free-wheel mechanism can be incorporated between the coupling and the rear axle to allow the rear wheel to overrun (allows the rear axle to be temporarily disconnected) during vehicle braking.

4.3.2 Hydraulic pump clutch pack actuation types

There are several different mechanizations using a hydraulic-type pump to develop hydraulic pressure in response to a speed difference. This resulting hydraulic pressure is then applied to engage a clutch pack. Two typical methods of generating hydraulic pressure are as follows:

1. Mechanical pump type
2. Rotary blade type

4.3.2.1 Mechanical pump type. A mechanical pump-type system can use a gerotor-, vane-, or piston-type pump, combined with an apply piston and a set of friction-based clutches. Typical applications use a gerotor-type pump. The housing can be connected to one of the axles (input) and the rotor can be connected to the other axle (output). When there is a speed difference between the axles, the pump begins turning and the fluid flow is initiated. This flow is then directed to an apply piston that will in turn press against a series of interleaved clutch plates. The greater the speed difference is, the greater will be the hydraulic pressure, and therefore the greater will be the amount of torque transferred.

Figure 11 shows a typical torque transfer versus speed difference curve for a gerotor-type pump. The curve can be shifted left or right in the design phase depending on the vehicle requirements. Examination of the graph in Figure 11 suggests that as the speed difference increases, the torque delivered is nearly proportional. The curve is actually progressive and the ease of engagement at lower speed differences helps to smooth out the engagement of the device. This correlation actually helps to protect the device from high speed partial engagement situations. Because the device relies on mineral-based oil for the hydraulic fluid, a temperature compensating bimetallic valve is typically used to adjust fluid flow based on the temperature-dependent viscosity properties of the fluid used. This valve helps ensure adequate performance over a wide range of fluid temperatures and viscosities.

4.3.2.2 Rotary blade type. Another type of self-actuating coupling that combines certain aspects of the viscous coupling and the pump/clutch-type coupling is the rotary blade coupling (RBC). This device consists of

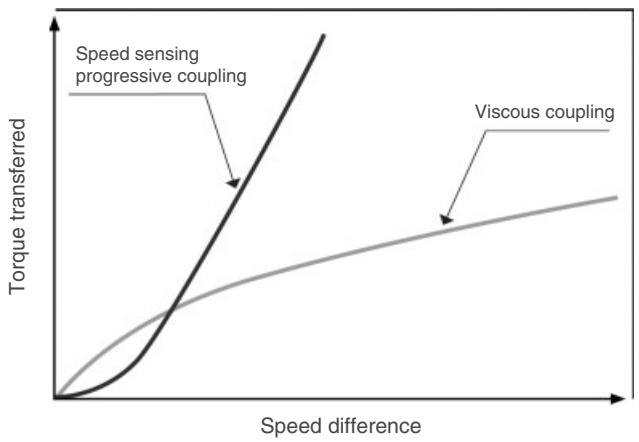

Figure 11. Generic gerotor-type passive progressive coupling torque characteristic. (Reproduced by permission of BorgWarner, Inc.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto086

a sealed chamber filled with silicone fluid containing a tri-bladed disc, an apply piston, and a clutch pack. When there is a speed difference across the unit, the relative speed of the blades moving through the silicone fluid develops a pressure gradient that pushes on the apply piston, which in turn exerts axial force on the clutch pack.

With increasing speed difference, the apply pressure is generated and thus a higher torque transfer is achieved. The triblade design also offers the opportunity for a different geometry on the front and backside of the blade, which allows for an asymmetric torque characteristic. This feature is useful when tuning a vehicle's throttle-off handling behavior.

4.3.3 Hydraulic resistance type

Hydraulic resistance couplings typically use an axial piston pump in combination with a hydraulic valve body to generate a locking pressure proportional to the speed difference. Basically the device creates a hydraulic lock effect to resist the speed difference. The valve body typically has a temperature-compensating mechanism and the ability to reduce the locking torque characteristic based on the absolute speed of the device.

The input shaft of the coupling contains a cam profile, whereas the housing (output side) contains the individual piston-type pumps. The pistons ride along the cam profile generating the hydraulic pump effect.

4.4 Active couplers actuation methods

On-demand active couplers are externally controlled by an ECU and generally fall into three categories of actuation:

1. Electromagnetic
2. Electrohydraulic
3. Electromotor

As compared to the various passive coupler technologies covered in the previous section, active couplers offer significant vehicle-level benefits. Active systems are externally controlled with access to various sensors (input speed, output speeds, yaw velocity, etc.) and an ECU to process these signals, directly controlling the actuation mechanism. Active systems are very versatile and can be integrated with other systems such as anti-lock braking, TC, stability control, and chassis control for improved vehicle-level performance. The system's capability is only limited by the number of sensors used and the control algorithm employed.

4.4.1 Electromagnetic actuated coupling

The conventional design for an electromagnetic actuated torque coupling consists of an electromagnetic coil; an all-metallic primary clutch pack and a three-piece welded clutch housing assembly with a nonconductive metal ring for electromagnetic field management; an armature; and a secondary clutch pack. Energizing the coil creates a magnetic field flow around the coil through the clutch housing and through the primary clutch plates. The metal armature is attracted by the magnetic field, which in turn, compresses the steel plates of the primary clutch. This action generates the torque in the primary clutch, which is then amplified by the cam mechanism to engage the secondary clutch (Figure 12). With increasing current to the coil, there is a corresponding increase in torque transfer.

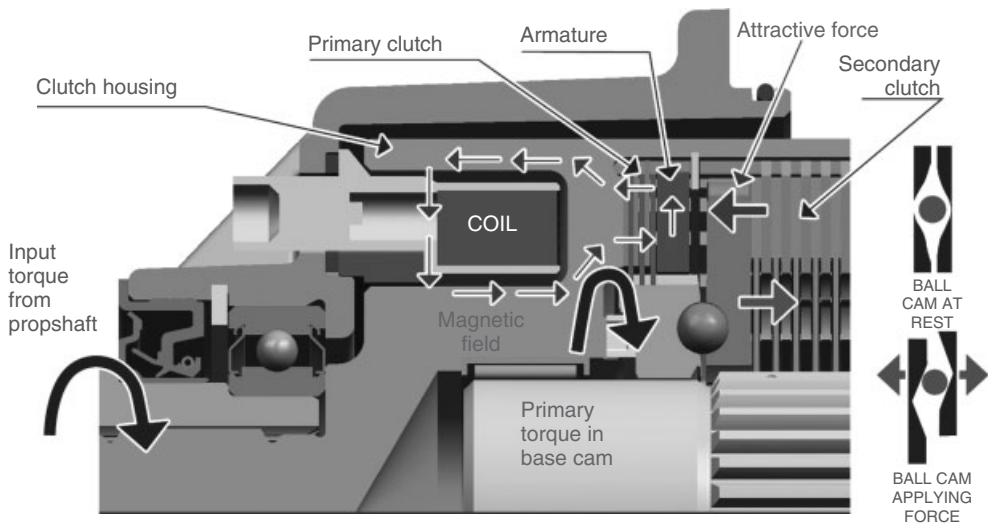

Figure 12. Conventional electromagnetic coupling function. (Reproduced by permission of BorgWarner, Inc.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The cam mechanism consists of a set of concentric balls reacting inside two opposing cams. The available torque in the primary clutch causes the input cam to rotate at a different speed than the output cam. The relative rotation of the cams allows the balls to move along the ramps of the cams to create axial force toward the base cam and the apply cam. The axial force that is put to the apply cam is directed toward the secondary clutch pack. This primary clutch torque represents about 10% of the output torque supplied by the system.

The secondary clutch pack consists of sets of friction and separator plates. The friction plates are splined to the output shaft. The separator plates are steel plates with specialized processing and finishing and are splined to the input shaft through the clutch housing. When the axial force from the ball-cam assembly (cam mechanism) is applied to this clutch pack, the compression of the clutch pack and the relative rotation of the input and the output components create the secondary clutch torque, which is about 90% of the output torque supplied by the system. The magnetic field path must travel through the primary clutch to attract the armature. This requires that the inner and the outer primary clutches be made of steel to allow the magnetic field to pass through.

In addition, a complex three-piece welded clutch housing assembly with a nonconductive metal ring is required for electromagnetic field management. Because the magnetic field must travel through the coil housing and across the metallic clutches, the field must bridge multiple air gaps. Because of these gaps, manufacturing and assembly processes must be highly controlled to minimize torque variations. This type of AWD coupling can be found in a wide range of applications.

Electromagnetic coupling technology can also be applied in such extreme vehicle applications as in the Porsche 911 Turbo (Type 997) in which the coupling transfers torque from the rear axle to the front axle.

Recently, there has been an evolutionary change to the primary clutch design and function. Instead of driving a magnetic circuit through the clutch, the primary clutch is now electromechanically actuated. An electromechanical force is generated by an electromagnet attracting the armature in a manner similar to a solenoid function. Three apply pins are connected to the armature and directly pull the primary apply plate which, in turn, compresses the primary clutch.

The compression action generates the torque in the primary clutch, which is then amplified by the cam mechanism to engage the secondary clutch. Because the electromagnetic field directly attracts the armature, there is only one air gap that the field must bridge. Because of this reduced gap, an all-metallic primary clutch design is no longer required nor is complex three-piece steel clutch housing necessary. Instead, an organic friction material-faced primary clutch and aluminum clutch housing can now be used.

In addition to the reduced complexity of this design, the use of an organic friction-faced primary clutch has an additional benefit. In the conventional design, the steel primary clutches tend to generate metallic debris over its lifetime: this wear can change the properties of the oil and deteriorate the frictional properties of the primary and secondary clutches. These changes can result in NVH issues. However, with the new actuation design, the source of metallic debris is eliminated because the primary clutches in this model are faced with organic-type friction material, thereby ensuring excellent NVH performance over the life of the application.

Electromagnetic couplings can also be applied to transfer case applications. The working principle is similar to that in the previously described conventional design. Energizing the coil creates a magnetic field flow around the coil, attracting the armature to the rotor. The armature is connected to one side of the cam mechanism, whereas the rotor is connected to the other side of the cam mechanism. The action of the armature generates the torque in the primary clutch, which is then amplified by the cam mechanism to engage the secondary clutch. This action is demonstrated back in Figure 12. With increasing current to the coil, there is a corresponding increase in torque transfer.

This type of RWD-based on-demand AWD transfer case application can be found in a wide range of vehicles from passenger cars to SUVs. This design also facilitates front axle disconnect systems because of its relatively low drag torque characteristic. This same technology can be used to provide both on-demand AWD to the rear axle of an FWD-based AWD vehicle and side-to-side torque transfer. Such a system is called a *twin on-demand layout*. The right and left wheels are individually coupled to the ring gear via the electromagnetic couplings.

Torque transfer to the rear wheels is achieved without a differential gearset. By actuating the couplings, torque can be transferred on demand to the rear wheels. This layout also provides significant side-to-side traction capability. In addition, if the couplings are controlled in conjunction with additional sensors (to detect the occurrence of lateral acceleration and yaw, for example), significant vehicle dynamics performance can be gained such as power-on torque vectoring in a turn.

4.4.2 Electrohydraulic actuated coupling

These active devices actively control hydraulic pressure to directly engage the clutch pack via an apply piston. The

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto086
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

hydraulic pressure can be generated in the following three typical ways:

1. Mechanical pump in conjunction with an electric feeder pump
2. Electric pump in conjunction with a pressure accumulator
3. Direct hydraulic pressure control using an electric pump

4.4.2.1 Mechanical pump in conjunction with an electric feeder pump. A typical mechanization of this type of system consists of a piston-type pump, which generates a pressure when there is a speed difference across the unit. The hydraulic pressure from this mechanical pump is electronically controlled by a variable flow valve to direct the apply pressure to the clutch. There is also a mechanical overload valve to handle torque truncation for driveline torque overload protection and a supplemental electric pump for added system response. Figure 13 shows a schematic representation of how a typical piston-type pump functions.

The performance of the electrohydraulic actuated coupling device can be tuned based on the software algorithms that control the position of the valve. The ECU is integrated into the device and measures the fluid temperature directly so that the software control can compensate for changing viscosity of the fluid. Fluid temperature measurement is used to gain a better understanding of internal temperature of the device and contains a built-in thermal protection strategy. There are three separate pumping circuits for this type of system, which are the piston pump, the electric feeder pump, and the apply piston. Each of these circuits is arranged in such a manner that the total output of the circuit is a smooth, continuous flow rate.

4.4.2.2 Electric pump in conjunction with a pressure accumulator. This further advancement to this design is the so-called "power pack" approach, in which an electric motor drives a hydraulic pump, in conjunction with a pressure accumulator and a variable flow control solenoid valve. The oil pump is controlled to charge the pressure accumulator to a high supply pressure and the solenoid valve meters the necessary pressure on-demand to apply the clutch. Such systems can apply the clutch independent of speed difference. Figure 14 shows such a system applied as an FWD AWD coupling.

4.4.2.3 Direct hydraulic pressure control using an electric pump. This more recent advancement in electrohydraulic clutch actuation not only provides direct

actuation of the clutch independent of speed difference, it does so without a pressure accumulator or pressure control solenoid or pressure sensor. An example of this type of system shown in Figure 15 uses an axial piston pump in combination with a centrifugal overflow valve mechanism, which allows accurate pressure control based on controlling the current to the pump motor. This type of system provides accurate and responsive performance with fewer components and with reduced complexity.

4.4.3 Electromotor actuated coupling

These active devices use a controlled electric motor to mechanically actuate the clutch. The most common approach is to use an electric motor driving a cam mechanism. Mechanical cam actuation consists of the electric motor driving a cam-type mechanism to translate rotational displacement into axial displacement. This can be achieved in several ways. An example is a system that uses an electric motor rotating a cam profiled output, which in turn causes the scissor-like mechanism to directly rotate a unidirectional ball cam mechanism, thereby inducing an axial force to compress the clutch pack.

5 CONCLUSION

FWD- and RWD-based AWD drivelines have unique architectures and also have some common torque transfer requirements. Actively controlled AWD torque transfer devices continue to grow in popularity as they enhance vehicle traction and handling performance while also contributing to higher system efficiency as compared to passive-type AWD systems. Actively controlled AWD torque transfer technologies will continue to evolve to deliver reduced mass and cost as well as increased response performance as part of fully integrated vehicle system together with brake-based TC and brake-based stability systems.

Clutch Wet

Yuji Fujii, Nimrod Kapas, and Jau-Wen Tseng

Ford Motor Company, Dearborn, MI, USA

1 INTRODUCTION

An oil-lubricated friction device has been utilized in automotive applications since the early twentieth century (Gott, 1991). It was first introduced as a means to simply couple or decouple rotating drivetrain components through a friction force (see Mechanics of Contacting Surfaces). A frictional interface of the wet clutch is lubricated with a transmission fluid (see Tribological Optimisation in the Powertrain) for cooling to protect the device from thermal damage. The fluid flow provides a significantly higher rate of heat rejection as compared to a dry friction device (see Dry Clutch). Largely speaking, there are two types of wet friction devices: wet plate clutch and wet band brake (Fujii *et al*., 2003). At present, the wet clutch is most commonly employed in a mass-production planetary-gear-based automatic transmission to alter torque paths for automated gear ratio changing (see Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly). The wet clutch is also found in a hydrokinematic torque converter (see Automotive Torque Converters) to establish a mechanical connection, as desired, between an engine and an automatic transmission input shaft. Most recently, it is applied as a torque coupling device in a hybrid electric vehicle powertrain or HEV (see Micro, Mild and Full Hybrid, Power Split Configurations). It switches on and off a transmission of engine torque into a driveline on demand. The wet clutch has also evolved as a tool to control a torque transmission level from one component to another. Specifically, a clutch actuation force (see Clutch Actuation) is modulated to achieve a desired level of torque transmitted across the slipping frictional plates. For example, the wet clutch technology is utilized as a vehicle launch device in a lay shaft automatic transmission, which is often referred to as *dual-clutch transmission* or *DCT* (see Dual Clutch Transmissions (DCT)—Layouts, Clutch Selection, Packaging, Actuation, Manufacturing & Assembly). Its slip control is a key to a smooth vehicle launch without inducing undesirable driveline noise, vibration, and harshness (NVH) disturbance (see Drive Train Noise, Vibration and Harshness, Launch Control) in the absence of a torque converter. A limited slip differential system or a torque split device in a transfer case may also employ a wet clutch-based device (see Passive and Active Limited Slip Differentials).

Although the wet clutch technology has been around over 100 years, its design continues to evolve to meet ever-increasing challenges in fuel economy improvement, drivability enhancement, and shift quality refinement. For example, in a typical 6-speed planetary transmission system, two to three wet clutch packs are open at any time during vehicle operations. They collectively result in nonnegligible amount of viscous drag, measurably affecting overall driveline efficiency (see Tribological

ISBN: 978-0-470-97402-5

Optimisation in the Powertrain and Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly). Automotive original equipment manufacturers (OEMs) and suppliers continue to look for clutch plate designs to lower viscous drag. During a typical shift event, one clutch is brought to an engagement, whereas another clutch is released in order to alter torque paths within gear sets. A mismatch in torque level and handshake timing between the on-coming and off-going clutches affects shift quality (Winchell and Route, 1961). It is important that the two clutches behave in a consistent and predictive manner in order to avoid an objectionable shift feel to a vehicle occupant. However, in practice, it remains a challenge to optimize a clutch deign to achieve low drag and consistent engagement and release controllability at the same time. New technologies, such as DCT, employ a wet clutch as a vehicle launch device to transmit torque from engine to driveline without the use of a hydrokinematic torque converter. The wet clutch slip control becomes very critical during vehicle launch to smoothly transmit a desired amount of drive torque from an engine side to a driveline without incurring an undesirable driveline NVH disturbance.

Regardless of its functional importance in drivetrain systems, wet clutch design analysis and optimization remain a challenge because of the complexity of physical processes in clutch operations. Open clutch analysis involves an interaction between multiphase fluid and rotating plates with grooves (Aphale, Schultz, and Ceccio, 2010; Takagi *et al*., 2011). Air bubbles are introduced at a high rotating speed, significantly affecting drag torque level. Engagement and release analysis requires a transient moving-boundary partial lubrication modeling (Cho *et al*., 2011). Fluid flow dynamically interacts with macro features such as plate grooves and microgeometry such as surface asperities. While the recent advancement in computational fluid dynamics methodologies may lead to a usable design support tool in the near future, clutch design improvement effort continues to heavily rely on a trial-and-error approach at time of writing.

This chapter presents an overview of the wet clutch technologies, including device construction, operating mechanisms, physical characteristics, and design practice. A typical wet clutch structure, components, construction materials, and key geometric features are described in Section 2. The wet clutch operating characteristics are explained in depth in Section 3. It includes the description of physical processes for open clutch, engagement and release behaviors in relation to fuel economy, automatic shift quality, and durability requirements. A clutch design practice based on the Systems Engineering is reviewed in Section 4. It also describes the recent trend in clutch design features, analytical tools, and test methodologies, followed by the concluding remarks in Section 5.

2 WET CLUTCH STRUCTURE

Wet clutches come in a variety of packaging configurations for different drivetrain applications. For example, a multiplate clutch for automatic shifting differs considerably from a single plate lockup clutch placed in a fluid-filled torque converter. Their design features also continue to evolve to meet ever-demanding controllability and durability requirements. However, the underlying operating principles remain the same to couple and decouple rotating components through wet friction. Accordingly, all the clutch designs include the common functional elements. This section describes the major components that are found in a typical wet clutch device. A clutch system for a planetary-gear-based automatic transmission is used for the illustration purpose as shown in Figure 1. Friction plates and separator plates are alternatively placed within the clutch housing. A set of friction and separator plates are called a *clutch pack*. The friction plates are mounted on a center hub, which is driven by a rotating drivetrain element. Separator plates are splined to the housing that is connected to another drivetrain element. The interface between the plates is lubricated with a transmission fluid. The plates are retained between the retainer ring on one side and the apply piston on the other end. When the clutch is open, friction plates and separators plate are allowed to rotate at different speeds while shearing fluid at the interface. When clutch engagement is commanded, an actuator applies a loading force onto the apply piston (see Clutch Actuation). A hydraulically driven actuator, depicted in Figure 1, is most commonly utilized for automatic transmission applications. The piston is stroked against a return spring while squeezing oil film at the frictional interface. The torque is initially transmitted through viscous shear between sliding plates. As the oil film is squeezed out, mechanical contact takes place between the friction and separator plates, partially transmitting torque through mechanical friction. As the engagement continues, the mechanical friction constitutes the entire engagement torque. The clutch engagement completes when the friction and separator plates are securely coupled. The construction and function of major components are described later for additional details.

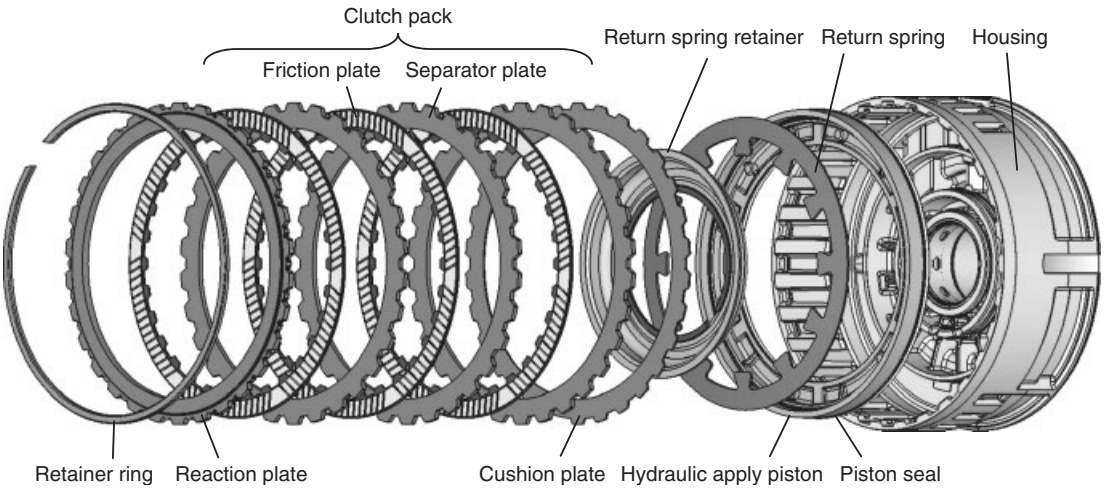

Figure 1. Major components of wet clutch system.

2.1 Major components

2.1.1 Friction plate

The primary function of the friction plates is to transmit torque from its spline-connected drivetrain element to the separator plates through wet friction (see Mechanics of Contacting Surfaces, Tribological Optimisation in the Powertrain). It is important that the friction plate provides stable friction characteristics under all operating conditions for smooth engagement, consistent release, and controlled slip. The friction plates must also possess sufficient static torque capacity when the clutch is functioning as a torque holding device. As illustrated in Figure 1, a typical friction plate, commonly referred to as the *double-sided plate*, is constructed with a friction material bonded to both sides of the steel core plate that has either internal or external spline. When the packaging space is limited, the friction material can be bonded on one side only, known as *single-sided friction plates*. In this design, the steel core plate also acts as a mating surface and heat sink for the adjacent friction plate. Thus, the steel core plate for the single-sided friction plate is significantly thicker than that for the doubled-sided plate. Shallow grooves are cut or pressed into the surface of the friction material lining in an application-specific pattern as a passive lubrication flow control device as later described in Sections 3 and 4. Alternatively, deep grooves can be formed between small friction material patches bonded to the core plate.

A friction material is made of organic fibers that are bonded together with resin as depicted in Figure 2. The structure is reinforced with synthetic fibers and certain chemical compounds for enhanced thermal and frictional

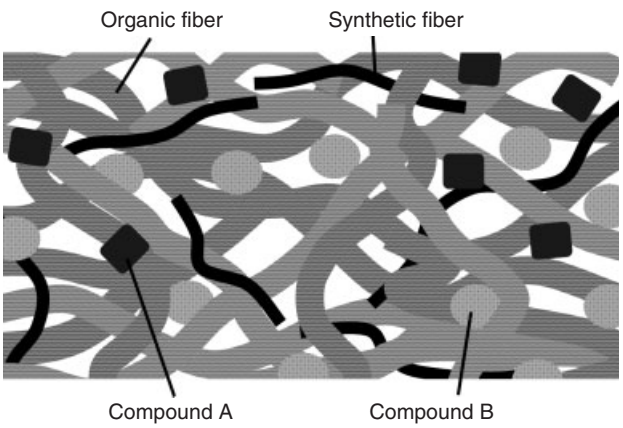

Figure 2. Friction material structure.

properties (Hirano *et al*., 2007). The compositions of fibers and the amount of pores within the structural matrix are considered important design parameters that affect oil flow within the material. In order to also adjust frictional characteristics, its surface layer may be embedded with friction modifier compounds. Both the structure and elements of friction materials are considered competitive information and not publically disclosed.

2.1.2 Separator plate

The function of separator plates is to transmit torque from its frictional interface to another gear element. The separator plate also acts as a heat sink to absorb heat generated during engagement and release. Thus, its thickness or thermal mass becomes an important design parameter to meet targeted slip conditions and duty cycles. The separator

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

plate is typically made from cold-rolled steel using either fine blanking or conventional stamping processes. A surface treatment for special micro-texturing may be employed to condition lubrication flow at the interface for fine-tuning frictional characteristics.

2.1.3 Reaction plate

A reaction plate, which is referred to as *pressure plate*, is the component located at end of the clutch pack as illustrated in Figure 1. It is placed directly against a retainer ring. It provides the reaction force against the clutch actuator, uniformly supporting friction and separator plates. Owing to the strength requirement, the pressure plate has a thick cross section and is typically made of powder metal. In some packaging deigns, a drivetrain component that is adjacent to the clutch pack may act as a pressure plate, providing the reaction force.

2.1.4 Retainer ring

A retainer ring is commonly used to retain clutch components such as a pressure plate and a return spring. It is made from spring steel and typically has a rectangular cross section. The retaining ring is formed by a coiling process. The ring has a circular shape in free state and is conformed into a noncircular shape in an installed position. This may present as an issue in applications that have small ring engagement depth. The ring may be pushed out under loaded conditions. For designs that require better conformance or higher retention force, a noncircular free-state shape retainer ring can be used.

2.1.5 Apply piston

In an automatic transmission system, a hydraulic actuator is most commonly utilized, although other types such as electromechanical or electromagnetic devices are also available (see Clutch Actuation). Its apply piston transforms hydraulic pressure into axial force exerted onto the clutch pack. Among the various types of piston designs, a stamped steel piston with a bonded seal and a machined aluminum piston with a loose seal are commonly employed in production applications. The reciprocating seal placed on the piston prevents the leakage of pressurized hydraulic fluid. Its design selection depends on seal drag requirements, sealing pressure, dynamic duty cycles, bore diameter, and seal groove tolerances. The most commonly used seals are O-rings, D-rings, and lip-type seals. A typical clutch piston is designed with a single hydraulic apply area. Alternatively, a clutch actuator may possess dual piston areas for enhanced torque controllability during engagement. Only the first piston area is initially pressurized, providing a low pressure-to-torque control gain for better slip management. Once the dynamic event is completed, the second area is pressurized to achieve high static torque capacity for securely holding the clutch pack. The dual-gain system can also be implemented through different approaches. For example, two hydraulic areas may act in opposing directions with differential cross sections. In this arrangement, the clutch has lower torque capacity when both areas are pressured while higher torque capacity is achieved by actuating a single area. In certain applications such as an automated engine start–stop system (see Micro, Mild and Full Hybrid), it is desired to lock the clutch piston in a pressurized position using an isolating valve without constantly delivering the pressurized fluid. However, maintaining a steady pressure level is difficult because of minute, yet continual fluid leakage across the piston seal. A hydraulic accumulator (see Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly) may be utilized to hold the clutch piston in place, complementing the isolating valve.

2.1.6 Piston return spring

A return spring pushes the piston back to its released position when the hydraulic pressure is lifted. A coil spring pack and a disk-type spring are most commonly used in automatic transmission clutches. The coil spring pack consists of multiple coil springs that are held together by a steel spring retainer. The disk spring, which is illustrated in Figure 1, is stamped from spring steel and formed into a conical shape through heat setting and tempering processes. The load is obtained by compressing and flattening its conical geometry. While both types of spring provide the same function, they have distinct load characteristics. The coil spring pack produces a relatively linear load curve with up to 10% variability. The disk spring, on the other hand, has a nonlinear load behavior. It generally has the highest spring rate at the installed height. The nonlinear characteristics provide robustness against stroke distance change caused by friction material wear. Another benefit of the disk spring is packageability with its small axial length. However, the disk spring tends to have a higher load variation in the range of $\pm 20\%$.

2.1.7 Cushion plate

An optional cushion plate is inserted between the apply plate and the hydraulically operated clutch actuator, as depicted in Figure 1, to mitigate the initial engagement shock. It may take a shape of a waved plate or a coil spring.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto090
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

It is sometimes difficult to precisely control hydraulic pressure as the piston approaches its end of stroke. A sudden change in piston motion may result in an undesirable pressure overshoot under certain operating conditions. The cushion plate provides the cushioning effects, slowing down the piston motion for smoother transient pressure profiles. It is often found for wet clutches utilized for drive and reverse engagements in a planetary-based automatic transmission.

2.1.8 *Apply plate*

An apply plate (not shown in Figure 1) may be inserted between the clutch pack and the clutch actuator piston. The function of the apply plate is to uniformly distribute loading from the actuator onto the clutch pack. Accordingly, it generally has a larger thickness for higher structural integrity as compared to separator plates. Depending on design geometry and maximum load requirement, the apply plate can be made from powder metal, fine blanking, or conventional stamping.

2.1.9 *Clutch housing*

Clutch housing encases all the major clutch components. As illustrated in Figure 1, a hydraulic piston is directly placed at the end of the housing case, forming a hydraulic chamber. A hydraulic control system feeds a pressurized fluid into this chamber for clutch actuation. The housing has spline joints that directly engage separator plates and transmit torque to either a transmission case or a rotating gear member. Holes or slots are added to the housing to provide cooling lubrication flow into the frictional interfaces and to exhaust it to the outside of the housing. The clutch housing is typically made of a formed steel cylinder with a welded hub or constructed with machined aluminum. Steel is a common choice of material for many applications. Cylinders can be formed by different manufacturing processes, such as flow forming, transfer die forming, or a combination of stamping and Grob forming. The use of aluminum allows the inclusion of complex geometries, casted spline, and nonuniform cross sections. However, extensive machining may be required at higher cost to create hydraulic passage, snap ring grooves, and piston bores. The aluminum housing tends to have lower structural integrity because of its material strength and higher porosity.

2.1.10 *Balance dam*

Wet clutches are classified into two types based on their specific roles in drivetrain applications, namely the brake clutch and the rotating clutch. While they provide the same function to couple and decouple gear elements, the power flow arrangements are different. The brake clutch is utilized to ground a gear member to a nonrotating element. In case of a planetary gear set, this provides a means to alter torque path for automatic gear ratio changing. The rotating clutch, on the other hand, couples two gear members, rotating at different speeds. When the clutch is fully engaged, the gear elements become mechanically coupled and rotate in unison. The rotating clutch is widely employed in a planetary-gear-based automatic transmission and also in DCT as a launch device.

As illustrated in Figure 3, the brake clutch and the rotating clutch have a slightly different design feature. The housing of the rotating clutch rotates at all time, exerting centrifugal pressure onto the fluid trapped in the hydraulic chamber. A special design consideration must be made to avoid the so-called clutch drift-on where the centrifugal pressure overcomes return spring force, inadvertently stroking the apply piston for partial engagement. Two design approaches are available to mitigate this condition:

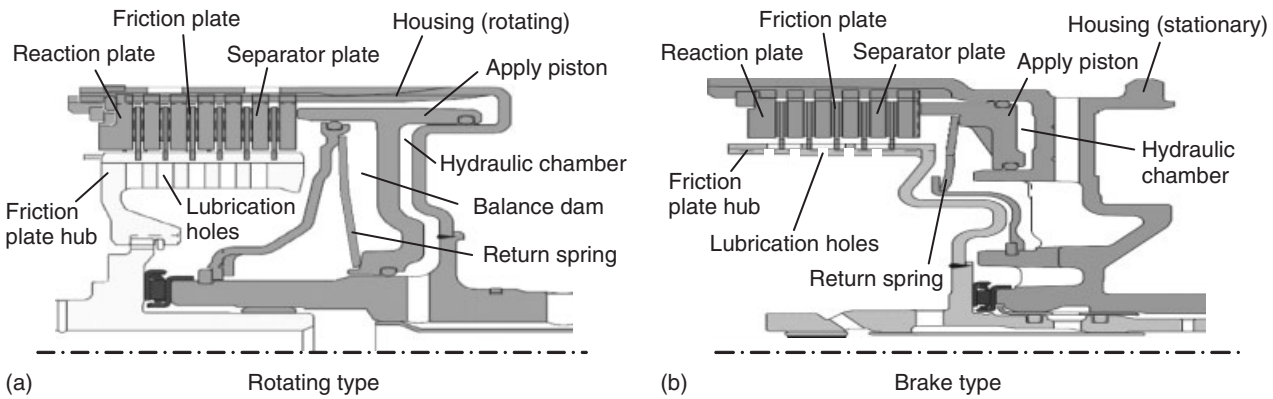

Figure 3. (a,b) Wet clutch design layout.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto090
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

one is to exhaust fluid in the hydraulic chamber by means of a ball check valve that is designed to open above a specific rotational speed. The second approach is to create a balance dam on the other side of the apply piston. A lubrication flow channel is designed to route transmission fluid into the balance dam. During the transmission operation, the centrifugal pressures on both sides of the apply piston cancel each other.

2.2 Lubrication design

The interface temperature rises significantly during repeated clutch engagements or extended slip control. In the construction of clutch assembly, a special attention must be paid to dissipate heat from the frictional interface to prevent the degradation of wet friction characteristics. That is, the temperature must not exceed a thermal limit of the friction material at any time. High temperature also accelerates the decomposition of transmission fluid additives, affecting wet frictional behaviors. A transmission lubrication system (see Tribological Optimisation in the Powertrain) is designed to deliver a targeted amount of cooling fluid into the clutch hub. The oil holes and slots are designed on the hub to uniformly distribute the lubrication flow across the clutch pack. The fluid flow rate must be at a sufficient level to provide adequate cooling effect. At the same time, it should not be excessive to avoid detrimental effects on open clutch drag and engagement behaviors. The drainage channels are designed into the clutch housing to efficiently exhaust fluid from the clutch pack.

3 OPERATING MECHANISMS

Clutch behaviors are highly sensitive to system configuration, design features, and operating conditions. Each application requires specific adjustments to achieve desired performance targets. This section describes open clutch behaviors, engagement and release mechanisms, followed by thermal characteristics. As previously mentioned, clutch drag reduction translates into fuel economy gain in an automatic transmission system. Robust clutch controls for superior drivability and shift quality rely on consistent and predictable clutch engagement and release processes. New drivetrain technologies such as DCT require demanding clutch duty cycles under challenging thermal conditions. The in-depth knowledge of wet friction mechanisms is a key to developing robust clutch systems. Clutch operating mechanisms and underlying physical processes are described later, based on multiplate clutch pack geometry for a planetary-gear-based automatic transmission.

3.1 Open clutch

When a multiplate clutch pack is open, friction and separator plates rotate independently at a relative slip speed, shearing the transmission fluid in-between. Each frictional interface is typically designed to have a clearance of 0.1–0.2 mm. The narrow clearance is critical to maintain engagement controllability, however, at the expense of open clutch efficiency. The clutch drag torque depends on many factors such as a number of friction interfaces, groove geometry, slip speed, fluid properties, flow rate, and temperature. Figure 4 illustrates typical drag characteristics as a function of slip speed for a clutch pack inside a warmed-up transmission system. Drag torque rises linearly in low slip range, peaks in the middle, and drops at high speeds. The physical explanation for this behavior is well established based on the fluid mechanics. The lubrication fluid flows into the friction interfaces from the inner hub as described in Section 2.2. The grooves on rotating friction plates pump and distribute fluid between the plates. At low speed, the friction interface is filled with lubrication fluid with fully developed laminar flow. As illustrated in Figure 4, the linear dependence of clutch drag on slip speed can be captured well by the Newton's law of viscosity (Kitabayashi, Li, and Hiraki, 2003):

$$T \approx rA\left(\eta \cdot \frac{v}{h}\right) \tag{1}$$

where T is drag torque, v is sliding speed, h is clearance, r is effective friction plate radius, η is dynamic viscosity, and A is friction surface area. At higher speed, the drag torque deviates from the linear behavior. This is because the centrifugal pumping effect exceeds fluid supply level, entraining air into the interface. The transition from single-phase to multiphase flow regime occurs around the peak torque location in Figure 4. Small air bubbles initially develop at the interface. The air volume grows larger at a

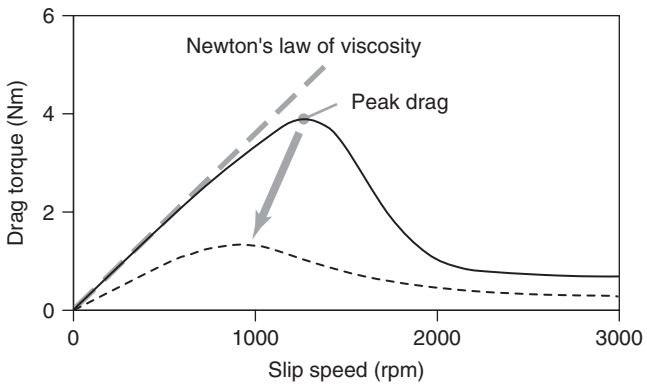

Figure 4. Clutch drag characteristics.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto090
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

higher slip speed, displacing the fluid and reducing viscous drag. One of the challenges in wet clutch design is to lower the overall drag curve, as depicted in the figure, without compromising engagement controllability. There are various design factors that can be adjusted to reduce the peak drag and shift its location (speed). Groove geometry, friction plate waviness, and fluid flow rate are among them. Although the principal mechanisms are understood for open clutch drag, it remains challenging to accurately model the effects of design variables because of complex flow geometry (Aphale, Schultz, and Ceccio, 2010; Takagi *et al*., 2011). Friction material and lubrication fluid also affect clutch drag characteristics. However, their changes are far more costly and require much longer lead time than geometry modifications.

3.2 Engagement

Clutch engagement is the process to couple friction plates and separator plates through wet friction. It begins with open clutch condition and ends when all the plates are securely grounded or coupled to rotate in unison. Clutch engagement torque, generated by wet friction, is directly transmitted to a vehicle drive shaft during automatic shifting. High sensitivity of clutch torque to operating conditions makes shift controls challenging. For example, Figure 5a illustrates the effects of temperature on transmission shift quality that can be actually observed in a vehicle (Fujii *et al*., 2003). The clutch actuator delivers nearly identical hydraulic pressure to the apply piston at hot and cold conditions. However, drive shaft torque profiles, which directly reflect clutch torque, differ significantly, creating inconsistent shift feel. Clutch engagement characteristics tend to be design-specific and vary widely, depending on applications. Thus, comprehensive knowledge on engagement mechanisms as well as underlying physical principles becomes a valuable asset to address unique challenges encountered during a clutch development process.

When a clutch engagement is commanded, an apply piston is hydraulically stroked to press all the friction and separator plates against the reaction plate. Lubrication fluid is squeezed out from the interfaces through complex flow geometry. During the initial phase, clutch torque is transmitted by wet friction that is primarily based on viscous shear between the rotating plates. As the fluid layer becomes thinner, a mechanical contact takes place between friction material asperities and separator plate, partially transferring torque through mechanical friction. Mechanical friction torque grows larger through the engagement process while viscous torque drops because of rising temperature and diminishing fluid volume at the frictional

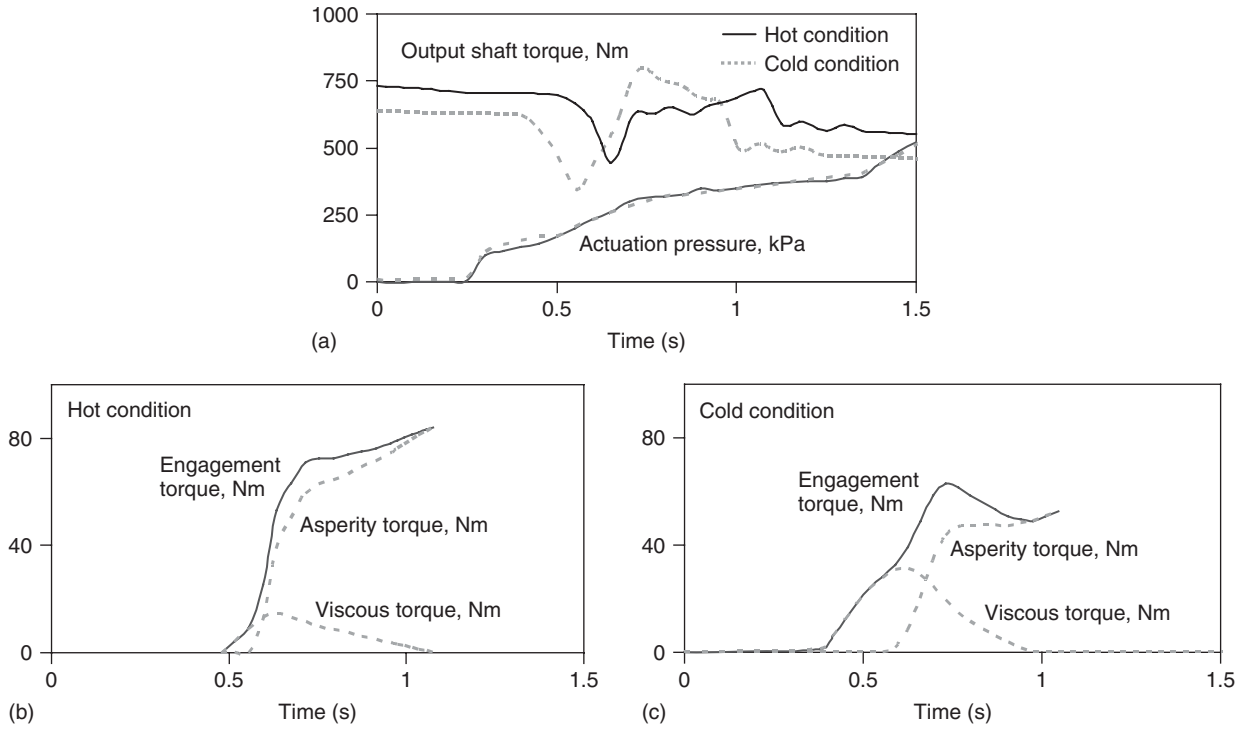

Figure 5. (a–c) Example of engagement behaviors.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto090
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

interface. Mechanical friction eventually constitutes the entire wet friction, transferring torque through asperity contact. A real contact area of the asperities is surprisingly small and limited to a small percentage of a nominal friction surface area even under loaded conditions (Otani and Kimura, 1994).

Clutch engagement characteristics are largely affected by the squeeze film process that is highly sensitive to both geometry and fluid conditions. The classical fluid mechanics theory can be employed to describe the physical principles involved in the squeeze film process (Hamrock, 1994). As illustrated in Figure 6, a relative rotation between the friction and separator plates carries the Couette flow. Lateral and translational plate motion creates pressure gradient, driving the Poiseuille flow. The Couette flow and the Poiselle flow move fluid in and out of the groove. The groove acts as a centrifugal pump to push the fluid across its channel. The fluid is transported by pressure gradient into the permeable friction material that has a porous structure. This complex squeeze film process can be captured by the average Reynolds equation (Patir and Cheng, 1978, 1979) derived from the Navier–Stokes equation under the assumption of uniform pressure across film thickness (z-direction):

$$\frac{\partial}{\partial x}\left(\frac{\phi_x \cdot \rho \cdot h^3}{12 \cdot \eta} \cdot \frac{\partial p}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{\phi_y \cdot \rho \cdot h^3}{12 \cdot \eta} \cdot \frac{\partial p}{\partial y}\right) = \frac{\partial}{\partial x}\left(\frac{\rho \cdot \overline{h_T} \cdot v}{2}\right) + \frac{\partial}{\partial x}\left(\frac{\rho \cdot \phi_s \cdot v}{2}\right) + \frac{\partial}{\partial t}(\rho \cdot \overline{h_T}) - u \tag{2}$$

where x and y are spatial coordinates; ϕ_x, ϕ_y, and ϕ_s are empirical flow factors that represent the effect of surface asperities on fluid flow; ρ is oil density; h is film thickness; p is fluid pressure; η is dynamic viscosity; $\overline{h}_t$ is average film thickness; v is linear sliding velocity, t is time; and u is exuding velocity of fluid into the porous friction material. The left-hand side of Equation 2 represents the Poiseuille flow driven by pressure gradient, and the first term on the right-hand side describes the Couette flow driven by sliding motion.

The average Reynolds equation forms a basis of comprehensive clutch engagement analysis. When coupled with heat transfer and asperity contact model (Greenwood and Williamson, 1966), its solution, in principle, provides fluid film thickness and asperity contact load for computing transient clutch engagement torque. However, a numerical method is yet to be established to solve the average Reynolds equation for complex three-dimensional clutch geometry. A practical application of the average Reynolds equation requires a considerable simplification in model geometry (Berger, Sadeghi, and Krousgrill, 1996; Fujii, Tobler, and Snyder, 2001). Nonetheless, it still provides valuable insight into wet friction characteristics as illustrated in Figure 5b and c (Fujii *et al*., 2002, 2003). Under hot fluid condition, clutch engagement torque largely consists of asperity contact torque. However, at cold condition, a combination of large viscous torque and delayed asperity contact results in a torque peak during the engagement process. This engagement behavior explains a large output shaft torque oscillation in Figure 5a observed in a vehicle at cold conditions. A recent trend in the high fidelity multi-physics clutch modeling is described in Section 4.2.

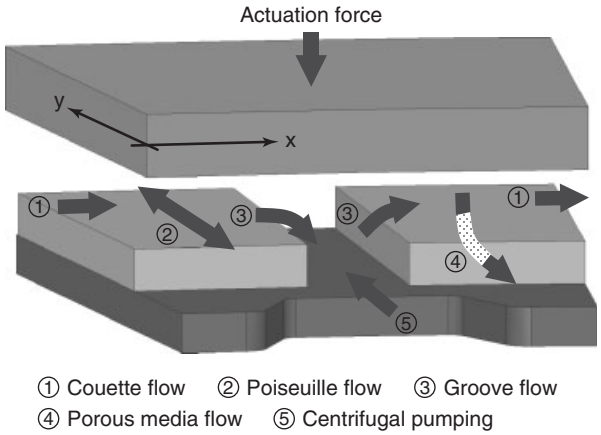

Figure 6. Fluid flow during engagement.

3.3 Release

The wet clutch release characteristics are particularly important for a clutch-to-clutch shift application (see AT Control—Actuation Methods & System Integration, Gear Choice, Gear Shift Strategy & Process, Adaptive Features). During the shift event, an off-going clutch must be released synchronously when another clutch reaches a certain torque level during its engagement process (Winchell and Route, 1961). A missed synchronization leads to inconsistent shift feel or unpleasant shift shock. However, a wet clutch often exhibits erratic breakaway in response to slowly dropping hydraulic control pressure. Figure 7 illustrates three distinct release behaviors often observed in an actual vehicle. Case 1 shows a nominal release behavior as the hydraulic pressure is gradually reduced. The clutch breaks away around 0.15 s when the holding torque capacity becomes smaller than the torque exerted onto the clutch pack. The torque transition is smooth before and after the breakaway. In Case 2, the clutch breaks away at the same timing. However, it goes through undesirable torque

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto090
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

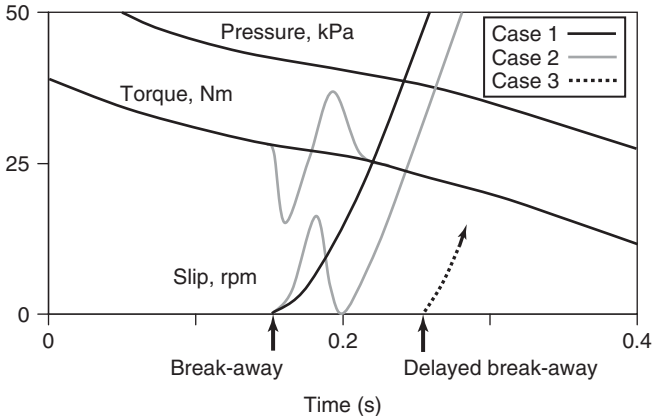

Figure 7. Example of release behaviors.

oscillation, momentarily re-engaging the clutch pack at around 0.2 s. In Case 3 where only the slip speed is shown in the figure, the clutch breakaway is significantly delayed, missing clutch-to-clutch synchronization timing, even through the hydraulic pressure follows the same profile as Case 1 and Case 2.

There are very few formal studies published in open literature for clutch release characteristics regardless of its importance. However, there is a significant amount of hands-on knowledge in industry obtained from product development experiences. This includes the physical steps involved in clutch release processes as illustrated in Figure 8. In Stage 1, the clutch is fully engaged. The static friction between the friction and separator plates provides a sufficient holding torque against the external load exerted on the clutch pack. In Stage 2, the external load overcomes the holding capacity as the hydraulic actuator pressure drops. The friction plate breaks away from the separator plate, whereas the transition from static to dynamic friction takes place. In Step 3, the sliding motion of the friction plate distributes the lubrication fluid from the groove into the frictional interface, establishing the partial lubrication condition (Hamrock, 1994). As the friction plate accelerates its motion, more fluid is entrained into the interface. The overall wet friction torque drops toward a drag level when the hydraulic actuator pressure is totally lifted.

The erratic release behavior depicted in Case 2 (Figure 7) can be explained by the release model in Figure 8. A certain plate design has a sizable fluid reservoir and drainage at the frictional interface. At the moment of breakaway, a large amount of fluids spreads into the interface, moving directly from Step 1 to Step 3. This jump creates a torque drop that is larger than static-to-dynamic transition. However, once the friction plate starts sliding, the fluid is quickly exhausted into the large drainage, reestablishing the asperity contact. The clutch torque momentarily rises, re-engaging the friction plate. The release behavior in Case 3 is often observed in actual transmission systems. It is thought to be caused by the variability of static friction under the presence of uncontrolled noise factors such as the interface temperature. The breakaway is delayed if the static friction becomes larger for a given level of hydraulic actuator pressure.

3.4 Thermal consideration

A wet clutch generates a large amount of heat during a coupling process. Thermal conditions must be adequately managed for robust slip controls, high durability, and application-specific duty cycles. The effects of temperature on clutch operating behaviors are very complex. However, the previous discussions on engagement and release mechanisms should prove useful to provide insight into specific thermal dependency for any applications. The following part focuses on the thermal considerations mainly related to durability and duty cycles.

Figure 9 illustrates transient thermal behaviors during consecutive clutch engagements for a planetary-gear-based automatic transmission. The friction material surface temperature rises during each engagement. The cooling effect is limited while it remains engaged. Once the clutch is released, the lubrication fluid flows into the clutch pack to cool down the frictional interfaces. However, the surface temperature does not drop to the pre-engagement level if a cooling duration is not sufficient. Accordingly, the peak temperature becomes higher during the subsequent engagements. A drive cycle thermal analysis is an important aspect of a clutch development process, especially for the applications that require demanding clutch duty cycles. It establishes cooling requirements and supports design optimization to adequately dissipate the thermal

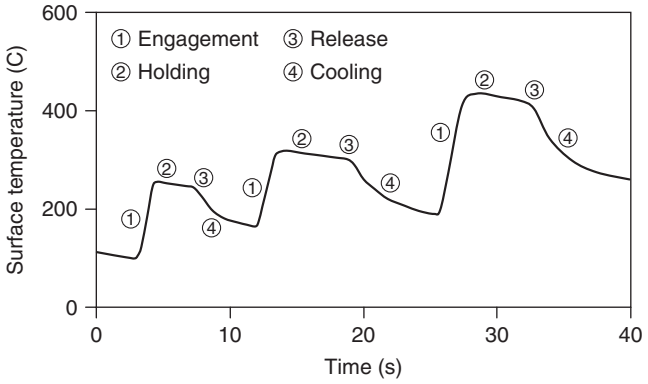

Figure 9. Example of clutch thermal cycles.

energy through convection, conduction, and radiation (see Tribological Optimisation in the Powertrain). A first-order clutch thermal cycle analysis is relatively straightforward. Assuming an average clutch torque T and a linear reduction of slip speed from ω_0 to zero over the duration of Δt, the total thermal energy for each engagement, E, can be readily estimated through the following equation:

$$E \approx T \cdot \omega_0 \cdot \left(\frac{\Delta t}{2}\right) \tag{3}$$

Equation 3 can be utilized to determine clutch cooling requirements, following specific engagement sequences in a target drive cycle. A typical cooling flow rate is 100–200 mL/min per each interface for a multiplate clutch pack in a planetary gear transmission. For demanding applications such as DCT launch clutch, the cooling requirement is substantially higher.

Generally speaking, a higher temperature accelerates the degradation of friction material and transmission fluid properties. It promotes a microstructural loss of fibers and resins, wearing off the friction lining. Fluid additives, such as a friction modifier agent, are decomposed at a higher rate, altering wet friction characteristics. In practice, a conventional step-ratio transmission system is designed to keep the bulk fluid temperature under 120°C range to protect additive properties. Its clutch duty cycle is monitored to prevent friction lining temperature from exceeding 300–400°C range. Excessive thermal conditions lead to serious failure modes that may result in a spontaneous loss of clutch functions. For example, a friction material surface can be glazed, temporarily or permanently losing its frictional capability (Yesnik, 2002). A friction lining may break off or delaminate from the core plate due to a severe structural damage. When the interface temperature exceeds the thermal limit of a separator plate, catastrophic thermoelastic instability may occur, resulting in a complete seizure of a clutch pack. More specifically, thermal deformation of a separator plate causes a local hot spot, which in turn promotes further plate deformation, resulting in a severely warped or coned separator plate (Audebert, Barber, and Zagrodzki, 1998; Zagrodzki and Farris, 1998).

4 CLUTCH DESIGN PROCESS

A challenge for higher fuel economy and superior drivability has transformed a once-mundane clutch design process into a sophisticated design optimization that requires the intimate knowledge of clutch operating principles. The new drivetrain systems demand a wet clutch with lower drag, enhanced torque controllability and higher durability. In order to balance overall clutch characteristics, a complex interaction between various design variables must be accounted, including component geometry, friction materials, and fluid properties. At present, a typical clutch design process follows a well-established practice from the Systems Engineering (INCOSE (International Council on Systems Engineering), 2010; US DOT (Dept. of Transportation), 2007) as a part of drivetrain system development. The Systems Engineering approach aims at reducing costly and lengthy engineering iterations in order to achieve drivetrain-level performance requirements. Among the clutch components, the friction plate assumes of particular importance because of its direct impact on both open clutch and transient torque characteristics. Figure 10 shows the so-called V-model from the Systems Engineering, highlighting its application to the friction plate design process as an example. In principle, all other components also follow the same developmental process in parallel. On the left side of V, the specifications and the requirements for a target driveline system are cascaded down to a clutch pack and to a friction plate level, including packaging constraints, performance requirements, operating conditions, and target costs. A thorough analysis of the requirements is a critical step toward finding a successful clutch design. The engineering iterations take place, as required, between the component, subsystem, and system levels on the left side of the system V process.

As one of the basic building blocks, friction plate design activities are defined at the bottom of the V-model. Geometric features are evaluated, accounting for primary interactions with other factors such as material characteristics, fluid properties, and operating conditions. The complexity of physical processes described in Section 3 makes the design optimization challenging, especially in the absence of predictive CAE (computer-aided engineering) tools for engagement and release analysis. Performance

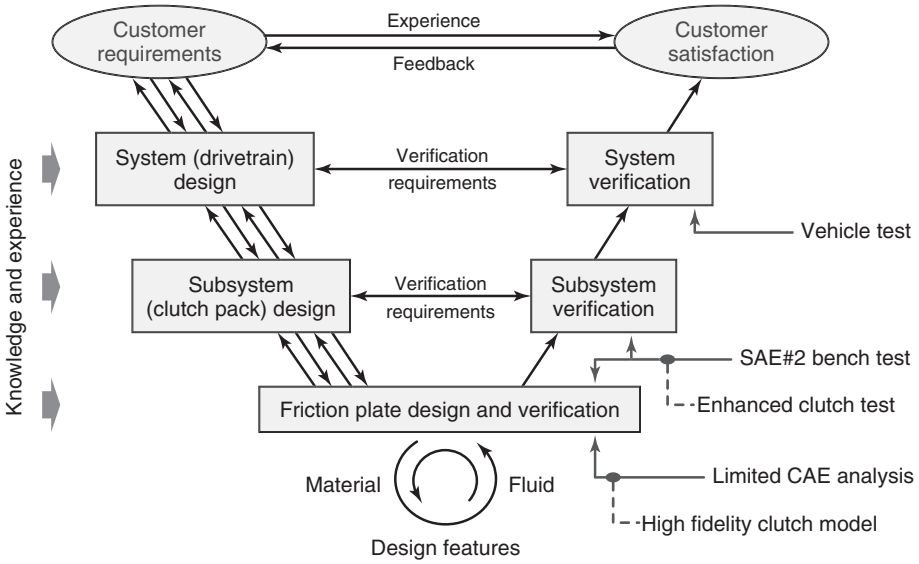

Figure 10. V-model for clutch design process.

evaluation tests are conducted on component benches, typically adapting the industry-standard SAE#2 test procedure (Fanella, 1994). The performance verification follows the right-hand side ladder of the V-model upward from the friction plate level. Thorough requirements analyses conducted on the left side of V form a basis for developing a successful performance verification plan.

The engineering iterations for performance verification on the right-hand side of the V-model are costly and time-consuming. For example, even if a clutch plate and a clutch pack pass verification tests as a component, a shift quality may still fail to meet the target metrics at a vehicle level. This can push the development work back to the subsystem or component levels after having invested significant resources for the prototypes and vehicle-level shift calibration work. A well-designed Systems Engineering approach is built on up-front planning, requirements analysis and robust engineering at all levels on the left side of V to reduce hardware changes and firefighting work downstream on the right side of V for a shorter development time.

The remainder of this section describes the recent trend in clutch performance optimization with a specific focus on friction plate design features. Then, two emerging engineering technologies, namely the high fidelity multi-physics clutch model and the enhanced clutch test method, are presented. They are expected to proliferate in the clutch design process to significantly enhance the up-front Systems Engineering practice.

4.1 Friction plate features

Friction plate designs are typically adjusted for every production application to optimize torque characteristics. Among the design variables, groove geometry is considered the most practical to fine-tune open clutch drag as well as engagement and release behaviors. The groove acts as a passive flow control device. The effects of groove changes are generally confined to torque characteristics without inadvertently affecting other requirements. Figure 11 illustrates three friction plates that highlight important groove design considerations, namely (i) overall pattern, (ii) groove shape, and (iii) groove volume. The plate A and the plate B have a radial groove pattern, whereas the plate C has a parallel pattern. There is no well-established engineering methodology to optimize overall groove layout. Accordingly, a number of distinct patterns are introduced to new production systems, largely based on empirical evidence and prior production experience. Although the pattern analysis remains challenging, analytical tools are routinely utilized to optimize individual groove geometry for open clutch conditions. For example, the plate A and the plate C have a conventional straight edge groove, whereas the plate B has a groove with complex asymmetric geometry. CFD (computational fluid dynamics) simulations are conducted to fine-tune flow geometry to enhance pumping capabilities for a given application. Coupled with groove shape optimization, there is a clear trend in production to widen or deepen the groove as illustrated in the plate B. A large groove increases average fluid film thickness between rotating plates, significantly reducing viscous

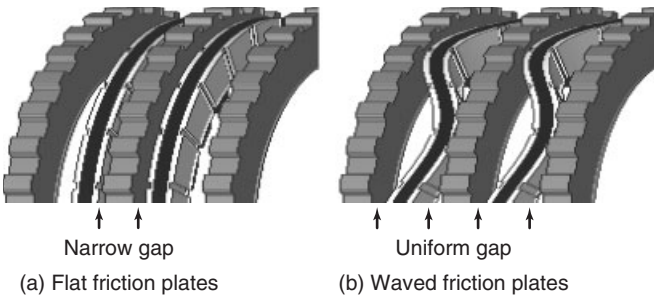

Figure 12. (a,b) Clutch plate clearance.

shear. However, the fuel economy benefit comes at the expense of clutch controllability. A large fluid volume at the interface tends to make the engagement and release behaviors more sensitive to operating conditions.

Another important design trend is a waved friction plate. It is known that both friction and separator plates slide back and forth along spline teeth when the clutch is open. This causes the clearance between some plates to be very small, resulting in large viscous drag, as illustrated in Figure 12a. To prevent the plates from sticking together, a friction plate is formed with several gentle waves in its circumferential direction as depicted in Figure 12. The waves in the figure are exaggerated for the purpose of illustration. The waves help to maintain uniform clearance on average between the plates for reduced viscous drag as in Figure 12b. The waves are designed to collapse at relatively small force levels during the clutch engagement.

4.2 High fidelity clutch model

The functionality of a wet friction device is built on complex physical processes that involve fluid–structure interactions. Its characteristics are highly sensitive to geometric features as well as operating conditions. There have been a number of attempts to analytically, computationally, and empirically capture wet friction behaviors since the 1970s, including Wu (1971, 1978), Patir and Cheng (1978, 1979), Yang, Lam, and Fujii (1998), Fujii, Tobler, and Snyder (2001), Fujii *et al*. (2002, 2003), Cao *et al*. (2004), Deur *et al*. (2005), Yuan, Liu, and Hill (2007), and Ivanovic *et al*. (2009). The earlier research activities often targeted certain physical processes to gain insight into specific clutch characteristics. Today's understanding on clutch operating mechanisms, described in Section 3, is built on those research accomplishments.

The inclusion of detailed geometric features in clutch simulations became possible in the 1990s with the advancement of FEM (finite-element method) and CFD technologies (Berger, Sadeghi, and Krousgrill, 1996; Davis, Sadeghi, and Krousgrill, 2000; Aphale, Schultz, and Ceccio, 2010; Takagi *et al*., 2011). In addition, the recent progress in multi-physics modeling methodologies offer a realistic possibility first time to enable up-front clutch performance analysis through high fidelity simulations. All the

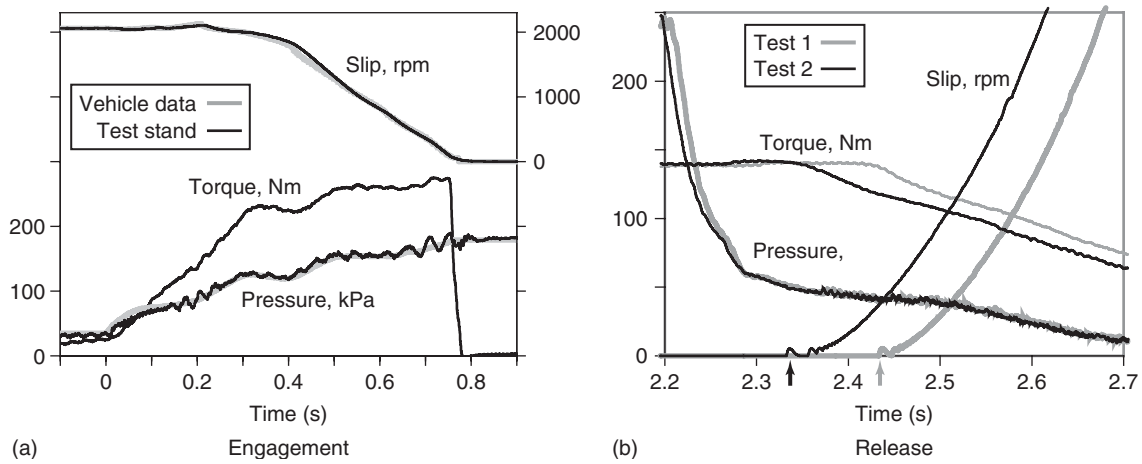

Figure 14. (a,b) Enhanced clutch test methodology.

key physical processes, such as multi-phase flow, squeeze film, porous diffusion, flow through asperities, and heat transfer, can be coupled together for open clutch and transient simulations while allowing rotational and translational plate motions (Cho *et al*., 2011; Cho, 2012). Figure 13 shows an example of three-dimensional high fidelity multi-phase flow simulations for open clutch drag analysis. A friction plate with complex groove geometry slides at 2000 rpm against a separator plate (not shown in the figure) that is 0.2 mm apart. The figure shows three-dimensional iso-surface where air volume fraction locally exceeds 0.9. Air penetrates into the interface from the outer edge of the plate and travels along the leeward side of the grooves. The presence of air is also observed over the segmented friction lining in the simulation. An analytical examination of flow behaviors provides valuable insight into the effects of groove depth, width, and wall shape for increased air entrainment and reduced drag. A new generation of high fidelity multi-physics modeling tools and methodologies appears promising for greatly enhancing up-front clutch design capabilities.

4.3 Enhanced clutch test method

A conventional clutch performance verification test follows the SAE#2 test standard that was developed in the 1970s. The SAE#2 standard defines the specifications for test rig, test procedures, and conditions to facilitate technical communications between OEM and suppliers (Fanella, 1994). The SAE#2 test stand is a type of an inertia-absorption component dynamometer. An electric motor spins friction plates at a target rotational speed, whereas separator plates are mounted on a stationary housing. When a clutch engagement is commanded, the motor becomes decoupled from the clutch plates. A pneumatic or hydraulic actuator applies a force onto a clutch piston, following a step-function profile. The engagement completes when the friction plates are securely grounded. The SAE#2 standard continues to provide a valuable common ground to cross-examine relative performance of various plate designs, friction materials, and the effects of fluid properties. However, SAE#2 procedures do not adequately represent clutch controls in contemporary drivetrain systems. Accordingly, SAE#2 test data do not correlate very well with clutch behaviors observed in an actual vehicle. At present, an enhanced SAE#2 clutch test stand is becoming increasingly available, equipped with programmable actuator and slip controller (Fujii *et al*., 2006). Figure 14 shows the examples of advanced clutch tests conducted on such an enhanced stand. An engagement test in Figure 14a follows actual pressure and slip profiles observed in a vehicle for evaluating clutch characteristics and control sensitivities under realistic shift conditions. A release test in Figure 14b demonstrates the breakaway behaviors that are also the subject of Section 3.3. As the actuator pressure drops, the clutch breaks away when its torque capacity becomes below the load level exerted on to the clutch pack. Test 1 and Test 2 exhibit very different breakaway timing even though their pressure profiles are nearly identical. This is due to the variability of static friction as previously discussed in Section 3.3. Clutch component characteristics obtained from programmable clutch test stands generally exhibit far superior correlation with vehicle-level assessment as compared with the standard SAE#2 test data. The application of the enhanced clutch test methodologies in the clutch design process significantly reduces a number of engineering iterations on the right side of the V-model for accelerated system development.

5 SUMMARY

The wet clutch provides critical functions in conventional automatic transmission systems. Its characteristics have a direct impact on fuel economy, shift quality, and drivability. Because clutch behaviors are highly sensitive to geometry and operating conditions, a clutch design engineer is generally required to adjust design features specifically for each application. They face a challenge to balance conflicting requirements in clutch efficiency and coupling behaviors. Although general-purpose CFD tools are commercially available, their applicability to up-front clutch design support is not well established. Accordingly, a clutch engineer is often forced to rely on prior experience and time-consuming trial-and-error-based design assessment. However, the recent advancement in commercial CFD tools, academic, and industry research present strong evidence that truly useful analytical tools will be available in the very near future.

New powertrain systems such as DCT (see Dual Clutch Transmissions (DCT)—Layouts, Clutch Selection, Packaging, Actuation, Manufacturing & Assembly) and HEV powertrain (see Micro, Mild and Full Hybrid, Power Split Configurations) continue to drive innovations in wet clutch technologies. In order to realize higher fuel-economy benefits, the clutch is often expected to function under unconventional operating conditions. For example, both extended clutch slip and severe duty cycles push the clutch components to their thermal limit. An overall structure must be designed to meet a required thermal rejection rate for a given cooling mechanism. A friction material (see Mechanics of Contacting Surfaces) and fluid additives (see Tribological Optimisation in the Powertrain) require ever-increasing thermal durability. This provides the challenges and great opportunities for clutch engineers for innovations.

Lastly, but not least importantly, it is worthwhile to note that the successful implementation of the wet clutch technology in all applications depends on a clutch actuation mechanism (see Automotive Torque Converters) and a control methodology (see AT Control—Actuation Methods & System Integration, Gear Choice, Gear Shift Strategy & Process, Adaptive Features).

Automotive Torque Converters

Donald Maddock
General Motors Company, Pontiac, MI, USA

1 INTRODUCTION

The torque converter is a hydrodynamic machine used in conventional automatic transmissions to transmit power from the engine to the transmission gear system. In its classical configuration, power flow is accomplished through the action of a moving stream of fluid, with no mechanical connection between input and output shafting. It provides a beneficial dynamic relationship between the torque-speed characteristics of reciprocating internal combustion engines and the tractive effort requirements of automotive vehicles. It also effectively isolates the driveline mass-elastic system from engine torsional disturbances.

1.1 Classification

Torque converters are a type of turbomachine. These devices are distinguished by having rows of rotating blades that exchange energy with a stream of moving fluid. Forces between the blades and fluid influence the motion of the fluid while producing torque on the blade system. In the simplest of turbomachines, there is a single transfer of energy. Pumps and compressors, for instance, convert shaft power to fluid pressure and velocity, whereas turbines do the inverse of this process. Torque converters are a bit more complex machines, with mechanical power transforming to fluid power and back to mechanical power.

Two related devices are prevalent in heavy-duty and off-road vehicles and are generalized with torque converters as hydrodynamic transmissions. While true torque converters have the capability to produce output torque that exceeds input torque, fluid couplings have no capability to multiply torque. Retarders are fluid couplings that have their output member grounded. They function as vehicle brakes.

1.2 Brief history

The torque converter was invented by DrIng Hermann Föettinger shortly before World War I (Voith, 1988). He was employed by the Vulcan ship works in Hamburg, Germany, and was involved in the application of steam turbine engines to naval vessels. Turbines had evolved significantly since their invention in the previous century and were achieving power levels well in excess of 20,000 kW. Gear systems were not yet available to durably match the high rotating speed of the turbine to the much lower optimum speed of the ship's propeller, leading Föettinger to conceive the torque converter to provide the necessary speed reduction. His early prototypes were soon followed by a successful transmission system that utilized separate torque converters to effect normal and reverse rotations of the propeller without needing to reverse the engine. Direction of motion was selected by filling one of the units with working fluid while evacuating the other (Wislicenus, 1947).

Hydrodynamic devices were introduced in passenger cars with the late 1930s Chrysler Fluid Drive and the 1940 General Motors' Hydra-matic. The Fluid Drive used a fluid coupling between the engine and a conventional manual clutch and layshaft (countershaft) transmission, whereas the Hydra-matic combined a fluid coupling with a fully automatic four-speed planetary gearbox. The post-World War years saw a proliferation of planetary automatic transmissions of various sorts and, with them, a number of different torque converter configurations. Some of these designs, particularly those produced by Buick in their line of Dynaflow transmissions, were quite sophisticated, combining several input, output, and reaction blade rows with internal gear sets and one-way clutches (Chayne, 1948). These units provided ratio coverage from vehicle launch to road load cruise conditions without sensible step gear ratio changes. By the early 1960s, however, improved transmission shifting technology made this sort of complex device unnecessary, and the automobile industry generally settled on the simple, three-element Trilok converter, which is in general use nowadays. In the 1970s, fuel economy concerns prompted the inclusion of a wet clutch within the envelope of the hydrodynamic unit, producing a device known as a *lock-up torque converter*. The clutch is externally controlled and, when desirable, directs power directly to the gear system. This eliminates energy loss associated with fluid motion through the blade system.

1.3 Attributes

Torque converters continue to be widely utilized in automotive transmissions because of their advantageous combination of operating characteristics. There is currently no other device that simultaneously allows an unloaded engine idle, smooth ratio changing on acceleration, and good driveline torsional vibration damping. They also transmit large amounts of energy without excessive power densities at any surface or interface.

Converters do provide a degree of challenge to the transmission designer. They are relatively large, heavy components, frequently causing packaging and mass target difficulties. They are expensive to tool and produce and tend to be sensitive to manufacturing variations.

In operation, the converter imposes loads on engine and transmission components that require additional structure and bearing content. Of greater consequence is that, compared to gear systems, even the best torque converter is an inefficient device, generating sizeable quantities of heat and impacting the fuel economy of the vehicle. The heat generation requires that oil-to-water or oil-to-air heat exchanger systems be included in the vehicle. The lock-up clutch, or torque converter clutch, partially overcomes the fuel economy problem but introduces other difficulties of its own.

2 CONSTRUCTION AND OPERATION

2.1 Mechanical arrangement

2.1.1 Mounting and shafting

A typical modern automotive torque converter is shown in Figure 1 and illustrated schematically in Figure 2. Externally, the device appears as a closed, sealed assembly that rotates with the engine crankshaft. The front closure,

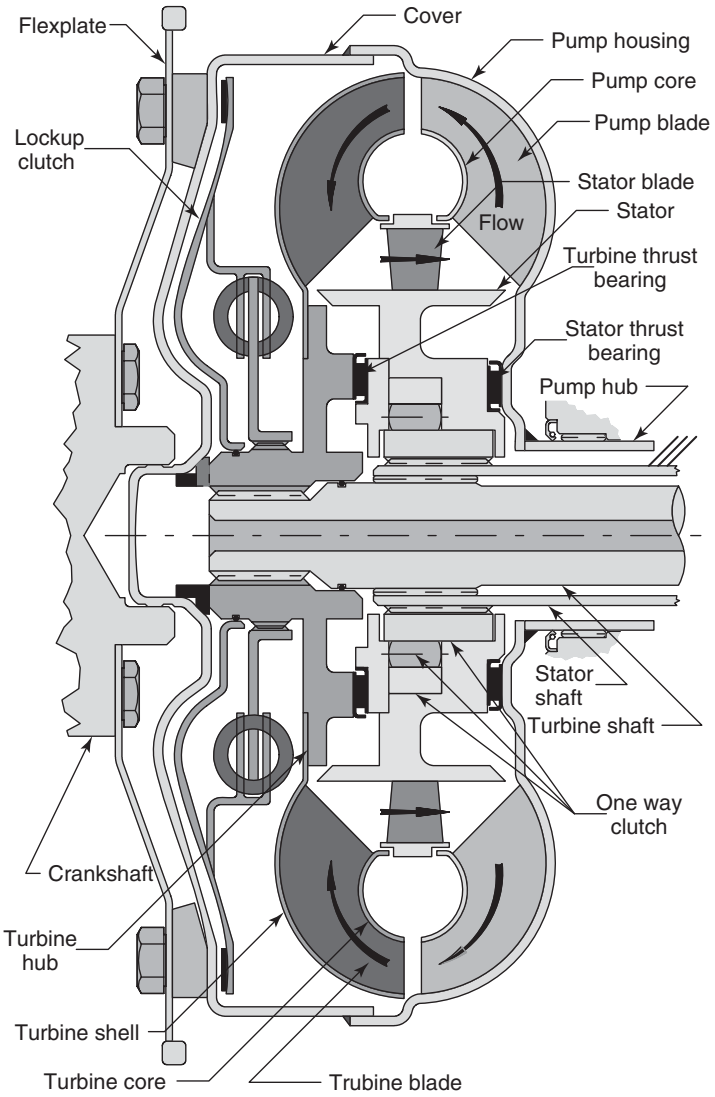

Figure 2. Torque converter schematic.

the cover, is piloted by a precision bore on the crankshaft axis. Power flows from the engine to the cover through a bolted connection to the engine flexplate. The rear of the converter is supported by a bushing or bearing affixed directly or indirectly to the transmission case, and the converter rotates within a partially sealed bell housing formed by the case, engine block, and access closures. Two concentric shafts enter the converter from the transmission. The outermost is fixed against rotation, whereas the inner shaft transmits power from the converter to the transmission gear system. Some transmissions, particularly transverse front wheel drive designs, have a third shaft inside the input shaft to drive the transmission hydraulic pump. Most rear wheel drive transmissions power the pump from the converter hub.

2.1.2 Cooling oil and clutch control

To function properly, the converter must be completely filled with transmission fluid and accommodate a constant through-flow of oil to carry off rejected heat. Two paths connect the converter to the transmission hydraulic system. One feeds cooling oil into the cavity between the converter cover and the lock-up clutch. The second removes hot oil from behind the stator and routes it to the transmission cooler (Figure 3a). Cooling flow thus directed moves the clutch out of contact with the cover surface, activating power transfer through the bladed elements. The clutch is applied by reversing the flow in the two paths. Feeding oil behind the stator raises the pressure behind the lock-up clutch, forcing it into contact with the cover surface

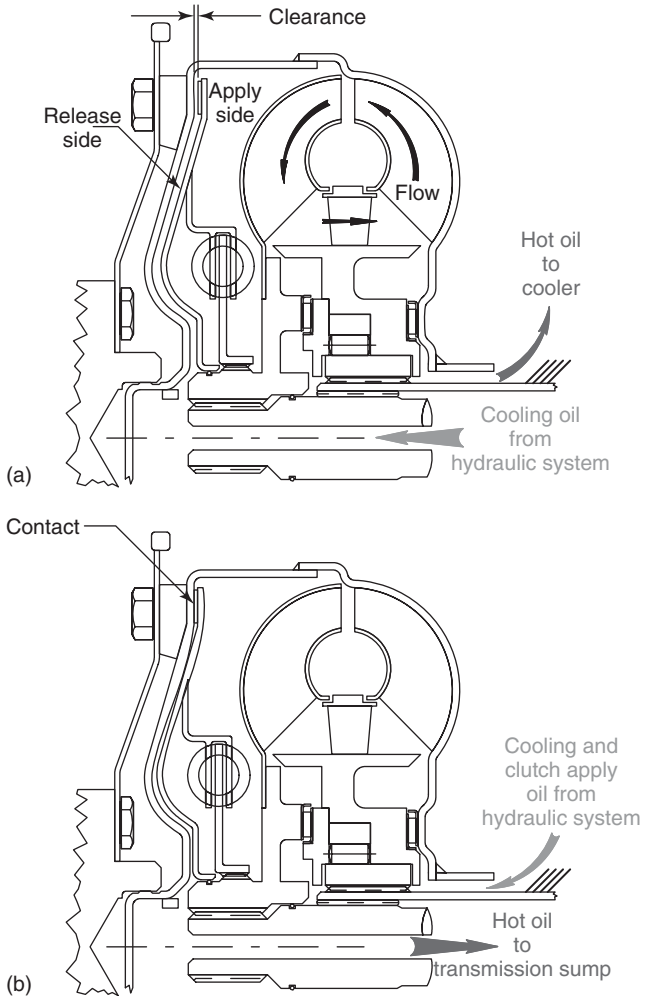

Figure 3. (a) Oil flow with clutch released. (b) Oil flow with clutch applied.

(Figure 3b). Power is then transmitted mechanically, and all hydrodynamic action stops.

In the applied position, the clutch effectively blocks cooling flow through the converter unless a bypass provision is incorporated. This is normally accomplished by adding grooves or a textured surface to the friction material, but some designs provide a third hydraulic circuit in the shafting.

2.1.3 Bladed elements

Three-bladed elements distributed around a roughly elliptical toroidal flow circuit form the hydrodynamic system of the torque converter. The working fluid circulates continuously from element to element, producing torque that delivers engine power to the transmission.

Mechanical power is first converted to fluid power in a mixed flow pump or impeller that forms the rear closure of assembly. The outer wall or housing of the pump is welded to the cover and thus rotates with the cover and flexplate. Working fluid trapped between the pump blades is subject to a centrifugal pressure field that pushes it radially outward between the blades. The stream thus developed must also rotate with the pump blades, and consequently the moving fluid gains angular momentum as it flows outward. This gain in angular momentum results from increased pressure on the leading blade flank, and the integration of this pressure over the blade area and radius produces the torque that loads the engine.

Fluid issuing from the pump continues into the turbine, where the stream's angular momentum is converted back into a mechanical shaft torque that is transmitted to the transmission gear system. The fluid process in the turbine is the inverse of that in the pump. Working fluid conducted inward by the blades looses angular momentum with radius, and this produces a transverse pressure gradient across the blade passage. Increased pressure appears on the trailing side of the turbine blade, and this creates a torque that passes through the turbine shell, turbine hub, and turbine shaft to the gear system.

Rotation of the turbine produces a centrifugal pressure gradient similar to the pump, and this pressure field opposes the flow induced by pump rotation. Consequently, mass flow through the elements decreases as turbine speed increases. The reduction in flow causes the torque-carrying capacity of the converter to diminish as the turbine accelerates and to vanish completely should the pump and turbine speeds become equal. Thus, the pump speed will always exceed turbine speed when the converter is functioning, and the ratio of turbine speed to pump speed, the operating point speed ratio, is a critical variable in the performance of the converter.

The stator or reactor is an axial flow element between the turbine and the pump. It is normally held against rotation by a one-way clutch, such that it overruns freely in the direction of pump rotation but resists motion in the opposite direction. The stator discharges the flow into the pump in the direction of the pump rotation, supplementing the torque absorbed from the engine. This requires that it turn the flow, producing an angular momentum gradient along the blade and a resultant shaft torque.

2.1.4 Materials and construction

Excepting the stator, automotive torque converters are almost universally constructed of stamped low carbon steel. The cover and housing form a highly loaded pressure vessel and thus are relatively thick, usually in the

3.0–4.5 mm range. The steel must support considerable cold working during manufacture, allow leak-free, low distortion welding, and retain its yield strength in heat-affected zones. Most pump assemblies are copper brazed, and the high temperatures and extended time at temperature are extremely detrimental to the mechanical properties of unmodified steel. The hot-rolled sheet for these components is often a specialty steel with specific chemistries that are formable, weldable, and temper resistant.

Core rings, turbine shell, and pump and turbine blades are lighter stampings of cold rolled steel sheet. Stock for blades that are to be built into unbrazed assemblies is often bright finished and processed to a quarter hard temper. Parts that will be brazed do not benefit from the higher cold work temper.

Sheet metal blades are usually retained to the shell and core stampings by a tab and slot arrangement. Pump shell tabs are set into blind embossed slots in the housing, as is evident from Figure 1. Turbine shell tabs and all core tabs project through open slots and are rolled over after assembly. In either case, the tab-rolled assemblies are reasonably strong and rigid. Brazing further improves blade retention and greatly enhances the pressure vessel quality of the pump assembly. It also seals incidental blade to blade and slot leaks, enhancing performance characteristics.

Stators are usually diecast aluminum, but some manufacturers use cast magnesium or molded thermoset plastics. With rare exception, the dies or molds are axially drawn, and this places some design restrictions on the blade contour. Both casting and molding permit the blade thickness to be varied rather freely along its length, however, enabling the application of highly advantageous airfoil blade shapes.

2.2 Shaft torques

2.2.1 Angular momentum equations

The essence of converter operation is that the continuously circulating volume of working fluid is accelerated and decelerated by the different blade systems in a manner that advantageous shaft torques are produced. These torques are a function of the size of the unit, the blade shapes, and the rotating speeds of the shafts. Although these relationships are developed by the blade system's complex internal pressure field, they may be illustrated by a simple analysis of the fluid velocities at the outlet of each element.

The shaft torque on any element is equal to the rate of change in angular momentum flux across that element:

$$T_i = \dot{M}_i - \dot{M}_{i-1} \tag{1}$$

In Equation 1, T_i represents the shaft torque on any element i, $\dot{M}_i$ is the angular momentum flux leaving that element at its outlet, and M_{i-1} is the angular momentum flux leaving the immediate upstream element. The angular momentum flux, the rate at which the angular momentum leaves the element, is defined as the product of the mass flow rate $\dot{m}$, the average radius of the stream from the axis of rotation r, and the component of fluid velocity S tangent to the direction of rotation:

$$\dot{M}_i = \dot{m} r_i S_i \tag{2}$$

Equation 2 reflects two assumptions. The first is the reasonably safe premise that the mass flow is identical at the outlet of all elements. This neglects leakage through blade retention slots and also ignores cooling flow, but these are much smaller than the working toroidal circulation. Second, and of greater importance, is the approximation of the outlet velocity profile by an average value of S which, when multiplied by an average value r, produces the same numeric value as integrating the velocity field from shell to core and blade to blade. This is sufficiently accurate for discussion purposes but is of marginal value for quantitative performance analyses.

Combination of Equations 1 and 2 produces the general torque equation:

$$T_i = \dot{m}(r_i S_i - r_{i-1} S_{i-1}) \tag{3}$$

Equation 3 states that the torque on any blade system is proportional to the change in the radius and tangential velocity product across the system.

If converter blades were simple flat radial surfaces with no curvature, the tangential velocity S would simply be the blade velocity at radius r. However, blades of this type would produce unsatisfactory converter characteristics. To produce desirable converter performance, the blades of each element are specifically shaped to alter the tangential velocity as a function of the mass flow. This is accomplished by angling the blades relative to the meridional surface of the torus.

Figure 4 illustrates the effect of pump outlet blade angle on the fluid tangential velocity at a typical operating speed ratio. In this and subsequent diagrams, the symbol U is the blade speed, F the fluid through flow velocity in the meridional plane, W the through flow velocity relative to the blade, and θ the blade angle. The algebraic signs of U, F and W are always positive, and θ is positive when it produces a component of W in the direction of pump rotation. Observing these conventions, the vector geometry produces the relationship:

$$S_p = U_p + F_p \tan\theta_p \tag{4}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

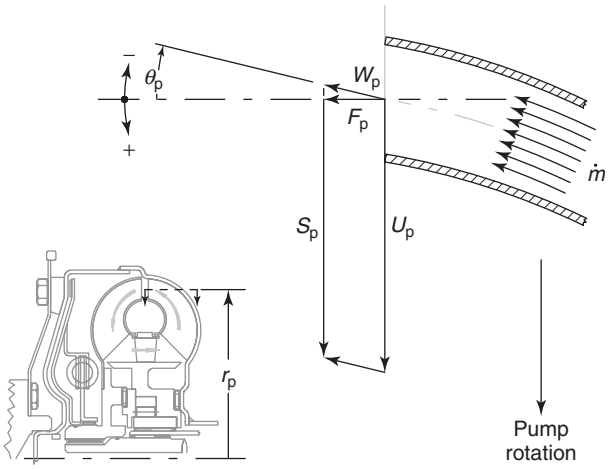

Figure 4. Pump outlet velocities at 0.5 speed ratio.

The subscript p in Equation 4 designates the pump, but the relationship holds generally for all the bladed elements.

Equation 4 is dominated by the blade speed term. The blade speed U_p is the product of the pump angular velocity ω_p and the pump outlet radius r_p:

$$U_p = r_p \omega_p \tag{5}$$

In a typical converter, the pump outlet radius exceeds the turbine and stator radii by 40–50%, and pump speed always exceeds turbine speed when power flows from the engine to the drivetrain. Accordingly, the pump outlet produces the highest tangential velocity in the converter and, as shown by combining Equations 2, 4, and 5, the highest angular momentum:

$$\dot{M}_p = \dot{m} r_p (r_p \omega_p + F_p \tan \theta_p) \tag{6}$$

The turbine blade captures the high momentum flow expressed by Equation 6, and by turning it sharply opposite to the direction of the pump rotation, produces very high shaft torque. The turbine velocities are represented in Figure 5 for a speed ratio of 0.5. Like the pump, the turbine angular momentum is obtained by combining Equations 2, 4, and 5:

$$\dot{M}_t = \dot{m} r_t (r_t w_t + F_t \tan \theta_t) \tag{7}$$

In the conditions illustrated by Figure 5, the effect of the large negative outlet angle exceeds the blade speed, resulting in a negative tangential velocity. In Equation 7, the always negative $F_t \tan \theta_t$ term exceeds the always positive $r_t \omega_t$ term. As the speed ratio increases, however, turbine blade speed will eventually overcome the effect of the negative outlet angle making tangential velocity and angular

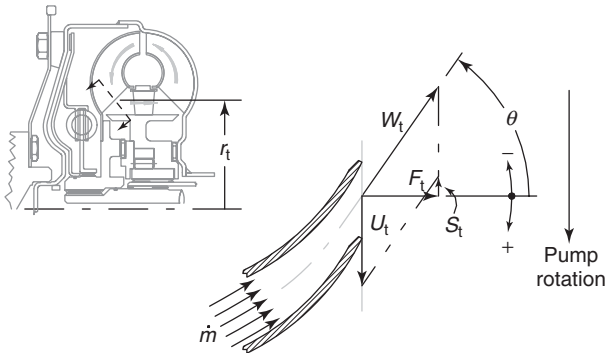

Figure 5. Turbine outlet velocities at 0.5 speed ratio.

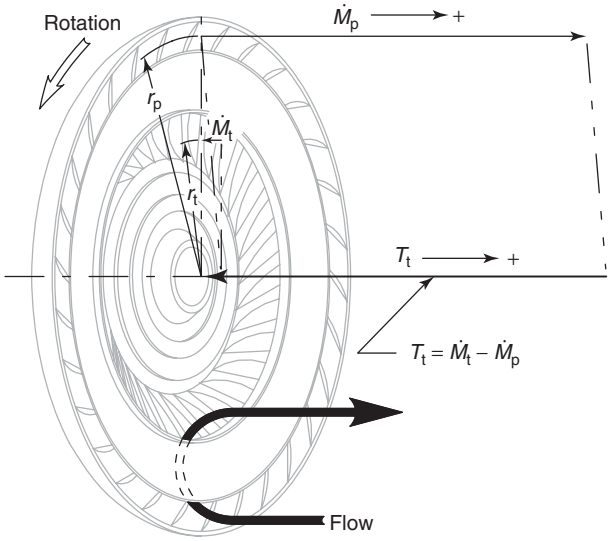

Figure 6. Turbine torque at 0.5 speed ratio.

momentum positive. This typically occurs when the turbine reaches about two-thirds of the pump speed.

The torque exerted on the turbine, as illustrated in Figure 6, is given by subtracting the pump angular momentum from the turbine angular momentum, as in Equation 1. When expanded with the pump and turbine speeds and geometries, this becomes:

$$T_t = \dot{m}[r_t(r_t \omega_t + F_t \tan \theta_t) - r_p(r_p \omega_p + F_p \tan \theta_p)] \tag{8}$$

Equation 8 will always produce a negative value for T_t. The second term, the pump angular momentum, is always a large positive quantity that exceeds the turbine angular momentum, even at high speed ratios. T_t is the torque exerted on the turbine by the transmission, and the negative value indicates that it is opposite in sense from the torque exerted by the engine on the pump. The torque exerted

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

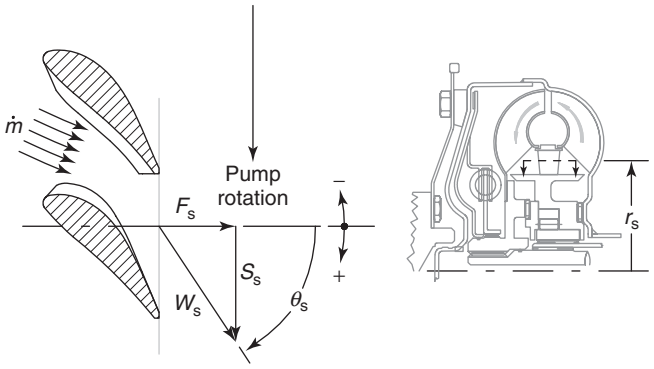

Figure 7. Stator outlet velocities at 0.5 speed ratio.

on the transmission by the converter turbine is opposite in sign and, therefore, has the same sense as the engine torque. The behavior of the turbine angular momentum as speed ratio increases, that is, starting negative and becoming positive, results in transmission input torque (converter output torque) decreasing as speed ratio increases.

The stator receives negative or low positive angular momentum from the turbine and turns the stream back in the direction of pump rotation. This is shown in Figure 7, again for a speed ratio of 0.5. Under these conditions, the stator is held against rotation by the one-way clutch. The stator blade speed is zero, so the angular momentum and torque equations have no $r_s\omega_s$ terms:

$$\dot{M}_s = \dot{m} r_s (F_s \tan\theta_s) \tag{9}$$

$$T_s = \dot{m}[r_s(F_s \tan\theta_s) - r_t(r_t\omega_t + F_t \tan\theta_t)] \tag{10}$$

Stator outlet angles are always positive, so stator angular momentum, as defined by Equation 9 and forming the first term in Equation 10, is always positive. Stator torque is illustrated in Figure 8 for the 0.5 speed ratio condition.

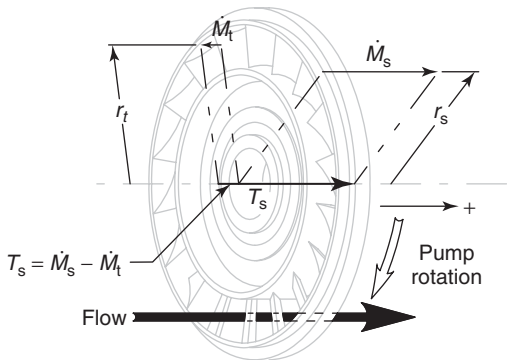

Figure 8. Stator torque at 0.5 speed ratio.

Turbine angular momentum is negative at low and moderate speed ratios but, for this particular converter, becomes positive at speed ratios above 0.66. It continues to increase, and at some higher speed ratio, will exceed the stator angular momentum. At that point, stator torque would become negative, forcing input torque higher than output torque. This being undesirable, the one-way clutch prevents negative stator torque by releasing when stator torque reverses. The stator then freewheels, attaining whatever rotating speed produces no momentum change across the blades. The speed ratio at which the stator overruns is known as the *coupling point*. Above the coupling point, the automotive torque converter losses its capability to multiple torque and thus behaves as a fluid coupling.

Again referring to Equation 1, pump torque is equal to pump angular momentum minus stator angular momentum. At speed ratios below the coupling point, the stator is held against rotation and stator angular momentum is given by Equation 9. The pump torque equation then becomes:

$$T_p = \dot{m}[r_p(r_p\omega_p + F_p \tan\theta_p) - r_s(F_s \tan\theta_s)] \tag{11}$$

Both terms of Equation 11 are always positive, so pump torque is always less than pump angular momentum. This is illustrated in Figure 9.

2.2.2 *Torque multiplication*

As only pump, turbine, and stator torques act on the converter, these torques must add to zero. The angular momentum equations establish the sense and magnitude of

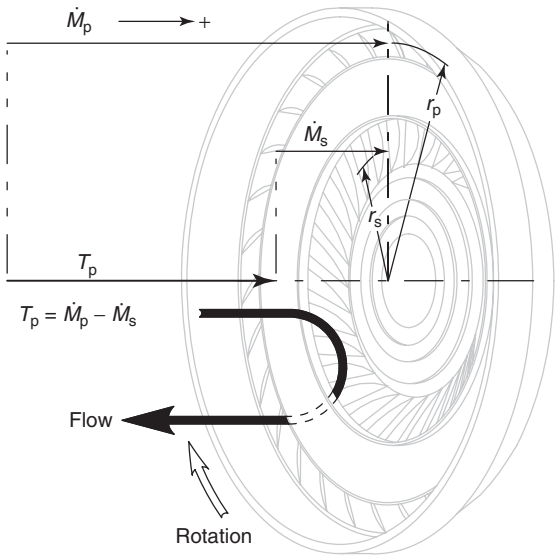

Figure 9. Pump torque at 0.5 speed ratio.

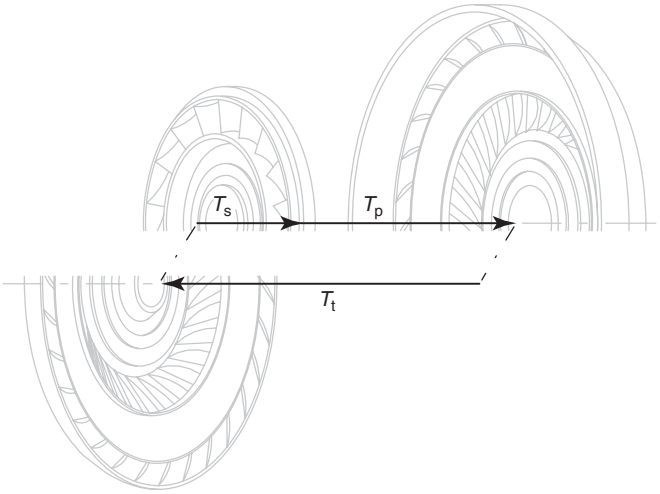

Figure 10. Torque multiplication at 0.5 speed ratio.

these torques, and as illustrated in Figure 10, establish that the magnitude of turbine torque exceeds pump torque by the value of stator torque. This capability is traditionally know as torque multiplication. At the coupling point, stator torque becomes zero and turbine and pump torques become equal. This equality continues at higher speed ratios, as the overrunning one-way clutch prevents any angular momentum change across the stator.

3 CONVERTER PERFORMANCE

The angular momentum equations explain the principles relating the element speeds and fluid mass flow to the shaft torques at a given operating point. However, the operation of a motor vehicle requires that the converter provide suitable relationships between the element torques and speeds under a wide range of conditions. These relationships, known collectively as converter performance, are critical to the performance, drivability, and fuel economy afforded by any powertrain. Further equations based on energy considerations can be used to build a simplified one-dimensional model that predicts converter performance, but these equations rely on coefficients that are not easily derived and consequently do not provide acceptably accurate predictions. Obtaining converter performance is thus an empirical process.

3.1 Performance measurement

3.1.1 Dynamometer equipment

Torque converter speed and torque characteristics are measured on a dynamometer system simulating loading conditions found in service. The converter is enclosed in a fixture that approximates the engine attachment to the converter cover on the input side and the transmission stator shaft, turbine shaft, and pump hub support on the output side. The converter pump is driven by an electric motor, and the turbine torque is absorbed by either a second motor or, on older systems, an eddy current brake. Input and output torques are measured by load cells that are subjected to the reaction torque at the motor and brake frames or by in-line strain gage torque meters in the drive shafts. Stator torque is not directly measured, as it must be the difference between the input and output torques. Transmission fluid is supplied to the converter through the fixture shafting by an external hydraulic power system, and cooling flow is controlled by regulating the converter inlet pressure and outlet back pressure. Inlet oil temperature is established by heaters in the hydraulic sump and an oil-to-water heat exchanger in a separate hydraulic loop. Outlet temperature is measured but not directly controlled, as it is a function of the converter operating point.

3.1.2 Test procedures

Established test procedures for torque converter performance measurement generally involve stabilizing converter operation at a number of operating points and recording pump and turbine speeds and torques at each point. Oil temperature and pressure at the fixture inlet and pressure at the outlet are held constant during the test and outlet temperature and flow rate are recorded at each test point.

The most common performance test is completed by regulating pump torque to a constant value and adjusting turbine speed to sequential values from zero to a maximum. Pump speed and turbine torque are recorded at each point. This is known as an *efficiency test*, and is usually repeated at two input torque levels.

Operation with the turbine stopped and the pump running at speed correlates directly to the vehicle standing with the engine running and the transmission "in gear." Converter behavior under these conditions is critical to idle fuel consumption and vehicle launch performance, so a specific *stall test* is normally run. The turbine shaft is locked against rotation, and the pump torque is regulated to a series of values. Pump speed and turbine torque are recorded at each test point. As no shaft power is removed from the turbine during a stall test, the entire energy input to the pump must be dissipated as heat. With most of this heat absorbed by the working fluid, a cooling cycle is executed between each stall point to prevent excessive oil temperatures.

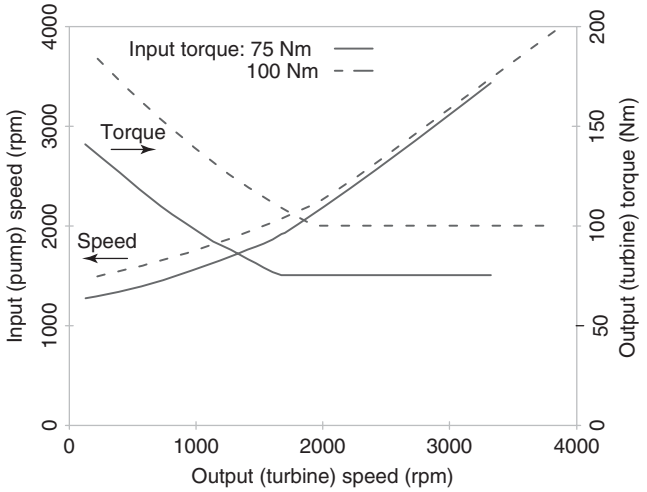

Figure 11. Efficiency test at 75 and 100 Nm.

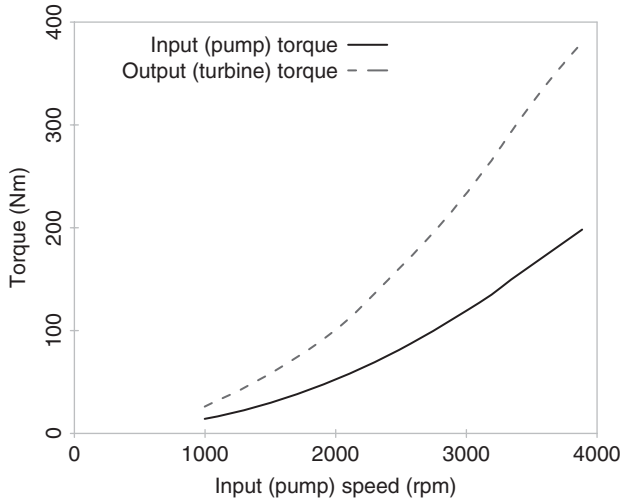

Figure 12. Stall test.

3.2 Performance test data

3.2.1 Measured performance

Typical converter efficiency test data obtained at two different pump torques are plotted on Figure 11. At both torques, the turbine torque is at its maximum at low turbine speed and decreases monotonically as the turbine speed increases. At some elevated speed, the turbine torque becomes equal to the pump torque, indicating that the converter has reached its coupling point and torque multiplication is no longer available. The torques then remain equal as turbine speed continues to increase. Pump speed climbs monotonically to the coupling point, with a gradual increase in slope. Beyond the coupling point, turbine and pump speeds become asymptotic. When the test torque is increased, both turbine torque and pump speed curves move upward and stretch along the abscissa, but the shape of the curves remains essentially similar.

Typical stall test data are shown in Figure 12. As pump speed increases, pump torque and turbine torque increase parabolically. Turbine torque exceeds pump torque at all values of pump speed.

3.2.2 Nondimensional performance

Stall and efficiency test data are combined to extend the efficiency test speed-torque characteristics of the converter to zero turbine speed. While this produces performance information covering the converter's entire operating speed range, the relationships only hold for the arbitrarily chosen constant input torque. However, the data gleaned from an extended test becomes much more useful and revealing when it is nondimensionalized. In this process, the speeds and torques at each test point are converted to dimensionless parameters formed from the test measurements, the density of the working fluid, and a length scale indicating the size of the converter. Formal dimensional analysis allows several formulations of the resulting parameters, but the most useful are the ratio of output speed to input speed, the ratio of output torque to input torque, and a factor combining the input speed, the input torque, the fluid density, and the converter diameter. These dimensionless ratios, illustrated in Figure 13, are known as the *speed ratio*, the *torque ratio*, and the *unit input speed*. In a concession to established practice, the shaft speeds N_I and N_O are measured in revolutions per minute rather than radians per second. Test equipment always exerts a degree of frictional drag on the input and output shafting, and these fixture losses must be deducted from the indicated motor torque and added to the indicated brake torque before the ratios are computed. The shaft torques, T_I and T_O, reflect the torques actually applied to the pump and the turbine. The outside diameter of the converter torus, D, measured over the pump blade outlet at the shell, is customarily used as the length scale. Finally, the fluid density, ρ, is a mild function of the operating temperature and should be obtained at the converter test temperature.

Once the series of converter test speeds and torques are converted to dimensionless ratios, the information may be used to analyze the performance characteristics of a converter design over its entire torque and speed operating ranges, without regard to the size of the unit or the density of the working fluid. The unit input speed parameter, $N_I\ (\rho D^5/T_I)^{1/2}$, is a very informative parameter, as it relates the converter's torque capacity to these quantities. It is a bit

Dimensional measurements and properties

Symbol	Measurement	Units
N_I	Input (pump) speed	[rpm]
T_I	Input (pump) torque	[Nm]
N_O	Output (turbine) speed	[rpm]
T_O	Output (turbine) torque	[Nm]
D	Converter torus diameter	[m]
ρ	Working fluid density	[kg m^{-3}]
μ	Working fluid viscosity	[kg m^{-1}s^{-1}]

Dimensionless ratios

Symbol	Parameter	Formula
n	Speed ratio	N_O/N_I
t	Torque ratio	T_O/T_I
u	Unit speed	$N_I\,(\rho D^5/T_I)^{1/2}$
E	Efficiency	$N_O T_O/N_I T_I$
Re	Reynold's number	$(\rho T_I/D\mu^2)^{1/2}$

Semi-dimensionless ratios

Symbol	Parameter	Formula	Units
K_I	Input K-factor	$N_I/T_I^{1/2}$	[rpm Nm$^{-1/2}$]
K_O	Output K-factor	$N_O/T_O^{1/2}$	[rpm Nm$^{-1/2}$]

Figure 13. Dimensionless ratios.

cumbersome to use for application studies, however, where the converter diameter and fluid are established constants. It is then normally replaced by the semi-dimensionless input K-factor, $N_I/T_I^{1/2}$, in which diameter and density are ignored. The input K-factor, or input capacity factor, may be visualized as the speed a given converter would attain when subjected to unit torque. A similarly formed output K-factor, $N_O/T_O^{1/2}$, is useful in studies matching converter characteristics to vehicle road load demands.

The very important converter efficiency, expressed as a percent, is the ratio of the output power, $N_O T_O$, to the input power, $N_I T_I$. Conveniently, it is equal to the product of the speed ratio, N_O/N_I, and torque ratio, T_O/T_I.

Performance data thus reduced are regularly used to model vehicle performance over a large range of engine maps, vehicle characteristics, and driving cycles. It is also used to predict the performance of geometrically similar converter designs of different sizes. However, there are some limitations that must be observed when acquiring data for these application studies and design development.

The dimensionless ratios do not capture the effects of internal mechanical friction among the pump, turbine, and stator and between the stator and ground. Internal pressure gradients create large axial forces on all three elements, and these forces load thrust bearings between the elements. The bearings generate a torque path between the elements that is of little consequence except at very low test torques. The stator one-way clutch similarly generates a small torque to ground when the stator is overrunning. This torque is also insignificant except at very low input torques.

Cavitation becomes an issue when converter charge pressure is low relative to the input power. Torque is developed when the velocity field inside an element produces a pressure drop across its blades. The pressure on the leading blade surface increases, whereas the pressure on the trailing side lessens. Without sufficient charge pressure superimposed over the hydrodynamic pressure field, the trailing side pressure will eventually fall below the vapor pressure of the working fluid. When this occurs, the fluid locally boils, generating a stream of vapor bubbles that propagate downstream. The resulting changes in the effective density of the fluid and disruptions to the local flow field produce significant undesirable deviations in performance.

Friction effects at low torque and the onset of cavitation at high torque define the proper range for acquiring test data for use in subsequent studies. Because both internal friction and the propensity to cavitate are highly dependent on a converter's specific design, the limits must be ascertained during development testing of any new converter. Fortunately, all converters present a very large range of torques that will allow accurate representation of their performance by the dimensionless ratios.

Torque converter performance is relatively insensitive to the large temperature-driven changes in viscosity common to mineral-based transmission fluids. Turbomachines, in general, are relatively indifferent to working fluid viscosity, and most converter test and driving cycles elevate fluid temperatures quite rapidly. However, viscosity effects have been found to become important when designs are resized or "scaled" over a large change in diameters. The ratio termed Reynolds number, $(\rho T_I/D\mu^2)^{1/2}$, in Figure 13 was

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

developed to improve scaling fidelity in cases where viscosity is likely to be important. As input torque and cooling flow temperature are normally constant during efficiency testing, the Reynolds number can be considered a test constant. The best scaling of converter performance data is afforded when the sample converter is tested at the Reynolds number applicable to the ultimate utilization of the test results.

3.2.3 *The efficiency plot*

The nondimensional performance characteristics of converters are illustrated graphically on the efficiency or speed ratio plot, Figure 14. Because torque ratio, unit speed, input *K*-factor, and efficiency are single-valued functions of speed ratio, it is used as the independent variable. As these curves are dimensionless, they can be constructed from torque and speed data measured at any appropriate input torque. Thus, the torques and speeds from either the high torque test (dashed line) or the low torque test (solid line) from Figure 11, extended to zero speed ratio with stall test data, will produce essentially the same speed ratio plot.

The performance characteristics illustrated on Figure 14 are very typical of modern passenger car and light truck converters. Torque ratio is maximum at stall, usually between 1.5 and 2.5. It decreases monotonically as speed ratio increases, and at the coupling point, approximately at 0.9 speed ratio, becomes exactly 1.0. Above the coupling point, the torque ratio remains constant at unity. The input *K*-factor is nearly constant from stall to about 0.6 speed ratio and then begins to climb. At the coupling point, the slope of the *K*-factor curve increases abruptly. If extended to very high speed ratios, the *K*-factor curve will approach the unity speed ratio abscissa asymptotically. Efficiency is always zero at stall and climbs to a maximum at or slightly before the coupling point. At and above the coupling point, the efficiency exactly equals the speed ratio. The slope of the efficiency curve at stall is exactly equal to the stall torque ratio.

3.2.4 *Performance parameters*

Torque converter performance data are commonly stored and transmitted in the speed ratio plot graphical format or in an equivalent tabular arrangement. Convenience frequently dictates, however, a shorthand method of describing converter performance. This is most useful when drawing comparisons between various converter designs or when specifying the performance target of a

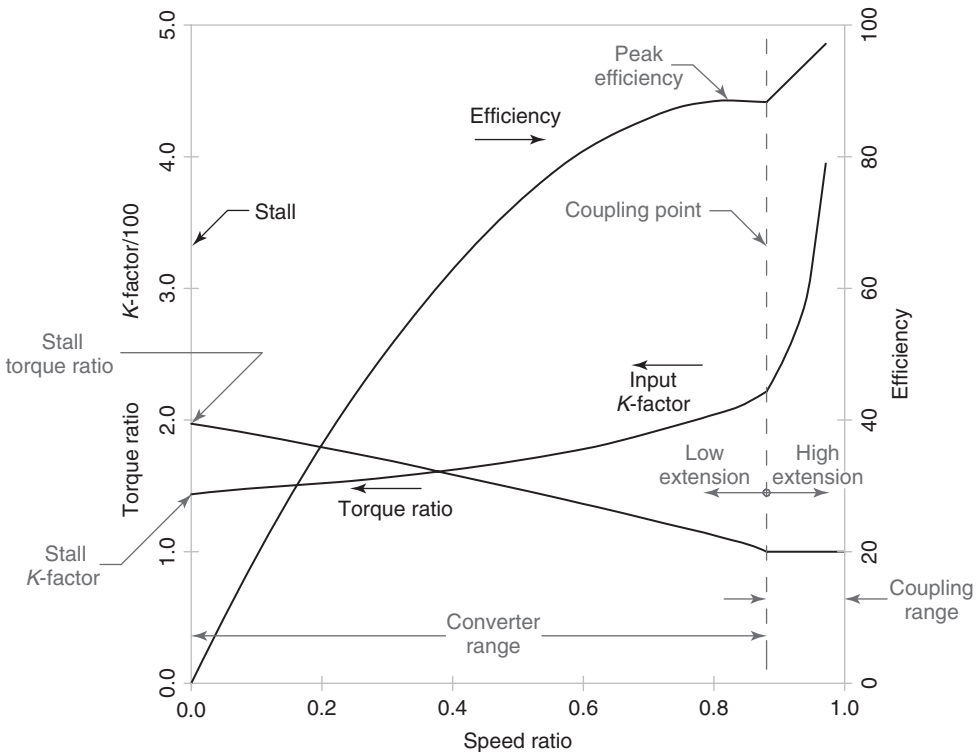

Figure 14. Efficiency or speed ratio plot.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

given application. A traditional terminology, noted on Figure 14, has evolved around several significant features of the speed ratio curve and this terminology is used to convey, somewhat qualitatively, the overall performance of a given unit.

As noted earlier, the stall characteristics of the converter are especially critical. The parameters of consequence at stall are the torque ratio and input *K*-factor, both of which are found at the intersection of their curves with the ordinate axis. The stall input *K*-factor is so important that is commonly appropriated as a model designation for a particular torque converter, and the stall torque ratio of the converter is usually quoted with the *K*-factor. Any reference to the "*K*-factor" and "torque ratio" of a converter may be interpreted as the stall values of these parameters even when the stall designation is not specifically mentioned.

The maximum of the efficiency curve before the coupling point is the "converter efficiency" or "peak efficiency." Its value directly affects the vehicle's fuel economy, particularly during low speed and transient driving.

The relative value of the speed ratio at the coupling point has recently assumed the connotation of "extension." This term was once interpreted in terms of converter output speed at the coupling point, but common usage has evolved to now reflect the speed ratio. It remains a comparative, rather than numerical measure: converters coupling below (roughly) 0.85 speed ratio are "low extension," whereas those coupling above 0.90 are "high extension."

3.2.5 *Converter coast characteristics*

Torque converters transmit torque from the turbine to the pump when vehicle dynamics drive the turbine faster than the engine. This occurs most frequently when the vehicle is decelerating with the throttle closed. Under these conditions, the speed ratio exceeds unity and flow between the elements reverses. The stator continues to overrun and the converter behaves as a fluid coupling, with input and output torques being equal. Very little torque is transferred until speed ratio exceeds 1.05, but the *K*-factor decreases very rapidly until a speed ratio of 2 is produced. The *K*-factor continues to decrease with further increases in speed ratio but at a much reduced rate.

4 CONVERTER MATCHING

The performance characteristics of the converter have a powerful effect on the performance and fuel economy of the vehicle, so the size and internal geometry of the converter must thus be properly chosen to produce characteristics that will optimize the vehicle attributes. The process of combining engine, vehicle, and converter parameters to attain the best balance of vehicle performance and economy measures is known as *converter matching*. Analysis of the interaction of the prime mover and the converter input is known as *engine matching*; determination of the interaction between the vehicle dynamics and the converter output is *vehicle matching*.

Both graphical and numerical techniques have been developed for matching analyses. The graphical methods predate the general availability of digital computers and are, consequently, limited in quantitative capability. Consequently, they have been largely superseded by highly sophisticated vehicle modeling software that characterizes the engine, torque converter, and gearbox with digital tables of experimentally obtained data. Efficiency test data, obtained at a single test torque and nondimensionalized as noted earlier, provides all the information needed to build the converter tables and allow subsequent simulation of the vehicle system over any route and driving schedule. Transmission producing organizations have large stores of performance data on many diverse converter designs, and the simulation programs allow rapid iteration through many designs to optimize a powertrain package.

All of these studies begin with a selection of converter designs that have a reasonable probability of matching the engine. The transient performance of the powertrain, and consequently the vehicle, during a heavy throttle launch is overwhelmingly determined by the interaction between the torque converter and the engine, so the initial selection of converter characteristics is made primarily on the basis of engine matching. In addition, although the graphical techniques are not quantitatively definitive, they provide a strong insight into the critical powertrain interactions that determine vehicle launch and early in-gear acceleration. Consequently, they continue to be used to guide the converter selection process.

4.1 Absorption curves

To facilitate engine matching, it is necessary to compare the engine's capability to develop torque with the converter's capability to resist that torque. Torque converter speed ratio plots are not convenient formats to facilitate this comparison, but contain all of the information needed to do so. The chart that has been developed to enable engine matching is the plot of "absorption curves," illustrated in Figure 15. These curves are based on the principle that both *K*-factor and torque ratio are single-valued functions of speed ratio. This is equivalent to stating that, at any given speed ratio, a torque converter will produce only one input *K*-factor and only one torque ratio. As the input *K*-factor

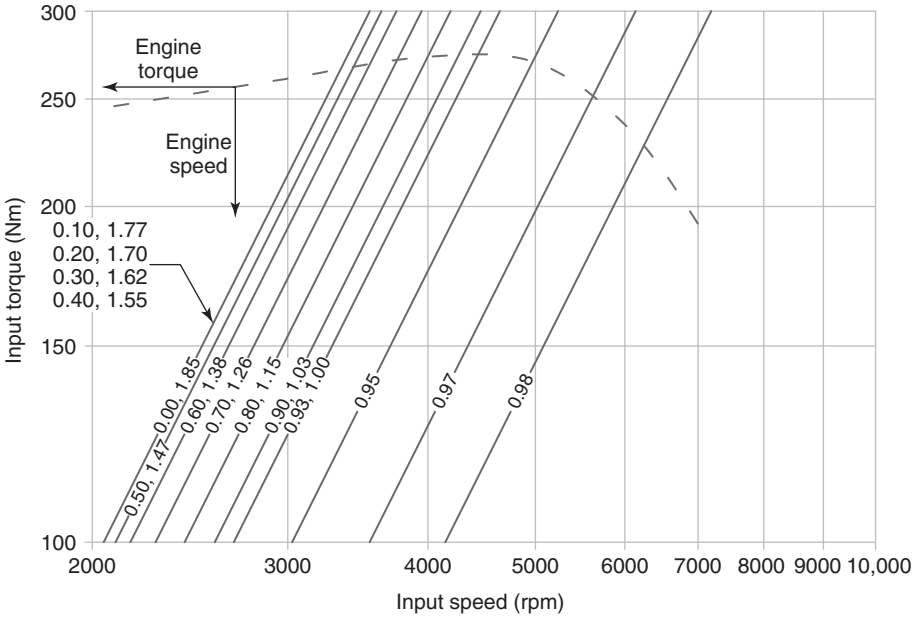

Figure 15. Absorption curves.

is defined as the ratio of input speed to the square root of input torque, the torque absorbed at a constant speed ratio is a parabolic function of the input speed:

$$T_I = N_I^2 / K_I^2 \tag{12}$$

When plotted on a linear grid of torque versus speed, this relationship will appear as a second-order curve, but on the log–log grid of Figure 15, it becomes a straight line with a slope of two. Anywhere on this line, the constant speed ratio and its unique torque ratio will apply. For a different speed ratio, another line will exist, again with a slope of two but its own unique torque ratio. The complete set of absorption curves is generated by figuratively stepping off incremental values along the abscissa of the speed ratio plot, reading the corresponding input *K*-factor, and plotting the corresponding absorption line. These lines are then labeled with the speed ratio and applicable torque ratio. Figure 15 shows several labels assigned to the left-most absorption line. This indicates that multiple speed ratios produce nearly identical input *K*-factors, and consequently superimposed absorption lines. On the speed ratio plot, this appears as a *K*-factor curve that is flat near stall.

As the output torque of the engine, corrected for parasitic loses, is the input torque to the converter, and the engine speed and converter input speeds are identical, the engine torque–speed curve may be plotted on the absorption curve grid. This is also illustrated on Figure 15. The intersections of the engine curve with the individual absorption curves are the match points. At any converter speed ratio, the match point is the condition where the engine's capability to produce torque is exactly equal to the torque converter's ability to resist torque. Consequently, the torque converter will hold the engine at the match point speed, and the engine will produce the match point torque. It follows that during transient engine acceleration, the converter will resist less torque than the engine produces until the match point speed is attained. The difference between the two torques is absorbed by the accelerating system inertia.

An immediate extension of the preceding discussion is that the output speed and torque of the torque converter at each match point can be computed from the absorption line speed ratio and torque ratio. By repeating these calculations for each of the absorption lines, the full output torque versus output speed curve for the combined engine and converter system can be produced. A sample of this type of curve is shown on Figure 16.

4.2 Engine speed regulation

Vehicle performance, by whatever measure, depends on the tractive effort produced at the drive wheels. The primary requisite for maximizing tractive effort, and therefore performance, is to properly position the torque converter absorption lines relative to the engine torque curve. The converter will then regulate the engine speed such that the maximum available engine torque is transmitted to the transmission gear system. Only three key lines must be

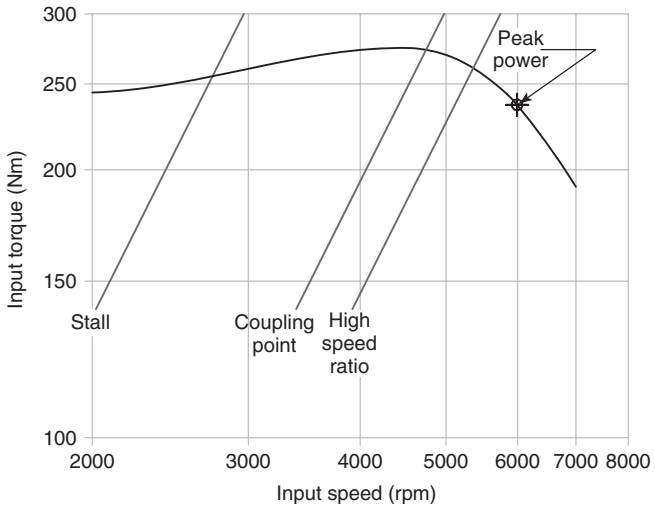

Figure 17. Three-line absorption curve.

considered: the stall line, the coupling point line, and a high speed ratio line. A three-line absorption plot is shown in Figure 17.

4.2.1 *Positioning the stall line—setting the stall K-factor*

Early in the launch event, maximum tractive effort is attained when the engine speed corresponds to the peak engine torque. This occurs when the stall line is positioned to intersect the engine torque curve at its maximum value. The engine speed at the intersection is known as the *stall speed* of the engine–converter combination. It can be verified in the vehicle by locking the brakes, selecting a driving range, and flooring the accelerator. As absorption lines are close together near stall (recall Figure 15), proper selection of stall speed assures good early acceleration. In general, engine speed will then be regulated by the converter to a narrow band near the torque peak until approximately 0.5 speed ratio is exceeded.

Unfortunately, high performance engines having their maximum torque at high engine speeds frequently require some compromise in stall speed. Torque converters are relatively inefficient devices at low vehicle speeds, and consequently a significant percentage of engine power is dissipated as converter heat during launch and acceleration. Engine power is directly proportional to engine speed, so elevating engine speed during launch produces additional converter heating. Not only must this heat be managed by the powertrain cooling system, but the wasted power ultimately represents consumed fuel. Additionally, the time required for the engine to spool up to an elevated stall speed makes the vehicle seem unresponsive, and the additional noise accompanying high engine speeds can likewise be unpleasant. It is thus common practice to limit the stall speed of such applications to approximately 2400 rpm (low power-to-weight vehicles) or 3200 rpm (high power-to-weight vehicles) and accept a decrease in starting tractive effort. Figure 17 shows such a condition, where matching the high engine torque peak would result in heat rejection and drivability problems. Setting the stall speed at 2660 rpm (260 Nm) rather than 4400 rpm (275 Nm) reduces the stall heat rejection rate by 43% at the cost of 5.5% in launch and early acceleration torque.

Positioning the stall line is a graphical analog to set the torque converter stall *K*-factor. The direct effect of this converter performance parameter on the starting tractive effort of the vehicle is the basis for its general acceptance as the single most important converter characteristic.

4.2.2 *The high speed ratio line*

The best tractive effort at the high speed extent of the launch event is attained when peak engine power is transmitted through the torque converter without attenuation. This requires that the converter efficiency be near 100% at the engine power peak. To approach this level of efficiency, the converter must be well into the coupling range before the engine reaches maximum power. As a 3% power loss in the converter can usually be accepted, the general objective is to position the 0.97 speed ratio line at the engine power peak. When less power loss is desired, an even higher speed ratio line can be placed at the peak, but this can exceed the capabilities of many normally sized torque converters.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Unfortunately, torque converter performance data does not always exist for speed ratios above 0.95. In practice, the acceptable high speed tractive effort criterion is usually based on the 0.95 speed ratio line by requiring it to intersect the engine curve well below the power peak. Figure 17 shows the desired condition of positioning the high speed ratio line well below the engine power peak.

4.2.3 The coupling point line

Within the constraints of stall speed and speed ratio at maximum power, it is desirable that torque multiplication be extended over the maximum range of engine speed. This means that the absorption line that represents the coupling point should be as far to the right as possible and intersect the engine curve no lower than the torque peak. The tractive effort during the middle of the launch event (0.5–0.9 speed ratio) will then be maximized, and there will be no unpleasant sag in the vehicle acceleration curve. The distance between the stall and the coupling point lines is proportional to the ratio of the coupling point *K*-factor to the stall *K*-factor. This ratio is sometimes called the *retention* of the converter, and it is qualitatively related to converter extension. It is important to part throttle crowd acceleration and launch.

Unfortunately, converter design features that move the coupling point line to the right also tend to move the intermediate speed ratio lines in the same direction. This is equivalent to imparting slope to the *K*-factor line on the speed ratio plot. *K*-factor slope in the 0.6–0.8 speed ratio range can mildly improve or degrade acceleration, depending on the shape of the engine torque curve, but is surprisingly detrimental to fuel economy. It is most difficult to control in converters that are intended to produce very high or low stall *K*-factors.

4.3 Vehicle perceived performance

Torque converter stall torque ratio and rotating inertia subtly influence vehicle performance in a manner not captured by engine speed regulation analyses. Figure 18 shows the first three seconds of a typical heavy throttle vehicle acceleration curve. Acceleration peaks approximately 1 s after launch and subsequently declines as increasing converter speed ratio reduces torque ratio. The maximum rate of change of acceleration, d^2V/dt^2 or jerk, occurs at about 0.5 s. The driver's perception of the vehicle's performance is greatly influenced by the value of peak jerk.

The numerical value of peak jerk is directly proportional to converter stall torque ratio and inversely proportional to the total engine coupled rotating inertia. The converter generally accounts for about one half of the total inertia, and its contribution is a very strong function of converter diameter. Thus, perceived vehicle performance is enhanced when stall torque ratio is maximized without increasing converter diameter.

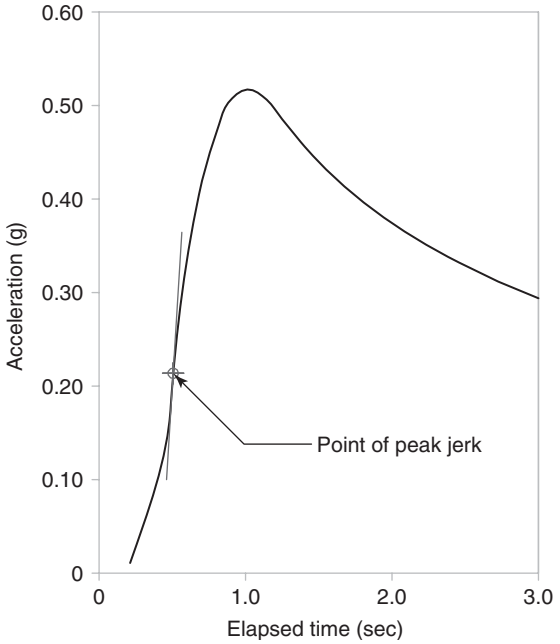

Figure 18. Vehicle acceleration versus time at wide-open throttle.

5 DESIGN CONSIDERATIONS

As noted earlier, the optimum performance and drivability of a vehicle is greatly enhanced by the proper choice of torque converter speed regulation and torque multiplication characteristics. Subsequently, maximizing the efficiency of the converter and fine-tuning of the input *K*-factor line yield significant enhancements to a powertrain's low speed and transient fuel economy. These steps determine the design of the converter hydrodynamic components.

5.1 Shaping the input *K*-factor curve

Proper speed regulation is attained by setting design variables to place the absorption lines at their best location relative to the engine curve, or alternately stated, obtaining the optimum input *K*-factors at the converter's stall, coupling, and high speed ratio points. However visualized, this process establishes the basic shape of the *K*-factor versus speed ratio curve by specifying its values at the three critical points.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

These points on the *K*-factor curve are primarily controlled by the size of the converter, the outlet angle of the pump blade, and the configuration of the stator blade. The influence of each of these features may be considered independently of the others, but their selection for a specific application is strongly dependent on the synergistic relationships between them and their influence on other important converter characteristics.

5.1.1 Diameter effects

Changing torque converter diameter raises or lowers the entire *K*-factor curve without changing its shape. The ratio of the coupling point and high speed *K*-factors to the stall *K*-factor remain constant, and consequently all of the absorption lines move by the same offset while maintaining their relative spacing. Increasing the diameter moves the lines to the left, equivalent to reducing the *K*-factors, whereas reducing the diameter moves the lines to the right, increasing the *K*-factors. This is shown in Figure 19 and is known as *tightening* or *loosening* the converter. The numerical *K*-factor change, as a function of diameter, is derived from the formula for unit speed:

$$K' = K(D/D')^{5/2} \tag{13}$$

Equation 13 applies at any speed ratio when the converter diameter is changed from D to D' while holding the torus design and all the blade angles constant. Computing new converter characteristics in this manner is known as *converter scaling*. It does not change torque ratio or efficiency appreciably, but as illustrated, the large exponent on the diameter ratio strongly effects the *K*-factors.

Two other effects influence diameter selection. Larger converters spread angular momentum changes across increased blade area and radii, thus reducing the leading to trailing side pressure gradient as a function of element torque. Reduced pressure gradient yields higher pressure on the blade trailing side, making the larger converter more resistant to cavitation. It also minimizes the intensity of the turbulent mixing at the outlet end of the blade, suppressing the generation of hydraulic noise.

Converter mass increases roughly with the cube of converter diameter, making thermal capacitance a similar function of diameter. Increased thermal capacitance reduces the converter's tendency to overheat during transient intervals of heavy throttle, low speed operation. Unfortunately, the engine-coupled rotating inertia increases at an even higher rate with diameter, sometimes exceeding a fifth power function. This can have a serious impact on the vehicle's perceived performance.

5.1.2 Pump outlet angle effects

Altering blade designs while holding diameter constant moves both the absolute and relative positions of the absorption lines. A typical absorption curve response to pump blade angle change is shown in Figure 20. These data represent three constant diameter torque converters, identical in all details except pump outlet angle. Increasing the pump outlet angle tightens the converter at stall and, to

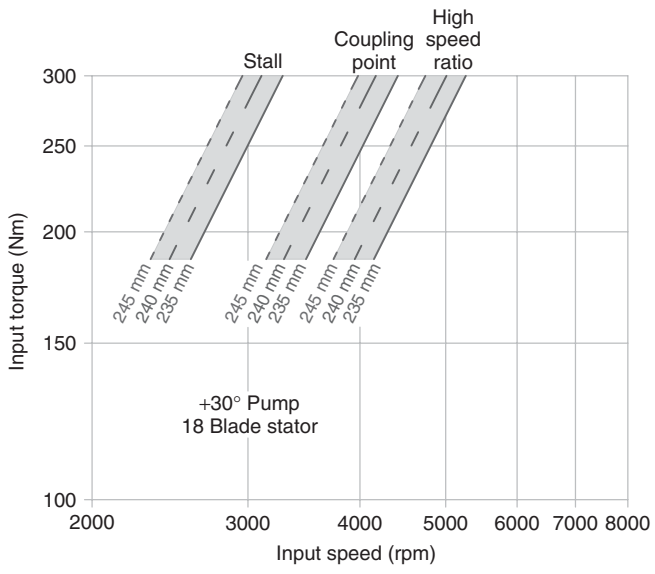

Figure 19. Absorption line response to converter diameter change.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

a milder extent, at high speed ratio. The coupling point is even less affected.

The three angles illustrated in Figure 20, +45°, +30°, and +10°, represent the approximate limits of current passenger car practice. Unlike diameter scaling, blade angle changes effect stall torque ratio and efficiency. Increasing pump outlet angle improves efficiency but degrades stall torque ratio to the degree that angles above +45° may produce marginal launch feel. Angles below +10°, although once very common, will produce measurably less than optimum fuel economy.

Pump angle influence trends are not apparent on absorption curves but are effectively demonstrated on the unit speed plot (Figure 21). Here, the independent variable is stall unit speed, the left ordinate is unit speed ratio and torque ratio, and the right ordinate is converter efficiency. Five pump outlet angles are shown: +45°, +30°, and +10° blades of Figure 20 and two additional designs of −15° and −35°. The relationships between outlet angle, stall *K*-factor, stall torque ratio, and converter efficiency are clearly nonlinear but monotonic. Also shown are the ratios of unit speed at the coupling point ($U_{coupling}/U_{stall}$) and high speed ratio point ($U_{0.95}/U_{stall}$). These parameters are identical with the *K*-factor ratios of a given converter, so they are directly proportional to the distance between the respective absorption lines on the log–log plot.

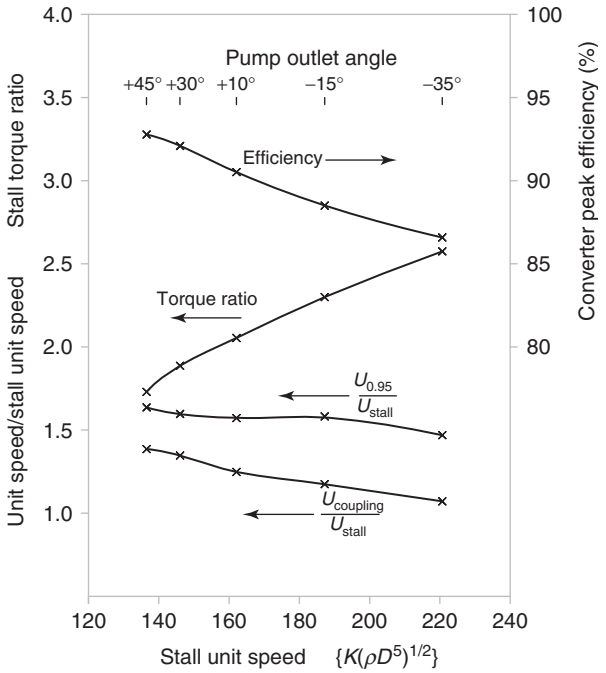

Figure 21. Converter performance response to pump outlet angle.

5.1.3 *Stator outlet angle effects*

Stator effects on absorption lines are highly dependent on the detailed design of the stator airfoil. The stator's short axial length, limited circumference, and wide blade spacing produce a strong synergism between its inlet configuration and thickness distribution that has converter performance influences not captured by outlet angle alone. In general, however, stall *K*-factor is strongly affected by stator outlet angle. Small increases in outlet angle yield large increases in stall *K*-factor, with somewhat smaller increase in the coupling point and high speed *K*-factor. With most airfoil designs, peak efficiency increases with outlet angle, plateaus, and then drops precipitously. Stall torque ratio may behave in a similar manner, or may decrease slowly at first and then more rapidly with increasing angle. Stator families typically have a small range of angles where overall performance is optimized.

Figure 22 illustrates the response of one converter to changes in stator outlet angle. The thin, relatively flat airfoil blade applied to this stator allows significant variation in exit angle without requiring redesign of the entire configuration. When the outlet angle is increased, the blade count is correspondingly reduced to accommodate the increased projection on shell and core circumferential space.

5.1.4 *Turbine outlet angle selection*

Unlike the pump and stator angles, the turbine outlet angle is not used to shape the *K*-factor curve. As the turbine and

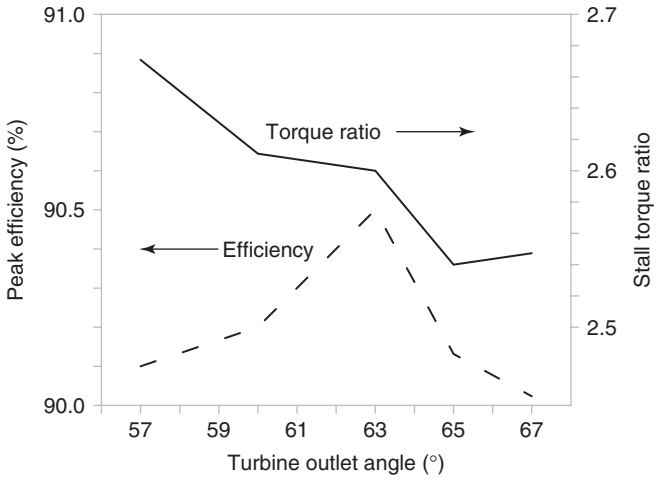

Figure 23. Stall torque ratio and peak efficiency versus turbine outlet angle.

stator torque equations indicate, the torque on both elements increases as the turbine outlet is made progressively more negative. This has such a powerful effect on torque ratio and efficiency that common practice is to set the turbine outlet angle to a very high negative value, usually in the neighborhood of -60°, where these parameters peak. With further increases in outlet angle, the blockage effects of the blade thickness and boundary layer begin to restrict the toroidal flow, causing a reduction in mass flow rate and decline in performance measures. This is illustrated for a typical converter configuration in Figure 23. On this unit, as turbine angle is swept from -57° to -67°, peak efficiency shows a definite maximum at -63° with stall torque ratio already declining. It is very probable that the exact location of the optimum angle for either of these measures is a function of other design features.

5.2 Tuning the torque ratio and efficiency curves

5.2.1 Hydraulic loss

The continuous circulation of working fluid through and between the converter-bladed elements involves a number of processes that dissipate energy. Turbulent eddies are created and dispersed, ultimately producing heat that cannot be recovered. The lost fluid energy accounts for the difference between the converter's input and output mechanical shaft power that directly define the efficiency curve. Decreasing the hydraulic loss at any speed ratio boosts the fluid mass flow. As the mass flow appears in all three torque equations, the torque ratio at that speed ratio increases, and efficiency, being the product of speed ratio and torque ratio, improves.

The equality between mechanical loss and hydraulic loss is best stated in terms of a pressure term rather than the more conventional hydraulic head:

$$N_O T_O - N_I T_I = \dot{m} P_L / \rho \tag{14}$$

The quantity $\dot{m}/\rho$ is the volumetric flow rate, Q, of the working fluid, so Equation 14 may be restated:

$$P_L = (N_O T_O - N_I T_I)/Q \tag{15}$$

In Equations 14 and 15, P_L is numerically the rate of energy loss per unit volume of flowing fluid. It may be visualized as the pressure required to push the working fluid around the torus and through the blade systems.

The pressure loss is traditionally represented as having two components: friction loss and incidence loss. Before the availability of modern computational fluid dynamics (CFD) programs, formulas developed for these components, with the torque equations presented earlier, provided the only means of analytically predicting the performance of new converter designs. With a number of empirical enhancements, they were used with some success for several decades. However, subsequent laser velocimeter and pitot probe measurements revealed that the actual converter flow field is much more complex than represented by these simple models, and they have been largely discarded as quantitative tools. Nevertheless, they continue to provide an effective means of guiding the selection of converter design parameters that minimize hydraulic energy losses, or at least distribute them across the operating range in an optimum manner.

5.2.2 Friction loss

Friction loss models the energy required to move the working flow around the torus without interaction with the blade systems. It was originally formulated as a form of pipe loss, complete with surface roughness, path length, passage hydraulic diameter, and average through-flow velocity terms. This level of sophistication was found to be neither necessary nor effective, and the loss can be represented in a much simpler manner:

$$P_f = c_f(\rho/2)(Q/A)^2 \tag{16}$$

In Equation 16, P_f is the loss attributed to conduit friction, A is a representative toroidal flow area, normally measured at the pump outlet, and Q/A is a representative toroidal velocity. The grouping $(\rho/2)(Q/A)^2$ is thus a kinetic energy term, and the coefficient c_f represents the fraction of the kinetic energy lost in the flow field. Studies have

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

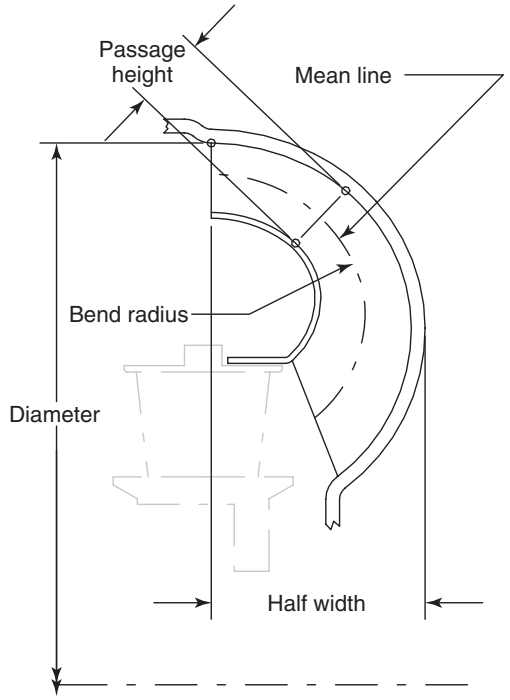

Figure 24. Torus design nomenclature.

shown that c_f is not constant but varies greatly with speed ratio.

Friction loss is strongly affected by torus design features, illustrated in Figure 24. Probably, the most important influence on c_f is the ratio of mean line bend radius to passage height. High passages that are sharply curved do not flow well, and this is equivalent to a high value of c_f. When packaging requirements impress a short half width on the torus, sharply curved passages are unavoidable and performance suffers.

5.2.3 *Incidence loss*

Incidence loss attempts to capture the flow energy that is dissipated when the flow stream approaches an element other than parallel to the blade inlet surface. When this occurs, the blade system must immediately redirect the flow as it moves onboard, and energy is dissipated in this abrupt change in velocity. The condition is illustrated in Figure 25 for the turbine inlet at 0.5 speed ratio. In this illustration, the subscript t indicates velocities just inside the inlet and subscript p refers to velocities at the pump outlet. The rotational speed difference between the two elements is not totally accommodated by the high turbine inlet angle, resulting in a change in tangential velocity, ΔS, immediately onboard the turbine. The incidence loss

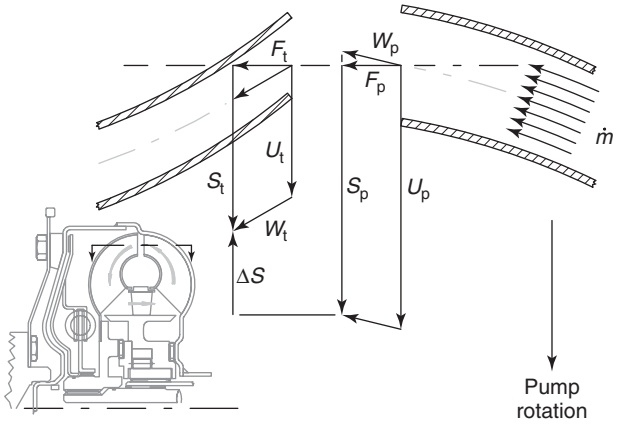

Figure 25. Pump outlet and turbine inlet at 0.5 speed ratio.

is defined as the kinetic energy related to this change:

$$P_i = c_i(\rho/2)(\Delta S)^2 \tag{17}$$

The incidence loss coefficient c_i represents the percentage of the energy change that is dissipated as heat. Little can be done to reduce c_i on the pump and turbine, as sheet metal construction does not provide a means of contouring the blade's leading edge. Conversely, cast stator airfoil blades are usually shaped to reduce incidence losses. The common approach to reduce incidence loss on all three elements is to establish blade inlet angles that minimize ΔS.

As the converter is operated over a range of speed and torque conditions, the direction at which the flow stream approaches each of the elements will vary. When the incoming flow is observed from the element's rotating reference frame, the angle of approach relative to the meridonal plane is known as the *relative entrance angle*. The difference between the relative entrance angle and the blade angle is the incidence angle. When the incidence angle is zero, ΔS will be zero and there will be no incidence loss.

Relative entrance angles are established by upstream and onboard velocities at the inlet of each element. This is illustrated for the turbine inlet in Figure 26. Although rotating speeds and the mass flow vary with torque, velocity triangles at a constant speed ratio are geometrically similar. Thus, the relative inlet angles are single-valued functions of speed ratio and may be illustrated as in Figure 27. The data shown are for a particular converter, but the trends are typical of most automotive designs. All three angles demonstrate a noticeable response, with the stator seeing the largest range of angles, followed by the pump and then the turbine. The incidence loss model, Equation 17, suggests that setting the blade inlet angles to match the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

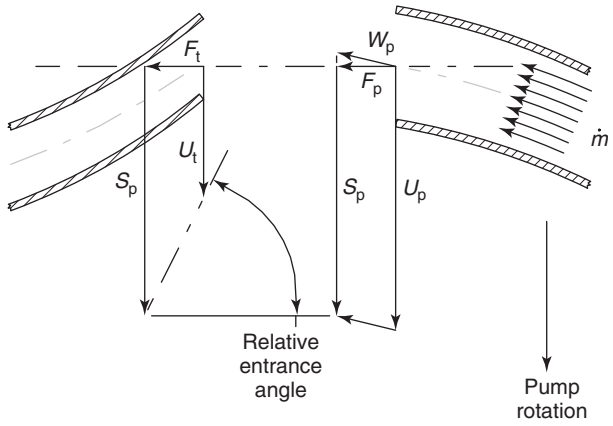

Figure 26. Turbine relative entrance angle at 0.5 speed ratio.

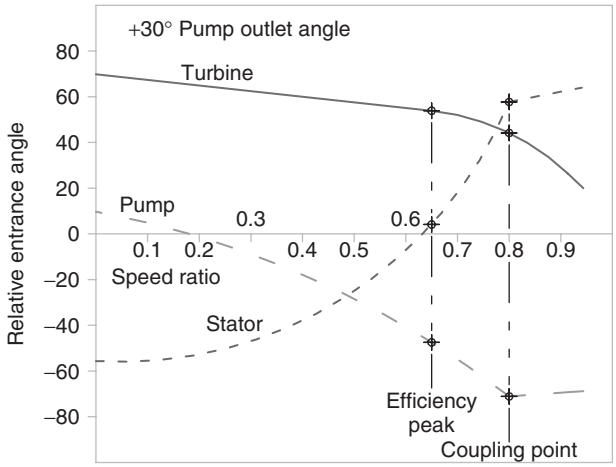

Figure 27. Relative entrance angles versus speed ratio.

low speed ratio-relative entrance angles would enhance the near stall performance, at some sacrifice at high speed ratio. Conversely, blade inlet angle settings at high speed ratio values of relative entrance angle would favor the peak efficiency and coupling range. Experience has proven this to be true, and the concept is used in practice to guide blade designs.

5.2.4 *Pump blade inlet angle*

Figure 27 shows the pump-relative entrance angle ranging from $+10^\circ$ at stall to -50° at the efficiency peak and continuing to -70° at the coupling point. Figure 28 illustrates typical performance compromises that result from a selection of pump blade inlet angles within this range. As expected, high values of inlet angle yield high stall torque ratio but suppress peak efficiency. Moving inlet angles in

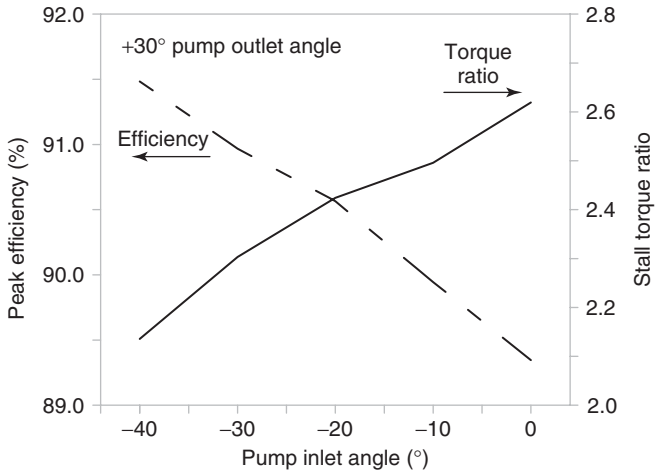

Figure 28. Stall torque ratio and peak efficiency versus pump inlet angle.

the negative direction result in monotonically decreasing torque ratio and increasing efficiency. The unit speed is shifted only slightly over this range of angles. Production pump inlet angles normally lie between -20° and -40° because of the impact of peak efficiency on fuel economy.

5.2.5 *Turbine blade inlet angle*

Figure 27 documents that turbine entrance angle is a very mild function of speed ratio between stall and the efficiency peak, with high values of turbine inlet angle favoring low speed ratios. Most converters respond to high values of turbine inlet angle by producing gains in stall torque ratio approaching 10% with little reduction of efficiency. Consequently, turbine inlet angles are usually set between $+55^\circ$ and $+60^\circ$.

5.2.6 *Stator blades*

The wide variation in stator entrance angle, as is evident from Figure 27, makes good performance at both low and high speed ratios difficult to obtain. Fortunately, stators are essentially nozzles, accelerating the flow field from inlet to outlet. High fluid velocity at the outlet is necessary to develop the optimum element torque and has the desirable propensity to reattach separated flows that are common at high incidence angles. In most converters, the stator torus area, established by the annulus between shell and core, is 10–20% smaller than the pump outlet area, further accelerating the flow. In addition, the airfoil shape provides a powerful mechanism for handling the difficult flow field.

As was noted earlier, the short axial length and small radii of the stator torus severely restrict the size of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto091
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

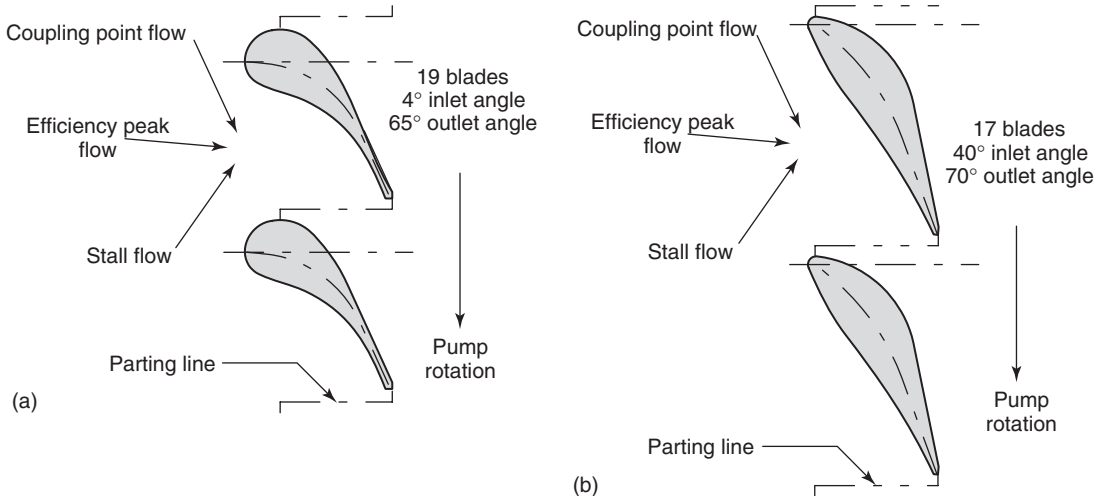

Figure 29. (a) Bullet nose stator blade. (b) High extension stator blade.

stator blade. Furthermore, molding dies require several millimeters of clearance between blades to allow for a parting line, forcing widely spaced blades. Significant velocity gradients are present across the outlet passage, and effective turning is measurably less than the mechanical blade angles. The short blade length causes the airfoil nose configuration and angle to have a strong influence on the outlet velocity distribution.

Two general stator blade forms are in broad use. The bullet nose blade shown in Figure 29a employs a large, bulbous airfoil to fair high negative angle, low speed ratio inlet flow into the stator. The blockage afforded by the airfoil thickness causes inlet flow to accelerate rapidly, reducing separation. The inlet angle is normally near 0°, producing nearly 60° of incidence at stall, but the fairing and early acceleration reduce c_i in Equation 17. The primary benefits of the bullet nose blade are very good stall torque ratio and low stall unit speed. Peak efficiency is only fair, and high speed ratio unit speed is mediocre.

Figure 29b illustrates a second common blade form. A number of different airfoils can be applied to this configuration, but all have a low thickness-to-length ratio and an angle difference between outlet and inlet of less than 50°. With a stall incidence over 90° and zero incidence occurring between 0.7 and 0.8 speed ratios, stall unit speed and torque ratio are definitely sacrificed for superior peak efficiency, coupling point extension, and high speed ratio unit speed. Being relatively thin, the blade makes no concession toward reducing c_i, but does not block high speed ratio flow. As was shown earlier, in Figure 22, this blade can be used effectively to very high outlet angles. This increases the coupling point unit speed, pushing the coupling point absorption line well to the right and increasing the coupling point speed ratio. Consequently, some organizations term this design the "high extension" stator blade.

In the production environment, stator tooling is much less expensive than pump tooling. Consequently, entire families of converters, with a wide range of performance characteristics, can be produced at reasonable cost by combining several stators of different designs with one or two pump assemblies. Figure 30 illustrates the range

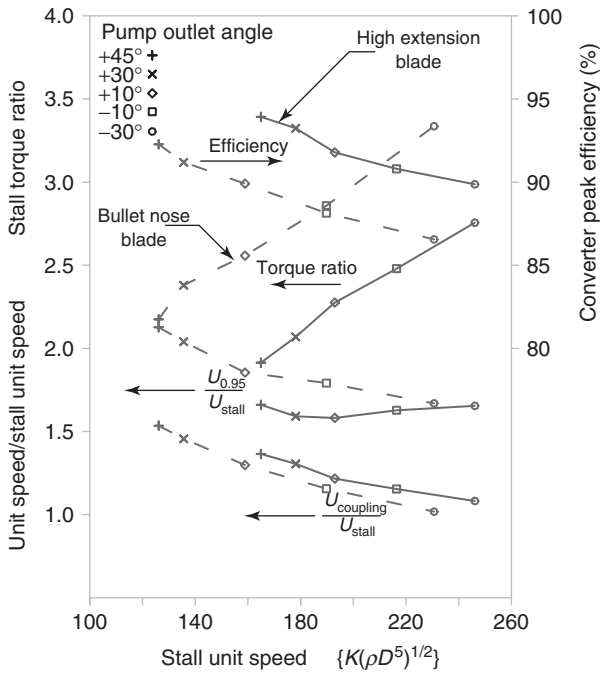

Figure 30. Converter performance response to pump outlet angle—bullet nose and high extension stators.

of performances generated by a typical bullet and high extension stator. Intermediate performance levels can be obtained by adjusting the thickness distribution and angle geometry.

5.3 Pressure vessel and thrust

When converter elements are rotating at speed and developing torque, large pressure gradients are established between and within the elements. These pressures, distributed over the projected areas of the elements, impose sizeable axial forces that must be accommodated. The pressure field is also distributed over the external walls of the converter, contributing to deflections during operation. There exists a synergism between element thrust and the converter deflection that influence the converter's mechanical design and its interface with the engine crankshaft.

5.3.1 Ballooning

The converter cover and pump housing, joined by the seam weld at the outside diameter, form a closed pressure vessel that must contain the internal pressure field and support centrifugal forces on its walls. The weldment's deflection under these combined loads is commonly termed *ballooning*. The pressure field has two components: the imposed static pressure, which is required to suppress cavitation, maintain clutch capacity, and establish cooling flow, and the intrinsic pressure caused by the motion and energy content of the working fluid. The pressure field is quite complicated when the blade systems are adding and extracting energy from the working fluid, but produces the maximum pressure vessel loading at very high speed ratios, when the elements are rotating at similar speeds. The pressure field is then essentially centrifugal, with an offset at the axis equal to the charge pressure. At any radius r, the local pressure P is given by:

$$P = \rho\omega_p^2 r^2/2 + P_C \tag{18}$$

In Equation 18, ρ is the fluid density, ω_p the pump angular velocity, and P_C the charge pressure, assumed to be imposed at the converter centerline. During vehicle operation, P_C is varied by the transmission control system in a typical range 350–900 kPa, and the centrifugal term at the periphery of a moderate size converter at high engine speed can exceed 3700 kPa.

When the parabolic function of Equation 18 is integrated over the relatively large areas of the converter pressure vessel and combined with the centrifugal force on the vessel walls, very significant stresses are produced. These stresses must be controlled to prevent excess elastic deflection and eliminate yielding. The converter is packaged tightly against nonrotating components where running contact would be ruinous, and internal splines and pilots must remain properly engaged. Yielding is unsatisfactory in any pressure vessel, as fatigue failures, with associated oil leakage, are likely if the steel is cycled into the plastic range.

Peak cover stresses are usually located in the corner between the drive lug and the seam weld (Figure 31). This is especially true on clutch-type converters where the sharp right-angle bend and subsequent clutch surface machining cause a relatively thin wall and stress concentration. Cover stresses are controlled by stock thickness and cover shape. Covers which have a relatively steep conical section extending from the inner diameter of the clutch surface to well inboard have been found to have the best ratios of peak stress to stock thickness. Unfortunately, the height of the cone tends to increase the length of the converter assembly. Flat covers, which provide compact packaging, do not possess good stress-to-thickness characteristics and occasionally demand high strength steel.

Pump housing stresses generally peak just outboard of the widest point of the torus of unbrazed pumps or just inside the inner edge of the torus on brazed pumps. Although the rated speed and pressure levels of the pump are always significantly improved by the gusseting effect of brazed blades, yielding, when it occurs, is much more severe. Pump housing stresses are otherwise controlled by stock-thickness selection.

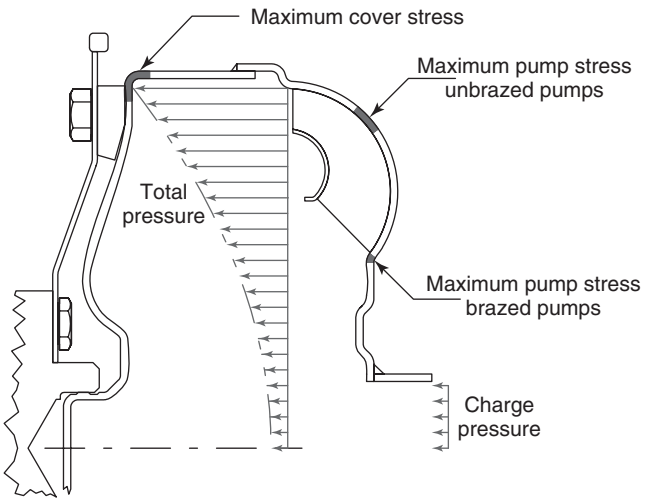

Figure 31. Pressure vessel loading and high stress areas.

5.3.2 *Element thrust*

Converter thrust is the sum of two separate axial forces exerted on the pump-cover weldment. One of these components results from the means used to exchange converter feed and exhaust oils between the converter and transmission. Routing oils through the converter hub subjects the hub area to the oil pressure. This produces a piston effect, pushing the converter toward the engine. The magnitude of this force is dependent only on the area of the hub and the converter charge pressure. It is termed *hub thrust* or *piston thrust*.

The second and more substantial thrust is produced by the integration of the converter's internal pressure field over the projected areas of each element. Element thrusts are substantial, as the projected areas are quite large and the pressure gradients across the elements can be significant. Normally, the turbine and stator thrust toward the converter pump, whereas the pump-cover weldment thrusts toward the engine. The force levels are strongly affected by element blade angles and torus configuration but, for a given design, are proportional to input torque and inversely proportional to converter diameter. As illustrated in nondimensional form on Figure 32, they are maximum at stall and decrease with speed ratio.

In the absence of other constraints, the pump-cover thrust will exactly balance the combined turbine and stator thrusts, with the loads transmitted through internal bearings between the elements. However, the torques being transmitted through the stator and turbine splines produce frictional lock between the elements and their shafts, preventing the stator and turbine from repositioning. The pump hub, however, has no such constraint. The pump's elastic ballooning characteristics allow it to deflect away from the stator, unloading the stator thrust bearing. Should this occur, the pump-cover thrust, equal to the sum of the stator and turbine thrusts, reacts against the engine crankshaft. Combined pump-cover and hub thrusts can easily exceed two metric tons, and this load is exerted against the engine crankshaft thrust bearing.

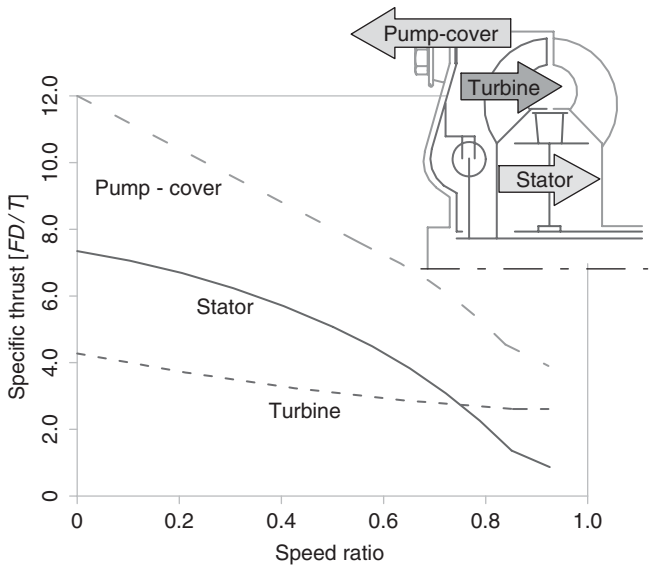

Figure 32. Converter element thrust versus speed ratio for a typical automotive torque converter.

As most engines are not capable of sustaining high crankshaft loads, the "floating pilot" mounting is used. In this arrangement, the cover pilot is allowed to slide freely in the crankshaft bore, whereas the converter position and drive are effected by a flexplate—a drive plate having a relatively soft axial compliance. During operation, pump-cover thrust deflects the flexplate toward the engine until internal contact is reestablished at the stator bearing. Crankshaft load is then determined by the flexplate rate, the displacement permitted by pump ballooning, and the hub thrust. Under even severe conditions, this is seldom more than a quarter of a metric ton. The remainder of the internal thrust is balanced at the thrust bearing.

6 CLUTCHING DEVICES

The torque converter clutch or lock-up clutch was first used in passenger car automatic transmissions in the 1949 Packard Ultramatic and a year later in the Studebaker Automatic Drive. As originally conceived, the clutch was intended to provide mechanical drive to the gear system input shaft during light throttle road load driving. Open converter efficiencies were generally in the 95% region at road load, so a roughly 5% fuel savings could be expected on steady-state highway driving. The designs were large, heavy, and expensive to produce, so with fuel economy not of paramount contemporary importance, the concept shortly fell into disuse.

The modern single-plate clutch configuration was introduced in the 1978 Chrysler TorqueFlite and was followed the next year by similar products from General Motors and Ford. These designs were intended to replicate the road load fuel economy improvements and to extend the gains to low speed, moderate throttle transient operation by implementing very aggressive apply schedules. This eliminated converter losses at lower vehicle speeds, and more importantly, lugged the engine into regions of optimum brake-specific fuel consumption (BSFC).

Mechanical drives have the propensity to pass torsion disturbances from engine-firing periodicity and its harmonics to the vehicle drivetrain and ultimately the

passenger compartment. The resulting noise and vibration being unacceptable, lock-up clutches must be equipped with torsional isolators, usually a radial arrangement of compression springs, to attenuate the engine-driven excitation. This places a compliance between the engine and transmission inertias, and results in an added normal mode of vibration to the driveline. The natural frequency of this mode must be tuned well below the engine-firing frequency in the regions of optimum BSFC, and this engenders numerous sophisticated isolator designs to provide very high compliance. The added complexity demands significant space in the already cramped transmission bell housing, and this has resulted in torus designs with very narrow half widths. Obtaining creditable hydrodynamic performance from these flat torus converters has proven to be a challenge.

Another very different approach to vibration management is to control the clutch to very low slip speeds just short of full lock-up. The clutch shares torque with the hydrodynamic circuit, and engine torsional vibrations are well isolated from the drivetrain. In these systems, the challenges are to accurately regulate the slip speed and to produce a friction interface that does not self excite. A number of proprietary friction materials, facing textures, and groove patterns have been developed to produce acceptable dynamic friction characteristics.

Dual Mass Flywheel

Jürgen Kroll and Ad Kooy
Schaeffler AG, Herzogenaurach, Germany

1 INTRODUCTION

The past few years have seen ever tighter restrictions on the permitted CO_2 emissions of automotive combustion engines as a result of EU regulations, and yet further tightening of the rules is on the horizon. Furthermore, from 2014, this regulation will also include light commercial vehicles. In light of this, significantly reducing the fuel consumption of vehicles has become a core task in the automotive industry. Drivers also want more economical vehicles because the costs at the pump have increased continuously and look set to rise even further. As the main load for propulsion is borne by the combustion engine even in a hybrid drive system, the aim is still to optimize the combustion engine further.

The focus is on making it even more efficient. It therefore makes sense to raise the combustion pressure using turbocharging. This permits an increase in the effective power rating with the same displacement (Basshuysen und Schäfer, 2010). The specific torque also increases. As a result, frequently used operating points can be placed in the ranges of low specific consumption. Looking at it another way, this means that the same power rating can be achieved with a lower displacement (downsizing). This effect is also beneficial for consumers, as they can expect equally good, if not better, driving performance despite lower consumption.

As narrow limits are set for the reduction in cylinder capacity from a thermodynamic perspective, in practice, the displacement reduction is achieved by reducing the number of cylinders. We can actually observe that six-cylinder engines are being increasingly replaced by four-cylinder engines and four-cylinder engines by three-cylinder engines. Two-cylinder units are even being used in some cases. Greater specific power rating and greater specific torque are generally used to design the engine features and powertrain such that the operating point of the engine can be shifted to a lower speed at a given driving performance (downspeeding). Figure 1 shows an overview of the development. The left side shows crankshafts for six-, four-, and two-cylinder engines.

Owing to a higher mean pressure, for a turbocharged petrol engine, the ignition pressure currently reaches values up to 120 bar; for a turbo diesel engine, up to 180 bar. However, the increase in the specific torque is associated with a stronger rotational irregularity in the engine. In simple terms: the greater the specific torque, the greater the rotational irregularity. This is expressed in torsional vibrations that run counter to the increasingly demanding expectations of automotive customers for vehicle comfort.

Downspeeding reinforces this finding in as much as lower engine speeds promote vibrations in the powertrain and boom (Figure 2). Without countermeasures, drivers would avoid this operating range and thus counteract the positive consumption effects that are possible. The reduction in the idle speed means that gearboxes tend to rattle at idle

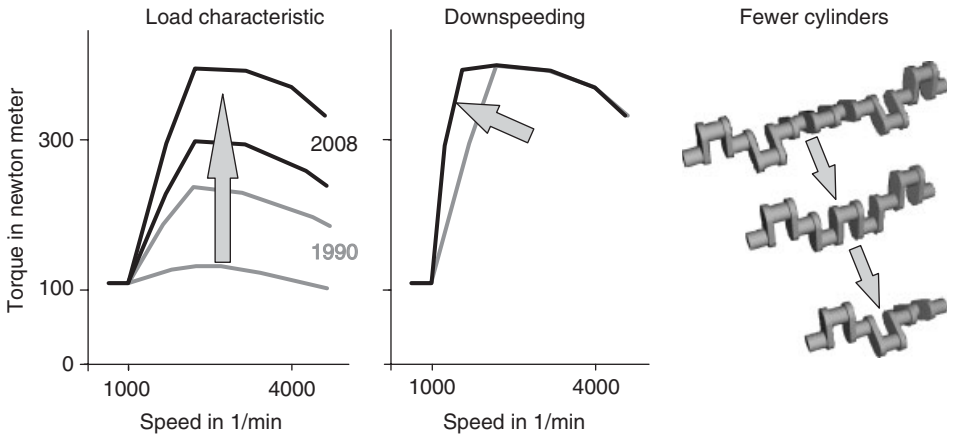

Figure 1. Development trends in engines.

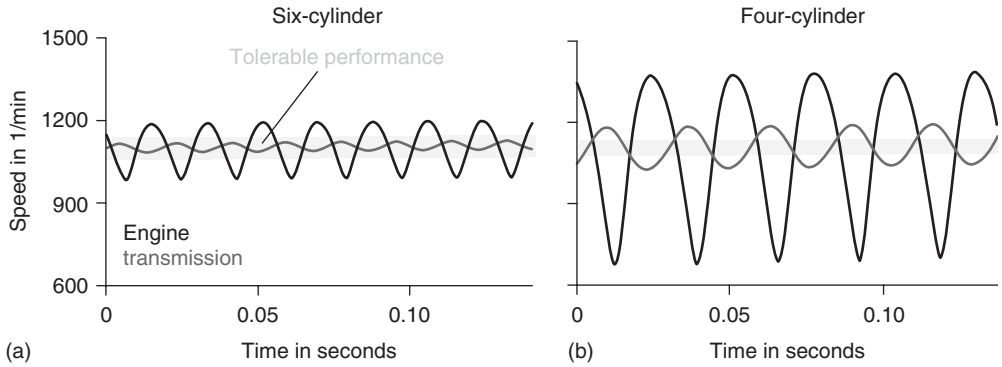

Figure 2. (a,b) Increasing demand for vibration isolation with downsizing and downspeeding.

speed. This loss in comfort has become more important over time because the lower viscosity gear oils used today, aluminum housing and reduced-friction toothed gear pairs only dampen the noise emitted to a limited extent.

To summarize: the possibilities of current engine technology can only be realized with an acceptable result for the customer using a powerful damping system. The conventional concept of a torsion damping clutch disk can no longer meet this requirement as the torsional vibrations that occur in modern engines can no longer be sufficiently absorbed. The following will show that the dual mass flywheel (DMF) fulfils this requirement.

2 ROTATIONAL IRREGULARITY OF PISTON ENGINES

2.1 Tangential force

Owing to the discontinuous way that the piston engine works and the oscillating mass forces, the tangential force that acts on the crank pin is irregular. Over the time of one working cycle, therefore, the actual angular velocity of the crankshaft is not constant (Küntscher and Hoffmann, 2006). The speed fluctuation is given by the degree of irregularity δ. The quieter the engine is to run, the smaller the value for δ must be. The following applies Equation 1:

$$\delta = \frac{\omega_{\max} - \omega_{\min}}{\omega_{\mathrm{m}}} \tag{1}$$

$\omega_{\max}$ indicates the greatest angular velocity of the crankshaft and $\omega_{\min}$ the lowest and ω_{m} the average. The average angular velocity ω_{m} results from Equation 2

$$\omega_{\mathrm{m}} = 2\pi n \tag{2}$$

In this equation, n represents the speed. Constant mean pressures result in approximately constant angular accelerations. As the irregularity is an integral result of this, it is largely dependent on the speed. The smaller the mass moment of inertia of the crank mechanism, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto092
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

greater the angular velocity difference $\omega_{max} - \omega_{min}$. As the speed increases, the degree of rotational irregularity quickly becomes very small, and as the speed decreases, the irregularity quickly becomes very high. In principle, this means that if a low degree of irregularity is to be achieved with a slow-running engine, a large flywheel must be used (Küntscher and Hoffmann, 2006). Further factors that influence the degree of irregularity are number of cylinders, pressure progression in the cylinder, geometry, and mass of the moving parts in the crankshaft drive and the combustion process.

2.2 Torsional vibrations and noise development

The powertrain executes partially rotating and partially oscillating movements as well as a swivel movement. The cyclical function of the piston engine accelerates and decelerates the moving power train parts, even when the engine is driven at constant load. This results in mass forces. They are differentiated by internal and external effects. The external effects consist of free forces and torques. They impose movements on the engine that transfer onto the supporting structure in the form of vibrations (Bosch, 2002).

The main cause of these structure-borne noise vibrations are the oscillating mass forces. The excitation as a result of the free mass forces and torques can only be influenced by mechanical balance (that is, the number and arrangement of the cylinders) or by balancer shaft (Lanchester balance).

The second source of structure-borne noise results from the irregular torque output. At lower speeds, it leads to booming or humming with ignition frequency and sometimes even to strong vibrations. This problem has a physical cause and cannot be influenced by the designer. The greater the specific torque of the engine, the more noticeable the humming and vibrating.

The engine also excites the vehicle as a whole, and in particular the gearbox. It swings against the vehicle, leading to rattling. The gearbox is primarily excited with the main excitation order. In a four-cylinder engine, this is the second order. In this context, "order" is the frequency with which an event occurs in relationship to the crankshaft speed (Basshuysen and Schäfer, 2010). A force of the first order changes its size with the crankshaft frequency; a force of the second order with double the crankshaft frequency.

Only with the development of a DMF was vibration isolation against the downstream powertrain achieved. This enabled the direct injection diesel engine for use in passenger cars to be developed on a large scale (Basshuysen and Schäfer, 2010).

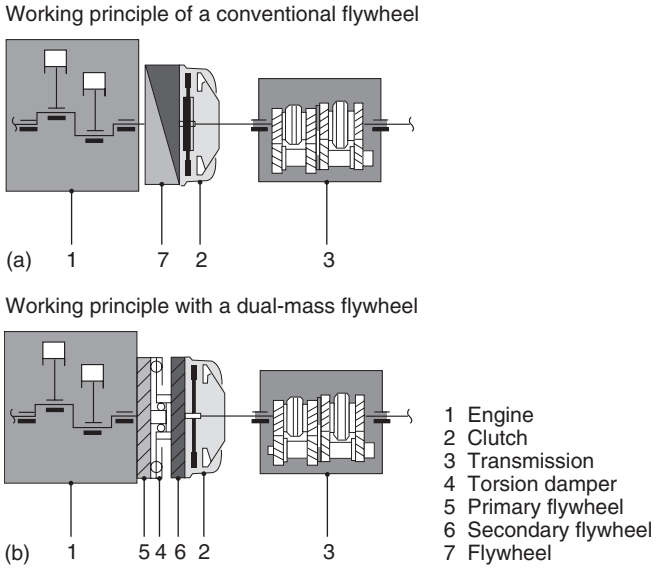

Figure 3. (a,b) Vibration isolation without and with DMF.

3 BASIC FUNCTION AND DESIGN

3.1 Function

The basic principle of the DMF is simple and efficient. With the additional mass on the transmission input shaft, the resonance point, which for the original torsional dampers lay between 1200 and 2400 rpm, is shifted to speeds that are considerably lower than idle speed. This means that the damper works postcritically, and excellent vibration isolation is present even from idle speed. In the usual design with a conventional flywheel and torsion damping clutch disk, the torsional vibrations in the low speed range are forwarded to the gears primarily unfiltered, as shown in Figure 3. This means that the tooth flanks of the gear wheels hit one another, which is perceived as idle rattle (Schaeffler Automotive Aftermarket GmbH, 2012).

In contrast, a DMF uses the spring damping system to filter out the torsional vibrations introduced by the engine and thus relieves the load on the gear components; as a result, the rattling stops. The effect is shown in Figure 4.

3.2 Structure

Figure 5 shows the structure of a standard DMF (Schaeffler Automotive Aftermarket GmbH, 2012). It consists of the primary flywheel (2) and the secondary flywheel (8). The two decoupled inertial masses are connected with one another via a spring damping system and twist-mounted against one another via a deep groove ball bearing or

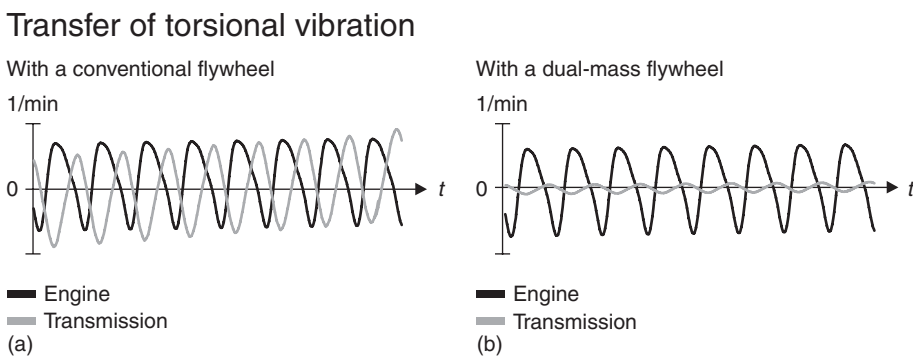

Figure 4. (a,b) Transfer of torsional vibrations from the engine to the gearbox without and with DMF.

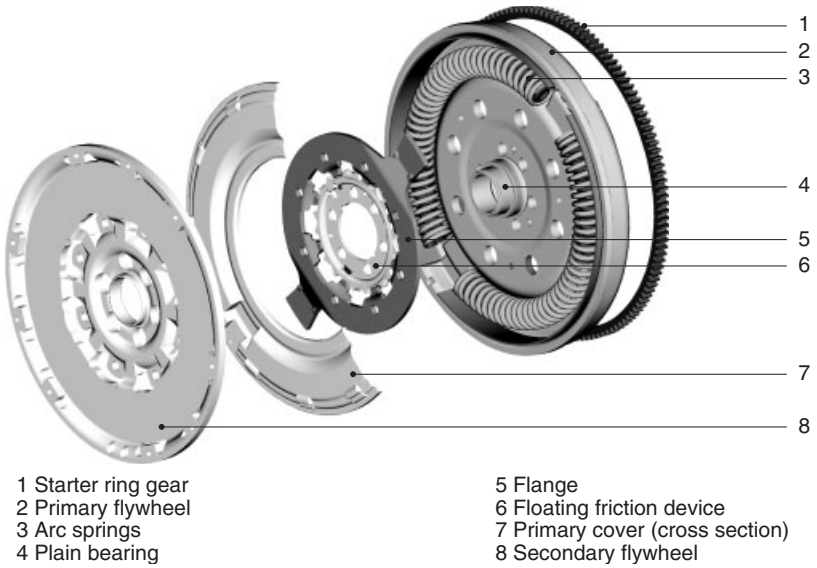

Figure 5. Structure of the DMF.

plain bearing (4). The primary flywheel with ring gear (1) assigned to the engine is bolted tight to the crankshaft. Together with the primary cover (5), it encloses a hollow space that forms the spring channel.

The spring damping system consists of the arc springs (3). They are positioned in guide shells in the spring channel and meet the requirements of an almost ideal torsional damper—at relatively low cost. The guide shells ensure a good guidance. Grease packing in the spring channel reduces the friction between arc spring and guide shell.

The engine torque is transferred from the arc springs via the flange (5). The flange is riveted to the secondary flywheel and, with its flange vanes, reaches between the arc springs. The secondary flywheel increases the mass moment of inertia on the gearbox side. It is fitted with ventilation slots for improved heat removal. As the spring damping system is in the DMF, a rigid design without torsional damper is usually used as a clutch disk.

3.3 Main components

3.3.1 Primary cover, primary flywheel, and arc spring stop

The primary flywheel (Figure 6) is connected to the engine crankshaft. Together with the crankshaft, it forms an inertial unit. Compared with a conventional flywheel, the primary flywheel of the DMF is significantly more flexible, which reduces the load on the crankshaft.

Together with the primary cover, it also forms the arc spring channel. Normally, this is in two parts and limited by the arc spring stops (Figure 7).

Figure 6. Primary cover and primary flywheel.

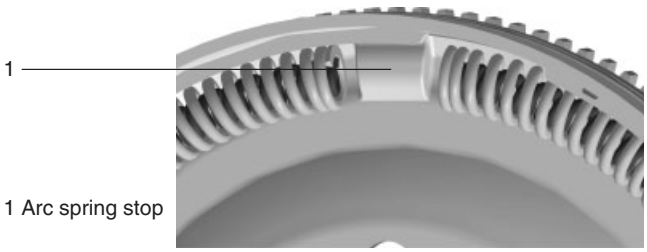

Figure 7. Arc spring stop.

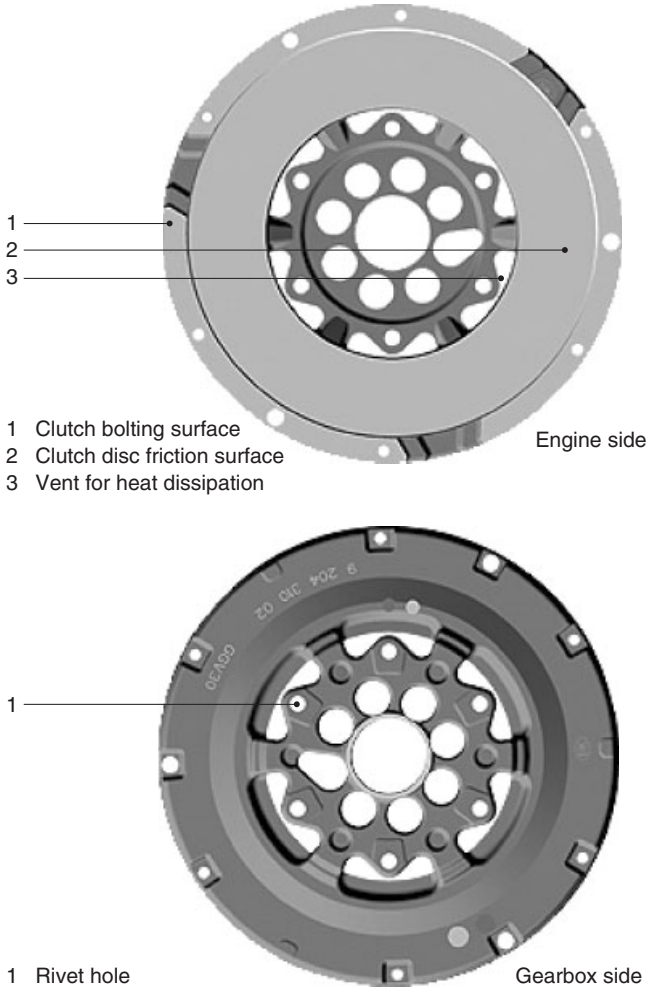

Figure 8. Structure of the secondary flywheel.

3.3.2 Secondary flywheel

The secondary flywheel connects the DMF to the powertrain on the gearbox side. Figure 8 shows the structure. In conjunction with the clutch, the flywheel transfers the modulated torque from the DMF. The cover of the clutch is bolted on at the outer edge. Inside the clutch, a spring mechanism presses the clutch plate against the friction surface of the secondary flywheel when the clutch is engaged. Friction allows torque transfer. The secondary side centrifugal mass consists principally of the secondary flywheel and the flange. The torque is taken up by the arc springs via the flange vanes (see also Section 3.3.4).

3.3.3 Flange

The flange (Figure 9) transfers the torque from the primary flywheel to the secondary flywheel via the arc springs and hence from the engine to the clutch. It is fixed rigidly to the secondary flywheel and is located with the flange vanes (arrows) in the arc spring channel of the primary flywheel. There is sufficient space between the arc spring stops of the arc spring channel and the arc springs for the primary wheel to move freely against the flange at idle speed.

3.3.3.1 Construction with fixed flange. In the construction with fixed flange (Figure 10), the flange is riveted to the secondary flywheel. The most simple form is the symmetrical flange, with both pressure and drive sides being the same. The admission point of the forces to the arc springs is thus at both the outer and inner areas of the end coil.

3.3.3.2 Flange with inner damper. On this model (Figure 11), the flange and side plates have spring windows on the inside, and springs sit in these windows. Because the trend for increasing engine torques is continuing, arc spring stiffness has to increase as long as the mounting space is the same. This leads to a deterioration in the vibration isolation. Friction-free inner dampers can counteract

Figure 12. Flange with slipping clutch.

this because they improve the drive isolation. They also have a further advantage: at high speeds, the arc springs are pressed strongly outward against the guide shell due to the high centrifugal force. This "deactivates" the coils, meaning that the arc springs stiffen and part of the spring effect is lost. Friction-free inner dampers can maintain a good spring effect because the inward springs are installed straight in the flange. Owing to their low mass and their radially short positioning, these springs are subjected to a substantially lower centrifugal force. In addition, friction in the spring windows is further reduced by the convex curve of the upper edge. This means that as the speed increases there is no increase in the friction and the effective spring rate.

3.3.3.3 Flange with slipping clutch. In contrast to the fixed design, the third type of flange is not riveted to the secondary flywheel. In this case, the flange is shaped as a disk spring. The disk spring is positioned at the edge by two holding plates (Figure 12). The cross section of the retainer is therefore fork shaped. The engine torque is transferred directly because of the friction torque between the retainer and the disk spring. At the same time, the slipping clutch protects the DMF from overloading.

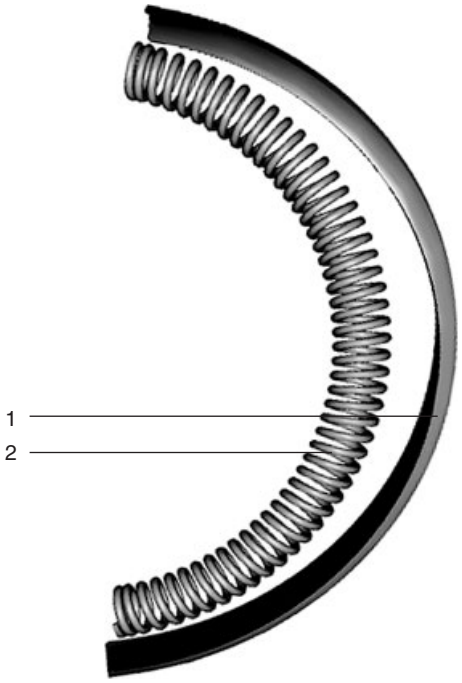

Figure 13. Arc spring with guide shell.

3.3.4 Arc spring

The arc spring is thus named because the coil spring with a large number of coils is installed in a semicircle (arc). This makes the best possible use of the mounting space available. The arc spring rests in the spring channel of the DMF and is supported by a guide shell (Figure 13). In operation, the coils of the arc spring rub along this guide shell generating friction, which is used for damping. The advantage is that the friction increases with the torsion angle. It is thus particularly high at the start and very low for the drive operating point. Stop damping can also be integrated. In order to reduce wear in the arc springs, the sliding surfaces of the arc springs are greased.

As there are countless variants of arc springs, a precisely aligned DMF system can be configured for every vehicle type and every load situation. In addition to single-stage springs, two-stage springs are also used—either as parallel springs (in various models) or as series springs. In practice, the individual types of spring are used in different combinations.

Single Springs. The most simple form of arc spring is the standard single spring (Figure 14).

Single-Stage Parallel Springs. Standard springs today are single-stage parallel springs (Figure 15). They consist of an outer and an inner spring of approximately the same length. Both springs are mounted parallel. The individual characteristic curves are combined to give a set characteristic curve.

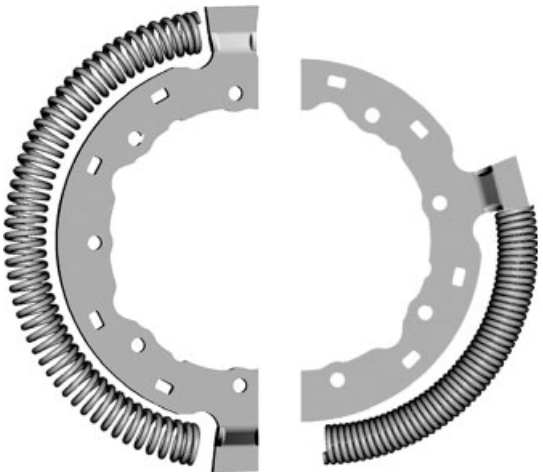

Figure 14. Flange with single spring, right compressed arc spring.

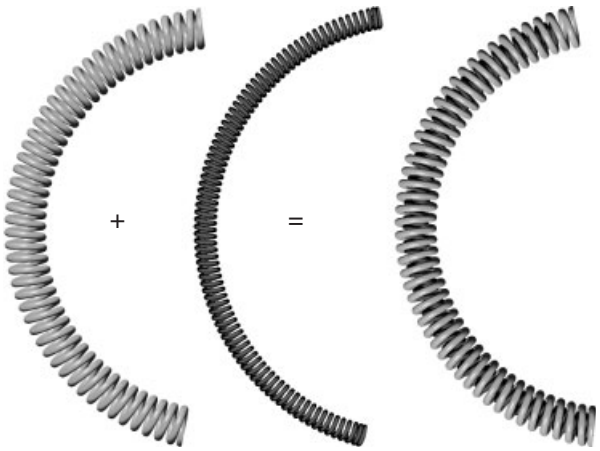

Figure 15. Composition of the single-stage parallel springs.

Two-Stage Parallel Springs. In the case of two-stage parallel springs, the two arc springs also lie one inside the other. The inner spring is shorter and is therefore activated later. The characteristic curve of the outer spring is adapted to the requirements for the engine start. As only the softer outer spring is loaded, the problematic resonance frequency range can be passed more quickly. At higher torque levels up to the maximum engine torque, the inner spring also comes into play. In the second stage, the outer and inner springs work together.

Three-Stage Arc Springs. These arc springs consist of an outer spring and two inner springs, of different strengths, mounted in series. Here, the two concepts of parallel springs and springs mounted in series are used together

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to achieve the optimum level of torsion balance at all engine torques.

4 SIMULATION AND DESIGN

4.1 Simulation

Ever decreasing development times for new car models and increasing cost-savings in the development phase mean that fewer and fewer test vehicles can be built. Simulation technology is therefore becoming increasingly important. The aim is to use simulation technology to optimize the products from the very beginning.

Firstly, all problematic operating points must be defined. The most important powertrain problems are summarized in the overview (Figure 16). These can generally be divided into three groups:

- acoustic problems (idle rattle and body boom);
- tangible problems (shaking);
- strength problems.

4.1.1 Efficient models

As the amount of computer time available is not infinite, efficient models with adequate levels of accuracy must be available for the simulations. To illustrate the vehicle for driving in drive, as described earlier, a model with nine rotating masses is used (Figure 17). Where possible, only the relevant natural modes and powertrain parameters are taken into consideration (Balashov *et al*., 2006). In contrast, all of the force-transmitting elements and excitation objects to be considered are modeled in great detail. The drive can operating state be described sufficiently accurately with this model.

Figure 18 outlines the analytical model, the comparison of measurement with simulation, as well as the target factors, in the same way as the above example for the start operating point, which can also be mapped well using simulation technology.

Operating point	Problem
Idle	Gear rattle
Drive	Gear rattle, boom
Coast	Gear rattle, boom
Engine stop	Gear rattle, clatter
Tip-in and back-out	Surging
Vehicle launch	Judder, rattle, surging
Engine start	Durability, comfort
Sub-idle speed resonance drive	Durability

Figure 16. Powertrain problems dependent on the operating point (from K06; 58).

The engine start is considered as a whole, in the same way as for drive operation. In addition to the DMF parameters, the engine, engine management, starter, and auxiliary equipment are considered. The target factors here are the start area between the actual and determined engine speed and the maximum torque in the DMF. While the evaluation of the start area represents a comfort factor, the target factor "maximum damper torque" is a strength factor. This procedure was developed correspondingly for all further operating points (Fidlin and Seebacher, 2006).

4.1.2 Whole vehicle consideration

When carrying out simulation calculations, the overall system observation is another essential feature. This looks at not only the DMF and the entire clutch system but also the entire powertrain, including engine and engine management. Considering the overall system also allows any problems in the interaction of the torsional vibration dampers with other components in the vehicle to be detected at a very early stage. The engine management, in particular, with idle-controller, smooth running regulator, load change dampers, etc., very often has complex interaction with the DMF.

Figure 19 shows the influence of engine management and starter speed on the engine start. The three diagrams show the engine and gearbox speed signals. First, we see a phase in which the engine is driven by the starter unfired. After a few cycles, the engine is fired up. The engine speed then runs through the DMF resonance, which often presents a problem for the calibrations.

A reduction in the starter speed by 30 rpm would have a considerable negative impact on the engine start (Figure 19, top right). The situation becomes critical if the starter is decoupled too early, for example, before the engine is fired for the first time. The result is unacceptable resonance vibrations that, in an extreme case, can lead to a resonance failure (Figure 19, bottom right).

Interactions between the complex transmission behavior of the DMF and the engine management often have a negative effect on driving comfort even in the idle speed operating state. To achieve perfect isolation with regard to ignition frequency, a degree of play is deliberately provided between the primary and secondary DMF mass. This successfully removes the troublesome idle rattle (Figure 20, left). However, the play and interaction of the set idle speed and the regulator parameters (PI-controller) can also excite low frequency vibrations and thus cause uncomfortable vibrations (Figure 20, right).

4.2 Design

4.2.1 Target factors, subjective evaluation, and sensitivity diagrams

In order to objectively evaluate the quality of a design, suitable target factors must be found. The aim therefore is to define the measurable physical factors that must be evaluated or determined, and the extent to which these measuring factors correlate to the subjective feeling.

The determination of the target factors for driving at full vehicle load in drive operating state is shown in Figure 21. Possible problem points here are idle rattle and

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto092
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

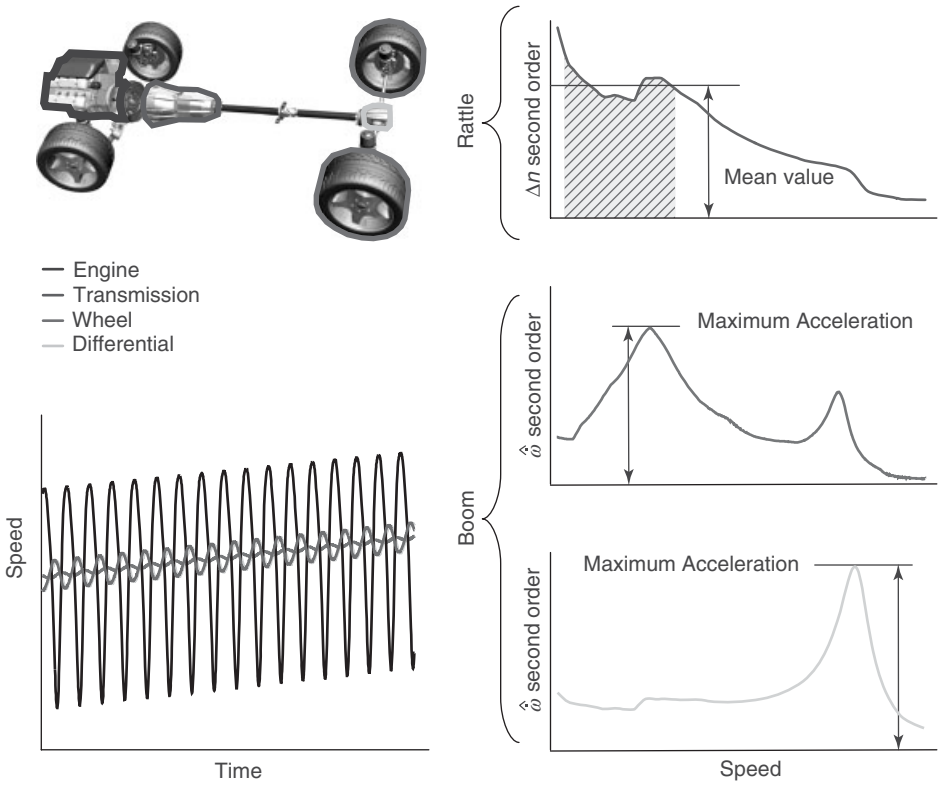

Figure 21. Evaluation of the target factors for rattle and boom at full load in drive.

body boom. To evaluate the quality of the driving in drive, the vehicle is accelerated with maximum torque. The speeds at transmission input, at final drive unit input (for rear-wheel drive vehicles), and at the wheel are measured in high resolution. Depending on the target factor, the signals are differentiated or integrated over time and their amplitudes are shown over the speed of the engine. To evaluate the idle rattle, the average amplitude of the fluctuations in the revolutions per minute of the transmission signal over the critical speed range is evaluated as the target factor (Fidlin and Seebacher, 2006). The body boom correlates accurately enough with the acceleration increases at the wheel and at the final drive unit input. At speeds under 1500 rpm, the maximum resonance magnification at the wheel is the target factor. A powertrain resonance can cause boom noises particularly in rear-wheel drive or four-wheel drive vehicles. The maximum acceleration magnification at the final drive unit input is evaluated as the target factor for this.

Ideally, these measurements are carried out with different DMF designs and various damper systems. This ensures that the largest possible range of measured target factors is covered. The installed systems are evaluated subjectively

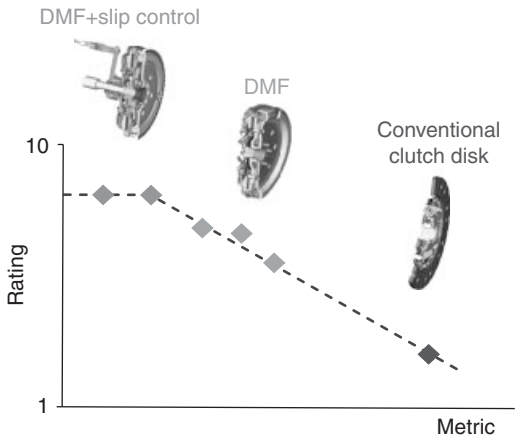

Figure 22. Sensitivity diagram using the example of the target factor humming at low engine speed.

at the same time as the measurements are carried out. By applying the subjective evaluations over the appropriate target factors, sensitivity diagrams are created.

Figure 22 shows the subjective evaluations applied over the target factors using the example of humming at low

engine speed. Rating 10 corresponds to driving without noise and rating 1 stands for unbearable body boom. For most customers, rating 8 is the target to be achieved, but at least rating 6 should be obtained.

4.2.2 *Chip tuning*

Chip tuning is a variant of engine tuning that requires no constructional changes to the engine. To increase performance, only the engine control unit parameters are changed. The modifications are generally aimed at the fuel mixture and the loading pressure of the turbo charger. Vehicle manufacturers occasionally use chip tuning to offer an engine with the same components in different power classes. In these cases, the tapping of the thermal and mechanical reserves is not a problem because these engines are also subject to production trials. There is a difference between this and retrofit chip tuning. The increase in performance and torque targeted here can exceed 30%. There is no check as to whether the powertrain can meet the increased demands in the long term.

Usually, the spring damping system of a DMF is designed specifically for the respective engine. If the maximum torque is in the range mentioned earlier or higher still than the value of the series engine, the safety reserve of the DMF is usually consumed or exceeded (Figure 23). As a result, in normal drive operation, the arc springs can be pressed together completely. This leads to a deterioration in the isolation (noises) or to vehicle shaking. As this happens with ignition frequency, very high load cycles occur that damage not only the DMF but also the gearbox, the drive shafts, and the differential (Schaeffler Automotive Aftermarket GmbH, 2012). The increased wear usually makes slow progress but can sometimes also lead to a sudden DMF failure.

5 FURTHER DESIGN CONCEPTS

5.1 Dual mass flywheel with centrifugal pendulum-type absorber

5.1.1 *Basic function*

The centrifugal pendulum-type absorber (CPA) is a persuasive option for improving DMF performance further. It is an absorber, that is, a secondary spring mass system outside the power flow. When this type of secondary spring mass system is excited with its resonance frequency, it moves in opposition to the exciting vibrations and thus ideally cancels them out. In a classic absorber connected via a spring (steel spring or elastomer), however, this effect only occurs at one frequency, namely the resonance frequency of the absorber. Two other resonance points arise—above and below the absorber resonance frequency—and have a very disruptive effect. A classic absorber is therefore unsuitable for the applications described here. The CPA works differently. Here, the restoring force of the absorber mass is determined primarily by the dominant centrifugal force and not by the negligible gravitational force (Kroll, Kooy and Seebacher, 2010). However, as this centrifugal force is speed-dependent (in contrast to the constant gravitational force), a speed-adaptive absorber is created, that is, an absorber whose natural frequency shifts as the speed changes. Thus, a fixed order of excitation can be absorbed but not a fixed frequency. This makes the CPA an ideal component for a piston engine as the pendulum is aligned

with the main excitation order and, theoretically at least, can cancel this out. The relevant restoring torque M is calculated from the pendulum mass (m), the radial distance of the pendulum to the center of the secondary flywheel (R), the length of the pendulum (L), the speed ω^2, and the vibration angle. The following applies Equation 3:

$$M = -mRL\omega^2 \sin\varphi \tag{3}$$

Figure 24 illustrates the precise relationship.

5.1.2 *Structure*

In practice, however, vibrations in the dimensions of a main excitation order cannot be canceled out by the absorber being positioned on the crankshaft or fixed flywheel as the cyclic irregularities of the engine are too great and the vibration angle and size of the absorber masses too small because of the mounting space restrictions. Instead, the CPA is coupled with the secondary side of the DMF, that is, with the element for which the level of the torsional vibrations has already been reduced to 10–20% of the initial value on the engine. As now only the residual vibrations in the ignition frequency have to be compensated, significantly lower pendulum masses and vibration angles are necessary (Reik, Fidlin and Seebacher, 2009). Under these conditions, a CPA can be easily integrated into the mounting spaces usually available. Figure 25 shows the basic form of a DMF with CPA.

The pendulum is a bifilar pendulum, that is, it has two suspension points. The absorber masses are suspended over bolts that move in kidney-shaped tracks in the pendulum masses and in the DMF flange (Figure 26). The absorber arrangement is defined via the design of the tracks (Kooy *et al.*, 2002). The masses do not rotate relative to the flange. All points of the pendulum describe the same track curve. A CPA arranged on the secondary side in this way produces a particularly effective vibration isolation

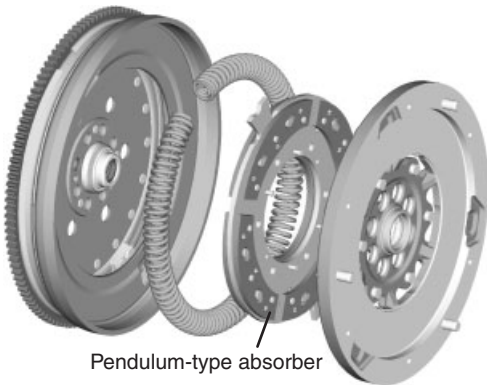

Figure 25. Design of a dual mass flywheel with centrifugal pendulum-type absorber on the secondary side.

with typical improvements in NVH (noise, vibration, and harshness) of two ratings. In experiments, a decoupling of up to 99% was achieved in combination with a DMF with inner dampers.

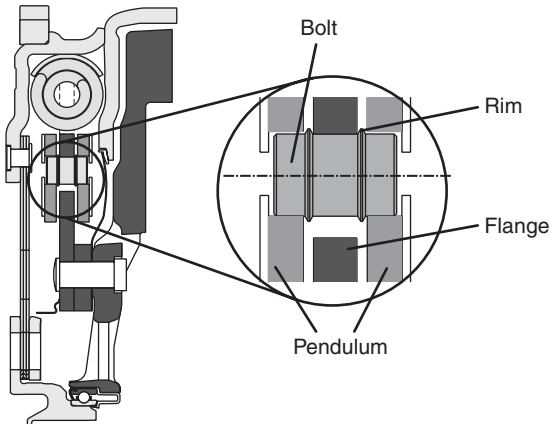

Figure 27. Friction-reduced pendulum positioning.

During the design and production, free vibration of the pendulum must always be ensured.

Friction in the CPA would cause a reduction in the buffered energy, the balance would be destroyed, and the secondary flywheel would start to swing again. Rims on the bolts enable the required, generally friction-free positioning of the pendulums (Figure 27).

The rims prevent contact between the pendulums and the flange and create only minimal friction as the relative speed in the contact area with both is minimal. The rolling friction coefficients must also be observed as, at speeds above 2000 rpm, they reduce the effect of the pendulums because of the high centrifugal force and thus significant rolling friction. Of course, not only the mass but also the radial position of the center of gravity is crucial for the energy absorption capacity.

Compared to the DMF with inner CPA (Figure 28), the axial arrangement is positioning the pendulum radially outward. By that tangentially more mass can be accommodated and the increased radial distance increases additionally the inertia of the pendulums quadratically. Especially, at very low speed, this concept is superior.

The DMF with an internal CPA combines the advantages of the long arc spring damper with a CPA in the same space. With an unchanged start performance, it achieves very good isolation over a wide speed range. In DMFs with external CPAs, the costs of the inner arc spring damper can be optimized using a smaller arc spring damper. The resulting shorter characteristic curves are more disadvantageous at the start but can be compensated in part by the increasingly common automatic starts resulting from the introduction of start/stop systems. The external pendulum means that the very good isolation can still be achieved effectively at low speeds. In a DMF with an external CPA, an inner damper can be integrated in addition to the normal arc spring damper. As a result of the basic isolation of the DMF, which is already good, the pendulums still work fully even at low speeds and thus enable isolation up to 99%.

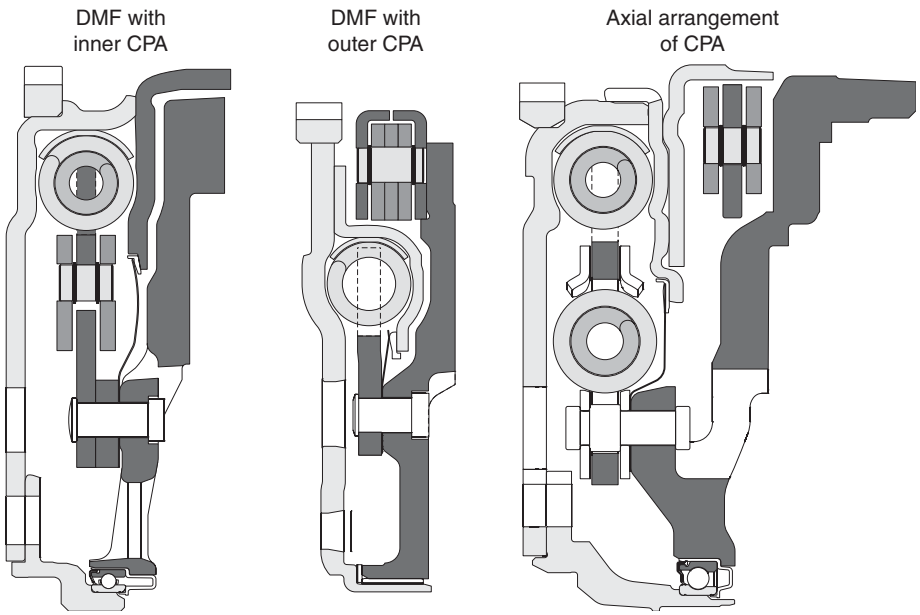

Figure 28. Possible arrangement of the centrifugal pendulum-type absorber in the DMF.

5.1.3 Design

The relatively complex interactions between the powertrain and the pendulum can be described in good quality with a simplified energy model that explains the main influencing factors (Figure 29). The simplified model assumes that the pendulum is positioned with no friction and that its natural frequency is precisely aligned with the respective main excitation order—on a four-cylinder engine this is the second order. Only the main excitation order is considered as excitation as higher orders generally have lower amplitudes and due to the higher frequency, also do not cause as much boom or rattling. For greater clarity, the rotating powertrain is shown as a linear vibration model.

The CPA becomes a linear absorber whose natural frequency automatically adapts to the excitation frequency. The absorber function means that its amplitude increases until the retroactive effect of the absorber has completely calmed the secondary flywheel. In this state, the energy passed into the secondary flywheel via the damper is completely buffered by the absorber.

The vibrational energy is therefore not destroyed but merely buffered, avoiding losses. What is interesting is that the ideal isolation is initially achieved without considering the inert mass of the secondary flywheel. The pendulum merely has to be capable of buffering the vibrational energy completely. Using simulations, we can actually show that a reduced mass moment of inertia of the secondary flywheel is not a direct disadvantage for the vibration isolation under the given condition.

The regulation inherent in the system also leads to an automatic adaptation to different excitations such as under partial or full load and represents a particular strength of the principle. If the excitation is low, the CPA responds with a smaller vibration angle and thus avoids overcompensation. The new optimal balance is set automatically with no additional regulation.

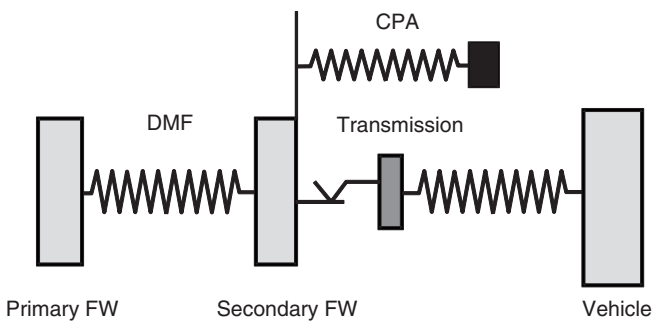

Figure 29. Linear vibration model.

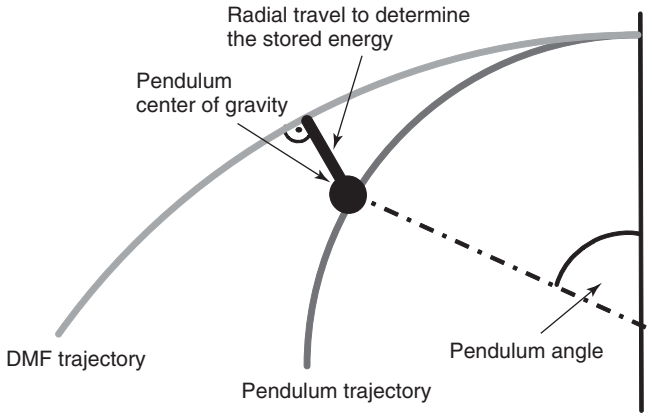

Figure 30. Radial migration of the center of gravity of the pendulum ("VDI_Buchtext," Figure 7). (Reproduced with permission from Kooy, Grahl and Gvozdev, 2011. © Ad Kooy.)

The mounting space and the centrifugal force loads restrict the maximum possible vibration angle of the pendulum considering the strength aspects. Together with the pendulum masses, the vibration angle defines the vibrational energy that can be stored. The vibrational energy is primarily buffered at the end of the track as a type of potential energy, whereby the centers of gravity of the pendulums have migrated inward radially (Figure 30). A larger vibration angle increases this radial path and thus increases the energy that can be stored more significantly than proportional increases in mass.

The maximum energy that can be stored in the pendulum is limited by the maximum vibration angle and increases quadratically with increasing speed. At low speeds close to idle speed, this results in a range in which the CPA cannot completely buffer the residual energy of the secondary flywheel (Zink and Hausner, 2009). The basic isolation of the damper is particularly important here. Arc spring dampers, with their very long springs, are particularly suitable. If the full engine torque is not yet present at speeds approaching idle speed, a two-stage system can achieve further improvements.

In addition to downspeeding, reducing the number of cylinders is a method of saving fuel that is already in widespread use. This leads not only to a significant increase in the degree of isolation demanded by the damper but also to a considerably elongated track geometry of the CPA because of the change in the excitation arrangement (Figure 31).

Identical energy storage capacity can be achieved with identical inertia via an identical radial path. As the number of cylinders reduces, the track width widens and becomes harder to align with existing mounting spaces. Current

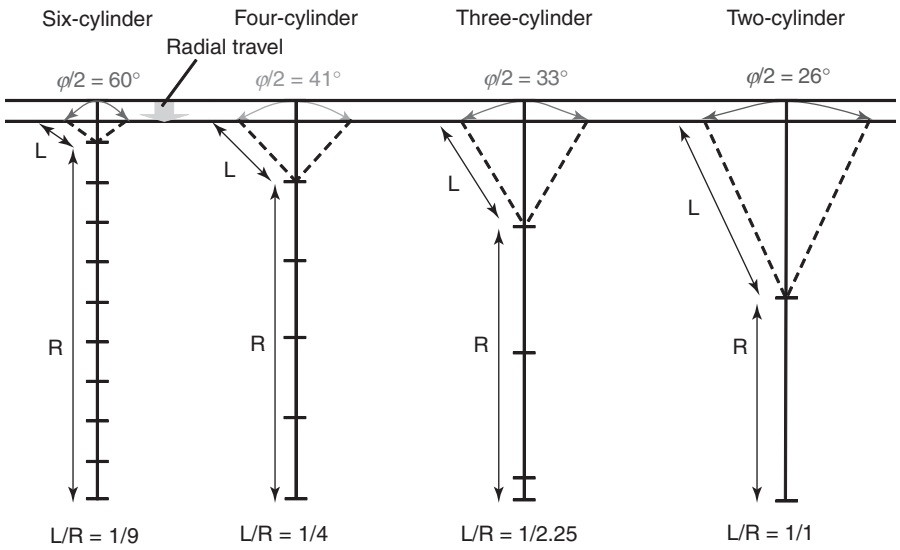

Figure 31. Influence of the number of cylinders on the track geometry of the pendulum with identical energy storage capacity.

systems with CPA also cover the requirements of two-cylinder engines.

5.2 Dual mass dampers for automatic gearboxes

DMF damper technology can be used not only for manual gearboxes but also for CVT (continuous variable transmission) and DCT (double clutch transmission). Here, the secondary mass in the gearbox is created by the conical disk set or the double clutch. In this case, power transfer is not achieved by frictional lockup between the secondary flywheel and the clutch disk, but with form-fit direct drive (spline) from the hub to the transmission input shaft (Figure 32).

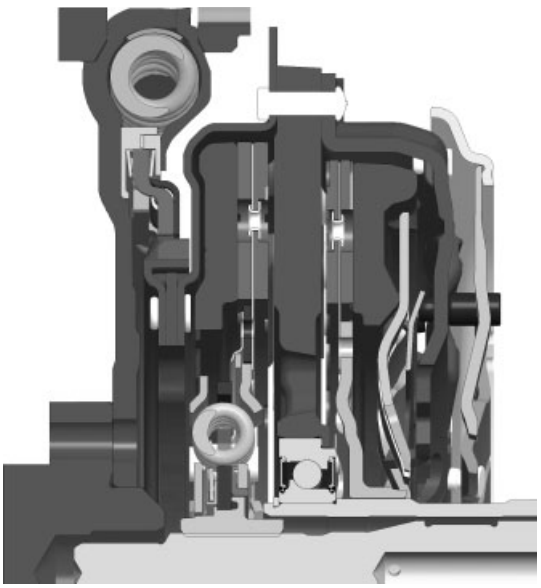

Figure 32. DMF for use with variable gearboxes or direct shift gearboxes.

6 EVALUATION AND OUTLOOK

6.1 Evaluation

The DMF can effectively isolate the downstream powertrain from the torsional vibrations caused by the engine. Comparable results cannot be achieved with a conventional system with clutch disk. The DMF with CPA demonstrates even further improved performance. In some cases, measurements in the vehicle showed an isolation of over 99% based on the rotational irregularity of the engine. This corresponds to an improvement of 2.5 ratings compared with a DMF without CPA. Figure 33 shows the potentials that the various models of this spring mass damper can develop.

This type of vibration isolation is a prerequisite for the successful implementation of downsizing and downspeeding concepts on the market to the extent that otherwise, the increased demands of vehicle drivers for noise comfort in their vehicles could not be met. In this case, however, a very advantageous (from a cost perspective) option for considerably reducing the fuel consumption in real driving operation would remain unused. The consumption simulation in NEDC (Figure 34) shows the potential savings; in each case, the prerequisite is the same excitation

in the gearbox. Compared with a system with single flywheel, a DMF shifts the driving range by 500–1300 rpm and thus enables a fuel saving of 14%. With a DMF with CPA, a further 7% fuel saving can be achieved by reducing the engine speed by a further 300 rpm.

6.2 Outlook

The further development of the DMF must and will be targeted at meeting the trend for even higher ignition pressures. Current forecasts indicate that 150 bar will be achieved for petrol engines. For diesel engines, up to 240 bar can be expected in the coming years. One approach here would be to modify the arc spring damper. Every improvement in this component makes the work of the CPA easier. One such measure is to reduce the arc spring friction using a better lubricant. A further option is a reduction in the spring rate and the associated reduction in the spring weight by increasing the design stresses.

The performance of the CPA can also be increased further. New pendulum concepts are currently being evaluated. They again indicate a significant step forward in improving isolation. This can be achieved through both a larger pendulum mass and through an improvement in the arc spring damper. Both approaches also reduce the residual energy on the secondary side that cannot be buffered in the lower speed range. This reduces the tendency toward booming noises further.

A further challenge will be in designing the DMF concept for vehicles in particularly price-sensitive market segments.

Articulated Joints and Couplings—Cardan and CV Joints

Wolfgang Hildebrandt
GKN Driveline, Lohmar, Germany

1 BASIC FUNCTION OF JOINTS AND DRIVESHAFTS

Articulated joints are coupling mechanisms for transmitting torque or rotary motion through an angle between an input shaft and an output shaft.

It can be differentiated from

- fixed joints, which only allow an angular displacement during rotation and
- plunging joints, which additionally also allow an axial displacement.

Driveshafts consist of a number of joints connected in series; a parallel displacement between input and output shaft is also possible (Figure 1).

2 CARDAN JOINT (ALSO: UNIVERSAL JOINT/HOOKE'S JOINT)

One of the oldest mechanical concepts to transmit torque under rotation is the so-called cardan joint, named after Geronimo Cardano (he used the principle of ring suspension back in the sixteenth century). It consists of two forks, which are connected to input and output side, and a yoke, which is guided in these forks, as shown in Figure 2.

Modern automotive applications include needle bearings between yoke and forks to allow a rolling sliding between yoke ends and fork; the needles are greased/oiled and sealed to protect the configuration against dust, dirt, and water; see Figure 3 as an application example.

2.1 Nonuniform transmission and reaction moments

When transferring a rotation from the first (input) shaft end to the second (output) shaft end of a cardan joint under an articulation angle β, the angular speed ω and the torque T between input side ($_{\text{index}}$ 1) and output side ($_{\text{index}}$ 2) display uneven, periodic rotary oscillations. The nonuniformity of the angular speed as function of the rotation angle α is described in formula 1.

$$\omega_2 = \omega_1 \times \cos(\beta)/[1 - \sin^2(\beta) \times \sin^2(\alpha)] \qquad (1)$$

When transmitting a torque, the so-called secondary torque T_S is generated, which is positioned in the articulation plane and perpendicular to the shaft.

Figure 4 shows in principle the equilibrium of torques at the joint in two different rotation positions.

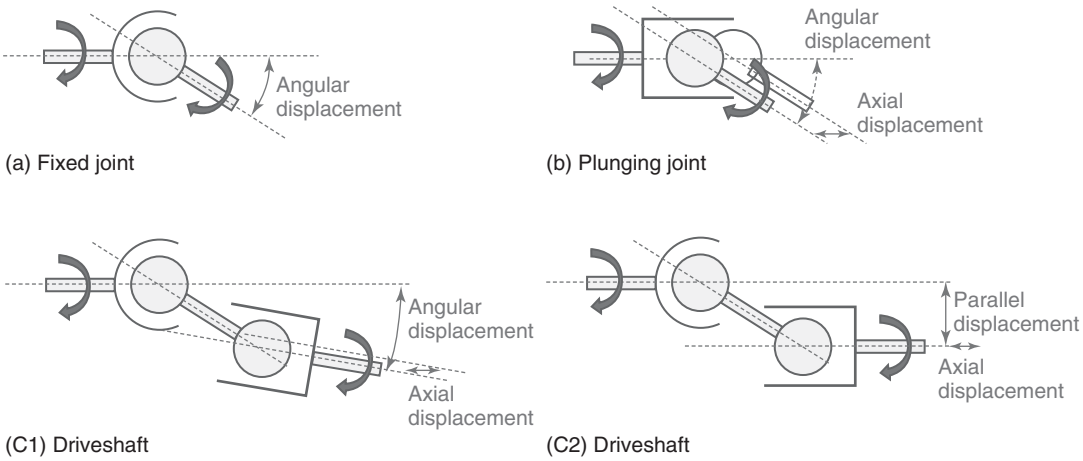

Figure 1. Joints and driveshafts: displacements.

Figure 2. Cardan joint concept.

For further details on kinematics, see, for example, VDI (2003).

2.2 Cardan joint assemblies with constant velocity behavior

The nonconstant velocity behavior of a single joint can be compensated by connecting two units in series, either as a W-bend or as a Z-bend configuration (Figure 5).

For these assembly configurations, it is essential that the connected forks of the joints are positioned in the same plane and furthermore the articulation angles of both individual joints are equal. Only under these conditions, the nonuniformity of the joints can be compensated one against the other.

Figure 6 shows as an application example a front axle configuration of a construction machine. By an external centering of the articulation plane in the axle housing, a constant velocity behavior can be achieved for specific articulation angles.

A constant velocity behavior of two cardan joints in series can also be achieved by *internal* centering. Figure 7 shows as an example a so-called *centered double cardan joint*, in which input and output fork are connected by a ball joint type centering device. This ensures that—for a given angle—for both cardan joints, the individual articulation angles are equal according to a "W-bend" configuration.

Figure 3. Cardan joint application example: propshaft for light commercial vehicle.

2.3 Automotive applications for cardan joints and its derivatives

Automotive applications for cardan joints are limited to those applications, where the impact of nonconstant-velocity behavior can be neglected or where the installation angle is small.

Cardan joints can be found, for example,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

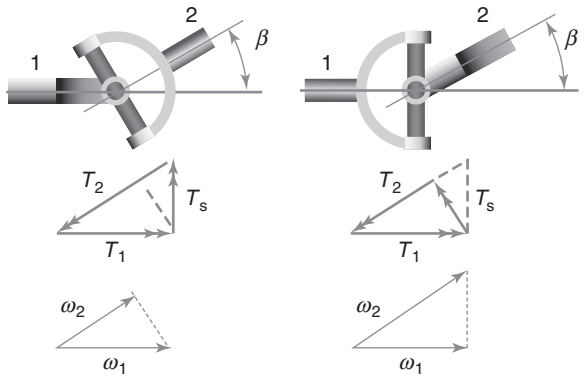

Figure 4. Torques T and angular speed ω for a cardan joint under articulation angle ß.

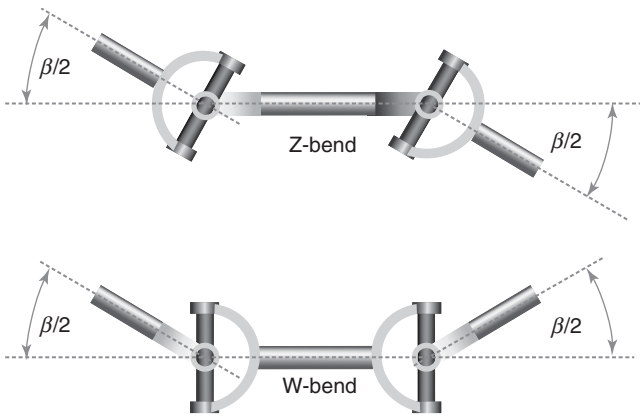

Figure 5. Configurations of cardan joints to achieve constant velocity behavior (Z-bend/W-bend).

- in the steering column of all types of automotive applications
- in propshafts, if installation angles are small
- in all-wheel-driven vehicles with hang-on front drive, where the front axle is designed as live axle.

3 CONSTANT VELOCITY (CV) JOINTS

For constant velocity (CV) joints, the angular speed on input side (ω_1) and output side (ω_2) are equal. Under the assumption, that the power transfer is loss-free, also the input torque T_1 and output torque T_2 must be equal. The necessary torque equilibrium for the joint is fulfilled, when a so-called "half-angle plane" or "homokinetic plane" is introduced, see Figure 8.

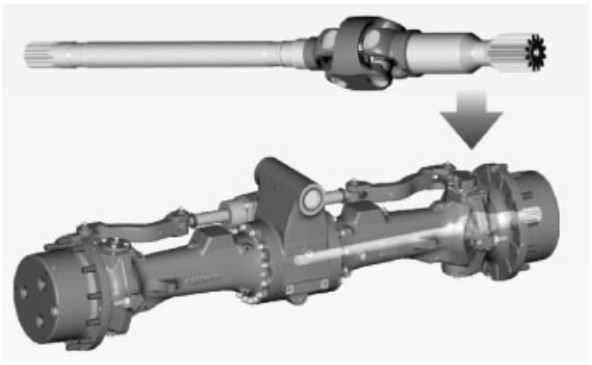

Figure 6. Application of two cardan joints in the axle housing of a construction machine.

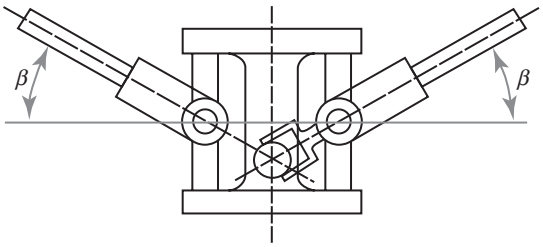

Figure 7. Principle of a centered double cardan joint.

Secondary torques T_{S1} and T_{S2} are—contrary to cardan joints—constant and independent from the rotation position.

$$T_{S1,S2} = T_{1,2} \times \tan(\beta/2)$$

3.1 Constant velocity ball joints

In constant velocity ball joints, balls are used as coupling elements between input side and output side.

The balls are guided in longitudinally elongated ball tracks. CV ball joints can be grouped into two base concepts: *radial separation* or *tangential separation* of input and output tracks (Figure 9).

All relevant developments date from first publications in the first decades of twentieth century:

The *radial separation of ball tracks* was originally proposed by Weiss (1929) (Figure 10), then later optimized as plunge ball joint by Altmann, Enke, and Rothweiler (1964). The balls are loaded perpendicular to the joint center (radius r_1), but—as disadvantage—only half of the balls are used for torque transfer.

The *tangential separation of ball tracks* was proposed by W. Withney in 1908, later significantly further developed by Rzeppa (1934), compare also Figure 11. While the effective

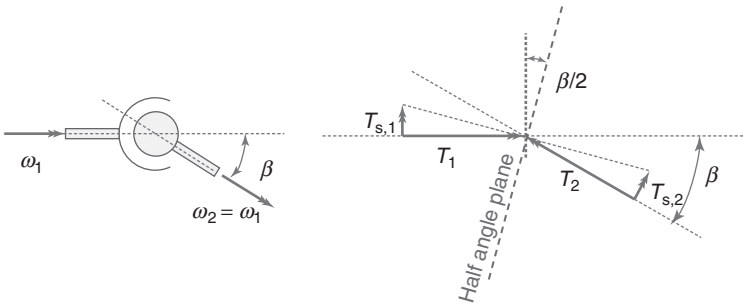

Figure 8. Constant velocity joint and torque equilibrium in the half-angle plane.

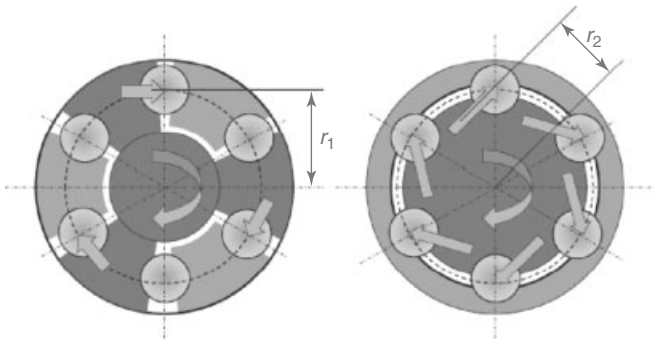

Figure 9. Base concept of CV ball joints; left: radial separation, right: tangential separation.

working radius r_2 for the balls is smaller compared to Weiss' principle, all balls are used for torque transfer.

Today, most of the current CV joints are based on Alfred Rzeppa's ideas and, therefore, will be in the focus of the following considerations.

3.1.1 Ball fixed joints

Ball fixed joints in the design as proposed by A. H. Rzeppa are the most commonly used constant velocity joints in automotive vehicle applications. They are typically positioned on the wheel side of a driveshaft for a front-driven vehicle with a maximum articulation angle of ~47°.

The principle of a Rzeppa type concept is shown in Figure 12.

The input torque is transferred via the shaft (1) through a spline connection (1b) to an inner race (2), in which balls (3) are positioned in longitudinally extended ball tracks. These balls are also guided in the outer race tracks (4), which by its splined stem (4b) is connected to the wheel hub. The balls (typical number of balls: 6, 8, or even more) are guided in a cage (5), which, on its spherical inner and outer diameter, is fixed between the inner race and the outer race. The whole configuration is greased and sealed against environmental influences by a boot (6).

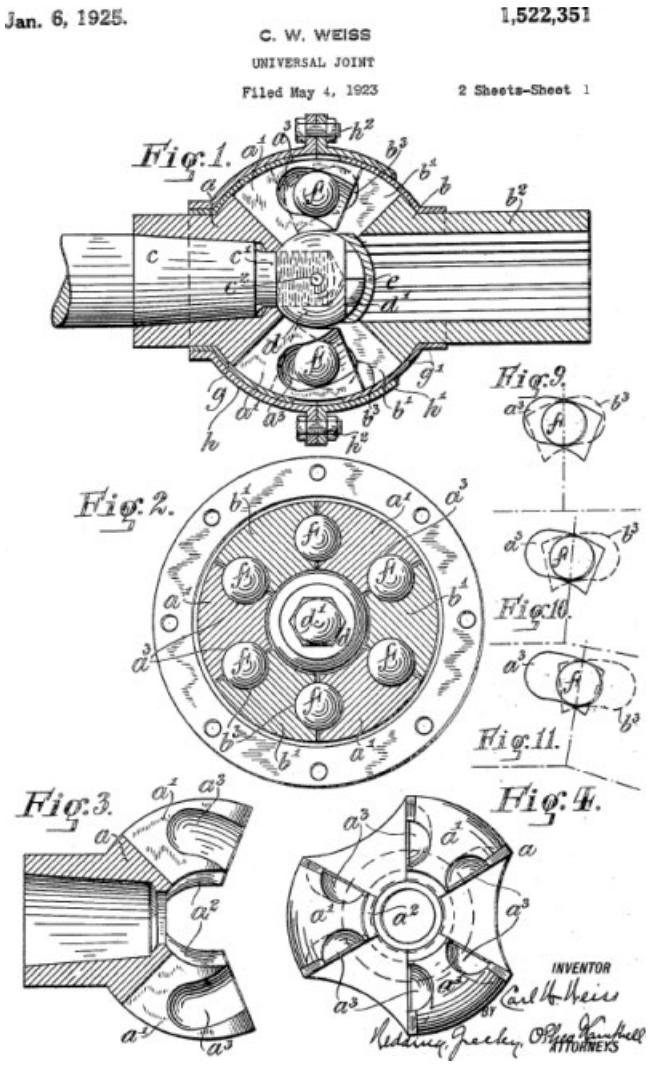

Figure 10. Extract from US patent 1522351. (Reproduced from Weiss (1929)).

All components are made of steel material and are heat treated to achieve a hardness of 57 and more HRC to withstand contact pressures up to 4000 N/mm^2 and more. Tracks and spheres are normally hard-machined (ground

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

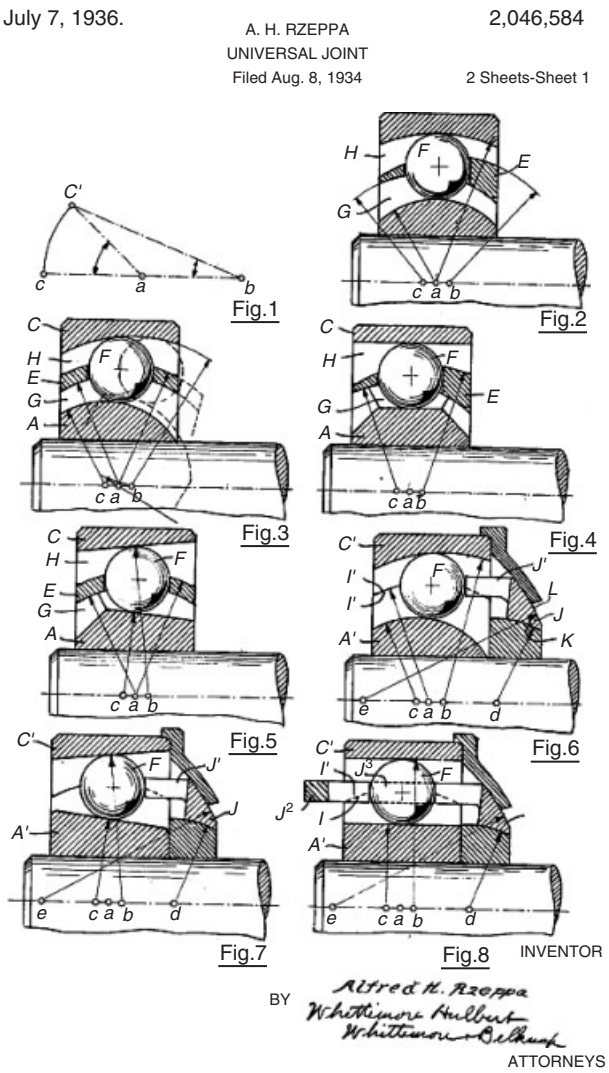

Figure 11. Extract from US patent 2046584. (Reproduced from Rzeppa (1934)).

or hard-turned and hard-milled) to compensate for the influence of hardness distortions; hereby, the rotational backlash of the joint configuration can be limited.

3.1.1.1 Steering mechanism of Rzeppa type joints. An essential feature of the displayed joint is the steering mechanism of the balls; the tracks are axially displaced against the ball plane by an axial offset e_O and an axial offset e_I in the inner race. This results in a mouth opening angle γ of the ball in the track contact (typical values are in the range of 10–18°), as shown in Figure 13.

When the joint is articulated by an angle β (Figure 14) and the longitudinal tracks (i.e., the track offsets e_O and e_I) are arranged symmetrically against the ball plane, each ball—and consequently also the cage plane—is positioned under an angle of $\beta/2$. This half-angle plane—as earlier shown in Figure 8—is essential to achieve a constant velocity behavior of the joint configuration (Figure 14).

3.1.1.2 Joint sizing. Macielinksi (1970) proposed criteria for joint size selection and joint life prediction. The lifetime of the joint is determined by the following relationships:

for a speed of $n < 1000$ rpm:

$$L\,[10^6\text{rev}] = 1,520,360\; n^{0.423}\;[T_{\text{nom}}/T \times A]^3$$

for a speed of $n > 1000$ rpm:

$$L\,[10^6\text{rev}] = 28,245,360\;\;[T_{\text{nom}}/T \times \text{A}]^3$$

where
L: calculated endurance life (revolutions)
A: angle factor with:
$A = [1-\sin(ß)] \times \cos^2(ß)$
ß: articulation angle [°]
n: speed [rpm]
T: torque [Nm]
T_{nom}: Joint application torque [Nm]

The joint application torque can be calculated using the so-called joint capacity factor (JCF).

$$\text{JCF} = m \times \text{pcr} \times {d_\text{B}}^2$$

where
m: number of balls
pcr: pitch circle radius
d_B: ball diameter

The joint application torque is then:

$$T_{\text{nom}} = k \times \text{JCF}$$

where
k: joint type related factor.

3.1.1.3 Longitudinal track forms. The maximum angle of the joint is on one hand limited by the contact of the shaft with the outer race and on the other hand by the support of the balls in the end positions of the outer and inner race tracks. By a modification of the longitudinal track form, a higher angle capability or an increase in the axial safety margin in the longitudinal track can be achieved (Figure 15). A straight track runout was proposed in 1973 (Welschof and Aucktor 1973), allowing a better ability to

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto095
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

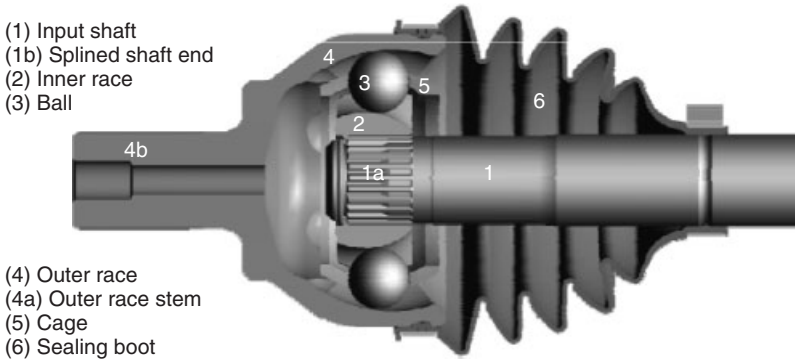

Figure 12. Rzeppa type ball fixed joint.

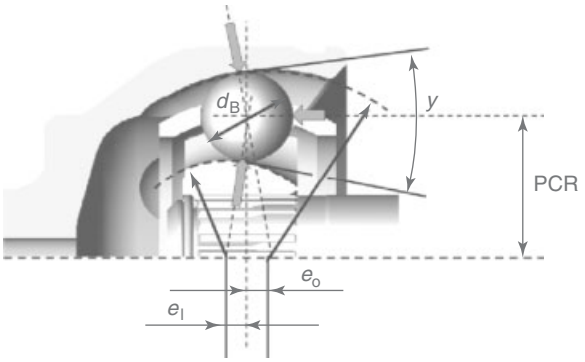

Figure 13. Track steering of a Rzeppa type joint.

apply forming processes for the component manufacture whilst increasing the angle up to ~50°. Other track form modifications, for example, introducing an angled straight track or an s-shape track, see also Schwärzler and John (1999), allow an increase in the angle to 52° and even more.

3.1.1.4 Transverse track forms. The transverse track form (Figure 16) defines the support of the ball inside the track and has some strong impact on the risk of local stress concentration during operation by a track edge contact.

The transverse track form can be described by the contact angle α and the track conformity value $K = r_T/r_B$.

A round track has a contact angle $\alpha = 0°$ and a conformity value of (typically) $K = 1.002\ldots 1.01$ and the advantage of an almost even pressure distribution over the complete track height. A gothic arch track or an elliptical track has the disadvantage that the complete track cross section cannot be applied with contact pressure. They do, however, display a higher tolerance sensibility, that is, the influence of manufacturing tolerances on the rotational backlash of the joint configuration is smaller. Furthermore,

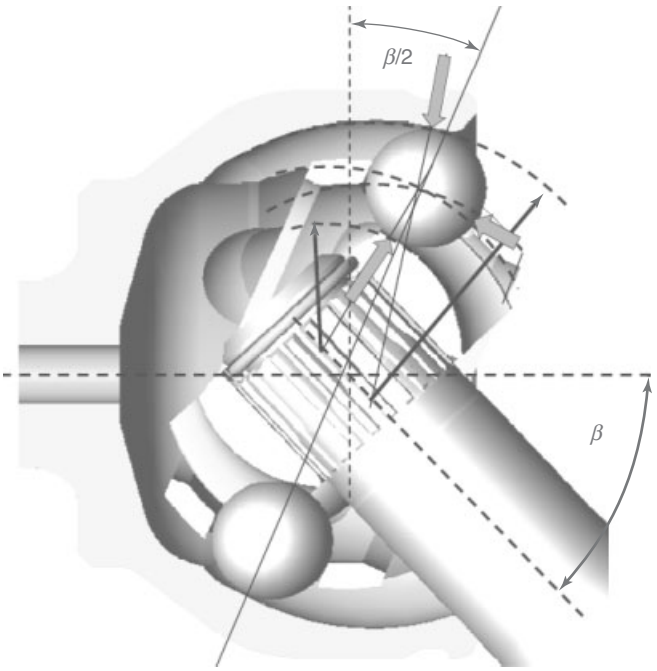

Figure 14. Articulated Rzeppa type joint with half-angle cage plane.

the risk of track edge contacts during high torque operation can be minimized. Typical values for both elliptical and gothic arch tracks are contact angle $\alpha = \sim 35° \ldots 45°$, conformity $K = \sim 1.03\ldots 1.05$.

3.1.1.5 Basic track layout and sphere forces. As shown in Figure 13, during torque transfer, the cage is loaded by an axial force caused by the mouth opening angle γ. As a reaction, the inner race is axially pushed against the cage inner sphere, whereas the cage itself is axially pushed against the outer race inner sphere.

During operation, these forces lead to friction forces in the spheres, which contribute to torque losses during

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

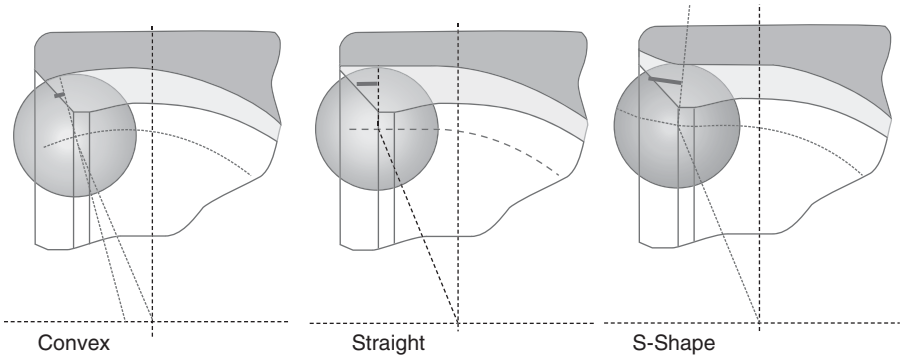

Figure 15. Longitudinal track form runouts in Rzeppa type joints (track safety margins highlighted in red).

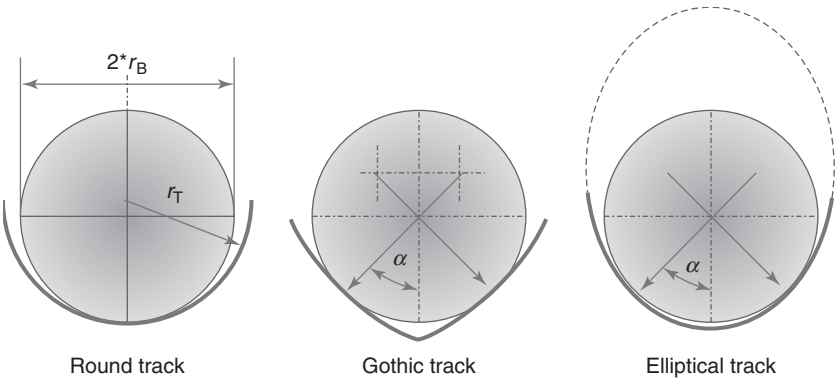

Figure 16. Transverse track forms.

operation and can result in overheating leading to damage of the joint. A reduction of the spherical forces is, to a certain extent, possible by a reduction of the track offsets but negative impact on the ball guidance need to be considered.

An alternative solution to reduce the resulting spherical forces is to arrange the individual tracks in such a form that their axial force components are compensated. By an alternating layout of the track openings, as shown in Figure 17, the axial forces on the spheres can be eliminated. Such opposed track layout can reduce losses in the joint by up to 35% and more, but the negative influence on the maximum achievable articulation angle needs to be considered, as the axial track safety margin becomes smaller. A combination of the opposed track configuration together with changes in the longitudinal track form was proposed (e.g., in Hildebrandt, Horst, and Rickell, 2006), providing a design that combines the advantages of the "opposed track configuration" with an angle capability of up to 52°. Case studies showed an improvement in fuel efficiency by up to 1.3% when considering this technology (in combination with adapted lubrication system) for high installation angle applications (Hildebrandt and Cubert, 2007).

3.1.1.6 Ball guidance by the cage. When rotating an articulated joint, the ball is travelling along the track with an oscillating movement. Owing to the offset of the tracks, the effective mouth opening of the ball varies with the rotational position.

Figure 18 shows the changes in the effective mouth opening angle (the so-called control angle that also considers the effect of the transverse track contact angle) under rotation as function of the articulation angle.

For small angles, the offset layout of the tracks still provides an axial force of the ball against the front cage window plane. With larger articulation angles, the effective mouth opening angle during one rotation can become zero or can even reach negative values, that is, the backward side of the cage window is loaded.

To avoid a locking between a parallel track configuration or to ensure a proper transition between positive and negative control angles, each ball needs to be guided and steered by the cage. Therefore, a narrow tolerance fit

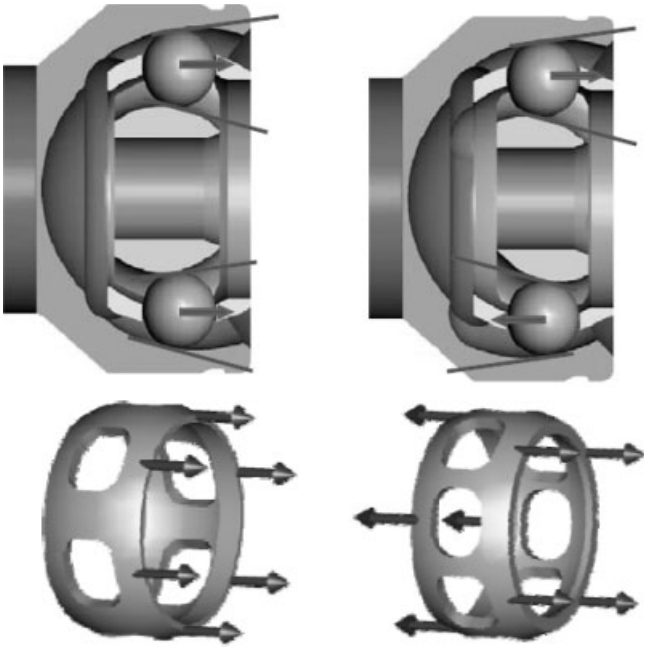

Figure 17. Rzeppa configuration (a) and opposed track configuration (b).

between ball and cage window is required, typically with maximum clearances of only a few 1/100 mm.

3.1.2 Ball plunging joints

Almost in parallel to the early fixed ball joint concepts from Rzeppa, Weiss, and others (Section 3.1.1), plunging joint concepts were also developed. They are typically used as inboard joints in automotive driveshafts. Major design parameters as described earlier (e.g., transverse track form, joint sizing, ball guidance in the cage) are also valid for these joint types.

A major differentiator is the type of steering mechanism, steering mechanism which, besides the articulation capability, must allow an axial movement between input and output.

3.1.2.1 Ball plunge joints with track steering. One of the most popular ball plunge joint with track steering is the VL type/cross groove joint, as shown in Figure 19.

The balls are guided in angled tracks (typically helix angles are in a range of 11°–16°), each of the balls is held in a crossing between an inner race and an outer race track.

Owing to an alternating opening of neighbored tracks, the cage is axially balanced in a similar way as described for "opposed tracks" (see Section 3.1.1.5, especially Figure 17).

In normal operation mode, neither the inner race nor the outer race is in axial contact with the cage. An axial plunge between inner race and outer race by a value of p is split into a relative axial displacement of the cage plane in the outer race by a value of $p/2$ and an axial displacement of the cage plane relative to the inner race also by the value of $p/2$. This leads to a very compact assembly of the joint in axial direction; the outer race only needs to allow approximately half of the axial plunge of the whole joint.

Figure 19a shows a flange type joint as a so-called *long plunge version*, which has no plunge limitations by a spherical contact. Such joint concept is typically used in combination with a fixed joint in a front-driven vehicle driveshaft.

Figure 19b shows a VL type joint in a monobloc type configuration with a closed outer race bottom. The plunge capacity of the joint is limited by a sphere contact between inner race and cage; such "inner stop" concept is typically used in rear axle driveshaft, connecting two VL type plunging joints in a floating configuration.

VL type joints typically provide a plunge capacity up to 50 mm and an angle capability of 22°.

3.1.2.2 Ball plunge joints with sphere steering. The DO type joint is a ball plunge joint with an angle capacity of up to 31° and a plunge of up to 50 mm. The base concept goes back to an invention of G. Devos (1964).

The joint consists of an inner race and an outer race, both with parallel track races. A ball cage is guided on its inner diameter on the inner race outer sphere. On its outer diameter, the cage is guided in a cylindrical diameter of the outer race (Figure 20).

By an axial displacement of the inner and outer diameter of the relative to the ball plane, the balls are guided on a half-angle plane during articulation. With this double offset steering mechanism, a constant velocity behavior is achieved.

During plunge, the subassembly of inner race, cage, and balls are moving relative to the outer race. Therefore, the joint is significantly longer than a VL type joint. But as a result of a straight track configuration, when introducing small functional clearance between inner race and cage sphere, the amount of sliding of the ball is reduced significantly. Owing to such "rolling plunge" design, the plunge resistance for a cage steering concept can be much smaller than that for a track steering concept.

The DO type joint is used in front-driven vehicles and can provide benefit for applications, where a high application angle is required, for example, in sport utility vehicles (SUVs).

3.2 Tripod joints

When in the sixties with the Austin Mini, the modern style front-wheel-driven cars started become the industrial trend;

first the tripod joint-equipped shafts were introduced in high volume production, mainly from French car makers.

Tripod joints are based on a different working principle to ball joints. In a tripod joint rollers are used for torque transfer; they are positioned on radially directed arms (pegs) and guided in longitudinal tracks.

3.2.1 Tripod joint driveshafts

Figure 21 shows as an historical example a tripod-equipped driveshaft (extract from historical catalog material (Spicer, 1979)). On the wheel side the so-called GE fixed joint (GE stands for Glaenzer Exterieur) is applied. On the

differential/inboard side, the so-called GI plunging joint (GI stands for Glaenzer Interieur) is used.

The in board joint GI transfers the torque from the differential into a joint housing (18) that is equipped with three longitudinal tracks. In these tracks, rollers are guided which are positioned on the arms of a tripod body (14). This structure allows a plunge and an articulation of the tripod body against the outer race.

Through the interconnecting shaft (5), the torque is transferred from the GI tripod body to the three longitudinal tracks of the GE shaft end, in which—again—rollers are guided. These rollers are positioned on a three-armed tripod structure, which is connected to the joint outer race end (1). A fixation device (2–4) suppresses axial movements of the GE joint configuration.

Both joints are sealed with boots and its boot clamping devices (9–13 and 20 for GI, 7–9 for GE).

The displayed configuration also includes a preload spring assembly between GI tripod and outer race (15–17) to ensure a proper fixation of the shaft in the differential.

3.2.2 Constant velocity behavior and orbital movement

While the importance of the half-angle plane to achieve a constant velocity behavior was described in Section 3, the

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

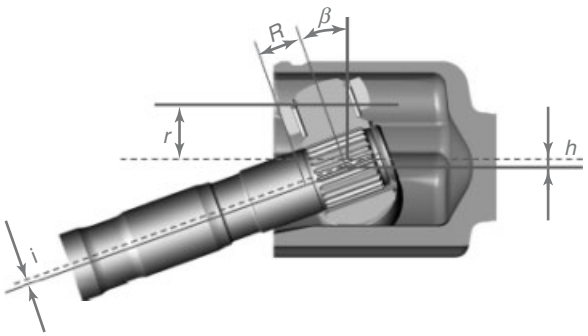

Figure 22. Orbital movement in a tripod type joint.

rollers are articulated by the full bending angle of the joint; therefore, a tripod joint does not have a half-angle plane.

Nevertheless, Orain (1976) could prove that such a concept can have a constant velocity behavior, as long as the center of the tripod body is free to make an orbital movement and the shaft is able to displace parallel to its axis (Figure 22).

This orbital movement takes place three times per revolution; the amplitude of the movement can be calculated using:

$$i = r/2 \times (1/\cos\ \beta - 1)$$

and

$$h = r/2 \times (1 - \cos\ \beta)$$

Here, the value i describes the amplitude of the movement relative of the shaft axis, and the value h refers to the same movement of the tripod center, but measured relative to the track center.

For typical shaft length in automotive applications, a constant velocity behavior of tripod-equipped driveshafts can be assumed.

3.2.3 *Axial force generation*

During articulation of a tripod type joint, the contact force between tripod body and tracks results in an axial force component, which is directed axially along the shaft axis (Figure 23). As a consequence, a tripod joint can generate axial vibrations if the working angles or the friction forces in the contact areas are too high ("shudder noise").

3.2.4 *Plunging tripod joint types*

The major functional properties of a tripod plunging joint depend on the guidance of the rollers on the pegs and on the contact conditions of the rollers in the track, as compared in Figure 24.

For front drive applications, typically, a needle bearing between rollers and pegs is applied to minimize the plunge resistance during an axial movement and reduce the generation of axial forces. Tripod joint concepts with a further degree of freedom between the roller and the peg can improve the rolling behavior of the roller along the track, as sliding friction under articulation is reduced or even eliminated (so-called shudderless joints).

Typical application examples of tripod plunging joints are shown in Figure 25. Figure 25a is a GI type joint for a front-driven vehicle application with a needle bearing support of the rollers directly on the peg, this being a very cost-effective solution for small angle applications. Figure 25b is a so-called AAR (angular adjusted roller) concept, in which the roller consists of an outer ring, an inner ring, and a needle bearing between these. The roller assembly is guided on a spherical end of the peg, which allows an articulation of the roller against the shaft axis and a positioning in the track; hereby, a rolling movement can be ensured even under larger articulation.

4 SIDESHAFT CONFIGURATIONS

4.1 Selection criteria for driveshafts in vehicle

The joint type selection for automotive driveshaft applications significantly depends on the plunge and angle requirements in the vehicle.

Front-driven vehicles require on the wheel side fixed joint concepts that allow a sufficient steering movement of the driven wheel and small vehicle turning circles. Therefore, maximum angle capabilities of $>45^{\circ}$, in some cases $>50^{\circ}$, are necessary. Preferred choices are fixed joints based on the Rzeppa principle or based on opposed track principle in combination with adapted longitudinal track forms (Section 3.1.1)

On the inboard side, the joint type selection is mainly determined by the plunge-angle characteristics of the joint. Figure 26 shows as an example the kinematics curve of a vehicle application. Depending on the suspension movement, a specific relationship between axial movement and articulation is required. The selected plunge joint concept (here GI type joint) must have a plunge-angle characteristics that allow a free suspension movement without collision of the joint internals. Furthermore, built-tolerances and the assemble ability of the driveshaft in the vehicle need to be considered.

The type of plunging joint also depends on the drivetrain configuration; vehicles with automatic transmission require a low high frequency plunge resistance to reduce the impact of engine/gearbox vibrations during idling; here, tripod type joints are preferred choice.

During change from drive mode to coast mode, a too high rotational backlash of a plunge joint can result in clonk noises caused by contact changes in the torque transferring components. Here, ball plunge joints with a narrow assembly fit can be preferred choice.

The axial force generation of a joint can lead to so-called shudder noises in the vehicle. Especially, for larger installation angle $>5^{\circ}$, shudderless tripod joints (as e.g., the AAR type joint, see Section 3.2.4) can be required to ensure noise-free torque transfer in all driving conditions.

Where for front-driven vehicles, a driveshaft typically consists of an outboard fixed joint and an inboard plunging joint, the driveshafts for rear-wheel-driven (RWD) vehicles can also consist of a series combination of two plunging joints. For high performance RWD vehicles, a combination of two VL type joints can be preferred choice due to a compact axial packaging and very small rotational lashes.

For the rear axle of a hang-on 4WD or for low cost rear-wheel-drive applications, combinations of two plunging joints of GI tripod are known from series production. As here the axial force generation and plunge resistance

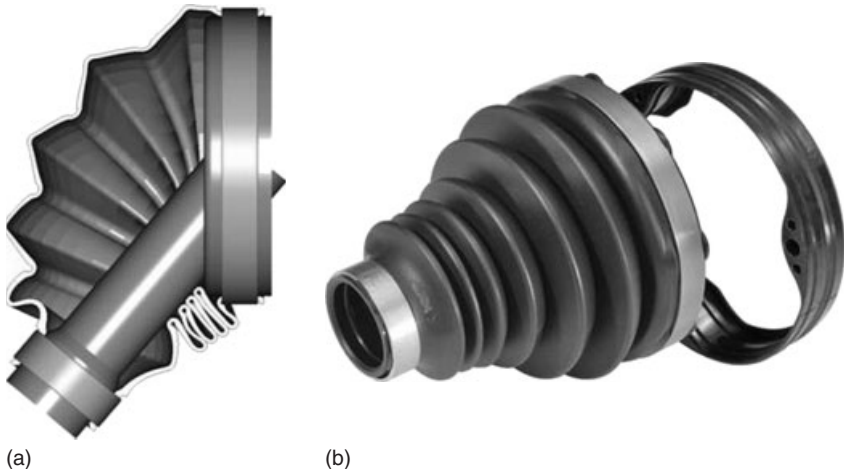

Figure 27. CVJ sideshaft sealing systems.

requirements are lower, concepts without needle bearing between roller and peg are also known.

When combining two plunging joints in a driveshaft, a centering is required to avoid disassembly or operation in an end position. For VL type joints, inner stops can be used (Section 3.1.2.1). For GI type joints, a centering can be achieved by means of springs in both joints (Figure 21).

4.2 Sealing systems

CV joints for automotive applications are typically sealed by a boot that is fixed on its larger diameter on the joint outer race and on its smaller diameter on the interconnecting shaft.

The design of the boot needs to be adapted to the specific joint concept to ensure good contact conditions under maximum articulation (Figure 27a). In case of non-round outer race shapes (e.g., trilobe shape of tripod type joints), an insert can be used as adaptor between the different shapes of the outer race and the boot.

Rubber material is more and more being replaced by thermoplastic elastomers (TPEs) that provide a better durability and improved resistance against environmental influences, and furthermore a reduced system weight and an improved material recyclability.

For front sideshaft applications typical ambient temperatures for the wheel side range from −40°C up to 100°C. For the inboard side, the boot surface temperature can achieve

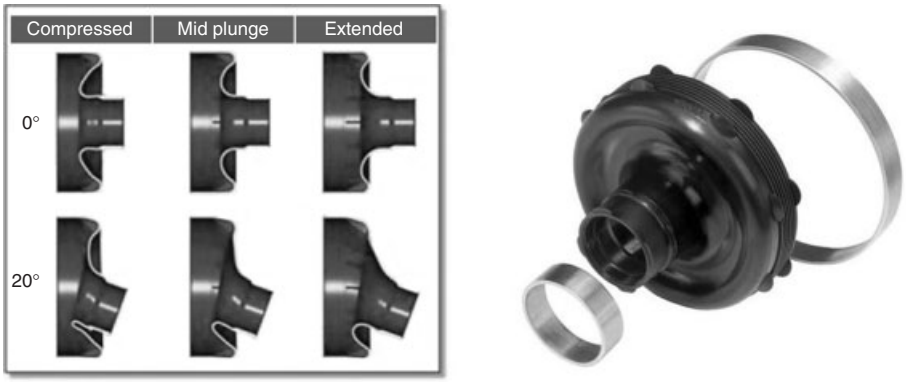

Figure 28. Diaphragm type sealing system for rear sideshafts.

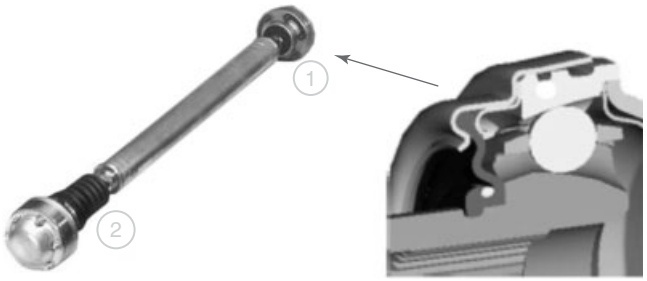

Figure 29. High speed sealing system for a CVJ propshaft application: (1) fixed joint, (2) plunge joint.

peak values of 150°C and more due to heat transfer from exhaust and catalytic converters.

For rear sideshafts, due to the reduced articulation requirements (maximum angle up to 25°), more compact diaphragm type sealing systems with plunge capability of up to 45 mm can be applied (Figure 28).

For high speed applications of constant velocity joints, for example, in propshafts, sealing systems are required to withstand the high centrifugal forces and also high temperature levels, typically caused by heat transfer from the exhaust system.

For these applications, high performance rubbers, HNBR, and silicone are preferred choices, whereas TPE materials so far can be regarded as niche.

Figure 29 shows as an example a propshaft with joint sealing systems for rotational speeds up to 11,500 rpm, articulation angles up to 5°, and 50-mm plunge capability.

4.3 Lubrications for constant velocity joints

In automotive applications, CVJs are typically lifetime lubricated with specially tailored greases. The lubrication and sealing system needs to withstand typical working temperatures of −40 up to 100°C (normal temperature range). For special applications, temperatures can reach up to 150°C (short period: 180°C) either with high internal heat generation of the joints (e.g., due to high installation angles) or due to external heating (e.g., from the exhaust system).

Typically, normal temperature greases are formulated with a lithium soap thickener, mineral oils and special additive packages. High temperature application greases are dominantly based on polyuria thickeners using synthetic or semisynthetic oils.

Owing to high contact pressures of 4000 MPa and more and the oscillating movement of the components, CVJs operate in the mixed or boundary lubrication regimes. Ball joint greases therefore normally use MoS_2 in combination with graphite as part of the additive package (but note that for tripod type joints, greases with MoS_2 can have negative impact on durability and function).

The friction coefficient of the grease has a strong influence on joint performance in the vehicle. For plunge joint, axial force generation and plunge resistance can be significantly reduced and can contribute to vehicle noise and vibration optimization. For ball type joints, a reduction of joint losses (in the range of −30% and more) with corresponding impact on vehicle fuel consumption and CO_2 emission can be considered.

4.4 Interfaces

The differential side of a driveshaft typically uses a splined connection between plunge joint outer race and differential side gear. For transverse engine installations, additional linkshafts or long stem outer races can be used to avoid unequal sideshaft length for left and right side. In these cases, an intermediate bearing is applied which supports the outer race via a bracket against the engine/gearbox housing.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

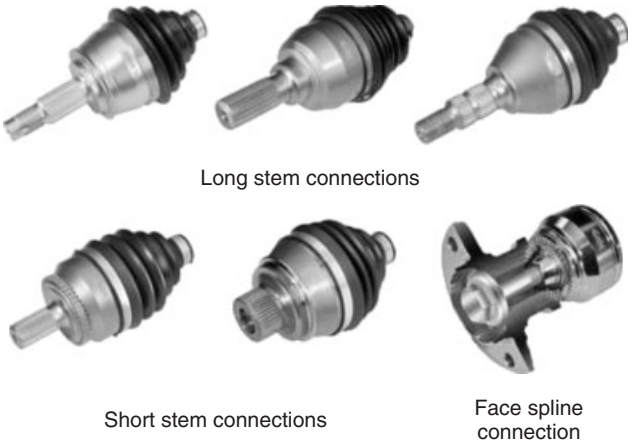

Figure 30. Wheel side driveshaft interfaces.

On the wheel side joint, the connection system is mainly determined by customer preferences. Figure 30 gives an overview of commonly used interface types between outboard joint and wheel hub unit. Both long and short stem connections use a radial spline for torque transfer to the wheel hub unit; a face spline connection uses an axial spline and provides a more compact packaging and assembly advantages.

Drivetrain Noise, Vibration, and Harshness

H. Rahnejat[1], S. Theodossiades[1], P. Kelly[2], and M.T. Menday[1]

[1] *Loughborough University, Loughborough, UK*
[2] *Ford Motor Company, Cologne, Germany*

1 INTRODUCTION

There is a plethora of noise, vibration, and harshness (NVH) concerns in the drivetrain system. These include low frequency, relatively large displacement inertial dynamics such as clutch take-up judder, which is the first torsional mode of the driveline system (Rabieh and Crolla, 1996; Centea, Rahnejat, and Menday, 2001). Another low frequency rigid body oscillation is driveline shuffle, which is the first torsional vibration mode, coupled with fore-and-aft oscillations of the vehicle, known as *shunt* (Farshidianfar *et al*., 2002). These concerns may be regarded as harshness, in the frequency range 3–10 Hz, depending on the drivetrain system, the driveline gearing, and the vehicle mass.

There are also vibration concerns at higher frequency range. One is the clutch in-cycle vibration, referred to in the industry as whoop; the resulting radiated sound during clutch movement (Hasebe and Aisin Seiki, 1993). Kelly, Rahnejat, and Biermann (1998) and Kushwaha *et al*. (2002) showed that the whoop phenomenon is as the result of the combustion fundamental frequency (half engine order vibration in the case of a four-stroke engine) from the firing of cylinders close to the flywheel. This induces conical motion of the flywheel, causing it to impact the clutch system during the clutch actuation process. The ensuing vibration of the clutch system is in the frequency range 150–250 Hz and is felt by the rough oscillations transmitted from the flywheel impacts and along the clutch cable to the clutch pedal as well as emanating as a whoop sounding noise from the driver's foot-well area. Hydraulic actuating clutch systems are also not immune from this phenomenon as the stick–slip oscillations of the actuator induce the same problem.

Another NVH problem is the transmission rattle, which is the result of impacting of gear teeth pairs. This phenomenon usually occurs in the case of unselected (unengaged) gears (Wang, Manoj, and Zhao, 2001; Theodossiades, Tangasawi, and Rahnejat, 2007; Tangasawi, Theodossiades, and Rahnejat, 2007), although contact separation or transmission error in engaged gear pairs can also contribute (Kim and Singh, 2001; De la Cruz, Theodossiades, and Rahnejat, 2010). Gear rattle has a broadband nature as perceived, because the resulting vibration at the impact sites travels along the structural members as a structure-borne wave and excites their modal behavior. As the drivetrain components are lightly damped, such impulse loading can result in structure-borne noise output. There is also clearly some airborne noise as well from the impact site itself, which can be heard in the absence of significant engine noise, for example, when the vehicle is idling. The nature of rattle is repetitive and at a given transmission speed may be regarded as a steady-state noise and vibration

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

problem. It may easily be confused with diesel engine knock.

In contrast, some other NVH concerns have a transient nature and occur as the result of driver behavior or road input. These include driveline *clonk*, which is an elasto-acoustic response of the driveshaft tubes (Menday, Rahnejat, and Ebrahimi, 1999). This phenomenon occurs when a high energy deformation wave travels from an impact site along the driveline, causing elastic deformation of the hollow thin-walled driveshaft pieces and excite their modal responses (Theodossiades *et al*., 2004). There is coincidence of some of the many structural natural modes of the tubes with their internal acoustic natural modes. This coincidence is referred to as *elasto-acoustic coupling*, leading to noise radiation, usually at quite high frequencies (500–5000 Hz), and emanating as a disconcerting metallic sound. Therefore, like many other NVH concerns, the term *clonk* or *clunk* is chosen onomatopoeically (Menday, Rahnejat, and Ebrahimi, 1999; Biermann and Hagerodt, 1999). The traveling wave is often caused by the impact of teeth pairs of engaged gears under impulsive conditions, such as with sudden clutch actuation, abrupt throttle tip-in or back-out actions, or misalignment of driveshaft pieces from coast to drive condition or as the result of road input. Any misalignment of shafts can also cause contact separation and impact on highly loaded hypoid gears of the differential, giving rise to a tonal sound output, referred to as *axle whine* (Kim and Lee, 2007; Koronias *et al*., 2010).

The impulsive action often leads to teeth pair impact, sometimes severe enough to cause torque reversal, thus leading to severe clonk conditions. Clonk can also take place with driveline shuffle and vehicle shunt (Krenz, 1985). With lower impulsive energy, the severity of clonk is attenuated and a sound more like a *thump* is heard. Side-to-side motion of the driveline pieces about the center bearing of the driveshaft or lateral motion of the driven axle can also cause another vibration concern known as *shudder*.

There are, therefore, many NVH concerns in the drivetrain system. These are mostly as the result of engine order vibration input, unexpected driver actions, road input, lash zones, and low structural damping. The situation has been exacerbated in recent years with the trend toward high output power-to-weight ratio vehicles and use of compact transmissions, differentials, and hollow driveshaft pieces. In this chapter, some of the aforementioned drivetrain NVH problems are discussed.

2 CLUTCH TAKE-UP JUDDER

Clutch judder is a low frequency phenomenon that occurs when the pull away gear has been selected and the clutch pedal operated, bringing the clutch into progressive engagement. The oscillations are readily felt at the driver's seat, this being a suitable location to measure the problem.

The role of the clutch in the slip maneuver is to synchronize the rotational speed of the engine/flywheel with the transmission shaft. When there is no relative angular velocity and the clutch is fully clamped, the clutch pedal is released and the engine torque drives the vehicle forward. During the transition from a fully disengaged to a fully engaged state, a longitudinal body vibration may be felt. This starts as a torsional vibration in the driveline and is reacted at the engine and body mounts before transmitting to the driver's seat. The judder mode is lightly damped and may continue for as long as the clutch slips, and it would be necessary to disengage the clutch in order to stop the judder vibration and prevent the clutch overheating.

Fore-and-aft driver's seat longitudinal acceleration is an adequate indicator of judder and this can be readily measured and subjectively correlated. It may be directly compared with the dynamic behavior of the engine mounts. Clutch judder should not be confused with two other similar low frequency vehicle vibrations; namely

- *Brake judder*, which occurs during braking and at a higher frequency.
- *Shuffle*, which occurs after application of the throttle and with the clutch fully engaged (i.e., it is not related to the friction contact between flywheel and clutch disk).

Both shuffle and judder occur when the first torsional driveline eigen-mode has been excited. For a rear-wheel-drive vehicle, this mode has a maximum amplitude response at the flywheel and has an in-phase response of minimum amplitude at the rear axle. The mode is reacted at the tire-road contact patch; consequently, the low frequency longitudinal oscillations of the vehicle occur.

As judder is a modal phenomenon of the driveline system, a multibody system analysis approach should be undertaken to simulate the conditions. One such model is reported by Centea, Rahnejat, and Menday (2001) for a cable-operated clutch system. The model showed that the propensity to judder was directly related to the slope of kinetic coefficient of friction μ with slip velocity, when its value is negative: $n = \frac{\mathrm{d}\mu}{\mathrm{d}v} < 0$. The larger the negative value of n is, the greater is the judder response. Figures 1 and 2 show increasing oscillations before fully clamped clutch with an increasingly negative slope n. Simulations and experimentation have also shown that the potential for judder is greatly reduced if the slip gradient of the clutch lining friction coefficient is held to be positive or at least zero for its useful service life. The challenge is to

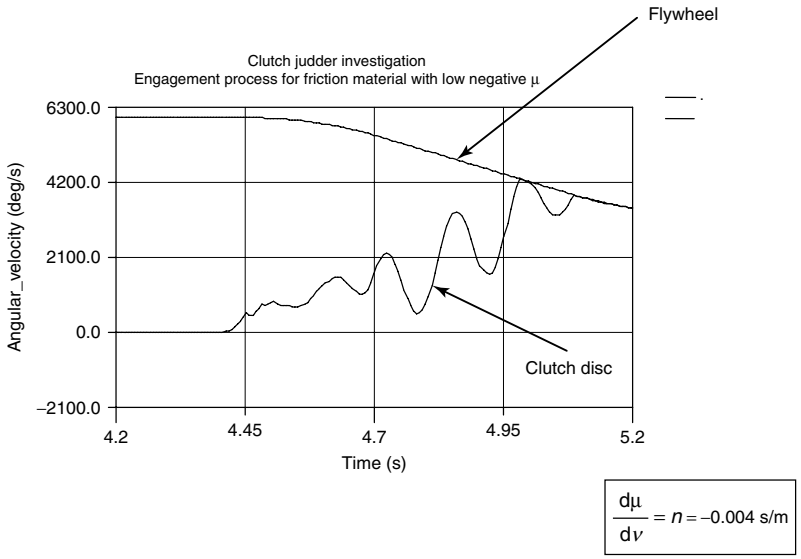

Figure 1. Take-up judder oscillations for low negative friction gradient with slip speed. (Reproduced from Centea *et al*. 2001. © Elsevier.)

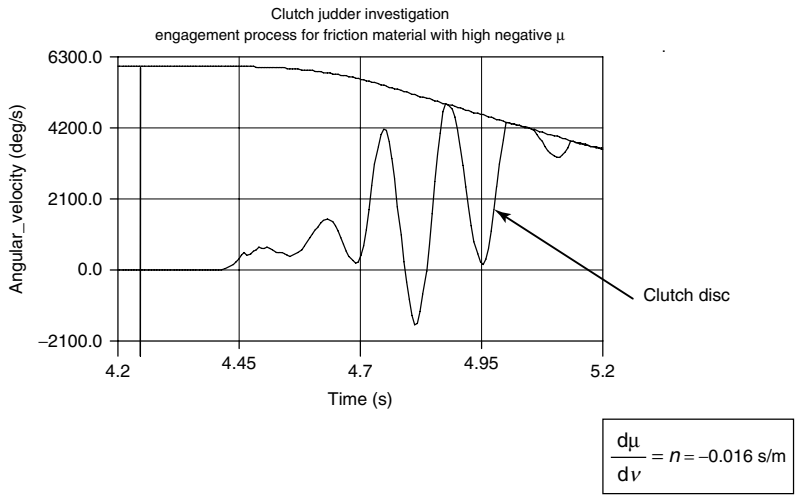

Figure 2. Exacerbated take-up judder with an increasingly negative friction gradient with slip speed. (Reproduced from Centea *et al*. 2001. © Elsevier.)

design a clutch friction disk that maintains these properties throughout service life.

3 CLUTCH IN-CYCLE VIBRATION (WHOOP)

As already mentioned in Section 1, during the clutch pedal movement and with some vehicles (especially those with diesel engines), a tactile clutch pedal vibration is felt, accompanied by a disagreeable noise. Therefore, the phenomenon occurs during the clutch transition state (from engagement to disengagement and vice versa), thus the reason for the chosen name. The accompanying noise is onomatopoeically termed as *whoop*.

Whoop is a transient dynamic phenomenon, occurring during the engagement and disengagement of the drive (engine) with the driven system (the drivetrain system). Figure 3 shows the measured response from the clutch pedal and the driver's foot-well area.

With all NVH phenomena, including clutch whoop, it is essential to determine the underlying cause of the problem

as a prelude to devising a root cause solution. In many cases, however, a root cause solution may be difficult to achieve or may contravene the overall vehicle development strategy, such as those resulting in an increase in the mass or inertia of components. Therefore, a palliative approach may be adopted, which requires the determination of the paths of noise and vibration propagation. Figure 4 shows the path of vibration transmittance from the engine, through the crankshaft–clutch system interface into the vehicle cabin. It can be seen that as the cylinders 3 and 4 are nearer to the flywheel–clutch interface, when ignition occurs,

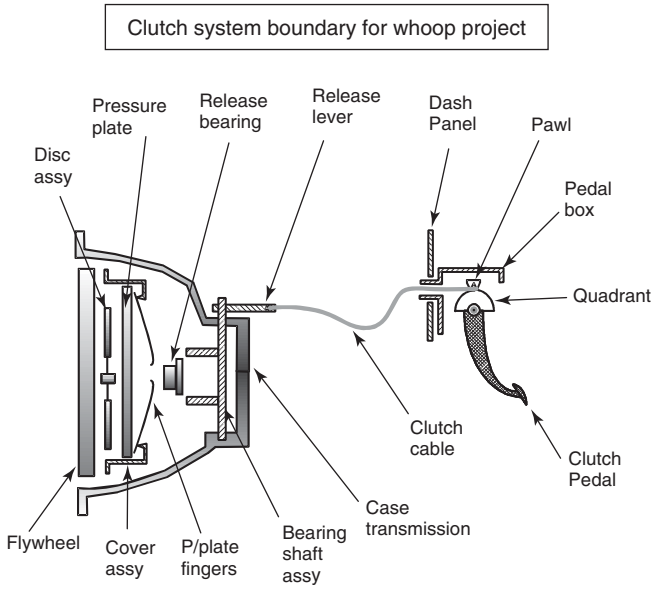

Figure 5. The boundary for the clutch whoop investigation.

increased vibration levels are noted along the transmission path to the clutch pedal.

To implement any root cause or palliative measure, it is necessary to undertake a fundamental study with a prescribed boundary of investigation. For the clutch whoop problem, the system of interest is shown in Figure 5. Clearly, any solution to an NVH problem should not exacerbate other NVH concerns (some of which are described in this chapter). It should also not result in any loss or deterioration of system function. Therefore, traditionally a large mass-stiffness damper known as the *Diehl-fix* has been added to the release lever to attenuate the traveling wave from the flywheel–clutch interface before reaching the clutch cable in cable-operated clutch systems. However, this mass damper often weighs 1–2 kg and occupies a volume of 100–200 mm^2 at a unit cost of $7. As already noted, lightweight and compact power trains are now regarded as essential design features, as well as reduced costs. Thus, other solutions are sought. Therefore, a fundamental study necessitates the development of detailed models for both an in-depth understanding of the phenomenon and parametric simulation studies, rather than expensive physical prototype testing.

A multibody dynamic model, comprising a four-stroke four-cylinder engine and a cable-operated clutch system, is reported by Kushwaha *et al*. (2002). The model includes combustion pressure, firing order of engine cylinders, crankshaft engine bearings, and crankshaft flexibility. Details of the model are beyond the scope of this chapter. Readers should refer to Kushwaha *et al*. (2002).

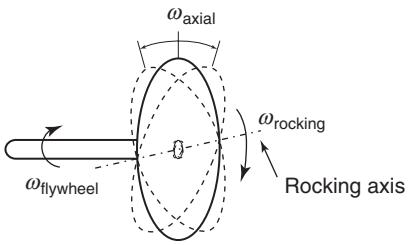

Figure 6. Conical whirl of the flywheel due to crankshaft flexibility.

With crankshaft flexibility included in the model, the applied combustion forces from each cylinder tend to induce combined torsional-bending deflections of the crankshaft. This leads to the conical whirl of the flywheel (Figure 6). This is known as *flywheel nod*.

For a four-stroke four-cylinder engine with a fairly rigid crankshaft, the spectrum of oscillations superimposed on the steady-state angular velocity comprises second engine order (twice the crankshaft angular velocity) and its full integer harmonics (Rahnejat, 1998). However, with increasing flexibility due to the use of lighter materials, spectral contributions due to combustion fundamental at half engine order and all its multiples remain resident on the crankshaft angular velocity. These affect the flywheel motion with its axial nodding causing an impact with the clutch system during the engagement and disengagement processes. The model by Kushwaha *et al*. (2002) predicts flywheel movement within 9% of that measured from the flywheel surface using a series of proximity devices. Figure 7 shows the spectral content of the flywheel axial

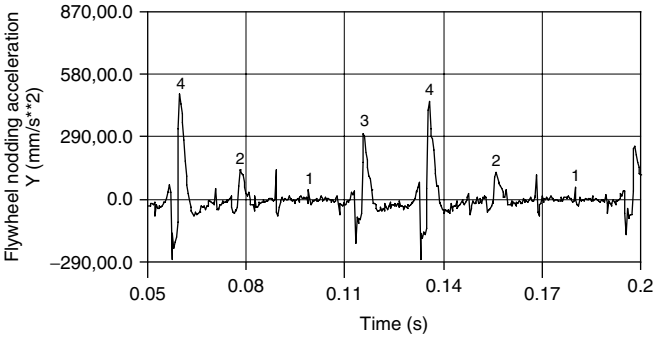

Figure 8. Increased flywheel nodding acceleration with firing of cylinders 3 and 4 proximate to the flywheel. (Reproduced from Kushwaha *et al*. 2002. © Sage/Institution of Mechanical Engineers.)

nodding motion. The increased flywheel movement due to the firing of third and fourth cylinders is sufficient to account for the clutch whoop problem (Figure 8). Note that for a four-cylinder four-stroke engine, the impulsive second order is main engine torsional signal.

4 DRIVELINE SHUFFLE AND CLONK

Shuffle is an uncomfortable tactile low frequency, fore-and-aft, lightly damped vibration of the vehicle. A shuffle mode may continue for several cycles. It can occur following a rapid throttle tip-in or back-out. A tip-in is a fairly rapid actuation of the throttle, whereas back-out is a rapid release of the throttle. In either case, the power flow along the drivetrain changes direction on account of ensuing

acceleration or deceleration (the drivetrain is defined as the torque path between the flywheel and the driven road wheels). The result is the application of an impulse, causing system oscillations, which are torsional for the drivetrain, accompanied and coupled with longitudinal motions of the vehicle (shunt). These occur at the lowest rigid body natural frequency of the system. The extent of oscillations depends on the stiffness and damping of the drivetrain, and in the case of the vehicle body, the longitudinal stiffness of the driven wheels' contact patch in series with the fore-and-aft stiffness of driven axle's suspension bushings. The oscillations are also affected by the lash rate in the torsional system (i.e., the drivetrain). Any rapid changes in the stiffness characteristics of the system can exacerbate the system response through impacts in the various lash zones. Therefore, cycles of shuffle may be accompanied by audible metallic clonk noises as the torque traverses the drivetrain lash during each cycle of shuffle (Krenz, 1985; and Arrundale *et al*., 1998).

Arrundale *et al*. (1998) reported a multibody driveline model, comprising elastic thin-walled driveshaft tubes. Throttle tip-in input from a four-cylinder four-stroke 1.8 L engine was used to drive the model. The results are shown in Figure 9, with low frequency cycles of shuffle at 5 Hz. In fact, shuffle response is often in the range 3–8 Hz, depending on the vehicle inertial properties and system stiffness. Hurried driver behavior in the form of rapid throttle action or release of clutch often introduces a sharp change in the input energy to the drivetrain system. Some of this energy is expended in vehicle shuffle, while the remainder causes impact in drivetrain lash zones and travels back and forth (in severe cases) along the drivetrain. The energy is often sufficient to excite modal response of lightly damped hollow structures such as the modern driveshaft tubes. These sharp high frequency oscillations can be seen with each cycle of shuffle response in Figure 9.

The clonk vibration signal was obtained by a laser vibrometer placed at a suitable distance near to a hollow driveshaft tube as the structural wave passes through it. The induced vibrations were measured by the vibrometer from a suitably reflective tape attached to the driveshaft tube. At the same time, the clonk sound can also be measured as sound pressure variation by a microphone directed toward the same target. A typical clonk noise signal is shown in Figure 10 (Gnanakumarr, 2010).

The signal comprises a ramp up duration of 80–200 ms, followed by an impact time of a few milliseconds and a much longer decay period as shown in the figure. It is

useful to look at the content of such signals in time frequency domain. Such a representation is known as a *wavelet*. Figure 11 shows a typical wavelet of a clonk vibration signal. The ordinate of the figure is frequency and its abscissa is time. Note that at the instance of impact the signal contains a broadband of frequencies; typically in the range 500–5000 Hz. Thus, the resulting wave front traveling along the drivetrain can excite a large number of modal responses of the system components, particularly those of hollow thin-walled structures, such as the driveshaft tubes that have a dense population of natural frequencies/mode shapes.

Theodossiades *et al*. (2004) showed that some of the excited structural modes of the driveshaft tubes are efficient noise radiators, giving rise to the clonk noise, which is metallic and accelerative in nature. These are generally the modes that are combined high frequency (many half-wavelength oscillations axially and around a tube's circumference) torsional and bending modes, usually referred to as *flexural modes*. The efficient noise radiating modes among the flexural responses are known as the *breathing modes* (Figure 12). There is also ringing noise during the decay of the clonk response.

There have been traditionally many palliative measures in order to take away the associated sharp metallic nature of the clonk noise, while still maintaining driveline's lightweight. These palliations have included use of sound absorbent media, such as foam filling the tubes, or use of a polymeric sandwich structure. The former can be an irritant substance and in some cases carcinogenic. Thus, its use is now prohibited in many places through directives and/or by legislation. The latter is considered to be expensive for high volume mass manufacture.

Gnanakumarr *et al*. (2006) described various methods of palliation of high frequency sharp metallic clonk response. In particular, they described the use of cardboard inserts fitted into the driveshaft tubes that reduce the sharpness of high frequency metallic noise contributions (above 2500 Hz) as shown in Figure 13 (note that higher noise level is represented by the dark tone in this figure within the lower rectangular region). The cardboard inserts break up the traveling standing structural waves, as well as attenuating the sound propagation by absorption. The secondary events are low frequency contributions because of the decaying ringing noise in the hollow cavity of the tubes.

5 TRANSMISSION RATTLE

Gear rattle is associated with the characteristic structure and airborne noises that are radiated to the environment by the impact of unselected (unengaged) transmission gear pairs (Sakai *et al*., 1981; Wang, Manoj, and Zhao, 2001). The phenomenon occurs at low teeth impact forces and is qualitatively similar to the sound produced by marbles in a shaken metallic can. Therefore, it has a distinct repetitive sound quality differentiating it from other noise NVH concerns (Dogan, Ryborz, and Bertsche, 2006). Rattle is induced by engine order vibrations (Rahnejat, 1998) in the presence of backlash in meshing teeth pairs. It is particularly noticeable in diesel vehicles with higher output torque fluctuations, where the intensity of rattle noise has found to be directly affected by the resulting engine order torsional vibrations (Tangasawi, Theodossiades, and Rahnejat, 2007; Theodossiades, Tangasawi, and Rahnejat, 2007).

Transmission rattle is a broadband NVH phenomenon as perceived by vehicle occupants and other road users alike (Figure 14 shows the response from a bearing cap of a transmission housing). It can cause unnecessary concern for the vehicle owner. Its spectral composition comprises engine order vibration, meshing frequencies of loose gear pairs, and structural modal response of the transmission casing. The higher band frequency due to structural response is because of traveling waves from the impact sites along the transmission output shaft and transmitted though the bearings onto the casing. Transmission rattle manifests itself under various operating conditions. In general, these are

- Idle/neutral rattle: The vehicle is idling and as the name indicates without any gear selected. The usual engine speed is in the range 600–1000 rpm.

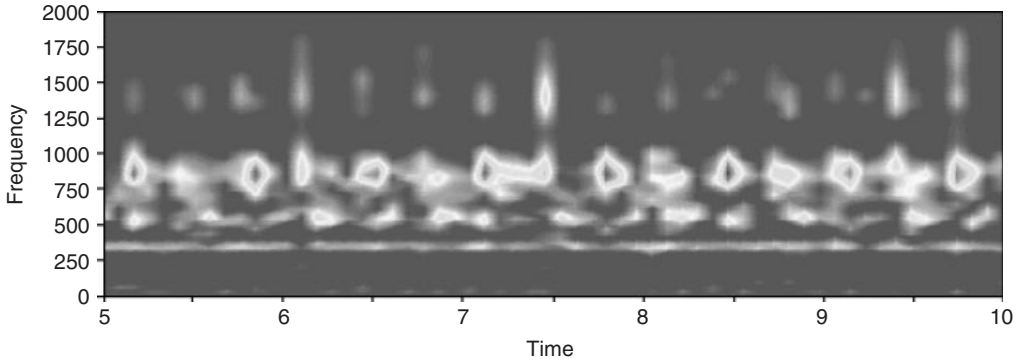

Figure 14. Wavelet of idle gear rattle from 2 L diesel engine vehicle.

- Creep rattle: The engine speed is low (600–1000 rpm) with vehicle driven in first or second gear.
- Drive rattle: The engine speed varies between 1000 and 2000 rpm with second, third, or fourth gear selected and with partially loaded throttle.
- Over-run rattle: The engine speed is between 2000 and 4000 rpm with second gear engaged and throttle at over-run position.
- Coast rattle: With floating throttle and the engine speed between 4000 and 2000 rpm and second gear engaged.

Various methods have been used in order to attenuate the effect of rattle. These include backlash eliminators, clutch predampers, controlled slip clutches, and dual mass flywheel (DMF), the last of which has been found to be the most effective, but a costly palliative.

Essentially, a DMF integrates the function of a usual solid mass flywheel with that of a tuned torsional spring-damper, often in the form of an arc spring (Figure 15). In this configuration, the primary flywheel is bolted onto the engine crankshaft and is free to rotate relative to the secondary flywheel. An arc spring transmits the torque between the primary flywheel and a flange, which is riveted to the secondary flywheel. With a positive load, the arc spring is pushed by the end stop on the primary side against the flange on the secondary side. With a negative load, the arc spring is pushed in the opposite sense by the flange against the end stop. Long travel of the spring at relatively low frequency achieves good isolation, while still maintaining sufficient stiffness to transmit the maximum engine torque. In this manner, spring stiffness can be tuned to act as a band-pass filter, removing or attenuating the

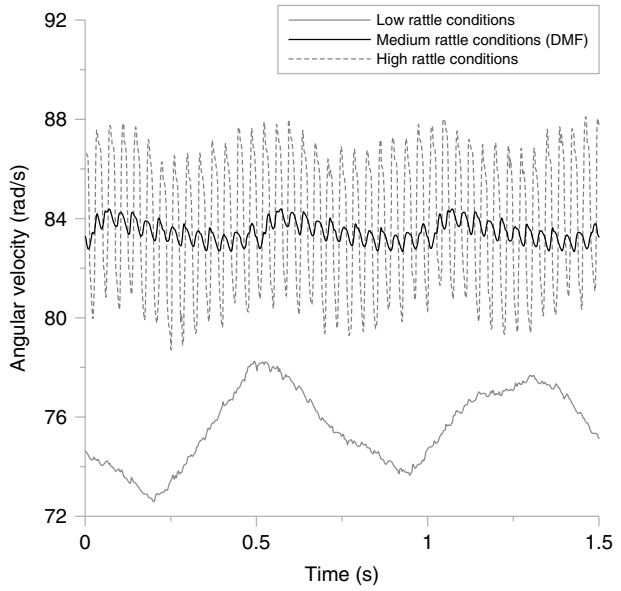

Figure 16. Torsional oscillations resident on the transmission input shaft. (Reproduced from De la Cruz *et al*. 2010. © Institution of Mechanical Engineers.)

significant engine order vibration contributions, depending on the engine type (number of cylinders and combustion signature). Therefore, lower amplitude oscillations are achieved, resident on the transmission input shaft. Note that these engine torsional vibrations are found to be the main contributory factor in transmission rattle (Tangasawi, Theodossiades, and Rahnejat, 2007; Theodossiades, Tangasawi, and Rahnejat, 2007; Dogan, Ryborz, and Bertsche, 2006).

The damping characteristics of the DMF can be further enhanced by attaching additional components to the arc spring, thereby creating friction between the spring coils and the flange. These components are usually referred to as *shoes* with an appropriate wedge shape to entrain grease, which is filled into the DMF enclosure, into the contact. Some vibration is therefore attenuate through viscous shear and drag introduced by the grease. Further description for DMF is given by Kelly *et al*. (2010).

All the palliative methods essentially attenuate the engine torsional vibrations resident on the transmission input shaft, thus reducing the impulsive nature of input between conjugate teeth pairs of unselected gears (Figure 16; De la Cruz, Theodossiades, and Rahnejat, 2010).

In Figure 16, the prevailing rattle condition is obtained from the transmission input shaft under various drivetrain configurations. The response, indicated by medium rattle is when a DMF is used, that for low rattle condition makes use of a clutch slip device as a predamper and the high rattle condition corresponds to no palliation (a solid mass flywheel is used and with no form of palliation). Gear rattle is easily noted and its intensity is often subjectively rated by NVH engineers. However, it is necessary to have an objective function, determining an acceptable level for the rattle noise. To achieve this, it is necessary to undertake quite in-depth numerical analysis, such as those reported by Tangasawi, Theodossiades, and Rahnejat (2007) for idle rattle condition and De la Cruz, Theodossiades, and Rahnejat (2010) for creep rattle. The former uses the *rattle ratio* for its objective function. This is the ratio of inertial torque of an idling gear (loose gear) to that of the resistive drag torque (caused by friction between the loose gear and its retaining output shaft, as well as some small contribution due to flank viscous friction between the gear meshing teeth pairs with their conjugate pinion teeth). Seaman, Johnson, Hamilton (1984) defined the *rattle threshold* as the angular acceleration at which an idle gear's inertial torque exceeds the drag torque (i.e., a rattle ratio exceeding unity). Rattle ratio can be regarded as an indication of rattle, but is not the best metric which can be used. A better ratio is defined by De la Cruz, Theodossiades, and Rahnejat (2010) as the *impulsion ratio*. This is the ratio of drive torque over the drag torque for a loose gear. Therefore, any torque reversal as the result of severe impact conditions can also be ascertained (Figure 17).

6 CLOSURE

In this chapter, a number of drivetrain NVH phenomena are described. Some aspects of analysis and palliation measures are also noted. In general, with an increasing trend toward lighter power train construction and higher output power, the propensity for occurrence of these phenomena and others are on the increase. In particular, there would be an increasing effort in power train hybridization as well as development of electric vehicles. These are likely to further introduce NVH issues. As a result, the need for in-depth investigation, particularly numerical analysis, would be increasing in the future.

Open Differentials

Joseph Palazzolo
GKN Driveline, Auburn Hills, MI, USA

1 INTRODUCTION

In the traditional drivetrain system for automotive passenger vehicles, there is a need for a device that can divide torque to the driving wheels equally from side to side. This mechanical device is known as a *differential*, specifically referred to as an *open differential* or, at times, a conventional differential. The open differential allows for a single input from the powertrain to be divided to the two outputs, typically the wheels. The open differential still accommodates the requirement of speed differences experienced in turn maneuvers while providing equal torque to the outputs. This equal torque balance of the conventional open differential can create drive force difficulties in the vehicle if one wheel has lost tractive effort as experienced with one wheel on a low coefficient of friction surface such as snow or ice. This is further discussed in Passive and Active Limited Slip Differentials regarding limited slip differentials.

2 COMPONENTS

For the sake of simplicity, this chapter discusses the most common-style axle differential, which is a bevel gear style. The bevel gear-style open differential consists of the following principal components, which are shown in Figure 1:

differential carrier;
differential pin;
differential pinion gears;
differential side gears.

Figure 1 is a two-pinion differential with squareback side gears. The large window area in the differential carrier is to allow for the assembly of the differential internal gears. There is a ring gear mounting flange with mounting holes for the fasteners. These mounting holes can be either clearance holes for the fasteners or threaded holes, in the case of transaxle style mounting structures.

There are other components, such as side gear washers and shims, pinion gear washers and shims, and differential pin retention fastener, but the main components to understand the operation are the four listed earlier.

The torque path through the differential is shown in Figure 2 and the components are further described later. The torque is applied through the ring gear bolted flange to differential case. The flow from the differential case to the wheels is outlined on the right. Progressing downward in the chart is when the engine is driving the wheels and upward is when the wheels are back driving the input (hypoid gear) that occurs during coast conditions.

2.1 Differential carrier

The differential carrier is usually bolted or welded to the input gear. The input gear is typically the hypoid ring gear in a traditional axle arrangement or it is the final drive output gear for transaxle systems. The torque from the powertrain is transferred to the differential carrier via this

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto097
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

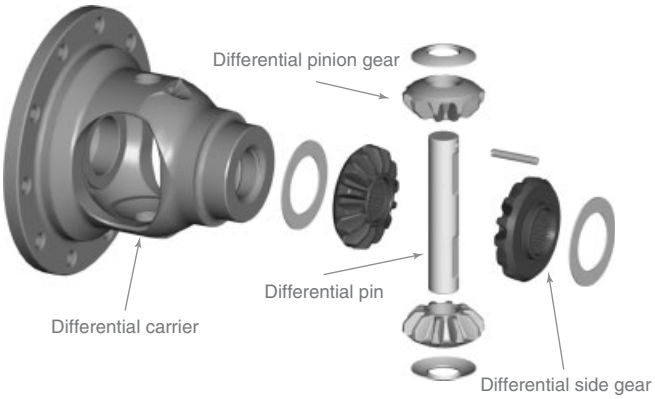

Figure 1. A typical open differential exploded view.

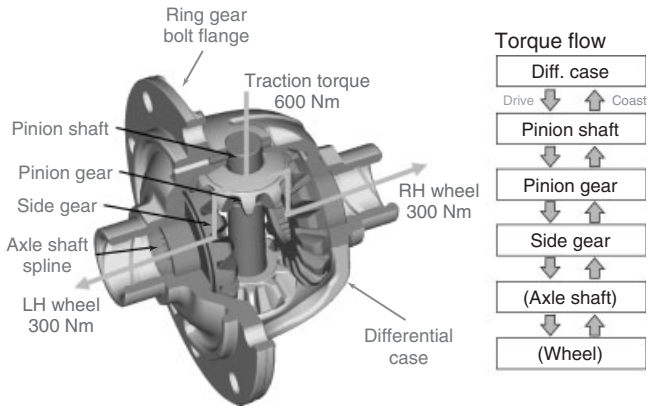

Figure 2. An open differential showing the powerflow.

ring gear and its attachment. The ring gear mounting flange must be rigid enough to support the thrust loads produced from the hypoid gear arrangement, whereas the differential case is supported on a set of bearings to allow it to freely rotate within the axle housing assembly. This is the single source of input torque and speed for the differential. In most applications, the differential case will be a single piece, machined casting with "windows" that allow access for machining and assembly. In other cases, specifically, when there are three- or four-pinion gears, the differential case may be a two-piece design that is split in order to allow machining and assembly of the individual case halves. The differential case is normally a cast iron construction that is machined after casting. Some high performance applications utilize forged aluminum as well for weight savings, but these are very special cases. The differences between single- and two-piece differential housings are illustrated in Figure 3. The two-piece version can be machined and assembled from the opening created when the housing halves are apart. Even though this diagram

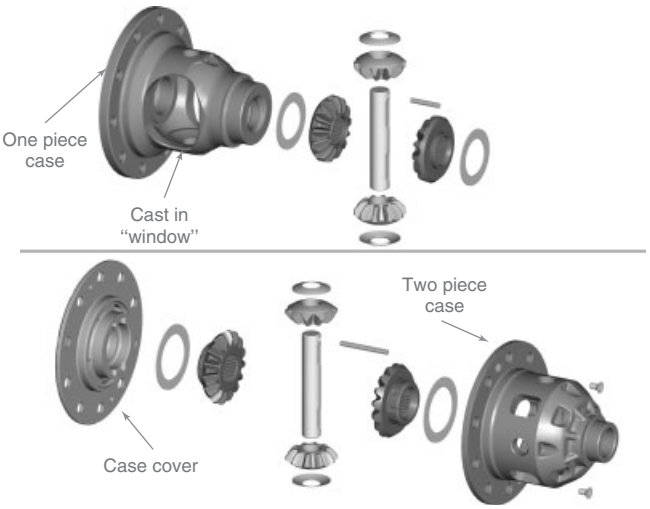

Figure 3. Illustration of a single-piece and a two-piece differential housing.

illustrates two-pinion differentials, the main reason for a two-piece housing is to allow for more than two pinions.

2.2 Differential pin

The differential pin is the next component to receive torque from the powertrain. It is located in the differential carrier and supports the differential pinion gears. Most standard open differentials have a single pin to locate the two-pinion gears. There are some applications that utilize a "T"-shaped, multipiece differential pin to support four-pinion gears. The differential pin not only locates the pinions and transfers torque but, in semi-float axle applications (see Axle Systems for more details), also acts as the thrust reaction member of the axle shafts. In the semi-float arrangement, the differential pin also acts as a mechanical method to retain the axle shaft retention device, which is typically a thick C-shaped steel washer as shown in Figure 4. The left side axle shaft illustrates the C-washer inside the side gear pocket with a clearance on the end of the shaft to the differential pin, whereas the right axle shaft illustrates the axle shaft motion being restricted by the differential pinion shaft. The differential pins are normally made out of heat-treated steel with special coatings to act as a bearing and wear surface for the pinion gears.

2.3 Differential pinion gears

The differential pinion gears ride on the differential pin and transfer power from the pin to the differential side gears. The pinion gears are normally smaller than the side gears.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto097
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

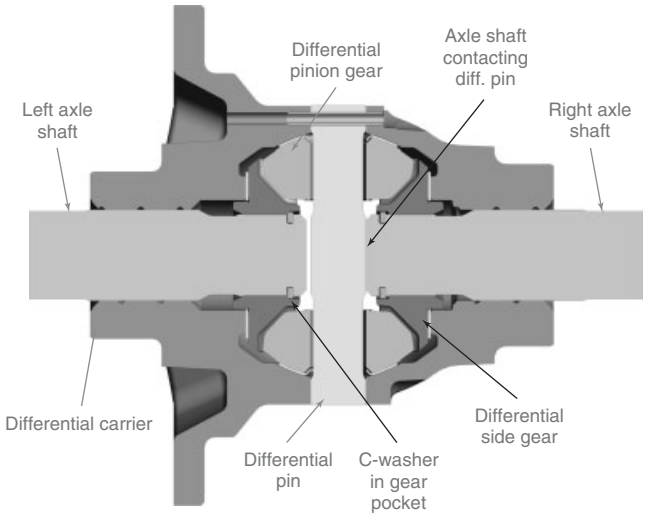

Figure 4. A typical two-pinion open differential.

The normal convention in gearing is to utilize the term *pinion* to describe the smaller of the two gears in mesh and the term *gear* is for the larger of the gear pair. A typical number of teeth a pinion gear is in the range of 8 to 10. The pinion gears mesh with the differential side gears and are perpendicular to the axis of rotation. This change in axis is one of the features of a bevel gear set. This bevel gear tooth arrangement utilized in differentials is a straight side gear geometry as opposed to spiral. The main reason for this is that the side gears and pinion gears in normal, straight-ahead driving conditions do not turn relatively. This is further explained in Equation 2.

The number of pinions is typically two or four, but there are some applications where three are used. Figure 5

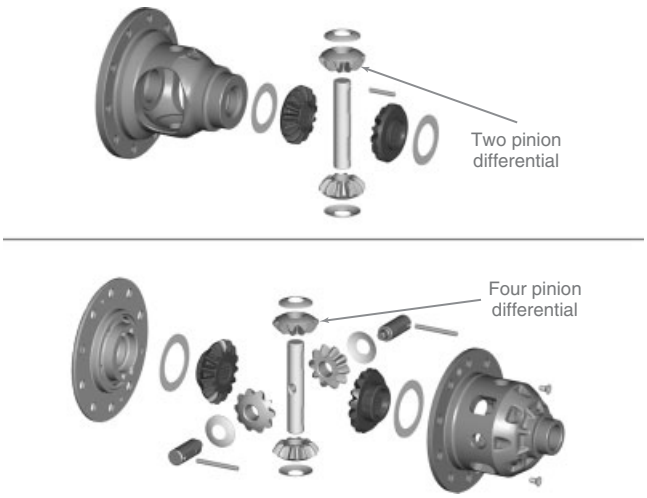

Figure 5. Illustration of differences between two- and four-pinion differential cases.

illustrates the typical differential case differences between a single-piece differential case and a two-piece differential case. The upper exploded view is a typical two-pinion differential case, whereas the lower view is of a four-pinion differential case. The main reason for a two-piece differential case is to allow for more than two pinion gears. The main reason to increase the number of pinions is to increase the torque-carrying capacity within a given packaging environment. Of course, there are manufacturing costs and weight concerns with adding more pinions that need to be considered. Most four-pinion differentials do not allow for "C-washer"-style axle shaft retention as well. In these situations, an outboard axle shaft retention method is utilized. There is a relatively simple equation that can be used to determine a suitable tooth combination.

$$2\,\frac{N_{\text{side gear}}}{N_{\text{p}}} = \text{whole number} \tag{1}$$

where the following symbols are:

$N_{\text{side gear}}$ = number of teeth of the side gear;
N_{p} = number of pinions (typically, 2, 3, or 4).

Equation 1 describes the tooth combination constraints that must be observed in order to assemble a differential with multiple pinions. From this equation, it can be quickly seen that a 14-tooth side gear can be a two- or four-pinion differential but never a three-pinion unit. While a 15-tooth side gear can be either a two or three pinion differential. A typical computer software package that is used to design the actual tooth profiles will adjust the face profiles, such that the gears will operate correctly but the designer must input the correct tooth combination.

2.4 Differential side gears

The other component that makes up the bevel gear set is the differential side gear and is the remaining piece of the torque flow puzzle as shown in Figure 6. This differential has a side gear with a squareback along with pockets for a C-washer-style retention along with spiral grooves machined in the differential housing to aid in lubrication of the axle shaft journal. This gear is the last component within the differential to transfer the torque and speed to the axle shaft. The connection method is typically an internal spline. Side gears normally have a tooth count in the range 11 to 16. There are differential-style bevel side gears that can be of either a squareback or a roundback face. There are many different reasons for each but that level of detail is outside the scope of this text.

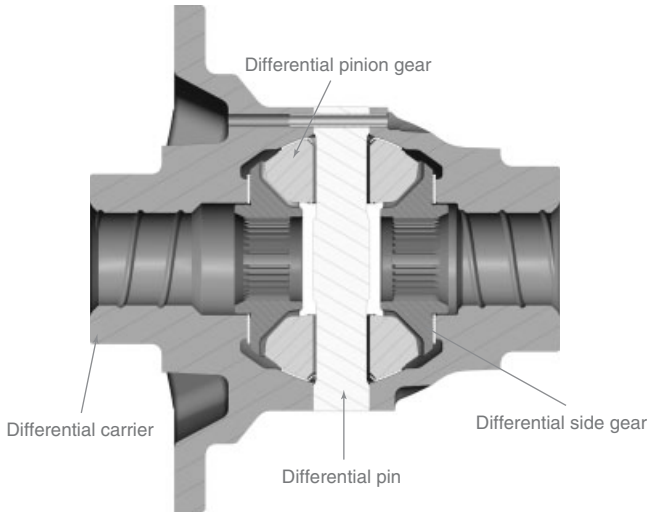

Figure 6. A cross-sectional view of an open differential.

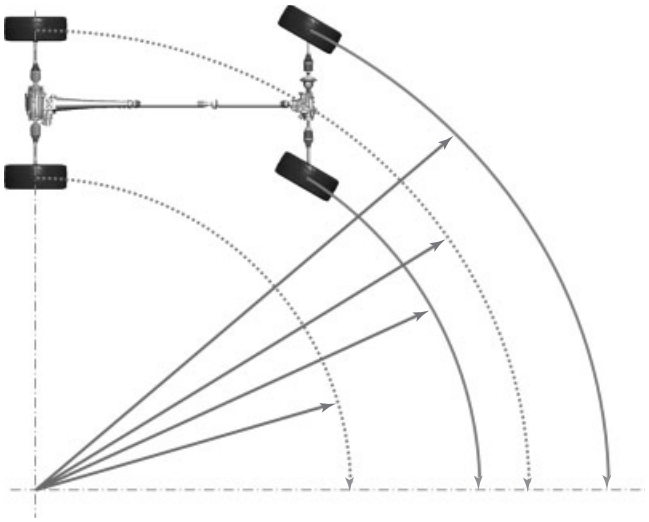

Figure 7. Vehicle cornering.

3 OPERATING PRINCIPLE

The open differential allows for speed differences across the outputs. These potentially varying rates are required to allow the tires to rotate independently during turn maneuvers or unequal tire sizes, pressures, and the like. The primary function of the open differential is to split torque between the two outputs. This provides uniform drive-force distribution across the outputs of the differential.

3.1 Speed relationship

Equation 2 describes the mathematical speed relationship of the outputs (left and right) for a typical axle differential. This simplistic equation works for any units, so one can substitute speed in revolutions per minute, miles per hour, kilometers per hour, and any other units as long as they are consistent. Assuming that a vehicle is traveling in a straight line and the wheels are rotating at the same speed, one can quickly see that the output connections are traveling at the same speed as the inputs.

$$2 \times \omega_{in} = (\omega_{left} + \omega_{right}) \tag{2}$$

where the following symbols are:

ω_{in} = input speed;
ω_{left} = left wheel speed;
ω_{right} = right wheel speed.

Example: 2×10 rpm $= (10$ rpm $+ 10$ rpm$)$.

Figure 7 shows that all four wheels travel through a different radius of curvature during a turn maneuver. The front differential (right side of the diagram) averages the front wheel speeds, whereas the rear differential (left side of the diagram) averages the rear wheel speeds. As the rear wheels travel in a smaller radius trajectory than the front, there is also a difference in the average of the front and rear speeds.

Even though this seems very simplistic in this form, the function of the differential can be misleading when in a vehicle on a service hoist. Imagine if the input to the differential is held stationary (which is what happens when the vehicle is in park) and rotate one wheel forward—so ω_{in} is zero and ω_{left} is some value, say 10 rpm—then ω_{right} must be negative 10 rpm. Therefore, one wheel spins forward and the opposite wheel will spin in the opposite direction at the same speed. This satisfies the equation and is mechanically a correct behavior of the differential, but can be confusing to the person spinning the tires.

3.2 Torque relationship

The open differential allows for speed differences between the outputs while maintaining a torque balance. Most engineers like to refer to the output torque as a fixed split ratio in percentages. Typically, it is referred to as a *50/50 differential*, as in most conditions, the open differential will split the input torque evenly between the outputs. There are some situations where this torque balance feature of the hardware can cause undesired performance and that the reader may have already experienced in driving maneuvers. Imagine that one wheel is on ice, whereas the other is on the dry road surface. The torque that can be reacted by the slippery ice surface is very low. The differential will

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto097
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

limit this torque to the other wheel as well. This balance means that the wheel with good traction may not have enough torque to propel the vehicle forward. Therefore, the vehicle is now with one wheel spinning and the other idled. Equation 3 illustrates the total available driving in the vehicle.

$$T_{in} = T_{min}\{T_{left}, T_{right}\} \times 2 \tag{3}$$

where the following symbols are

T_{in} = input torque;
T_{min} = the smaller of the output torques;
T_{left} = left output torque;
T_{right} = right output torque.

Further examination of Equation 3 shows that if one of the output torques is very small, then twice a small number is still a small value. The open differential in this situation is "traction limited" and cannot deliver more torque than can be reacted by the spinning wheel.

One method that can be utilized to visually depict an open differential with one wheel spinning is a simple pulley arrangement with different masses on either end of the rope as shown in Figure 8. The smaller mass represents the wheel on a slippery surface, whereas the larger mass represents the wheel on a good adhesion surface. The open differential has no means to counteract this pictorial mass difference and, therefore, the side with more mass indexes downward freely.

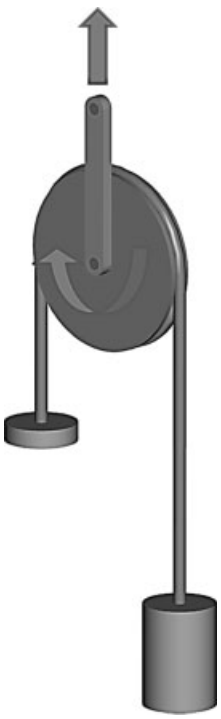

Figure 8. Open differential—pulley analogy.

There are a few methods to counteract this situation. One common method is to increase the torque on the spinning wheel. This can be easily achieved by applying a braking force to that wheel. The driver can easily perform this maneuver by lightly depressing the brake pedal while accelerating. This will create a reaction torque at the spinning wheel that will be *biased* to the opposite via the differential. This braking force can be automatic from the modern-style traction control system that applies brake pulses to the spinning wheels for the driver. Another method is to provide a mechanically or electrically actuated device in parallel across the wheels to combat this torque and speed differences. This is further discussed in Passive and Active Limited Slip Differentials.

3.3 Torque bias ratio

The phrase *biasing torque* across the differential is used to describe the phenomenon when torque is transferred from one of the outputs to the other. There is even a need to refer to the amount of change of that torque from the outputs and often called *torque bias ratio* (*TBR*).

$$\text{TBR} = \frac{T_{high}}{T_{low}} \tag{4}$$

Equation 4 quickly begs the question, how can the open differentials have higher torque on one output when compared to the other when the differential is supposed to balance torque? If the open differentials were frictionless and ideally spun freely without any resistance, then the TBR would be unity. The mechanical components do not perform ideally and there is some friction in the system along with inefficiency in the torque transfer. In Passive and Active Limited Slip Differentials, this friction is further discussed as a means to increase vehicle performance.

On the basis of the gear geometry and relationship between the side and the pinion gears along with the interface of the pinions to the differential pin, there are thrust forces exerted between them that create a friction torque during speed difference events. The friction force generated between the side gear and its washer is mathematically expressed in Equation 5.

$$F_{gw} = \mu_{sg} \times \left(\frac{\sin\alpha_g \tan\theta_g}{R_{sg}}\right) \times \left[\frac{(DG_{od} + DG_{id})}{4}\right] \tag{5}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto097
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where the symbols are as follows:

F_{gw} = friction between side gear and its washer;
μ_{sg} = coefficient of friction between the side gear and its washer;
α_g = side gear pitch cone angle (°);
θ_g = side gear pressure angle (°);
R_{sg} = side gear pitch circle radius;
DG_{od} = outside diameter of the side gear washer;
DG_{id} = inside diameter of the side gear washer.

A typical value range for the side gear pitch cone angle is 50–60° and the pressure angle is 20–35°.

The side gear thrust force in combination with friction between the side gear back face and the side gear washer creates a resistance to speed difference between these surfaces. A typical value for the coefficient of friction (μ) of these steel components is 0.13. There is also friction present between the differential pinion gear bores and the differential pin shaft along with the differential pinion gears and the pinion gear washers. The friction force between the pinion gear and the differential pin is expressed mathematically in Equation 6.

$$F_{ps} = \mu_{ps} \times \left(\frac{1}{R_{pg}}\right)\left(\frac{D_{ps}}{2}\right) \tag{6}$$

where the symbols are as follows:

F_{ps} = friction between the pinion shaft and the pinion gear bore;
μ_{ps} = coefficient of friction between the differential pin and the pinion bore;
R_{pg} = pitch circle radius of pinion gear;
D_{ps} = pinion shaft's outside diameter.

The last frictional area to represent mathematically is the friction between the pinion gear and its washer.

$$F_{pw} = \mu_{ps} \times \frac{(\tan\theta \cos\alpha_s)}{(R_{pg}\ (\sin\alpha_s + \mu_{ps}\ \cos\alpha_s)} \times \left[\frac{(DP_{od} + DP_{id})}{4}\right] \tag{7}$$

where the symbols are as follows:

F_{pw} = friction between the pinion gear and its washer;
μ_{ps} = coefficient of friction between the pinion gear and its washer;
θ = pinion gear pressure angle;
α_s = side gear pitch cone angle;
DP_{od} = pinion washer's outside diameter;
DP_{id} = pinion washer's inside diameter.

Now that all of the friction components are expressed, their effects on TBR can be analyzed. Each of the friction components has been separately expressed along with its own coefficients of friction. More often than not, the coefficient of friction is same for all the interfaces but one could, theoretically, design different frictional interfaces to adjust the differential behavior. Equation 8 describes the TBR in terms of the frictional force relationships described earlier.

$$TBR = \frac{(1 + F_{gw})[1 + (F_{ps} + F_{pw})]}{(1 - F_{gw})[1 - (F_{ps} + F_{pw})]} \tag{8}$$

4 PLANETARY-STYLE DIFFERENTIALS

As mentioned earlier, bevel-style differentials are the most common for side-to-side even torque split differentials applications. It is also possible to achieve the same mechanical properties utilizing planetary gear arrangements. The main difference with planetary arrangements is that they are typically narrower and larger in diameter when compared to bevel-style differentials. Just like bevel differentials, planetary differentials utilize straight cut or spur gears. There are three main elements of the planetary—the ring gear, the sun gear, and the planet carrier. The ring gear has internal spur gear teeth, whereas the sun gear has external spur gear teeth. The carrier locates the planets and allows them to spin independent of the carrier—much like the bevel-style pinion spinning on the differential pin. In order to achieve the torque split requirements, an idler planet is inserted to maintain the correct direction of rotation during speed difference maneuvers. The additional planet in the mesh reverses the direction of rotation and is often referred to as a *compound planetary arrangement*.

The torque ratio is balanced as long as the number of teeth on the sun gear is half the number of teeth on the ring gear. The input is the ring gear, whereas the sun gear and the carrier gear are the outputs.

Passive and Active Limited Slip Differentials

Joseph Palazzolo
GKN Driveline, Auburn Hills, MI, USA

1 INTRODUCTION

On the basis of the traction limited behavior of an open differential, as described in Basic Open Differentials, there has been a need to develop a differential device that will overcome the shortcomings of the open differential. This device is referred to as a *limited slip differential* (*LSD*). At the same time, it is preferred for the LSD to mimic the open differential performance in normal driving conditions and only intervene during excessive wheel slip events. There are a numerous types and arrangements of LSDs, each having its own unique performance characteristics. These characteristics can be considered advantageous and at times detrimental to the vehicle performance or behavior. One must keep in mind that the main reasons for a type of LSD can be to overcome the distinctive traction limited characteristic of an open differential or to deliver a higher performing vehicle driving behavior. With so many variants of these devices in the market, it is best to categorize them as two basic types: active and passive. The active devices have some sort of electronic control system typically with feedback, whereas the passive devices respond purely mechanically. The different types of devices that are in either the production vehicles or the most commonly encountered vehicles in the aftermarket will be reviewed in this chapter. Please keep in mind that there are many devices that have a similar function under different brand names in the aftermarket. The basic principles are the same and will be described here.

The LSD is unique, with two potential torque paths through the device. The primary torque path is through the open differential. Therefore, the torque is from the ring gear flange to the differential pin, then to the differential pinion gears, and finally the side gears as reviewed in Basic Open Differentials. The secondary path is utilized when the open differential portion alone cannot transfer the power based on the traction limited behavior of the open differential. The speed or torque difference within the differential, which is caused by a slip event, requires additional means to transfer the power, which is the limited slip device. During this event, the secondary path typically flows through a clutch pack to the differential gears. The key differentiator in the various style devices is the means utilized to engage the clutch pack. The limited slip mechanism is reacting to the speed difference from one output of the differential to the other. The mechanism will always try to transfer torque from the faster spinning wheel to the slower spinning wheel in order to equalize the speeds across the outputs. The device is basically diverting speed to the slower wheel in an effort to balance the output speeds. This explains why the phrase "limited slip" is used to describe the devices.

2 PASSIVE LIMITED SLIP DIFFERENTIALS

The term *passive* refers to the fact that the devices in this category are differentials that are purely mechanically engaged without any electrical feedback from the vehicle or driver directly. There are basically two styles of mechanical self-actuation methods employed for passive style LSDs. These differentials respond to either a speed or a torque difference from the outputs of the differential or at times, a combination of both. As such, these units are commonly referred to as *speed sensing* or *torque sensing*. The term *sensing* can be a little misleading, as these devices do not have any electrical sensors but rather mechanically sense a speed or torque difference. On the basis of the speed or torque difference, the LSD will react accordingly to a typically predetermined performance characteristic.

As these units are purely mechanical devices, they can cause some other vehicle system concerns based on this interaction. Imagine that there is an event in the vehicle where a speed difference is preferred (such as an antilock brake system (ABS) event), and the passive LSD will not allow that speed difference to occur freely. In this situation, there can be a system characterization issue and additional ABS tuning involved in order to calibrate for this interaction. It is possible to have a passive LSD function with ABS or stability control; the development and vehicle tuning engineers just need to understand the mechanical behavior of the differential and adjust the brake system logic accordingly. With the proper attention allotted to the total system interaction, both systems, ABS and passive LSD, can work in harmony.

Through examination of Figure 1, it is evident that there are two distinct potential paths of torque flow through the differential. The normal path is through the traditional open differential style gears. There is an alternative path through the limited slip device that governs the unit when the bevel gear arrangement is no longer adequately controlling the slip across the unit. This parallel path of power is where the different style limited slip devices are installed. A generic review of the more common styles of devices in the market is included later in this section.

2.1 Limited slip differential construction

There are two means to mechanically link an LSD device. It is common to describe the performance of the LSD by referencing the two outputs of the differential, which are the wheels for an axle application. This common convention is a great method to describe the generic function, but skips some of the important mechanical behavior that is required to design and analyze the limited slip device.

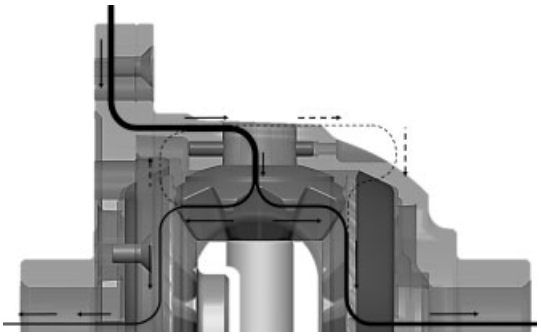

Figure 1. A phantom view of a typical limited slip differential.

If the LSD device is truly connected across the outputs of the differential, it is referred to as a *shaft-to-shaft style LSD*. Even though this is the most common method used to pictorially describe the function, it is not very common in actual hardware application. The vast majority of production vehicles do not use this style construction, as it is mechanically difficult to link all of the components together and adds more complexity with additional concentric shafts. There are still some basic concepts that need to be reviewed with this style architecture and will help explain the alternate, more common, construction method of shaft-to-housing. For illustrative purposes, it is assumed that the vehicle is traveling in a right-hand turn maneuver. In this event, the speed of the left wheel is greater than the speed of the right wheel, $\omega_L > \omega_R$. The kinematics is reviewed in Basic Open Differentials. The LSD device will transfer torque from the faster spinning left wheel to the slower spinning right wheel. The device will basically try to match the speed across the differential's outputs by diverting the torque. As the bevel gear style differential will split the torque equally and the LSD device will add torque to the slower right side wheel, the following equations describe the torque potential in the system.

$$T_L = \frac{T_{in}}{2} - T_c \tag{1}$$

$$T_R = \frac{T_{in}}{2} + T_c \tag{2}$$

where the following symbols are

T_L = torque of the left wheel
T_R = torque of the right wheel
T_{in} = input torque
T_c = torque of the LSD clutch

If a left-hand turn maneuver is experienced, the right wheel is the faster spinning wheel and the above-mentioned

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

equations are similar, just needing to exchange the signs of operations, adding LSD torque to the left wheel and subtracting for the right wheel.

The other mechanical method to configure the LSD and the most common is actually with the LSD clutch device mechanically connected between the side gear and the differential case. With this configuration, the above-mentioned equations need to be slightly modified but still govern the torque transfer. In this case, the substitution of $T_c/2$ in place of T_c yields the following: Right-hand turn ($\omega_L > \omega_R$):

$$T_L = \frac{T_{in}}{2} - \frac{T_c}{2} \quad (3)$$

$$T_R = \frac{T_{in}}{2} + \frac{T_c}{2} \quad (4)$$

As discussed earlier, for the shaft-to-shaft configuration, exchanging the signs of operation for a left-hand turn and these equations describe the torque transferred. Even though the more common architecture, with the LSD between the side gear and the differential carrier, is easier mechanically to design, there is a trade-off in the amount of LSD clutch torque transferred, which is half of what it could be for a given size clutch. This just means that the LSD device needs to be sized accordingly for the configuration. This is one of the main reasons that the LSD clutch pack is often two separate packs behind each of the differential side gears.

2.2 Preload

Preload is a term used to describe a fixed torque that must be overcome before the differential freely allows a speed difference. Typically, preload is achieved from a mechanical spring. In Figure 2, a coil spring is shown to represent preload. On the basis of the $T_c/2$ reviewed earlier, there are two clutch packs in the device. Another method to explain preload is that there will be a fixed torque between both outputs up to the preload value independent of road surface conditions. This fixed torque is basically a torque that must be overcome before the differential unlocks, which will allow a speed difference to occur. If a speed difference is required and the torque is below the preload value, then the differential will mimic the performance of a mechanically locked differential, which will not allow speed difference. Typically, the mechanical torque preload is in the 50–150 N-m range before the LSD will allow differentiation within the unit. Preload is a great feature to aid with traction and handling but needs to be integrated with care. If too much preload is in the system, then the tires may not be allowed to easily differentiate in turn maneuvers at low speeds. The tires overcoming this excessive preload during a turn event may cause wind-up across the differential, and the driver will surely notice this driveline wind-up. Conversely, at high speeds, there may be a positive yaw-damping effect associated with higher preload. The ideal condition would be to have the flexibility to vary preload torque based on the vehicle speed and turn events. Figure 3 shows the torque transferred from the outputs of the differential. The solid line shows the performance of a traditional open differential; as the open differential typically has a 50/50 torque split output, the line has a slope of 45°. The effect of preload shifts the curves by the amount of the preload and is shown with dashed lines, but the slope of the curve is constant. The upper right quadrant of the graph represents a drive condition with left and right turns, whereas the lower left quadrant represents a coast condition with left and right turns.

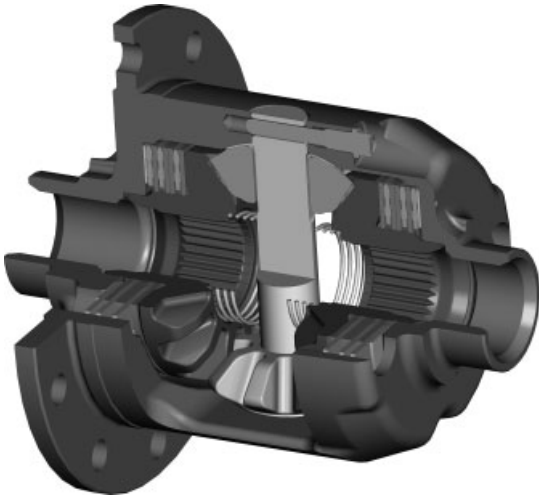

Figure 2. A model of a typical limited slip differential.

2.3 Speed-sensing differentials

As the name suggests, a speed-sensing LSD is a device that responds to excessive wheel speed difference across the unit. As the outputs of the differential are mechanically attached to the wheels, the device is responding to excessive tire slip or speed differences of the wheels. There is a characteristic locking torque transferred across the differential in relation to this speed difference as shown in Figure 4. The horizontal axis of this graph is the speed difference, whereas the vertical axis is torque transferred. There are two curves plotted showing the difference between a digressive (shown as a dashed line) and progressive locking (shown as a solid line) behaviors of the differential. One needs to be aware that the speed difference is across the device and not absolute vehicle speed that is being referenced.

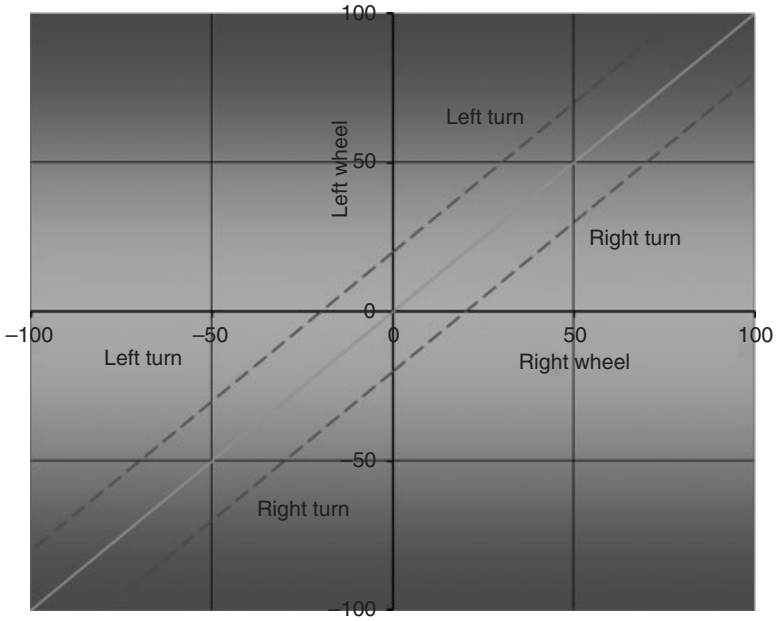

Figure 3. Preload graph. (Reproduced by permission of Joe Palazzolo.)

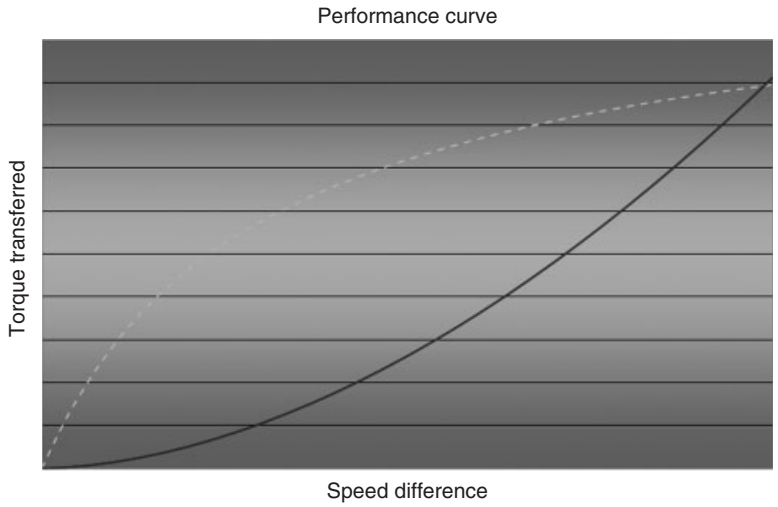

Figure 4. Performance of a speed-sensing differential. (Reproduced by permission of Joe Palazzolo.)

Most speed-sensing LSDs employ some sort of pump device that reacts to the speed difference to allow the pumping device to generate pressure. This pressure is then applied to a piston that applies a compressive force to a clutch pack. By the nature of the pump device, this style LSD is reactive to wheel slip after the slip has occurred. Not all of the devices employ a clutch pack, but it is most common to have a clutch pack. The different technologies will be reviewed in the following sections.

2.3.1 Viscous control technology

The viscous control technology uses fluid friction in order to transfer torque during slip events across the differential in a digressive performance curve as shown earlier. The Harry Ferguson Limited Research Department first discovered and applied the fluid dynamics properties of a unique fluid that resists motion when it experiences shear stress. In the absence of any shear stress, the fluid returns to it normal state. The fluid that is utilized is silicon based with a typical

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

kinematic viscosity range between 50,000 and 500,000 centistokes. The silicone fluid has very stable physical properties over a wide range of operating temperatures, especially when compared to traditional mineral-based oils. The fluid used for viscous control devices is not shared with the rest of the differential and is enclosed in a separate sealed housing. These units are filled for life and the fluid, therefore, does not require any service interval over the lifetime of the vehicle. In this sealed chamber, there are two sets of steel plates that are mechanically attached to the two elements of the differential. When there is a speed difference across the differential, these steel plates resist the motion through the fluid dynamics of the silicone fluid. This resistance from the fluid shear creates a torque across the plates and, therefore, the slip speed difference is minimized based as a function of the fluid viscosity, fluid fill amount, temperature, and slip speed. Figure 5 is a cutaway of a typical viscous, passive LSD by GKN. Notice the separately sealed chamber and viscous plates on the right side of the differential. As the device does not rely on mechanical friction and also requires a separate sealed chamber, the biasing device is nonsymmetrical.

Figure 5. Viscous differential style LSD.

2.3.1.1 Viscous coupling. The viscous coupling style control devices can operate in two potential modes during speed difference events. The first mode is normal viscous operation and follows a digressive curve, as shown in Figure 4. During slip events, that device will transfer torque per the characteristic curve and the amount of torque delivered is adequate for most situations. There can be a second mode of operation that is technically called *self-induced torque amplification* or more commonly referred to as *hump mode*. The term *hump mode* refers specifically to the fact that the shape of the torque transferred versus speed difference curve resembles a camel hump. As shown in Figure 6, the torque transferred is on the vertical axis with absolute time on the horizontal axis. The slip speed is held constant during this event. After several seconds, the torque-transferred curve sharply increases and transferred full torque in order to overcome the vehicle situation. This "hump mode" is actually an overheating protection mechanism to shelter the viscous device from excessive heat and wear. This increase in torque allows the vehicle to overcome the slip condition that requires additional torque when compared to the first mode of operation. The viscous coupling is a device that has a fixed volume of fluid and operating volume.

Figure 7. Cutaway of a ViscoLok differential.

Figure 8. The hydraulic pump limited slip differential. (Reproduced by permission of Joe Palazzolo.)

2.3.1.2 ViscoLok technology. The term *ViscoLok* refers to a unique fluid shear pump that utilizes silicone fluid as the pumping fluid. The main concept is similar to that of the viscous coupling but there is a significant difference. This unit has a single pump mechanism that shears the fluid during speed difference events. For this device, the fluid volume is not fixed as compared to the viscous coupling. As the fluid pump shears the fluid, the temperature and pressure increase. This increase in pressure is applied to a piston that, in turn, applies a wet clutch pack. This allows for a higher torque transferred in a given package volume and utilizes traditional clutch plate technology with a unique speed-sensing application. As seen in Figure 7, the viscous shear pump is the plastic disk on the left of the piston. The pump operates in a separate chamber and the piston reacts to the increased pressure to apply the multiplate clutch pack.

2.3.2 *Hydraulic pump technology*

Another common speed-sensing LSD is configured with a hydraulic pump mechanism in combination with a clutch pack. In this style device, the hydraulic pump creates the fluid flow based on the speed difference across the device. The most common style pump is a gerotor style arrangement as shown in Figure 8 that is driven off of the speed difference of the wheels. The pump pressure applies a clutch pack to provide the limited slip functionality. The inner and outer rotors can be seen on the left of the differential and share common oil with the differential. This fluid flow is directed to a hydraulic piston that in turn applies a clutch pack. This style device is said to have a progressive locking characteristic based on the shape of the torque transferred versus speed difference performance curve. There is even a variant of this device that has integrated electronically controlled valve that regulates the apply pressure on the clutch pack. The hardware architecture is the same as the mechanical device with the addition of the pressure control valve.

2.3.3 *Flyweight technology*

This multiplate LSD technology is unique when compared to the others discussed earlier, in that the engagement mechanism is triggered through speed difference but makes use of centrifugal flyweight technology. The flyweights are triggered to centrifugally advance at approximately 100 rev/min speed difference. The flyweight engages a cam ramp mechanism that is located behind one of the side gears, which applies force to a clutch pack. The two engagement flyweights are oriented such that they allow the device to engage in either forward or reverse direction of travel of the vehicle. The clutch pack is located between the cam plate and the differential housing. There is also a reaction block in between the side gears to transfer the load to the opposite gear. This indirect force transfer compresses the additional clutch pack on the opposite side of the LSD for added torque-carrying capacity. This LSD also has a supplementary flyweight mechanism that utilizes centrifugal force again to temporarily bypass the LSD function above speeds of approximately 20 mile/h (32 km/h). This is a unique feature, which allows for LSD functionality at lower vehicle speeds and the unit mimics the performance of an open differential at speeds above 20 mile/h. On the basis of this speed-dependent functionality and the fact that the LSD function is designed to be restricted based on vehicle, some engineers will refer

to this device as the governor lock or gov-lock for short. As shown in Figure 9, the cylindrical mechanism of the flyweight-style LSD is the engagement device, whereas the longer more oval-shaped device above the cylinder is the governor mechanism that disables the limited slip functionality at higher speeds.

2.4 Torque sensing

The term *torque sensing* refers to the fact that this classification of LSD devices responds to torque differences across the outputs of the differential. These devices are also influenced by not only the speed across the outputs but also the internal torque reaction and separating forces within the bevel differential side gears. There are many different styles of devices in the category and the technologies will be reviewed with some of the governing torque-transfer characteristics.

2.4.1 Cone clutch-style friction technology

The basic function of the cone-style LSD is to mechanically limit the speed difference exhibited across the outputs through a tapered ring and mechanical friction. The side gear separating forces during speed difference events are applied to the tapered ring. The tapered ring acts as an energy-absorbing device and resists this speed difference motion to yield the limited slip effect on the differential. Figure 10 shows the typical cone-style LSD with the tapered rings between the differential side gears and housing. There is also a coil-type preload spring installed between the side gears.

The bias torque or locking torque calculation method is similar to that of an open differential with the addition of the friction clutch from the tapered clutch rings. Equations 6 and 7 from the open differential (see Basic Open Differentials) describe the frictional force generated from the interface between the pinion shaft and bore and the pinion gear and its washer, respectively. Those equations are repeated below for reference:

$$F_{ps} = \mu_{ps}\left(\frac{1}{R_{pg}}\right)\left(\frac{D_{ps}}{2}\right) \tag{5}$$

where the symbols are as follows:

F_{ps} = friction between the pinion shaft and the pinion gear bore;
μ_{ps} = coefficient of friction between the differential pin and the pinion bore;
R_{pg} = pitch circle radius of pinion gear;
D_{ps} = pinion shaft outside diameter.

$$F_{pw} = \mu_{ps}\frac{(\tan\theta\ \cos\alpha_s)}{[R_{pg}(\sin\alpha_s + \mu_{ps}\ \cos\alpha_s)]}\left[\frac{(DP_{od} + DP_{id})}{4}\right] \tag{6}$$

where the symbols are as follows:

F_{pw} = friction between the pinion gear and its washer;
μ_{ps} = coefficient of friction between the pinion gear and its washer;
θ = pinion gear pressure angle;
α_s = side gear pitch cone angle;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

DP_{od} = pinion washer outside diameter;
DP_{id} = pinion washer inside diameter.

The additional frictional force that needs to be accounted for is the force resulting from the side gear and the tapered friction ring. The equation is very similar to Equation 5 from the open differential (see Basic Open Differentials) with the additional friction from the tapered clutch. The new equation is mathematically described as follows:

$$F_c = \mu_c \left(\frac{\sin \alpha_g \ \tan \theta_g}{R_{sg} \ \sin \beta_c} \right) \left[\frac{(DG_{od} + DG_{id})}{4} \right] \quad (7)$$

where the symbols are as follows:

F_c = friction between the side gear and the tapered clutch;
μ_c = coefficient of friction between the side gear and the tapered clutch;
α_g = side gear pitch cone angle (°);
θ_g = side gear pressure angle (°);
R_{sg} = side gear pitch circle radius;
β_c = tapered ring angle (°);
DG_{od} = outside diameter of the side gear washer;
DG_{id} = inside diameter of the side gear washer.

With the above equations developed, the torque bias ratio can be described in terms of the friction forces as the following:

$$TBR = \frac{(1 + F_c)}{[1 + (F_{ps} + F_{pw})]}(1 - F_c)[1 - (F_{ps} + F_{pw})] \quad (8)$$

There is an added benefit of the addition of a clutch device in an LSD in the ability to preload the clutch. Typically, the preload is achieved using a mechanical spring element in the system that applies a known load to the friction surface. This known load acts to lock the differential up to the point of its torque capacity from preload. This is analogous to the force required to impart motion to a block on a surface; the effect of preload is increasing the weight of the block. In order to understand the initial preload, the resulting torque from the interfaces is described as follows:

$$T_{tc} = \left(\frac{F_k}{\sin \beta_c} \right) \left[\frac{(\varphi_{od} + \varphi_{id})}{4000} \right] (\mu_c) \quad (9)$$

where the new symbols are as follows:

T_{tc} = friction torque of a single cone clutch (N-m);
F_k = preload spring force at assembly (N);
φ_{od} = friction clutch outer diameter (mm);
φ_{id} = friction clutch inner diameter (mm).

$$T_{cg} = F_k \left[\frac{(\gamma_{od} + \gamma_{id})}{4000} \right] (\mu_{gc}) \quad (10)$$

where the new symbols are as follows:

T_{cg} = friction torque of a single side gear and the cone clutch (N-m);
γ_{od} = outside diameter of the friction surface of the retainer (mm);
γ_{id} = inside diameter of the friction surface of the retainer (mm);
μ_{gc} = coefficient of friction between the side gear and the cone clutch retainer.

The clutch torque can now be described as follows:

$$T_c = 2T_{tc} + 2T_{cg} \quad (11)$$

Finally, the initial preload torque is:

$$T_i = T_c(1 + TBR) \quad (12)$$

2.4.2 *Multiplate friction technology*

Multiplate LSDs are called such, as they utilize a clutch pack that consists of a series of multiple friction clutch and steel reaction plates in order to provide the limited slip functionality. There are many different types of friction materials that are used and each has its advantages and disadvantages. These materials can be sintered bronze, bonded paper, carbon fiber, and even molybdenum coatings to name a few. Just like the cone-style device, these style units react to the separation force of the bevel gears from the torque in the system along with the speed difference across the bevel gears.

There are two broad categories with further subcategories within each shown in Figure 11. TL stands for Traction-Lok, whereas LOM stands for Lok-O-Matic.

2.4.2.1 External pressure. The first category is the external pressure style where the preload apply force is developed external of the bevel differential gear set. The spring is between the differential housing and the back face of the side gears. The preload torque relationship is given in Equation 13 and this is a trapped torque across the differential. When this initial preload torque is overcome in the vehicle, the reaction torque of the mechanical device will govern the performance characteristic of the unit.

$$T_c = (r_2)\,\mu\,(F_k) \left(\frac{n}{1000} \right) \quad (13)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

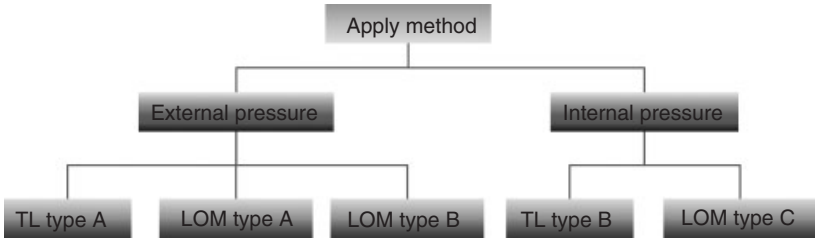

Figure 11. A multiplate LSD summary chart.

where the new symbols are as follows:

$r_2 = \left[\frac{(RC_{od}+RC_{id})}{2}\right]$ = friction radius of the clutch plate (mm);
F_k = total spring force on one side of LSD (N)
RC_{od} = friction clutch outside radius (mm);
RC_{id} = friction clutch inside radius (mm);
n = number of friction surfaces on one side of the LSD.

In addition, the preload or initial torque is simply twice the clutch torque.

$$T_i = 2T_c \tag{14}$$

This initial torque applies to both the external pressure-style TL and LOM units.

2.4.2.2 Internal pressure. The internal pressure-style units have the preload spring packaged mechanically in between the differential side gears. The initial or preload torque is described in Equation 15 and now introduces a new term *transfer ratio*.

$$T_i = T_c(1 + R'_t) \tag{15}$$

where R'_t is the transfer ratio and defined accordingly in the following sections for the TL and LOM-style devices. The clutch torque is the same as Equation 13.

2.4.2.3 Trac-Lok style with preload. The traction lock-style LSD is often abbreviated as Trac-Lok or just TL. It consists of a traditional-style open differential, bevel gear arrangement with a series of flat clutch, and reaction plates between the differential side gears and the differential housing. As this arrangement reuses much of the open differential geometry, it is the most common style in production. The clutch plates are typically preloaded mechanically with a spring. This preload can be from either Belleville or helical coil-style compression springs between the clutch pack and the side gears. This is referred to as *external* pressure, as the preload force is exerted from outside of the differential gears to the clutch pack. There is also an internal pressure style where the preload force and spring is mechanically in between the differential gears. The internal style arrangement is the most common in production with a couple of minor variants on spring style, mainly a series of compression springs or an s-shaped spring.

2.4.2.3.1 External pressure-style (TL type A). The TL style with external pressure for torque transfer has a preload torque as described earlier along with an additional clutch pack force based on the bevel gear differential specific geometry. This additional force happens when the side gears are moving relative to one another. In Figure 12, there is a typical TL-style LSD, such that the preload of the clutch pack is achieved typically from Belleville-style spring washer between the differential housing and the clutch pack represented by the arrows. This is referred to as *external* pressure, as the apply force is generated outside of the differential gears.

The locking ratio percentage is based on the gear geometry as follows:

$$f_1 = (r_2)\,\mu \left(\frac{\tan\theta_g \sin\alpha_g}{r_1}\right) n \tag{16}$$

where r_1 is the operating radius of the side gear (mm) and expressed as follows:

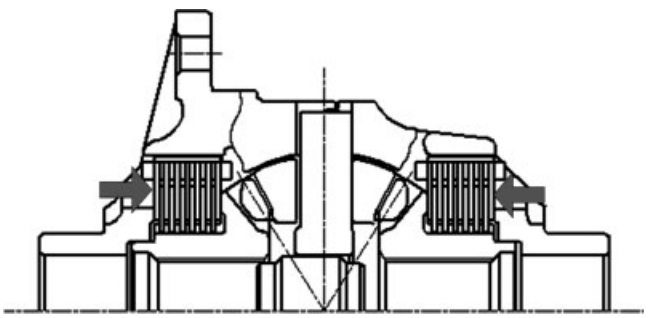

Figure 12. Cross-section drawing of a traction lok limited slip differential.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

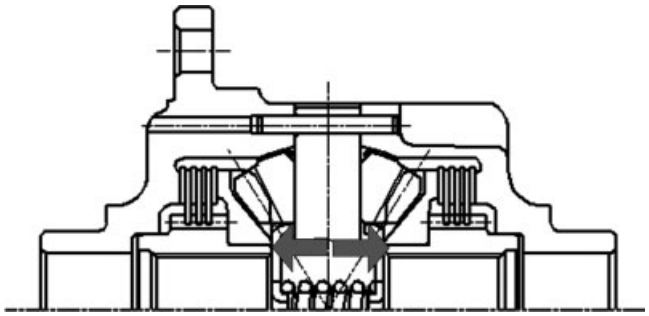

Figure 13. A cross-section drawing with the clutch pack preload in *internal* pressure.

$$r_1 = \frac{(R_1 + R_2)}{2} \tag{17}$$

with R_1 and R_2 as the operating contact radii of the side gear. Now the transfer ratio, R_t^1 can be expressed below.

$$R_t^1 = \frac{(1 + f_1)}{(1 - f_1)} \tag{18}$$

2.4.2.3.2 Internal pressure-style (TL type B). For the internal pressure style, the clutch torque equation is the same as Equation 13, but the initial torque relationship must consider the transfer ratio gradient term. In Figure 13, the clutch pack preload is achieved from the coil-style spring that is located in between the side gears. On the basis of the position of this spring being within the differential gears themselves, it is referred to *internal* pressure. The transfer ratio, R_t, term is based on some of or all of the following depending on the style of device; differential gear geometry, ring gear torque, and the cam geometry if the differential is a cam-style unit. In this context, $R^2{}_t$ is the transfer ratio term and is equal to

$$\frac{(1 + f_2)}{(1 - f_2)} \tag{19}$$

$$f_2 = \mu\ (r_2)\ (n) \left[\frac{(\tan\ \theta_g\ \sin\ \alpha_g)}{r_1} \right], \quad \text{similar to 16}$$

$$R_t^2 = \frac{\left\{ T_c + \left[\frac{(R'_t \times T_r)}{(1 + R'_t)} \right] \right\}}{\left\{ \left[\frac{T_r}{(1 + R'_t)} \right] - T_c \right\}} \tag{20}$$

where the new variables are as follows:

T_r = ring gear torque (N-m).

Figure 14. A cutaway LOM-style differential.

2.4.2.4 Lok-O-Matic style with preload. The term *LOM* refers to a style of LSD that has an inner differential housing that is nested within the outer ring gear housing as shown in Figure 14. This inner housing has a cam profile interface with a mating cam profile on the differential pin. There is another level of intricacy, as the cam surface interface with the ring gear-supported differential housing and the differential-supported inner housing. On the basis of the number of these pressure ring lugs and geometry, the pressure applied to the clutch pack can be tailored and even different from drive torque to coast torque. These cam profiles can add ring gear force to the clutch plate apply force and alter the performance characteristic of the LSD.

Just like the TL style, the clutch plate apply force can be external or internal with the addition of the ring gear torque influence. Therefore, the LOM-style device not only gives the design engineer the ability to tailor torque bias ratio based on the number of clutch plates and preload force but also adds cam angle and direction of torque application. There are three types of LOM units that will be described; the first two use external pressure for preload—one with side gear thrust adding to the bias torque and the other without, whereas the third unit utilizes internal pressure for preload along with ring gear torque. Some of the equations that describe the torque transfer ratio are the same as the TL style and will be noted accordingly. As shown in Figure 15, the inner differential housing is split and will separate based on the reaction forces from the cam surfaces and the differential pins. These cam-separation forces are depicted in this figure based on cam angle. This force reaction can be tailored during the design process in order to achieve a range of torque bias ratios.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

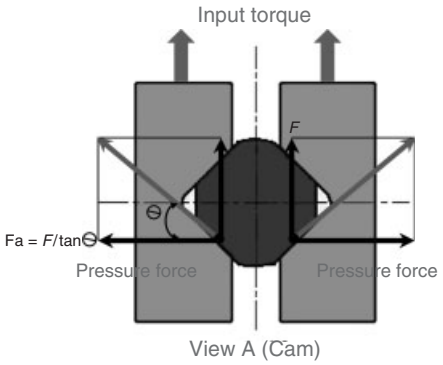

Figure 15. Cross-sectioned LOM differential cam mechanism.

2.4.2.4.1 LOM with external pressure and side gear force (LOM type A). This style LSD utilizes pressure applied to the clutch pack from outside of the bevel differential gears. This force is generated between the clutch pack and the ring gear support housing as shown in Figure 16. The LSD is mechanically arranged such that there is a clearance between the side gears and the ring gear support housing. This axial clearance allows the side gear to also separate and contribute additional clamp load on the clutch pack. Mechanical preload is achieved with Belleville-style spring washers that are located between the outer differential housing and the clutch pack and represented by the arrows.The locking ratio is described mathematically as follows:

$$f_3 = \mu\,(r_2)\,(n)\,\frac{(\tan\,\theta_g\,\sin\,\alpha_g)}{r_1 + (\tan\alpha/r_3)} \tag{21}$$

where the new variables are as follows:

$\alpha =$ cam angle (degrees);
$r_3 =$ operating radius of cam (mm).

$$R_t^3 = \frac{(1+f_3)}{(1-f_3)} \tag{22}$$

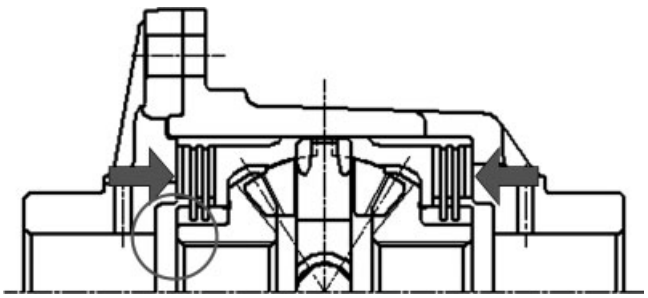

Figure 16. LOM type A.

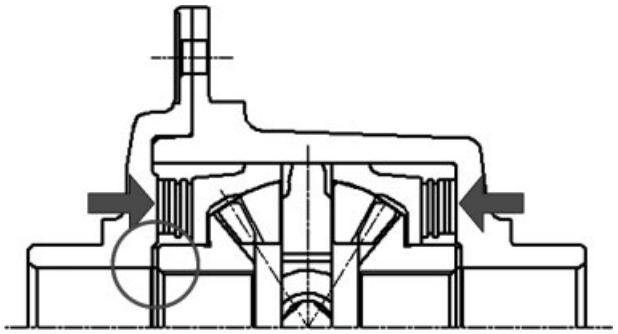

Figure 17. LOM type B cross-sectional view.

2.4.2.4.2 LOM with external pressure without side gear force (LOM type B). This style LOM LSD is similar to LOM type A except that there are thrust washers in place that limit the interaction of the differential side gear separation forces into the torque bias of the differential, as shown in Figure 17.

The locking ratio is similar to that of the LOM type A except that the side gear separating forces are omitted from the analysis, as there is a thrust washer between the side gear hub and the differential case, which positively locates the side gear relative to the clutch pack.

$$f_4 = \mu\,(r_2)\,(n)\left(\frac{\tan\alpha}{r_3}\right) \tag{23}$$

$$R_t^4 = \frac{(1+f_4)}{(1-f_4)} \tag{24}$$

2.4.2.4.3 LOM with internal pressure (LOM type C). This internal pressure-style unit is similar to the TL style with the addition of the cam profile forces during slip events. On the basis of that, the device is a combination of the TL and LOM performances and is mechanically shown in Figure 18. The preload force generated from within the differential side gears via coil springs. The coil springs are installed and compressed at assembly of the differential.

The equations are already described earlier but need to be applied differently. The force from these cam surfaces further applies the clutch pack. The locking ratio is the same as Equation 21 for f_3; the transfer ratio is as follows:

$$R_t^5 = \frac{\left\{T_c + \left[\frac{\left(R_t^3 \times T_r\right)}{\left(1+R_t^3\right)}\right]\right\}}{\left\{\left[\frac{T_r}{\left(1+R_t^3\right)}\right] - T_c\right\}} \tag{25}$$

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

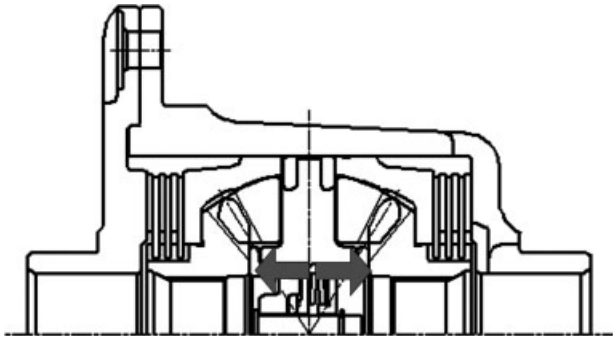

Figure 18. An LOM type C cross-sectional drawing with internal pressure.

2.5 Helical differentials

The helical-style LSDs utilize parallel- or crossed-axis helical gears instead of traditional bevel gears for the differential function as shown in Figure 19. The traditional bevel differential gears are replaced with helical side gears along with the mating element gears. Close inspection reveals that the element gears are supported on the outside diameter of the gear teeth instead of separate shafts and bearings. All of the mechanical friction developed for these gears is what provides the bias within the differential. With this style of arrangement, the torque is proportioned based on the internal friction and thrust forces developed using the helical gear geometry. These devices exhibit a mechanical control-style system between the input drive source and the two outputs. The control system is from simple mechanical friction and applies force at a distance, which creates a torque resistance. The apply force is generated from the input torque from the ring gear to the differential housing. On the basis of the coefficient of friction and gear geometry, the locking torque is developed. As the thrust forces change direction from drive to coast, it is possible to alter the bias torque using low friction washers to tailor the performance for torque transfer during drive events and open differential functionality during braking events.

There are four main areas of purposely designed friction in this LSD and are as follows: side gear to differential housing, side gear face to side gear face, element face to differential housing, and lastly side gear to element gear mesh. Of all these friction forces, the largest contributor is the side gear reaction forces with the respective element gears. This is not to say that the other frictional aspects are negligible. The specific mathematical derivation of expression of this device is quite lengthy and readily available in the literature.

The torque bias ratio of (Chocholek, 1988) this style can be as high as 6.0; however, for typical original equipment applications, the TBR is kept below 3.0 : 1. Higher values are possible and typically used for purpose-built racing applications. On the basis of the gear geometry and subsequent thrust forces, it is possible for the TBR to be a high value in the drive condition and a lower value in the coast condition. This variation in TBR allows the helical differential to mimic an open differential performance during coast conditions such as an ABS event.

Figure 19. A typical helical-style limited slip differential.

3 ACTIVE LIMITED SLIP DIFFERENTIALS

Active LSDs share many of the same components as the passive units with the added ability to electronically control the locking torque across the differential outputs. As the differential is electronically controlled, the term electronic limited slip differential (eLSD) is commonly used to describe these differentials. This electronic control system allows the unit to act as an open differential or have a locking torque, up to the clutch pack torque capacity. This locking torque can be adjusted based on the control system. For example, there may be a desire to have the active differential that maintains a clutch pack preload of 200 N-m in straight-line driving with an immediate reduction to 50 N-m when the vehicle encounters a turn maneuver. This electronic activation can be triggered independent of vehicle or wheel speeds or torques. The devices can be preemptively engaged before excessive wheel slip. These

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto098
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

style devices are typically found on high end modern vehicles and offer additional benefits over passive devices.

The electronic system would typically have a steering wheel angle sensor that would communicate to the electronic control unit that a turn maneuver is executed and the system would respond accordingly. There are many different scenarios and software algorithms that are developed when this type of hardware is available. The main advantage is the ability to control bias torque independent of slip speed. Of course, we cannot forget that the device is still diverting torque from the fast wheel to slower wheel or providing a preload torque before the eLSD allows for speed differences.

3.1 Vehicle system interaction

With any of these devices installed in a vehicle, there are certain system interactions that must be considered. There can be a trade-off between pure straight-line acceleration and traction maneuvers versus high speed cornering behavior. How the device interacts during ABS events or electronic stability control events needs to be considered. The vehicle sensor set that is available has a very important role in the overall system refinement. Most modern vehicles have the following sensors and signals available: four wheel speeds, steering wheel angle, vehicle yaw rate, throttle position, ABS/ESC active, clutch position, and off-road switch. With these sensors in place, the eLSD control software algorithm can be structured to accommodate vehicle maneuvers that include straight-line acceleration, high speed stability, and vehicle dynamics corrections while in a turn.

3.2 Direct actuation style differential

The first eLSD application subcategory is an actuation method that can be achieved either hydraulically or electromechanically with the main feature being the ability to engage the clutch pack independent of vehicle or wheel speeds. This direct actuation method allows the driver to select full lock mode and also allows the vehicle design engineer the ability to preemptively engage the LSD before any slip events. As shown in Figure 20, the direct actuation eLSD utilizes a separate electric motor that can independently drive a ball ramp mechanism in to apply the clutch pack. The ball ramp mechanism converts rotational motion from the electric motor to axial motion to apply the clutch pack.

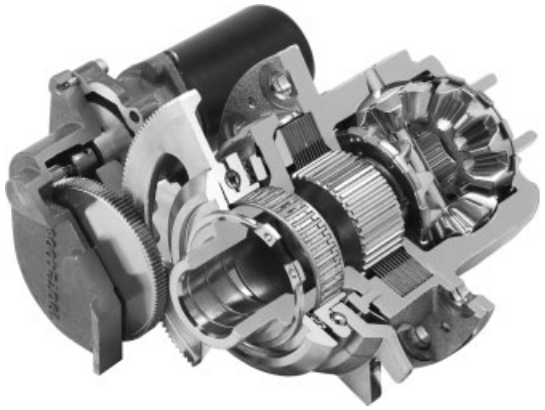

Figure 20. Direct actuation via electric motor-driven ball ramp mechanism.

3.3 Indirect actuation style differential

The indirect method is such that a pumping device or electromagnetic coil with a pilot clutch will apply the clutch pack but requires a small amount of wheel rotation to engage. The difference between this and the direct method is a slight delay in vehicle response. Depending on the vehicle conditions, this slight delay may be considered negligible but there is a performance difference.

3.4 Electronic torque-vectoring differential

With all of the above-mentioned style devices, the main functionality is to provide a locking effect across the differential based on the torque capacity of the clutch along with the performance of the apply system. Typical LSDs basically can vary the locking torque across the outputs or make the outputs travel at the same speed. Electronic torque vectoring (ETV), on the other hand, has the ability to change the output speeds of the differential relative to each other. With an ETV system as the differential, there is an additional gear-ratio mechanism that is electronically controlled that can either increase or decrease the speeds of the outputs. In Figure 21, there are ETV modules bolted to either side of a traditional open differential axle. There are two separate electric motors to actuate the clutch packs that act as brakes across the planetary style gearing. This planetary style gearing is what provides the ratio offset across the outputs. The effect of trying to change the speed of the wheels causes a torque reaction that preloads the suspension and helps the vehicle turn more sharply as compared to an open differential. The engagement device is typically actuating a clutch pack arrangement that acts as a brake to slow down one of the gear train elements to provide the necessary speed relationship. An ETV is far superior

Figure 21. A cutaway display of an entire rear axle. (Reproduced by permission of Joe Palazzolo.)

Figure 22. A sectioned electronic locking differential.

to an eLSD in most vehicle dynamic events; however, for a pure traction event such as straight-line hill climb with ice on one wheel and asphalt on the other, the ETV system will not perform, as well as typical LSDs. This is probably the only maneuver where ETV is not superior to an LSD.

3.5 Electronic locking differential

The locking differential-style units are unique in that they allow for a rigid mechanical lock across the differential. This is typically achieved with some sort of sliding collar or positive engagement face spline. These devices are electronically actuated but require the driver to select for the true lock-mode functionality. These units are intended for off-road usage, as, when engaged, they do not allow for any speed difference across the outputs of the differentials. As they are a rigid mechanical coupling across the wheels, if one wheel encountered a significant reduction in tractive effort, the device is capable of delivering total drive torque to the other wheel. The drive torque is not limited to the capacity of a clutch pack or other device, as described earlier for limited slip devices. This is why the term *locking* or *lockers* is used to describe this arrangement. A very important design issue is to make certain that the axle system can support delivery of 100% of total drive torque to one wheel, if one of these devices is installed in the vehicle. There are also pneumatic-style actuated locking differentials available in the aftermarket to support the

off-road enthusiast, whereas original equipment-installed units are electrically actuated. Figure 22 is a cutaway of an electronically controlled locking differential that shows the electromagnetic coil for actuation of the mechanism. The torque-carrying portion is achieved via dog clutch-style tooth engagement. This provides for a rigid mechanical lock across the outputs of the differential. With this rigid lock, the differential function is bypassed and the unit acts as a solid unit when the system is engaged. As dog clutch teeth are employed for the torque transfer, the speed difference across the outputs must be relatively low in order for the system to engage.

4 SUMMARY

There are many different styles of LSDs that are available on the market. These range from passive and active devices, along with true locking and even vectoring units. The different styles of LSDs that are speed sensing and torque sensing can be pictorially represented with a simple pulley analogy. The traditional pulley with equal weights would represent an open differential with homogeneous coefficient of friction on both output wheels. The differential-style devices are summarized in Figure 23. The torque-sensing differential can be represented by mechanical friction slowing the pulley motion, whereas speed sensing is with the pulley attached to a fan blade. These can be combined for torque and speed sensing. An active system can be represented with a controlled brake on the pulley. Finally, the locking differential has a cogged positive lock in the pulley.

Clutch Actuation

Joško Deur[1] and Vladimir Ivanović[2]

[1] *University of Zagreb, Zagreb, Croatia*
[2] *Ford Research and Advanced Engineering, Dearborn, MI, USA*

1 INTRODUCTION

The clutch actuator is a mechatronic system that provides means of controlling a variable that directly influences the clutch torque. For widely used plate clutches (see examples in Figure 1a, c, and d), the influencing variable is the clutch normal force F_n, which relates to the clutch torque τ_c in the proportional manner (Figure 2, see Dry Clutch and Clutch Wet):

$$\tau_c = \frac{2}{3}\frac{r_o^3 - r_i^3}{r_o^2 - r_i^2} N_f \mu(\omega_s, \vartheta, F_n) \cdot F_n(u) \qquad (1)$$

where N_f is the number of active friction surfaces, r_o and r_i the outer and inner radii of friction plate, respectively, and μ the friction coefficient. Apart from the precise normal force control by means of actuator control variable u (e.g., voltage or position), the clutch torque control law needs to include adaptation with respect to friction coefficient variations because of changes of clutch slip speed ω_s, friction interface temperature ϑ, and the normal force F_n itself. Here, the interface temperature ϑ should be estimated online based on a clutch thermal model fed by the dissipated power $\tau_c\omega_s$ and a measured "heat sink" temperature.

For band clutches (Figure 1b), the clutch torque is again adjusted by means of force control; however, in that case, this is the band pushing force, which corresponds to the spatially distributed band-drum normal force (Fujii, Tobler, and Snyder, 2001). On the other hand, some electromagnetic clutches do not include moving parts for controlling the normal force; however, the clutch torque is rather dependent on the solenoid current-controlled magnetic flux density in a "smart" magnetic medium such as magnetorheological fluid (MRF) or magnetic particles (MPs).

The clutch actuation systems can be divided with respect to several aspects listed in Figure 3. Firstly, it matters if whether the actuator is designed for a wet or a dry clutch, and plate or band clutch. Secondly, the supervisory clutch control task determines whether the clutch operates in an intermittent mode (typically, clutch engagement; see Automatic Transmissions - geartrain combinations, components, design considerations, hydraulic system, packaging, manuf., assembly) or a continuous-duty mode (e.g., torque control in driveline applications; see Axle Systems), which has influence on both clutch and clutch actuator designs. Thirdly, there are many actuation design concepts, starting from the conventional hydraulic and pneumatic systems, through more recent electromechanical and electromagnetic systems, to emerging MRF and MP concepts. Fourthly, the design concepts can be divided into different categories with respect to the actuator transmission type, which include direct actuation, lever actuation, ball ramp systems,

ball screw drives, and worm gears. Finally, the clutch control system can be designed according to two basic concepts: actuator force/torque control and actuator position control, whereas some actuators have combined the features of force/torque and position controls.

From the standpoint of clutch actuator design and control system synthesis, it is important to understand various factors that influence the clutch static and transient behaviors. For instance, the steady-state accuracy of clutch torque control is affected by mechanical friction and magnetic hystereses. On the other hand, the clutch transient performance is influenced by the clutch clearance and the actuator backlash, as well as the actuation system structural compliance. The thermal effects have direct influence on the clutch friction coefficient and, thus, on the clutch torque, and in some cases (e.g., dry clutches and/or position-controlled systems), the clutch pack thermal expansion can affect the steady-state accuracy. Finally, the friction material wear tends to increase the clutch clearance, and at the same time, it affects the friction coefficient behavior.

2 VARIOUS DESIGN CONCEPTS OF CLUTCH ACTUATION SYSTEM

2.1 Hydraulic system

2.1.1 Structure of hydraulic actuation system

Figure 4 shows the functional diagram of an electrohydraulic control system. Mechanical energy supplied by the internal combustion engine (ICE) or an electric motor (EM) is converted into hydraulic energy through a positive

displacement pump of gerotor, vane, gear, or axial piston design (Merritt, 1967), which is stored in a hydraulic accumulator (Figure 6d). Depending on the target application, control valves, which are operated through an electronic control unit, are used to control flow direction, flow rate, and/or pressure of the hydraulic energy. The hydraulic energy is finally converted back into the mechanical energy by a hydraulic piston connected to the clutch pressure plate (Figure 1a). Note that the fluid flow and/or pressure can also be controlled directly by controlling the pump speed or volume. This efficient approach can be applied for systems with one or multiple clutches if only one is actuated at the time. The complexity and cost of the system are reduced in this way, because the hydraulic accumulator and pressure/flow control valves (FCVs) are eliminated and consequently simpler system of oil filtration is required.

2.1.2 *Description of main control elements*

The time response and accuracy of hydraulic actuation systems are generally defined by the dynamics of pump, accumulator, control valves, line flow, and clutch pressure plate piston and oil properties (e.g., Merritt, 1967; Watechagit and Srinivasan, 2003). The key elements are electronically controlled pressure reducing valves (PRVs) that are used as either (i) direct large-flow clutch actuation valves or more often (ii) low flow signal-level devices that

provide operating pressure signal for the main pilot operated three-way spool-type large-flow PRV (Merritt, 1967). Figure 5 shows the schematics of three typically used three-way PRVs: (a) pulse-width-modulated solenoid (PWMS), (b) variable bleed solenoid (VBS), and (c) variable force solenoid (VFS).

The PWMSs (Figure 5a; see, e.g., Cho, Oh, and Lee, 2002) are mostly used at the signal level, but can also be used as the direct actuation valves. They do not include control pressure (p_c) feedback. Depending on the solenoid state (energized or de-energized), the control port is connected with either the supply or the exhaust port, respectively. The control pressure is controlled by the duty-cycle ratio of a PWM signal with the period of around 16 ms. As such, the control signal is characterized by oscillations and it is sensitive to the supply pressure variations.

The VBSs (Figure 5b) are used as signal-level devices. The control pressure is adjusted by controlling the oil bleeding based on a balance between the solenoid and the pressure feedback force on the valve element (ball, conical, or flat as in Figure 5b; (Holmes and McKenna, 2001). The solenoid force is controlled by varying the magnetic flux through the air gap d by means of controlling the solenoid current based on the duty-cycle adjustment of PWM armature voltage signal. In terms of control pressure oscillations, the VBSs are better than PWMSs; however, they are still sensitive to the supply pressure oscillations.

The VFSs (Figure 5c) are based on a balance between the solenoid and the pressure feedback force on the valve spool. The solenoid force is controlled in the same manner as on VBSs, that is, through the duty cycle of PWM solenoid voltage signal with a high carrier frequency (e.g., 200 Hz), which provides virtually ripple-free control pressure (Lee *et al*., 2010). They can be designed as low flow or large-flow valves and can be, therefore, used at signal or direct actuation level, respectively.

2.1.3 *General facts and application examples*

The hydraulic/electrohydraulic actuators have been broadly used for the purpose of automotive clutch actuation because of large output/weight ratio, fast response, easy conversion of engine/EM output into hydraulic power elsewhere in the vehicle where space is not critical, safety, high reliability, good packaging, and the best ability for clutch torque closed-loop control because of direct relation between the hydraulic pressure and the clutch pack normal force (Yoshioka *et al*., 1985; Turner and Ramsay, 2004; Francis, Haselton, and Pritchard, 2006). Therefore, in some application fields such as torque converter automatic transmission (AT), hydraulics have been used exclusively. However, the main disadvantage of these systems is relatively low efficiency mainly because of internal losses and poor duty cycle when the pump is driven by a mechanical drive. According to Turner and Ramsay (2004), the hydraulic actuation systems may represent 50% of the total transmission losses. This loss share can be reduced if the pump is driven by an EM, but losses associated with leakage and flow still remain. Another disadvantage of these systems is sensitivity to the operating temperature as a consequence of change of oil viscosity and valve solenoid coil resistance, which directly affects the response time (it typically reduces with decreasing temperature).

Figure 6 shows examples of electrohydraulic clutch actuation systems categorized according to the field of application. Wet clutches in conventional *torque converter ATs*

(Figure 6a and b) are usually controlled in the open-loop manner using three-way PRVs. The clutch pressure is not measured because of the cost reduction and packaging reasons. The closed-loop pressure control is, though, a subject of research activities (see, e.g., Zheng *et al*., 2009). An accumulator is used in parallel with clutch actuator cylinder in order to provide smooth engagement after clutch filling phase by avoiding large pressure overshoot, oscillations, and instability. The clutch pressure is controlled by pilot-operated PRVs (Figure 6a; Lewis and Bollwahn, 2007; Watechagit and Srinivasan, 2003) or emerging direct large-flow three-way PRVs, that is, VFSs (Figure 6b; Kondo *et al*., 2007). The PRVs are always of spool type with internal pressure feedback loop similar to the VFS in Figure 5c with difference that the spool control force is provided by pressure signal instead of the solenoid (Merritt, 1967; Watechagit and Srinivasan, 2003). The pilot-operated PRVs are operated by pressure signal provided by an additional low flow pilot PRVs (Figure 6a) such as PWMS, VBS, or VFS.

The direct three-way PRVs (large-flow VFS) are also used for controlling *wet clutches* in *dual clutch transmissions* (DCTs; see Dual Clutch Transmissions (DCT) - layouts, clutch selection, packaging, actuation, manufacturing & assembly), as shown in Figure 6c (Mustafa *et al*., 2010; Balau, Caruntu, and Lazar, 2011). Instead of using the hydraulic accumulator, this system uses a small discharge (constant bleeding) orifice. The oscillations and instability can be avoided in this way, because the PRV spool does not need to cross the dead zone to reduce the clutch pressure after the filling phase.

In order to avoid a significant influence of mechanical friction hysteresis (Section 3), the hydraulic actuation systems for *dry clutch control applications* (Figure 6d) are based on closed-loop control of clutch engagement bearing position using three-way proportional FCVs similar to the VFS in Figure 5c but with the absence of control pressure feedback. These systems can be found in *DCTs* with normally open dry clutches (Figure 1d; Hadler *et al*., 2008) and AMTs (*automated manual transmissions*; Figure 1c; see Automated Manual Transmissions (AMT) - system design considerations, clutch operation, shift actuation alternatives) with normally closed dry clutches (Montanari *et al*., 2004). Figure 6e shows another concept of electrohydraulic actuator for AMT clutches (Oberlack and Reul, 2006) that combines the features of electromechanical and hydraulic actuation systems. A brushless DC motor (Section 2.3) drives a hydraulic piston through a ball screw. The piston is connected through a hydraulic line to another piston that actuates the clutch. The clutch piston position is measured and fed back to the control unit, which controls the driving EM. A pressure-based feedback can also be implemented, as needed. Similar actuation system has been proposed for driveline clutches by Francis, Haselton, and Pritchard (2006). Note that this actuation concept is in essence related to pump-based control.

Next to the ATs, wet clutches are widely used in *driveline applications* such as active limited slip differentials (ALSDs; see Passive and Active Limited Slip Differentials) or torque vectoring differentials (TVDs; see Axle Systems). In terms of hydraulic control system, they can be divided into PRV-based systems (Figure 6f and g) and pump-based systems (Figure 6h and i). PRV-based control is similar to the previously explained AT clutch control. However, in order to provide better accuracy and favorable response time for a small number of clutches (one or two), the clutch actuation pressure is controlled in the closed-loop manner. Figure 6f and g shows implementation variations with a two-way PRV (Ross *et al*., 2007) or a VFS (Morselli *et al*., 2003), respectively. Note that the system in Figure 6g includes a small discharge orifice bored in the clutch piston for the same reason as explained earlier for the DCT wet clutches.

The pump-based system in Figure 6h shows the clutch control system for a TVD with two superimposed clutches (Sackl, Eibler, and Linortner, 2008), where one clutch is actuated at the time. The positive displacement pump is driven by a four-quadrant speed-controlled electric servomotor, thus providing the possibility of closed-loop pressure control. The clutch actuator pressure is measured by two redundant sensors. The system air bleeding is provided by pressure relief valves at specific instants, for example, when pressure spikes are filtered by opening the valves. Another pump-based pressure control system is shown in Figure 6i (Nilsson *et al*., 2011). In this case, the pump controls the pressure by commanding the pump DC motor armature current reference (i.e., the motor/pump torque). System air bleeding is again realized through the pressure relief valve.

2.2 Pneumatic system

The basic principle of pneumatic systems is very similar to the hydraulic systems. The difference is related to the working medium, which, in this case, is the compressed air. The air is an easily compressible gas, which introduces significant compliance in the system dynamics. Its density is significantly influenced by temperature, which affects volumetric flow through the control valves, and thus the overall system response. This nonlinear behavior coupled with nonlinear friction effects in pneumatic cylinders and valves, as well as variations of the accumulated air pressure, makes the pneumatic systems demanding in terms of control. Note also that the working pressure used in pneumatic systems is by more than one order of magnitude

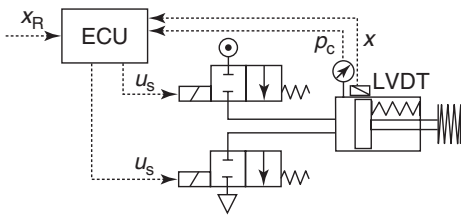

Figure 7. Electropneumatic actuation system.

lower than in hydraulic systems, thus making them inconvenient where high actuator force (i.e., high force density) is needed.

The pneumatic systems are used for transmission clutch actuation purposes on commercial vehicles (e.g., trucks or buses) because of available compressed air supply. The transmissions are of AMT type with normally closed dry clutches (Figure 1c) for which an accurate and robust release bearing position is required (Montanari *et al*., 2004; Langjord and Johansen, 2010). Figure 7 shows a typical electropneumatic clutch actuation system (Langjord and Johansen, 2010). It is based on cheap and simple ON/OFF solenoid valves. More expensive and larger servo valves can also be used, but even simple ON/OFF valves with proper control can give an acceptable system behavior. Note that the cylinder pressure and position are measured and fed back to the control unit. The control unit outputs the voltage signal for the control valves.

2.3 Electromechanical system

The electromechanical systems comprise an electric motor (EM) for the clutch actuation. Both linear and rotary motors can be used. While the linear motor-based systems are in the research/development stage (Wheals *et al*., 2009), their rotary motor-based counterparts have found many production applications, some of which are described below. Besides the EM, the electromechanical actuation systems comprise an additional device to transform rotational motion of the motor into linear motion at the clutch pressure plate, and it can be of ball ramp, screw drive, or lever-based design (Figure 8). Their main advantages when compared to the electrohydraulic systems (Section 2.1) include (Turner and Ramsay, 2004) a high efficiency (up to 95%), excellent motor control accuracy, and a great modularity and ease of implementation in existing transmission or driveline hardware. The main disadvantages of the electromechanical systems relate to smaller force/torque density and a significant influence of the actuator transmission friction, backlash, and/or compliance effects on the overall control performance (Section 4).

2.3.1 *Ball ramp mechanism*

Ball ramp-based system for an ALSD is illustrated in Figure 8a (Gassmann and Barlage, 2004; Ivanović *et al*., 2012a). A geared permanent-magnet DC motor is used to engage the clutch through a ball ramp mechanism that converts the motor torque into a high clutch-pack normal force. By combining bevel gears with ball ramp, a very high reduction ratio between the pressure plate displacement and the driving motor angle can be achieved (<0.2 mm/rev). The ball ramp mechanism consists of input and output disks with oppositely arranged grooves with defined slope (ramp), and balls placed in the grooves. Here, the slope is constant along the groove length, whereas in some actuator designs, a nonlinear slope may be used in order to provide quicker response during transition through clutch clearance zone. The ball ramp system is a part of the differential case, but it does not rotate together with the case. This is achieved by separating the ball ramp system from the case by three needle bearings. The motor is equipped with an electromagnetic brake in order to improve the system efficiency by holding the de-energized motor in a desired position for specific control tasks (e.g., locking the differential).

The ball ramp input disk is driven by the DC motor. The output disk rotation is constrained by a spring-damper system fixed to the differential housing, which allows for linear motion and only small amount of rotational motion during the clutch disengagement. The role of the damper is to reduce stress on the ball ramp elements during the clutch disengagement interval, when the output disk is pushed back by the coned disk return spring. The output disk is axially connected, but not physically bonded to the clutch press plate, that is, the actuator can only push the press plate but cannot pull it during the disengagement phase. The ball elements of the ball ramp assembly are characterized by significant compliance (Ivanović *et al*., 2012a), which introduces load-dependent rolling resistance (friction) that affects the efficiency and also control performance (Section 3).

2.3.2 *Ball-screw mechanism*

An alternative to the ball ramp mechanism is a highly efficient and stiff ball screw or planetary lead screw, as illustrated in Figure 8b (Turner and Ramsay, 2004). Note that the reduction ratio in this case (typically 1 mm/rev) is significantly lower when compared to the ball ramp system. Therefore, this type of actuator may be considered as a quasi-direct actuation, that is, together with the motor, it represents an electric cylinder. In order to boost the reduction ratio, and consequently reduce the motor

power/size, the electric cylinder may be combined by another mechanism such as lever system (Section 2.3.3).

2.3.3 Lever-based mechanism

Figure 8c illustrates a lever-based electromechanical actuator for the DCT dry clutch in Figure 1d (Wagner *et al*., 2009; Ivanović *et al*., 2011). The actuator consists of a lever, a brushless DC motor connected to a precise ball screw, a cart with lever fulcrum roller and additional auxiliary rollers, a leaf spring, and a pair of preloaded helical energy source springs. The motor drives the ball screw, which is directly connected to the cart that holds the fulcrum roller. The lever is leaned onto the fulcrum roller and loaded by the energy source spring force F_s and the engagement bearing load F_b. As such, the lever maintains torque equilibrium of these forces acting through their respective lever arms. The higher the fulcrum position x_f is, the higher is the engagement bearing force F_b. The lever has a specific nonlinear profile providing that the lever moves toward the dual clutch assembly when pushed by the fulcrum roller. Hence, the lever at the same time moves radially with respect to the screw drive center line and rotates around fulcrum roller, thus maintaining the torque equilibrium.

The driving EM provides torque required to oppose the axial component of the fulcrum–lever contact force (defined by angle β), the drive acceleration torque, and friction in motor, ball screw, and fulcrum rollers. For safety reasons, a passive clutch opening must be provided in case of system/power supply failure. This is provided by a sufficiently large value of the fulcrum–roller contact angle β for any actuator position. If the lever rotational angle would significantly differ from its initial value, this condition could not be met. The lever geometry and parameters are, therefore, optimized, so that the lever angle deviations are minimal, and also to provide close-to-linear relation between the actuator motor position and the clutch normal force.

Owing to the nonlinear lever geometry, the motor torque versus actuator position static curve is rather flat, but it includes a wide hysteresis because of actuator friction (Ivanović *et al*., 2011). As such, the system may be regarded as a ball (roller) ramp system, with a movable roller, elastically suspended output plate, and a nonlinear (ball) roller ramp contact, shaped in order to meet specific requirements.

2.4 Electromagnetic system

Electromagnetic systems utilize solenoids to generate magnetic flux circulating through the surrounding ferromagnetic yoke and armature parts, and an air gap between them. The magnetic flux generates the magnetic force acting on the armature that carries the piston and is suspended by a return spring. The larger the solenoid current is, the larger is the magnetic flux and the magnetic force. The flux versus current static curve includes a magnetic hysteresis (Section 3). For the common case of DC current magnetization, the magnetic force increases as the air gap reduces. The force response time depends on the solenoid time constant and also on the time constant related to the eddy current effect (Section 2.5).

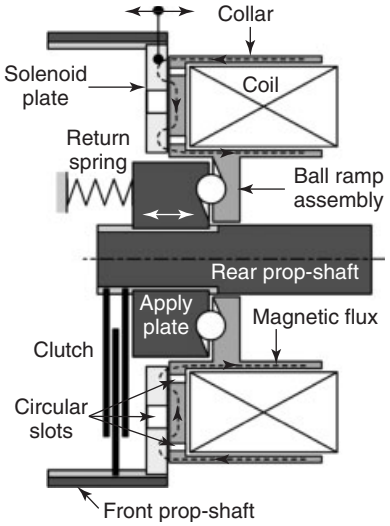

Figure 9. Electromagnetic ball ramp clutch actuation systems. (Adapted from Hrovat *et al*., 2000. © Taylor & Francis/CRC Press.)

The electromagnetic actuation systems can be direct or indirect. In the case of direct actuation, the electromagnetic force is directly associated with clutch normal force by appropriate clutch design (Kunii *et al*., 2005). The same reference proposes the use of an additional solenoid, the so-called search solenoid, which provides online reconstruction of the magnetic flux for the purpose of compensation of the flux/force variations with the air gap change.

Figure 9 shows an example of the indirect wet clutch actuation, which is used for torque control of a wet clutch in a 4 WD system on-demand transfer case (Hrovat, Asgari, and Fodor, 2000). The clutch is used to control the slip speed between the front and rear prop shafts. The system comprises a solenoid surrounded with a collar and a solenoid plate, ball ramp assembly with a return spring (cf. Section 2.3), and a wet clutch assembly. The solenoid is fixed to the stationary housing, whereas the collar is connected to the ball ramp input disk. The ball ramp output disk (the apply plate) and the solenoid plate are connected by spline couplings to the rear and front prop shafts, respectively. For the de-energized solenoid, the collar rotates with the rear prop shaft speed. When the solenoid is energized, a magnetic flux is established through the collar and solenoid plate and the corresponding magnetic force is generated. Note that the collar and the solenoid plate comprise circular slots that properly define the path of strong magnetic flux between the collar and the plate.

When a slip speed occurs between the two prop shafts because of the tendency of rear axle spinning, the generated magnetic force between the collar and the solenoid plate increases sliding friction force between them, thus reducing the collar speed. This induces a relative speed between the collar and the apply plate, which causes the apply plate to move axially, thus pressing the clutch pack and developing the clutch torque that reduces the rear prop-shaft speed. The clutch normal force is proportional to the friction torque (i.e., the magnetic force) between the collar and the solenoid plate as long as the relative speed between them exists. A mechanical hysteresis can be expected in this relationship because of the ball ramp friction (Section 2.3).

2.5 Magnetorheological fluid (MRF) and magnetic particle (MP) systems

A special feature of MRF/MP clutches is that their actuation system is fully electromagnetic. That is, the clutch is controlled by changing the rheological/magnetic properties of MRF/MP medium by means of solenoid current control. This greatly simplifies the actuator design and improves the control performance, as there are no moving actuation parts and related friction, backlash, and compliance effects.

There are three basic types of MRF/MP clutches: plate, bell-shaped, and bevel clutches (Lampe, 2000). The plate and bell-shaped clutches are similar to the plate and band friction clutches (shown in Figure 1), respectively, with the main difference that the gaps between the plates and the drum and case, respectively, are filled by the MRF/MP medium. The bevel clutch may be regarded as a "combination" of plate and bell-shaped clutches. Figure 10 shows a bell-shaped MP clutch used as a soft starting

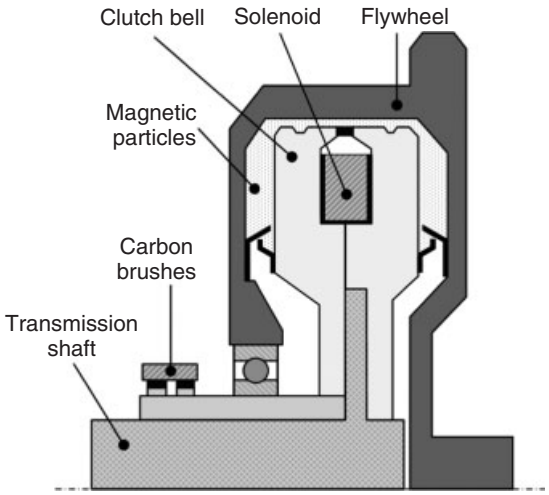

Figure 10. Magnetic particle clutch. (Modified from Sakai, 1988 and Fachkunde Kraftfahrzeugtechnik, n.d.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto102
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

device for a continuously variable transmission (Sakai, 1988). Changing the solenoid current I results in a variable magnetic flux density B in the MP (or MRF) medium, which gives the possibility of adjusting the shear stress $\sigma(B)$ and, correspondingly, the clutch torque $\tau_c(B)$ (see Lampe, 2000 for torque equations for the different clutch types). The clutch is designed based on the well-known electromagnetism laws and known MRF/MP medium static curves $\sigma(B)$ and $B(H)$, where the magnetic field H is directly related to the solenoid current (similarly as with the electromagnetic clutch).

On the basis of the notes from Rabinow (1948), Wheals *et al*. (2004), and Kawai *et al*. (1988), it appears that the main advantages of the MRF clutches (where micron-sized MPs are suspended in oil) include smooth operation, less emphasized particle wear and related torque loss, less emphasized abrasiveness (e.g., with respect to seals), and good oxidation and water adsorption resistance. On the other hand, the MP clutches should have significantly smaller drag torque (because of the absence of viscous torque component), the particles could resist approximately twofold larger temperatures than MRF (which results in a larger thermal capacity), and there is no MRF's specific effects such as fluid thickening. In order to significantly mitigate the MR fluid thickening and particle settling effects, proper oil additives are used according to Carlson (2001) and Jolly, Bender, and Carlson (1998).

The MRF/MP gap should be as small as possible to reduce the current and, thus, the power consumption. However, for high speed clutches with a narrow gap, the centrifugal particle settling can occur, thus leading to a loss of torque consistency. According to the theoretical and experimental analyses presented by Lampe, Thess, and Dotzauer (1998) and Lampe (2000), the centrifuging effect may be avoided by increasing the MRF thickness to approximately 3 mm.

The clutch torque response speed is predominantly affected by (Lampe, 2000) (i) the current delay due to the solenoid inductance and (ii) the additional delay of magnetic flux response due to the effect of eddy currents (note that the MRF/MP delay typically equals a couple of milliseconds and may be neglected). As shown by Lampe (2000) and Deur, Herold, and Kostelac (2009), the current delay can be substantially reduced by a short duration, controlled forcing of solenoid voltage in a similar manner as done for reducing the DC motor armature current delay. The eddy current effect on torque response delay can effectively be overcome only by a slotted design of the magnetic core. The slot width should be less than 3 mm to reduce the eddy current-related response time constant well below 100 ms (see Lampe, 2000; Deur, Herold, and Kostelac, 2009).

3 MAIN FEATURES OF STATIC AND DYNAMIC BEHAVIORS OF CLUTCH

Starting from the clutch actuator design features elaborated in Section 2, this section describes the main effects that influence the steady-state and transient behaviors of clutch torque control system.

3.1 Main effects affecting accuracy of clutch torque control

3.1.1 Clutch clearance

The clutch clearance, as well as the backlash in the actuator components, should be as small as possible to reduce the pure delay of clutch torque response during the clutch engagement. On the other hand, the clearance should be large enough to avoid significant drag torque of wet clutch and safely provide zero drag torque of dry clutch. The conflicting requirements are obviously more difficult to be met for wet clutches, as (i) the viscous drag torque is inversely proportional to clearance and (ii) the fluid film squeeze resistive force (Section 3.1.5) opposes the actuator force and increases the pure delay. On the other hand, in the case of dry clutches, the friction lining is thicker and wears faster. This would result in a progressive increase of clearance, and consequently in increase of the response pure delay and change of the control static curve (particularly for the lever-based actuator). To avoid/mitigate these effects, the dry clutches are equipped with a wear compensation mechanism (Figure 1d), which keeps the clearance below a predefined value (typically, around 0.5 mm). The MRF/MP clutches have a fixed and relatively large value of clearance/gap (Section 2); however, this does not have any significant influence on torque response delay.

Regardless of whether the wear compensation mechanism is present in the particular friction clutch, the control algorithm should include a routine for fast passing through the clearance/backlash zone and the so-called soft landing, where the clearance parameter should be identified by an auto-tuning routine (Section 4). For the electromagnetic actuator and also the lever actuator to some extent, additional compensation/mapping is needed to accurately provide the demanded normal force in the presence of clearance-related actuator position offset variations (Section 2).

3.1.2 Friction hysteresis

The friction hysteresis inherently appears in the force/torque-controlled clutch actuation systems. Here, the

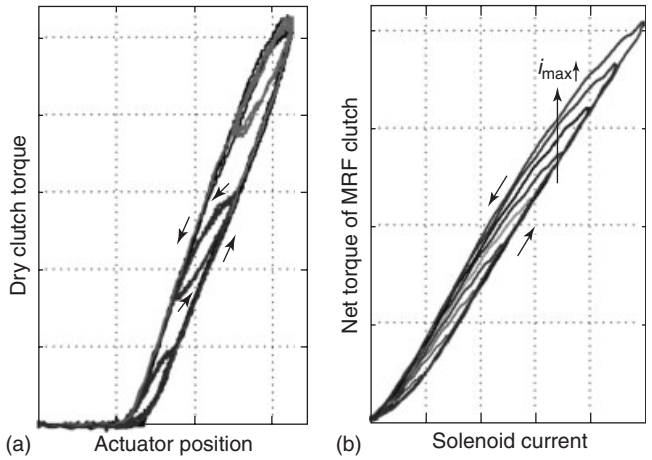

Figure 12. Recorded actuator hystereses for lever-based dry clutch (a) and MRF clutch (b).

actuator can be regarded as a force/torque source device, and any friction resistance in the actuator reduces the net normal force. This results in a clockwise hysteretic dependence between the actuator force (or current, voltage, and pressure) and the clutch normal force F_n, as illustrated in Figures 11a and 12a on the examples of ball ramp wet clutch actuation (Ivanović *et al*., 2012a) and lever-based dry clutch actuation (Ivanović, Deur, and Tseng, 2012b), respectively. As the ball ramp load corresponds to the normal force (Section 2), the ball ramp friction grows with the normal force, that is, the hysteresis width increases with F_n (Figure 11a). In the presence of dynamic friction effects (Armstrong-Hélouvry *et al*., 1994), the friction hysteresis may become narrower for the narrower-operating region (Figure 12a).

Although the friction compensation algorithms have been widely applied in *closed-loop*, speed- and position-controlled servo systems (Armstrong-Hélouvry *et al*., 1994), they cannot be equally effectively applied in an *open-loop* force/torque control system. This is due to the fact that the clutch actuation mechanism is often in or close to the zero-speed (stiction) region, which is relevant for force control and where it is difficult to estimate friction. Gassmann and Barlage (2004) propose a robust (nonmodel-based) friction compensation method based on the injection of oscillatory signal (the so-called dither) into the actuator DC motor armature voltage reference. They demonstrate that the hysteresis width can be significantly reduced when the dither signal is applied.

One of the major advantages of the position-controlled clutch actuation systems is that they are not prone to friction hysteresis, provided that a part of the actuation mechanism upstream the element with dominant friction is rather stiff. Figure 11b indicates that the same ball ramp actuator has a hysteresis-free static curve when it is expressed in the actuator motor position instead of the motor current. Therefore, the position-controlled system has a good potential for favorable clutch torque control accuracy, provided that the normal force versus position map in Figure 11b is independent of operating parameters (e.g., oil temperature) or that it can be adapted online. Such a control system may be extended with a friction compensator for further performance improvement (e.g., reduction of an initial pure delay due to the friction-induced standstill interval).

3.1.3 Magnetic hysteresis

Magnetic hysteresis $B(H)$ is an inherent property of the ferromagnetic materials. In the clutch actuation systems, it manifests itself in a similar manner as the friction hysteresis, which is illustrated by the comparison of lever-based and MRF clutch actuator static curves in Figure 12. The MRF clutch shows a significant effect of narrowing hystereses (Figure 12b). Although this effect can be rather accurately modeled (Deur, Herold, and Kostelac, 2009), the effectiveness of model-based compensation may be doubtful, particularly under the (quasi)steady-state conditions. Therefore, it is of importance to design the electromagnetic clutches (including the MRF/MP ones) using the soft ferromagnetic materials having a narrow hysteresis.

3.1.4 Structural compliance in clutch actuation mechanism

The force/torque-controlled actuation system should be rather stiff, in order to transfer the generated actuator force to the clutch normal force without generating axial/torsional vibrations. It should be noted that although the actuator friction typically acts as a strong vibration damper, notable vibrations may still be excited for abrupt transient (e.g., clutch landing, see Section 3.2) if the actuation mechanism is not stiff and the control strategy is relatively crude (soft landing and/or active damping routines are absent).

On the other hand, for position-controlled or combined actuation systems, there should be compliance downstream the element with dominant friction (cf. Section 3.1.2). This is because the actuator motor position control is based on the actuator stress–strain curve (Figure 11b), which cannot then be very stiff in order to avoid a very narrow range of motor position control. Examples of compliance elements in position-controlled and combined systems are ball ramp compliance (Figure 8a) and diaphragm spring support point compliance (Figure 1d).

3.1.5 Fluid film squeeze resistance

During the wet clutch engagement, the fluid first need to be squeezed from the clutch before the asperity contacts are established and the clutch torque is developed. The fluid film squeeze process is characterized by generation of the fluid resistive force that should be considered in the clutch actuator design stage. Assuming an ungrooved, nonpermeable plate clutch (Figures 1a and 2), the fluid resistive force is given by (Berger, Sadeghi, and Krousgrill, 1997):

$$F_{fs} = -\underbrace{12\eta Q(r_\mathrm{i}, r_\mathrm{o})\frac{1}{h^3}}_{b_\mathrm{fs}(h)}\frac{\mathrm{d}h}{\mathrm{d}t} \tag{2}$$

where

$$Q(r_\mathrm{i}, r_\mathrm{o}) = \frac{r_\mathrm{o}^4 - r_\mathrm{i}^4}{16} - \frac{r_\mathrm{i}^2(r_\mathrm{o}^2 - r_\mathrm{i}^2)}{8} - \frac{(r_\mathrm{o}^2 - r_\mathrm{i}^2)^2}{16\ln(r_\mathrm{i}/r_\mathrm{o})} - \frac{r_\mathrm{o}^4 - r_\mathrm{i}^2 r_\mathrm{o}^2}{8}$$

where h is the effective fluid film thickness, $\mathrm{d}h/\mathrm{d}t$ the fluid film squeeze speed, and η the fluid dynamic viscosity. For the clutch with the number of fluid gaps denoted by N'_f (note that $N'_\mathrm{f} = N_\mathrm{f}$ is valid for the typical case of double-sided friction plate), the fluid film thickness and speed may be calculated as $h = (x_{\mathrm{pp,max}} - x_\mathrm{pp})/N'_\mathrm{f} + h_\mathrm{min}$ and $\mathrm{d}h/\mathrm{d}t = v_\mathrm{pp}/N'_\mathrm{f}$ (Ivanović *et al*., 2012a), respectively. Here, the variables x_pp and v_pp denote the press plate position and speed, respectively, and $x_{\mathrm{pp,max}}$ and h_min are the press plate position and the film thickness at the rated normal force F_n (note that owing to asperity roughness, there is a residual $h_\mathrm{min} \neq 0$ even for large/rated F_n).

Ivanović *et al*. (2012a) have experimentally identified the damping factor $b_\mathrm{fs}(h)$ in Equation 2 for the active differential, grooved wet clutch from Figure 8a, and shown that it accurately satisfies the inversely proportional relation $b_\mathrm{fs}(h) \sim h^{-3}$, with the h_min identified to be 12 μm. However, the damping factor magnitude was fourfold smaller than the one predicted by Equation 2, which was explained by the neglected fluid flow through the grooves and the friction material permeability. The fluid resistive force F_fs has been found to be two order of magnitudes lower than the rated clutch normal force, which is explained by a large rated normal force (40 kN), relatively low maximum press plate speed (approximately 2 mm/s), and a large number of fluid gaps ($N_\mathrm{f} = N'_\mathrm{f} = 20$). This means that the resistive force F_fs may be neglected from the standpoint of actuator design of the particular ALSD clutch. Of course, this conclusion may not hold for other wet clutches, such as those used in ATs.

3.1.6 Friction coefficient variation

The experimentally identified, multidimensional dependence of the clutch friction coefficient μ in Equation 1 is shown in Figure 13 for the case of ALSD wet clutch (Ivanović *et al*., 2012a). The clutch's separator plates are made of hardened steel and the friction plates contain friction material made of woven carbon fabric to which a phenolic resin has been applied. The identification results indicate that the coefficient of friction (COF) varies in the range from 0.06 to 0.12, which points to the boundary lubrication operating conditions (Hamrock, Schmid, and Jacobson, 2004). The COF decreases with rise of the clutch friction interface temperature ϑ and the normal force F_n. In the low slip speed range, it predominantly shows a rising

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

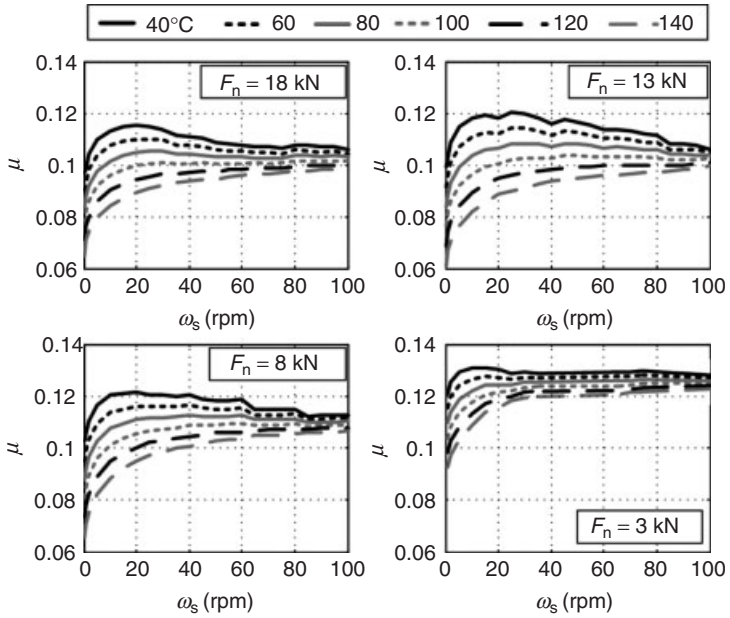

Figure 13. Static curves of ALSD wet clutch friction coefficient. (Reproduced from Ivanović, 2012a. © Sage.)

dependence on the slip speed ω_s. Exceptionally, this dependence can have a negative gradient at low temperatures. The negative gradient is generally undesirable, as it relates to a negative friction damping coefficient that can cause judder vibrations (Crowther *et al*., 2004).

The COF typically reduces with the clutch wear. This property can be used for the purpose of clutch wear monitoring for those actuators that are not equipped with the position sensor (Fei *et al*., 2008), for example, the hydraulic ones used in the AT applications. Moreover, the clutch/fluid wear is usually associated with the increasing sensitivity to negative COF gradient related to the judder appearance.

The dry clutch COF usually varies in the range approximately from 0.3 to 0.4. It generally shows similar trends in terms of dependence on slip speed, temperature, and normal force as in the case of wet clutch, including the likely appearance of negative gradient at low slip speeds and low temperatures (Deur *et al*., 2012).

3.1.7 Clutch pack thermal effects

During the clutch engagement, the clutch dissipates the power $\Phi_f = \tau_c \omega_s$ (Figure 2 and Equation 1), which is converted into the heat flux that warms up the clutch. As the clutch pack heats up, it thermally expands, thus potentially affecting the accuracy of normal force control. The effect occurs with the position-controlled actuation systems (and to a lower extent, with the combined system), because for a given actuator/press plate position, the temperature rise-related thermal expansion drift causes the normal force rise and potentially large clutch torque control errors (Deur *et al*., 2012). The problem is more emphasized if the thermal expansion is stronger (e.g., for dry clutches) and if the actuation mechanism is stiffer. It can be overcome by estimating the thermal expansion-related overlap and correspondingly reducing the actuator position reference to keep the normal force equal to the demanded force (Section 4).

The thermal expansion compensation, thus, requires estimation of the clutch interface temperature ϑ (the separator plate temperature for wet clutch and the flywheel/press plate temperature for dry clutch). The temperature information is also needed for friction coefficient estimation, as well as for the clutch temperature monitoring. The temperature estimator is based on online simulation of a lumped parameter clutch thermal model (open-loop estimation). Although the heat transfer concerns multiple distinctive thermal masses (see the example of a wet clutch in Figure 14), the model may be described by a single differential equation (Ivanović *et al*., 2012a):

$$C_{sp}\dot{\vartheta} = \Phi_f - H_e(\omega_s, \tau_c)(\vartheta_c - \vartheta_{oil}) \tag{3}$$

where $C_{sp} = m_{sp} c_{steel}$ is the separator plate thermal mass and ϑ_{oil} the measurable oil sump temperature. The heat transfer factor H_e is a rising (typically linear) function of the slip speed ω_s, which accounts for the clutch fluid pumping

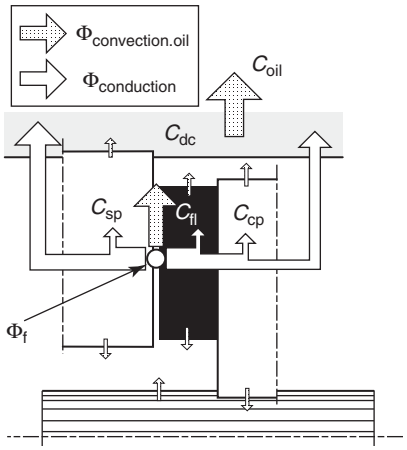

Figure 14. Schematic diagram of wet clutch thermal model. (Reproduced from Ivanović, 2012a. © Sage.)

effect. The factor H_e is also found to be linearly dependent on the clutch torque τ_c, which is predominantly due to the reduced-order model structure. For a favorable model accuracy, the factor H_e may also include an empirically tuned time-variant lag dynamics. The dependence on τ_c and the lag dynamics diminish if the full, third-order model is designed according to the scheme in Figure 14 (Ivanović *et al*., 2012a). However, parameterization of such a model is more complex and it may turn out to be less accurate than the simple model (3).

For the dry clutch, the press plate temperature ϑ_{pp} can be significantly higher than the flywheel temperature ϑ_{fw} (owing to a smaller press plate mass), and the yoke temperature ϑ_{yo} is typically significantly lower than the flywheel temperature and higher than the bell-housing temperature ϑ_{bh}. Therefore, the model should include three state variables to be estimated (ϑ_{pp}, ϑ_{fw}, and ϑ_{yo}, with the former two being equal to the friction interface temperatures) (Hoić *et al*., 2012), whereas the bell-housing temperature ϑ_{bh} can be either measured or estimated from external, power train temperatures. The thermal expansion model is also generally more complex for the dry clutch when compared to the wet clutch.

3.2 Main features of clutch torque transient response

Figure 15 shows the ALSD wet clutch response for a crude, torque-based clutch control, characterized with the maximum (uncompensated) clutch clearance and the absence of soft landing intervention. This worst-case/low performance scenario is intentionally used to clearly illustrate the main effects of the clutch response and give motivation for control system improvements described in Section 4. The response with respect to actuator DC motor armature current reference step is divided into four phases, for which the main influencing effects are listed in the legend of Figure 15 (Ivanović *et al*., 2012a).

The initial, *pure delay phase* is predominantly determined by the clutch clearance, and also with the motor speed limit, and to a lower extent with return spring, friction, and fluid squeeze loads. The *clutch activation dynamics* is characterized by an abrupt lag dynamics with a significant clutch torque overshoot and a certain oscillatory behavior. The overshoot and oscillatory behavior

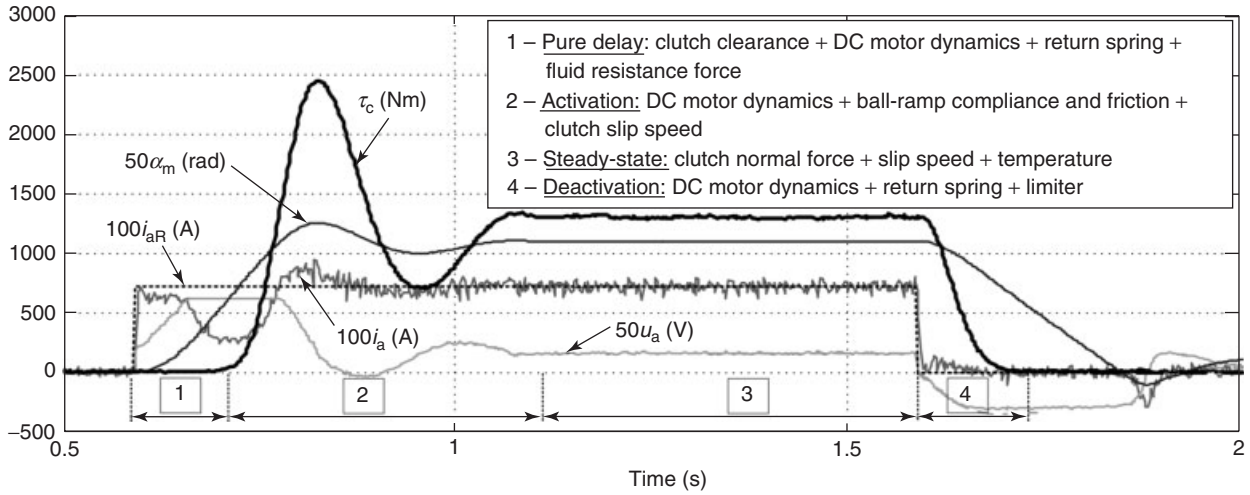

Figure 15. Active differential wet clutch response for crude, torque-based clutch control. (Reproduced in part from Ivanović, 2012a. © Sage.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto102
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are due to the uncontrolled high speed landing in combination with the actuator inertia and compliance effects. The response damping is relatively good because of the significant amount of friction. It should be noted that the response can be significantly slower for very small clutch slip speeds, because during the transient, the clutch can then become locked, and thus uncontrollable (Ivanović *et al*., 2012a).

The steady-state clutch torque is determined by the developed normal force and the clutch friction coefficient, Equation 1, as well as by the actuator mechanism friction hysteresis (Figure 11a). The clutch torque response during the *clutch deactivation phase* is relatively fast, as the actuator motor torque is zero and the return spring is strong enough to quickly disengage the ball ramp actuator. The motor position response back through the clearance region is somewhat slower and shows some "bouncing" when "hitting" the mechanical limiter position.

4 CLUTCH ACTUATION CONTROL SYSTEM

On the basis of the insights and control/estimation ideas described in Section 3, this section presents details of the two distinctive clutch control concepts. Without a loss of generality, the presentation utilizes the example of ALSD wet clutch (Figure 8a).

4.1 Force/torque-controlled system

Here, the actuator directly commands a variable that is related to the clutch normal force (or flux density for the MRF/MP clutches). This can be armature voltage, solenoid voltage, or fluid flow. In order to provide more accurate and generally faster control, it is more appealing to command the variable that is directly proportional to the actuator torque/force, and that would be the armature current, solenoid current, or fluid pressure. However, such variable should be sensed to be fed to the corresponding controller, which increases the actuator price and is, thus, rather prohibitive for multiclutch systems such as ATs.

The open-loop force/torque controller may be divided into three subsystems: (i) dynamic subsystem for reference shaping including clearance compensation and soft landing, (ii) actuator command mapping, and (iii) friction compensation. In the simplest, purely open-loop applications (e.g., those in ATs) there is no feedback information from the actuation system, so that the clutch engagement can solely be controlled by shaping the time response of reference variable (e.g., valve solenoid voltage). In the more demanding, continuous torque control application (e.g., driveline system clutches or startup clutches), the clutch actuators are usually equipped with sensors such as motor position/speed or sometimes current/pressure sensors. This facilitates the application of auto-tuned clearance compensation and soft landing control intervention, where both rely on the "bite"-point detection based on observing a sudden peak in actuator motor armature voltage/current or speed when the asperity contact is established. In this case, the clutch torque demand can be transformed to the actuator command mapping block without shaping. The transformation map may also include the clutch/oil sump temperature input, because it notably determines the torque control accuracy. Separate maps can be used to correct for the influence of other factors such as clutch slip speed, motor winding temperature, and clutch wear. The maps are identified experimentally for a wide range of conditions, that is, some significant calibration effort is needed. Finally, the actuator command (the armature voltage u_a in the case of ALSD clutch) can be perturbed by a dither signal to reduce the effect of actuator transmission friction (Gassmann and Barlage, 2004).

The lever-based actuator (Figure 8c) may be regarded as an indirect force-source system, so that the force-controlled structure can conveniently be applied to it, as well. The fact that the engagement bearing force does not solely depend on the actuator command—the fulcrum/motor position, but also on the lever angle depending on the engagement bearing position/load, does not have a major consequence on the force-controlled system structure since the "combined force/position control effect" can be captured by the proper multi-dimensional actuator command mapping. Alternatively, the physical model-based mapping may be used.

4.2 Position-controlled system

The main disadvantage of force/torque-controlled system relates to difficulties with friction compensation, which can result in significant static and transient errors in actuators with dominant transmission friction effects (e.g., electromechanical actuators, Sections 2 and 3). This can be overcome using the position-controlled system structure, which is shown in Figure 16 based on Ivanović *et al*. (2009) and Deur *et al*. (2012). Using the estimated clutch coefficient of friction μ (COF, Section 3), the demanded torque τ_{cR} is transformed to the normal force demand F_{nR}. In order to avoid the algebraic loop, the COF-map's input F_n should be obtained by filtering F_{nR} or directly from τ_{cR} using a prescribed/constant COF. The normal force demand

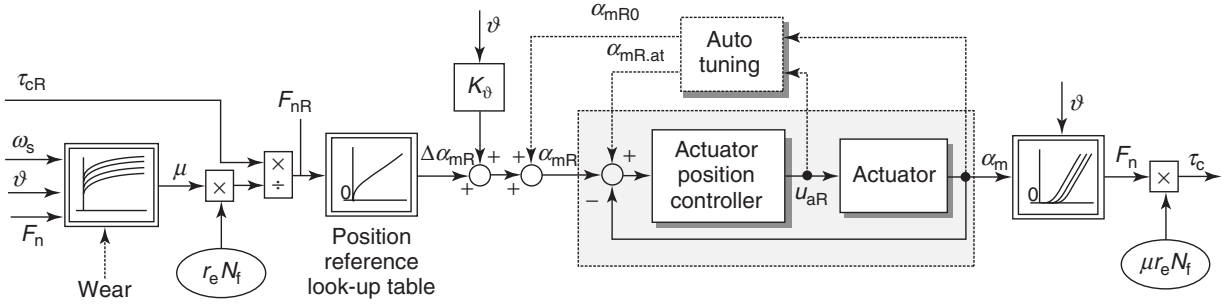

Figure 16. Block diagram of position-controlled system. (Adapted with permission from Ivanović, 2009. © ASME.)

F_{nR} is referred to the actuator motor position using the empirically determined 1D map (Figure 11b). A 2D map can alternatively be used if the transmission compliance characteristic $F_n(\alpha_m)$ is significantly influenced by the (oil) temperature.

The obtained, net actuator position command $\Delta\alpha_{mR}$ is corrected by the position offset calculated from the clearance compensation auto-tuning routine. As the thermal expansion-related position offset may be regarded as a negative clearance (or overlap), the thermal expansion effect may be compensated for by adding the actuator position reference offset calculated as a product of the estimated friction interface temperature ϑ and a negative value of the thermal expansion gain K_ϑ. The gain K_ϑ can be obtained by test rig-based experimental identification, that is, from the gradient of actuator position versus temperature curves for the constant/regulated normal force. Alternatively, the corrective, slowly changing, thermal- and other disturbance-induced position offsets can be calculated from a slow integral-type clutch torque controller, which utilizes the engine torque observer during the intervals of reliable engine torque estimation (Deur *et al.*, 2012).

The auto-tuner estimates the clutch clearance and tunes the corresponding actuator position reference offset α_{mR0}. It is executed sporadically when the clutch is not in use (e.g., every time the engine is turned off). The clearance identification is based on ramping up the actuator position reference $\alpha_{mR,at}$, and detecting/holding the position at which the armature voltage suddenly rises, indicating the motor torque rise at the "bite" point.

The experimental response in Figure 17 illustrates the effectiveness of the laboratory-tested actuator position-based clutch torque control system in both small- and large-signal operating modes. The fast, aperiodic, and steady-state accurate response is achieved in different operating modes and operating points without using friction compensator. The response is very repeatable and steady-state

torque error is lower than 10% for the considered case of cool oil.

5 CONCLUSION

In parallel to the introduction of new concepts of clutch-based automatic transmission (AT) and active driveline systems, there have been significant research and development efforts in designing novel clutch actuation systems. As most of the new transmission and driveline systems are based on a single or dual clutch, where often a continuous clutch torque control is required, there have been strong opportunities and demands for developing more advanced clutch actuation systems including feedback control subsystems. The traditional electrohydraulic actuators have, therefore, been facing a strong competition, mostly from various designs of electromechanical actuators, and also from electromagnetic and sometimes MRF/MP actuators.

The hydraulic actuators remain to be exclusively used with torque converter ATs, because of a superior force density and favorable packaging features for such multi-wet clutch systems. The electromechanical actuators gain their presence in various driveline applications and in some specific transmissions such as those based on dry clutches. This is because of their good modularity/ease of assembly, high efficiency, and excellent control features of EMs. The direct electromagnetic actuators have a low force density, and they should, therefore, be used in high speed/low torque clutch applications (e.g., active differentials with geared stationary clutches/brakes) or they should be combined with a mechanical transmission (e.g., ball ramp mechanism). The MRF/MP clutches offer a strong potential in terms of great simplification of mechanical system and excellent control performance; however, they are still rarely applied in automotive drive trains because of the inferior torque density compared to friction clutches. To successfully compete with the electromechanical actuators in the demanding applications, the electrohydraulic actuators have been evolved toward more efficient designs (variable-flow pumps are employed instead of valves) and improved control features (pressure and/or position feedback is utilized).

The success of modern clutch actuation systems is strongly associated with the performance of clutch torque control strategies. On the other hand, the control system design and calibration largely depends on the quality of experimental characterization and modeling of the clutch actuator dynamics, as well as on the choice and characteristics of sensors. Hence, to achieve a favorable performance-to-cost ratio, the design of the overall clutch actuation system requires a fully mechatronic approach from the early stage of development.

ACKNOWLEDGMENT

It is gratefully acknowledged that the authors' research work on the electromechanical, MRF, and MP clutch actuation systems, whose results are partly presented in this chapter, has been supported by the Jaguar Cars Ltd and the Ford Motor Company.

Launch Control

Andrew P. Harrison
Drive System Design Ltd, Warwickshire, UK

1 INTRODUCTION

Launch control means many things to different people. It can mean simply the method by which a vehicle accelerates from rest or a dedicated function designed to extract the maximum possible acceleration from a vehicle in a race or simulated race start event.

The manner in which a vehicle moves at low speed can be a dominant feature in determining both the subjective and the objective performances of a vehicle. Traditional automatic transmissions employed a torque converter as their launch device (*see* Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly). Tuning of low speed attributes including creep, torque multiplication, response, and feel was traded against cost, efficiency, package, and weight through careful manipulation of the component design (*see* Automotive Torque Converters). The continuous search for better efficiency has led to the development of new transmission concepts (*see* General Introduction—Basic Definitions, Structure of Part 4), many of which employ friction clutches as the launch device. By combining a friction clutch with an electronic control system, it is possible to maintain many of the desirable attributes of the torque converter while improving overall system efficiency and also introducing additional features and modes of operation.

This chapter discusses first the attributes most desirable of a modern launch control system and then moves on to discuss common control techniques applied to friction clutches in the modern automobile.

2 MAIN TEXT

In this chapter, "launch control" is used as an umbrella term including all aspects of the control of a vehicle moving at low speed and directly or indirectly influenced by the launch device. Detailed discussion is focused on the subjects of low speed maneuvering (creep and hill hold), vehicle launch for maximum subjective feeling (pullaway control), and vehicle launch for maximum acceleration (performance launch control).

2.1 Torque converters and their role in defining the ideal pullaway characteristic

The torque converter has been the main launch device for automatic transmissions (*see* Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly) for many decades and therefore is for many drivers their first or only experience of an automated launch device. Two inherent features of a torque converter, which are seen by many as desirable attributes to be maintained in any alternative concept, are that of creep and hill hold.

2.1.1 Creep

The term *creep* is used to describe the tendency of a torque converter-equipped vehicle to want to move at a low speed whenever drive is engaged. Holding the vehicle at rest or travelling at a speed below the creep speed of the vehicle requires the driver to apply the brakes or select neutral.

Creep is seen as a positive attribute of a torque converter, assisting the driver in maintaining control of a vehicle during very low speed maneuvers by facilitating the use of a single pedal to control the vehicle motion. Therefore, while not universal in its implementation, it is usual to design the control system for a launch clutch such that it partially engages the launch clutch in this condition and simulates the creep behavior of a torque converter-equipped vehicle.

A negative side effect of the creep torque applied by the torque converter is the additional engine load, which can significantly increase idle fuel consumption and emissions. Therefore, many systems have been developed to reduce this load by temporarily selecting neutral when the brake pedal is applied. One such early system and its operation are described by Forster and Eltze (1978). In this system, the transmission temporarily selects neutral via a switch mounted on the brake pedal activating a servo valve, which in turn removes the control pressure from the clutch. Modern systems recreate this functionality through electronic control of clutch apply pressure.

It is desirable that a launch clutch that features simulated creep, be it mechanically or electronically controlled, should maintain this feature and reduce the load on an engine because of simulated creep torque when the brake is applied.

2.1.2 Hill hold

Hill hold is used to describe the ability of a vehicle to hold stationary on an uphill gradient without the brakes being applied.

The creep torque inherent of a torque converter is a function of the slip across the converter (*see* Automotive Torque Converters) and therefore changes with both the engine and the vehicle speed. A vehicle in creep on a level road will achieve a constant speed when the slip reduces sufficiently that the wheel torque generated by the torque converter is equal to the road load experienced by the vehicle.

Increasing the gradient increases the road load and therefore equilibrium is achieved at a lower vehicle speed. Eventually, a gradient can be achieved at which the creep torque is no longer sufficient to overcome the road load and the vehicle is held at rest.

Further, increasing the gradient will eventually cause the vehicle to start to roll backwards, increasing the slip across the converter and in turn increasing the torque at the wheels. Although on this higher gradient the torque converter is unable to prevent the vehicle rolling back, it will still provide some significant restoring torque helping the driver to maintain control and/or launch the vehicle on the gradient.

The gradient on which the vehicle will fail to accelerate from rest and the gradient on which the vehicle will start to roll back are significantly different values. This hysteresis is created by the tire static rolling resistance and the static friction in the driveline. It is the ability of a torque converter-equipped vehicle to hold on this range of gradients, which is described as its inherent hill hold capability.

2.2 Launch control for maximum acceleration performance

In motorsport applications, the term *launch control* is often used to describe a system that, through a combination of traction control and clutch torque capacity regulation, attempts to achieve the maximum possible acceleration of a traction-limited vehicle. Seen as a driver aid, capable of achieving significant improvement in both ultimate vehicle performance and repeatability of race starts, such systems have been banned from Formula 1 since the start of the 2008 season.

Similar systems applied to road cars may be considered to be enhancing both performance and safety of the vehicle.

Vehicle performance is improved because of both the maximum vehicle acceleration and the maximum gradeability of the vehicle being increased.

Vehicle safety is increased by allowing an unskilled driver to accelerate away from a hazard in the minimum period of time.

2.2.1 Maximizing available wheel torque

The ideal launch control system will maintain the vehicle at the traction limit from the moment the launch is initiated until a vehicle speed is achieved beyond which insufficient power is available.

With a friction clutch launched vehicle, maximum wheel torque is available when the transmission is in its lowest gear (maximum torque multiplication) and the engine is at peak torque engine speed. Therefore, the simplest approach to maximize the wheel torque available to the launch control system is to control the engine to the speed at which it is capable of delivering maximum engine torque. This approach is often used on low powered vehicles and particularly those which are not traction limited during launch.

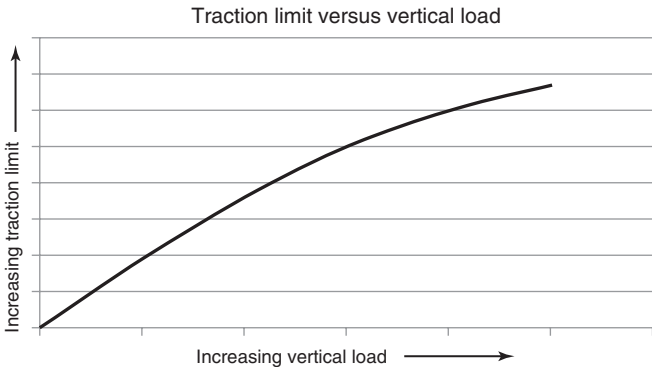

Figure 1. Trend of increasing traction limit with increasing vertical load.

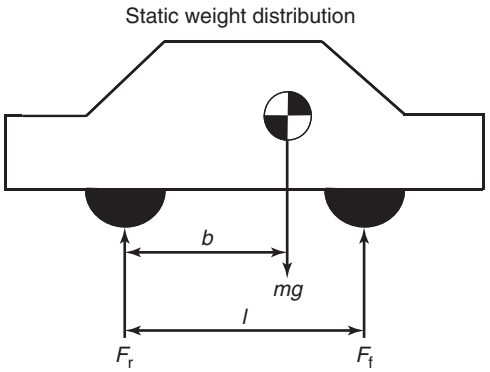

Figure 2. Variables used in calculating the static weight distribution of a vehicle.

However, a number of situations arise where it may be advantageous to set an alternative engine speed setpoint.

If sufficient torque is available to exceed the traction limit at engine speeds below the maximum torque engine speed, then a significant reduction in clutch slip energy can be achieved without impact on vehicle performance by lowering the engine speed setpoint.

If insufficient torque is available to exceed the traction limit, then additional torque may be generated by raising the engine speed to a level above the maximum torque speed before launch, and then transferring the additional kinetic energy stored in this rotating inertia to the vehicle for an additional acceleration effort during the launch event. This technique can be useful both for low powered vehicles and also as a method for compensating for initial lag on turbocharged vehicles where the steady state torque delivery may not be available until a time period after the launch event has been initiated.

2.2.2 *Static weight distribution*

The maximum tractive effort a tire is able to support is a function of the vertical load applied to it. Increasing vertical load results in increasing traction until the tire eventually becomes overloaded. Figure 1 shows a typical trend in increasing traction limit with increasing vertical load.

When a vehicle is at rest, the load on the driven axle is a function of the total mass of the vehicle, the location of the center of gravity, and the length of the wheelbase as shown in Figure 2.

The static axle loads are given by the equations:

$$F_f = \frac{mg \times b}{l} \tag{1}$$

and

$$F_r = mg - F_f \tag{2}$$

where

F_f = Static front axle load (N)

F_r = Static rear axle load (N)

m = vehicle mass (kg)

g = acceleration due to gravity ($N \cdot kg^{-1}$)

b = position of center of gravity ahead of rear axle (m)

l = length of wheelbase (m)

Table 1 shows the typical range of front to rear static weight distribution distributed by vehicle type and powertrain layout. The values are taken from various sources across the internet, and where sources do not agree, an average of the published values has been taken.

This variation in static weight distribution explains the difference in traction experienced by many owners in conditions of low friction and hence low rates of acceleration. Drivers of front-engine rear-wheel-drive vehicles will often be stranded unable to climb a gradient when drivers of similarly equipped front-engine front-wheel-drive vehicles are able to continue their journey.

2.2.3 *Dynamic weight transfer (steady state)*

When a vehicle accelerates, the tractive effort is created at the contact between the tires and the ground. However, the

Table 1. Typical front/rear weight distribution in modern road cars

Powertrain Layout	Example Vehicle	Front Axle Weight (%)	Rear Axle Weight (%)
Front-engine, front-wheel drive	Ford Focus RS	63	37
	Saab 9-5	60	40
	Corsa GSI	63.4	36.6
	Volkswagen Scirocco	64	36
Front-engine, rear-wheel drive	Mazda MX-5	50	50
	Toyota GT86	53	47
	Mercedes SLS	47	53
	Corvette Stingray	50	50
Front-engine, four-wheel drive	Volvo V70R	54	46
	VW Golf R	60	40
Mid-engine, rear-wheel drive	Lotus Elise	38	62
	Lotus Evora	38.7	61.3
	McLaren MP4-12C	42.5	57.5
	Ferrari 458	42	58
	Porsche Cayman S	45.3	54.7
	Renault Clio V6	40.4	59.6
Mid-engine, four-wheel drive	Audi R8	44	56
	Bugatti Veyron	44	56
	Lamborghini Aventador	43	57
Rear-engine, rear-wheel drive	Porsche 911 GT2	37	63
Rear-engine, four-wheel drive	Porsche 911 Carrera 4	40	60

center of mass of the vehicle will usually reside at some height above this ground plane and hence a moment arm is created, which must be balanced, in steady state, by weight transfer between the two axles. In the case of acceleration in the forwards direction, weight will be transferred from the front to the rear axle.

The weight transfer to the rear of a vehicle during acceleration is given by taking moments about the front axle contact patch as defined in Figure 3:

$$\Delta F = \frac{ma \times h}{l} \tag{3}$$

where

ΔF = Weight transfer toward rear axle (N)

m = vehicle mass (kg)

a = longitudinal acceleration of vehicle ($\mathrm{m \cdot s^{-2}}$)

h = height of center of gravity above ground plane (m)

l = length of wheelbase (m)

This dynamic weight transfer leads to the traction advantages seen by rear-wheel-drive vehicles when compared to front-wheel-drive vehicles at high rates of acceleration and also explains why, as acceleration levels increase, the traction benefit of four-wheel-drive systems is progressively reduced. This is being best illustrated when considering the top classes in the sport of drag racing where the fastest accelerating vehicles in the world can be found. Top fuel dragsters and closely related classes run as rear-wheel-drive vehicles. The rate of acceleration is sufficient that the weight transfer to the rear axle completely unloads the front axle and often the vehicle can be seen to be carrying its front axle clear of the ground for the initial section of the race.

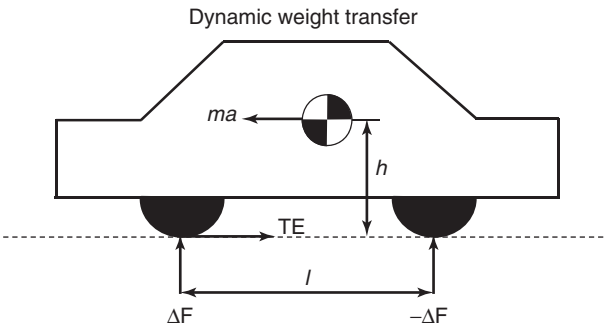

Figure 3. Variables used in calculating the dynamic weight transfer of a vehicle.

2.2.4 *Dynamic weight transfer (transient)*

A further consideration important when designing a launch control system is the influence of the design of the tires

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto103
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and vehicle suspension system on the initial weight transfer. The weight on the driven axle is transferred to the tires via the vehicle suspension, and therefore as the vehicle transitions from its static to dynamic condition the suspension system is required to support the additional vertical load. During the initial transient, any additional vertical load is supported only via linkage forces created by features such as anti-squat geometry (*see* General Introduction—Basic Definitions, Structure of Part 4) and by forces generated in the suspension dampers because of the rate of deflection of the suspension. Further forces are then generated by the suspension springs and tire sidewalls as the suspension deflection approaches its steady state condition and the full weight transfer is established.

2.2.5 *Aerodynamic downforce and its influence on traction*

Formula 1 racecars are generally accepted as being able to drive upside down on the roof of a tunnel at speeds in the region of 130 km/h. With a mandated minimum rear axle load of 342 kg, this indicates that the total combined downforce effect of the wings and bodywork at this speed must be equivalent to at least 342 kg. Assuming that the lift coefficient of the vehicle is constant (*see* Fundamentals, Basic Principals in Road Vehicle Aerodynamics & Design), this means that at a speed as low as 70 km/h, well within the traction-limited launch window, a Formula 1 car can already be creating an additional 100 kg or 30% of static axle load. Referring back to Figure 1, we can appreciate that this has a significant impact on the available traction and must be considered in determining the traction limit.

By contrast, most road vehicles generate low levels of lift (negative downforce) and therefore effectively reduce the load on the drive axle as the vehicle accelerates. Even the most extreme road cars only produce moderate levels of downforce. One of the highest downforce producing road cars currently in production is the Ferrari Enzo, and this is only claimed to generate 760 kg of downforce at 300 km/h. Comparing this back to the Formula 1 car example quoted earlier, and making the same assumption regarding constant lift coefficient, this equates to just 40 kg of downforce at 70 km/h and continues to be negligible until a speed beyond that at which the vehicle ceases to be traction limited.

2.2.6 *Integration with traction control systems*

Many modern vehicles are equipped with some form of traction control system designed to reduce wheelslip by modulating engine torque, brake apply torque, or a combination of both (*see* The potential for handling improvements by global chassis control). Integration of clutch and traction control systems is a key aspect of achieving an optimum launch in a modern vehicle and it is the traction control system that becomes fully responsible for achieving the best possible rate of acceleration once the launch clutch is fully engaged.

2.3 Pullaway control considerations

In this chapter, pullaway control is used to differentiate from launch control in that pullaway control is used to describe the process of accelerating a vehicle from rest at some level below the maximum possible. In this condition, the priorities move from outright performance to achieve a balanced compromise among emissions, acceleration feel, durability, and performance.

2.3.1 *Acceleration feel*

Achieving a successful subjective feeling during vehicle launch can be a compromise between initial response and ultimate acceleration. Unlike the performance launch, the control system will usually not be forewarned of an impending acceleration request (via a launch mode button, double foot start, etc.) and therefore the usual conditions for the start of a pullaway event will be vehicle stationary, foot brake applied, accelerator pedal released, engine speed at idle, engine load at creep torque, or lower. The torque available at this engine speed will usually be able to support only a modest rate of acceleration and therefore the engine speed must be allowed to rise in order that sufficient torque becomes available to meet the driver's demand for acceleration. However, any torque used to accelerate the engine is not available to accelerate the vehicle. Therefore, a compromise must be found between the immediacy of response and the ultimate rate of acceleration achieved.

Achieving the correct compromise is a key skill of the vehicle development engineer. However, a key attribute used by many vehicle manufacturers to assess the response of a vehicle to a driver demand is that of the "4 s distance." This is defined as the distance traveled by a vehicle within the first four seconds elapsed time after the driver demand for acceleration is received. Maximizing this distance will involve finding the optimum balance between engine torque used initially to accelerate the engine to a speed at which greater torque is ultimately available and engine torque used to immediately accelerate the vehicle.

2.3.2 *Comfort*

Where the situation or vehicle type demands a comfort-oriented launch, the goal of the pullaway control system is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto103
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

to transition from the start condition to the driver-demanded rate of acceleration with the least disturbance to either the driver or the passengers while completing this transition in an acceptable and safe period of time.

As with shift control (*see* General Introduction—Basic Definitions, Structure of Part 4), many attempts have been made to objectively quantify what is a comfortable pull-away. However, the general acceptance is that maximizing comfort is achieved by minimizing jerk through the pull-away event.

2.3.3 Sportiness

Achieving a sporty pullaway feel is in many ways about creating the opposite attributes to that of a comfort-focused pullaway. An immediate response, noticeable with a sudden change in acceleration, will usually be perceived as sporty. Similarly, if this wheel torque is applied in a sudden and aggressive manner, the tires will be more prone to slipping. While wheel slip is generally to be avoided for maximum performance, a tire struggling for grip will generally be perceived by most drivers as an attribute of a sporty launch.

2.4 Clutch control methodologies

2.4.1 Introduction

Automated launch clutches have been in existence for many years. Many early clutches had no electronic control and regulated the clutch apply force via mechanisms such as centrifugal force and manifold vacuum. These early systems remain relevant today as their operation forms the foundation for the control algorithms incorporated into many modern electronic control systems.

2.4.2 Modern electronic control methods

Modern launch clutches are controlled via increasingly complex control algorithms running inside an electronic control unit. Actuation is via either electrohydraulic or electromechanical means. Electrohydraulic systems are generally found on higher performance systems and control the capacity of the launch clutch using hydraulic fluid as the power transfer means. Electromechanical systems control the capacity of the launch clutch via electrically driven actuators acting directly onto the launch clutch actuation system.

Development of launch control systems has typically been an evolutionary process with the early passive systems giving way to electronic systems, which mimicked the operation of the passive systems. These systems have then evolved to become more and more complex bringing the benefits of both increased functionality and increased robustness of performance in service.

Launch control systems control two actuators, the engine torque and the clutch torque capacity. Two basic control targets are defined for the system, achieving a desired engine speed profile and achieving a desired vehicle acceleration profile.

For a viable system, each one of the actuators must be assigned to each one of the control outputs. In reality, both systems must closely interact to achieve the necessary system-level performance. Selection of the appropriate allocation of targets occurs not only because of engineering principles but also because of commercial and political constraints within engineering companies, and both techniques have found widespread application within the industry. The strengths and weaknesses of each approach are discussed in the following sections.

2.4.2.1 Engine speed control via clutch regulation. The most common methodology for launching a vehicle in use today involves the launch clutch being allocated the task of controlling the engine speed to a target profile. The engine torque output is a function of driver demand and engine speed as per a manual vehicle. When the driver demand is increased, the engine speed rises in response to the increase in engine torque. The launch clutch then responds to this rise in engine speed by increasing its torque capacity and hence the reaction torque on the engine. In turn, this reaction torque is transferred to the wheels via the transmission and driveline and results in a change in vehicle acceleration.

When a traction event is detected by the traction control system, a torque decrease is requested from the engine, the speed falls, and the clutch control responds by reducing its torque capacity thereby reducing the torque at the wheels.

This method allows the launch control function to be developed largely independently from the other vehicle systems and generally requires the lowest level of integration and change from the other vehicle systems to support its introduction. However, the discussion of the multiple stages between detecting a traction event and the system reaction being achieved highlights how significant improvement can be made by interfacing the traction control directly to the clutch capacity and by directly controlling engine speed via engine torque regulation. However, it is this method of control which dominates in the market place. This is due to the majority of vehicle architectures being established for either manual or torque converter AT-equipped vehicles, and hence introducing a launch clutch using this methodology requires the minimum of revision to the base vehicle architecture.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto103
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.4.2.2 Engine speed control via engine torque control. With this methodology, the control of engine speed is achieved by manipulating the engine torque output and the launch clutch is directly responsible for controlling the vehicle acceleration via wheel torque control. Intervention from external systems such as traction control can be achieved directly through commands to the launch clutch and the system performance is robust to variations in the engine torque response. This approach allocates each of the actuators the role in which it has direct control and therefore the role that allows the powertrain to deliver the highest possible level of performance.

The challenge of this approach is that it carries little commonality with the operation of a conventional vehicle and therefore requires a dedicated vehicle architecture. For this reason, this approach is usually only found on vehicles where the powertrain is solely or primarily equipped with an automated launch clutch.

2.4.3 Special functions

A key characteristic of a launch clutch is its ability to regulate torque independent of slip speed up to the point where slip is reduced to zero. When combined with an electronic control system, this facilitates both the maintenance of key driving features carried forward from torque converter-equipped transmissions and often the enhancement of these features to a higher level of robustness or performance.

2.4.3.1 Hill hold. First introduced in Section 2.1.2, hill hold is used to describe the ability of a vehicle to hold stationary on a gradient. Combining a launch clutch control system with a directional speed sensor allows the hill hold capability of a vehicle to be enhanced to prevent rollback on gradients up to and including that possible with the engine torque available at the current engine speed.

2.4.3.2 Creep control. Introducing an electronically controlled launch clutch facilitates the introduction of closed loop creep control functionality utilizing output shaft speed sensing, wheel speed sensing, or a combination of both. In this condition, the control system is able to offer consistent vehicle acceleration and speed control across a range of road gradients and independent of engine speed setpoint.

Control Systems and Strategies for Automated Manual and Double Clutch Transmissions

Bruno Müller, Götz Rathke, Michael Reuschel, Uwe Wagner, Stefan Winkelmann, Marco Grethel, and Jürgen Gerhart

LuK GmbH & Co. KG, Bühl, Germany

1 INTRODUCTION

Over the past few years, automated transmissions that build on manual transmission technology and generally use similar technologies have changed the world of transmission technology considerably. The most well-known representatives of this include automated manual transmission (AMT) and double clutch transmission (DCT). Figure 1 shows the transmission concepts with basic design examples. They offer the driver more than a considerable increase in comfort; thanks to the automatic shift point selection that can be designed optimally, consumption can also be reduced.

The first series application of a DCT was in the six-speed DCT from Volkswagen in 2003 (known internally as *DQ250*), which was based on an oil-cooled, that is, "wet," double clutch. The potential of this transmission concept for fuel consumption and response time enabled Volkswagen to gain new market shares. As a result, further applications for the technology developed quickly.

Yet despite its benefits, the AMT has remained a niche product since its launch. It is a different story for the DCT, for which high sales opportunities are predicted, particularly on the European and the Chinese market. DCTs receive additional thrust from the hybridization of the powertrain. The integration of electric motors in and on existing transmission systems is an important focus for development worldwide. The cost-intensive hybrid drives promise considerable consumption potential, particularly when used in urban regions with frequent stop-and-go traffic. Owing to their effective competitive marketing, they are regarded by the general public as a serious alternative to classic powertrains. The additional possibilities of the electric motor integrated in the transmission can be implemented particularly cleverly in connection with a DCT. Details of the system architecture, hardware, software, and future developments of AMT and DCT are discussed later.

2 SYSTEM ARCHITECTURE

2.1 System components

From the driver's perspective, the automated transmission is responsible for setting the required speed safely and comfortably at all times. To do this, the transmission system must guarantee a suitable wheel torque progression through the interaction of multiple components (for more details on construction and operation see Automated

Manual Transmissions (AMT)—system design considerations, clutch operation, shift actuation alternatives and Dual Clutch Transmissions (DCT)—Layouts, Clutch Selection, Packaging, Actuation, Manufacturing & Assembly). Figure 2 shows this basic interaction.

2.1.1 Controller and actuator

To fulfill this requirement, the control system actuates the clutches to set a driving torque at the transmission input and, using the shift mechanism, selects the appropriate transmission ratio in the transmission. Depending on the design, the automated transmission also controls the clutch cooling for wet clutch or clutches or the actuation of a parking lock.

Irrespective of the specific design of the system, clutch and transmission actuation follow basic functional structures. This means that first of all, the energy required for clutch operation must be provided. Electric motors supplied with power by the vehicle battery or hydraulic pumps driven directly by the engine are used for this purpose.

Actuators convert the energy supplied into actuation travel or an actuation force. Thus, electromechanical actuators convert the rotational movement of the electric motor into a longitudinal movement. The ratio can be purely mechanical with the aid of a lever or hydrostatic with the aid of master and slave cylinders with hydrostatic lines. If the energy is provided via hydraulic pumps, the actuators are valves that control the pressure provided by the pump and distribute it to the downstream elements of the actuation system.

Finally, the actuation system establishes the connection between the actuators and the clutch and creates the clamp force in the clutch. In electromechanical systems, actuation is via engagement bearings; in hydraulic systems, generally via rotating slave cylinders.

Via the clamp force, the clutch defines the torque transferred from the engine to the transmission. In contrast to dry disk clutches, wet-running multidisk clutches require an additional element for clutch cooling.

The control system and software of the automated transmission require information from the functional structures to enable them to control the transmission system safely and comfortably (Figure 3). Sensors are generally used to observe the behavior and state of the components. Where the use of sensors is not possible

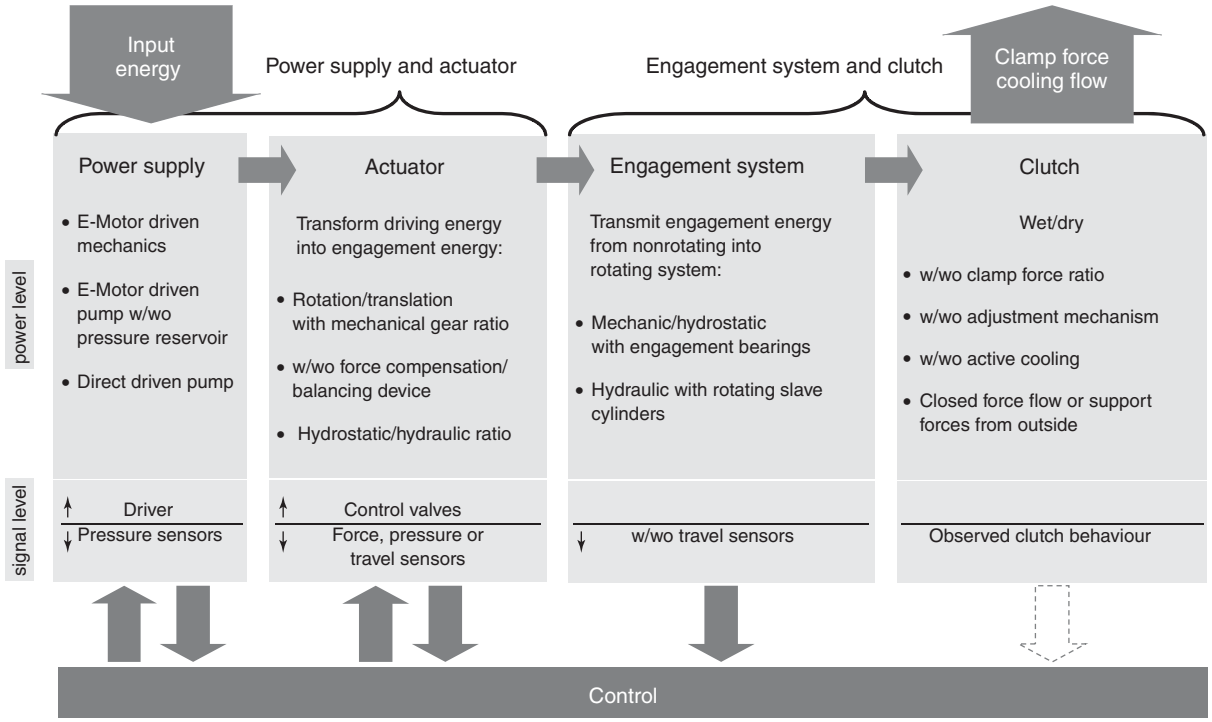

Figure 3. Functional structure of the clutch control. (Reproduced with permission from Schaeffler.)

for technical or cost reasons, software strategies must continuously assess the system behavior in real time based on models.

For the control of the transmission actuation, the same structures apply concerning power supply and actuator mechanisms as for the clutch actuation. However, the actuators have a direct effect on the transmission gearshift rails, set the gears, and actuate the parking lock—where this function is provided for in the system.

2.1.2 Designs

The requirements for function and quality of the system and the boundary conditions of requirement management (Pohl, 2008) determine the specific design of an automated transmission (Figure 4).

Basic decision criteria for the system design are low CO_2 emissions with simultaneous high comfort, reliable function at all times and a long life. These are supplemented by high demands in terms of mounting space requirements, system weight, and component complexity. More recent criteria also include the possibility for hybridization and/or stop–start capability of the system (Steiger *et al.*, 2013)

The various criteria are weighted in the context of the overall vehicle design in order to determine the importance of the advantages and disadvantages of each design variant. This applies both to the clutch concept (wet multidisk clutch and dry friction disk clutch) and to the selection of the actuating mechanism and actuation.

For example, a wet-running multidisk clutch is used primarily for vehicles with a high mass and engine power, as the wet-running clutch can dissipate the frictional power that arises more easily. This has a positive effect on service life and reliability. At the same time, however, the clutch cooling required can increase energy consumption.

In contrast, a dry friction disk clutch is distinguished by high energy efficiency—particularly if it is equipped with an electromechanical actuation. However, the design variant may reach mounting space and life limits more quickly (Wagner *et al.*, 2009).

2.2 Design and concept landscape

In addition to the selection of the optimum mechanical components for the particular use case, the integration of the automated transmission into the electronic vehicle architecture must also be considered. As, to a large extent, the mechatronic system takes over the responsibility for safe function and proper use from the driver of the vehicle, the requirements for functional safety must be made an integral part of the system design. For this purpose, ISO 26262

defines a procedure module together with required activities and work products as well as methods to be applied in development and production.

2.2.1 Central versus local control system

An important question in the system design is whether and to what extent the intelligence of the manual transmission should be distributed. Highly integrated control units with sensors and actuators that connect all tasks and all requirements (temperature, fatigue limit, and functional safety) in one device have the advantage of reduced system and assembly costs. They also provide the option of a complete system test before installation in the transmission unit. The reduction in the number of cables and contact and connector transitions also helps to provide increased system reliability (Stark and Schuch, 2010).

The alternatives are architectures in which a main control unit communicates with intelligent sensors and actuators via a bus system. This enables high resolution signals to be processed directly as well. Requirements from functional safety can also be distributed to the intelligent actuators.

2.2.2 Functional integration in the powertrain management

Automated transmissions exchange data and commands intensively with the engine control unit as well as the chassis and safety systems [electronic stability program (ESP), antilock braking system (ABS)]. To achieve high driving comfort at all times, the interfaces between the systems must be precisely aligned. Examples are the required reduction in engine torque during gearshifts for an AMT, or the required precision of the engine torque signal: in the AMT, the torque intervention ensures that the engine speed does not increase in the period in which the clutch is open during a gearshift. The torque calculated by the engine control unit is used by the transmission control system to compare the models for calculating the torque transferred from the clutches. These models run internally. If an automated transmission is integrated in a hybrid powertrain, this results in additional mechanical, electric, and electronic interfaces that have to be optimized as part of the boundary conditions and criteria described.

2.3 Integration into the vehicle

Irrespective of the specific design, an automated transmission is only one part of the overall vehicle system. The high complexity and the strong interaction between the subsystems require intensive alignment and testing of the subsystems as well as the overall system. Ultimately, comfort, performance, and NVH aspects can only be assessed in the vehicle.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto104
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.3.1 *Vehicle alignment*

In the vehicle, the effects of the automated transmission are directly evident to the driver: the clutch torques transferred determine the vehicle acceleration. The shifting characteristic curves define when each gear is activated and therefore have a considerable influence on the characteristics of the vehicle. Thus, the alignment of the automated transmission, that is, the development and parametrization of control unit software functions are very important.

The alignment defines the comfort or sportiness of the vehicle ride, as well as having a direct influence on the load for the individual transmission components and on CO_2 emissions. Thus, starts with very high engine revolutions per minute are deemed to be sporty. However, they increase the load on the start-up clutch considerably. The continuous alignment of actual load and load assumed during the design of the system is an important part of the development process.

2.3.2 *System and subsystem tests*

Validation, that is, proving the durability of the transmission system and its subsystems, is not based solely on real vehicle tests. In practice, numerous calculations and virtual simulations are used. For example, load spectrums with which the endurance requirements can mapped nested on a time basis are derived based on individual vehicle measurements or design data. Environmental influences such as temperature or humidity are considered in accordance with ISO 16750.

3 HARDWARE

To implement AMT or DCT controls, numerous hardware components have to work together. These include several design variants of electric motors, control units, sensors, and, depending on the design, an electrohydraulic, electromechanical, or hydrostatic actuating mechanism. Depending on the combination and design of these components, various concepts can be considered and types of actuation systems developed that satisfy not only the specific requirements of the OEMs but also the individual applications. Regardless of how different the transmission actuation systems are individually, all systems contain electric motors, control units, and sensors.

3.1 Electric motors

In principle, direct current servo motors are used in the actuators for clutch and transmission control. They contain coils and permanent magnets and have to be commutated so that the motor coils can be controlled correctly in accordance with the angle of rotation.

In conventional direct current motors (DC motors), the stator contains the magnets and the rotor the copper coils. The current for controlling the motor is supplied to the coils from outside via the mechanical commutator (carbon brushes). The commutator constantly reverses the polarity of the motor coils depending on the angle of rotation. This causes the motor to rotate in a specific direction. Therefore, there is no need for a commutation sensor in DC motors.

For brushless direct current motors (BLDC motors), the arrangement is exactly the opposite: the rotor contains the magnets, the stator the copper coils. This means that the coils can be contacted directly. The commutation is electronic rather than mechanical and via the control unit. An angle sensor that records the angle of rotation and transmits it to the control unit is generally required. This is evaluated in the commutation module and the motor coils are controlled according to the angle of rotation in the power stage. Owing to the advantages of the BLDC motor (including increased efficiency, increased energy density, lower inertia, lower EMC emission, and the possibility of optimizing the speed/torque characteristic), this type of direct current motor is often used in clutch/transmission actuators. To increase the power density further, rare-earth magnets are generally used nowadays instead of ferrite magnets. The costs of rare-earth magnets have risen exorbitantly since 2010, meaning that the benefits of the high power density must always be weighed against the costs.

The rotary sensor is also no longer necessary. In this situation of control without sensors, the angle of rotation is determined via the voltage and current signals. The motor start-up and fast changes in the motor speed are particularly critical as they can only be captured very slowly or very imprecisely via the current/voltage measurement. Therefore, at present, sensorless motors are only used in a few dynamic drives, such as pump drives.

During the relative measurement of the rotor position, angle increments are sent to the control unit in the form of pulses so that the control unit can recognize whether and how the motor is rotating. The motor speed is also derived from this angle information. Usually, multiple digital Hall sensors, which detect the magnetic field of a sensor magnet, are used. These sensors enable good dynamic and precise control of the rotor position to be realized as part of the sensor resolution.

With electromechanical actuators, it is important to know precisely where an actuator is. If an incremental sensor is used, an actuator must move to a reference point to determine the absolute position. Starting from this point,

the control system counts the sensor pulses and, if the sensor resolution and mechanical ratio are known, can continuously calculate the precise position of the actuator. After a control unit reset, however, the stop position has to be retaught.

If the reference position and referencing operations are not desired, absolute sensors are used. The sensor immediately shows the current angle position or actuator position of the motor even after a control unit reset.

3.2 Control units

Control units are usually customer-specific solutions. Stand-alone units (control units mounted on the chassis), local control units (control units mounted on the transmission), or integrated control units can be used (Stark and Schuch, 2010). Figure 5 shows an example of an integrated transmission control unit. Stand-alone units generally do not contain any sensors. They are not installed in or on the transmission, but as a separate electronics box in a suitable installation space in the vehicle. Attachment units have fixed connections to the transmission and are subject to increased vibration and temperature loads. Sensors and actuators are connected via an electrical harness. The mechatronics solutions of integrated transmission control systems represent the highest level of integration (Stark and Schuch, 2010). Here, the mechanics, hydraulics, electronics, sensors, and actuators are integrated in one unit.

The control units must satisfy high requirements in terms of vibration and temperature resistance. In printed circuit board technology, control units can be used on a conventional fiber glass epoxy resin up to an ambient temperature of ~125°C. Temperatures of more than 150°C and vibration loads of up to 50 g are much too high for most housed semiconductor components (Stark and Schuch, 2010). Thus, design solutions with ceramic interconnect devices and unhoused semiconductor components are used. Thick film substrates, LTCC (low temperature co-fired ceramic) multilayer circuits, and DBC substrates (direct bonded copper) are available. Figure 6 shows the different substrate technologies.

As an alternative to central control units, it is also possible to distribute the intelligence to multiple local control units. This provides a technology that opens up completely new paths for system architecture. This applies above all in combination with an electromechanical clutch and gearshift actuation (Müller *et al*., 2010).

Where possible, the sensors of transmission control systems are integrated directly in the control system electronics. This eliminates the need for contact interfaces that require sealing and costly cabling work. It also avoids the risk of electromagnetic interference engaging on the line between the sensor and the control unit. However, the sensor integration is usually associated with high mounting space requirements in the control unit as the control unit has to be directly connected to the point to be evaluated. Figure 7 shows an example of the structure of a control unit.

Multiple control units are connected with a communication bus via a communication interface. The most common form is the CAN bus. Future developments of control units with FlexRay are conceivable. The LIN bus is too slow for the applications in the area of actuator control of a double clutch (Mayer, 2006).

3.3 Sensors

To increase robustness against wear and mechanical tolerances, noncontact sensors are generally used. Position, angle, torque, and speed sensors are used, as well as pressure sensors. The information from pressure sensors from the hydraulic line between the actuator and the clutch can be used to calculate the clutch torque transferred. Position sensors convert the position of the release bearing (measured in the actuator or on the slave cylinder) into an electrical signal using the magnetic or inductive principle. As this position is not proportional to the clutch torque over life, temperature, and other influencing factors, a software adaption must take place to calculate the torque information from the position information.

Speed sensors measure the transmission input speed, the transmission output speed, and the wheel speeds.

3.4 Designs

There are various concepts with different actuators for the shift operation and for actuating the clutches for the DCT and AMT design: electrohydraulic actuating mechanisms and electromechanical actuating mechanisms. The initial costs for an electrohydraulic actuating mechanism are higher than those for an electromechanical one. However, as the number of actuation points and power requirements increase, the hydraulic solution becomes less expensive as compared to an electromechanical one. In general, the electromechanical actuating mechanism has a lower power input, which ultimately has a positive effect on a vehicle's fuel consumption.

3.4.1 Electrohydraulic actuating mechanism

Hydraulic systems are known for being able to achieve movements quickly and precisely at high loads (Drexler *et al*., 1988). The high power density of the function components also make them interesting for vehicle applications. Thus, hydraulic actuator systems have proved themselves in automatic transmissions for many years.

However, internal leakages, the low temperature behavior, and the wide speed range of pumps driven by combustion engines require technical tricks to ensure problem-free and energy-efficient function in modern vehicles. The simple and cost-effective expansion of a functionality of an existing hydraulic system is in contrast to the high initial expense.

Common hydraulic systems generally contain the following components: delivery pump, valves for distributing the volume flow, that is, for cooling the clutch and valves for varying the pressure level, and thus the force in the actuator. The valve functions are generally grouped in assemblies known as *valve chests* or *hydraulic blocks*. In these assemblies, the pressure oil flows from valve to valve in channels or bores. The valve chests are generally placed inside the transmission housing and are thus protected against many environmental influences. If they are mounted on the outside of the transmission, corrosion protection and sealing to the outside present special requirements.

The method of provision of the hydraulic energy plays a key role particularly with regard to the efficiency of the hydraulic systems. Classical pumps driven by combustion engines are characterized by the shortest conversion routes from the rotation energy of the drive motor emitted to the hydraulic energy for the actuator system. However, the fact that the pump displacer size is defined by the minimum required flow rate at relatively low engine speeds and thus supplies too much oil at higher engine speeds is disadvantageous from an energy perspective.

A better demand orientation for energy provision can be realized using a pump drive form that is independent of the combustion engine speed (e.g., via an electric motor). However, some of this energy advantage is consumed by the longer efficiency chain. For further energy provision concepts, the demand situations must be considered in more detail, as the requirements for the volume flow source can be considerably different even with identical or comparable hydraulic power. This is shown by common demand situations such as low volume flow at high pressure and high volume flow at low pressure. There must also be an analysis of which demands occur permanently, frequently, or rarely.

The necessity of components for energy storage (accumulator) and conversion of pump characteristics (ejector or hydrotransformer) can be derived from this knowledge. To achieve the best possible demand orientation at optimized efficiency, modern supply sources use mixed concepts for hydraulics rather than just one pump. Two examples on the market also show this: Volkswagen uses powerpack hydraulics for its seven-speed DCT DQ200. This involves a small, electrically driven high pressure pump with a pressure accumulator to provide the system with high volume flows at short notice (Hadler *et al*., 2008). Mercedes-Benz has equipped its seven-speed DCT 7G DCT with a minimized, permanently driven main pump and an additional electrical pump (Wörner *et al*., 2011).

The logical processes for controlling the actuators are represented via a number of valve types and valve functions. In addition to the requirements for direct valve function (valve characteristic, dynamics, and hysteresis), particular attention must be paid to reducing the valve losses (including leakage) during the design of the valves.

Therefore, there is a clear trend away from pilot operated toward directly controlled valves. A further fundamental differentiation in the valves is in the selection of the material for the pistons and the direct valve environment (valve bore). Direct valves work with coated aluminum pistons that are operated directly in a valve chest made of aluminum casting. In contrast, cartridge valves have steel pistons that are operated in a steel sleeve. In turn, these steel sleeves are installed in a valve chest or a hydraulic block.

Interfaces are required both for the clutch actuation and the shift actuation. These can be realized hydraulically or mechanically. In the latter case, linear, swivel, or rotation motors are integrated in the hydraulics. Depending on the interface, pressure or path sensors are used to provide the transmission control unit with feedback about the current

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

function execution. Thus, the output can be controlled directly or adaptively or regulated actively via pressure or path sensors.

3.4.2 *Electromechanical actuating mechanism*

The electromechanical actuating mechanism is deemed to be a particularly efficient actuation system. To actuate a DCT, an average power input from the vehicle electrical system lower than 25 W can be realized in a representative cycle. This can reduce the fuel consumption by 1–2% compared with conventional actuation systems. When designing and selecting the elements that transfer power, attention must be given to ensure that the holding currents and effort for ratio adjustment are minimized. If new electric motors, sensors, and control units or even new mechanical elements are to be used, the development costs for an application-specific actuating mechanism are relatively high. In the meantime, however, there is a large set of existing components for electromechanical solutions as well.

In addition to the electric motors, sensors, and control unit, an electromechanical system needs actuator specific software, for example, referencing, plausibility, and safety strategies, such as fault detection and replacement strategies. To convert the rotary motion of the motor into an axial engagement motion, simple spindle nuts or more complex elements such as a ball screw drive or a planetary roller spindle drive can be used. Further mechanical elements are transmission ratio elements such as spur gears, crown gears, or bevel gears, worm gear transmission, or lever ratios. Depending on the mounting space and characteristics, compensation springs that level a nonlinear load progression can also be helpful to support the electric motor.

Depending on the control task, the actuation systems are equipped with additional sensors. The closer the sensor is placed to the effective working point, the easier the control task generally is, but the more difficult the design integration and connection of the sensors. Therefore, the approach is generally to use the simplest and fewest sensors—in the best case, only the sensors in the electric motor—which in turn requires more software intelligence.

In the past, electromechanical transmission control systems were controlled by control units mounted on the chassis. However, to improve the separation of the transmission system from the vehicle, there is a trend toward attached control units or integration of the control system in the transmission, as is already standard for automatic transmissions. Further elements, such as an engagement lever and release/engagement bearings or gearshift forks, are required as an interface with the transmission in order to guide the actuation movement and force to the required effective working point.

Various designs in current vehicle models provide convincing evidence of the diversity of an electromechanical actuating mechanism. In the development of the AMT for the VW up compact car therefore, particular attention was given to design the required actuation systems for gear selection and clutch control such that mounting space and weight were optimized (Schäfer, 2011). The gearshift for engaging gears consists of two independent electric motors. One selects the gearshift rail and the second one engages or disengages the gears by a conventional gearshift shaft with switching finger. The actuator for opening and closing the clutch is operated by a further electric motor. As a mechanical compensation spring that compensates the counterforce of the clutch spring is used, the electric motor only consumes the frictional forces during opening and closing operations.

Two DC motors are also used for the Opel Easytronic gearshift module. The selection axis is designed for short reaction times and the shift axis for high shift loads. The gear actuator finger is driven by a worm gear and a shift elasticity. The shift elasticity consists of springs that are pulled up under torque. It is required to reduce the torque and force peaks that occur on the synchronization or another stop due to the high inertia of the motors and to improve the controllability of the synchronous force. The motors are premounted to a gear actuator module in an aluminum housing (Figure 8).

For a DCT with an electromechanical clutch actuating mechanism, it is obvious that the DCT gearshift actuation has an electromechanical design (Kimmig *et al*., 2010). An example of this type of gearshift actuation is the LuK Active Interlock actuator (Figure 8). The special design of the

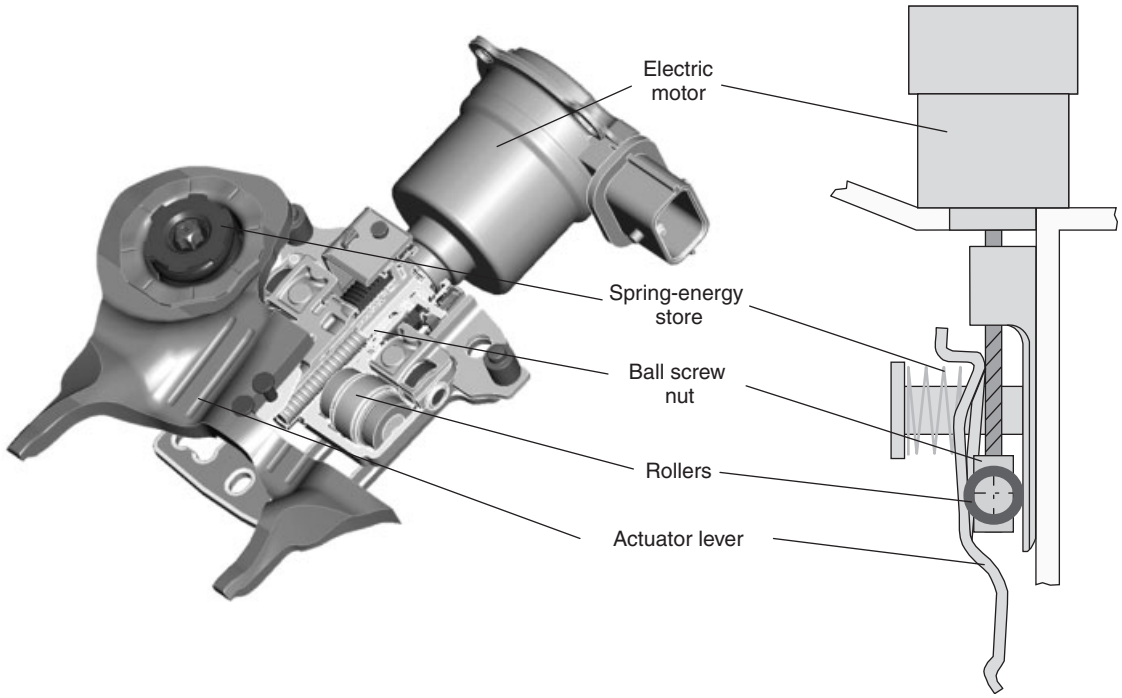

Figure 9. Electromechanical lever actuator for clutch actuation. (Reproduced with permission from Schaeffler.)

shift and eject fingers means that it is possible to preselect and engage the gears in both partial transmissions in any combination. The finger geometry together with the inner shaft rail geometry forms the so-called active interlock. It prevents mechanically impermissible gearshifts meaning that the expensive sensors on the gearshift rails are no longer necessary.

A further design principle uses an electromechanical lever actuator for clutch control (Figure 9). This creates the force required for closing the clutch via a stored-energy spring. The force takes effect at the outer end on the engagement lever designed as a rocker (Kimmig *et al*., 2010). An electric motor screwed onto the transmission housing creates an adjusting movement, via a ball screw drive, in tension rollers arranged between the lever and the transmission wall. These tension rollers form the central lever bearing point. Thus, the bearing point and therefore the effective lever ratio can be changed via the electric motor. For the electric motor, this results in a lower, almost constant force level and thus enables a considerable reduction in the motor size for the clutch actuator.

The use of an actuating mechanism with controller drums also promises low energy consumption (Faust, Bündner, and DeVincent, 2010). Two electric motors that actuate one controller drum each via two-stage ratios are used to shift the gears. Both controller drums are identical and each has only one groove for moving the gearshift forks. The use of this principle means that no additional mechanical lock is required for preventing multiple gears being engaged simultaneously in the same separate subtransmission in the event of a malfunction. The controller drums are controlled by motors integrated in a mechatronics unit via a cascade of gears. In addition to the transmission control system with power stages and motors for gearshift, the mechatronics unit also contains the power stages for the motors on the lever actuator.

A hydrostatic line may also be used to actuate clutches. An electromechanical master cylinder moves a closed-oil column that in turn actuates a slave cylinder, which then actuates a clutch, for example, via a release/engagement bearing. The advantages of a hydrostatic connection are the high flexibility of the wiring, low elasticity to minimize the actuation losses, and a ratio that can be adjusted via the cylinder sizes. The temperature-specific volume expansion of the fluid is a disadvantage, which is why a connection to the reservoir has to be established regularly to enable volume compensation.

The new hydrostatic clutch actuator (HCA) provides a further powerful component for automated clutch control. This is shown in Figure 10. Owing to the extensive optional equipment, this actuating mechanism can be tailored for a wide range of applications. The design selected also allows good scalability of the components. Use as an individual actuator for clutch-by-wire applications or for controlling

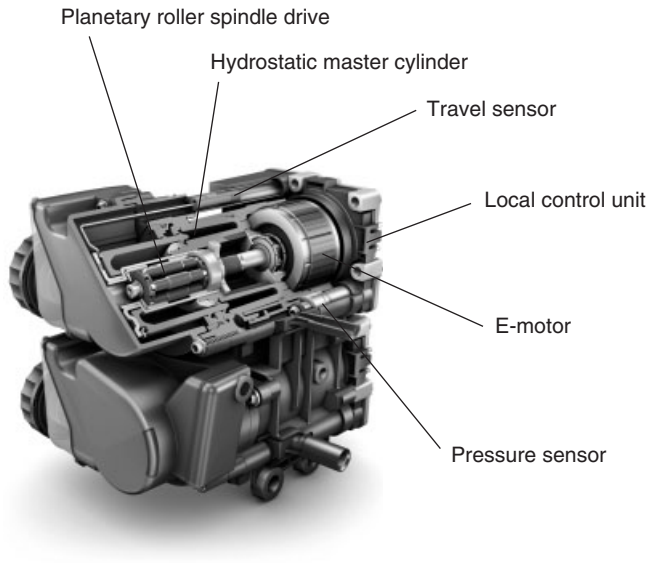

Figure 10. Hydrostatic clutch actuator. (Reproduced with permission from Schaeffler.)

hybrid clutches is also possible, in addition to use in DCTs. The use of a planetary roller spindle drive with very high ratio means that further ratios are not necessary. A large master cylinder in the form of an annular piston can also be used. This means that the actuator can have a very compact design. This type of hydrostatic actuator is used, for example, in the Honda "Intelligent Double Clutch Drive" hybrid system. This system has been optimized for very low fuel consumption. At the same time, this clutch actuator offers a previously unattained precision for dry and wet clutches from 100 to 500 Nm. Thanks to the target path regulation on the clutch, a lower hysteresis and better micro-control behavior are achieved than with a pressure control that could also be represented with this actuating mechanism. Therefore, the HCA is also suitable for very demanding control tasks.

4 SOFTWARE

4.1 Task

In modern vehicles, the software or function control has a key role. The aim is always to control a number of different actuators reliably, robustly, and precisely (Küpper, Serebrennikov and Göppert, 2006). Because these actuators take over complex and extensive tasks in automated transmissions or in the chassis control, the higher level functional logic is particularly important. Through, for example, appropriate control logic and adaption routines, this functional logic must provide a consistently high comfort over the entire life. At the same time, relevant diagnostic and safety tasks must be fulfilled to ensure that at all times, hardware faults are detected reliably and no safety critical driving situations can occur. A new task is the definition of interfaces for interactions with modern communication and entertainment systems.

The following insight into the software and function modules of automated transmission systems focuses on AMTs with single clutch (AMT) and DCTs. However, many aspects can also be applied to torque converters and hybrid systems. For a deeper insight, special aspects of the functional logic of the DCT will be addressed. In particular, the process of a gearshift from first to second gear under traction will be considered.

4.2 Software structure

4.2.1 Embedded software

Embedded software is used in systems that are generally characterized by restrictive boundary conditions such as low memory capacity, low CPU timing, or CPUs with a low bit rate (16-bit or 32-bit). The main causes are firstly, the multitude of up to 100 control units in one vehicle, and secondly, the high cost pressure for vehicle manufacturers.

The software is often programmed manually in the classic way using ANSI C, supported by corresponding structogram editors. However, code generators are also used in numerous projects. The main reason for this is that programs such as Matlab/Simulink are used in the development of relevant functional algorithms. These are well suited to mapping control-oriented functions. Using appropriate code generators, such as Targetlink, these graphical models or structures can be transferred into executable code with little effort. Requirements of this type of code, such as the avoidance of floating point operations or the definition of application accesses, can thus be implemented easily. Further benefits include direct consistency between the simulation model and the related code.

4.2.2 Concept

Core requirements of the architecture or the software concept are reusability and simple maintenance. This is guaranteed by a modular structure. At the same time, high reusability increases the degree of maturity of the functions. If attention is given to good maintainability from the beginning of development, this ensures that existing functions can be extended without problems. The example

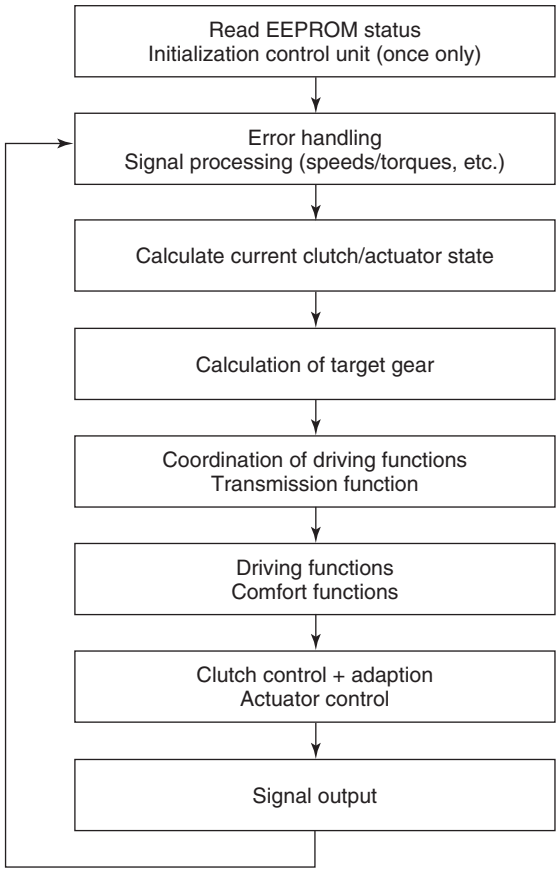

Figure 11. Signal flow diagram of the actuation of a double clutch transmission. (Reproduced with permission from Schaeffler.)

of a signal flow diagram for controlling a parallel shift transmission in Figure 11 illustrates the principle structure of the software and its main functions.

4.3 Function modules

A distinguishing feature of modular function concepts is that certain functional tasks are clearly assigned to certain functions or software modules. Therefore, we can describe the functions of an automated transmission using individual function modules.

4.3.1 Gear selection strategy

Automatic or automated transmissions usually have six to nine gears. Therefore, one of the basic functions is to select a suitable gear that best corresponds to the driver input. This task must also be seen from the perspective that the large gear spread often provides the possibility of realizing one and the same driving situations in different gears.

A sensible or appropriate driving gear is oriented not only around the engine speed range defined as permitted but also around the demands of the driver with regard to dynamics and operating efficiency. Both aspects can be determined by evaluating driver actions on the accelerator pedal, brake, selector lever, or—depending on the equipment—shift paddle. One simple option is to define the shift points on a gear-specific basis via the accelerator pedal angle and the driving speed. In many concepts, this basic information is refined via dynamic driver recognition, the incorporation of GPS data, and the recording of other environmental conditions such as traffic density. As a consequence, the determination of the correct driving gear or the operating strategy has become a defining feature of vehicle brands. The situation is similar for the preselection gear that is engaged on the inactive shaft. Company-specific different concepts are also effective here.

4.3.2 Coordination and protection functions

The appropriate driving function must be selected based on the driving situation and the corresponding target gear. This selection is made in a central coordination function that also guarantees that the clutch and transmission controls act in alignment with each other. In parallel to this coordination, relevant monitoring functions ensure that there is no damage to the transmission hardware or other operating-relevant functions. For example, a hill-start situation with the foot brake applied is interpreted as misuse. A reducing engine torque intervention can signal to the driver that this state can damage the vehicle. Further optical, haptic, or acoustic signals to the driver are possible.

4.3.3 Driving functions

A whole range of driving functions are available for an automated transmission. These range from creep functions, launch and driving functions, and the shift function to stopping functions. They are supplemented by efficiency functions such as start–stop systems and coasting functions.

A central function for DCTs is a shift operation with no interruption in tractive power. This must be realized quickly and with comparable comfort to that of an automatic torque converter transition. As an example for the various shift types, Figure 12 shows a shift under traction from first to second gear. Owing to high driver sensitivity at low speeds and the typically high gear spread, this transmission stage is vitally important.

The shift contains the following phases: in phase 1, any existing excess torque on the clutch is reduced and driving takes place specifically with slight clutch slip of

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

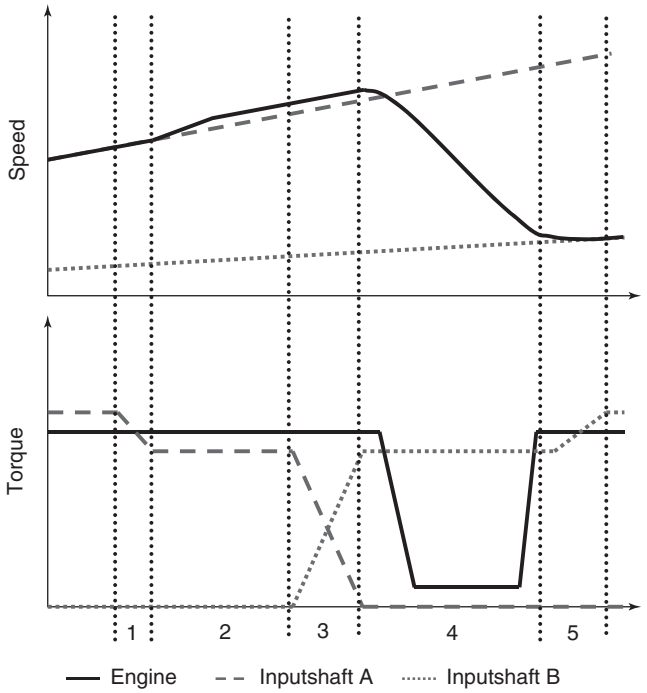

Figure 12. Shift phases (example upshift). (Reproduced with permission from Schaeffler.)

approximately 10–20 rpm. This means that the clutch torque transferred can be determined relatively precisely before the shift begins. This precision is helpful for the subsequent torque transfer.

Provided the required target gear has already been preselected, phase 2 is not necessary. If this is not the case, there is a waiting period until the required target gear is actually engaged. In phase 3, there is then an overlapping in which the clutch torque is overlapped in ramp form from the outgoing to the incoming clutch. This torque overlapping phase cannot be perceived by the driver. It is important that the total torque corresponds to the respective driver input torque. This total torque is adjusted accordingly for accelerator changes during the shift. The torques of the outgoing and incoming clutch can be corrected by observing the clutch slip during this time.

In phase 4, the speed is finally adjusted to the target gear. This generally takes place via an engine intervention. Reducing the engine torque results in a corresponding reduction in engine speed. Therefore, this phase can be perceived as a shift acoustically and optically on the rev counter. The engine intervention is withdrawn promptly before the engine speed approaches the target shaft speed. In this context, the difficulty for the control system is that at the end of the speed adjustment phase, the clutch torque must match the engine torque and the engine speed must be close to the transmission input speed. The result is that the engine speed runs gently into the target shaft speed. In phase 4, an additional boost torque can be set on the clutch. This provides the impression of acceleration during the shift. In phase 5, the clutch moves to excess torque again.

4.3.4 *Comfort functions*

Dry automated transmission systems are highly efficient. However, this advantage is generally at the cost of lower transmission damping properties. In order to still achieve high driving comfort despite this, additional comfort functions must be provided. These include a controlled isolation system. In applications with no dual mass flywheel, this ensures that in certain operating ranges in which strong engine excitation would occur, a minimal slippage leads to a decoupling of vibrations. Slippage values of 10–30 rpm are typical for this operating range. In transmission systems with dry clutches, the effect of partial slippage damping is used for this.

A further measure for increasing comfort is the use of a load-reversal damping function. This is implemented such that the clutch torque is slightly greater than the engine torque in driving operation. In the case of an abrupt loadchange, for example, due to sudden acceleration, the excessive powertrain torques that occur are reduced by short-term slippage. This function supplements the load switch damping of the engine control unit.

In certain cases, judder of the clutch can occur in automated transmissions. This judder can be both geometric and friction-induced judder. To dampen both types, damping functions are being developed that lead to a reduction in the vibration amplitudes through a corresponding modulation of the clutch torque.

4.3.5 *Hardware-related functions*

The hardware-related control functions ensure that the transmission actuating mechanism is controlled reliably and such that it can be reproduced. In clutch control, the actuator is controlled in accordance with the adapted clutch characteristic curve. Depending on the clutch type, corresponding compensation in the sense of pilot controls can be executed. In a typical case, for example, speed or temperature effects are compensated in whole or in part. Selected points on the clutch characteristic curve in Figure 13, such as the touch point/bite point and frictional coefficient, are adapted. The touch point can take place both via the evaluation of torque balances and via the evaluation of changes in speed on the inactive shaft.

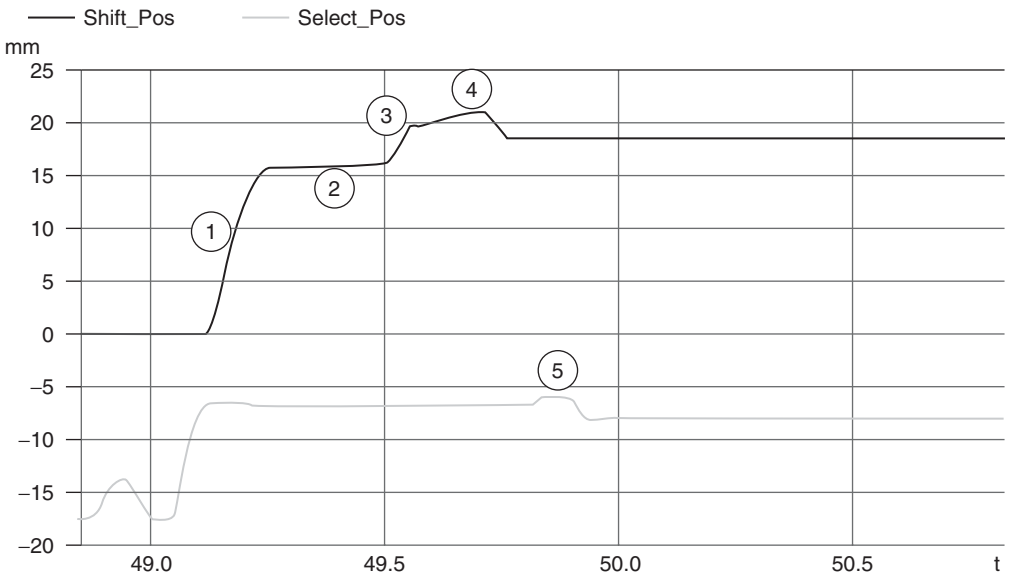

Figure 14. Actions in the transmission when engaging a gear. (Reproduced with permission from Schaeffler.)

In the same way as the shift operation already described, Figure 14 describes the actions required in the transmission when the second gear is engaged.

In the initial state, the second subtransmission is in neutral. In a first step (1), the switching finger is moved to the synchronous position. This takes place at a controlled speed, whereby the speed is reduced before the adapted synchronous position is reached.

The speed is also controlled during the synchronization phase. However, an upper force limit must not be exceeded.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto104
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

As soon as the synchronization has taken place, the gear stop position is approached with position control (3). To verify this position, a sensing operation takes place in the shift direction to check or correct the adapted values.

As incremental sensors are generally used for cost reasons, it is important to check the reliability of this actuator position. This degree of reliability is reduced, for example, if the sensors detect a Hall error or an unexpected blockade situation. Depending on the operating situation, after this type of reduction in reliability, a validation of the transmission position is requested via referencing.

A further hardware-related function is the actual actuator control. With actuators with electric motors, movement is generally in a position-controlled or speed-controlled state. With hydraulic valves, a current-controlled or position-controlled mode is generally used. Depending on the actuator concept, a voltage-controlled mode can also be used for switching valves, for example.

4.3.6 *Safety concept*

To prevent critical operating states from arising, a safety concept for transmission control systems is state of the art. This is based on the requirements of ISO 26262. The aim is to ensure, for example, that the vehicle cannot start driving itself, that is, a clutch torque build-up is prevented if no driver presence is safely detected.

4.3.7 *Diagnostics concept/error handling*

Error handling is often based on a modular, generic concept, whereby the error variables in the sense of DTCs (detection trouble codes) are limited to a few error routines. A majority of the DTC routines are typically used for all vehicles (DTCs for engine signals or actuator errors).

In many cases, there is a differentiation between customer-specific and customer-independent routines in the signal recording routines. The aim of this is to ensure that no unnecessary overhead is created. When an error is detected, a corresponding status bit is usually set so that the driving/comfort functions that access it can access corresponding replacement values. Replacement strategies only have to be used in exceptional cases, for example, if certain signal information or hardware components are no longer available.

4.3.8 *End-of-line routines*

To ensure that automated transmissions drive reliably and comfortably at all times from the beginning of production, certain transmission-relevant parameters are adapted during the production process. Special end-of-line routines learn these parameters. These routines can also be used subsequently for teaching in a garage if, for example, hardware components have been replaced.

4.3.9 *Hardware drivers*

To control the corresponding actuators (electric motors, valves, etc.), the control unit on which the software is operated must have corresponding hardware drivers. Often, valve drivers are used that generally modulate a high frequency voltage. The self-adjusting currents are actuator-dependent and range from just a few amperes up to 100 A. At high currents in particular, this represents a high demand on the load capacity of the vehicle electrical system. This is one of the reasons why vehicle electrical systems are subject to permanent further development.

5 TECHNOLOGY DRIVERS FOR FUTURE DEVELOPMENTS

In Europe, the general trend toward automation and the availability of the manual transmission as a basic technology have led to intense developments in recent few years, in particular for DCTs. If the automated forms of manual transmission are also to continue to expand and compete with classic automatic transmissions, however, further improvements must be implemented in the areas of efficiency (including weight and mounting space), comfort, and costs. The same applies for the start/stop capability and the capacity of the systems for hybridization. The actuating mechanisms of these transmissions always play a key role. This leads to the technology drivers listed below for the actuating mechanisms.

To reduce the power input of the actuating mechanisms, on-demand systems will prevail. These are systems that adapt their power input to the required actuator power. In the case of hydraulic actuators, this means that the pumps must be controlled on a demand basis. Furthermore, the leakages must be reduced by reducing the gap and/or the nominal working pressure. In the case of electromechanical actuators, nonlinear ratios offer a starting point for reducing the base powers and thus enabling the construction of servo motors (including the electronic power unit) that are smaller and thus more efficient.

However, in order to construct these smaller and more efficient servo motors, the degree of integration must increase further. For electromechanical actuators, this means that additional mechanical functions will be used in an attempt to reduce the need to install electric motors. It is also to be expected that the mechatronic system components engine, control unit, sensors, and mechanics

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

will be integrated more deeply. In a further step, it may even be possible to integrate the clutch actuating mechanism in the clutch. These types of solutions are currently being investigated based on dry double clutches.

One very important cost driver for DCT actuating mechanisms are rare-earth materials. These materials are used for magnets with high power density for sensors, electrohydraulic valves, or electronically commutated electric motors. The market prices for rare earths have risen exorbitantly in recent years. Therefore, motors that use as little magnetic material as possible are increasingly being used. Sensors that can be constructed without this magnetic material are also being developed. Further cost reductions for sensors can be achieved through standardization and integration in the TCU (transmission control unit). Furthermore, more intelligent software should reduce the number of sensors used. However, it is not just the electronics that are cost drivers—the mechanics and hydraulic modules are also cost drivers. For these modules too, attempts must be made to reduce costs via standardization or module solutions and thus an increase in quantities.

Current development efforts around increasing comfort, additional functions, hybridization, and start–stop capability place additional requirements on the performance and functionality of the actuating mechanisms. Initially, this means that the TCUs and in particular, their controllers, are becoming more powerful. However, for functional enhancements, additional actuator elements for controlling the additional control elements, for example, of hybrid clutches are required. This will increase the complexity of the actuator system. For start/stop and hybrid operation in particular, actuators are required that can be operated independently of the combustion engine. At least one energy storage device must be provided to allow actuator operation to restart the engine.

However, the greatest challenge is in covering the increasing complexity through increasing performance requirements and the reduction of cost, weight, and mounting space.

AT Control—Actuation Methods and System Integration, Gear Choice, Gear Shift Strategy and Process, Adaptive Features

Takashi Shibayama
JATCO Ltd., Fuji City, Japan

1 INTRODUCTION

In order to understand the basic concept and outline of AT control, the following topics are discussed. Torque converter clutch control, idle neutral control, idle stop control, and launching clutch control are also briefly discussed in this chapter.

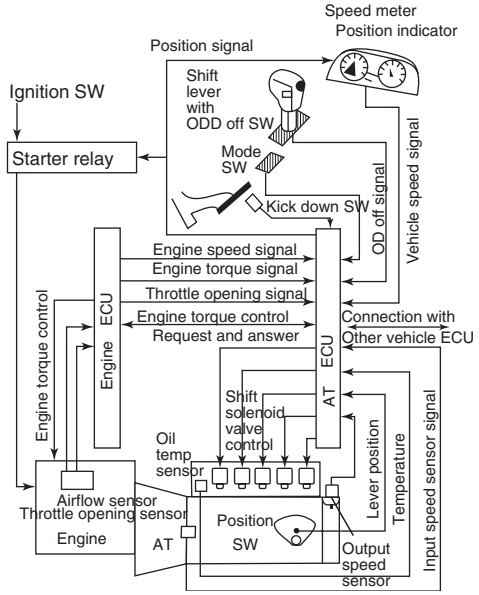
2 AT CONTROL SYSTEM

Figure 1 shows a typical AT control system that has several sensors, actuators, and communication interfaces. The most important sensors are speed sensors by which the AT ECU (electronic control unit) can detect gear ratio, slip ratio of the torque converter, vehicle speed, etc. (Shinohara *et al*., 1989) The AT ECU makes gear ratio changes by detecting vehicle speed and engine throttle opening, according to the predetermined shift schedule. The position sensor is used for changing shift schedule for L range, sensing R range, etc. Most AT control systems include a kick down switch for detecting the driver's intention for rapid vehicle acceleration and selecting a lower gear ratio to maximize performance. The intake airflow sensor of the engine is used for calculating engine crank shaft torque, which is very important for providing the proper hydraulic pressure to control shift smoothness and preventing unwanted slippage of the friction clutches and brakes. A temperature sensor is used for detecting ATF temperature, which is an important parameter for maintaining consistent shift feel at varying operating temperatures. The sensor can also be used to detect over heating situation and initiate a "fail safe" mode to protect the transmission from damage. Also for low ATF (automatic transmission fluid) temperatures, like just after engine starting, some adjustment for the ATF viscosity change can be compensated by this sensor.

The table in Figure 1 shows typical devices used for AT control. Communication between the engine and the AT is essential to ensure smooth and quick shifts. During shifting, engine torque control is very effective to improve shift



Category	Device	Major act of the device
Sensor	Engine speed sensor	To detect torque converting slipping ratio
	AT input speed sensor	To detect gear ratio of AT
	AT output speed sensor	To detect gear ratio of AT
	Vehicle speed sensor	To detect wheel slip
	Position sensor	To detect P.R.N.D.L opening range
	OD off SW	To inhibit over drive range
	Mode SW	To switch mode, for example, economy or sporty
	Kich down SW	To detect driver's high intention for acceleration
	Engine throttle opening	To detect driver's intention for acceleration
	Engine airflow meter	To detect engine output torque
	Temperature sensor	To detect AT oil temperature to know viscosity of oil
	Other sensor	It depends on the purpose of some additional special control For example, hydraulic pressure sensor, SW, g sensor, ect.
Actuator	Solenoid value	To execute AT shifting by controlling hydraulic pressure
	Engine torque adjusting device	To adjust engine torque during AT shifting
	Indicator lamp	To indicate P.R.N.D.L range status to driver
	Starter relay	To allow engine starting during P.N range only
Communicater	Engine - AT communicator	To agree engine torque adjust during AT shifting
	Other vehicle ECUs - AT communicator	To make communication with ADS, ASCD, NAVT, ect. for some additional special control
	*Recently, both above communications are usually done by CAN network	

Figure 1. A typical AT control system. (Reproduced by permission of Jatco, Ltd.)

quality. Finally, the vehicle CAN network enables good communication with other vehicle ECU's such as ABS (antilock brake system) and NAVI (automotive navigation system). The AT ECU can even change shift schedule by watching this information.

3 AT SHIFT CONTROL PROCEDURE

Figure 2 shows a typical 1 to 2 shift control process. The AT ECU calculates vehicle speed based on output speed sensor signal and calculates throttle opening based on

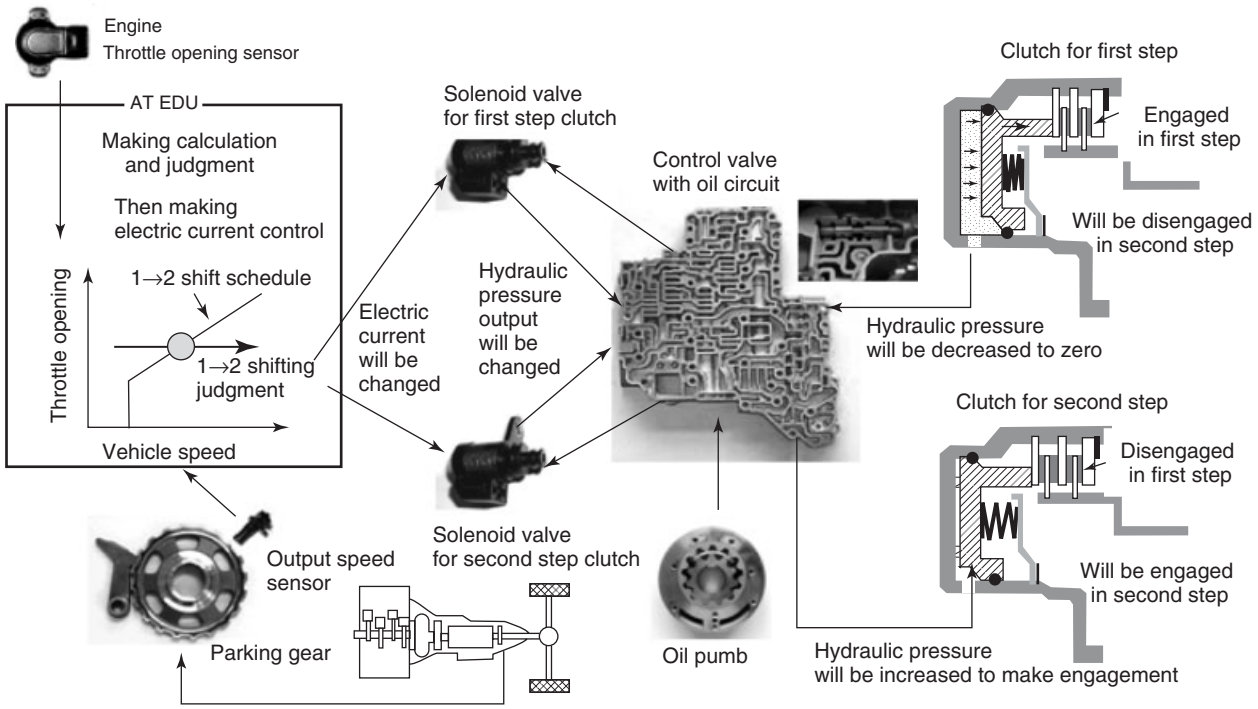


Figure 2. A typical 1 to 2 shift control process. (Reproduced by permission of Jatco, Ltd.)

throttle sensor signal. During acceleration, vehicle speed will increase and when the speed exceeds the 1 to 2 shift line, the shifting decision will be made. Then, the AT ECU will change the electric current of solenoid valves, thereby changing their hydraulic pressure output. This hydraulic pressure output from the solenoids is then directed through the oil circuit in the control valve body to the shifting clutches. By this process, first clutch status will be changed from engagement to disengagement, whereas second clutch status will be changed from disengaged to engaged.

4 BASIC CONCEPT OF AT SHIFT SCHEDULE DESIGN

For making an adequate shift schedule, designers have to understand the torque converter characteristics. Figure 3a shows the conversion characteristics as a function of throttle opening. A throttle opening of 8/8 is the widest opening, and 0/8 is the idle condition. By its hydraulic conversion characteristics, the torque converter will produce a high output torque when the vehicle stationary similar to that of an electric motor.

This torque converter output torque forms the input torque to the transmission gear train that consists of planetary gears and clutches to make several shift steps as discussed in (see Automatic Transmissions—Geartrain Combinations, Components, Design Considerations, Hydraulic System, Packaging, Manuf., Assembly). Figure 3b shows the gear train conversion characteristics, in the first step and second step as an example.

Now, as an example, consider design for a 3/8 throttle 1 to 2 shift point. As is shown in Figure 3c, there is a difference in output shaft torque between the first step and the second step. In the first step, the torque is high initially but quickly decreases as engine speed and output speed. On the other hand, in the second step, a higher speed is available but the output shaft torque continues to decrease. It becomes obvious that the cross point is the best shift point to provide the most powerful acceleration. Figure 3d shows the cross point shifting schedule strategy.

Upshift schedules are investigated considering the above-mentioned cross point. Figure 3e shows a typical first to second upshift schedule. In addition, Figure 3f shows a typical upshift schedule. Here, throttle opening is popularly used for calculating engine torque as well as detecting the driver's acceleration intention. Vehicle speed is used instead of output shaft speed, which is more apparent when the test driver test drives a vehicle.

Figure 4 shows various shift schedule adjustment issues. Figure 4a shows adjustment for shift feeling improvement avoiding hesitation or harsh shift. Actually, the shift schedule is usually set before the cross point, because deviation torque caused by engine inertia energy has to be considered to avoid harsh shift during shifting.

During 1 to 2 shifting (or any upshift), as engine speed goes down, an inertia torque is generated because of the change in engine rotational speed. The additional torque is added onto the second gear output torque as shown in the figure. Thus, it is popular to set shift points a little bit before the cross point. Figure 4a shows a typical upshift point design concept.

Figure 4b shows downshift schedule adjustment to avoid busy shift. As is shown in the figure, usually the hysteresis between upshift and downshift is provided. This hysteresis is necessary to guard against frequent up- and downshifting at or near the shift line with slight throttle opening changes. Such frequent up- and downshifting is called *busy shift* or *shift hunting*, which is most often seen when going up a grade or hill.

The right side of Figure 4b shows an example of such busy shifting risk. In the figure, road load line is added, for example, 0% road load, 3% road load, and 6% road load. As is shown in the figure, a wider throttle opening is required on a steeper hill, in order to maintain a fixed vehicle speed. On a steep hill, the greater throttle requirement to maintain vehicle speed can easily place the throttle in between the upshift and downshift lines. A slight movement of the accelerator pedal can trigger a downshift or upshift repeatedly. Greater hysteresis can minimize this shift busyness or hunting. This greater hysteresis enables wider throttle opening before a downshift is triggered and also tends to inhibit upshifting until hill climbing is over.

Fuel economy is another important issue for shift schedule adjustment. Figure 4c shows the fuel economy map of an engine. There exists an optimal operation point for fuel economy. Therefore, designers always check their shift schedule to aim at frequent usage of this optimal area. Sometimes, the investigation result tells the designer to use a higher engine speed to get good fuel economy. However, it depends on characteristics of the engine. Usually, a low engine speed is good for fuel economy.

Shift schedule adjustment for wide throttle opening is another important issue. When the throttle opening is wide, the driver is asking for good acceleration; therefore, in a wide throttle opening condition, acceleration performance gets priority. On the other hand, in the small throttle opening area, fuel economy is most important. Therefore, such investigations using engine fuel economy maps are often done for the small throttle opening area.

In actual traffic, drivers sometimes want to make full power acceleration utilizing engine max power. For such a purpose, a kick down area is usually adopted. There

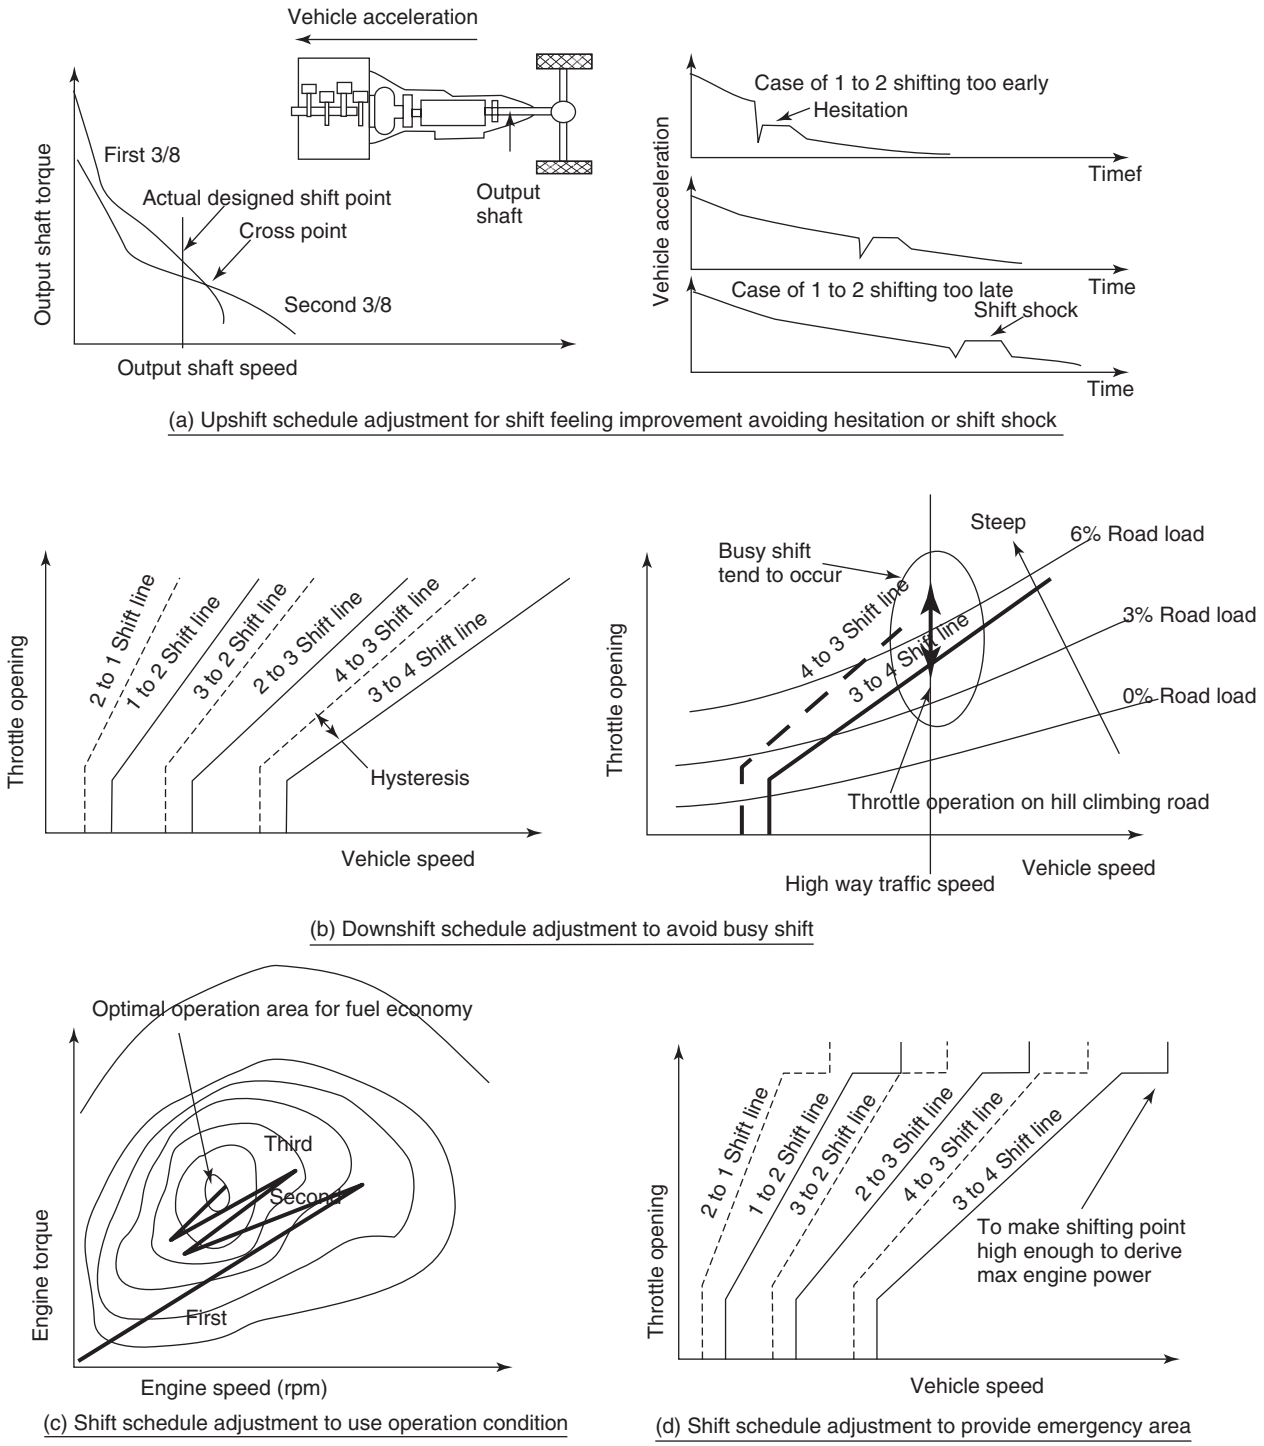

Figure 4. (a–d) Various shift schedule adjustments. (Reproduced by permission of Jatco, Ltd.)

are two ways to accomplish this: one is to watch only throttle opening. The other one is to facilitate a kick down detecting switch, which has some resistance force (or "detent" feel) to push on. By the resistance force, the driver can notice where the limit of normal control is and from where kick down control begins. The switch is a convenient device for drivers, some systems make a clicking sound when the switch is stepped on, thereby providing feedback

information to the driver. Once the kick down area is entered, down shifts will be made as available as possible, and engine max power operation can be achieved. Figure 4d shows such a shift schedule with kick a down area.

As discussed earlier, basic concept of AT shift schedule design has three important points of view.

(i) Driving PowerAbility of obtaining good acceleration performance and keeping vehicle speed without busy shifting. In emergency conditions, max power can be derived.
(ii) Fuel EconomyPossibility to use optimal engine operation point.
(iii) Shifting SmoothnessTo consider adequate shift timing to avoid hesitation and shift shock.

5 VARIOUS ADDITIONAL CONTROL FOR AT SHIFT SCHEDULE

There are various additional shift schedule controls; Figure 5 shows variations (Yamaguchi *et al.*, 1994; Petersmann, Seidel and Moellers, 1990; Stebar *et al.*, 1990).

6 CONTROL FOR GOOD AT SHIFT FEELING

During gear shifting, especially, during upshifting, fluctuation on output torque will be caused as is shown in Figure 6. Just after shifting has been started, clutch capacity for high

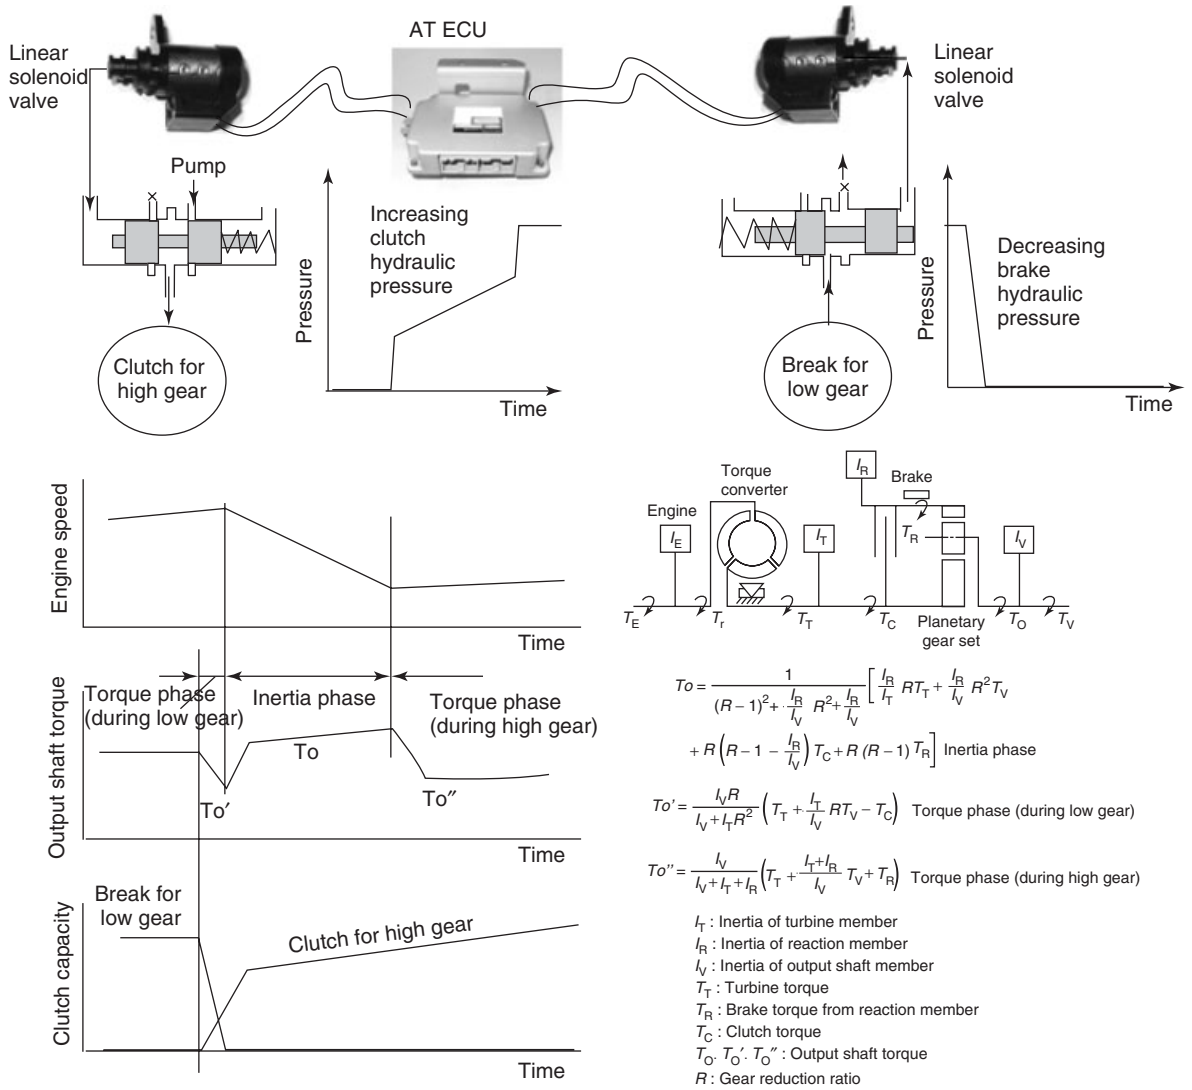

Figure 6. A typical upshift feeling control system. (Reproduced by permission of Jatco, Ltd.)

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

gear will increase, and by that increase, conflict (or "tie up") between the clutch for low gear and the brake for high gear will be caused. By the conflict, output shaft torque will be temporarily decreased, this period is called *first-torque phase*. Then, engine speed will go down and additional output torque, caused by an inertia torque generated because of the change in engine rotating speed, will be added. This period is called *inertia phase*. Finally, shifting will be completed and "second-torque phase" will come. For shift control, it is very important to control such torque fluctuations. If the fluctuation is too large, drivers feel it as harsh shift. Harsh shift can be prevented by precise control of clutch capacity.

The output shaft torque To, To′, To' can be calculated by theoretical calculations, as shown in Figure 6 (Society of Automotive Engineers, 1962). As is shown in the theoretical output torque formula, the output shaft torque is influenced by clutch torque capacity. In other words, output torque can be controlled by precise clutch capacity control. Referencing this theory, an AT shift control system is "controlling the engaging clutch hydraulic pressure, and the disengaging brake pressure precisely, to obtain expected torque fluctuation wave form." The solenoid valves and ECU provide this pressure control.

Proportional solenoid valves are often adopted for such precise clutch hydraulic pressure control. Output pressure is almost linear in relation to the electric current going through the solenoid.

During shifting, the AT ECU provides electric current control to the solenoids, in order to obtain adequate increasing hydraulic clutch pressure (Wilfinger and Thompson, 1988).

This increasing hydraulic pressure is very similar to the gradual clutch engagement of a manual transmission. A driver of a manual transmission is making similar control to obtain smooth shift feeling.

In actual calibration, optimal pressure control is derived empirically. Figure 7 shows the calibration methodology (Shinohara *et al.*, 1989).

If clutch pressure increases suddenly like case 1, harsh shift will result. On the other hand, if clutch pressure increases too slowly or at too low a level like case 3, shift duration will become too long, thereby providing a slip feeling. The calibrator watches and evaluates shift feel and decides on optimal pressure shape.

Such calibration is executed at first on the test bench with a dynamometer using the transmission and engine only. After test bench calibration has been completed, final calibration using an actual vehicle will be executed.

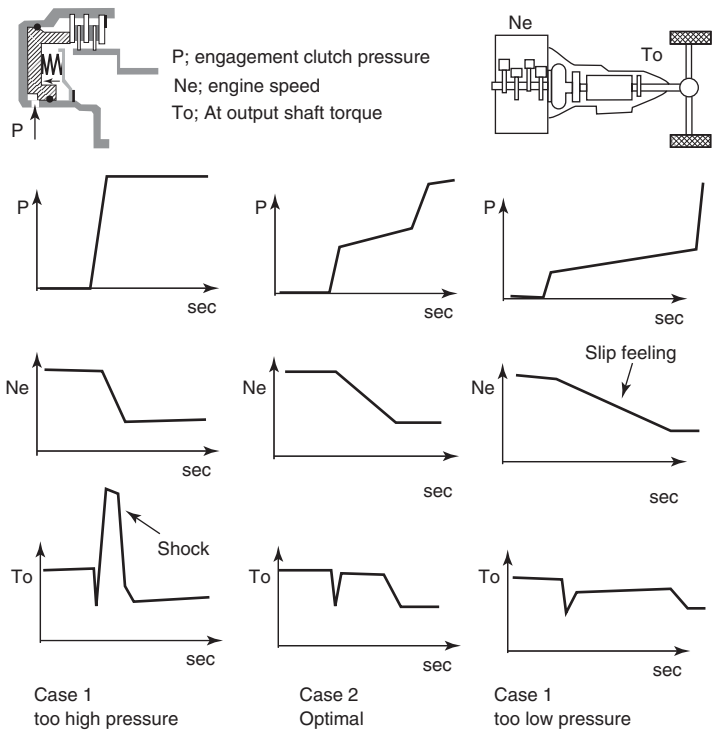

Figure 7. Clutch pressure calibration methodology. (Reproduced by permission of Jatco, Ltd.)

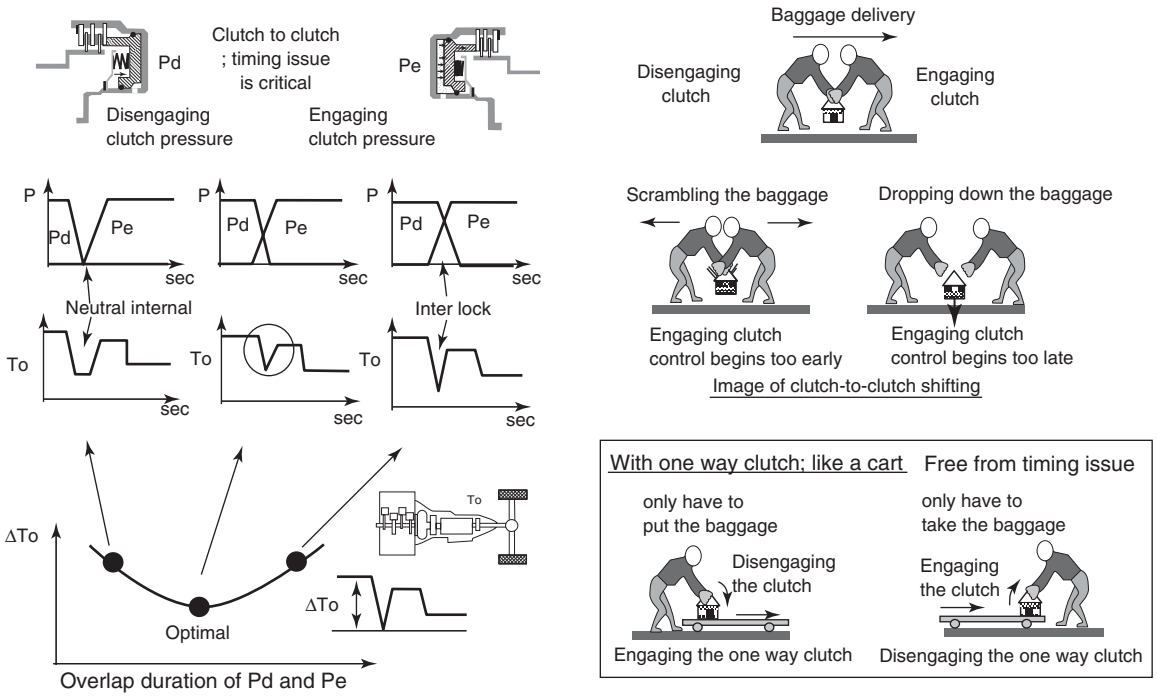

Figure 8. The usefulness of the one-way clutch for the shift feeling control. (Reproduced by permission of Jatco, Ltd.)

In vehicle calibration, calibrators evaluate not only harsh shift but also quickness, response, time lag, engine sound changing feeling, etc. All factors that drivers may notice will be checked.

If a one-way clutch is adopted, such calibration is very easy. Shift control has to be achieved using the engaging clutch. However, if a one-way clutch is not applied, shifting control becomes more difficult. Clutch-to-clutch shifting control has many difficulties.

Figure 8 shows the image of such difficulty of clutch-to-clutch shifting control and the usefulness of the one-way clutch. Clutch-to-clutch shifting is like baggage delivery from one person to another person (Society of Automotive Engineers, 1973). Timing is critical. If engaging person begins his work too early, conflict may happen. On the other hand, if engaging person begins his work too late, the baggage will drop down to the ground. This is the difficulty of clutch-to-clutch shifting control.

With a one-way clutch, the delivery is like using a cart. Disengaging person only has to put the baggage on the cart and engaging person only has to take the baggage from the cart, so, shifting control becomes free from timing issues. This is the reason why many ATs adopt one-way clutches. If a one-way clutch is eliminated, cost and space will be saved, but shifting control becomes much more difficult.

However, with recent remarkable improvements of hardware and software, clutch-to-clutch shifting control is becoming more widely used, the evolution of control technology has conquered the difficulty of clutch-to-clutch shifting control.

Cutch-to-clutch shifting control calibration is shown in Figure 8. Calibrators search for the best timing to obtain minimum fluctuation of transmission output torque. Beginning of disengaging clutch pressure decrease and beginning of engaging clutch pressure increase timing is critical. Both neutral interval and interlocking causes large output torque fluctuations. The fluctuation will be minimal at optimal timing control. With optimal control, the fluctuation of output torque will become almost the same as that of one-way clutch shifting.

There are many control approaches to make optimal pressure control.

Time Table Type. Making a timing table for various shift conditions

Sequence Control Type. Facilitating pressure sensor or pressure sensing valve that detects pressure movement.

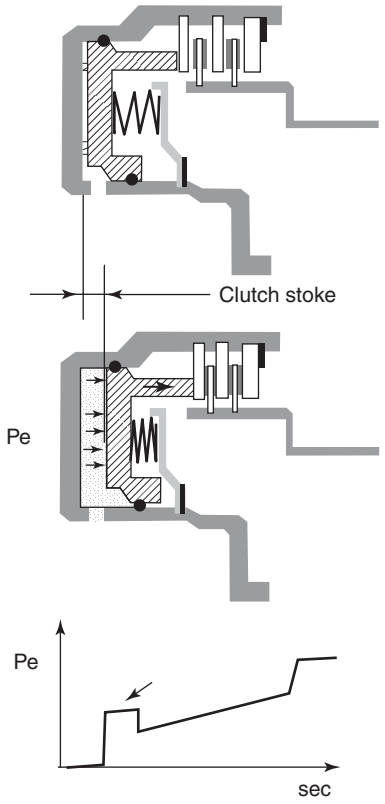

Figure 9. Precharge control to reduce time lag. (Reproduced by permission of Jatco, Ltd.)

Adaptive Learning Control Type (Narita, 1991). Watching engine speed carefully and making slight pressure adjustments for subsequent shifts.

Real-Time Feedback Type. Watching engine speed or pressure carefully and making real-time adjustment.

In actual control, the time lag caused by clutch stroking taking up free play is an important factor to consider. To reduce the time lag, precharge control is sometimes adopted. Figure 9 shows the precharge control. Until clutch piston stroke is over, the controller keeps clutch inlet pressure slightly high, and by this high pressure, large oil flow into clutch pressure chamber can be obtained.

The precharge control is especially important for garage shifting (N to D and N to R selector movement) control. Because the time lag is an important evaluation point, the controller has to reduce time lag by prestroking the clutch as much as possible.

However, the slightly high pressure becomes harmful if high pressure remains after clutch stroking. The remaining high pressure to the piston will result in harsh shift feeling.

Therefore, duration of precharge should be kept to an optimal time length by adopting some adjusting control: for example, constant map for various conditions or some adaptive learning control. Here, the influence of oil temperature is very large. At low temperatures, viscosity of the ATF is high, so precharge duration should be longer: for example, garage shifting control just after engine starting in winter.

7 ENGINE—AT INTEGRATED SHIFTING CONTROL

During AT shifting, the engine speed has to change to adjust its speed to the next gear position. During upshifting, the engine speed goes down, and during downshifting, engine speed rises up. Engine-AT integrated control can assist with this engine speed change. During upshifting, the engine ECU reduces engine torque to help engine speed going down, and during downshifting, the engine ECU increases engine torque to help the engine speed to increase. This is the basic concept (Kondo *et al*., 1990).

As discussed in Section 5, transmission output torque is related to engaging clutch torque capacity and turbine torque. Therefore, if engine torque makes a change, then transmission output torque will be affected. For the integration control, the detail design is investigated considering the theoretical formula described.

Figure 10 shows detail for engine-AT integrated control. By reducing engine torque during upshifting, shift duration can be shortened and the heat generated on the friction material in the engaging clutch can be reduced. Shift feeling is improved to have quick, sharp feeling, and durability of friction material can also be improved. Therefore, this integrated control has become very popular for AT shifting control.

Recently, throttle control of the engine has been improved greatly by introducing electronic throttle control. By this new system, the engine ECU can increase its output torque during downshifting. This is very effective in making the down shift feel quick and sharp. Therefore, many ATs with manual shift control for sports cars adopt this control to produce quick and sharp shifts.

Engine torque control is effective for not only helping the engine speed change but also preventing sudden torque rises during downshifting. The right side of Figure 10 shows integrated control during downshifting. By temporarily reducing engine torque, the sudden rise of driving force can be prevented and harsh shift can be avoided.

8 EXAMPLE OF DETAIL TIME CHART FOR SHIFTING CONTROL

As for typical upshifting and downshifting, a detailed timing chart for shifting control is described in Figure 11. Examples are clutch-to-clutch shifting, second to third upshifting on the left, and third to second downshifting on the right.

9 OTHER AT CONTROL

As the final section of this chapter, other AT control functions are described.

Figure 12 shows various other AT controls

9.1 Torque converter lock-up control

In order to improve fuel economy, the torque converter is locked up during cruise driving. At low vehicle speeds, "controlled slip" control is often adopted. By this slip control, lockup clutch facing material is slowly slipped around 20–70 rpm. Vibration coming from the engine can be filtered by the slight slipping and that slip control produces a much lower loss than the normal "open" torque converter without lock-up slip control. This control is also done with solenoid valves and hydraulic valves as is shown in Figure 12a. The control device is similar to that of shifting control. For slip control, feedback control is adopted watching converter slip speed detecting engine speed and turbine speed.

9.2 Idle neutral and idle stop control

Recently, idle neutral control and idle stop control have become popular because they help to improve fuel economy significantly. In D range stop condition, the engine increases fuel consumption to prevent engine stall, owing to the resistance load of the torque converter imparting drag on the engine. To reduce such loss, idle neutral or idle stop control is adopted.

This control is applied in a very narrow area. Figure 12b shows applied area of idle neutral control. It is applied in the condition of vehicle almost stopping and throttle opening is almost zero. Clutch pressure for forward is released and the clutch is disengaged.

In preparation for after the traffic signal turns green, clutch pressure is set at a slight pressure level to keep the clutch piston prestroked. Subsequent pressure increase to the clutch provides drive torque capacity to enable no-delay drive-away. This is the key point of this control. The pressure increase needs to be carefully calibrated to minimize output torque disturbance, which can be noticed particularly in start/stop city traffic.

For idle stop control, an electrically driven auxiliary pump is sometimes adopted, because oil pressure becomes completely zero during engine shutoff. Therefore, to realize quick recovery of forward clutch engagement, auxiliary pump oil pressure is utilized.

Figure 12c shows such system with an auxiliary electrically driven pump. A check valve is installed into the oil circuit and this valve will open if main pump pressure goes close to zero and the auxiliary pump pressure is increased.

9.3 Launching control by multiplate wet clutch

AT used for large Displacement engine or AT for hybrid systems, the torque converter is sometimes eliminated. Instead of a torque converter, a multiplate clutch is used as a launching device as is shown in Figure 12d. Control devices and method are similar to normal shifting clutches. These launching clutches have to endure high speed slipping conditions, so heating energy into the friction clutch plates is a critical issue, especially during hill climbing or traffic jam conditions. The clutch has to provide a creeping force for sustained low speed driving up the hill. Large heat generation is caused by such long duration slipping. Thus, in this system, an effective lube cooling system for the clutch is a necessity to protect the friction clutches.

Engine/Transmission Matching

Gabriele Virzi' Mariotti
Universita' di Palermo, Palermo, Italy

1 VEHICLE LOAD CALCULATIONS

1.1 Introduction

A vehicle in motion with a possible trailer has to overcome forces that are named *motion resistances*. As motion can take place, the engine has to be able to generate an equal and opposite force to the resistances instant for instant.

Motion resistances vary with the vehicle kind and as a function of the road; moreover, they depend on hills or curves, in the instantaneous direction of the motion. To compare the motion resistance of several vehicles, they can be referred to the unitary weight (specific resistances r expressed in newtons per kilonewton). In the case of towing, they are distinguished as resistance to the wheel periphery and the hook resistance.

1.2 Road loads

Motion resistances are subdivided in two classes (Stagni, 1980; De Gregorio, 1970):

- accidental road loads and
- ordinary road loads.

In general, they are a function of the speed. Knowing the speed v and the weight P, and determining the single resistances, the total value of the resistance can be calculated as

$$R_{\text{tot}} = P \cdot \sum r \tag{1}$$

This value has to be equal to the traction load T generated by the engine and applied to the wheels:

$$T = R_{\text{tot}}\,[\text{N}] \tag{2}$$

The power furnished to the wheels is given by

$$N_{\text{w}} = \frac{T \cdot v}{3600}\,[\text{kW}] \tag{3}$$

with v the vehicle speed in kilometers per hour. The horse power is given by

$$N_{\text{w}} = \frac{1000}{750 \times 3600} \times T \cdot V = \frac{T \cdot v}{2700}\,[\text{hp}] \tag{4}$$

Power to weight ratio means the power of the vehicle for every kilonewton of weight.

1.2.1 Accidental road loads

1.2.1.1 Hills and towing. Indicating the angle of inclination of the road with the horizontal by α, the added load due to the hill is $P \cdot \sin\alpha$. The slope of the road is given by (Figure 1)

$$\tan\alpha = \frac{h}{l} = \frac{i}{100} \tag{5}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

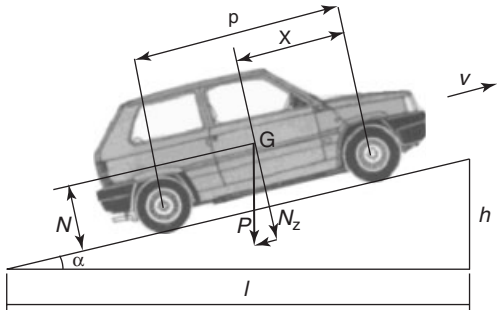

Figure 1. Loads in hill and vehicle size.

i being expressed in percent. One has

$$N_z = P \cdot \cos\alpha$$
$$T = P \cdot \sin\alpha \tag{6}$$

Because the road slope does not exceed 10–15%, $\sin\alpha \approx \tan\alpha$, so the hill resistance is

$$R_h = P \cdot \sin\alpha \cong P \cdot \tan\alpha \quad \text{or} \quad R_h = \frac{Ph}{l} \tag{7}$$

The specific resistance is

$$r_h = \frac{R_h}{P} = 1000 \cdot \tan\alpha \quad [\text{N/kN}] \approx 10i \tag{8}$$

With a steep road, the reaction of the ground becomes $N_z = P \cdot \cos\alpha$; this influences the evaluation of the rolling resistance (Section 1.2.2.1), which is also influenced by the tire stiffness. If the road is slopping down, gravity gives a favorable component to the motion and the resistance has a negative value.

A vehicle can overcome the maximum hill resistance at the adhesion limit under the following condition:

$$10i \cdot P \leq 1000f \cdot L \tag{9}$$

where f is the adhesion coefficient and L [kN] is the adhesion weight, that is, the vertical load on the driving wheels; 1000 is a factor to regulate the measurement unity. In general, the traction load $T = 1000f \cdot L$, but if L is equal to P [kN] like in a four-wheel-drive (4WD) vehicle, the traction load assumes its limiting value

$$T = 1000f \cdot P \quad [\text{N}] \tag{10}$$

The total specific resistance to motion in a hill is

$$r_{tot} = 10i + r_{ord} \tag{11}$$

where r_{ord} indicates the value of the ordinary (rolling and aerodynamic) specific resistances. Also,

$$R_{tot} = P \cdot r_{tot} = 1000f \cdot P \tag{12}$$

so that

$$r_{tot} = 1000f \tag{13}$$

That is a condition to the adhesion limit. Finally, the gradability is

$$i_{max} = \frac{1000f - r_{ord}}{10} \tag{14}$$

If $L < P$, the difference Q [kN] $= P - L$ is the weight on the supporting wheels. By putting

$$m = \frac{Q}{L} \tag{15}$$

one has

$$1000f \cdot L = (r_{ord} + 10i_{max})(L + Q) \equiv (r_{ord} + 10i_{max}) \cdot P \tag{16}$$

and

$$i_{max} = \frac{\dfrac{1000f \cdot L}{L+Q} - r_{ord}}{10} = \frac{1000f\dfrac{1}{1+m} - r_{ord}}{10} \tag{17}$$

In the case of a towing vehicle, the implicit assumption is made that r_{ord} of the driving vehicle and of the tow are equal (this is not strictly true); moreover, the ratio m is a function of the slope. In the case of 4WD, m assumes the value 0, and in towing m is equal to $L/(Q+M)$, with M [kN] the tow weight.

Indicating P_a as the weight on the front wheel and P_p as the weight on the rear wheel, z the height of the center of gravity, p the wheelbase, and x the distance of the center of gravity from the front axis, the equations of the rotation and translation equilibrium are (Figure 1) (Fessia, 1948)

$$-Pz\sin\alpha + P\cos\alpha(p - x) - P_a p = 0$$
$$P_p + P_a = P\cos\alpha \tag{18}$$

For a front-drive vehicle ($L = P_a$, $Q = P_p$), one obtains

$$m = \frac{\dfrac{x}{p} + \dfrac{z}{p}\dfrac{i}{100}}{1 - \dfrac{x}{p} - \dfrac{z}{p}\dfrac{i}{100}} \tag{19}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

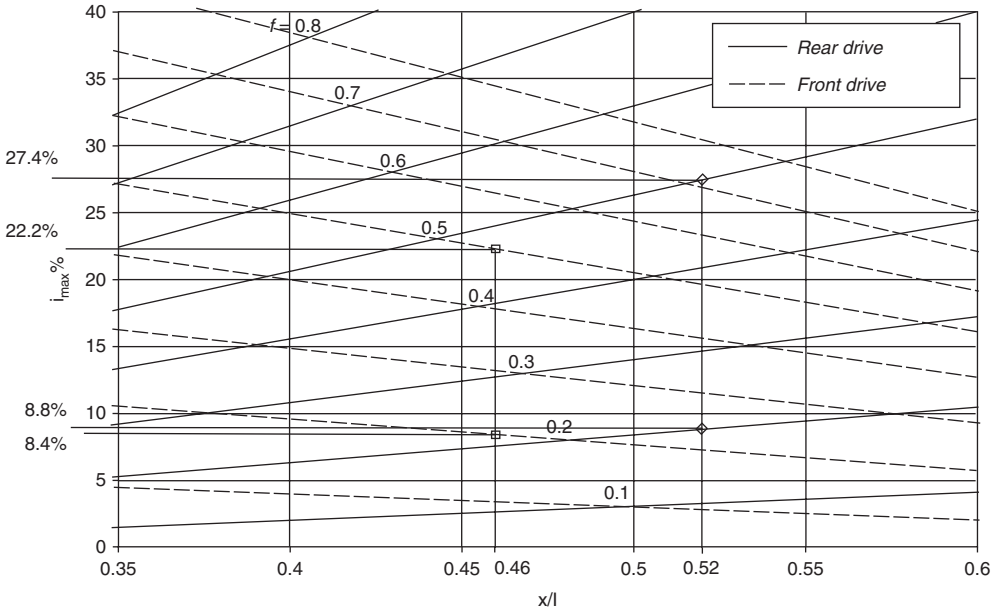

Figure 2. Graveability with ordinary resistances (20 N/kN) ($z/p = 0.25$).

For a rear-drive vehicle ($L = P_p$, $Q = P_a$), one obtains, instead

$$m = \frac{1 - \frac{x}{p} - \frac{z}{p}\frac{i}{100}}{\frac{x}{p} + \frac{z}{p}\frac{i}{100}} \tag{20}$$

Figure 2 shows the comparison of the gradability between vehicles ($y/p = 0.25$, $r_{ord} = 20$ N/kN) for several values of the adhesion coefficient. On low adhesion ($f = 0.2$), a front drive with $x/p = 0.45$ and a rear drive with $x/p = 0.52$ are equivalent; the surmountable limit hill is equal to ~8% for both vehicles. On mean adhesion ($f = 0.5$), the front drive climbs up the hill 22.2%, while the rear drive climbs up 27.4%. By varying the ordinary resistance more or less, the situation does not change much. Both the vehicles climb up the same hill in very different conditions: the front drive climbs in full understeering, at the limit of the adhesion, while the rear drive climbs in conditions of oversteering, with high utilization of the rear adhesion. Downhill has a contrary effect and the front drive is more stable.

1.2.2 Ordinary resistances

1.2.2.1 Rolling resistance. Rolling resistance consists of the resistance induced in the wheel bearings and that induced by the wheel–ground contact. The former is negligible and can be determined by the theory of bearings. The latter is due to the rolling friction between the wheel and the ground and to motion unevenness.

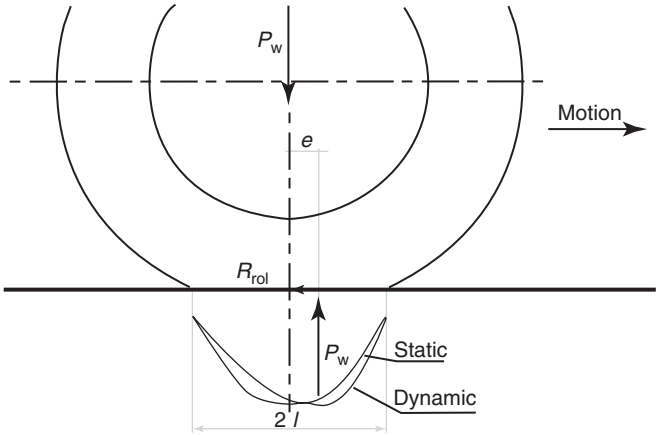

Figure 3. Pressure on wheel–ground contact.

When the wheel does not run, the diagram of the contact pressures is symmetrical: the reaction P_w is equal and opposite to the weight on the wheel (Figure 3). If the wheel is in motion, both elastic hysteresis and inertia distort the pressure diagram, so that the reaction is subjected to a displacement, indicated by e. The rolling resistance is given by

$$R_{rol} = \frac{P_w \cdot e}{R_0} \tag{21}$$

The eccentricity e (hence the specific resistance) increases with the speed v, and is proportional to the track length $2l$. R_0 is the rolling radius of the wheel. The specific

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

resistance for rolling friction increases with the weight and diminishes when the diameter increases. This resistance can be ascribed to several causes of energy loss:

1. Elastic hysteresis and mechanical inertia of the tire sidewalls subjected to deformation (contact with the ground);
2. Local sliding between the contact surfaces in the wheel track due to the slipping;
3. Motion of the compressed air inside the tire due to section reduction in correspondence to the contact.

Eccentricity cannot be determined by theory, so the resistance may be determined experimentally only. Experimental results show that starting from zero until about 50 km/h, the unitary resistance is quasi constant; the resistance increases very fast for greater values. The parameters influencing the rolling resistance are the rolling radius and the aspect ratio. In general, the increase of the radius and the decrease of the aspect ratio cause a decrease of the rolling resistance. Some empirical formulae used in the practice are as follows:

Andreau relationship:

$$r = \frac{1}{{p_0}^{0.64}}\left[20 + \frac{v^{3.7}}{1.29 \cdot 10^6 \cdot {p_0}^{1.44}}\right] \quad [\text{N/kN}] \qquad (22)$$

where
p_0 inflation pressure [bar]
v speed [km/h].

Kamm relationship: The Kamm formula presented by the Society of Automotive Engineers (SAE) is

$$r = k\left(5.1 + \frac{5.5 \times 10^5 + 90P_w}{p} + \frac{1100 + 0.0388P_w}{p}v^2\right) \times [\text{N/kN}] \qquad (23)$$

where k assumes the value 1 for conventional tires and 0.8 for radial tires; the normal force P_w is measured in newtons, the inflating pressure p in newtons per square meter or pascals, and v is the speed [m/s]. Both Equations 22 and 23 refer to rolling conditions on smooth and dry surfaces. The Andreau equation does not consider the weight on the wheel; both do not consider the size of the tire (Figure 4).

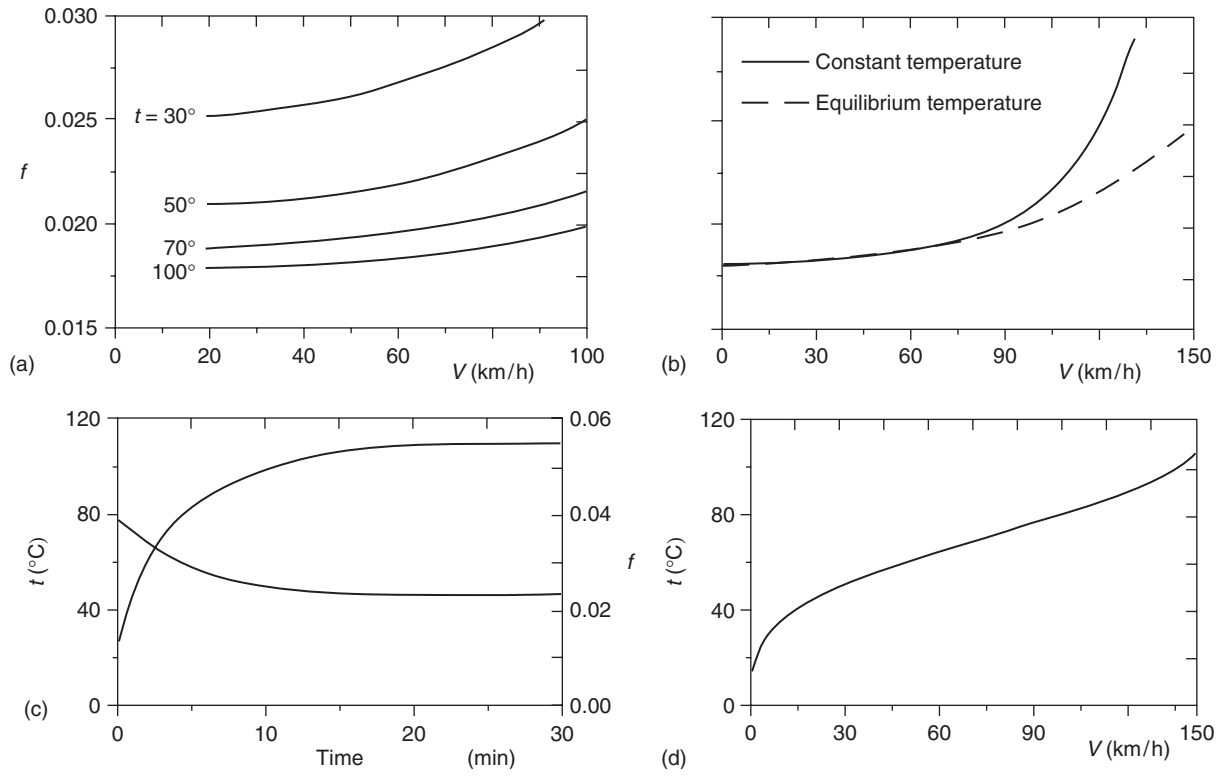

Figure 4. (a) Rolling coefficient as a function of the temperature at constant speed. (b) Comparison between the law $f(v)$ at constant temperature and at the equilibrium temperature at each speed. (c) Decrease in time of the rolling resistance and increase of the temperature in a tire rolling at 185 km/h. (d) Equilibrium temperature as a function of the speed. (From Figure 2.11, p. 48 in Genta, 2003. Reproduced by permission of World Scientific Publishing Co Pte Ltd.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

Binomial Formula:

$$r = a + bv^2 \quad [\text{N/kN}] \tag{24}$$

where a [N/kN] assumes different values depending on the road surface:

$a = 8–10$ for smooth concrete
$a = 20$ for rough concrete
$a = 10–12$ for smooth asphalt
$a = 16–18$ for not much rough asphalt
$a = 22$ for very rough asphalt, and
$a = 15–25$ for sand.

b [$\text{N s}^2/\text{kN/m}^2$] depends on the type of tire; for example, 5×10^{-3}.

v is the speed [m/s].

De Gregorio relationship:

$$r = 15 + 0.00003(v - 50)^3 \quad [\text{N/kN}] \tag{25}$$

v is expressed in kilometers per hour. For $v < 50$ km/h, the resistance is assumed as constant and is equal to 15 N/kN.

Figure 5 shows a comparison between the formulas reported earlier. All the relationships give good results until $v \leq 100$ km/h; only SAE and binomial formula are in accordance for higher speeds.

Rolling resistance is the cause of heat production. The thermal power [W] in the tire is

$$W = P \cdot w = P \cdot r \cdot \left(\frac{v}{3.6}\right) \tag{26}$$

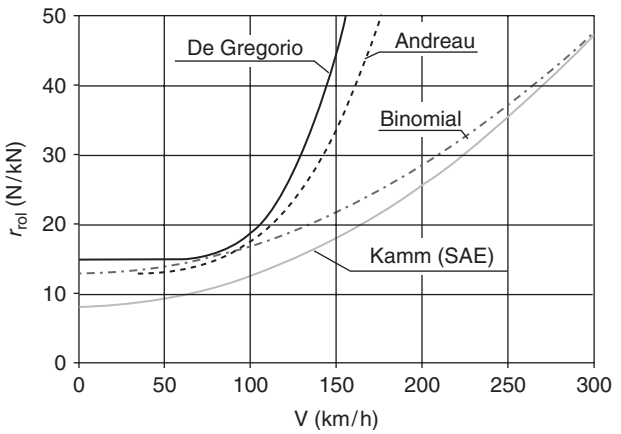

Figure 5. Comparison between the formulas for rolling resistance. SAE: $k = 1$, $P = 800$ N, $p = 2$ bar; Andreau $p_0 = 2$ bar; binomial: $a = 13$, $b = 5 \times 10^{-3}$.

where w is the unitary thermal power [W/kN] and is referred to the weight P [kN]. It is transmitted to the surroundings trough the walls of the tire. Also,

$$W = P \cdot w = K \cdot \Delta T \tag{27}$$

where K indicates the global coefficient of thermal conductivity and ΔT [°C] is the temperature difference between the tire and the surroundings (both w and K are increasing functions of the speed). The working temperature of the tire has to be limited both for preventing the risk of explosion and avoiding excessive wear.

SAE has developed test practices to measure the RRC (rolling resistance coefficient or specific resistance) of tires. These tests (SAE J1269 and SAE J2452) (Terziyski and Kennedy, 2009; Popio and Luchini, 2007) are usually performed on new tires. When measured using these standard test practices, most new passenger vehicle tires have reported RRCs ranging from 7 to 14 N/kN. In the case of bicycle tires, values from 5 to 25 N/kN are achieved. In the latter two cases, the effect of air resistance must be subtracted or the tests performed at very low speeds. ISO 28580 (2009) (International Standards Organization) is used to test rolling resistance in Europe.

1.2.2.2 Aerodynamics and wind. A body in motion in a fluid mass (air) with speed v with respect to the ground (the air is assumed motionless regard to the ground) is subjected to a resistance R_a, which is a function of

- the shape and size of the body,
- the density ρ and viscosity μ of the fluid medium, and
- the speed v.

Resistance can be determined by making use of the similitude theory (Stagni, 1980). The following relationship can be written:

$$R_a \equiv f(\text{Le}, \rho, v, \mu) \tag{28}$$

where Le is the length of the vehicle. Expressing R_a in a power series, one has

$$R_a = \sum C(\text{Le}^a \cdot \rho^b \cdot v^c \cdot \mu^d) \tag{29}$$

where C is a constant. Expressing the dimensional homogeneity of both terms

$$(\text{kgm/s}^2) \equiv (\text{m})^a (\text{kg/m}^3)^b (\text{m/s})^c (\text{kg/ms})^d \tag{30}$$

For kg one has $1 = b + d$
for m $1 = a - 3b + c - d$
and for s $2 = c + d$.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

giving

$$b = 1 - d$$
$$c = 2 - d$$
$$a = 3 - 3d - 2 + d + d + 1 = 2 - d \qquad (31)$$

Then

$$R_a = \sum C \cdot (\mathrm{Le}^{2-d} \cdot \rho^{1-d} \cdot v^{2-d} \cdot \mu^d)$$
$$\equiv \sum C \cdot \rho \cdot \mathrm{Le}^2 \cdot v^2 \left(\frac{\mu}{\mathrm{Le} \cdot v \cdot \rho} \right)^d \qquad (32)$$

with d being an unknown exponent. Equation 32 can be written as

$$R_a = C \cdot \rho \cdot \mathrm{Le}^2 \cdot v^2 \cdot \phi \left(\frac{\mathrm{Le} \cdot v \cdot \rho}{\mu} \right) \qquad (33)$$

where φ is an unknown function of the Reynolds number (Re)

$$\mathrm{Re} = \frac{\mathrm{Le} \cdot v \cdot \rho}{\mu} \qquad (34)$$

R_a can be written in the following way:

$$R_a = \frac{1}{2} C_d(\mathrm{Re}) \cdot \rho \cdot S \cdot v^2 \qquad (35)$$

where S is the area of the main section of the body in a plane normal to the motion direction x, and C_d (or C_x) is the drag coefficient characterizing the external shape of the body and is a function of the Reynolds number.

Equation 35 is written considering the expression of the resistance of a disk having section S, lapping up a fluid stream having speed v, when turbulence effects downstream the disk (tail effect) are neglected (C_d (Re) = 1).

In reality, six aerodynamic coefficients can be attributed to a body in motion inside a fluid mass: three for the resistance calculation along the coordinate axes, and three for the moment calculation around the same axes (Genta, 2003; Hucho, 1998). In the case of a vehicle, the more important coefficients are the coefficient C_d along the translation direction and the coefficient along the normal axis outgoing from the ground C_z, (or C_l) which is named the *lift coefficient*; it has the effect of creating a vertical force that is added algebraically to the weight force. The coefficient along the y direction is important for sensitivity to the lateral wind. Among the three rotation coefficients, the pitching coefficient C_{My} around the y-axis is more important because it influences the trim of the vehicle; the equation to calculate the moment coefficient is analogous to Equation 35, considering a reference volume ($S \cdot \mathrm{Le}$, where Le is a generic length, for example, the wheelbase) instead of the main section. Aerodynamic coefficients can be determined numerically by computational fluid dynamics (CFD) or by wind tunnel experiments.

Wind tunnel: It consists (Figure 6) of a Venturi tube with a test room C. The honeycomb grid R has the purpose of avoiding turbulence in the tunnel. A fan placed at the end of the tube and set in action by an electric engine generates the necessary airflow. In general, the fan works in aspiration mode. The model M is placed at the center of the room C and is supported by one or more beams connected to the dynamometric balance B. Moreover, the wind tunnel is equipped with control devices permitting the measurement and the regulation of the air speed and of the characteristics influencing the viscosity and the density (temperature, pressure, and relative humidity). The capacity of the wind tunnel is determined also by the section of the test room; if this section is wider, the models can be larger and the measurements more reliable.

Scale effect: Measurement accuracy depends on the scale model. In the immediate surroundings of any body, the fluid flow is laminar rather than turbulent. If the model is of a very small scale, the small protuberances will not be reproduced faithfully, because they are not contained in the laminar layer, unlike a model in scale 1:1. An analogous effect gives the walls roughness, which is greater in the model for working reasons. Vehicle 1 and the model 2 have

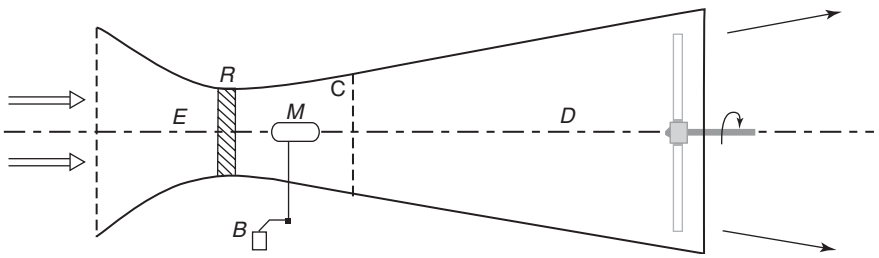

Figure 6. Scheme of wind tunnel.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the same drag coefficient if

$$\rho_1 v_1 \frac{l_1}{\mu_1} = \rho_2 v_2 \frac{l_2}{\mu_2} \tag{36}$$

If the environmental conditions outside and inside the tunnel are equal, from Equation 36 one has

$$v_1 = v_2 \frac{l_2}{l_1} \tag{37}$$

Determination of the drag coefficient is convenient at speed equal to $\frac{2}{3}v_{max}$ and no more than 100 km/h; it is the speed suggested by standards (Comitato Unificazione Nazionale Autoveicoli) CUNA NC 003–01 (2004) and CUNA NC 003–02 (2004) (today they are European standards) for the determination of the fuel consumption on the road. If the test room is wide enough, the test on motorcycles and vehicles can be executed in 1 : 1 scale. In the case of other vehicles, or if the test room is not wide enough, the test needs a model in reduced scale, with the disadvantage that it is impossible to obtain the speed in the tunnel very close to the speed of sound, c. This situation does not hold the validity of Equation 28 because the aerodynamic coefficients are functions also of the Mach number (Ma):

$$\mathrm{Ma} = \frac{v}{c} \tag{38}$$

This is a disadvantage because the maintenance of the same Re and Ma is not possible in the case of test on small scale models. The speed in the tunnel can be reduced by making use of the fluid at a greater density, maintaining Re as constant, and following Equation 36. Studies conducted recently (D'Anca, Mancuso, and Virzì Mariotti, 2005) show that the drag coefficient varies very little with the speed for a road vehicle, at least starting from a certain value of the speed; this helps the solution of the problem. CFD tests are executed on a Maserati Biturbo model; only a half the vehicle is analyzed because of the longitudinal symmetry of the model and the symmetry of the motion field. The model is a flat-bottomed vehicle, has no rear view mirrors, has smooth rim covers, and does not present prominences because of handles, lights, and so on. CFD analysis gives the result $C_d = 0.472$. Comparison with the value obtained by the White method (Section 1.2.2.2), namely $C_d = 0.4735$, is rather satisfactory. On the same model, another analysis was carried out to confirm the validity of C_d value at $\frac{2}{3}v_{max}$ by determining the variation versus the vehicle speed. The results are reported in (D'Anca, Mancuso, Virzi' Mariotti, 2005); they show only a qualitative validity and cannot be generalized because aerodynamic coefficients are functions of the shape. Moreover, the results are obtained by two-dimensional simulations because the three-dimensional simulation requires a computational effort that is beyond our ability at this time. For the purpose of forecasting the vehicle performance on the road, the aerodynamic coefficients are considered as constants by neglecting their variation with the Reynolds number and with the speed in particular. This established a negligible cause of error at low speed.

Ground effect (Cogotti, 1998; Stagni, 1980; Katz, 2006): It is assumed that airflow has a relative speed v with respect to the ground, which is contrary to the reality. This is another cause of inaccuracy of the wind tunnel tests. The fluid speed diagram between the ground and vehicle has a semi-parabolic trend, while the trend is parabolic in the model (Figure 7). This changes the pressure distribution.

A better way to eliminate or reduce ground effect is the use of a double-mirror-like model. The traveling band model is less valid but also efficient, but the solutions are very expensive and require a very wide wind tunnel.

Aerodynamic resistance of a vehicle can be considered as the sum of factors such as

- the head effect (wind pressures exerted on the front),
- the tail effect (wind pressures exerted on the rear),
- the wall effect (resistance diffused along the lateral walls, roughness, concentrated resistances).

Experience shows that both the ratio of the total length of the vehicle to the mean diameter of the main section and the head shape influence head and tail effects. The regularity of the lateral surfaces, in particular the lower surface, influences the wall effect.

The tail effect can be negative or positive. It is due to the presence of a vortex in the rear of the vehicle depending on the shape of the rear bonnet. In general, the vortex induces a negative pressure opposing a resultant force to the motion, increasing the drag coefficient. If the rear of the vehicle is finely shaped, the pressure can induce a favorable force to the motion, reducing the drag coefficient. Pressure distribution on the Maserati Biturbo model and the streamlines of the airflow are shown in (D'Anca, Mancuso, Virzi' Mariotti, 2005).

Style variations: They have great importance on the value of the aerodynamic coefficients. Effect of some particular variation of the bodywork are shown in (D'Anca, Mancuso, Virzi' Mariotti, 2005). Also in this case the vehicle is a Maserati Biturbo. The results are useful for manual optimization of the bodywork. However, there are other parts that influence the aerodynamic coefficient, such as wheels and cavities and tank. Another example is the manual optimization of the geometry of FIAT Bravo

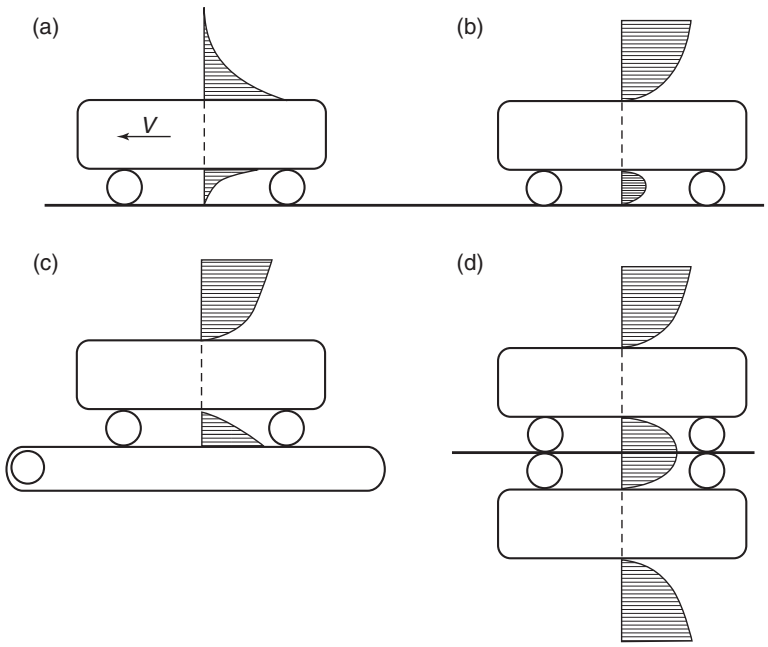

Figure 7. Ground effect and equipment for its reduction. (a) Reality; (b) fixed ground model; (c) traveling band model; and (d) mirror-like model.

Blueprint (Terranova, 2009; Milone, 2011). The purpose is the reduction of the motion resistance of the vehicle; then the drag and lift coefficients are determined.

Three different configurations for the front bumper are examined, eliminating the zones where the flow has quasi-zero speed and is stagnant.

First configuration: Modification of the inclination angle from 14.24° to 13.30° (Figure 8a). Drag is reduced by 1.7% and lift is increased by 28%.

Second configuration: Following the condition of optimum nose (Janssen and Hucho, 1975) (Figure 8b), drag is reduced by 2.7% and lift is reduced by 4.6%.

Third configuration: Two configurations (Buchheim, Deutenbach, and Luckoff, 1981) in Figure 8c, varying the height of the point stagnation, give the following results:

- *Configuration A*: height $z_s = 221\,\text{mm}$; $C_d = 0.33$; $C_l = 0.13$,
- *Configuration B*: height $z_s = 149\,\text{mm}$; $C_d = 0.33$; $C_l = 0.06$.

CFD analysis on configuration B shows that the zone at low speed in the front end (Figure 9) reduces its extension and the flow is not stagnant. The reduction of the drag coefficient is 3.6%, while lift reduction is 66%.

Study on a small rear spoiler over the rear window shows that it can give lower aerodynamic resistance and a better lift effect. Analyses are executed on a FIAT Bravo model by varying the length of the wing contour and the incidence angle with respect to the horizontal. Figure 10 shows the several lengths for the incidence angle −20°, and Figure 11 shows the results for the length 75 mm. The drag coefficient is optimum for a length 75 mm and incidence angle −25°. The lift coefficient reaches 0.33, while the corresponding apparent reduction of the weight is equal to 12.3% at the maximum speed.

CFD analyses are executed on the complete model, obtaining a drag coefficient reduction of 7% and a lift coefficient increase of 60%. Figure 12 shows the trend of the streamlines in the modified configuration. Instead, a negative C_l value induces an increase of the apparent weight with an increase of the force on the tire–ground contact (greater ability of acceleration and greater stability), but with an increase of the rolling resistance and an increase of the drag coefficient.

Portion of aerodynamic drag that is linked to the generation of lift is named the *induced drag* (Genta, 2003; Dabbene, 2009). In the case of vehicles with a high power to weight ratio, the use of negative aerodynamic lift allows the transfer of all the power on the wheel–ground contact. Aerodynamic pitching moment causes strong variation of the forces exerted by the wheels on the road (Figure 13a). The pitching moment is considered positive if it increases the load on the front wheels. The lift of the wing is due to a difference of pressure, which induces a lift force (Figure 13b). If the wing has an infinite length, there is no induced

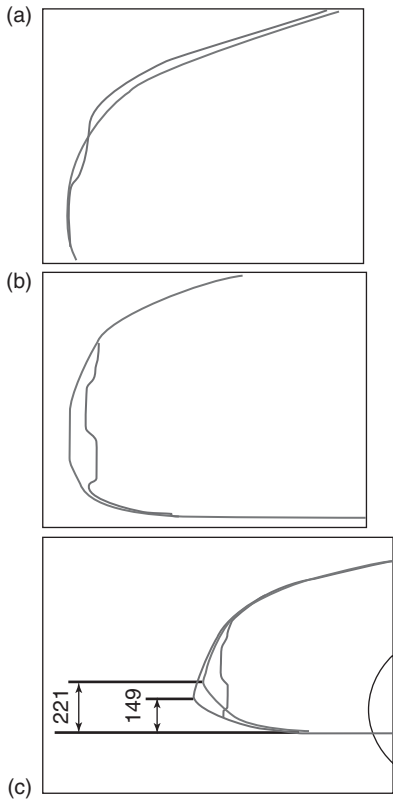

Figure 8. Modification of the high part of a FIAT Bravo front bumper (a), optimum nose condition (b), and stagnation point position (c).

drag, but in the case of finite length the vortex at the tips is deflected backwards (Figure 13c). An unfavorable situation is when the breakaway of the fluid is total on the entire superior surface: one has the stall, and the lift effect is reduced totally (Figure 13d). The study on the wing profile was executed in the past generating national advisory committee for aeronautics (NACA) profiles, which are optimized wing profiles to choose in accordance with the requested performances. In the automotive field, they are used for the design of spoilers with the aim to negate the lift coefficient (Schenkel, 1977; Katz, 2006). The minimum drag coefficient is due to the drop shape. It has to be hit by the fluid along its symmetry axis and thus it is ~0.05 if there are no other bodies in the neighborhood. The ground has a negative effect given that drag coefficient increases by ~150% because of the fact that the streamlines have to remain parallel to the ground. If the vehicle is supposed to be in motion in contact with the ground, the optimum shape is the semidrop (or semilune). However, the distance of the vehicle from the ground cannot vanish, and this solution gives high values of the drag coefficient.

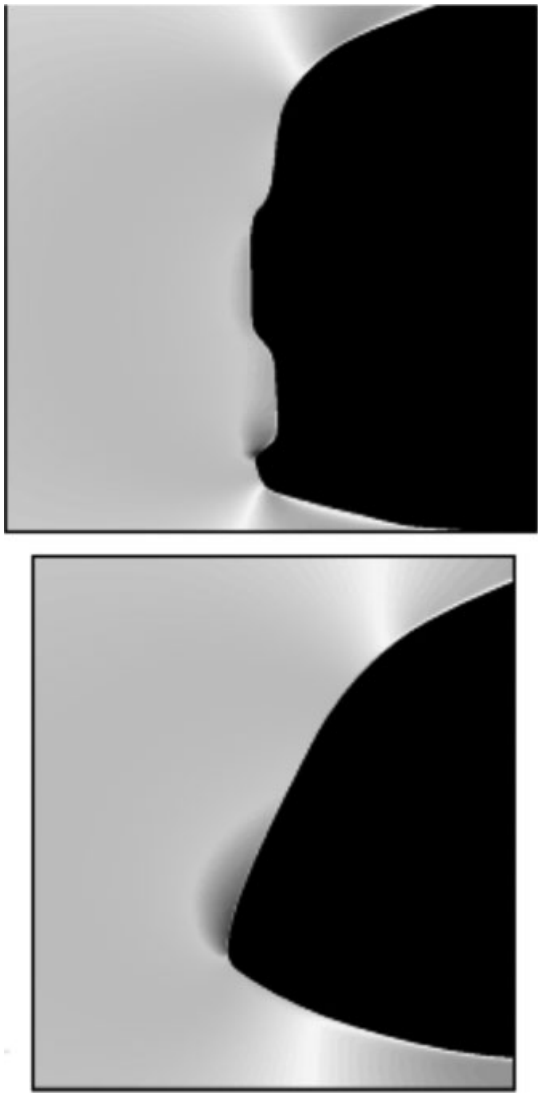

Figure 9. Comparison between the speeds (head effect) in the original model FIAT Bravo and configuration B (top).

If the vehicle is in a symmetrical position with regard to the flow, with roll and aerodynamic angles equal to zero, the side force, the rolling moment, and the yawing moment are equal to zero. In general, the coefficient C_y is a function of the roll and sideslip angles, while it can also be a function of the steering angle in race vehicles. Moreover, it is a function of the width to height ratio. For small variations of the above parameters, the aerodynamic coefficients C_y, C_{Mx}, and C_{Mz} can be approximated by a linear function. For a preliminary evaluation, the following empirical relationship is suggested:

$$C_y = \beta \frac{\text{lateral area}}{\text{frontal area}} (0.005 + 0.0019 n_f) \qquad (39)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

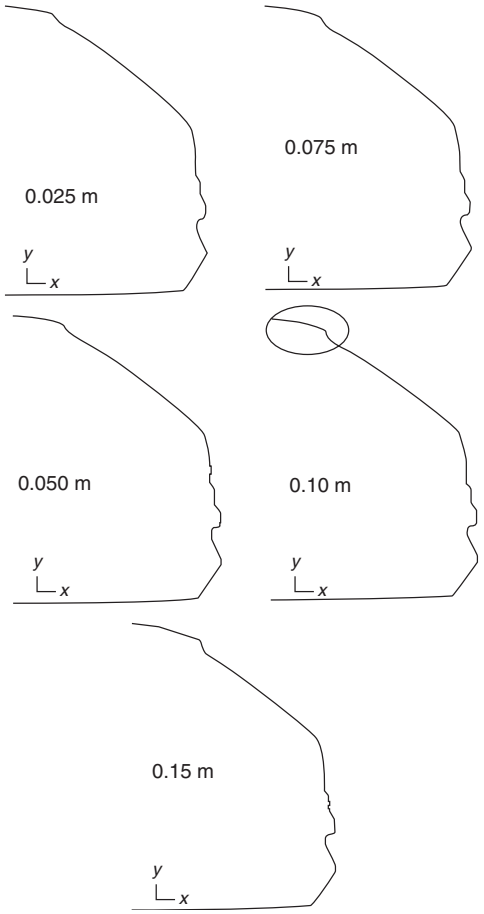

Figure 10. Configuration spoiler −20° (FIAT Bravo).

where β is the aerodynamic sideslip angle (the angle that the speed vector makes with the longitudinal axis of the vehicle) and n_f is a numerical factor that can be obtained experimentally or from data on similar vehicles.

White's method: The method proposed by White (1967–1969) is useful for the evaluation of the drag coefficient C_d. The vehicle is divided in nine parts, with as many different configurations, as shown in Table 1. A weight x_i is assigned to every part and is introduced in the empirical relationship

$$C_d = a_0 + \sum_{i=1}^{9} x_i \cdot a_i = a_0 + a_i \sum_{i=1}^{9} x_i$$
$$= 0.16 + 0.0095 \sum_{i=1}^{9} x_i \quad (40)$$

The coefficients a_0 and a_i are obtained by statistical analysis of the results in wind tunnel tests. Formula (40) gives C_d with an approximation of 7%. The nine parts are

- the plant contour
- the outline
- the crosswise section
- the windscreen plant
- the windscreen–roof intersection
- the plant
- the rear interior compartment–tail intersection
- the rear part
- the floor.

Today, the White method is replaced by modern CFD methods. All the same, it is useful for the validation of experimental or computational results.

1.3 Acceleration (inertia)

When the vehicle is subjected to a speed variation (positive or negative acceleration), it is subjected to an additional resistance because of inertia, given by

$$R_{acc} = \frac{a \cdot P}{g} \quad (41)$$

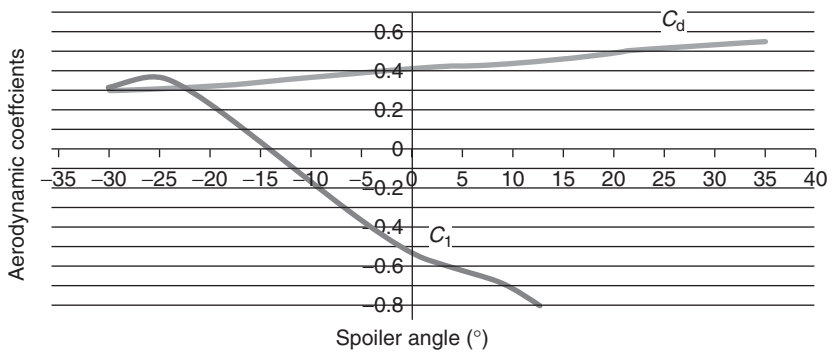

Figure 11. Trend of aerodynamic coefficients versus the spoiler angle; spoiler length 75 mm (FIAT Bravo).

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

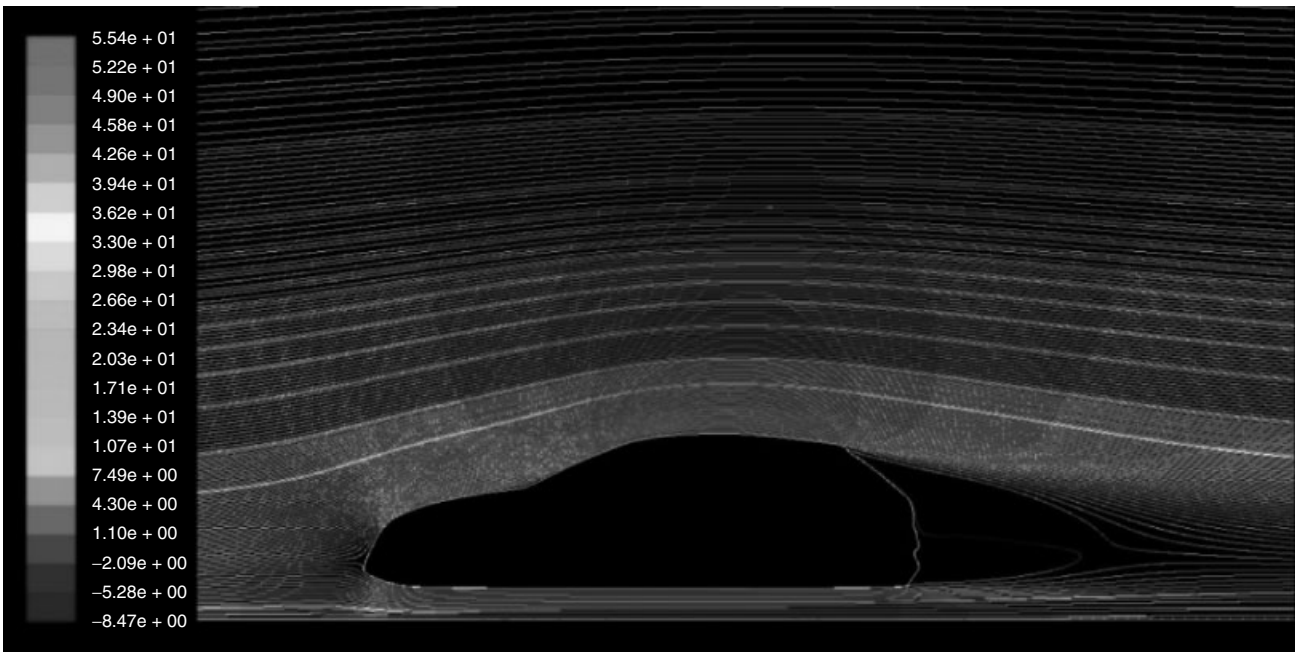

Figure 12. Streamlines *X*-velocity [m/s] (FIAT Bravo).

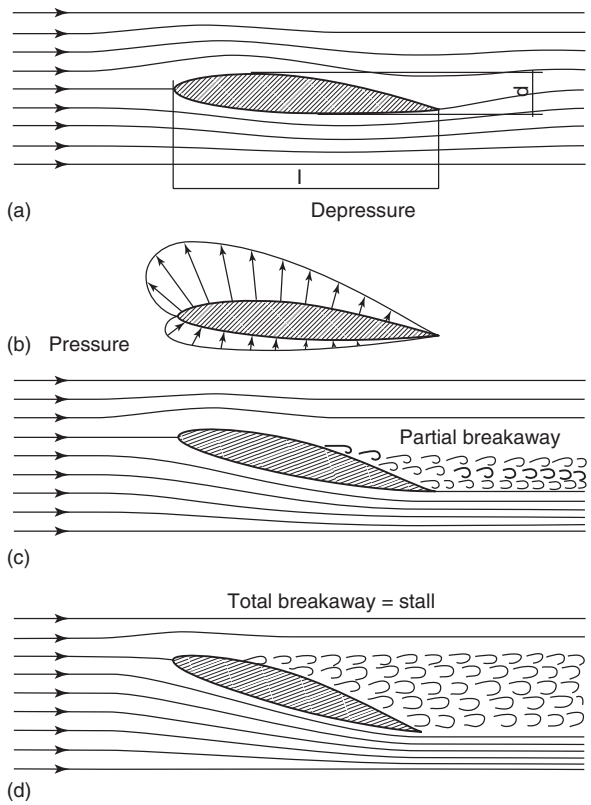

Figure 13. Vorticity in a wing.

where a is the vehicle acceleration, P is the vehicle weight, and g is the gravity. Dividing by P, the specific resistance is obtained as

$$r_{\text{acc}} = 1000 \cdot \frac{a}{g} \cong 102 \cdot a \quad [\text{N/kN}] \tag{42}$$

Considering the inertia of all the rotating mass (gears, shafts, wheels, etc.), the total kinetic energy of the vehicle is the sum of the kinetic energy of motion E_c of the entire vehicle and the kinetic energy of rotation of all the rotating masses, that is,

$$E_c = \frac{1}{2}\frac{P}{g}v^2 = \frac{1}{2}\frac{P}{g}(\omega_r R_0)^2 = \frac{1}{2}J_v\omega_r^2 \tag{43}$$

$$\frac{1}{2}J_v'\,\omega_r^2 = \frac{1}{2}J_m\omega_m^2 + \frac{1}{2}J_t\omega_t^2 + 4\frac{1}{2}J_r\omega_r^2 + \frac{1}{2}J_v\omega_r^2 \tag{44}$$

where J_v' is the equivalent inertia of the entire vehicle, J_v is its equivalent inertia without the rotating masses, J_m is the moment of inertia of the engine, J_r is the moment of inertia of one wheel, and J_t is the moment of inertia of the transmission shaft; ω_r is the angular speed [rad/s] of the wheels, ω_m that of the engine, and ω_t that of the transmission; R_0 [m] is the rolling radius of the wheels; and the ratio P/g is the vehicle mass [kg]. One has

$$\omega_m = \omega_r/(\tau_1\tau_p) \qquad \omega_t = \omega_r/\tau_p \tag{45}$$

(Reproduced from Morelli, 1970. © A. Morelli.)

In the above, τ_1 is the ratio of the first gear and τ_p is the axle ratio. Substituting into Equation 44, one has

$$J'_v = \frac{J_m}{(\tau_1 \tau_p)^2} + \frac{J_t}{\tau_p^2} + 4J_r + \frac{P}{g}R_0^2 \qquad (46)$$

The inertia coefficient in the first gear is

$$k_I = \frac{J'_v}{J_v} = \frac{gJ'_v}{PR_0^2} \qquad (47)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

The inertia coefficients of the other gears are obtained by substituting τ_1 with the considered gear ratio in Equation 46, considering the variation of the moment of inertia as a function of the pair of gears in contact. The inertia coefficients are slightly greater than 1. The equivalent inertia of the vehicle in neutral position is

$$J_v^n = \frac{J_t}{\tau_p^2} + 4J_r + \frac{P}{g}R_0^2 \tag{48}$$

and the inertia coefficient is

$$k_n = \frac{gJ_v^n}{PR_0^2} \tag{49}$$

The quantities J_m and J_t have to be calculated considering the inertia of the rotating parts of all the linked masses.

The maximum available acceleration of the vehicle depends on the power to weight ratio. In general, the acceleration is higher at start, and diminishes with the increase of speed, both because the motion resistances increase with the speed and because the traction is reduced. Introducing the inertia coefficient, Equation 42 becomes

$$r_{acc} = k_m 1000 \cdot \frac{a}{g} = k_m 102 \cdot a \quad [\text{N/kN}] \tag{50}$$

The inertia coefficient k_m changes with the inserted gear.

2 GEAR RATIO SELECTION

2.1 Introduction

An engine giving constant power versus the rotation (i.e., electric one) is optimum for the traction, assuming that the kinematic connection between the engine shaft and wheels is fixed. When the continuous use of the maximum power of the engine is not possible, a gear drive system is necessary, and consequently both the running cost of the vehicle and the energy consumption increase. The *power characteristic* is the curve relating the power to the rotation number [rpm] (De Gregorio, 1970; Bencini, 1956). The power N is the product of the angular speed and the engine torque C [Nm]:

$$N = \frac{\omega \cdot C}{1000} = \frac{2 \cdot \pi \cdot n}{60} \cdot \frac{C}{1000} \quad [\text{kW}] \tag{51}$$

Here, ω is the engine angular speed [rad/s] and n [rpm] the rotation number (Figure 14).

An engine having a constant characteristic of the torque is defined *rigid* (so that the power has a linear trend); in contrast, the engine at constant power is defined *elastic* (so that the engine torque has a hyperbolic trend). In

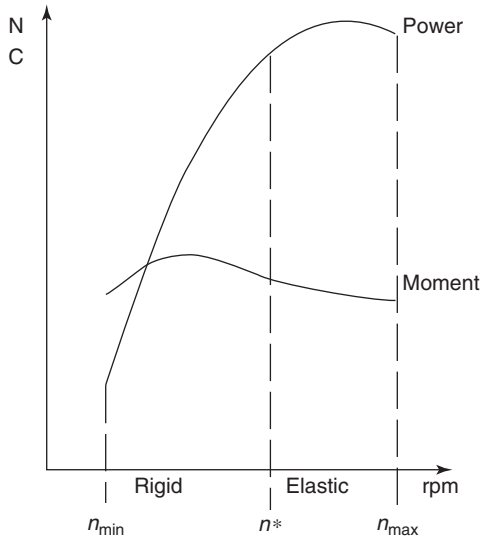

Figure 14. Characteristic of an internal combustion engine.

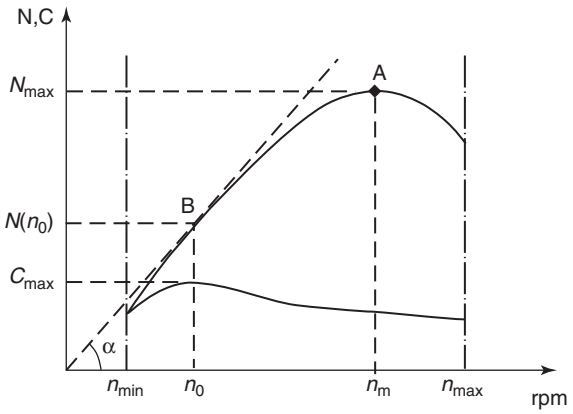

Figure 15. Maximum torque rate.

general, internal combustion engines have small elasticity because the developed power increases proportionally to the rotation number. The engine is rigid in the zone between n_{min} and n^* and is elastic between n^* and n_{max} because the characteristic is flat at the maximum power rate. The characteristic curves of Otto and Diesel engines have very similar trends (Figure 15).

2.2 Power characteristic

If the engine characteristic is not flat, the vehicle requires a gear drive in the rigid zone to increase the traction at low speed. The gear ratio has to be very low at the starting point. Moreover, the choice of a certain number of gears permits the correction of rigidity, so that the curve of the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

engine torque is very close to an equilateral hyperbola. An internal combustion engine presents the maximum torque at a certain intermediate rate n_0 (Figure 14). For this value, the engine torque curve has a horizontal tangent, while the power curve has a tangent through the origin. In fact,

$$\left(\frac{dC}{dn}\right)_{n=n_0} = 0 \tag{52}$$

Because $N = C \cdot n$, one has

$$\frac{dN}{dn} = n \cdot \frac{dC}{dn} + C \tag{53}$$

and

$$\left(\frac{dN}{dn}\right)_{n=n_0} = C(n_0) = \frac{N(n_0)}{n_0} = \tan\,\alpha \tag{54}$$

In correspondence of the rotation rate n_0, the excess of power is maximum, and then the maximum acceleration can be obtained. The gear change is convenient near n_0 for consumption reduction.

At rotation lower than n_{min}, the combustion is uneven or missing and the power is not sufficient to balance the internal friction of the engine. The characteristic of power presents a certain concavity toward the bottom because of the fact that the several efficacies of the engine are not constant. The maximum rotation number n_{max} is slightly higher than at the maximum power rate. It allows the implementation of a greater speed than that at maximum power rate, when possible (i.e., on light downhill). In general, the maximum rotation number and the maximum power rate can be evaluated by thermo-fluid dynamical analysis and by reducing the masses in the motion of the engine.

Engine torque and power curves are obtained experimentally by the *engine bench*. The engine works at full introduction, and engine torque and power are measured by a dynamometric brake varying the number of rotations. The curves are obtained by interpolating the obtained measurements. The consumption tests are executed by the same bench. Following the international rules, power curve obtained by the bench does not consider the absorption of numerous auxiliaries, such as the fan, pump of the coolant, and generator; they absorb 7–10% of the developed power.

In general, the power characteristic of an automotive engine can be represented by a cubic parabola:

$$N = an^3 + bn^2 + cn + d \tag{55}$$

The four constants a, b, c, and d can be determined by the data of maximum power and maximum engine torque. Both high power engines and motorcycle engines are exceptions. They need a more accurate analytical definition. When possible, the aspect of the curve may be improved by increasing the parabola order and adding other points with known values of torque or power.

Small losses of power in the gear drive and in the axle are considered by introducing the efficacy of the transmission, given by the product of the single efficacy of the parts in the kinematic chain, that is,

$$\eta_t = \eta_1 \cdot \eta_2 \cdot \cdots \cdot \eta_n \tag{56}$$

Indicative values are reported in Table 2. The efficacy of the transmission is greater if the vehicle rides in direct gear. Just as an indication, in direct gear $\eta_t = 0.93$; in reduced gears $\eta_t = 0.87$; and if the gear drive has no step gear, the efficacy increases and $\eta_t = \sim 0.91$.

The measured power has to be corrected as a function of the conditions of pressure and temperature. The correction has to be executed using relationships indicated by the standardization institutions. The more important ones are SAE method (SAE J1349, 2004)

$$N_{cor} = N \cdot \left[1.176 \cdot \left(\frac{990}{p_d} \cdot \sqrt{\frac{273+t}{298}}\right) - 0.176\right] \tag{57}$$

ISO method (ISO 1585, 1992)

$$N_{cor} = N \cdot \left(\frac{990}{p_d}\right)^{1.2} \left(\frac{273+t}{298}\right)^{0.6} \tag{58}$$

where N and N_{cor} are the measured and the corrected power, respectively, p_d is the pressure of dry air [hPa], which is found by subtracting the vapor pressure p_v from the actual air pressure; and t is the air temperature [°C]. Equation 57 is

Table 2. Efficacy of several parts of mechanical transmission (also for vehicles with two or three wheels).

	Type	Efficacy
Gears	Straight toothed	0.98
	Helical toothed	0.97
	Conic toothed	0.96
	Hypoid toothed (efficacy diminishes if the eccentricity increases)	0.90
Chain	Roller	0.95
	Silent	0.98
Belt	Timing	0.95

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

valid in the case of spark ignition for temperatures between 15 and 35°C and dry air pressure between 900 and 1050 hPa (90–105 kPa). Instead, Equation 58 is valid only if the ratio $0.93 \leq N_{cor}/N \leq 1.07$ with a reference temperature of 25°C and a pressure 99 kPa. In the case of compression ignition, it becomes (Commission Directive 32002L0041, 2002; Commission Directive 31988L0195, 1988)

$$N_{cor} = N \cdot f_m \left(\frac{990}{p_d}\right)\left(\frac{273+t}{298}\right)^{0.7} \tag{59}$$

And, in presence of a turbo supercharger

$$N_{cor} = N \cdot f_m \left(\frac{990}{p_d}\right)^{0.7}\left(\frac{273+t}{298}\right)^{1.5} \tag{60}$$

The coefficient f_m is given by

$$f_m = 0.036\frac{q}{r} - 1.14 \tag{61}$$

where q is the correct flux of the fuel [mg/L/cycle] for liter of total volume, and r is the ratio between the pressures of the output and input of the supercharger ($r > 1$). Equation 60 is valid if $40\,\text{mg/L/cycle} < q/r < 65\,\text{mg/L/cycle}$. If the ratio is lower, f_m assumes the value 0.3; and if it is greater, f_m assumes the value of 1.2. The test is valid if $0.9 \leq N_{cor}/N \leq 1.1$. The above relationships replace the earlier CUNA, DIN (Deutsches Institut fur Normung), and other obsolete European rules.

2.3 Road loads versus speed

2.3.1 Diagram T–v

The performance of the vehicle can be foreseen by knowing the characteristic of power and engine torque (Heisler, 2004; De Gregorio, 1970; Bencini, 1956). To do it, one has to know

- the gear ratios $\tau_1, \tau_2, \ldots, \tau_v$,
- the axle ratio τ_p, and
- the rolling radius R_0 of the tires.

The axle ratio is established with the appropriate design criteria on the basis of the performances of the engine power. τ_p is implemented by

$$\tau_p = \frac{n_p}{n_c} \tag{62}$$

where n_p is the number of pinion teeth at the end of the transmission shaft and n_c is the number of gear teeth at the differential box ($\tau_p < 1$). Traction T is given by

$$T = \frac{1000N}{\frac{2\cdot\pi\cdot n}{60}\cdot R_0}\cdot\frac{1}{\tau_n\tau_p}\cdot\eta_t\cdot[\text{N}] \tag{63}$$

where N is expressed in kilowatts, R_0 is the rolling radius [m], η_t is the transmission efficacy, τ_n is the ratio of the inserted gear, and n [rpm] is the engine's angular speed. The traction characteristic $T = T(v)$ can be obtained from the characteristic $N(n)$ by Equation 63, changing the abscissa, as

$$v = \frac{2\pi n}{60}\tau_n\tau_p R_0 \times 3.6 \tag{64}$$

with v [km/h] and a 3.6 conversion factor. By making the hypothesis that there are four gears, indicating τ_3, τ_2, and τ_1 the ratios of the third, second, and first gear, respectively, and assuming the ratio of the fourth gear to be equal to 1 (it is an ancient solution), the traction characteristic in third, second, and first gear are obtained easily (Figure 16). P_3, the corresponding point in third of P_4, has abscissa

$$X_3 = X_4 \cdot \tau_3 \tag{65}$$

and ordinate

$$Y_3 = \frac{Y_4}{\tau_3}\cdot\frac{\eta_3}{\eta_4} \tag{66}$$

where η_3 and η_4 are the transmission efficacy in the third and fourth gears, respectively. Figure 16 is completed with the curve of the resistance power obtained considering ordinary resistance and hill resistance, so that

$$R_{tot} = \frac{1}{2}C_d\rho S v^2 + r_{rol}P + 10iP \quad [\text{N}] \tag{67}$$

where r_{rol} is the specific rolling resistance, i is the hill resistance in percentage (downhill is considered negative), and P is the vehicle weight [kN]. Lift effect can be considered by calculating P in the following way:

$$P = \frac{1}{1000}\left(P_s - \frac{1}{2}C_l\rho S v^2\right) \quad [\text{kN}] \tag{68}$$

where P_s [N] is the static weight of the vehicle, and C_l is the lift coefficient; if it is positive, an apparent reduction of the weight is obtained. If the lift effect is neglected, the weight is constant and the resistance curves are parabolas having axes coincident with the ordinates. The zone between the traction curve and abscissa axis represents the possible working field of the vehicle. Figure 16 shows that a hill resistance of 6% can be surmounted in fourth gear, and that the same hill can be surmounted in third gear at a greater speed. If the working field corresponding to two different gears is superimposed, the gear change is possible.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107

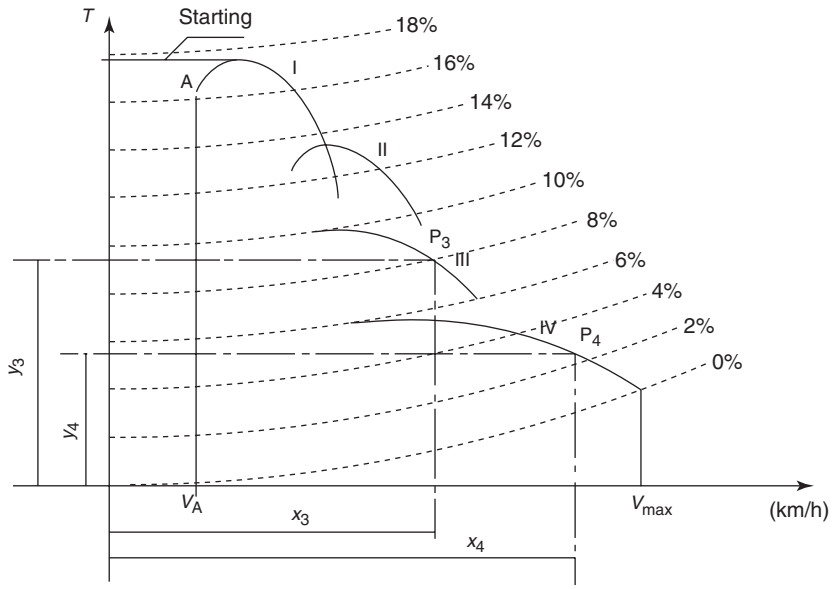

Figure 16. Traction versus speed.

Characteristic in first gear does not start from the ordinate axis because the engine cannot run under the minimum rotation number. The abscissa of the point A gives the minimum speed of the vehicle with the inserted engine; a lower speed than v_A requires the sliding of the clutch. For this reason, the acceleration at the starting point is considered constant, as is customary.

Traction characteristic of the vehicle can be obtained by Figure 16, knowing the point of gear change. Fixing the speed, the useful traction for the acceleration can be obtained by subtracting the resistance by the traction of the engine:

$$T_u = T\eta_t - R_{tot} \quad [N] \tag{69}$$

Because

$$N_u = T_u v = \frac{d}{dt}\left(\frac{1}{2}k_m \frac{P}{g}v^2\right) = k_m \frac{P}{g}va \tag{70}$$

the acceleration is

$$a = \frac{gN_u}{k_m P v} = \frac{gT_u}{k_m P} \quad [m/s^2] \tag{71}$$

with k_m is the inertia coefficient of the inserted gear. Diagram a–v in Figure 17 is useful to obtain the curve of speed and space versus time in the way described in the following paragraph.

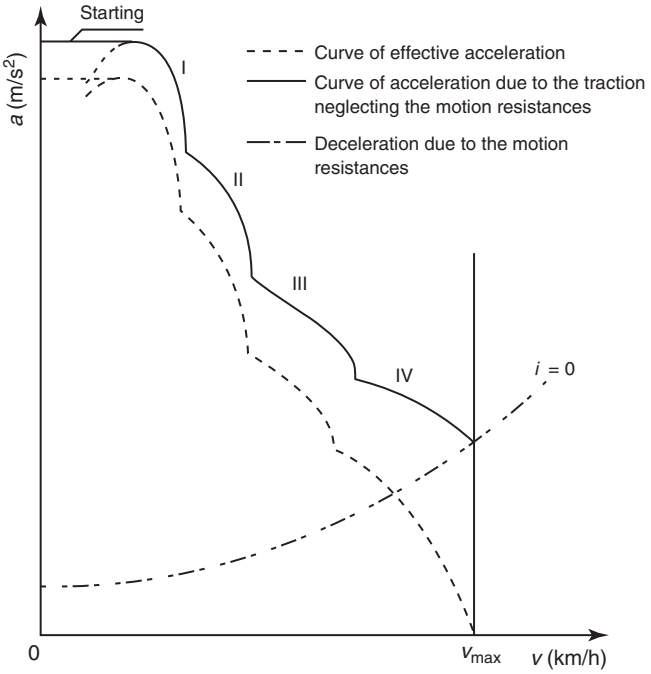

Figure 17. Acceleration versus speed curves; the vertical lines represent the gear changes.

2.3.2 *Diagrams N–v*

The estimate of the performance can be also executed by the construction of diagrams of power versus speed (De Gregorio, 1970; Heisler, 2004; Bencini, 1956). The speed

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

[km/h] is reported in the abscissa, while the power [kW] is reported in the ordinate. The curves of the resistance power are cubic parabolas approximately

$$N_r = R_{tot} \cdot \frac{v}{3.6} \cdot \frac{1}{1000} = \frac{R_{tot} \cdot v}{3600} \quad [kW] \qquad (72)$$

where R_{tot} is given by Equation 67 and v by Equation 64. Equation 64 converts the rotation of the engine into vehicle speed and then allows the construction of the used curves with several gears. The power characteristic of the engine has to be reduced by the efficacy of the transmission in the inserted gear, and the position of the point M (Figure 18) is in correspondence with the curve of the resistance power in plane if the axle ratio has the optimum value (Section 2.4.1). The speed corresponding to the point M is the maximum speed that the vehicle can reach in plane; slightly greater speed can be reached on a light downhill, without exceeding the maximum rotation rate. The diagram gives the following information:

1. Maximum hill resistance on the given gear;
2. Maximum speed with the given gear on a given hill;
3. The gear permitting the maximum speed on a given hill;
4. Cruise level, which is defined as the speed corresponding to the maximum engine torque rate.

Figure 18 shows also the resistance power on road with slope 2%. Until the speed v_n, the required power is negative for the gravity effect.

If the vehicle rides at speed v_n (at constant speed with disengaged engine), 2% is the harmful limit downhill. By increasing the number of gears, the extension of the dotted area is reduced, so that one has better utilization of the engine with better ability of acceleration and overcoming hills. In general, the maximum and minimum ratios are fixed with the performance of speed and hill; better ability of acceleration is obtained choosing the ratios by attempts, in order to make lower the dotted area.

Adaptation of the engine to the vehicle is the whole objective to obtain the requested performance compatible with the performances of the engine. Given a vehicle (S, C_d, P) and an engine with given characteristic of power and torque, the connection has to be implemented so that the performance is the more satisfactory, eventually for the optimum of one in detriment of others. The more reliable compromise constitutes the problem of the preliminary design of the vehicle (maximum speed, consumption on the road, acceleration, surmountable hill, towing, etc.).

2.4 Limits

2.4.1 Axle ratio calculation

The maximum achievable speed v_{max} can be obtained by solving Equation 72 versus the speed, putting

$$N_r = \eta_t \cdot N_{max} \qquad (73)$$

That is a limit condition. The axle ratio τ_p can be determined using Equation 63 by putting $v = v_{max}$ and $n = n_m$ [rpm], which is the maximum power rate (Figure 19), and putting τ_n equal to the highest gear ratio τ_υ. If the gear drive has a direct connection, τ_υ assumes the value 1, whereas if the highest ratio is implemented by a pair of gears, it assumes values very close to 1 because the two gears do not have the same number of teeth, to avoid the

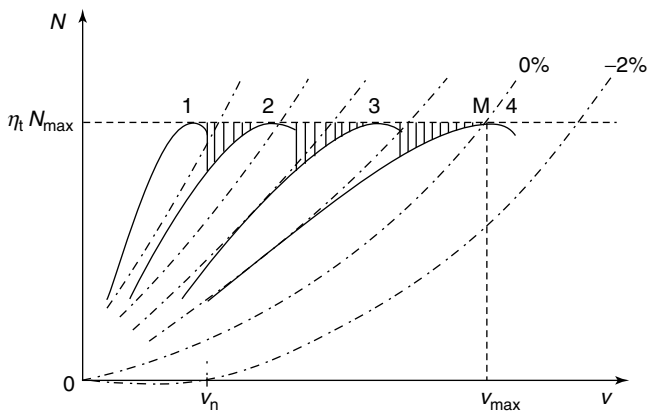

Figure 18. Four-gear N–v diagram.

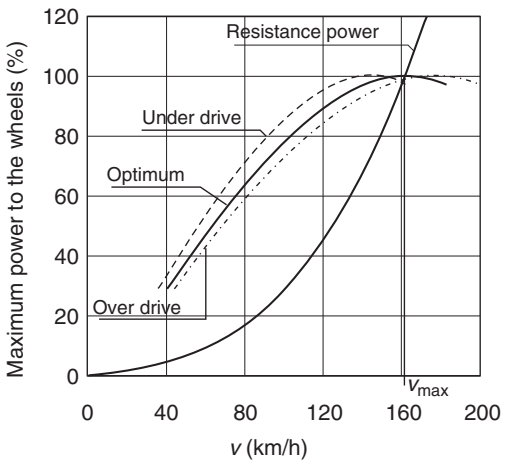

Figure 19. Determination of the optimum axle ratio.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

continuous contact between the same teeth. One has

$$\tau_{opt} = \frac{60}{2\pi n_m} \frac{1}{\tau_\upsilon R_0} \frac{v_{max}}{3.6} \tag{74}$$

The value calculated by Equation 74 is called the *optimum axle ratio*; the characteristic curve intersects the curve of resistance power corresponding to the maximum power rate. It is the value that allows the maximum speed with the selected engine.

If the intersection point corresponds to a greater or lower rate than the maximum power, the maximum speed of the vehicle will be lower than the possible one. For this reason, a decrease of the maximum speed is obtained if $\tau_p \neq \tau_{opt}$; a different ratio is chosen to obtain an improvement of other performances. In fact, greater ability of acceleration and greater gradability are obtained with $\tau_p < \tau_{opt}$ (underdrive), while the consumption on the road is lower if $\tau_p > \tau_{opt}$ (overdrive). In reality, small variations of τ_p give sensible improvements in some performances, while the consequent speed variation is only a percent of theoretical v_{max}. Moreover, the fact that the ratio τ_p is given by Equation 62, such as the ratio between two entire numbers, compels the designer to modify the optimum value. This is true also for all the other gears. By Figure 20, the following performances are obtained by increasing τ_p:

- Cruise level increases, with reduction of the consumption on the road (the fuel consumption is lowest at maximum engine torque).
- Minimum speed on the road increases. This is a negative aspect for urban running and for the urban drivability. A minimum speed of about 40 km/h should be ensured.
- Power reserve for the acceleration diminishes. This reduces the vehicle burst.

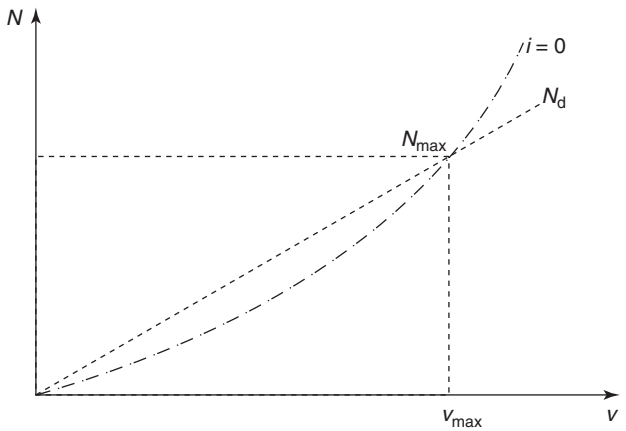

Figure 20. Maximum power on the vehicle and maximum speed.

2.4.2 *Top speed and power*

A limit exists to the power that may be implemented on the vehicle and transmitted to the wheels. If L is the adhesion weight and f the value of the longitudinal adhesion coefficient, the traction T_{max} is given by

$$T_{max} = f \cdot L \tag{75}$$

Equation 75 in term of power is

$$N_d = \frac{f \cdot L \cdot v}{3600} \quad [kW] \tag{76}$$

Fixing f and L for a given vehicle and for the wheel–ground coupling, the power is a linear function of the speed v, and then is

$$N_d = \frac{f \cdot L \cdot v}{3600} = R_{ord} v = A_0 \cdot v + B_0 \cdot v^3 \tag{77}$$

given that R_{ord} is a function of v^2. Neglecting the lift effect, A_0 and B_0 are constants and contain the conversion factors of the measurement units. Then

$$v_{max} = \sqrt{\frac{1}{B_0}\left(\frac{f \cdot L}{3600} - A_0\right)} \tag{78}$$

which expresses the maximum speed of the vehicle on $i = 0$ in absolute terms, as Figure 20 shows. The corresponding maximum power is

$$N_{max} = \frac{1}{\eta_t} \frac{f \cdot L}{3600} \cdot \sqrt{\frac{1}{B_0}\left(\frac{f \cdot L}{3600} - A_0\right)} \tag{79}$$

which is the admissible value of the maximum power on the vehicle.

2.4.3 *Minimum ratio*

A limit exists to the minimum ratio imposed by the maximum traction applied to the wheels. The traction is

$$T_m = \frac{\eta_t \cdot C_{max}}{R_0 \cdot \tau_{min} \tau_p} \tag{80}$$

As the wheels do not skid, one has

$$T_m \leq T_{max} \tag{81}$$

Then

$$\tau_{min} = \frac{\eta_t \cdot C_{max}}{R_0 \cdot f \cdot L \cdot \tau_p} = \frac{\eta_t \cdot C_{max}}{R_0 \cdot f \cdot \tau_p} \frac{1+m}{P} \tag{82}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where C_{max} is the maximum engine torque, η_t is the transmission efficacy, R_0 is the rolling radius of the wheels, P is the weight of the vehicle, τ_p is the axle ratio fixed in the previous way, and m is the ratio defined by Equation 15 and obtained by Equation 19 or 20. A lower value than given by Equation 82 is not useful because the greater part of the traction is not used, so that $\tau_1 \geq \tau_{min}$. Moreover, if the wheels begin to skid, f diminishes and the transmitted traction decreases further.

The maximum hill can be determined by Equation 17. In a first approximation, the quantity r_{ord} can be calculated by neglecting the aerodynamic resistance and the variation of the rolling resistance, as the vehicle speed is very low. This permits the calculation of m and of the ratio τ_{min} by Equation 82. Note that 4WD traction permits a lower gear ratio, with greater possibility of gradability. The calculated ratio has to be rounded up to consider the number of teeth of the gear drive that implements it. This permits the determination of the first gear ratio τ_1. The relative position of the curves is shown in Figure 21, which is a condition of tangency as the motion resistance can be approximated by a straight line. The calculated hill resistance can be overcome with a speed corresponding to the point M. The road irregularity, which introduces a diminishing of the speed, induces a deceleration of the vehicle until the stop. In other words, the gradability is not stable because the resistance power is greater than the wheel power if the speed does not correspond to the maximum engine torque rate. In reality, the run is stable if the residual acceleration has the value a_M. The corresponding power N_{acc} is given by

$$N_{acc} = k_I \cdot a_M \cdot \frac{P}{g} \cdot \frac{v_M}{3.6} \cdot \frac{1}{1000} \quad [kW] \tag{83}$$

where k_I is the inertia coefficient in the first gear. The vehicle is able to run on the hill if

$$i^* = i_{max} - k_I a_M \frac{100}{g} \tag{84}$$

The second term of the right-hand side is obtained by Equation 50. Curve i^* is drawn by putting $a_M = 0.3$ m/s with an inertia coefficient 1.4 and an adhesion coefficient 0.6. This permits the stable run of the vehicle between the speeds corresponding to the points A and A′.

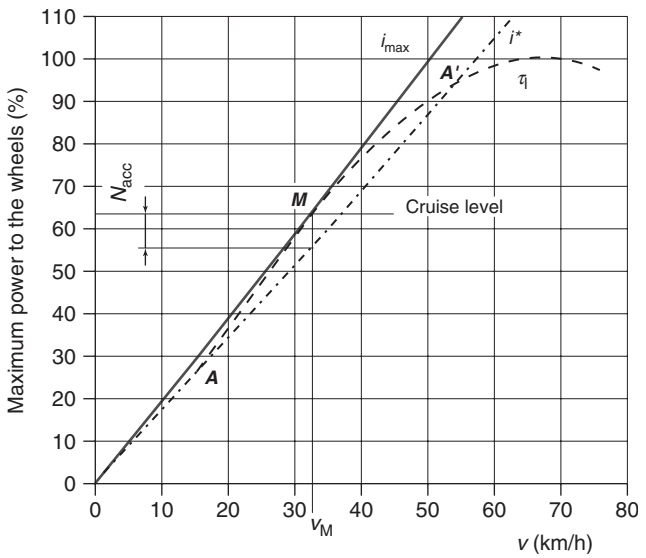

Figure 21. Minimum gear ratio and maximum hill.

2.5 Intermediate ratios selection

Transmission has a fixed number of gear ratios, so that the curves should be interrupted for loss of engine rotation between each gear change. For a saloon car or light van having a large power to weight ratio, a five or six gearbox is adequate to maintain the traction effect without high loss in engine rotation during the gear change. Heavy goods vehicles hauling large loads have a low power to weight ratio, and the fall-off of engine rotation is so high so that higher gear ratios are necessary. A comparison between Figures 22 and 23 shows that the diminishing of engine rotation is very small by doubling the gear ratios. To avoid too large and heavy gearboxes, a better way of extending the gear ratios is the use of a two-speed auxiliary gearbox in series with a conventional one. The combination of main and auxiliary gearboxes can be designed to be used as a splitter gear change or a range gear change (Figure 23). Also, in the case of a splitter gear change, the high ratio is kept nearly equal to 1. The second gear ratio is chosen so that it splits the main gearbox ratio steps in to half. The splitter indirect ratio normally is set 1.1–1.4 : 1, and it is set to 1.2 : 1 in Figure 23.

Ratios between the top and bottom gears have to be spaced in order to provide the traction effort as close to the ideal as possible. Intermediate ratios can be selected using a geometric progression as a first approximation. This requires the engine to operate within the same speed range in each gear to obtain the best fuel economy. The limits are the rotations n_H and n_L. Neglecting the change of the road speed, the speeds are v_1, v_2, v_3, v_4, and v_5 if the number of gears is equal to 5 (Figure 24). The gear ratios are τ_1, τ_2, τ_3, τ_4, and τ_5, and the overall gear ratios are obtained multiplying them by τ_p. The following

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

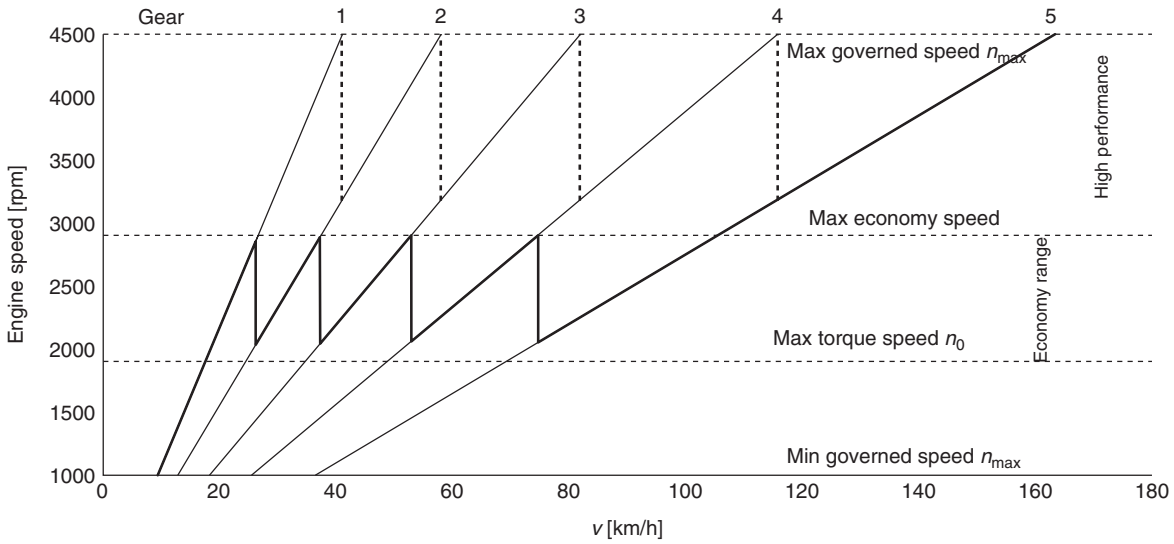

Figure 22. Engine speed ratio chart for a vehicle employing a five-speed gearbox.

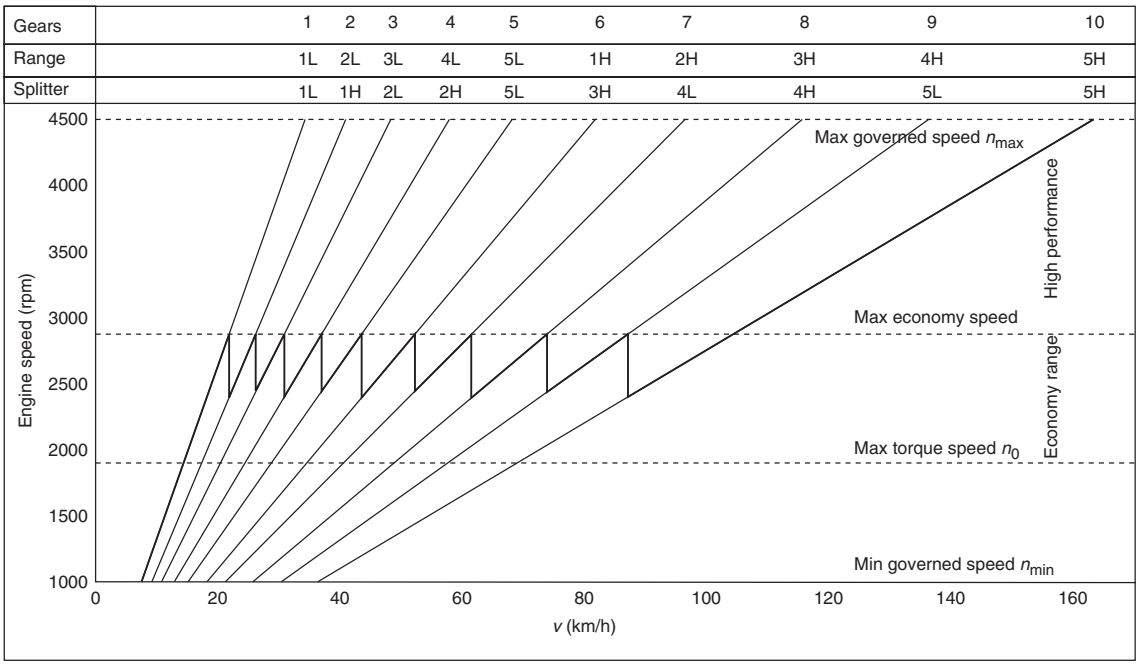

Figure 23. Engine speed ratio chart for a vehicle with a 10-speed range or a splitter change gearbox.

relationships are obtained:

$$\begin{aligned} v_5 &= n_H\tau_p\tau_5 & v_4 &= n_L\tau_p\tau_5 \\ v_4 &= n_H\tau_p\tau_4 & v_3 &= n_L\tau_p\tau_4 \\ v_3 &= n_H\tau_p\tau_3 & v_2 &= n_L\tau_p\tau_3 \\ v_2 &= n_H\tau_p\tau_2 & v_1 &= n_L\tau_p\tau_2 \\ v_1 &= n_H\tau_p\tau_1 \end{aligned} \tag{85}$$

Eliminating the speeds, one has

$$\tau_2 = \tau_1\frac{n_H}{n_L} \qquad \tau_3 = \tau_1\left(\frac{n_H}{n_L}\right)^2$$

$$\tau_4 = \tau_1\left(\frac{n_H}{n_L}\right)^3 \qquad \tau_5 = \tau_1\left(\frac{n_H}{n_L}\right)^4 \tag{86}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

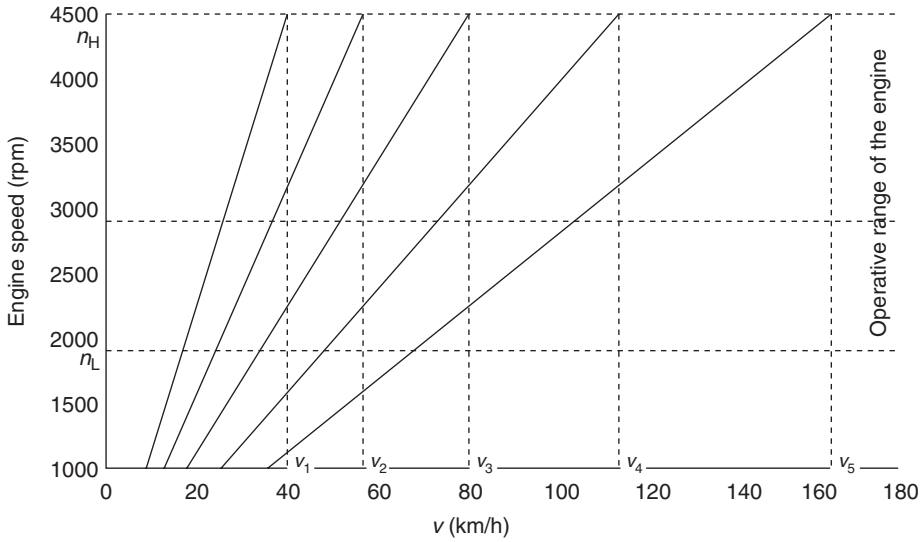

Figure 24. Gear ratio selected on geometric progression.

In general, the first gear ratio is known ($\tau_1 \geq \tau_{min}$), and the highest ratio τ_υ is equal to 1 or has a value very close to 1. By fixing the number υ of gears, the value of the generic ratio τ_n is given by the following relationship:

$$\tau_n = \tau_1 \left(\frac{\tau_\upsilon}{\tau_1} \right)^{\frac{n-1}{\upsilon-1}} \qquad n = 1, \ldots, \upsilon \tag{87}$$

The ratio k of the geometric progression is

$$k = \frac{n_H}{n_L} = \sqrt[\upsilon-1]{\frac{\tau_\upsilon}{\tau_1}} \tag{88}$$

The determination of n_H and n_L can give indications on the need of a splitter or range gear change. A correction can be executed choosing a few lower values if the performance in acceleration or ability to surmount hills has to be improved, and a few higher values if the consumption has to be diminished.

The overall number υ of the gears depends on the following characteristic:

1. n_{min} and n_{max} rates and ratio between the corresponding engine powers. If the characteristic is flat, the number of gears decreases;
2. Maximum engine power;
3. Vehicle acceleration. The characteristic of pickup improves by increasing υ.

Power–speed characteristic can be represented also in logarithmic coordinates. Their use was useful in the past, as the curves have to be drawn by hand. Today, the spread of computers does not make it convenient.

2.6 Vehicle acceleration

The starting, with the sliding of the clutch, takes a time T_a, so that the vehicle begins the acceleration phase by increasing the speed. In this phase, a human factor is present in the way the driver operates the clutch. It is customary to consider the acceleration to be constant during the entire starting time, for the purpose of this article. If the engine is at maximum torque rate and at full introduction

$$\frac{dv}{dt} = \left(\frac{C_{max}}{\tau_1 \tau_p R_0} - R_{rot} \right) \frac{g}{k_1 P} \tag{89}$$

2.6.1 Acceleration, speed, and space diagrams

To forecast the performances on the road, that is, in plane road, the diagrams N–v (or T–v) have to be completed by making some hypotheses on the gear changes. Also, this aspect is influenced by a human factor, because the driver's maneuver may be executed in several ways. Figure 25 shows a possibility. The drive change occurs in order to obtain the maximum torque in the successive gears and the maximum performance in terms of acceleration.

For the first condition, the starting is represented by a straight line linking the origin with the point of maximum torque in the first gear, like the tangent to the curve. All diagrams are drawn by making the hypothesis of the engine working at full introduction. Fixing a generic point A having speed v [km/h], the powers of interest are (i) the resistance power N_r [kW], (ii) the available power at wheels N_u [kW] at full introduction, and (iii) the available power

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

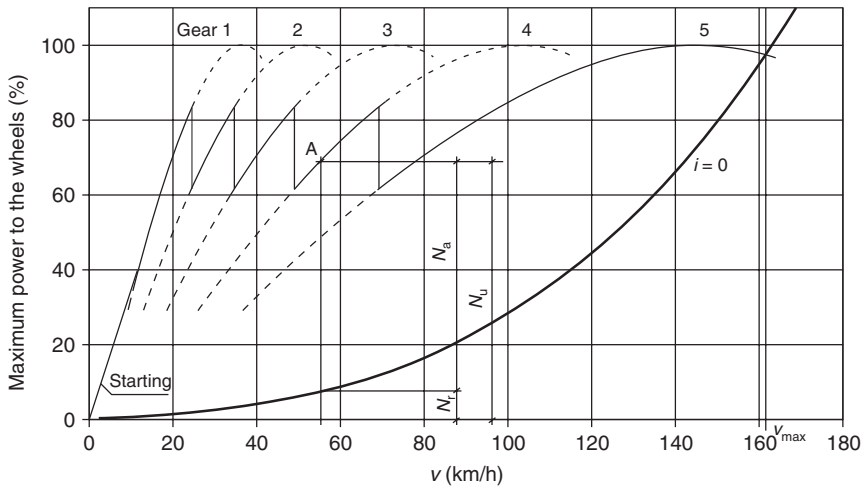

Figure 25. Hypothesis of maneuver of gear changes. The driver executes the change, represented by vertical lines, in order to obtain the maximum torque in the inserted gear.

for the acceleration $N_a = N_u - N_r$. The acceleration is given by

$$a = \frac{dv}{dt} = \frac{(N_u - N_r) \times 3.6}{v} \frac{g}{k_m P} \quad [m/s^2] \qquad (90)$$

where k_m is the inertia coefficient in the inserted gear, P [kN] is the vehicle weight, and g is the gravity. Acceleration versus the speed can be thus drawn, and it is similar in all respects to the graph of Figure 17 (in dotted line). To improve the performance forecast, the drawn curve may be corrected to consider the time t_l due to the change gears. During this time, the engine is disconnected from the wheels and the useful power is equal to zero, so that the vehicle suffers a deceleration d that is given by Equation 90, putting $N_u = 0$.

$$d = -\frac{N_r \times 3.6}{v} \frac{g}{k_n P} \qquad (91)$$

where k_n is the inertia coefficient in neutral position. This deceleration acts on the vehicle during the time of gear change depending both on a human factor and on the gearbox construction. It produces a diminishing of speed, which is given by

$$\Delta v = d \cdot t_l \qquad (92)$$

A more accurate definition is not necessary because the gear change time is small and assumes the value 0.5 s for an automated gearbox until 2.0 s, or more for a nonsynchronized gearbox. Then, the graph a–v is shown in Figure 26. Of course, the lines of gear change have to

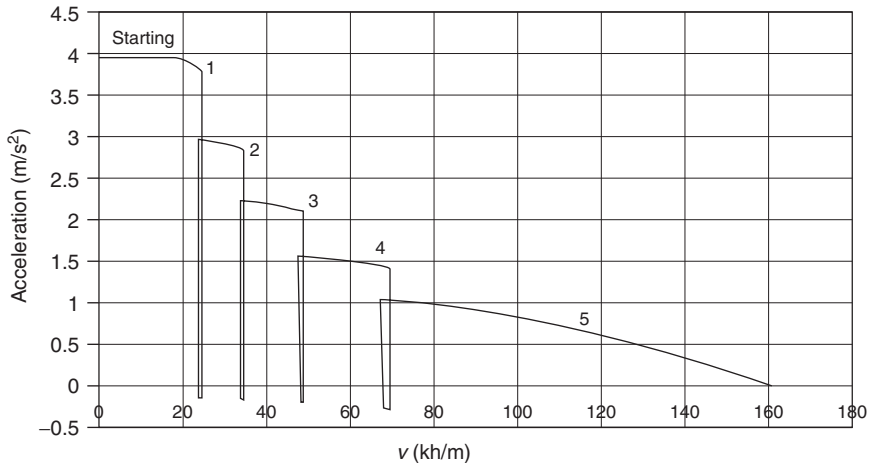

Figure 26. Acceleration versus speed considering the time of gear change, which is taken as 1.5 s.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

be considered as approximate. Now the graph v–t may be drawn because

$$a = \frac{dv}{dt} \tag{93}$$

One has

$$t = \int_0^v \frac{dv}{a} \tag{94}$$

The diagram $1/a$–v can be integrated by a numerical method. For example, the use of a spreadsheet foil gives satisfactory results using Simpson's rule applied to the inverse of acceleration $1/a$. The optimum gear ratios make the time minimum by Equation 94; in this way, the graph of Figure 27 is obtained. It shows the times of gear change and the corresponding speed reductions. The curve is asymptotic to the value of maximum speed. The covered space versus time can be drawn (Figure 28) by a further integration. The curve of the space is asymptotic to a straight line having an angular coefficient equal to v_{max}. The time t_p is the waste of time to accelerate the vehicle and is the difference between the time to cover the distance s_0 with standing start and the time to cover the same distance with a constant speed equal to v_{max}.

To increase the ability of acceleration, the inertia moments of the rotating parts have to be reduced, in order to reduce the inertia coefficients. Very advantageous is the reduction of the time of gear change, which shows the utility of devices to make the insertion of the gears easy, reducing the mass in motion and automating.

2.7 Engine map and kilometric consumption performance

Equal consumption curves q [g/kW/h] are obtained experimentally by the engine bench and are drawn on diagram N–n or C–ω [rad/s] (Bencini, 1956; Heisler, 2004; Genta,

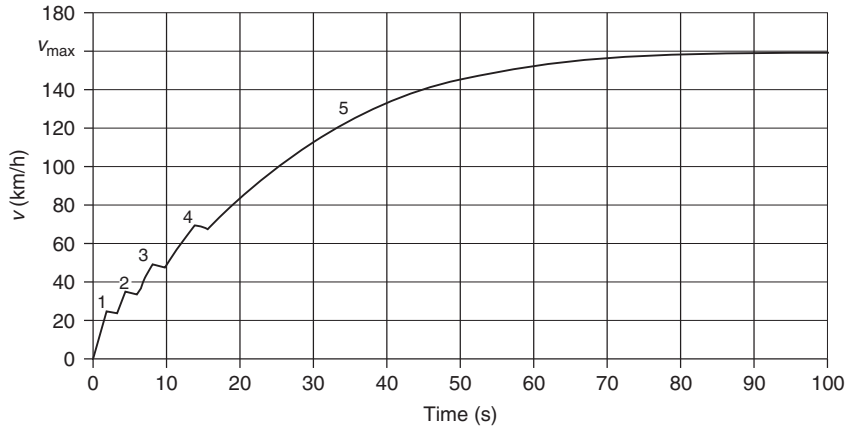

Figure 27. Speed versus time.

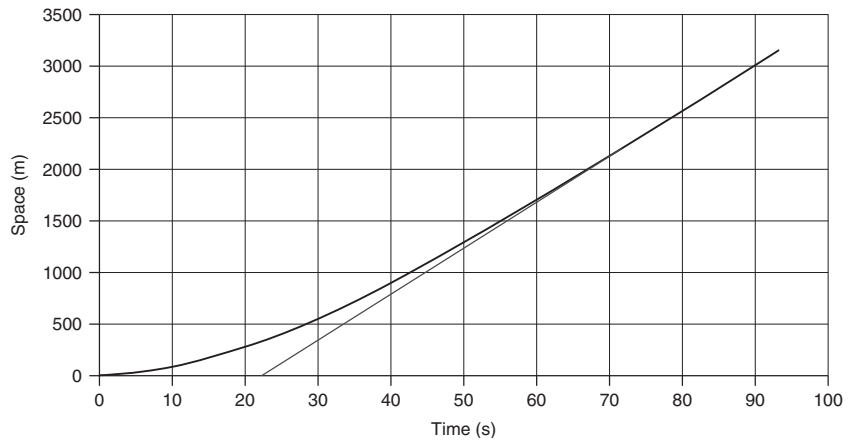

Figure 28. Space versus time

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.
This article is © 2014 John Wiley & Sons, Ltd.
DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

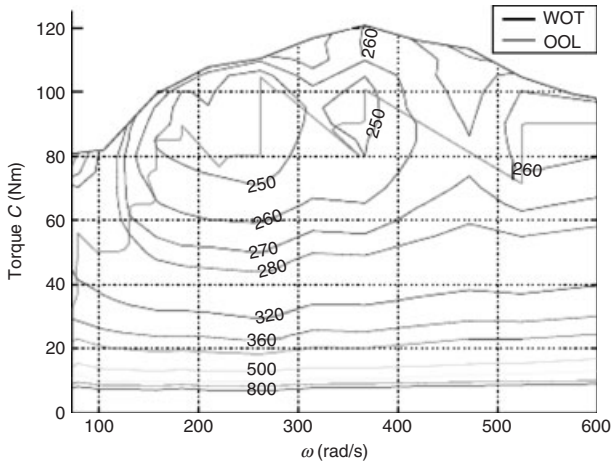

Figure 29. Static fuel map [g/kW/h] SI engine. $C_{max} = 120$ Nm at 3500 rpm, $N_{max} = 60$ kW at 5700 rpm.

2003). Figure 29 shows an engine map with the curves of equal consumption for all open throttle and optimized throttle. The line "WOT" represents the maximum obtainable torque by varying the rotation number of the engine; instead, the line "OOL" connects the points of minimum consumption of fuel.

Figure 30 shows both the power and torque characteristics and the corresponding specific consumption for the map of Figure 29. The power characteristic is obtained using a fourth-order polynomial, as the third-order one by Equation 55 is not satisfactory. Of course, the constraints of maximum power and maximum torque are respected. Specific consumption depends on the rotation rate n and on the introduction x, intended like a percentage of the full power, so that $0 < x < 1$. For example, the power corresponding to the point A in Figure 30 is 40 kW; the full power at the same rotation rate is 56.65 kW, so that the introduction corresponding is $x = 40/56.65 = 0.706$. The lines of specific consumption q are determined by interpolating the data in Figure 29. Both the lines at full introduction and at $x = 25\%$ of the power are shown in Figure 30. The interpolation versus n is executed with a polynomial of the second order, as a greater order does not give satisfactory results. The specific consumption increases, reducing the grade of introduction of the engine and has a minimum corresponding to the maximum torque rate. The economy range is a zone where the specific consumption has a minimum value and is the zone of normal working of the engine.

The interpolation of q versus x is not easy, as the curves at high percentage are close to the full introduction curve $x = 1$, so that both the linear and parabolic interpolation are not satisfactory. The work requires more advanced techniques of interpolation. After doing this, a definition of $q = q(x, n)$ at the entire field is obtained (Scamardi, 2007; Terruso, 2008; Terruso and Virzi' Mariotti, 2009). The precision is low because of the uncertainties of the extrapolation and in the experimental determination.

The minimum value of consumption for unity of run, in plane and in speed, is the maximum performance of kilometric consumption. The hourly consumption of the engine is defined by

$$C_t = \frac{q \cdot N'_w}{\eta_t \cdot \rho} \quad [\text{L/h}] \tag{95}$$

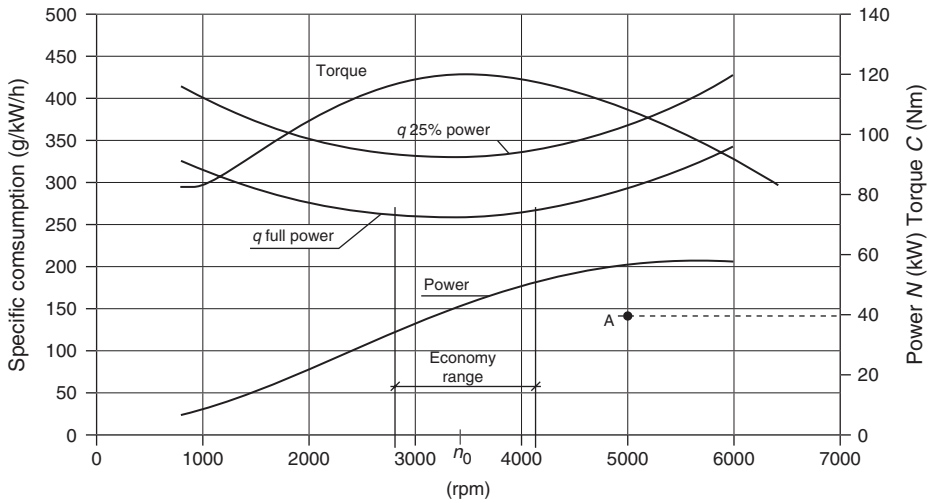

Figure 30. Characteristic of power, torque, and specific consumption of the engine.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto107
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where q is the specific consumption of the engine [g/kW/h], ρ is the density of the fuel [g/L], and η_t is the transmission efficacy. The available power N'_w to the wheels is a percentage of the full power N_w:

$$N'_w = xN_w = x\eta_t N \tag{96}$$

In the case of a hybrid vehicle, the power furnished by the electric motor has to be subtracted by Equation 96. Substituting Equation 96 into Equation 95 gives

$$C_t = \frac{x \cdot q \cdot N_w}{\eta_t \cdot \rho} = \frac{x \cdot q \cdot N}{\rho} \quad [\text{L/h}] \tag{97}$$

Fixing the C_t value, Equation 97 allows the calculation of x for a given value of n (or of the speed v), so that the curves at constant C_t may be drawn. Of course, the points with $x > 1$ have to be discarded. An example is shown in Figure 31, which is drawn for an overdrive, but the curves at constant C_t are associated with the curve of use, so that for the other gears they are drawn by changing the gear ratio to calculate the speed in the abscissa. The resistance power at $i = 0$ is also shown; the consumption in plane road at speed v_{max} is equal to ~21/L/h, while the consumption at speed 100 km/h ($\frac{2}{3}v_{max}$ is greater, following CUNA rule) is about 5.5 L/h. The graph of C_t versus time may be drawn after the construction of curves similar to Figure 25 and the successive figures, and then the necessary fuel C on a given stretch can be determined by the relationship

$$C = \int_{t_1}^{t_2} C_t dt \tag{98}$$

Introducing a suitable conversion factor; t_1 and t_2 indicate the interval of the time.

The total consumption for 100 km is defined by

$$C_{100} = \frac{C_t}{v} \cdot 100 \quad [\text{L/100 km}] \tag{99}$$

By substituting Equation 97, one obtains

$$C_{100} = \frac{x \cdot q \cdot N_w}{\eta_t \cdot \rho \cdot v} 100 = \frac{x \cdot q \cdot N}{\rho \cdot v} 100 \quad [\text{L/100 km}] \tag{100}$$

Curves at constant consumption corresponding to 100 km of run, for every use condition (v, i, τ), can be calculated by an analogous procedure knowing the vehicle speed v.

Figure 32 shows the curves at constant C_{100} in the case of an overdrive. If the vehicle rides on a plane road at speed v_{max}, the consumption is ~12 L/100 km, while riding at speed 100 km/h the consumption is about 5.5 L/100 km. Figure 33 shows the curves in the third gear; at constant speed 100 km/h, the consumption is ~6.2 L/100 km, while it increases to ~18 L/100 km at full acceleration. C_{100} curves depend on the gear ratio and have to be determined for every gear, unlike C_t. The family of curves can be reported in the N–v diagram to obtain an overall representation of both thermodynamic and economical performances of the vehicle. In general, a greater consumption corresponds to lower gear ratios. Also, the ratio

$$C_d = \frac{v}{C_t} = \frac{100}{C_{100}} \text{ [km/L]} \tag{101}$$

is used in practice; it defines the number of kilometers covered by 1 L of fuel.

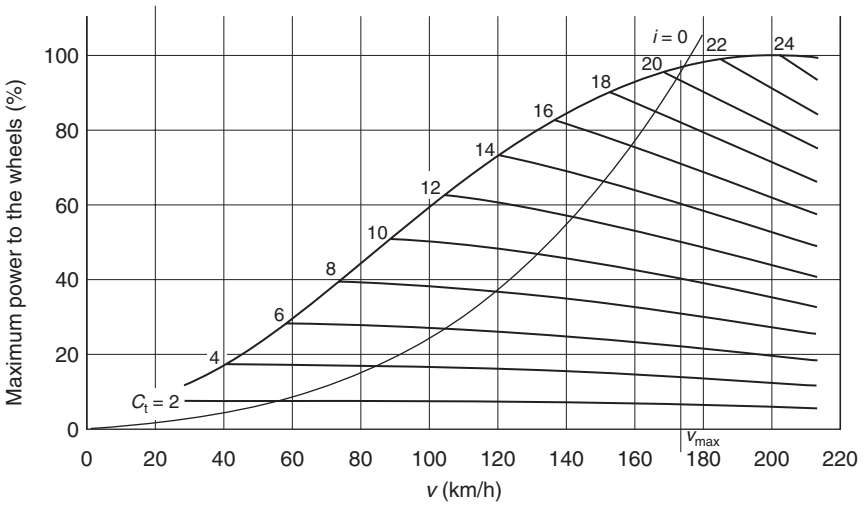

Figure 31. Curves at constant C_t [L/h] for an overdrive; $\eta_t = 0.95$; $\rho = 785$ g/L.

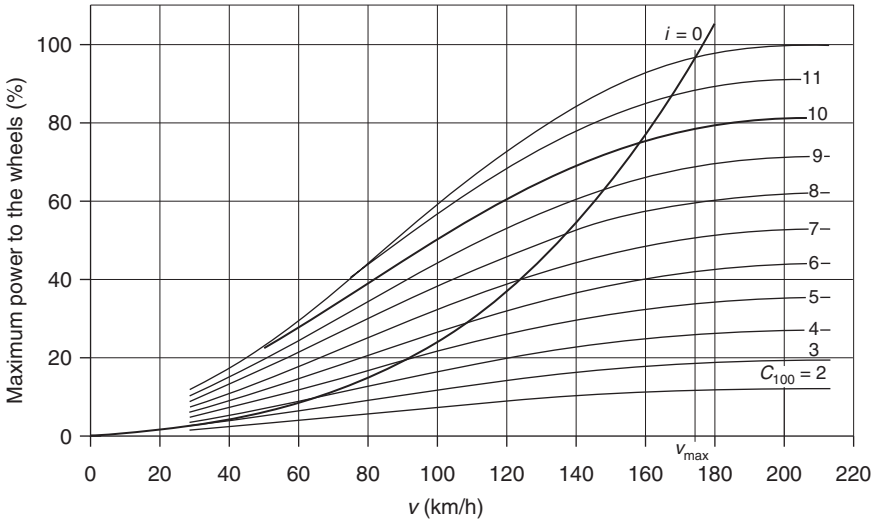

Figure 32. Kilometric consumption curves [L/100 km] for an overdrive.

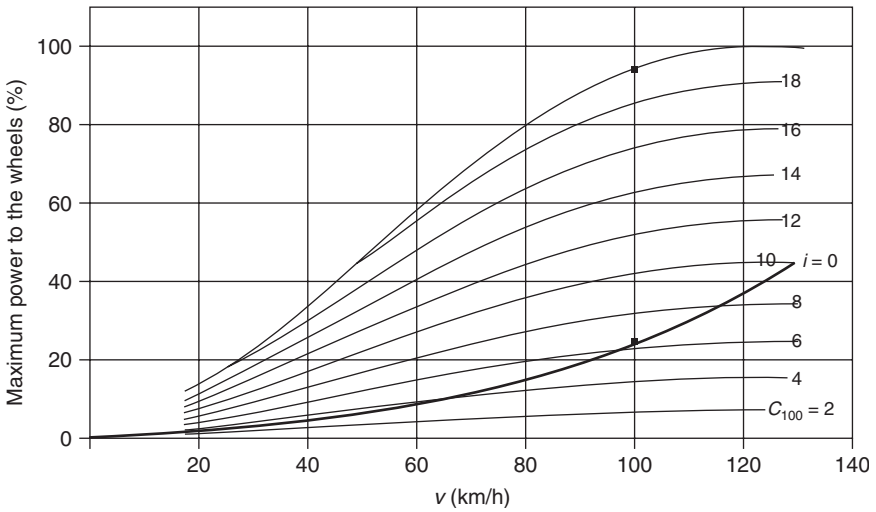

Figure 33. Kilometric consumption curves [L/100 km] in third gear.

A vehicle can be considered as a thermal machine, receiving energy (fuel) and furnishing work (transport), so that the overall efficacy of the change of thermochemical energy of the fuel into mechanical energy used by the vehicle during the motion can be calculated. The energy furnished to the vehicle in 1 h for a determinate mechanical performance (N, v, i) is

$$E_f = C_t \cdot \rho \cdot H_i \quad [\text{kJ/h}] \tag{102}$$

where ρ is the density of the fuel [kg/L] and H_i is the net heat value [kJ/kg]. Introducing C_{100}, one has

$$E_f = \frac{C_{100} \cdot v}{100} \cdot \rho \cdot H_i \quad [\text{kJ/h}] \tag{103}$$

The mechanical energy used in 1 h is

$$E_u = 3600 \cdot N \quad [\text{kJ/h}] \tag{104}$$

N [kW] being the power. The overall efficacy is

$$\eta_{cv} = \frac{E_u}{E_c} = \frac{3600 \cdot N}{C_t \cdot \rho \cdot H_i} = \frac{3600 \cdot N}{\frac{C_{100} \cdot v}{100} \cdot \rho \cdot H_i} = \frac{3600 \cdot N \cdot C_d}{v \cdot \rho \cdot H_i} \tag{105}$$

The efficacy varies with the transmission ratio and assumes values between 0.25 and 0.3 for a passenger car.

Consumption for kilonewton of transported load Q_u is

$$C_u = \frac{C_{100}}{Q_u} = \frac{C_t}{Q_u \cdot v} \cdot 100 \quad [\text{L/kN/100 km}] \qquad (106)$$

This parameter expresses the goodness of the engine (C_t) and of the vehicle (performance v and utilization Q_u) at the same time.

Kilometric consumption varies with v and i. The consumption assumes different values depending on the inserted gear at the same speed. The consumption at $\frac{2}{3}v_{max}$ is not indicative, as the consumption depends on

- the mean commercial speed v_{mc}, which in general is much lower than $\frac{2}{3}v_{max}$;
- the altimetry variation of the road (if the run is closed, the loss energy in the hill is recovered in part in the downhill motion);
- the acceleration and deceleration of the vehicle during the run;
- the time of thermal rate of the engine (at the starting, a part of the energy is lost in heating the coolant).

Today, other data are declared, such as the urban consumption and consumption on a mixed way.

2.8 Drivability

Handling is a dynamic property of the vehicle that is not to be mistaken with the maneuverability. Both these properties constitute the drivability of a vehicle. The maneuverability can be defined as the maximum obtainable performance, quantized by the necessary time to execute a maneuver, starting from an initial point until the arrival, satisfying the physical constraints (maximum forces supported by the tires and maximum engine torque) and geometry (the vehicle has to remain inside the route). Handling is, instead, defined in terms of the maximum obtainable performance considering also the driver limits, for example, the speed to apply the brakes, the gas, and the steering. In other words, handling is linked to the answer characteristic of the vehicle considering the physical and mental effort required by the driver. Very important is the facility of the driver to integrate with the vehicle.

Kinematic steering (Pollone, 1970; Stagni, 1980) is defined as the motion of a vehicle on a curved trajectory determined by the pure rolling of the tires, so that the sideslip angles are equal to zero. The center of instantaneous rotation O has to be the same for all the wheels (Figure 34). Referring α and β as the steering angle of the two front wheels, the following relationships are valid:

$$\frac{OC}{AC} = \frac{1}{\tan\beta} = \frac{R_2 + \frac{s}{2}}{p} \quad \frac{OD}{BD} = \frac{1}{\tan\alpha} = \frac{R_2 - \frac{s}{2}}{p} \qquad (107)$$

where p is the wheelbase, s is the front carriage, and R_2 is the radius of curvature at the rear carriage. Subtracting Equations 107, the following relationship is obtained:

$$\frac{1}{\tan\beta} - \frac{1}{\tan\alpha} = \frac{s}{p} \qquad (108)$$

That is known as the *Ackermann fundamental equation*. Today, steering systems are derived by the "Jeantaud quadrilateral" (Figure 35), but do not satisfy Ackermann relationship, so that a steering error is committed. One has

$$\tan\gamma = \frac{d}{p} \cong \frac{s}{2p} \qquad (109)$$

Moreover

$$a \cong \frac{s}{10} \qquad (110)$$

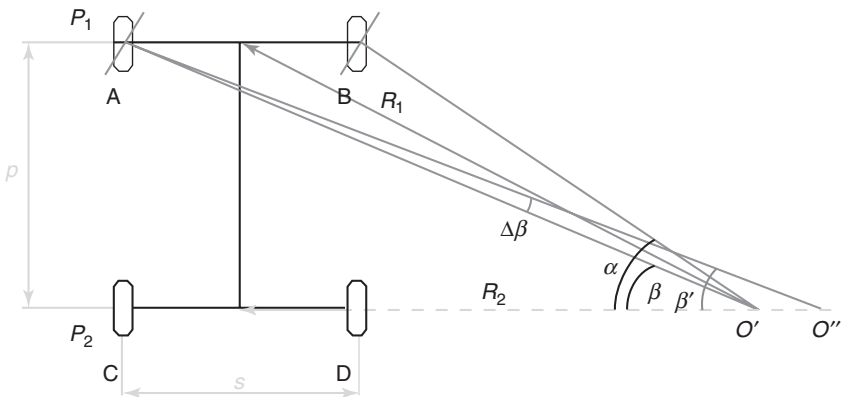

Figure 34. Ideal steering of the vehicle and steering error.

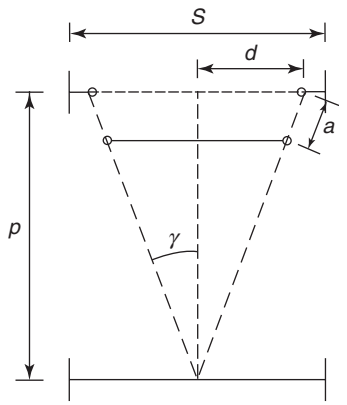

Figure 35. Jeantaud quadrilateral.

a and γ are two parameters to correct for the reduction of steering error. In particular, the designer has to reduce the steering error at low values of steering angle in order to improve the drivability during the runs with low steering angle (roadway or mixed way). This reduces the additional resistance in curves.

Figure 36 shows that the steering error can be strongly reduced increasing the γ value. α and β are the steering angles of wheels A and B, respectively (Figure 34). $\Delta\beta = \beta - \beta'$ is the steering error committed by Jeantaud quadrilateral with regard to the ideal condition of Ackermann.

The acronym 4WS indicates four-wheel steering. The working is divided in to *in contra phase* and *in phase*. The first is used when the vehicle has low speed on road; the rear wheels have steering angle of opposite sign than front wheels. The second is used when the vehicle runs at high speed; the rear wheels have steering of the same sign.

The elk test (Figure 37) (or moose test) (De Gaetano, Guerrera, and Virzì Mariotti, 2003; Lo Guasto, 2011) is executed to verify the stability of a vehicle during the execution of sudden steering to avoid unexpected obstacles on the road. The test is carried out on a dry surface; traffic cones are disposed at S along the way, the road, and its side

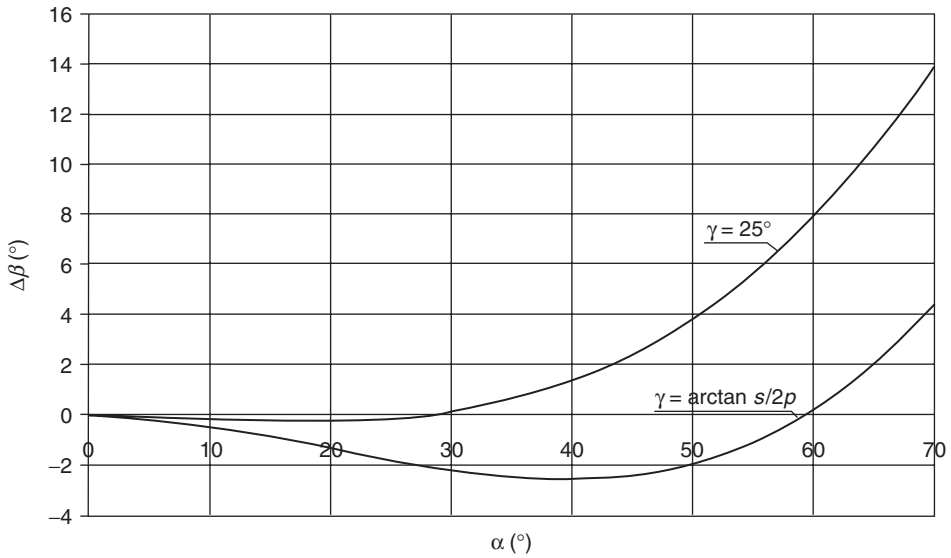

Figure 36. Steering error with increasing value of γ.

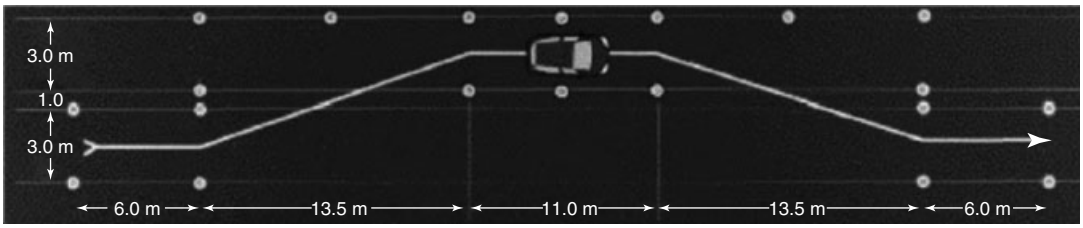

Figure 37. Elk test.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

to simulate the obstacle; and the vehicle is at full load. In the neighborhood of the obstacle, the driver steers suddenly toward the opposite lane to return at once in the run lane. The test consists in the overcoming of the way at 120 km/h. This allows the comparison of the data of two-wheel drive (2WD) and 4WD, such as sideslip angles of the wheels, angle and jaw speed, roll, force in the ground–tire contact, and percentage error in the trajectory. The way the stability test is conducted consists of an initial part at constant speed long 70 m, a gap of 30 m, a part on the left lane of 20 m, and a successive return to the right lane. In the simulation, the control logic of the vehicle is of type "closed loop," given that the driver executes corrections on the trajectory. Typical data may be imposed in the following way: driver preview time = 0.73 s, driver time lag = 0.4 s. The first time corresponds to the prevision of the driver on the trajectory, and the second is the reaction time. They constitute a human factor with similar values to the real drivers. The vehicle is a saloon car of class D at three volumes, with long wheelbase (Table 3), and the overall duration of the handling test is 7 s. The simulator furnishes the data of both the vehicles; as an example, Figure 38 shows the front load F_x in the motion direction.

Results can be validated by comparing longitudinal force F_x, the side force F_y, and the aligning moment M_z with the values obtained by the Pacejka magic formulae. The necessary coefficients may are assumed from the international literature for a saloon car having a mean size (i.e., Genta, 2003), while the vertical load F_z ($=P_w$) is obtained by the same simulation: so, like the sideslip angle, the camber angle and the longitudinal slip. Another comparison may be executed between the vertical load obtained by the simulation and the vertical load obtained by the following theoretical relationship (Stagni, 1980):

Table 3. Vehicle data.

Total mass	1530 kg
Sprung mass	1370 kg
Unsprung mass	160 kg
Height	1.471 m
Length	4.620 m
Width	1.795 m
Carriage	1.550 m
Front camber	-2°
Front toe in	-1°
Rear camber	-4°
Rear toe in	0° 4WS vehicle 1° 2WS vehicle
Front king pin	10°
Front caster	7°
Rear kingpin	10°
Rear caster	5°
Front spring constant	153,000 N/m
Rear spring constant	82,000 N/m
Tires	215/55 R17
Rear wheels maximum steering	3.5°

$$\frac{\Delta F_{z1}}{F_{z1}} = \frac{2a_0}{g}\left[\frac{h'}{s} + \phi\frac{h''}{s}\frac{P}{F_{z1}}\left(\frac{m_1}{m_s - \phi \cdot P \cdot h''}\right)\right] \quad (111)$$

The symbols are listed in Table 4. An analogous formula can be written for the rear carriage, by changing the index 1 in 2. m_s [Nm] is called the *crosswise stiffness moment*; applying it around the longitudinal axis of the vehicle, a roll angle equal to 1 rad is obtained. It is the sum of the values on the front carriage m_1 and on the rear carriage m_2:

$$m_s = m_1 + m_2 = 2b_1^2k_1 + 2b_2^2k_2 \quad [\text{Nm}] \quad (112)$$

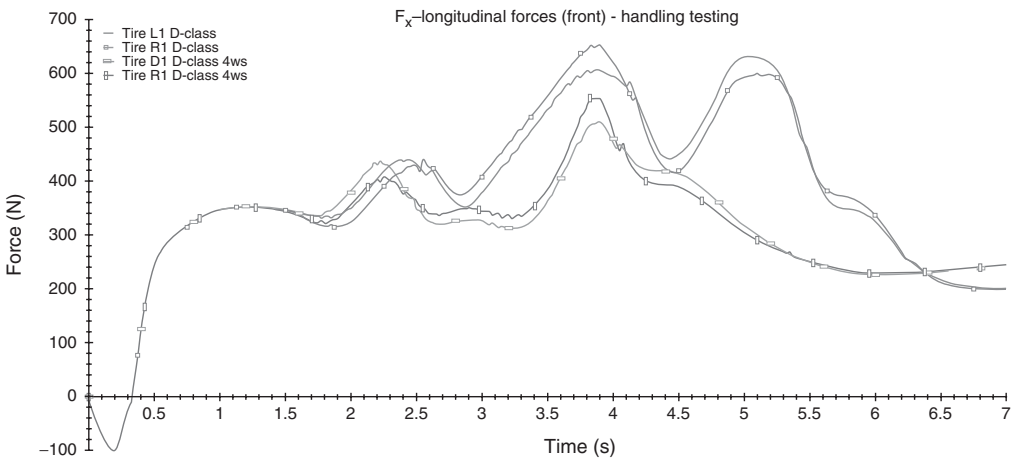

Figure 38. Front load F_x.

Table 4. Data for drivability.

a_0	Centrifugal acceleration of the vehicle	[m/s^2]
φ	Ratio between sprung and total mass	—
F_{z1}	Weight acting on the front carriage	[N]
F_{z2}	Weight acting on the rear carriage	[N]
ΔF_{z1}	Weight difference between the wheels of the front carriage	[N]
P	Vehicle weight	$F_{z1}+F_{z2}$
s	Front carriage	[m]
G′	Center of gravity of the sprung mass	—
G″	Center of gravity of the unsprung mass	—
h'	Distance between G′ and G″	0.205 m
h''	Distance between G″ and the ground	0.335 m
h	Height of the center of gravity $= h'+h''$	0.540 m
$2b_1$	Distance between the constraints of the front springs	0.900 m
$2b_2$	Distance between the constraints of the rear springs	1.460 m

where k_1 and k_2 [N/m] are the front and rear spring stiffness, respectively. A 4WS vehicle has a better performance because the front and rear sideslip angles are lower than for a two-wheel steering (2WS) vehicle, resulting in greater vehicle stability. A 2WS vehicle has a greater yaw and can be maneuvered with only greater difficulty. Also, roll angle and roll speed improves much in the 4WS vehicle, as the displacements of the weight due to centrifugal acceleration are reduced. The force F_z is always lower in the 4WS vehicle.

Handling test is executed in a different way than the previous test. Because the 4WS system works contra phase under 60 km/h, the test speed varies between 10 and 50 km/h. The chosen way is similar to the elk test.

Figure 39 shows the handling map of a 4WS vehicle. It is obtained by simulating several tests in the way, for several values of speed. The map has the speed v of the vehicle as abscissa and the bend value of the trajectory as ordinate; moreover also the steering angle varies. Each maneuver is represented by a point. Knowing the speed and the bend, the optimum value of the steering angle can be determined. The same tests are executed on 2WS vehicle, obtaining the handling map of Figure 40.

For the same values of speed and bend, a 4WS vehicle needs a lower steering angle compared to a 2WS vehicle, so that is more handy; in fact, it is advantaged by the contra phase steering (3.5°) of the rear wheels, which increases the handling in notable way.

Another test of drivability is the *slalom test*. The vehicle is subjected to a repeated sequence of curves that reaches harsh stress. The centrifugal force compels the vehicle to a trajectory error, forcing the driver to make sudden corrections.

Please note that the abstract and keywords will not be included in the printed book, but are required for the online presentation of this book which will be published on Wiley Online Library (http://onlinelibrary.wiley.com/). If the abstract and keywords are not present below, please take this opportunity to add them now.

The abstract should be a short paragraph of between 150–200 words in length and there should be 5 to 10 keywords

Abstract: This chapter deals with the forecasting of vehicle performance on the road, according to the installed engine. It begins with Section 1, which shows the calculation of the resistance to motion, that is, the forces that the vehicle must overcome to advance on flat roads and uphill. The calculation excludes accidental resistance in curves because it is not essential for predicting the behavior of the vehicle on the road. Section 2 begins with the power characteristic, the forecast by traction–speed and power–speed diagrams, calculation of gear ratios, and then passing to the limits to the estimated acceleration, feature consumption, and distance. This chapter concludes with a section on the drivability of the vehicle, and sets out the advantages of four-wheel-drive vehicles.

Keywords: motion resistances; inertia coefficient; performance forecast; power characteristic; torque characteristic; traction–speed diagram; power–speed diagram; consumption diagram; maneuverability; handling

Emission Control Systems—Oxides of Nitrogen

Soonho Song

Yonsei University, Seoul, Korea

1 INTRODUCTION

Facing the reinforced emission regulations for oxides of nitrogen (NO_X), many approaches have been proposed and applied to control NO_X emissions from current engine systems. NO_X control technologies can be grouped into two categories: (i) in-cylinder control and (ii) aftertreatment systems.

In-cylinder control provides NO_X reduction before and during the combustion process by decreasing the gas temperature and controlling the chemical reactions of combustion. In-cylinder control technologies include the following:

- Combustion control by optimizing the spark timing for spark ignition (SI) engine and injection strategies for compression ignition (CI) engines.
- Applying exhaust gas recirculation (EGR) to control combustion temperature and chemical reactions.
- Intercooling under boosting systems to control intake air temperature.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto108
Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

Aftertreatment systems provide the means to reduce already formed NO_X after combustion process via chemical reactions between the exhaust gas and other chemical components such as catalysts. Aftertreatment technologies could include the following:

- three-way catalyst in the SI engine and
- selective catalytic reduction (SCR) and NO_X adsorber in the CI engine.

In the SI engine system representing the gasoline engine, the problems of NO_X emission are less important because most of the NO_X reduction can be achieved using a three-way catalyst. However, in CI engine system representing the diesel engine, there will much room for improvement to develop a suitable and effective de-NO_X technologies. (see NO_x Formation and Models).

2 NO_X CONTROL TECHNOLOGIES

2.1 In-cylinder control in SI engine

2.1.1 Spark timing and EGR

Spark timing significantly affects NO_X emission levels. However, retarding the SI to reduce NO_X has been limited in order to avoid performance degradation. Thus, EGR has been combined to control NO_X with spark timing. EGR is combustion technology to reduce NO_X by recirculating cooled exhaust gas back into the combustion chamber. A more detailed description of EGR will be discussed in Section 2.2.2.

As shown in Figure 1, both EGR and spark retard (delaying the spark timing and hence the start of combustion) effectively decrease the NO_X emissions by reducing the peak combustion pressure and flame temperature.

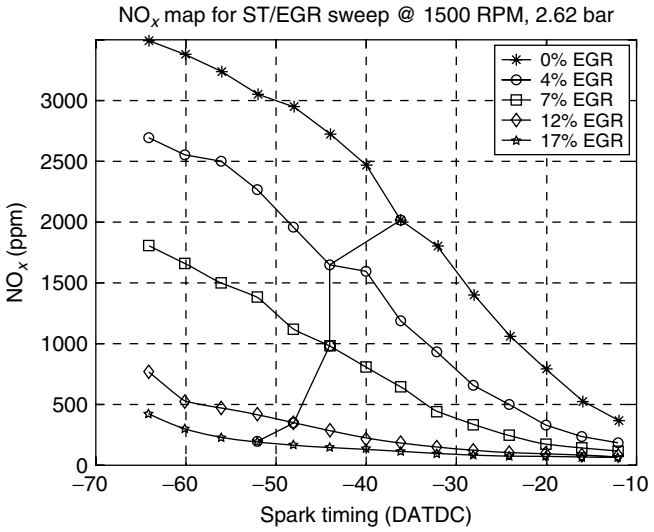

Figure 1. NO_X at different EGR/ST settings. (Reproduced by permission of American Automatic Control Council. (Haskara *et al.*, 2006).)

As maximum brake torque (MBT) spark is the optimal spark setting for fuel economy, EGR is left as the most suitable remaining control variable for NO_X emissions. (see Spark Ignition Combustion).

2.2 In-cylinder control in CI engine

2.2.1 Fuel injection system

2.2.1.1 Injection timing. Adjustment in injection timing is one of the fundamental means of reducing NO_X emissions. Mechanical fuel injection systems were the first to incorporate variable injection timing. However, as electronics become more prevalent in diesel engine control, electronically controlled injectors have become the preferred means for the achieving variable injection timing; offering unprecedented flexibility in injection timing settings.

While NO_X reduction via retarded injection timing retard can be effective, there would be significant trade-offs in terms of fuel consumption and particulate matter (PM) emissions. In many cases, these trade-offs must be dealt with through additional engine design enhancements. One early approach to reduce the fuel penalty associated with retarded injection timing was to reduce ignition delay using a high compression ratio and higher injection pressures. Additional measures such as reductions in oil consumption, increases in charge air pressure, increases in injection pressure, reductions in injector nozzle hole size, reductions in engine friction losses, and reductions in intake manifold temperature can also be taken to control fuel consumption and increases in PM emissions. Thus, injection timing itself has a clear limitation in its ability to reduce NO_X emissions. This places a practical lower limit of around 4 g/kWh NO_X that can be achieved with injection timing retardation. Further NO_X reductions have required additional measures such as injection rate shaping, pilot injections, as well as EGR and NO_X aftertreatment. While injection timing retardation is no longer the primary means of NO_X control, it is still an important tool that can be used in conjunction with other control measures to provide further NO_X reductions (Jääskeläinen, 2010).

2.2.1.2 Injection pressure. As demands for lower emissions, improved performance, and reduced fuel consumption have intensified, one prominent trend in fuel injection system design that has gained momentum is a steady increase in maximum injection pressure in new diesel engines. Figure 2 represents one of the dilemmas of increase fuel injection system pressure—while brake-specific fuel consumption (and PM) can be reduced, NO_X emissions

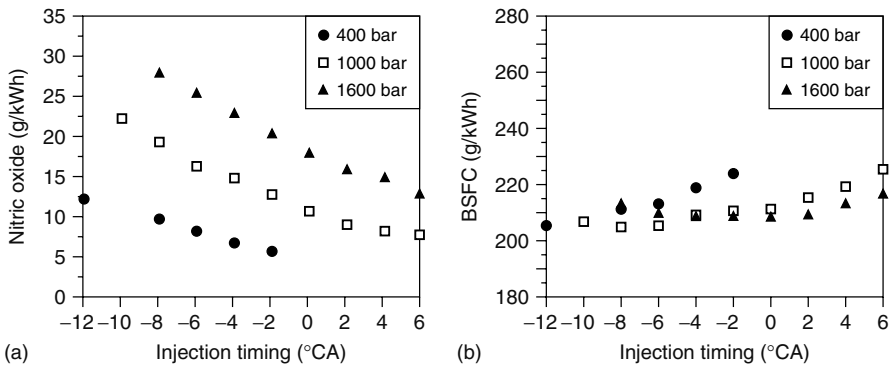

Figure 2. (a,b) Effect of injection pressure and injection timing on NOx and BSFC. (From Hountalas *et al.*, 2004. Copyright © 2004 SAE International. Reprinted with permission.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

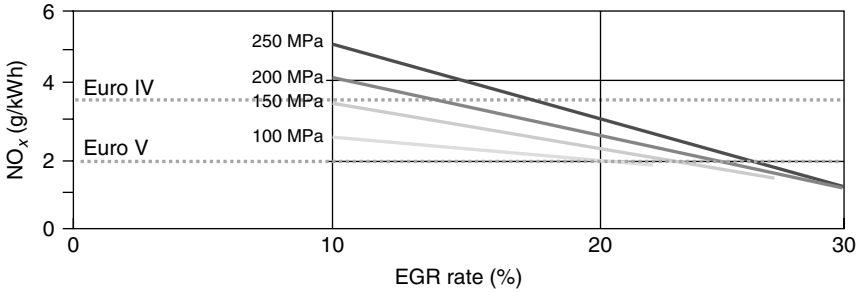

Figure 3. Relationship between EGR rate, injection pressure, and NO_X (Single cylinder, 2-L engine. Constant start of injection. BMEP 15 bar, $\lambda = 2.0$, 1500 rpm.)

have shown to increase. One reason for the increased NO_X emissions is the advanced combustion phasing with higher pressure—for *the same start of injection angle, fuel injection at a higher pressure shortens the combustion duration* and advances combustion phasing. One way of addressing this challenge is using cooled EGR because higher injection pressure can enable reductions in NO_X when combined with other control measures such as cooled EGR, which will be introduced in Section 3.2.1. EGR can provide the necessary NO_X reductions but will require higher fuel injection pressures to control the PM emissions and avoid significant BSFC penalties than NO_X abatement approaches using other technologies (Figure 3). As an example, it has been suggested that Euro VI heavy-duty standards can be achieved with 250 MPa pressure if NO_X aftertreatment is used—perhaps with lower levels of EGR—while 300 MPa would be required if only EGR is used to control NO_X (Jääskeläinen, 2010). (see Petrol Fuel Injection Systems and Diesel Fuel Injection Systems).

2.2.2 *Exhaust gas recirculation (EGR)*

EGR is a highly effective method for the internal combustion engines measure to lower NO_X emissions. A distinction is made between:

- *Internal EGR, which is determined by valve timing and residual gas, and*
- *External EGR, which is routed to the combustion chamber through additional lines and a control valve.*

2.2.2.1 Principle of operation. In general, the most important factor contributing to the NO_X reduction effect of EGR is a decrease in the peak temperature inside of the cylinder during combustion. The effects leading to the lower peak temperature can be broken down into (i) a dilution effect, (ii) a thermal effect, (iii) a chemical effect, and (iv) an added-mass effect (Ladommatos *et al.*, 1996; Maiboom, Tauzia and Hétet, 2008).

- *Dilution Effect*. Decrease of inlet O_2 concentration, whose principal consequence is the deceleration of the mixing between O_2 and fuel resulting in the extension of flame region. Thus, the gas quantity that absorbs the heat release is increased, resulting in a lower flame temperature. As a result, one consequence of the dilution effect is the reduction of local temperatures that can also be considered as a thermal effect ("local" thermal effect). Another consequence of the dilution effect is the reduction of the oxygen partial pressure and its effect on kinetics of the elementary NO formation reactions.
- *Thermal Effect*. EGR contains significant amounts of water and carbon dioxides (CO_2), both of which have significantly higher specific heat capacities than air. The effect of increased specific heat capacity is the thermal effect. As already mentioned, intake air dilution with EGR can simultaneously introduce the dilution and thermal effects.
- *Chemical Effect*. The recirculated water vapor and CO_2 are dissociated during combustion, modifying the combustion process, and the NO_X formation. In particular, the endothermic dissociation of H_2O results in a decrease of the flame temperature.
- *Added-Mass Effect*. If adding a diluent to the intake charge results in an increased mass flow rate, an additional effect is introduced. This added flow has an additional heat capacity because of its mass. This is different from the thermal effect because of any specific heat capacity differences that may exist.

Figure 4 illustrates the effect of charge dilution on the oxygen mass fraction and the product of intake charge mass and heat capacity (mCp) as might occur in an engine with EGR. All effects may occur simultaneously making it difficult to ascertain which are most important. The dilution effect only accounts for the reduction in oxygen mass fraction; the thermal effect for differences

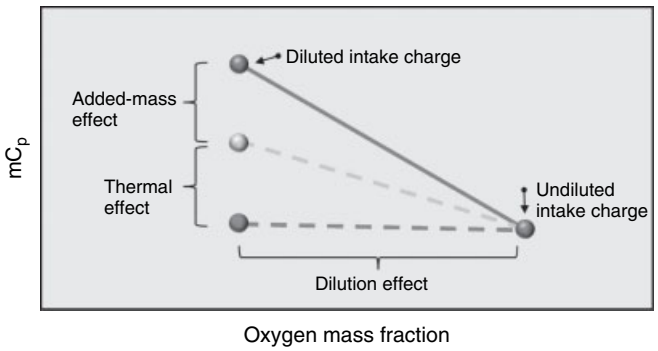

Figure 4. Conceptual view of EGR effect. (Based on data from Ladommatos *et al*., 1996.)

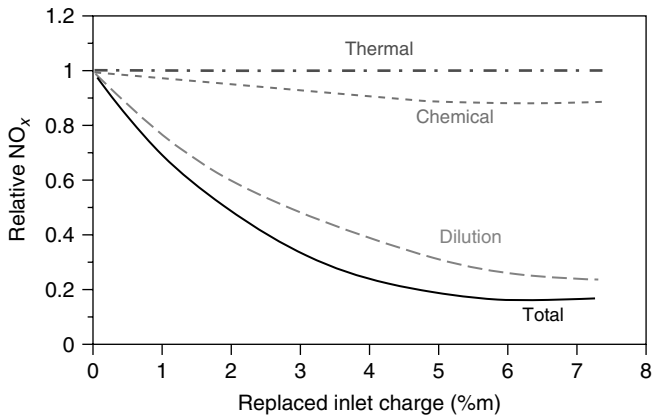

Figure 5. EGR effects with pure CO_2 charge dilution. (Based on data from Ladommatos *et al*., 1996.)

in average-specific heat and the added-mass effect for differences in intake charge mass. The chemical effect may also be present. Figure 5 shows the relative NO_X reductions for the thermal, chemical, and dilution effects in isolation and for the combined NO_X reduction for these three effects when charge dilution is made with pure CO_2. Intake charge and fuel mass flows were fixed, so there is no "added-mass" effect. It is apparent that most of the NO_X reduction from CO_2 is through the dilution effect with a small additional contribution due to a chemical effect. The thermal effect was found to be insignificant at dilution levels up to 7% even though CO_2 has a considerably higher specific heat capacity than air (1.24 and 1.16 kJ/kg at 1000 K, respectively). This is hardly surprising as adding 6% CO_2—the amount present with ~50% EGR—to air increases the specific heat capacity by less than 0.5% (Khair, 2006).

2.2.2.2 External EGR. External EGR is usually distinguished as follows:

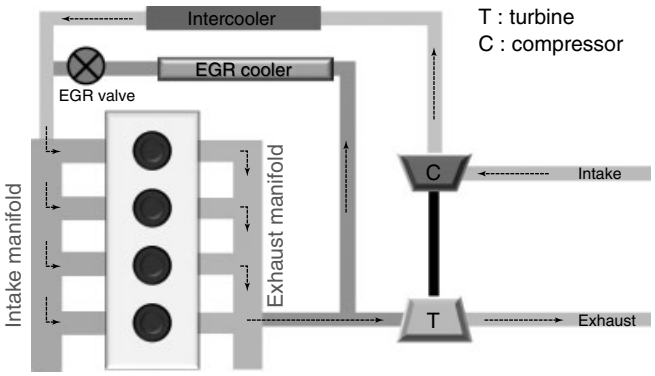

Figure 6. Schematic of HPL EGR.

– *High Pressure Loop EGR*. High pressure loop exhaust gas recirculation (HPL EGR) is generally used in light-duty vehicles. From Figure 6, it is implied that a pressure difference exists between the exhaust and intake manifold without which EGR could not flow from the former to the latter. In turbocharged heavy-duty diesel engines, it is often difficult to introduce EGR into the intake manifold. The problem is that intake manifold pressures are usually greater than exhaust system pressures. To circumvent this dilemma, exhaust is intercepted at a point upstream of the turbocharger where exhaust pressure is higher than that of the intake manifold. A portion of the exhaust flow is returned to the engine cylinders through an electronically controlled EGR valve after being cooled as shown in Figure 6. This approach is commonly referred to as *HPL EGR* (Khair, 2006).
– *Low Pressure Loop EGR*. Another type of EGR implementation in heavy-duty diesel engines is the low pressure loop system (LPL EGR). This system is often employed in conjunction with particulate filter-based aftertreatment systems, where several benefits may accrue. Rather than sourcing EGR from a preturbine location (as in the HPL EGR case), LPL EGR systems use exhaust that has been filtered through diesel particulate filters. Figure 7 shows a schematic representation of an LPL EGR system where EGR was recirculated from a point downstream from the DPF. This alternate configuration sought to preserve turbocharger performance by supplying exhaust gas from a point downstream of the trap (Figure 7), thus allowing all the exhaust to be utilized in the turbine. At this location, exhaust gas pressure is at a lower level than that of the intake manifold. To promote flow, EGR is introduced back in the engine just upstream of the turbocharger compressor. The pressure difference between points downstream of the trap and upstream of the turbocharger is generally adequate

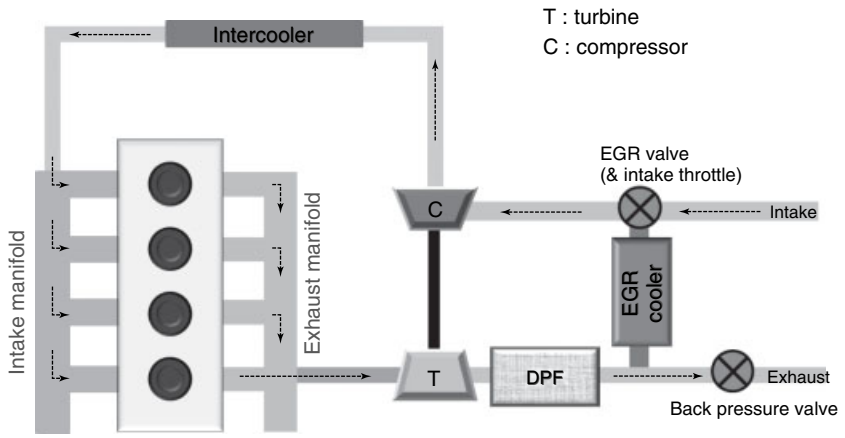

Figure 7. Schematic of LPL EGR.

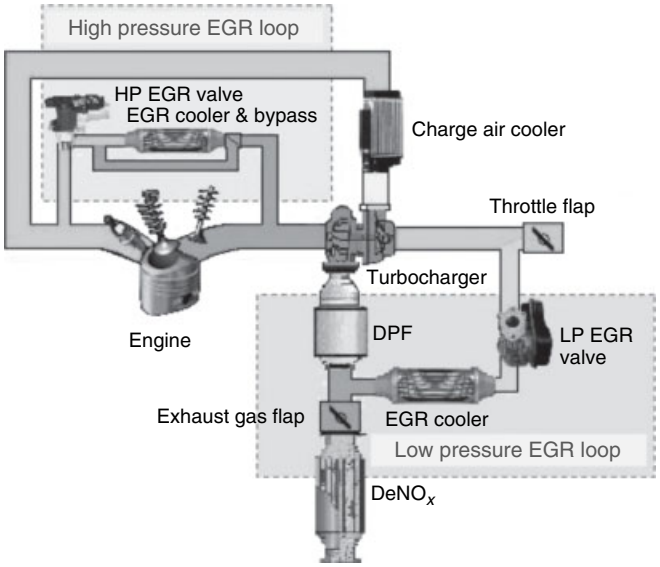

Figure 8. Schematic of dual-loop EGR.

for EGR flow rates needed to reduce US FTP NO_X to at least the 2.0 g/bhp-h level for heavy-duty diesel engines.

– *Dual-Loop EGR*. Some engines may be equipped with waste-gated turbochargers, where some of the exhaust gas bypasses the turbine at high engine speed conditions. Bypassing exhaust around turbochargers generally reduces exhaust manifold pressure as well as the pressure difference between exhaust and intake manifolds above peak torque speed. In such cases, the future types of EGR, a newly developed, dual-loop EGR system, which has combining features of HPL and LPL, have become a common option to consider as shown in Figure 8 (Park *et al*., 2010). In Figure 8, EGR is sourced from a point upstream of the turbine (preturbine) as in an HPL configuration and delivered precompressor as in an LPL configuration. While this system presents some of the same adverse features of the LPL EGR system, it provides an adequate pressure difference between the exhaust and intake manifolds. This allows EGR rates for substantial NO_X reduction without needing a pump or the application of excessive exhaust back pressure to drive EGR into the engine.

2.2.2.3 Internal EGR. An alternative way of achieving NO_X reduction through combustion products is performed through the residual exhaust gas. In theory, if it were possible to retain these combustion products in the cylinder until the next combustion cycle, then it would be possible to achieve NO_X reduction without the complication of an external EGR system with its many components and their control. The use of residual gas for NO_X reduction is commonly referred to as *internal EGR*, even though exhaust gas is not recirculated but generally retained in the cylinder. In some cases, exhaust gas products may be returned to the cylinder through the exhaust valve actuation. Therefore, the term *internal EGR* could still be correctly employed as the acronym for exhaust gas retained as well as exhaust gas returned. An example of the exhaust gas returned is pulse EGR. In the pulse EGR system, the exhaust valve is reopened during the intake stroke by means of a modified exhaust valve cam lobe design. This modified design features a second lobe on the valve cam referred to as a *sublift lobe* as shown in Figure 9. As the piston moves from top dead center to bottom dead center during the intake stroke, the sublift cam lobe lifts the exhaust valve off of its seat and allows higher pressure exhaust to return to the cylinder. Of course, the timing and the degree of valve lift as well as the pressure difference across the exhaust valve

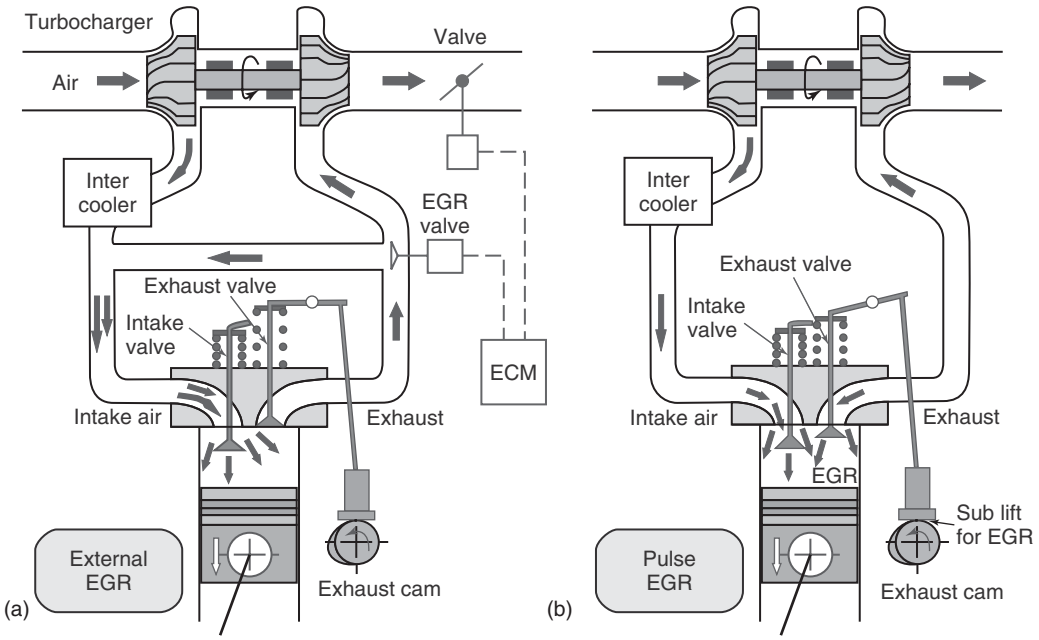

Figure 9. (a,b) External EGR(HPL) versus internal(pulse) EGR. (Reproduced with permission from Khair, 2006. Source: Diesel Progress. (c) EcoPoint.)

are extremely important parameters in controlling the rate of the exhaust gas returned.

An added modification over the pulse EGR system can be achieved if the function of the sublift lobe can be made to be more flexible and controllable. This flexibility can be provided through variable valve actuation (VVA). VVA mechanisms generally allow the control of the timing of the valve lift, the rate of the valve lift, the valve lift, and the number of valve openings. Control of these parameters may be limited at times and have limited impact on performance and emissions depending on a complex array of technical conditions. For instance, the closeness of the piston crown to the valve face may limit either the valve lift timing or the total valve lift itself. Therefore, system optimization is usually performed to obtain the best results within the overall physical and technical limitations of the system (Khair, 2006).

2.2.3 Charge air cooling

In modern engines, it is also important to ensure that the temperature of the charge does not become excessive. In modern boosted engines, this is a real possibility. Excessive temperatures can lead to reduced charge density and higher combustion temperatures, which can affect NO_X emissions. While turbochargers and superchargers increase charge air density, they also increase the temperature of the air in the intake manifold. As emission standards became increasingly stringent, additional increases in charge air density were needed. While this could be achieved through compression to higher pressures, this would require more expensive compression equipment and would further increase cycle temperatures. On the other hand, if intake manifold temperature could be reduced, the intake density could be further increased and more air could be supplied to the engine without necessarily increasing the intake manifold pressure. Cooling the air with a heat exchanger as it leaves the compressor is a common way to achieve this charge air cooling. Such a heat exchanger is referred to as a charge air cooler (CAC), intercooler, or aftercooler. Increasing demand for improvements in fuel economy and exhaust emissions has made the CAC an important component of most modern turbocharged engines. By controlling intake air temperature, up to 75% of NO_X reduction can be achieved by combining with other de-NO_X technologies (Jääskeläinen and Khair, 2011). (see Turbocharging and Diesel and Diesel LTC Combustion).

2.3 Aftertreatment systems in SI engine

2.3.1 Three-way catalytic converter (TWC)

A catalytic converter is a device used to convert toxic exhaust emissions into nontoxic substances. Inside a catalytic converter, a catalyst stimulates a chemical reaction in which noxious by-products of combustion

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto108
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

undergo a chemical reaction. The type of chemical reaction varies depending on the type of catalyst installed. In SI engine, three-way catalyst is applied to reduce not only carbon monoxide (CO), unburned hydrocarbons (HC), but also NO_X.

2.3.1.1 TWC construction. The three-way catalyst is created by coating the internal converter substrate with the following key materials:

- *Platinum/Palladium*: Oxidizing catalysts for HC and CO
- *Rhodium*: Reducing catalyst for NO_X
- *Cerium*: Promotes oxygen storage to improve oxidation efficiency.

2.3.1.2 TWC operation. As exhaust gases flow through the converter passageways, they come in contact with the coated surface that initiates the catalytic process. As exhaust and catalyst temperatures rise, the following reaction occurs:

- Oxides of nitrogen(NO_X) are reduced into simple nitrogen (N_2) and carbon dioxide (CO_2).
- Hydrocarbons (HC) and carbon monoxide (CO) are oxidized to create water (H_2O) and carbon dioxide (CO_2).

Three-way catalysts are effective when the engine is operated within a narrow band of air–fuel ratios near stoichiometry, such that the exhaust gas oscillates between rich (excess fuel) and lean (excess oxygen) conditions. However, conversion efficiency falls very rapidly when the engine is operated outside of that band of air–fuel ratios as shown in Figure 10. Under lean engine operation, there is excess oxygen and the reduction of NO_X is not favored. Under rich conditions, the excess fuel consumes all of the available oxygen before the catalyst, thus only stored oxygen is available for the oxidation function. Closed-loop control systems are necessary because of the conflicting requirements for effective NO_X reduction.

2.3.1.3 Oxygen storage. Three-way catalytic converters (TWCs) can store oxygen from the exhaust gas stream, usually when the air–fuel ratio goes lean. When insufficient oxygen is available from the exhaust stream, the stored oxygen is released and consumed. A lack of sufficient oxygen occurs either when oxygen derived from NO_X reduction is unavailable or when certain maneuvers such as hard acceleration enrich the mixture beyond the ability of the converter to supply oxygen. (see Stoichiometric Exhaust Emission Control).

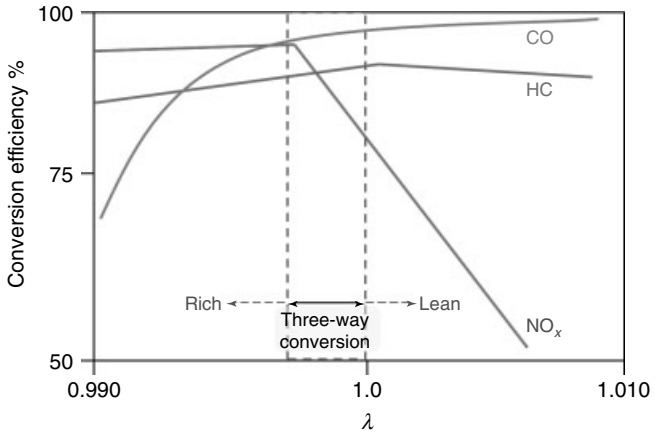

Figure 10. Lambda region for control of three-way catalyst.

2.3.2 *NO_X adsorber for lean burn spark ignition engine*

The concept of the NO_X adsorber/catalyst has been developed based on acid–base wash coat chemistry. It involves storage of NO_X on the catalyst wash coat during lean exhaust conditions and release during rich operation. The released NO_X is catalytically converted to nitrogen, in a process similar to that occurring over three-way catalysts (TWC) widely used in stoichiometric gasoline engines. Normally, three-way catalysts are inactive in converting NO_X under lean exhaust conditions, when oxygen is present in the exhaust gas. By alternating the lean storage and rich release-and-conversion phases, the applicability of the three-way catalyst has been extended to lean burn engines. The technology was first commercialized on gasoline direct injected (GDI) engines. More detailed explanations for NO_X absorber will be introduced in Section 2.4.2.

2.4 Aftertreatment systems in CI engine

2.4.1 *Selective catalytic reduction (SCR)*

SCR system is an aftertreatment system that reduces the emitted NO_X after combustion in CI engines. SI engines can be an adopted TWC system. SI engine is operated at all times with an air/fuel ratio at or close to stoichiometry in which there exist enough reducing gases for NO reduction. However, CI system is different from SI engines. CI engines operate in an air index range between $\lambda = 4$ at idle and $\lambda = 1.2$ at full load that makes NO_X reduction by TWC impossible. Hence, for controlling NO_X for diesel engines and lean-burn gasoline engines, special treatment or SCR of NO_X is necessary.

2.4.1.1 Reductants. Several reductants are currently used in SCR applications including anhydrous ammonia, aqueous ammonia, urea, or hydrocarbon. All those reductants are widely available in large quantities. Pure anhydrous ammonia is extremely toxic and difficult to store safely but needs no further conversion to operate within an SCR. It is typically favored by large industrial SCR operators. Aqueous ammonia must be hydrolyzed in order to be used, but it is substantially safer to store and transport than anhydrous ammonia. Urea is the safest to store but requires conversion to ammonia through thermal decomposition in order to be used as an effective reductant. Hydrocarbon such as diesel fuel is used as reducing agent that can be added into exhaust stream via in-cylinder postinjection or in-exhaust secondary injection. This is the most attractive feature of HC-SCR because it can make exhaust systems simple and inexpensive.

2.4.1.2 Ammonia-SCR. Two forms of ammonia may be in SCR systems: (i) pure anhydrous ammonia and (ii) aqueous ammonia. Anhydrous ammonia is toxic, hazardous, and requires thick-shell, pressurized storage tanks and piping because of its high vapor pressure. Aqueous ammonia, NH_3–H_2O, is less hazardous and easier to handle. A typical industrial grade ammonia, containing about 27% ammonia and 73% water by weight, has nearly atmospheric vapor pressure at normal temperatures and can be safely transported on highways.

A number of chemical reactions occur in the ammonia-SCR system, as expressed by Equations 1–5. All of these processes represent desirable reactions that reduce NO_X to elemental nitrogen. Equation 2 represents the dominant reaction mechanism (Cho, 1994). Reactions given by Equation 3 through 5 involve nitrogen dioxide reactant. The reaction path described by Equation 5 is very fast. This reaction is responsible for the promotion of low temperature SCR by NO_X. Normally, NO_2 concentrations in most flue gases, including diesel exhaust, are low. In some diesel SCR systems, NO_2 levels are purposely increased to enhance NO_X conversion at low temperatures.

$$6NO + 4NH_3 \rightarrow 5N_2 + 6H_2O \quad (1)$$

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O \quad (2)$$

$$6NO_2 + 8NH_3 \rightarrow 7N_2 + 12H_2O \quad (3)$$

$$2NO_2 + 4NH_3 + O_2 \rightarrow 3N_2 + 6H_2O \quad (4)$$

$$NO + NO_2 + 2NH_3 \rightarrow 2N_2 + 3H_2O \quad (5)$$

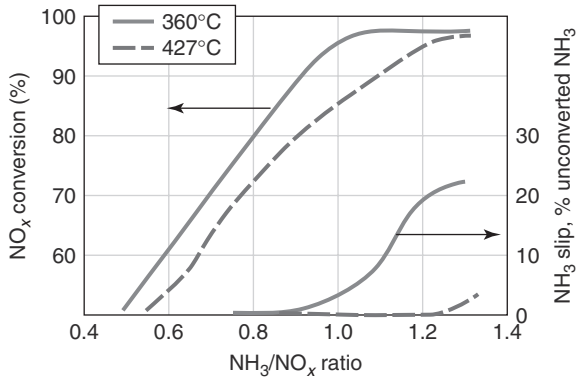

Figure 11. NO_X conversion and Ammonia slip for different NO_3/NO_X ratios. (Reproduced with permission from Majewski, 2005. Source: Dieselnet.com © Ecopoint Inc., 2005.)

The SCR process requires precise control of the ammonia injection rate. An insufficient injection may result in unacceptably low NO_X conversions. An injection rate that is too high results in release of undesirable ammonia to the atmosphere. These ammonia emissions from SCR systems are known as *ammonia slip*. The ammonia slip increases at higher NH_3/NO_X ratios. According to the dominant SCR reaction (Equation 2, the stoichiometric NH_3/NO_X ratio in the SCR system is about 1. Ratios higher than 1 significantly increase the ammonia slip. In practice, ratios between 0.9 and 1 are used, which minimize the ammonia slip while still providing satisfactory NO_X conversions. Figure 11 shows an example relationship between the NH_3/NO_X ratio, NO_X conversion, temperature, and ammonia slip (Heck, Farrauto and Gulati, 2009). The ammonia slip decreases with increasing temperature, whereas the NO_X conversion in an SCR catalyst may either increase or decrease with temperature, depending on the particular temperature range and catalyst system.

2.4.1.3 Urea-SCR. Owing to the toxicity and handling problems with ammonia, there has been a need for more convenient SCR reductants. From the technical point of view, the alternative reductant has to easily and completely decompose to ammonia, producing no harmful by-products, under the conditions in the SCR reactor. From the commercial perspective, the perfect reductant would be nontoxic, easy to transport and handle, inexpensive, and commonly available. Urea, $CO(NH_2)_2$, which meets the criteria of nontoxicity and safety and is commercially available, became the reductant of choice for use in mobile SCR applications. In the SCR process, water solutions of urea are injected into the process gas stream and evaporated, followed by decomposition of urea. The overall process of urea decomposition is often described by the following

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto108
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

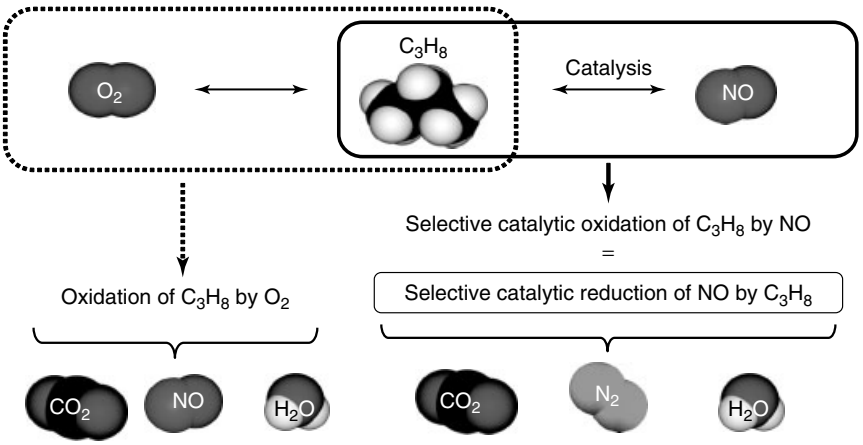

Figure 12. A schematic of selective catalytic reduction of NO with hydrocarbons. Hydrocarbons are selectively oxidized by NO.

hydrolysis reaction (Equation 6) (Forzatti, 2001):

$$CO(NH_2)_2 + H_2O \rightarrow CO_2 + 2NH_3 \quad (6)$$

In practice, however, the decomposition of urea proceeds through two separate reaction steps, involving an isocyanic acid (HNCO) intermediate. In the first step, HNCO and one molecule of ammonia are formed by thermolysis of urea, followed by hydrolysis of the HNCO with the formation of a second NH_3 molecule:

$$CO(NH_2)_2 \rightarrow NH_3 + HNCO \quad (7)$$

$$HNCO + H_2O \rightarrow NH_3 + CO_2 \quad (8)$$

While urea starts to decompose already at around 160°C, the decomposition cannot reach completion in the gas phase at temperatures typical for diesel exhaust and at the residence time in SCR systems. It is believed that only up to about 20% of the urea decomposes to HNCO and NH_3 in the gas phase at 330°C and only about 50% decomposes at 400°C (Kleemann *et al.*, 2000). The remaining urea decomposes only after reaching the surface of the catalyst. It was also shown that HNCO is very stable in the gas phase, requiring an oxide surface to catalyze its decomposition to NH_3. In effect, most of the urea decomposition—especially at low temperature conditions—will occur on the catalyst surface, rather than in the gas phase. In laboratory bench tests, the effects of urea decomposition were visible in the inlet section of the SCR catalyst (Sluder, Storey and Lewis, 2005).

2.4.1.4 Hydrocarbon-selective catalytic reduction. In an SCR of NO_X with hydrocarbon reaction, small amount of hydrocarbon is added to the exhaust gas via in-cylinder postinjection or in-exhaust secondary injection. Injected hydrocarbons act as reducing agents for the NO_X reduction reaction. In a diesel exhaust, oxygen exists in a few percentage by volume, whereas NO_X in a few hundred parts per million. Therefore, supplied hydrocarbons may tend to react with oxygen rather than nitrogen oxides. Then, using the appropriate catalyst system, oxidation of hydrocarbons by NO_X can be achieved. This reaction is very selective, because extremely small amount of NO_X oxidizes hydrocarbons instead of oxygen that exists in a few percentages in a diesel exhaust. Next, Figure 12 illustrates the overall reaction of selective of unselective oxidation of propane with O_2 and NO (Lee, 2007).

2.4.1.5 Catalysts. SCR of NO_X with ammonia was first discovered over a platinum catalyst. The Pt technology can be used only at low temperatures (<250°C), because of its poor selectivity for NO_X reduction at higher temperatures. Two groups of base metal SCR catalysts—vanadia and zeolite based—were later developed, which can operate at higher temperatures and have wider temperature windows, as illustrated in Figure 13.

Platinum catalysts lose their NO_X reduction activity above approximately 250°C. A V_2O_5/Al_2O_3 catalyst was used first for higher temperature applications. However, its use was limited to sulfur-free exhaust gases because the alumina reacted with SO_3 to form $Al_2(SO_4)_3$, resulting in catalyst deactivation. To solve this problem, a nonsulfating TiO_2 carrier was used for the V_2O_5, which then became the catalyst of choice. These catalysts functioned at higher temperatures and over a broader temperature range than Pt. Other base metal oxides, such as tungsten trioxide (WO_3) and molybdenum trioxide (MoO_3), are often added to V_2O_5 as promoters to further decrease the SO_3 formation and to extend catalyst life. The upper temperature limit of

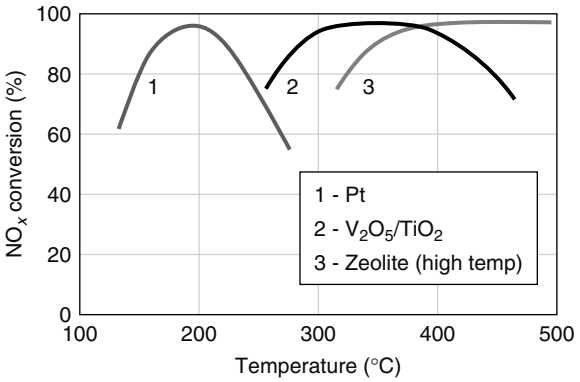

Figure 13. Operating temperature windows for different SCR catalysts. (Reproduced with permission from Majewski, 2005. Source: Dieselnet.com © Ecopoint Inc., 2005.)

Table 1. SCR catalyst technologies.

Catalyst	Temperature Range (°C)
Platinum (Pt)	175–250
Vanadium (V_2O_5)	300–450
Zeolite (high temperature)	350–600
Zeolite (low temperature)	150–450

vanadia catalysts—about 450°C—is still insufficient for certain hot gas applications, such as gas-fired cogeneration plants. Zeolite-based catalysts have been developed and commercialized in the 1990s that function at higher temperatures. Finally, ion-exchanged zeolites of greatly improved low temperature activity (at the expense of a reduced upper temperature limit) have been developed for mobile applications. The operating temperature ranges for different SCR catalyst technologies are shown in Table 1. These temperature ranges should be considered as being approximate. Catalysts are under development, especially for mobile SCR applications, which are characterized by increasingly wider temperature windows (Figure 14).

For HC-SCR, the first efficient catalyst was ion-exchanged Cu/ZSM-5, but the catalyst has the major problem reported as the hydrothermal stability and deactivation by a prolonged exposure to temperatures of the order of 800°C. Therefore, many researchers concentrated on metal oxide catalyst. The priority was given to PGM (platinum group metal) catalysts. In addition, base metal/metal oxide catalysts have been studied extensively with the purpose of making a durable and N_2 selective lean-DeNO_X catalyst. Typically, copper (Cu), cobalt (Co), nickel (Ni), iron (Fe), and silver (Ag) were supported on alumina (Al_2O_3), titania (TiO_2), or zirconia (ZrO_2) (LEE, 2007).

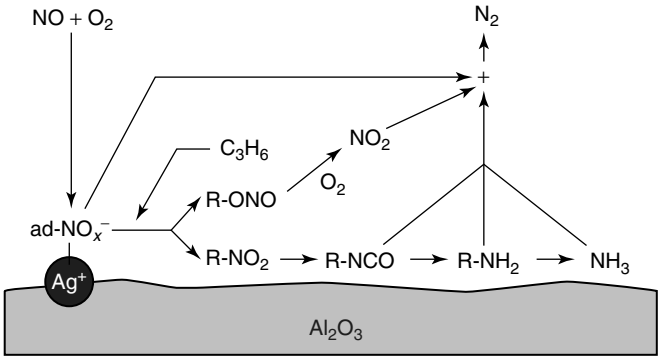

Figure 14. Proposed reaction mechanism of C_3H_6-SCR over low loading Ag/Al_2O_3 catalyst.

2.4.2 NO_X adsorber

2.4.2.1 Principle of operation. NO_X adsorber technology reduces NO_X via cyclic operation from which an example of one cycle is illustrated in Figure 15. The catalyst traps NO_X when the engine is run in a lean-burn mode. The nearly complete removal of NO_X for some time period (almost 2 min) as shown in Figure 15 is one of the primary characteristics that makes NO_X adsorber catalysts a leading candidate for lean-burn aftertreatment systems. The catalyst has a certain NO_X trapping capacity; and once this capacity approaches some level of saturation, unacceptable amounts of NO_X will slip through the catalyst. At or before this point, the catalyst is exposed to a rich environment or exhaust, which induces NO_X release from the surface and reduction to N_2. In the experiment described by Figure 15, this rich period begins at 10 min into the cycle. The rich event also results in the recovery of some or all of the original trapping capacity of the surface (Epling *et al.*, 2004; Majewski, 2007).

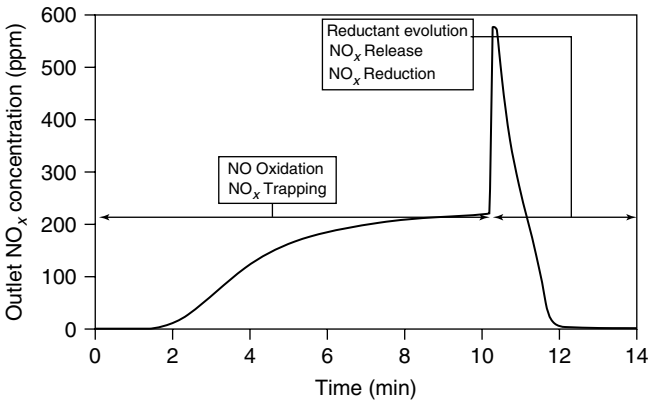

Figure 15. NO_X release profile in NO_X adsorber.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto108
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

2.4.2.2 Chemical reactions. The overall chemical reactions of catalyst operation during the cycle can be described by these five reaction steps:

- *Step 1*. NO oxidation to nitrogen dioxides (NO_2),
- *Step 2*. NO or NO_2 adsorption on the surface in the form of nitrites or nitrates,
- *Step 3*. Reductant evolution when the exhaust is switched to rich conditions,
- *Step 4*. NO_X release from the nitrite or nitrate sites, and
- *Step 5*. NO_X reduction to N_2.

Such operations of the catalyst require a combination of strong basic properties to accomplish storage of NO and NO_2 (step 2) and redox catalytic properties to facilitate all of the steps. Thus, NO_X adsorber catalysts are typically composed of at least one alkali- or alkaline-earth component and at least one precious-metal component, which are supported on a high surface area refractory oxide.

The NO_X adsorption/reduction mechanism is illustrated in Figure 16 (MECA 2000). The catalyst wash coat combines three active components: (i) an oxidation catalyst, for example, Pt, (ii) an adsorbent, for example, barium oxide (BaO), and (iii) a reduction catalyst, for example, Rh.

- *NO Oxidation*. NO_X emissions from the diesel engine are composed mostly of nitric oxide, NO, but most NO_X trapping materials more effectively adsorb NO_2 compared to NO, or NO_2 may even be the required intermediate compound for NO_X adsorption. In the first step, described by Equation 9, nitric oxide reacts with oxygen on active oxidation catalyst sites (Pt) to form NO_2.

$$NO + {}^1\!/_2O_2 \rightarrow NO_2 \qquad (9)$$

- *NO_2 or NO Adsorption*. Extensive NO_X accumulation occurs on the catalyst surface, owing to NO_X adsorption in the form of nitrates or nitrites with the formation of ionic bonds. Equation 10 represents adsorption of NO_2 by the storage material in the form of barium nitrate.

$$BaO + NO_2 + {}^1\!/_2O_2 \rightarrow Ba(NO_3)_2 \qquad (10)$$

- *Reductant Evolution*. Once exhaust is switched to the rich condition, oxygen is replaced by reducing species, including hydrocarbons, carbon monoxide, and hydrogen.
- *NO_X Release from the Nitrite or Nitrate Sites*. When the engine runs under excessive fuel conditions or at elevated temperatures, the nitrate species become thermodynamically unstable and decompose, producing NO or NO_2, according to Equations 11 and 12 (Brogan, Clark and Brisley,1998; Erkfeld *et al*., 1999).

$$Ba(NO_3)_2 \rightarrow BaO + 2NO + {}^1\!/_2O_2 \qquad (11)$$

$$Ba(NO_3)_2 \rightarrow BaO + 2NO_2 + {}^1\!/_2O_2 \qquad (12)$$

- *NO_X Reduction to Nitrogen*. Under rich conditions, the nitrogen oxides are reduced by HC/CO/H_2 to N_2 over the reduction catalyst, in a conventional three-way catalyst process. One of the possible reduction paths is described by Equation 13.

$$NO + CO \rightarrow {}^1\!/_2N_2 + CO_2 \qquad (13)$$

The above set of reactions allows for an understanding of the basic NO_X adsorber chemistry, but the actual chemical and physical processes are more complex, and have yet to be fully explained. A more detailed analysis should also include other reaction paths and species, for example, barium carbonate and barium hydroxide that coexist with barium oxide on the catalyst surface.

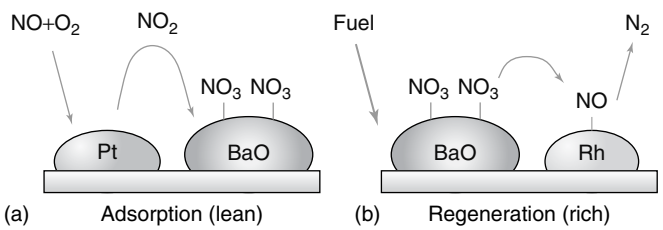

Figure 16. (a,b) NO_X adsorption and reduction mechanism. (Adapted from Manufacturers of Emission Controls Association, MECA 2000.)

2.4.2.3 Regeneration. During the adsorption cycle, the adsorber is gradually converted into its nitrate form (e.g., barium nitrate) and the adsorption capacity becomes saturated. At this time, the stored NO_X needs to be released and catalytically reduced in a process called the *regeneration*. At lean exhaust conditions, NO_X is released from barium sites at temperatures above 450–500°C. The regeneration occurs at much lower temperatures if a short pulse of fuel-rich mixture is provided. NO_X adsorbers can fully regenerate at 250°C, with the onset of a partial regeneration at temperatures as low as 150°C, if the air-to-fuel ratio is maintained at $\lambda < 1$. Therefore, the operation of the adsorber catalyst system involves continuous cycling through lean and rich fuel condition.

3 APPLICATIONS

3.1 SI engine

NO_X control in SI engine is affected by TWC control. Thus, closed-loop control has been proposed to maintain efficient operation of TWC.

3.1.1 Closed-loop control of TWC

The closed-loop control system for TWC was designed to rapidly alternate the A/F ratio slightly rich and then slightly lean of stoichiometry. Three-way catalysts operate in a closed-loop system including a lambda sensor (also called *oxygen sensor*) to regulate the A/F ratio. The closed-loop control works as follows:

- *When the A/F ratio is leaner than stoichiometry*, the oxygen concentration of the exhaust stream rises and the carbon monoxide concentration falls. This provides a highly efficient operating environment for the oxidizing catalysts (platinum and palladium). During this lean cycle, the catalyst (containing cerium) also stores excess oxygen that will be released to promote better oxidation during the rich cycle.
- *When the A/F ratio is richer than stoichiometry*, the carbon monoxide concentration of the exhaust gas increases and the oxygen concentration decreases. This results in very efficient operating condition for the reducing catalyst (such as rhodium). The oxidizing catalyst maintains its efficiency as stored oxygen is released.

3.1.2 Catalysts

While the original three-way catalyst used the combination of Pt and Rh, typically in a 5 : 1 ratio, further development has led to a multitude of formulas, including Pt/Pd/Rh, Pd/Rh, Pd only, etc.

3.2 CI engine

3.2.1 Exhaust gas recirculation

3.2.1.1 Detroit diesel corporation's heavy-duty engine. The typical cooled HPL EGR system was designed for the DDC Series 60. The engine was equipped with a variable geometry turbocharger that was used in the control of the EGR system. The EGR employed for this engine setup was a high pressure loop system where a portion of the exhaust was taken from upstream of the turbocharger. The EGR then flew through an EGR control valve responsible for controlling the EGR rate. Pressure taps upstream and downstream of the EGR control valve monitored the pressure difference across the EGR valve and were connected to a transducer providing a feedback signal monitoring the EGR rate. EGR proceeds through an EGR cooler with water from the engine jacket cooling water system and flows through an EGR pipe to the intake manifold where it mixes with cooled charge air before being inducted into the engine.

3.2.1.2 AUDI's light-duty engine. The discussion regarding EGR is not limited to heavy-duty engines but extends to engines powering light-duty vehicles as well. One application that is representative of other production-style applications is shown in Figure 17, which is a schematic representation of a passenger car type EGR system. The EGR system is a high pressure loop, cooled EGR configuration. A portion of the exhaust is channeled through an EGR control valve and proceeds to the EGR cooler. From the cooler EGR flows to a throttle valve assembly where it is mixed with filtered, high pressure, fresh combustion air that had been cooled through an intercooler to recover some of its density. The mixture of air and EGR is then inducted into the engine through

its intake manifold. The use of intake throttling is needed to increase EGR rate for purposes of achieving the target NO_X reduction.

3.2.1.3 STT Emtec's retrofit EGR system. The EGR technology has expanded its penetration beyond the light- and heavy-duty original equipment manufacturers into the retrofit market, mainly for heavy-duty applications. Retrofit kits—typically utilizing low pressure loop EGR—have been developed, which can provide up to about 40% NO_X reduction capability. In some applications, it is possible to achieve even greater NO_X reductions with a slight degradation in fuel economy.

A schematic of the STT Emtec DNO_X system—a retrofit EGR kit that has been used in many heavy-duty diesel engine applications in Europe and in the USA—is shown in Figure 18.

3.2.2 Selective catalytic reduction

3.2.2.1 BOSCH GmbH's Denoxtronic. Commercial deployment of urea-SCR systems depends on the development of not only the catalyst but also the urea injection system. The schematic of a urea system developed by Bosch is shown in Figure 19 known as *DENOXTRONIC 2.2*. The *DENOXTRONIC 2.2* has been designed for use in the heavy- and medium-duty segments. An integrated pump in the supply module of the DENOXTRONIC feeds the reducing agent AdBlue/DEF (a 32.5% solution of urea in water) from the tank to the dosing module. This injects the AdBlue/DEF directly into the flow of exhaust gas upstream of the SCR catalytic converter. The urea is then converted via hydrolysis into ammonia required for the further reaction. In the second step, inside the SCR catalytic converter, the ammonia reduces the exhaust gas nitrogen oxides into harmless water and nitrogen. The electronic control can be integrated into the engine control unit (ECU) or, alternatively, into a dosing control unit (DCU). The control unit matches the amount of AdBlue/DEF precisely to the relevant engine parameters. In this way, it is possible to reduce NO_X emissions by up to 95%.

3.2.2.2 Nissan's urea-SCR. A schematic of the commercial urea-SCR system launched in Japan by Nissan Diesel is shown in Figure 20. The system was installed on a 13-L, 6-cylinder and turbocharged diesel engine rated 280 kW@1800 rpm. The engine meets the JP 2005 NO_X limit of 2 g/kWh through the SCR aftertreatment. NO_X reduction efficiency in the SCR system was reported at about 70% (average from various conditions during field testing). The SCR catalyst system includes a preoxidation catalyst, a zeolite-based SCR catalyst, and an NH_3 slip catalyst. The urea dosing system was supplied by Bosch. This urea metering unit can provide minimum NH_3 slip and optimum time for NO_X reduction. To enable operation in cold climate conditions, system components incorporated electric heaters, controlled based on the temperature of the urea solution and ambient air. The urea tank was also

equipped with an engine coolant heater (Hirata *et al.*, 2005).

3.2.3 NO_X adsorber

3.2.3.1 US Environmental Protection Agency (EPA). One of the first NO_X adsorber demonstrations on a medium heavy-duty engine was presented by the US EPA with dual flow path exhaust emission control system as shown in Figure 21. NO_X reduction efficiency was 84% over the SET (supplemental emission test) at an equivalent 818,000 miles of engine operation with the test system. The data shows that improvements continue to be made in the area of NO_X adsorbers with respect to overall performance and thermal durability (Laroo and Schenk, 2007).

3.2.3.2 Johnson Mattey Inc. A NO_X adsorber catalysts and a Cu-based SCR catalyst were developed specifically for combined NAC+SCR applications by Johnson Mattey Inc. A 3.0L 2007 Mercedes E320 Bluetec passenger vehicle equipped with an NAC+SCR emission control system was used to evaluate the performance of the NAC and SCR components developed. The catalyst configuration and catalyst volume of the emission control system are containing a 0.6-L diesel oxidation catalyst (DOC), a 3.2-L NO_X NAC, a 3.5-L catalyzed soot filter (CSF), and a 2.5-L SCR. The newly developed Cu SCR catalyst exhibited exceptional stability against high temperature lean/rich aging and excellent low temperature NH_3-SCR activity. When tested as a combined system on a vehicle, the improved catalysts achieved high NO_X reduction efficiency

up to 93% during an FTP cycle as shown in Figure 22a. Furthermore, significantly improved NH_3 generation was achieved on the new NAC component by the reduction of its oxygen storage capacity and the incorporation of a Pd component from Figure 22b. It was clear that the SCR component had sufficient NH_3 storage capacity to store this NH_3 and utilize it for further NO_X reduction (Chen *et al*., 2010).

Pistons

Sanjeet Kanungo

Tolani Maritime Institute, Pune, India

1 INTRODUCTION

The only component of the engine that works against all the odds of high fluctuating temperatures, pressures, and more importantly varying velocity makes piston the most important element of the internal combustion engine. The connecting rod design encompasses all the varying forces arising due to change of reciprocating and gas forces to rotational forces. The crankshaft is designed purely on the effects of the rotational, reciprocating forces and torque. In contrast, piston is subjected to the adversaries of very high inertia forces arising due to the high piston speeds as is common in automobile engines, high temperature fluctuations as combustion is limited to one-fourth of the stroke and consequent high pressures. The fluctuations are more pronounced in automobile engines, as engine may not achieve steady state while underway because of traffic signals, bends, unequal road contours, and textures.

The piston is a key engine part, which is used to compress gases within the combustion chamber or cylinder of an engine. The piston is sealed with a piston ring, often constructed under freezing temperatures, to allow expansion and therefore complete sealing, to seal the chamber to prevent leaks, or dangerous gases escaping. As the piston moves downward, a valve opens to allow fuel and air mixture into the chamber, this fuel charge is then compressed, combusted, and expelled as in SI engines. The motion is thus transferred through the propeller shaft, through a differential and gear box, into the axle and ultimately onto the road via the tire.

2 PISTON AND RING DEVELOPMENT

2.1 Design features and considerations

The main function of the piston itself is twofold:

1. It acts as a moving pressure transmitter, by means of which the force of combustion is impressed on the crankshaft through the medium of the connecting rod and its bearings.
2. By supporting a gudgeon pin, the piston provides a guiding function for the small end of the connecting rod. Figure 1 shows the general view of piston and piston rings.

The piston assumes a trunk form to present a sliding bearing surface against the cylinder wall, which thus reacts against the side thrust arising from the angular motion of the connecting rod. As the piston is a major reciprocating part, it must of necessity be light in weight to minimize the inertia forces created by its changing motion—bearing in mind that the piston momentarily stops at each end of

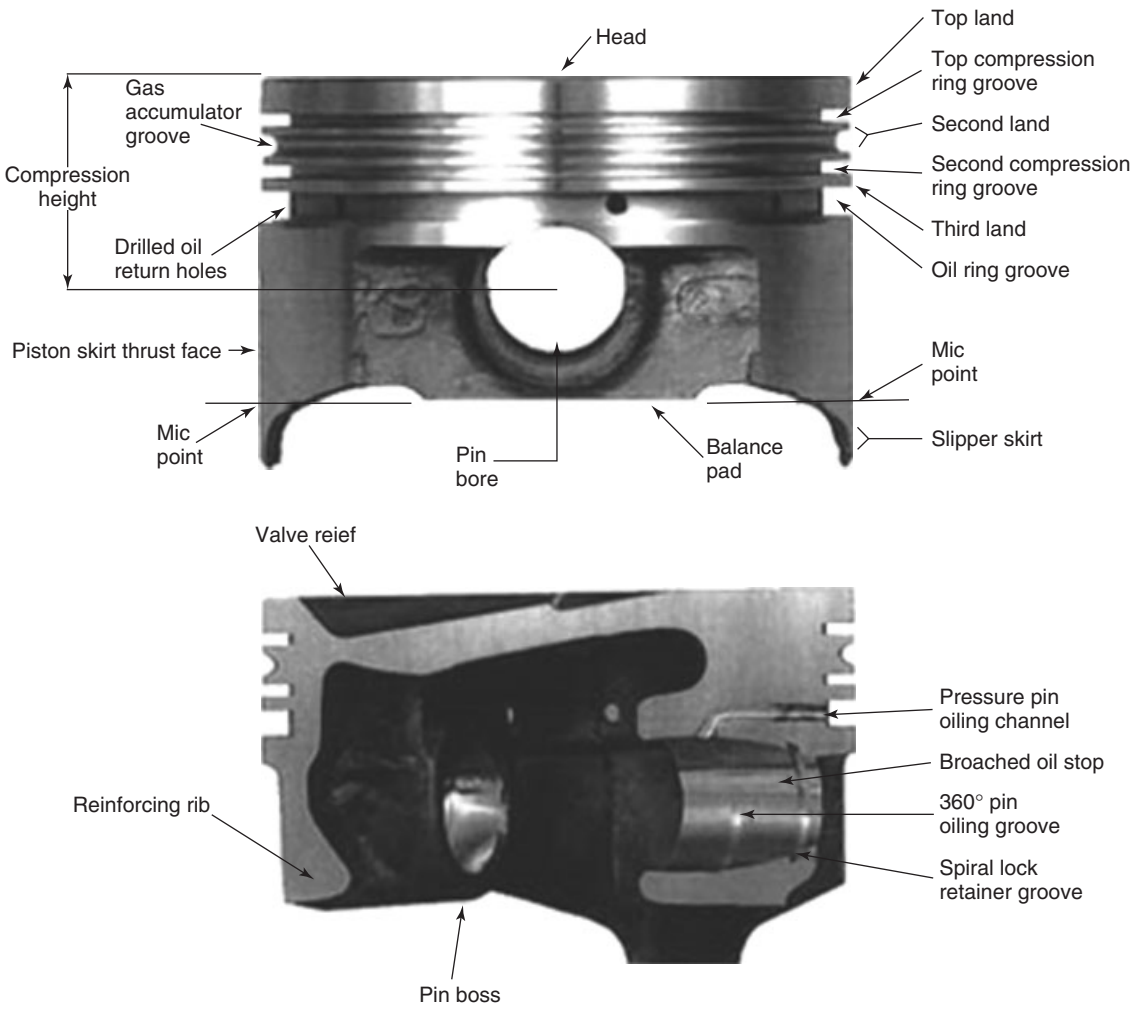

Figure 1. Cut section of an automobile piston. (Reproduced with permission from JE pistons.)

its stroke! Another, perhaps obvious, requirement is that the piston must be able to withstand the heat of combustion and should operate quietly in its cylinder, both during warm-up and at the normal running temperature of the engine.

To perform its sealing function efficiently, the upper part of the piston is encircled by flexible metal sealing rings known as the *piston rings*, of which there are typically three in number for petrol engines. In combination, the piston rings perform several important functions, as follows:

1. The upper compression rings must maintain an effective seal against combustion gases leaking past the pistons into the crankcase.
2. These rings also provide a means by which surplus heat is transmitted from the piston to the cylinder wall and thence to the cooling jacket.
3. The lower oil control ring serves to control and effectively distribute the lubricating oil thrown on to the cylinder walls, consistent with maintaining good lubrication and an acceptable oil consumption.

2.2 General description

The piston is a cylindrical piece of metal (always made from nice light aluminum alloy as far as we are concerned), which moves up and down in the cylinder. Automobile pistons are limited to single forgings, unlike large power medium speed engines with composite arrangement, such that the cast iron piston crown is capable of withstanding the high pressures and the light aluminum skirts not only aid in transferring the heat to the inner wall but more importantly contribute to reduction of inertia weights.

The piston is made of essentially seven parts. The piston's top or crown takes the brunt of combustion's forces and heat. Consequently, the crown is the hottest

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

part of the engine after the spark plug (for a SI engine). It must therefore be quite thick so as to not collapse, though it is not always the thickest part of the piston. Moving down the piston, the next thing is the ring groove. The closely manufactured groove accepts the third part, the precisely made piston ring. In the four-stroke engine, natural harmonics cause the ring to rotate as the piston goes up and down in the cylinder. This helps the groove stay clean of carbon. The solid pieces between the grooves are called *ring lands*. They support the shock loads the rings receive during combustion. The next part is the piston pin hole. This hole accepts a pin that connects the piston to the connecting rod. The hole is offset from the piston's center slightly so that when the piston and rod reach top dead center (TDC), they do so at slightly different times. This spreads the shock loads at high revolutions per minute, easing stresses on the connecting rod and eliminating a noise called *piston slap*. Surrounding the hole inside the piston are pin bosses, thick masses of metal that support the pin when it is inserted in the hole. The pin bosses are sometimes the thickest part of the piston. In some cases, they are not as thick as the crown. In either case, however, the thickness of these two parts is important, as it determines much about how the piston deals with heat. Last in the line is the piston skirt. The skirt is the bearing portion of the piston. It slides against the cylinder wall, bearing the force of combustion on the power stroke, and the loads of compression on the compression stroke. There are also stresses involved with revolutions per minute that the piston and cylinder are designed together to deal with. The skirt is the part of the piston most in need of lubrication. Thus, most lubrication problems show up on the piston skirt first.

The crown is considerably thicker as compared to the wall thickness of the skirt and is given shapes principally to accommodate the exhaust and inlet valves without compromising on the clearance volume and at the same time to effectively contribute to mixing of air and fuel and easy flame path.

Some of a diesel engine lubricant's most important basic functions are control of deposits, prevention of wear, and resistance to breakdown and thickening in service. Compression ignition, as utilized in the diesel engine, can lead to the production of unburnt fuel and carbon particles. These combustion by-products form combustion chamber and piston deposits and enter the crankcase along with blow-by gases. It is primarily deposits that may form on the top ring land, that portion of the piston wall above the top piston ring, and the susceptibility of the engine to these deposits, that determines the style of lubricant required. Hence, the lubricant for any particular diesel engine is determined by the design of that diesel engine, and largely by the design of the piston.

The volume between the piston and the cylinder wall, above the top ring and below the top of the piston crown, is called the *crevice volume*. Reducing the crevice volume increases a diesel engine's efficiency and reduces the amount of unburnt fuel and soot in the exhaust gases.

A piston with a larger clearance between the piston and cylinder wall, that is a piston with a "cutaway" crown land, will need a top ring located high on the piston to achieve an acceptably low crevice volume. The rings of a piston with a cutaway crown land will be exposed to higher forces from the combustion chamber gases through the wider clearance between piston and cylinder wall. These higher forces on the top rings will produce better ring action and minimize oil consumption. Control of hard carbonaceous deposits in the top ring land is the major requirement in diesel engines with reduced clearance between the piston and cylinder wall (Figure 2).

Four-cycle diesel engines from different areas of manufacture have different design features, such as the position of the top piston ring, power to capacity ratios, and sump

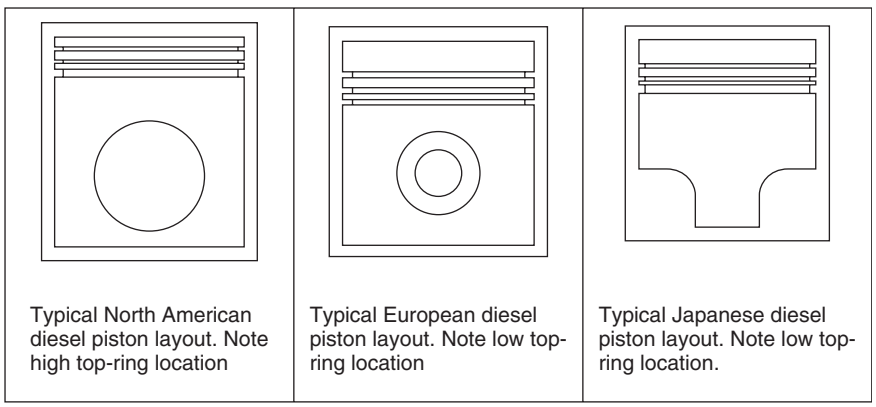

Figure 2. Some piston types with different crown lands.

Figure 3. Antipolishing rings on a liner.

capacity. They are also subjected to differing operational expectations, such as extended oil drain intervals and the likelihood of their operation with high sulfur fuel. Deposits on land lead to bore polishing, increased oil consumption and reduced engine life.

This problem of bore polishing encountered due to the high crevice volume can be overcome by insertion of an antipolishing ring in the liner at the top part just above the maximum travel of the first piston ring. Figure 3 shows an antipolishing ring used in medium speed diesel engine.

2.2.1 *Piston shapes*

There are two important ways in which pistons are shaped. First, the piston is not round but elliptical in shape. The reason is the aforementioned pin bosses. The bosses' mass makes them absorb a lot of heat, which makes them expand more than any part of the piston. If the piston was instead made round, it would not be when fully warmed up. That would be a problem. Therefore, the width of the piston at the area of the bosses is narrower than it is elsewhere. The resulting shape (looking downward onto the piston crown) is an ellipse (an oval). Marine pistons are sometimes called *cam ground*, which refers to the same thing (however, it is not the shape that is being referred to in that case, but rather the machine that produces it). Secondly, all pistons have a taper. That is, the diameter of the piston at its crown is considerably smaller than its diameter at the skirt. The reason is the same as for the piston's ellipse. Only this time it is the crown, not the pin bosses, that necessitates the shape. The crown absorbs so much heat that it must be made smaller so that when fully heated, the piston will be straight.

The shape of the piston crown depends on the shape of its combustion chamber and its compression ratio. In diesel engines, the combustion chamber may be formed totally or in part in the piston crown, depending on the method of injection, so they use pistons with different shapes. Piston design has a great influence on the power output and efficiency of the motor. Pistons can be either round or oval, with a protruding, flat or concave crown. The piston head shape can also be made to induce swirling or vortices in the combustion gases to promote more even mixing and better combustion.

New technologies are being developed for gasoline direct injection engines as well. In direct injection engines, fuel is injected directly into the cylinder during the intake stroke (instead of being injected into the intake manifold near the intake valve outside of the combustion chamber), (U.S. Pat. 6, 3250, 40). This provides better atomization of the fuel and better combustion, but in order to maximize the benefits, the piston head must be carefully shaped. The piston head for direct injection has what is called a *bowl*. This bowl has two effects; the main objective is to deflect the incoming fuel spray toward the spark plug and secondly to direct it around the combustion chamber.

Direct gasoline injection also allows higher compression ratios of about 12 times versus the standard 10.5 (Singer, 1999). The result is a cleaner burning, more powerful and more efficient combustion process (Singer, 1999). Another side effect of spraying the fuel off of the piston head is to keep it away from the spark plug. If fuel hits the spark plug prematurely, it will combust and leave sooty deposits on the plug, reducing its effectiveness (Singer, 1999).

Piston heads can also simply have recesses that allow for better combustion (Haman and Craft, 1997). More complex designs cut away material around the circumference of the piston to achieve better mixing (Pouring, 1988). The yin-yang arrangement that is intended to induce swirl in the combustion gases (Yunick, 1986). With correct piston head shape, stress concentrations can be all but eliminated.

Efforts to enhance combustion by optimizing in-cylinder flows fall into two broad categories: (i) those that invigorate combustion by promoting tumble, swirl, and other in-cylinder flows throughout the engine's intake and compression strokes and (ii) those that use squish to create turbulence mainly in the vicinity of TDC on the compression stroke.

Three main piston-crown shapes and their respective merits and demerits are discussed. A flat piston has a small crown surface area and consequently has the merits of small heat losses and low weight. A horizontal-squish piston is effective at promoting combustion, but small

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto111
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

valve diameters are necessary to provide a squish area. During high speed operation, therefore, there is a tendency for air volumes to decrease and for performance to be concomitantly limited. A slanted squish piston is well suited to a pent roof combustion chamber in which ignition takes place at a central point between the four valves (the typical combustion-chamber configuration in recent engines), and it has the merit of providing a squish area without requiring any reduction in valve diameter. However, it has the demerits of a relatively large piston-crown surface area and relatively high weight. It has been reported that slanted-squish pistons suppress knock by accelerating combustion toward the end of the combustion process.

The skirt, an extended portion of the crown, appears like a hollow cylinder with no apparent use. However, skirts in four-stroke engines have the important role of transferring the side thrust generated because of the angularity of the connecting rod to the engine block. In so doing, they also act as medium of transfer of heat from piston crown to the cooled engine block. As skirts are intended to transfer the side thrust, they are fulcrum about the gudgeon pin, such that the horizontal component of the small end thrust of connecting rod is effectively transferred to the skirt and then on to the engine block as shown in Figure 4. However, the skirts also contribute to frictional loss because of its rubbing against liner. This leads to ovality of the liners. Developments are in the offing to simulate the piston movement as in large two-stroke slow speed crosshead engines, where skirts do not lean on the liner. Skirts are made oval to reduce the frictional contact and additionally coated with antifriction polymer coatings to reduce the abrasive wear.

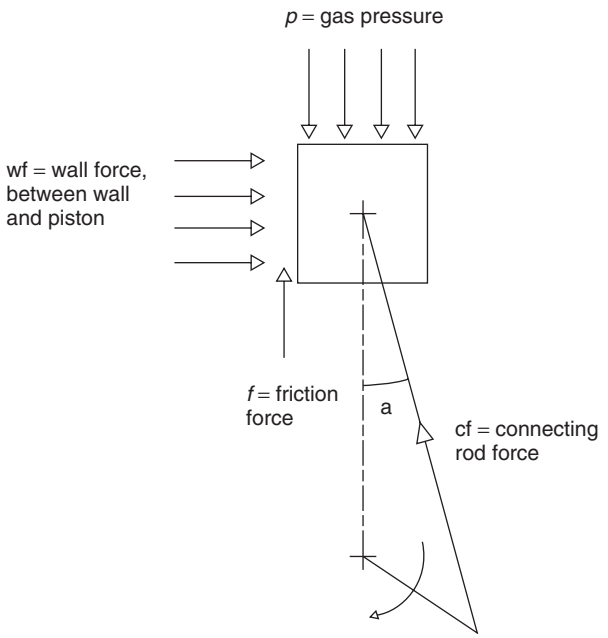

Figure 4. Forces acting on piston during combustion stroke.

As said earlier, it is important to keep the piston weight as light as possible to reduce the inertia effects. However, the prevailing pressures and temperatures influence the thickness and material. This in turn governs the weight of the piston.

In petrol engines, the combustion characteristics are largely different from the way diesel engines. Petrol engines do not self-ignite as a source of ignition always aids in combustion, thereby reducing the need of a high compression pressure. Moreover, external source of ignition helps flatter and lower peak pressure over a large crank angle for a given mean effective pressure. This reduction in peak pressure and the associated temperatures alongside a splash cooling from the crank throw aids in achieving a lighter piston. Therefore, petrol engines are generally made of aluminum, which are lighter and can with stand the temperature close to 400°C safely without loss of strength.

In contrast, diesel engines work under the principle of self-ignition, wherein air is compressed to the extent that the directly injected fuel into the compressed air can self-ignite. Thermodynamically, this calls for a lot of work done and the temperature of the air rises to ignite the initial part of injected fluid with the preset ignition delay thus providing spontaneous ignition to the incoming fuel, leading to a large uncontrolled combustion and thus high pressure rise. High pressure rises are also accompanied by high local temperature, although this temperature falls down rapidly as the piston moves down. This pressure rise calls for high strength and thus higher thickness across sections. It will thus be prudent to say the diesel engine pistons are heavier than petrol engine pistons.

Rings development: piston rings for automotive engines cater to the following functions:

1. Ensure sealing of the combustion space from the crankcase for better power output and prevent blow-by.
2. Spread the oil uniformly to prevent wear of liner.
3. Scrap the excess unregulated oil back to the crankcase.

Failure to achieve this leads to the following:

1. Engine not developing the required power.
2. Crankcase getting pressurized.
3. Crankcase oil becoming black.
4. Carryover of oil to the combustion space, thereby fouling the exhaust passage.

3 MATERIALS AND COATINGS

The pistons in automobile engines as stated earlier are made of single metal, generally aluminum and in some rare cases cast iron, but are rarely composite. Most automotive engines use aluminum pistons that move in an iron cylinder. The average temperature of a piston crown in a gasoline engine during normal operation is typically about 300°C (600°F) and the coolant that runs through the engine block is usually regulated at approximately 90°C (190°F). Aluminum expands more than iron at this temperature range so for the piston to fit the cylinder properly when at a normal operating temperature, the piston must have a loose fit when cold. Expansion coefficient is a function of the silicon content of the aluminum alloy.

Forging requires alloy compositions lower in silicon content. Forged pistons have a finer microstructure than cast pistons with the same alloy composition. The production process results in greater strength in the lower temperature range. A further advantage is the possibility to produce lower wall thicknesses—and hence reducing the piston weight.

These have higher expansion coefficients than cast alloys. Therefore, it is not the forging, but the alloy selected that dominates the expansion coefficients and thus the piston to cylinder clearances required. More silicon means lower expansion coefficient. However, hardness and brittleness go up as silicon content goes up. Modern cast pistons have lots of silicon content. These alloys are termed *hypereutectic* (more than eutectic mixture, which is 12% silicon in aluminum). Because higher silicon contents make the alloy harder and more brittle, alloys used in forging are necessarily lower in silicon. The resulting alloy is tougher, sometimes stronger, more resistant to detonation damage and more suited to extreme use such as racing. However, it has a higher expansion coefficient requiring more piston to cylinder clearance to allow for the piston to grow when it heats. This is particularly true when using a steel or iron bore as steel and iron have lower thermal expansion coefficients than aluminum.

For aluminum pistons operating in steel cylinders, the key figure of merit is the difference in thermal expansion coefficients between steel and aluminum.

The majority of pistons are produced by gravity die casting. Optimized alloy compositions and properly controlled solidification conditions allow the production of pistons with low weight and high structural strength.

In addition, aluminum metal matrix composite materials are used in special cases. Pistons with Al_2O_3 fiber-reinforced bottoms are produced by squeeze casting and used mainly in direct injection diesel engines. The matrix holds the reinforcement together. Aluminum matrix composite refers to a class of material where aluminum is the metal matrix reinforced by materials such as SiC, Al_2O_3, TiC, TiB_2, graphite, and certain other ceramics.

Apart from the reinforced material, the morphology of the reinforcement too is of importance. The three major morphologies are continuous fiber, chipped fiber or whisker, and particulate. With further options such as reinforcement volume fraction and reinforcement orientation and aluminum alloy composition and heat treatment, a wide range of materials and resultant properties are feasible. The main advantage, apart from a general improvement of the mechanical properties, is an improvement of the thermal fatigue behavior. Squeeze casting process is a combination of gravity die casting and closed die forging. The technique in which metal solidifies under pressure within closed die halves. The applied pressure and the instantaneous contact of molten metal with the die surface produces rapid heat transfer that yields a pore-free casting with mechanical properties approaching the wrought product.

Squeeze casting offers high metal yield, nil or minimum gas or shrinkage porosity, excellent surface finish, and low operating costs. The patent on this process seems to be that of James Hollingrake in 1819 from Manchester. The steps involved in this process are (i) pouring of metered quantity of liquid metal with adequate super heat in to the die cavity, (ii) application of pressure on the liquid metal and maintaining the same until the solidification is complete, and (iii) removal of the casting and preparation of the die for the next cycle. The process is basically divided into two types: direct and indirect. The direct process is where the squeeze pressure is applied through the die-closing punch itself, whereas in the indirect process, the squeeze pressure is applied after closing of die, by a secondary ram.

The advantages of cast pistons with higher silicon alloy are

- lower expansion coefficient,
- less bore clearance,
- less noise on start up when pistons are cold, and
- better long-term wear in "normal" applications because the excess silicon hardens surfaces.

The advantages of forged pistons with lower silicon content are

- greater toughness,
- resistance to cracking,

- tolerance of abuse, and detonation
- but at the cost of greater required piston to cylinder clearance to accommodate the higher thermal expansion coefficient.

KS Kolbenschmidt uses two alternative steel materials for the production of the current monoblock steel pistons. The quenched and tempered $42CrMo_4V$ steel is considered a very good compromise between formability, material strength, resistance against scaling, machinability, and cost. Microalloyed or AFP steel grades offer cost advantages for medium-duty applications.

Schunk Kohlenstofftechnik offers pistons made of special carbon materials with significant advantages compared to conventional piston materials. The most important characteristics of these pistons are a low specific weight, high temperature and thermal shock resistance, a low coefficient of thermal expansion as well as excellent wear resistance, and low friction properties. The highlights of this piston are increased in mechanical strength with the increase in temperature unlike other materials. This enables the usage of such pistons in engine with very high thermal loads. A reduction in weight contributes a fuel saving of 5%. Low thermal expansion and shock resistance helps for dimensional stability and low crevice volume. The self-lubricating properties help for emergency running even when piston lubrication fails.

3.1 Coatings

Coatings of any kind should meet the following functional requirements:

- A thermal barrier coating on the piston crown.
- A friction reduction coating on the piston skirts.
- A wear-resistant coating on the piston grooves and piston rings.
- Oil shed coating.

These coatings, in turn, aim at the following:

- Increased power
- Reduced emissions
- Better response
- Increased overhaul periods
- More resistance to catastrophic failure.

The thermal barrier coating gives a more consistent finish to the top of the piston crown. It helps reflect heat into the combustion chamber, rather than dissipating it through the piston materials and thus improves combustion speed and the completeness of the combustion process. In other words, thermal barrier coatings increase the thermal impedance. However, this increase in combustion temperature and trapping the power rather than dissipating it does require reduced timing advance but will pay back dividends on higher revolutions per minute motors or on engines with short rod/stroke ratios where piston acceleration away from TDC becomes a problem for power transfer into the pistons at high revolutions per minute.

One thing to note here is that as the thermal barrier coating improves torque delivery by accelerating the burn rate inside the engine, it can be used to boost torque output on cars with centrifugal superchargers or large turbochargers to give better response before the boost builds.

Overall, it may seem like it's disadvantageous to trap more heat in the chamber and that it possibly reduces the octane, boost, or timing limits of the motor but this is not true. The increased heat can be counteracted with timing reduction without power loss (as the burn rate is maintained) and the added advantages are that the thermal coating helps spread the heat out over the entire crown area of the piston, thus protecting any thin or weak spots from being pummeled to failure. In addition, in the rare event that you do have some minor detonation in the engine because of high load, a bad fill of gas, or some other factors, the thermal coating prevents piston pitting due to minor occurrences of detonation and thus it prevents the creation of hot spots on the piston crown, which could have become hot beds for further detonation and a prevented runaway toward total piston failure.

The low friction coating on the piston skirt reduces frictional losses between the piston sides and the cylinder walls. This protects the pistons from damage and scuffing on cold starts, if the engine is overheated or overboosted (and the piston expands due to heat), and during oil starvation conditions.

Reducing friction in the engine delivers more horsepower to the crank, improves the engine's operation, and gives the engine crisper response. One study showed that using lower profile skirts, with proper friction coating, as well as lower friction wrist pins can reduce the total engine internal friction by 40%.

It is well known that the piston rings rotate in their respective grooves leading to what can be closely associated to fretting wear. Continuous wear of this kind will lead to less gas force acting behind the piston rings and hence loss of sealing.

Oil clinging to the underside of the crown adds to the weight of piston and so the coating should repel the oil.

No specific coatings are being highlighted for wide range of high temperature application coatings is available in the market. Figure 5 shows the coatings ranging polymers to

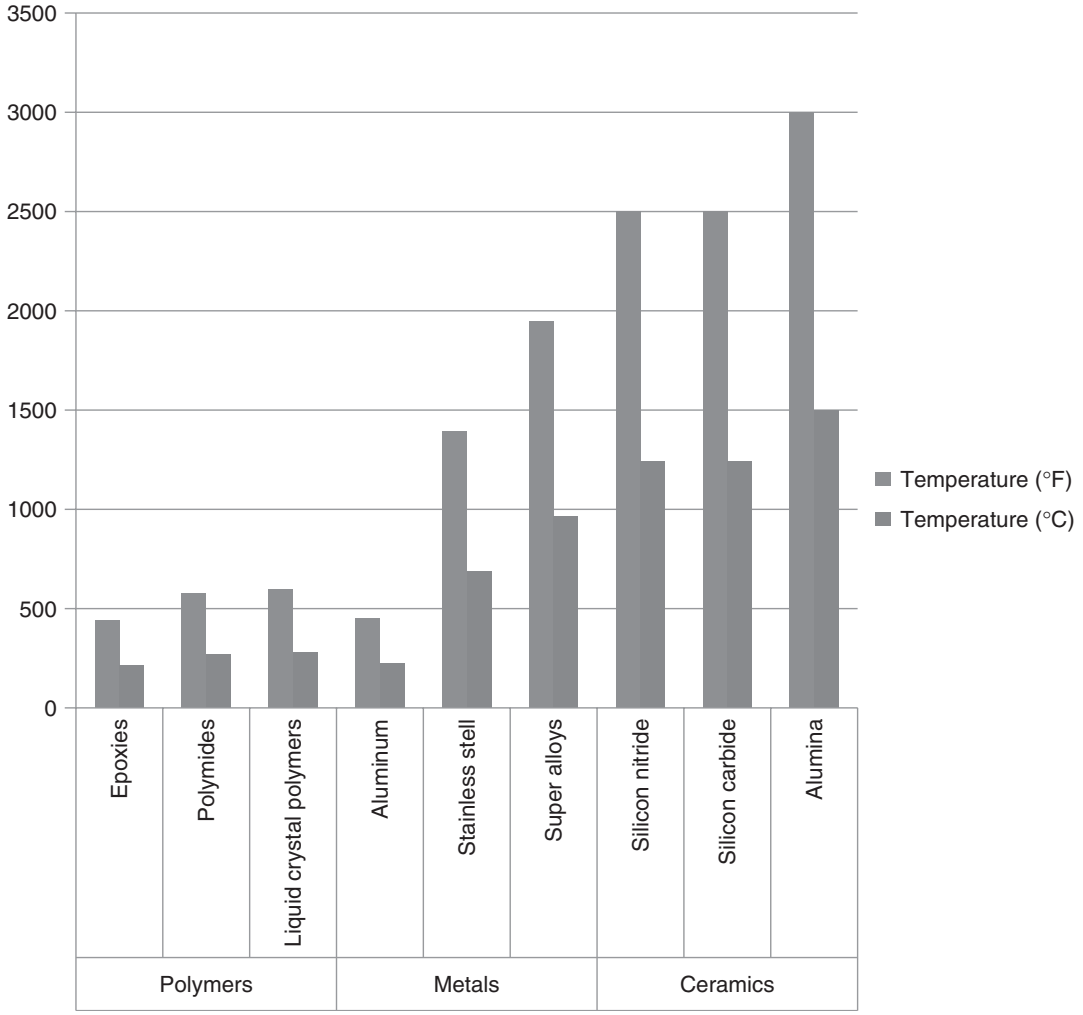

Figure 5. Coating types for different temperatures ranges.

metals and cermets. Choice of coatings also affects the cost. Hence, prudence has to be exercised for selection of materials. Aluminum pistons can be easily anodized to enhance its hardness and thus its wear resistance. Thermal barrier coatings are applied by either mechanical bonding or metallurgical bonding. Delamination is a possibility in mechanical bonding, commonly applied by high velocity oxy fuel (HVOF), plasma spray, and so on. Metallurgical bonding can be achieved by laser cladding, which is in vogue in bigger pistons.

4 TEMPERATURE CONTROL AND PISTON COOLING

Piston temperature has to be controlled for two primary reasons:

1. To prevent thermal weakening of the material.
2. To avoid knocking.

Materials become structurally weak when the operating at temperatures half the melting point. Thermal fatigue setsin at such temperatures and yielding is inevitable. Therefore, the surface temperatures have to be closely controlled. In case of aluminum, it is around 200°C.

A hot piston can additionally lead to early combustion and thus promote knocking. It is pertinent to note here that four-stroke engines (automobile engines generally are) have the inertia forces reversing every 90°, and the period when inertia forces are upward, the small end bearings get oil for lubrication. Knocking will affect the lubrication because of the predominating gas forces and the bearings will starve.

Therefore, effective cooling is of paramount importance. A large share of the heat absorbed by the piston top is

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto111
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

transferred by the piston ring belt area. The remainder is essentially removed by the oil lubricant impinging on the underside of the piston. Automobile pistons get copious amount of lubricating oil, acting as coolant through drilled passage of the connecting rod and the piston gudgeon pin assembly. Connecting rod big end can also be provided with scoops for splashing the oil on the underside of the piston crown and inner face of skirt. Excess oil is scraped back to the crankcase by the scraper rings.

With increment in power, the piston temperatures are bound to rise. One method of reducing the temperature of the piston is by the use of a heat-pipe cooling system. This system allows for a channel inside the piston skirt that directs heat away from the piston itself. This greatly increases the heat transfer through the piston, which does not help the efficiency of the engine, but would allow for the use of special light alloys to form the piston (Wang *et al*., 2000). Magnesium and its alloys have much larger creep rates than other metals and therefore can usually not sustain the same load and temperatures as steel or aluminum. A heat-pipe system can drastically reduce the temperature of the piston crown from about 700°C to only 350°C (Wang *et al*., 2000). Therefore, using heat-pipe technology makes it easier to employ magnesium alloys in pistons.

The piston cooling configuration is of particular importance for the design of the monoblock steel piston. The decreased heat transfer capability of steel results in increased surface temperatures that require more supply of oil through the piston cooling nozzle. A stable oil jet at high pressures and reduced piston wall thicknesses between the cooling gallery and the combustion bowl, where the most extreme temperatures in the piston are observed, are the basis for high functionality and long life.

Piston cooling gallery is created for operation in high temperature environment such as in turbo engines, through oil circulation. The key factors for the design of the cooling gallery are the distance to the bowl rim and the thermal shielding of the top groove. The crown-cooling gallery piston has a curved cooling gallery, giving it a larger surface area that can remove more heat from the critical combustion chamber area and top-ring groove without allowing increased emissions. Additional height and surface of the cooling gallery enables increased heat transfer factors because of cocktail shaker effect and heat flow. The cocktail shaker effect is due to the inertia of the resident oil in the gallery at TDC. The splashing effect of the oil due to this enable oil reaching the difficult corners of the thrust side of the hot piston (Figure 6).

The monoblock steel piston design can be further improved by introducing drilled holes that connect the inner

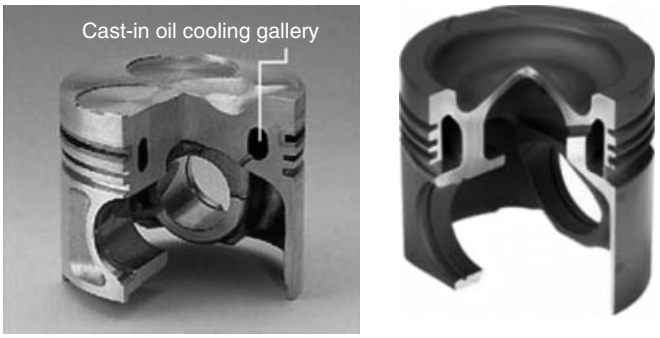

Figure 6. Pistons with cooling gallery. (Reproduced with permission from KS Kolbenschmidt. © KSPG AG.)

chamber with the outer cooling gallery. The added cooling effect reduces the surface temperature below the combustion bowl by approximately 25°C. This has the advantage of less carbon build and a reduction of oil evaporation from the piston surface, resulting in much less oil in the blow-by gas and lower emissions to the environment. Such cooling effect also results in smaller bore-to-piston clearance resulting in smoother and more fuel-efficient engines. Figures 7 and 8 show a general over view of the oil consumption and the operating temperatures of automotive engines.

The role of the piston rings in maintaining the piston temperature is equally noteworthy. Piston rings make a physical contact with the bottom land of the piston groove and its side flank with the water-cooled or fin-cooled liner. This provides for a good conductance of thermal flux.

Heat gradient set up between the hot piston crown and the relatively cooler skirt aids in keeping the piston temperatures under control. Hence, aluminum skirts additionally help.

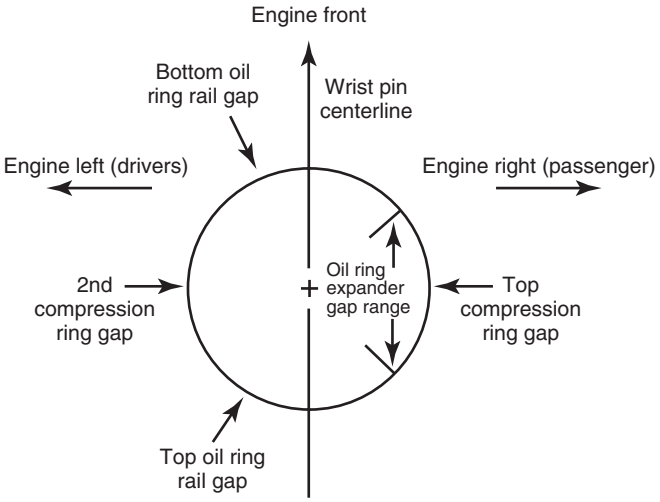

Figure 9. Ring orientation diagram.

5 RING PACK DESIGN

5.1 Materials and design features

The materials and design features of piston rings should meet the three functional requirements. They are as follows:

1. Prevent high pressure gas from leaking through the piston and liner interface, which would result in power loss.
2. Distribute the lubricating oil effectively to reduce friction between ring and liner and prevent lubricant oil migrating to the combustion chamber and getting burnt.
3. To serve as an effective conduit for heat dissipation from piston to the cooled liner.

The first ring commonly identified as the top ring does the sealing job. The third ring is an oil ring and regulates the oil flow. The second ring is primarily a scrapper ring and scrapes of the excess oil back to the crank case. Figure 9 shows the common ring assembly procedure to avoid blow past. Figure 10 shows the general arrangement of piston rings and their terminologies.

Three ring systems are common in automobile engines with the exception in racing engines with no second ring as height of the piston is a major restriction. In large engines, four or five ring system is adopted. Here, the second and third rings are essentially backup rings for the top ring. The top ring is that such cases are not fully gas tight and the sealing is thus achieved by labyrinth effect (Figure 13). This reduces the loading on the first ring and the material and design is thus different. With respect to the automobile engines, the top ring is designed to offer full gas tight seal.

Compression rings as stated earlier experience the toughest environment with respect to temperature and pressure. If the velocity and acceleration profile of the piston ring is plotted, it can be easily traced that it has maximum speed at mid-stroke and obviously very low at both dead centers. This proves to be beneficial at mid-stroke where hydrodynamic lubrication is possible with very less lubricating oil. Toward either end, the lubrication goes into mixed film and finally boundary regime. In addition at TDC, during the power stroke, the temperature and pressure both are high and create a high radial force, squeezing out the lubricating film. Effective lubrication is possible by barrel-shaped face profile. Failure to provide such profiles will result in high wear rates.

Thermal analysis of the piston rings shows large contact force at the either open ends, which is known as *butt*. Butt clearance of certain degree is provided to consider the thermal expansion. Failure to do this will lead to ineffective sealing and collapse of the ring. As stated earlier if the contact force at the butt end is more, this implies that there will be nonuniform contact and hence more chances of blow past. This can be reduced by negative oval casting (Figure 11).

Scrapper ring has a tapered face showing that it cannot accumulate oil on its upper edge to scrape it in the upward direction toward the combustion chamber. However, it can very effectively accumulate oil on it lower edge to scrape it down to the crankcase, thereby preventing excessive consumption of oil.

Oil control ring (Figure 12), wherever employed, has a two-land edge backed up by coiled spring to enhance

conformability with the liner. Two lands are used to ensure that at least one of the lands will control the oil during anytime of the engine cycle.

5.2 Ring dynamics

About 20/25% of mechanical friction losses comes from the piston rings rubbing against the liner. As a result, reduction in piston ring friction has the potential to improve fuel efficiency, fuel consumption, and emissions.

The piston ring secondary motions can be divided into piston ring motion in the transverse direction, piston ring rotation, ring lift, and ring twist. These types of motion result from different loads acting on the ring. Loads of these kinds are inertia loads arising from the piston acceleration and deceleration, oil film damping loads, loads owing to the pressure difference across the ring, and friction loads from the sliding contact between the ring and the cylinder liner. The forces acting on the ring are shown in Figure 13 (Ejakov, Diaz, and Chock, 1999).

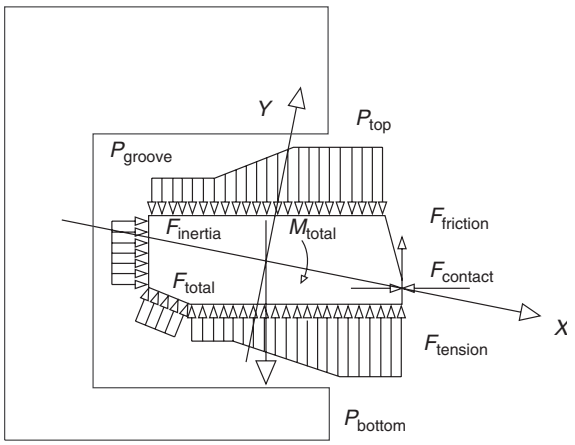

Figure 13. Force diagram of piston ring. (From Andersson, Tamminen and Sandström (2002) (After Ejakov, Diaz, and Chock, 1999).)

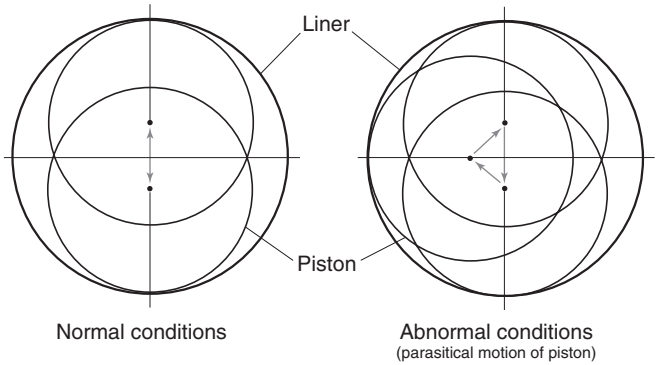

Figure 14. Parasitical motion of piston in a liner.

The gas pressure above, below, and behind the ring produces resultant forces on the ring section (Dowson, 1993). The inertia forces acting on the piston rings, as well as those acting on the other reciprocating crank mechanism components, change proportionally to the square of the engine speed (Röhrle, 1995). The side loading of the piston against the cylinder wall is a result of the articulated joint of the connecting rod (Röhrle, 1995). The shearing of the lubricating film, the sliding friction forces, and the contact pressure between the ring and the liner cause normal and tangential forces on the ring face.

The elastic distortion of the piston and liner can affect the effective geometry of the ring face and cylinder liner contact, which causes a nonuniform distribution of the contact pressure between the cylinder liner and the piston ring face and can thus lead to increased blow-by and oil consumption (Dowson, 1993).

As stated earlier, piston rings rotate in their grooves and exhibit what is called *fretting wear*. These can be observed by equally spaced patches both on the bottom groove land and on the rubbing surface of piston. These are unavoidable and are interestingly interpreted in four stroke engines. This is due to parasitical rotary motion of the piston (and accordingly piston rings) can be produced not only nonuniformly heated liner but also bend crankshaft, inaccuracy manufacture, and poor assembling (Figure 14).

The piston ring rotation is induced by the fact that the liner diameter varies over the stroke. The diameter variation is due to thermal deformation and wear. The ring will always be pressed toward the liner wall, thus the ring will expand and compress over the stroke. The continuous movement of the ring in combination with a variation in friction conditions and piston movements will then cause the ring to rotate in a stochastic way.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto111
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

In addition to rotation, the piston rings also slam against the groove. These lead to wear of the grooves. The first ring that experiences the maximum contact pressure due to the primary sealing as well as secondary sealing also experiences wear. To mitigate the risk earlier failure and down time because of wear, the critical parts such as top piston ring and the groove bottom lands are coated with wear resistant coatings, the common among them being chromium coatings deposited by mostly electroplating. This coating meets the functional requirement of a hard coating with a suitable hardness, but the process of deposition is not environment friendly because of the release of chromium hexavalent mist (an ozone depleting layer). Suitable cermet coatings such as tungsten carbide cobalt matrix, nickel chromium, custom-blended chromium carbide, and nickel chromium-based coatings have proved their mettle with a suitable deposition technique. HVOF or plasma spray process is some of the common thermal spray process employed by industries. However, laser cladding or laser glazing methods are replacing the other thermal spray process because of the nature of metallurgical bonding without any distortion. This prevents delamination of the thermal coating and thus less risk of failure.

6 DEFECTS AND FAILURES

The study of pistons of their rings and the cylinder liner which together go into making of an effective sealing and thus influencing good combustion will be incomplete without understanding the defects and taking corrective actions thereafter. A lot of automobile manufacturers have been gracious enough to cite the defects on the mentioned components arising due to various operating reasons. It is urged that readers should have generous reading of "Piston damages" published by MSI Motor Service International GMBH. Figure 15 shows some photographs of the crown,

Axle Systems

Joseph Palazzolo
GKN Driveline, Auburn Hills, MI, USA

1 INTRODUCTION

With careful examination of a typical passenger car or light truck, it is clear that there is a single engine that can drive two or more wheels. In addition, it can be seen that in rear-wheel drive powertrain layouts, the axle assembly is connected to the powertrain with a long shaft called a *propshaft* or a *driveshaft*, whereas, on a front-wheel drive powertrain layout, the axle functionality is combined within the transaxle. For the purpose of this chapter, the main focus will be on traditional rear axle assemblies, but the theory and practice can be applied to front axles as well. The primary function of the axle assembly is to translate the axis of rotation from the longitudinal direction to the transverse direction in the rear-wheel drive vehicle. Simply put, the propshaft is configured to be running fore-aft in the vehicle and the axle outputs are perpendicular to that in order to divert the power to the wheels. There is a unique gear arrangement that provides this perpendicular powerflow and it is referred to as a hypoid gear set.

2 BASIC FUNCTIONS

There are two generic categories of axle; *live* and *dead*. The *dead* axle is an axle that does not transfer power to the wheels and mainly acts to support the vehicle weight and suspension loads. These are typically found on the rear suspension of a front-wheel drive-based car. At times, they are referred to as *twist* beam axles. In contrast, the *live* axle transfers mechanical power to drive the wheels and is the main focus of this chapter. From here forward, the term axle will refer to a live axle arrangement.

2.1 Structural functions

As a beam element is located between the wheels and the chassis of the vehicle, the axle is required to support vehicle level loads. The first and the most obvious load is the actual rear vehicle weight. The axle structure must be able to carry the portion of the fully loaded vehicle that is distributed to the rear wheels from the chassis and any additional loads from passengers and cargo. The axle structure must also transmit and react both driving and braking torque reactions from the powertrain to the wheels and in turn from the wheels through the foundation brakes. The axle assembly also provides the mounting brackets and surfaces for the suspension components such as springs (leaf or coil), suspension arms, and the shock absorbers. The axle must also be able to resist the wheel loads that are applied to the structure when cornering events are encountered. The rear wheels do not articulate like the front wheels and are, therefore, dragged through a turn. This dragging actually produces significant loads on the wheel

hub flange portion of the axle assembly and the entire axle wants to travel straight as opposed to following the vehicle chassis in the turn. Some performance applications will make use of a panhard rod or track bars or even a Watt's linkage to counteract this transverse motion of the axle relative to the chassis during turn events. These are basically transverse-mounted suspension links to limit the range of side-to-side motion of the axle assembly relative to the chassis. The specific loads are very dependent on the type of suspension and spring arrangement. Two of the common types are leaf spring or Hotchkiss style and coil spring with a multilink (typically, three- or four-bar trailing arm) suspension arrangement. There are many variants of suspension arrangements with advantages and disadvantages to each. The specific detail of them is readily available in the public domain literature.

2.2 Mechanical functions

From a basic overview, the axle assembly needs to mechanically transmit torque at the required speed from the propshaft to the wheels. With mechanically transferring this power, the direction of the torque flow is translated 90° with a hypoid gear set. The hypoid gear set provides torque multiplication and speed reduction based on its gear tooth combination. In the traditional axle drivetrain system for automotive passenger vehicles, there is a need for a device that can divide torque as well to the driving wheels equal from side to side. This mechanical device is known as a *differential*, specifically referred to as an *open differential*. The open differential allows for a single input from the powertrain to be divided to the two outputs, typically the wheels. The open differential still accommodates the requirement of speed differences experienced in turn maneuvers while providing equal torque to the outputs. This equal torque balance of the conventional open differential can create a drive force issue in the vehicle if one wheel has lost tractive effort as experienced with one wheel is on a low coefficient of friction surface such as snow or ice. The details of open differential are covered in Basic Open Differentials, with the need and functionality of limited slip differentials, as reviewed in Passive and Active Limited Slip Differentials.

3 AXLE CONSTRUCTIONS

There are two main types of rear axles that cover the majority of passenger vehicle applications, which are beam- and independent carrier-style axles. The main difference is that the beam-style axle has rigid tubes that are part of the axle housing structure. These tubes typically have the suspension and brake mounting brackets rigidly attached to this structure. The beam axle also has the axle shaft supported inside this structure and is responsible for axle shaft and wheel bearing retentions.

Figure 1. The independent carrier-style axle.

In contrast, the independent carrier-style axle housing, as shown in Figure 1, supports the hypoid gearing and differential but does not transfer the vehicle weight, brake-reaction loads, or suspension motion through the axle structure. Typically, there are halfshafts (or side shafts) between the output of the differential and the wheel hubs to transfer the drive torque. These halfshafts allow for the wheel hubs to move through suspension travel without transferring the suspension loads to the axle housing. The brake forces are also supported within the wheel hub arrangement and not through this inboard-mounted axle housing. Basically, the suspension and brake loads are decoupled from the axle. This allows the chassis and suspension engineers much more flexibility to optimize the systems without the constraints of a beam axle system.

3.1 Beam axles

There are a few differential arrangements of beam axles, but the two most common are the cast center style with pressed-in tubes and the stamped and welded axle housing structures. The cast center style is commonly referred to as the *Salisbury style*, whereas the stamped and welded types are commonly referred to as the Banjo-style axle. The most common arrangement is the cast center type, but there are some original equipment manufacturers that still utilize the Banjo type.

3.2 Cast center section

The cast center section-style axle, as shown in Figure 2, uses a cast center section with the axle tubes pressed in place. The center portion is a single casting with an opening on the rear surface for assembly and service access. The

Figure 2. Cast center-style beam axle.

tubes are retained via the press fit and redundant slug welds that are visible as circles near the top of the axle tube interface portion. The suspension and brake hardware mounting brackets are welded to the axle tubes accordingly. The hypoid gears, bearing, and differential are assembled from the rear-facing surface of the axle. There is a typically stamped steel or cast aluminum cover bolted to the rear that seals this large access port. One of the main advantages of this style axle structure is weight and cost to produce. Most of this style axles are designed and assembled with select fit shims for gear location and bearing preloads, which helps to reduce the manufacturing cost associated. While this arrangement aids in initial cost mitigation, service procedures can be more difficult. This style typically is configured with the axle shaft retention mechanism located inside the differential. This axle shaft retention is commonly referred to as semi-float and will be described later. The cast center arrangement normally does not utilize a separate pinion cartridge and this geometry is cast and machined directly as a part of the main housing. This arrangement requires that the bearing preload is disturbed to adjust pinion mounting distance shims.

3.3 Stamped center section

The stamped- and welded center-style axles will be referred to as *Banjo style* as shown in Figure 3. This arrangement of axle housing consists of a series of stamped steel sections. These stampings are arranged in fixtures and welded together to achieve the complete axle assembly. The rear portion of the axle housing is a part of this welded assembly and, therefore, the differential and hypoid gears must be installed from the forward-facing portion of the axle housing. There is a cast gear carrier that supports the gears, bearings, and differential. The gear carrier, when it is fully assembled, is commonly referred to as the third member. There are some advantages to this style axle arrangement from a service standpoint. Mainly, the end consumer can have multiple third members preassembled and change them relatively quickly if desired. Another

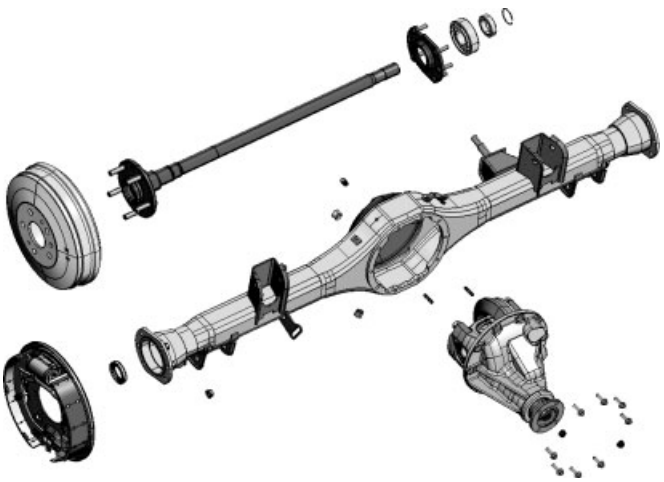

Figure 3. This is an exploded view of the typical stamped-style axle housing, commonly referred to as Banjo style. (Reproduced by permission of Joe Palazzolo.)

characteristic of this arrangement based on the assembly process and inability to access the differential is that the axle shaft retention mechanism must be outboard of the differential. This axle style employs what is known as three-quarter float wheel-end bearing arrangement, which will be reviewed later. One of the disadvantages or manufacturing concerns with this style axle structure, besides the complexity of assembly, is the correct alignment of all of the critical geometry for wheel bearings and gear case mounting throughout the welding and potential subsequent distortion process. In addition, there is a concern for minor leaks from the series of welds that are required to join all of the stamped pieces together. These welds provide the structure and act to seal the axle housing assembly. All of these items have been overcome with modern manufacturing processes and quality control systems. Some of the Banjo-style axle housings utilize a pinion cartridge arrangement that allows for the separation of bearing preload and pinion mounting distance. The pinion cartridge can be shimmed separately to achieve the desired mounting distance without disturbing the pinion bearings. This also requires additional parts and another potential leak path as a design trade-off.

3.4 Wheel-end bearing configurations

There are three main architectures of wheel-end bearing configurations and axle shaft retention schemes that are most common for automotive applications. The differences among the three different types is mainly how the axle shaft will be transferring torque to the wheel hub directly

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto112
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

and whether it is carrying a portion of the vehicle mass and bending loads while rotating.

3.4.1 *Full-float wheel end*

The term *full-float wheel-end bearing* refers to the axle shaft retention and bearing strategy that totally isolates the axle shaft from the vehicle loading conditions. In this structure, the axle shaft is responsible solely for transferring the drive torque from the differential to the wheel hub. Referring to Figure 4, the tell-tale axle shaft bolts are at the left end of the diagram. Close examination will reveal the two tapered roller bearings that support the wheel hub to the axle housing. This load path isolates the axle shaft from the vehicle loads and is a very robust design solution. This is by far the most robust wheel-end bearing arrangement and, no surprise, the most expensive. In this architecture, the wheel hub is mounted directly to the axle housing and there is no endplay (or side-to-side motion) of the wheel assembly. The key differentiator is that the wheel hub is supported by separate bearings and transfers the vehicle loads directly back to the axle housing. The axle shaft is such that it can be removed from the axle and the vehicle wheels and tires will still support the vehicle. A quick visual indicator of a full-float axle shaft is that the axle shaft will have a series of bolts that attach it to the wheel hub that can be seen from the center of the wheel. On the basis of the separation of load and the ability of this arrangement to support heavy vehicle arrangements, this structure is often used for the heavier end light truck applications (under 8500 pound GVW) and medium and heavy truck applications.

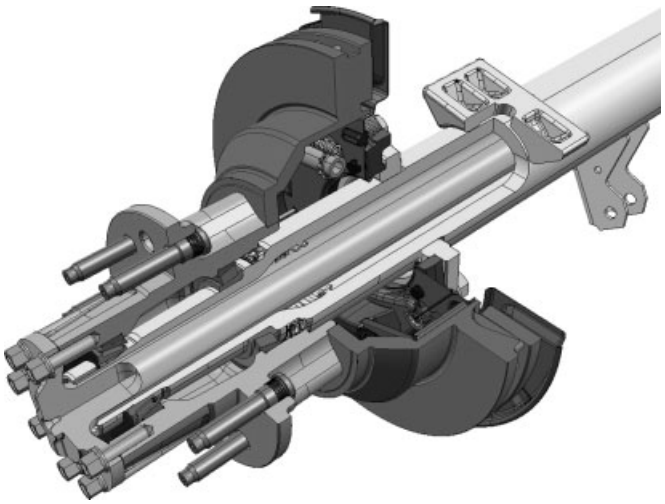

Figure 4. A partially cutaway view of a full-float wheel-end bearing arrangement. (Reproduced by permission of Joe Palazzolo.)

3.4.2 *Three-quarter float wheel end*

The three-quarter float wheel end, as shown in Figure 5, describes a wheel-end strategy that carries torque and partial vehicle load through the axle shaft. The axle shaft is still retained at the wheel end like the full-float style with the added difference in the bearing load path. The bearing load path for the vehicle mass is transferred through the axle in the axle housing. This wheel-end and axle shaft retention is commonly used on the Banjo- or third-member-style axle housings. There are a few different style bearing and seal arrangements that can be found on this style wheel end. The main function is the same and most applications use a greased and sealed bearing at the wheel end, whereas some of the higher loaded applications will use a tapered roller bearing that shares the lubricant with the main axle components.

3.4.3 *Semi-float wheel end*

The semi-float wheel end is the most common arrangement and is paired with the cast center-style axle housing structure (Figure 6). The axle shaft is actually retained with a special washer that is installed in a groove that is machined on the shaft end and located inside of the differential itself. In order to gain access to the washer, the axle must allow for access to the differential after it has been installed and the cast center with its rear access portion allows for this. The semi-float axle shaft uses a simple cylindrical roller bearing to support the axle shaft that used the axle shaft

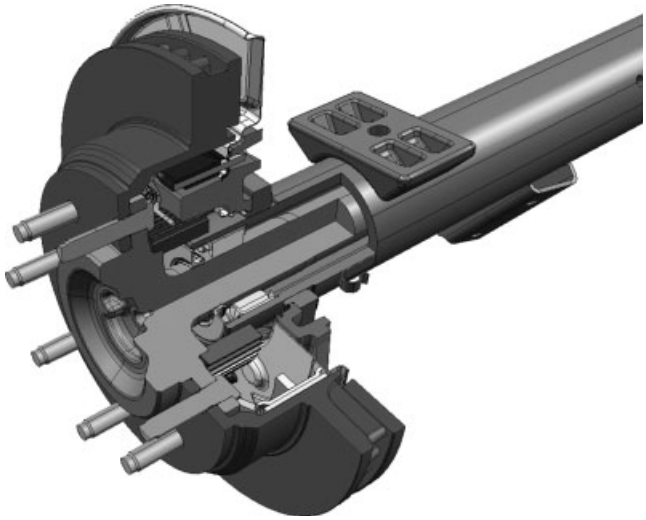

Figure 6. The semi-float wheel-end bearing arrangement. (Reproduced by permission of Joe Palazzolo.)

journal as the inner bearing race for a more economical solution. This bearing shares the lubricant with the main axle components. In operation, the axle shaft is subjected to not only torque to drive the wheels but also full vehicle loads and retains the wheel. On the basis of the geometry constraints of this style of axle, it exhibits the most endplay of the three types reviewed. This endplay needs to be considered when disk-style brakes are employed.

4 INDEPENDENT CARRIER AXLES

There is an additional axle arrangement that isolates the axle housing system completely from vehicle load. This type of axle is commonly called an independent carrier axle. The axle tubes and axle shafts from a typical beam-style axle are replaced with halfshafts and a suspension geometry that reacts to the vehicle loads. In this axle arrangement, the vehicle weight and suspension travel do not change the position or load the axle housing. This provides for additional freedom in suspension design along with packaging advantages and often found on luxury and sports cars.

5 HYPOID GEARING

5.1 Main functions

There are three main functions of the hypoid gearing; mainly, it provides a 90° direction change, provides torque multiplication, and acts as a mechanism to distribute lubricant to the gears and bearings. The fundamental geometry of a typical automotive hypoid is that the angle of the output gear, commonly called ring gear, is at angle, that is, 90° in relation to the input gear, commonly called the pinion gear. The angular relationship is often referred to with the Greek symbol alpha, α. With any two gears in mesh, the smaller of the two mating gears is referred to as the pinion and the larger as the gear. The fundamental function of the hypoid is to increase torque from the input to the output along with decreasing speed, or simply stated that torque and speed are inversely proportional. The torque ratio for the hypoid is the number of teeth on the ring gear divided by the number of teeth on the pinion. For example, a 41-tooth ring gear meshing with an 11-tooth pinion would yield a torque ratio of 3.7272, which is typically rounded to 3.73 : 1. The speed ratio is the inverse of that and 0.26829 : 1 for the example tooth combination. During the gear ratio selection process, it is typically desired to have a full hunting tooth combination to help with noise reduction and wear concerns. The term *hunting ratio* refers to the mathematical relationship between the tooth combinations of the gear set. A simple means to determine if a ratio is hunting or not is to examine the factors of the tooth combination and make certain that there are no common factors, excluding one, of course. For example, a 13-tooth pinion driving a 39-tooth ring has a common prime factor of 13 between the tooth pairs. This means that the pinion teeth will mesh with the same 13 teeth on gear, three times per revolution. For optimal noise and wear, it is desired to have the gear teeth always meshing with different teeth on the mating gear. The typical corrective action, for example, would be to increase the number of teeth on the ring gear to 40 and, therefore, there are no longer any common factors. The ratio changes slightly now to 3.08 : 1 compared to the 3.00 : 1. The last function that the hypoid gears perform is to adequately distribute the lubricant from the axle sump to the gears, bearings, and seals in all driving conditions. The gear system is supported with certain axle housing geometry features and ports to aid in channeling and retaining the lubricant. Figure 7 illustrates the oil flow from the axle housing sump being carried by the ring gear during its rotation to the pinion bearing oil port. The tapered roller bearings pump oil from their small diameter to the larger. There is a need for sufficient oil flow to the cavity between the pinion bearings to insure life of the bearings. There is also a return port for the pinion tail bearing to return oil back to the sump and not flood the pinion seal.

5.2 Design methodology

The term *hypoid* is derived from the fact that the pitch cones of the gears have a hyperbolic shape; more specifically, the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto112
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

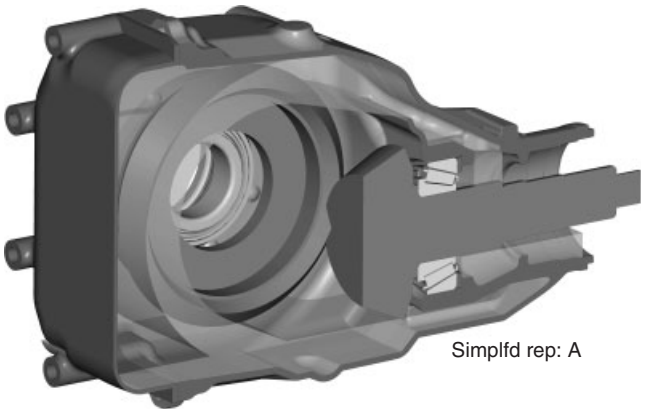

Figure 7. Axle oil flow illustration.

tooth form is created by a hypocycloidal curve. The hypoid gear set is very similar to a spiral bevel gear arrangement with the addition of an offset. The pinion axis of rotation does not intersect the gear axis of rotation, as shown in Figure 8. In this figure, two reference planes are displayed between the centerline of the ring gear and the axis of rotation of the pinion. The distance between these two planes is referred to as the hypoid offset. This offset factor also changes the paradigm of typical torque ratios equal to the ratio of the pitch diameters. As the hypoid gear teeth have different pressure angles and profiles of curvatures, it is possible to design an uncharacteristically large pinion even with a numerically large torque ratio. The offset allows such an arrangement to be possible and this allows for an overall stronger gear set.

The actual design equations and analysis are quite extensive with over 150 variables with approximately 30% of them requiring an experimental approach of trial and error with an iterative process until a suitable result is found. In order to have an appreciation of the amount of work that has been completed in this analysis area since the first commercial application of a hypoid axle in 1925 by Packard Automobiles, it is necessary to review some of the history behind hypoid gears. Even with the first hypoid available, the fundamental engineering behind the concept

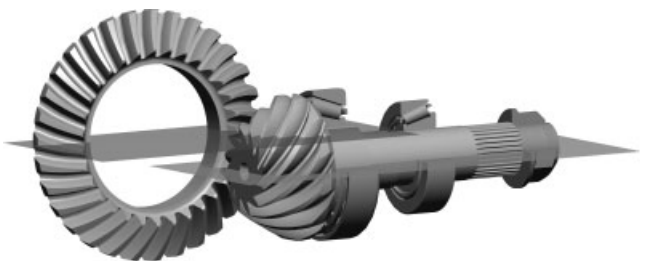

Figure 8. Hypoid offset illustration.

was not truly understood and no good design practices were in place for at least another 10 years. From the mid-1930s to -1970s, engineers applied physics and math to understand and develop kinematic relationships to design and manufacture these necessary gears for the automotive industry. To this day, these base equations, which are presented below, are at the core of the design optimization process for hypoid gears. This is a unique gear design problem, as besides the basic inputs of tooth combination, diameter of ring gear, pinion offset, and the like, the engineer needs to estimate the gear tooth cutter radius in the initial design process. Therefore, the engineer needs to be aware of the manufacturing tools and techniques upfront in the design process. Hypoid gears are the only gears that require this level of information in order to design the gears. From trial and error over the years, this is the only method that produces consistent results. Below are the five equations with five unknowns that need to be initially estimated and then iterated to find the exact solution for a given set of design inputs (Griffith, 1968).

$$A = \frac{1}{2}\left(\frac{D}{\sin\Gamma - F}\right) \tag{1}$$

$$r = A\left(\frac{n}{N}\right)\left(\frac{\sin\Gamma}{\cos\gamma}\right)\left(\frac{\cos(\psi - \varepsilon)}{\cos\psi}\right) \tag{2}$$

$$\sin\varepsilon = \frac{E}{(\cos\gamma\,(A\sin\Gamma + r\cos\Gamma))} \tag{3}$$

$$\tan\gamma = \frac{r}{A}\left(\frac{\cos\psi}{\cos(\psi - \varepsilon)}\right) \times \left\{1 + \left[\frac{A}{r_c}\left(\frac{\cos\varepsilon}{\cos\psi}\right) - \tan\psi\right] \times [\tan\psi - \tan(\psi - \varepsilon)]\right\} \tag{4}$$

$$\cot\Gamma = \frac{\tan\gamma}{\cos\varepsilon} \tag{5}$$

where the following five symbols are unknown:

A = mean cone distance of gear (inch);
r = distance from the mean point to the centerline of pinion, normal to the pitch cone (inch);
ε = offset angle of pinion (°);
γ = pitch cone angle of pinion (°);
Γ = pitch cone angle of gear (°).

where the following seven symbols are known:

n = number of teeth of pinion;
N = number of teeth of gear;

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto112
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

ψ = spiral angle of pinion (°);
r_c = mean radius of gear cutter (inch);
D = pitch diameter of gear (inch);
F = face of gear (inch);
E = offset of pinion (inch).

On the basis of the complexity of these calculations, they have been automated, to an extent, with computer-based tools. The most common of these is from the machine supplier, The Gleason Works. The other major tool and vendor is Oerlikon-Klingelnberg. Hypoid gears are so unique that the manufacturers of the equipment have also developed software tools to analyze the gear geometry along with the manufacturing tools. Some of these design tools do not produce stress values for ratios that are numerically below 1.8; therefore, if ratios lower than this are required, alternate stress analysis methods are required. These alternate methods can be finite element analysis or even altering offset to zero and temporarily modeling the gear set as a spiral bevel. These alternate methods are just estimates to help guide the design process and should never be used as absolutes.

On the basis of the complexity of the design process and the number of variables, this section will concentrate on the macro-level geometry and descriptions. There are four main geometry elements for an axle, of which two are adjusted during the assembly process. The first geometry feature is hypoid offset, which is the distance that the centerline of the pinion is away from the centerline of the ring gear. For typical automotive rear axle applications, the pinion is below the centerline of the ring gear. The offset dimension is typically 15–20% of the ring gear diameter. Hypoid offset is often given the symbol E and is a design parameter, but is not adjustable. The offset distance is machined into the cast center section of the axle. The next nonadjustable geometry feature is the shaft angle. For automotive applications, the ring and pinion axes are at 90° in relation to each other. This shaft angle is commonly referred to with the Greek symbol alpha, α, which is shown in Figure 9. This illustration shows references planes through the rotation axes of the gear and the pinion.

The next two geometry features are adjusted during the assembly process to achieve optimum durability and noise performance of the gears. These are pinion mounting distance, designated P, and ring gear mounting distance, designated G. The pinion mounting distance is the distance from the centerline of the ring gear to the pinion gear back face. This is illustrated in Figure 10 with two reference planes to depict the concept of pinion mounting distance. The ring gear mounting distance is the distance from the pinion centerline to the ring gear back face, as shown in Figure 11. Similar to Figure 10, except this time, the planes

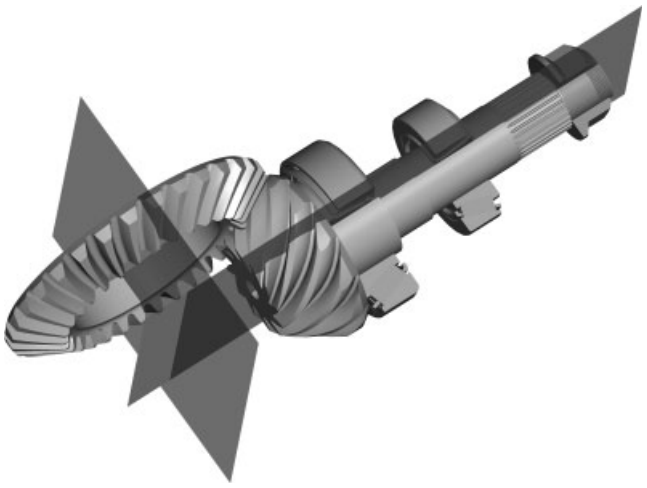

Figure 9. Shaft angle alpha illustration.

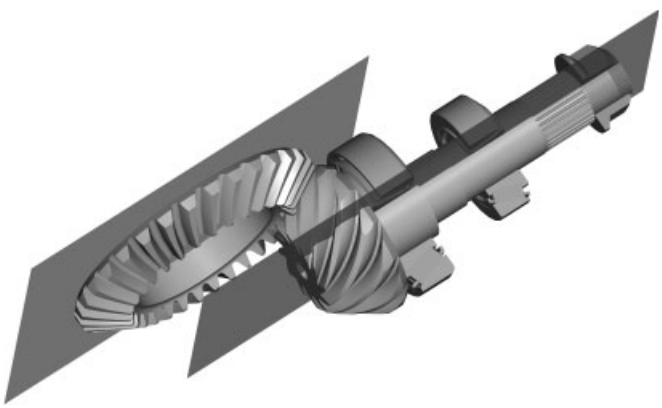

Figure 11. Ring gear mounting distance illustration.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto112
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

are oriented to show the ring gear mounting distance. On the basis of difficulty of measuring at assembly, this dimension is measured and translated to an actual assembled gear mesh backlash value for assembly and service procedures. These two adjustments in gear mounting positions are so critical to correct operation of the gear pair that there is a special test performed on each gear set. This test is referred to as a *single-flank test* and determines the ideal location of these gears in relation to one another based on the manufacturing tolerances and final gear form. The pinion distance is recorded and select fit shimmed during assembly, whereas the ring gear mounting distance is translated to an actual backlash value for the gear to be installed. The main reason for translation gear mounting distance to backlash is to allow for ease of assembly and service. It is virtually impossible to measure ring gear mounting distance in the complete axle assembly, whereas ring gear backlash is relatively simple to measure.

The other unique geometry, in addition to offset, for a hypoid gear set is the spiral angle of the gear teeth. The spiral angle for the ring and pinion are opposite hand in order to operate correctly. Most automotive rear axle applications have the pinion located below the centerline of the ring gear with a left-hand spiral, whereas the mating ring gear is the opposite hand with a right-hand spiral angle. The typical spiral angle range is between 35° and 55° for the pinion.

6 BEARING CONSIDERATIONS

Any rotating members in a car and specifically axle assembly are supported by bearings. These bearings need to support and carry radial and axial loads as required. The main contributor for loads along the axis of rotation of the bearings is from the hypoid gear separation forces. The main contributor of radial loads is from the mass of the component's rotation and the weight of the vehicle. In this section, the loads associated from the hypoid gear mesh are reviewed. For the complete axle structure design, loads from the vehicle mass, wheels, suspension, cornering loads, and brakes must also be considered.

6.1 Hypoid load calculations

The hypoid gear arrangement creates three loads that are centered at the gear mesh point. These loads must be translated back to the bearing support structure based on the geometry and span of the bearings and axle layout. There are many different bearing support structures that have been used and range from straddle-mounted gears along with direct and indirect mounting strategies. These are all explained in the literature (Radzevich, 2012).

6.2 Preload

Most automotive axles utilize tapered roller bearings to support the thrust loads that are generated from the hypoid gear arrangement. There have been some recent axles that utilize tandem ball bearings; however, the main focus of this section is tapered roller bearings, and the theories are similar when tandem ball bearings are utilized. In order to properly locate and transfer load across the bearings, tapered roller bearings must be assembled with a fixed amount of preload, typically a value in the range 4000–6000 N (900–1350 pound force) is desired based on typical automotive size bearings. Of course, these values are just estimated for a typical light-duty automotive application. Another term to use instead of preload is interference fit, specifically that the bearings are initially installed in the axle in a situation where the bearings are forced into a smaller space than they would statically accommodate. The exact amount of interference to maintain the desired preload needs to be analyzed based on the characteristics of housing, shaft, and bearing deflection and fits, to name a few. There are many factors along with design and assembly methods that all contribute to the process for determining and setting bearing preload.

Preload can also be affected by the housing material selection, specifically when aluminum is utilized, as it has a greater rate of thermal expansion. For the pinion bearings, the higher coefficient of thermal expansion may be balanced, as the distance between the housing bearing seats increases (which increases the preload) and the bearing bores also increase in diameter, which decreases the bearing installed height (which decreases the preload). The net result is typically a balance back to the original preload but this is a function of the span between the bearing seats and the fit of the bearing cups in the housing. For the differential carrier bearings, the preload needs to be set higher to accommodate this thermal expansion in aluminum. As the axle temperature increases during operation, the housing will expand faster than the internal steel components, which results in a loss in bearing preload.

6.2.1 Pinion bearing preload

There are two common methods to achieve and control adequate pinion bearing preload. It is important to have the correct amount of preload without overloading the bearing. In order to properly space and preload the pinion bearings, there is a pinion spacer that is assembled in between the

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto112
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

pinion bearing cones. At times, this pinion spacer is referred to as a preload limiter. The spacer also makes certain that there is a correct amount of pinion shaft elongation and subsequent clamp force on the drive flange. On the basis of the desire for ease of assembly for volume production, the pinion tail bearing cone is a slip fit to the pinion shaft. There must be enough clamp load of this bearing race between the spacer and the drive flange to guarantee that this bearing race does not rotate on the shaft.

The solid spacer-style preload limiter is one method for this clamp load and bearing race retention. This spacer is a select spacer that is selected during the assembly process. The exact length of the spacer is based on the exact measurements of all of the components involved, namely bearing heights, housing machining, pinion shaft machining, and press fit tolerance for shaft and housing. On the basis of these factors, the select fit spacer is chosen and assembled on the pinion. As a final check, the assembled pinion torque-to-rotate is measured and compared to a specific range based on the preload required, a typical range for this torque-to-rotate is 15–28 in-lbs (1.7–3.2 N-m). On the basis of the load that the spacer is subjected to, along with the pinion shaft bending while loaded, the spacer needs to be strong enough to not deform under these conditions. The solid spacer arrangement does allow the pinion nut to be tightened to large torque (i.e., 250 ft-lbs (340 N-m)) to make certain that the nut does not loosen over time.

The other method that is more common is to design and develop a spacer that can accommodate the range of manufacturing tolerances of all of the components while still maintaining proper bearing load under all conditions. The collapsible spacer is the typical method for this. This spacer is designed as a tube with a section that is prebent to allow the spacer to buckle in a controlled manner when loaded, as shown in Figure 12. This deflection allows the spacer to decrease in length while still providing a resistive load to the bearings. The spacer acts like a spring in the bearing mounting system to balance load versus deflection. The pinion shaft will deflect or bend under high loads and the collapsible spacer will maintain adequate bearing load throughout this deflection. This spacer is designed with a very specific and predictable compressive load versus deflection curve. This curve has an initial amount of deflection that achieves a high load and then the slope of the curve approaches zero. The flat portion of the curve allows the spacer to maintain the desired bearing load while still accommodating deflection in the system. Designed properly, the spacer is installed in a stable condition statically and maintains equilibrium throughout all dynamic operating conditions. On the basis of the physical arrangement of this spacer, during installation, the pinion nut is tightened until the desired torque-to-rotate on the bearings is achieved. Once achieved, the nut can no longer be tightened further or loosened without replacing the spacer; it is a single use spacer. As the nut cannot be tightened further, there must be a secondary mechanism in place to assure that the nut does not loosen or leak. The most common practice is to utilize a thread-locking sealant on threads and the nut flange to retain the nut and seal the interface.

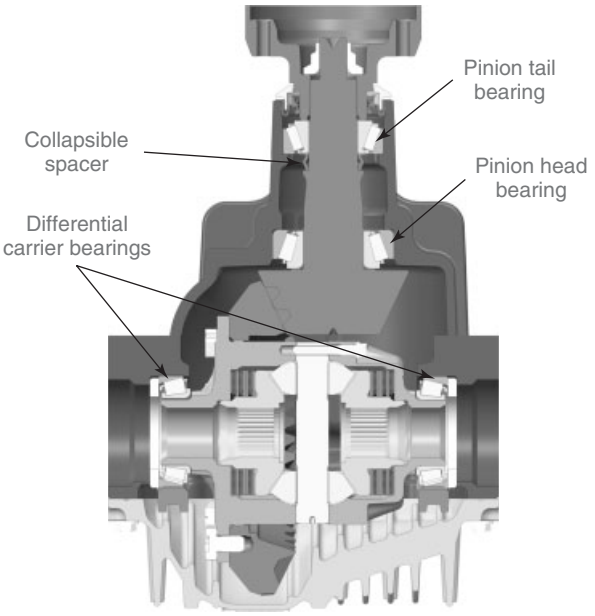

Figure 12. Axle center section cross section.

6.2.2 *Differential carrier bearings preload*

The differential carrier is supported by tapered roller bearings, and as stated earlier, these bearings need to have a predetermined amount of controlled preload in order to provide sufficient load-carrying capacity and durability. There are three common methods utilized to achieve carrier bearing preload. These are with large adjuster nuts, select fit snap rings and solid shims with bearing caps. There are some designs that even combine the snap ring fit for one side and bearing cap for the other. Along with developing the correct preload, the ring gear mounting distance is adjusted and verified with a backlash verification process. There is also a final visual check of the bench contact (low torque) of the gear in the final assembled position. If the contact pattern is incorrect, the gear set mounting and shims will be changed to obtain the correct contact pattern.

7 MANUFACTURING METHODS

There are two mainstream manufacturing processes to cut hypoid gears. The traditional method of single indexing has been used for decades and was the most common until the late 1990s and early 2000s. The single indexing refers to the fact that a single gear tooth gap is completely cut at a time in the gear blank before the next tooth gap is cut. The second process is a continuous indexing process where both the gear cutter and the gear blank rotate while the tooth gaps are all partially cut or indexed. The gear teeth gaps are basically all completed at the same time. Independent of which gear manufacturing is employed, the typical process steps are generically as follows: gear forging, gear blank machining, tooth machining, heat treat, grind bearing journals, lapping, and finally, annealing of pinion threads. There may be additional processes required based on heat-treat distortion, length of pinion shaft, and other factors that may require pinion shaft straightening. For increased strength, there may be a shot-peening process and, of course, several part washing steps.

7.1 Face milling (five cut)

Traditional face milling is a single indexing process as described earlier and has been used to produce hypoid gears for quite some time. This process is often referred to as the *five-cut process*, as there are five discreet cutter heads and potentially five machines required to produce the ring and pinion gears for high volume production. The pinion requires three unique cutter heads; namely, one for rough cutting the tooth slot, another to finish cut the convex surface, and a third to finish cut the concave surface of the gear tooth form. The ring gear requires two cutter heads for finishing of the convex and concave surfaces of the gear tooth. This process is typically performed with a lubricant to increase tool life. The face-milling process produces a tapered tooth surface as seen in Figure 13. The tooth surface is outlined to highlight the trapezoidal nature of the surface. This process is adjusted by controlling and evaluating the tooth contact pattern during the manufacturing process. Specifically, the pinion tooth-form machining is adjusted to provide the desired position and shape of the contact pattern. These changes to the machining are not without problems, but the producers of these gears have learned how to handle these changes.

7.1.1 Face mill completing

There is a subset of face milling with a slight difference in that the entire tooth profile is cut with a single cutter head and is very similar to the face-hobbing process regarding material per cutter head. On the basis of this, only two cutter heads are required to cut the ring and pinion gears. However, the face mill completing process still removes material one tooth gap at a time. This process is usually the precursor for grinding operation.

7.2 Face hobbing (two cut)

Face hobbing is a gear-cutting process that is known as *continuous indexing* and became more popular in the late 1990s to modern day. There were a few changes to the manufacturing process that were all introduced along with face hobbing. The ability to cut the gear teeth without lubricant or dry-cutting along with a reduction in tooth-cutting time by approximately 30% was also enabled by face hobbing. With the introduction of high speed carbide cutter blades, the blade life was increased by almost a factor of 3. Lastly, the fact that only two-cutter heads and machines were required as compared to the five for face milling helped this process become the mainstream for the automotive industry. There are still legacy machines and components that are using the face-milling process; however, most new designs are face hobbed. The face-hobbing process produces a parallel tooth form as compared to the tapered tooth of the milling process as shown in Figure 14.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

7.3 Lapping/grinding

After the gears are heat treated, there are two postheat-treat or hard-finishing processes that can be used to aid in final finishing and improving of the gear tooth surfaces. The first and the most common is a lapping process. For this process, a very abrasive material, specifically a silicon carbide material in oil, is put in the gear mesh while the ring and pinion gears are rotating under light torque. The gears are not only rotating but also being slid along the contact pattern to evenly remove any surface defects and *wear* the gears together. As the pinion acts as the tool to finish the gear and the gear as the tool to finish the pinion, the gears are a matched set after the lapping process and must stay together. It is no longer possible to mix and match the ring gear or pinion after lapping. The lapping process also created some desirable microstructure to aid in overall noise reduction of the gear set. As the pinion and ring gears are used together during the lapping process, a completed gear set is delivered and there is no subsequent machining required.

The second process is a grinding process, where the material that is removed is controlled and brings the gear tooth profiles back to design intent and corrects for manufacturing and heat-treat deviations. In order to grind the tooth profiles, they must be face milled or produced from a single-indexed process. It is not possible nowadays to grind gears that were produced from a continuous indexing process. A ground gear set is not a matched set and the ring and pinion gears can be intermingled. There are trade-offs with both of these processes. If the heat-treat process and subsequent distortion is controlled reliably and minimized, small amounts of material are only required to be removed and lapping is preferred. Contrarily, if large heat distortion and larger amounts of material are required to be removed, then grinding is preferred.

Supercharging

Scot Streeter[1] and Matt Swartzlander[2]

[1]*Eaton Corporation, Galesburg, MI, USA*
[2]*Eaton Corporation, Marshall, MI, USA*

1 INTRODUCTION

By definition, the term *supercharging* as related to internal combustion engines is to increase the mass of charge air in the cylinder beyond the level capable by natural aspiration. In combination with the appropriate air/fuel ratio (AFR), the combustion pressures and useful specific work output are increased beyond the levels achievable for nonsupercharged applications. Typically, supercharged applications are discussed in terms of boost pressure referring to the peak pressure the device creates in the intake manifold. It is common to hear in North American engineering circles discussion of an application making numbers such as "12 pounds" of boost or "15 pounds" of boost when the actual unit of measure is PSI (pounds per square inch). These numbers are actually gaging pressure numbers above atmospheric pressure levels, hence, the term *boost* and why these performance levels cannot be achieved by naturally aspirated operation.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition)
ISBN: 978-0-470-97402-5

There are several ways to provide the work input to the supercharging device in applications that can be generally divided into two categories: mechanical and fluid drives. The term *supercharger* is generally associated with mechanical-drive devices, whereas the term *turbocharger* is the most common approach to a fluid-drive system. The scope of this chapter is to focus on the aspects of the device typically termed a *supercharger*.

2 COMPRESSOR DESIGN

The roots type compressor in its most basic form consists of an input shaft driving a pair of counterrotating rotors or impellors to move air from the inlet to the outlet of the device. As there is no internal compression in the roots device, a simple bypass loop can effectively eliminate unnecessary mass flow through the device when the operating conditions of the engine do not require the additional mass flow to meet the break mean effective pressure (BMEP) targets for the requested speed/load point demanded by the operator. When the bypass is fully open, the parasitic losses associated with the device are limited to the internal frictional losses and any throttling losses associated with the bypass flow restrictions. While these numbers are quite small relative to other parasitic losses is the system, the incorporation of a clutching device in the system can completely eliminate these losses when the supercharger is disengaged from the drive system (Figure 1).

2.1 Drive input system

The device is directly driven as an accessory on the engine most commonly via the Front Engine Accessory Drive

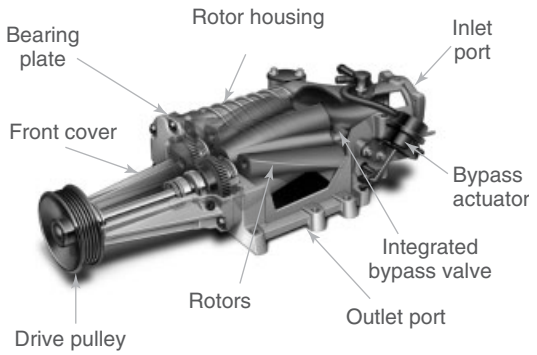

Figure 1. Supercharger component detail. (Reproduced by permission of Eaton Corporation.)

(FEAD) belt system. It is either in the general serpentine routing or potentially driven with a separate belt via a double pulley at some other location on the FEAD. For most engine applications, the supercharger belt ratio will generally increase the supercharger speed from 1.7 to 2.5 times the engine crankshaft speed. For gasoline, these ratios are typically sufficient when the supercharger is employed alone for the application. When a supercharger is used in conjunction with a turbocharger in a compounded configuration, the supercharger is typically clutched out at roughly half engine speed and, as such, a much higher overall drive ratio is required. For these types of applications, internal step-up gearing may be utilized within the supercharger or an additional belt ratio may be applied with a three-pulley system. This is also true for compression ignition where the peak engine speed is typically much lower than a gasoline spark ignition engine. Figure 2 shows an internal step-up gear configuration for a supercharger.

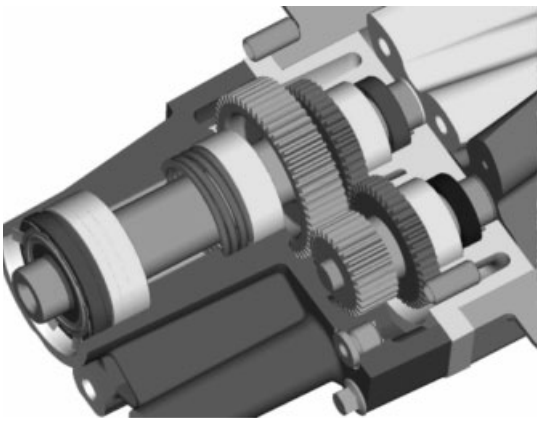

Figure 2. Supercharger step-up drive configuration. (Reproduced by permission of Eaton Corporation.)

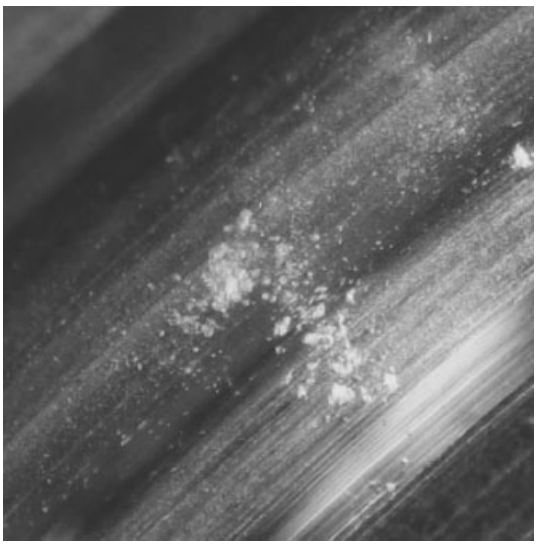

Figure 3. Supercharger bearing spalling. (Reproduced by permission of Eaton Corporation.)

The pulley on the supercharger is coupled with an input shaft supported on two bearings to provide the torque to drive the two rotors. The length of the input shaft, and subsequently the "snout" of the supercharger, can be varied in length to provide belt access while positioning the device in the optimal location of the engine. Care must be taken to assess the dynamic belt loads on the pulley to get the correct bearing design characteristics and assure that the application life requirements are met. If these loads are too high, given the overall duty cycle for the application and the bearing speed/load capacity, bearing raceway pitting can occur ultimately leading to premature bearing failures. Figure 3 shows the onset of microspalling in a supercharger pulley bearing raceway.

Additional areas of concern are that the cantilever loading does neither cause excessive stress in the front cover of the device nor cause a sealing issue in the joints between the bolted components of the device. The assessment of these conditions is typically assessed via finite element method (FEM) to ensure a robust design.

2.2 Input drive coupling

The input shaft system is connected to the rotor timing gears via a coupling that provides the necessary compliance in the appropriate degrees of freedom to couple the input shaft and rotor bearing systems. While a direct coupling between the input shaft and the timing gears is feasible, as shown in Figure 3, this is not desirable because the direct connection of the engine torsional excitation to the timing gears can cause gear rattle during unloaded

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

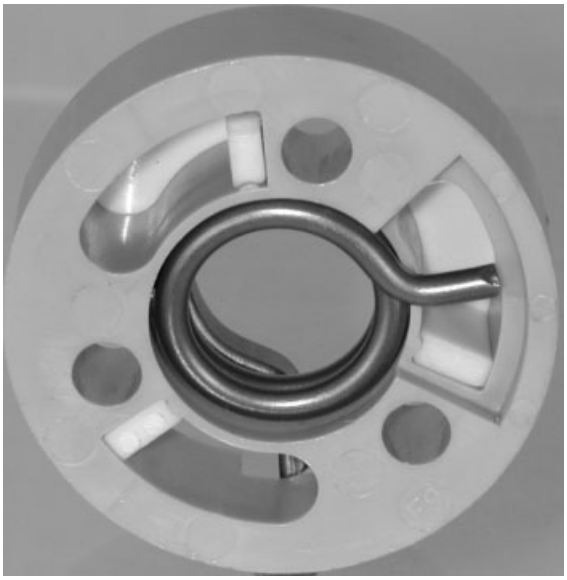

Figure 4. Supercharger torsional isolator. (Reproduced by permission of Eaton Corporation.)

operation. Most modern original equipment manufacturer (OEM) superchargers contain a torsional isolator between the input shaft and the timing gears to decouple firing torsional frequency from the gears (Figure 4).

These isolators are typically developed with dynamic systems models for the appropriate excitation frequency attenuation given the coupled inertia in the system.

2.3 Timing gears/lubrication

The timing gears are included in the system to prevent contact of the rotors during operation. As the rotors are designed to minimize the rotational inertia of the system, these types of materials do not make good load bearing candidates and will spall if in intimate contact. To prevent the contact of the rotors, the gear pair backlash is designed to be tighter than the rotor mesh backlash. The gear tolerances and the housing system tolerances that control gear and rotor center distances must be very tightly controlled during the manufacturing process. The gear design must account for the root stress, the contact stress, and the transmission error as they relate to gear acoustic performance (Figure 5).

Figure 5 shows a pair of supercharger timing gears on a vibration signature dynamometer.

Most modern OEM superchargers in production today use a very tightly toleranced profile quality spur timing gear. While helical gears can improve the contact ratio, timing the helical gears in concert with helical rotors is

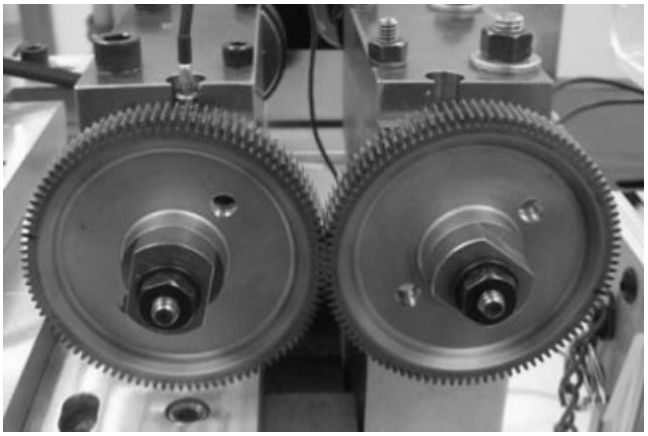

Figure 5. Gear torsional excitation assessment. (Reproduced by permission of Eaton Corporation.)

a very difficult process because of the thrust loads and deflection encountered during assembly. As the power transmission through the device is carried by the gears, the gear cavity is typically oil lubricated. While oil could be supplied via a feed and return line to the engine, it is very common for the supercharger to have a self-contained oil supply utilizing a high quality synthetic lubricant. These types of devices are considered "sealed for life" and require no maintenance for the life of the engine/vehicle. The gearbox must be sealed to retain the lubricant and the rotor shaft seals in the application have to survive with shaft speeds in excess of 20,000 rpm. In addition, the seals and churning losses in the oil are contributors to the parasitic losses and need to be designed specifically to minimize friction and viscous shear losses for the application to maximize efficiency.

2.4 Rotors

The timing gears then drive the rotors that actually pump the air from the inlet to the outlet of the device. Key design considerations to maximize efficiency are the rotor lobe geometry, rotor helix angle, number of lobes, rotor-to-rotor clearance, rotor-to-housing clearance, and the inlet/outlet port sizes and shapes. The system clearances directly impact the leakage between air transport volumes in the system and contribute negatively to low speed efficiency more so than high speed efficiency. Conversely, the porting of the device, as well as the inlet and outlet plumbing of the entire engine induction system, can cause choking because of either higher pressure drop or inefficient fill/expel events and generally have a greater negative impact on high speed efficiency. The air transfer process can be

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto113
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

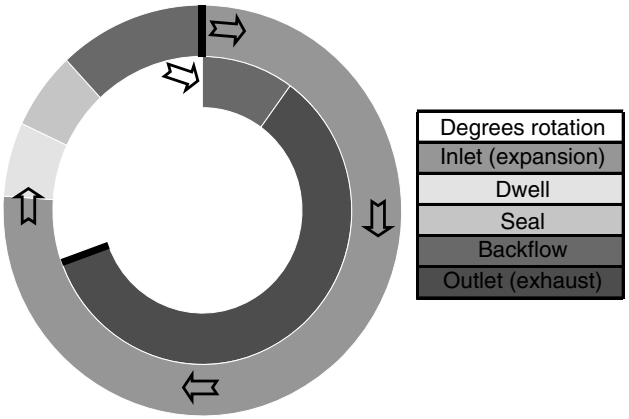

Figure 6. Supercharger air-handling timing diagram. (Reproduced by permission of Eaton Corporation.)

categorized into low pressure and high pressure events as follows.

1. Low pressure expansion—The time the transfer volume starts to expand until it comes completely out of rotor mesh.
2. Low pressure dwell—The time the transfer volume is completely expanded during the inlet process.
3. Low pressure seal—The time the transfer volume is sealed from the inlet and outlet.
4. High pressure backflow—The time the transfer volume is initially exposed to the high pressure manifold.
5. High pressure discharge—The time the transfer volume is completely exposed to the outlet port.

Transport time is a function of rotational speed and is typically referred to in degrees to take the time domain out of the equation. This helps with simplicity of explaining the geometric events but does negate the fluid dynamic impact on these events (Figure 6).

To optimize the rotor design, we want to control changes in the mass momentum of the charge air to the greatest extent possible. This can be achieved by matching the transport volume expansion rate with in inlet mass flow rate to avoid excessive changes in momentum (Figure 7).

Figure 7 demonstrates this goal of keeping velocity $V3 \leq$ velocity $V1$.

Figure 8 shows the dramatic improvement in these characteristics that Eaton Corporation achieved with its TVS® supercharger relative to their previous generation.

As mentioned earlier, the lower speed efficiency is governed by clearance in the device and leakage between air transport volumes. To optimize the efficiency at lower speeds, coating can be utilized to minimize the clearances in the device while still preventing metal-to-metal contact that would induce spalling and subsequent durability concerns. One innovation addressing this concern is the use of an abradeable coating on the supercharger rotors that wear into a match fit on the device. The rotors are coated before assembly and then assembled as interference fit. As the unit is rotated during a break-in operation, the coating then abrades and is expelled from the unit yielding an essentially zero clearance configuration. The volumetric efficiency improvement typical of this type of coating is shown in Figure 9.

2.5 Ports

The inlet and outlet port shapes are primarily governed by the rotor configuration. If the ports are small compared to the optimum rotor timing, you will choke the flow or allow insufficient duration for the intake and exhaust events to occur. If the ports are excessively large compared to the rotor geometry and timing, you will generate leakage between the inlet and exhaust transport volumes. In Figure 10, the inlet ports show the difference between available port area for high and low twist rotors.

On the outlet port, the port edge is typically aligned with the rotor tip helix and exposes roughly half of the rotor length. With sufficient twist in the device, there is actually communication between transport volumes during the backflow portion of the exhaust event. This helps reduce the momentum of the high pressure in-rush of air to the exhaust volumes and minimizes the pulsation magnitude in the outlet. An exhaust (outlet) port is shown in Figure 11. The position of the outlet port can be used to tune the peak efficiency of the supercharger based on pressure ratio. The smaller the port, better efficiency is created at higher pressure ratios, the larger the port, better efficiency is present at lower pressure ratios. Setting the port mid rotor bores provides a good compromise for most applications (Figure 11).

The backflow geometry for pulsation control is shown in Figure 12.

3 PERFORMANCE MEASURES AND MAPPING

The performance of a supercharger is primarily gaged with two primary measures: volumetric efficiency and isentropic (thermal) efficiency. The measurement techniques are typically governed by industrial standards such as the Society of Automotive Engineers (SAE) standard J-1723. These standards provide consistency in test configurations to provide comparable results across the industry.

By design, roots type and screw compressors are positive displacement pumps and have a fixed geometric volume of displacement per revolution of the device. The typical descriptions of the devices incorporate this displacement to denote the size of the device. This may be listed in cubic inches, cubic centimeters, or liters of displacement per

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

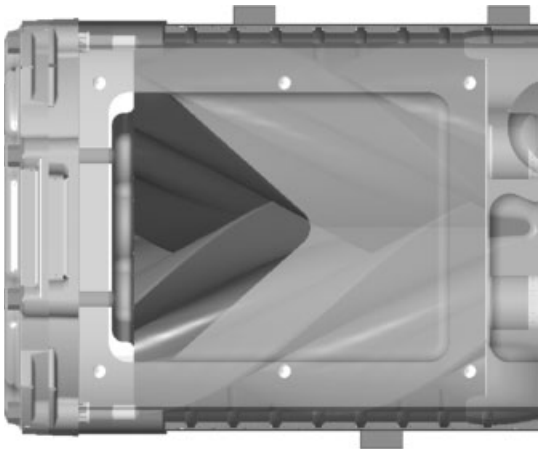

Figure 11. Outlet port geometry. (Reproduced by permission of Eaton Corporation.)

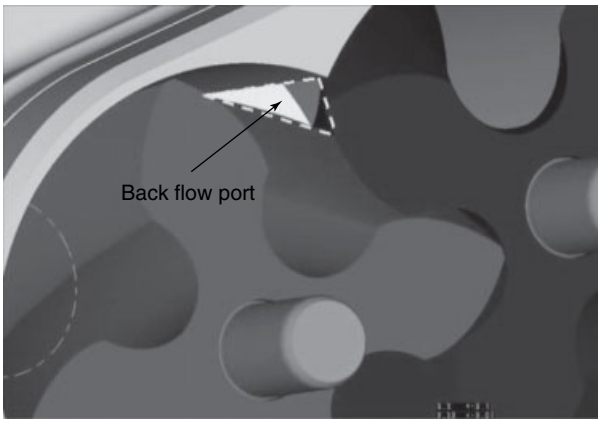

Figure 12. Internal backflow port geometry. (Reproduced by permission of Eaton Corporation.)

revolution. Before the introduction of Eaton's TVS supercharger, they would denote a model in terms of cubic inches of displacement per revolution (e.g., M90 = 90 in^3/rev). With the TVS supercharger, the nomenclature switched to cubic centimeters of displacement per revolution. An equivalently sized supercharger generating 90 in^3/rev displacement would be equal to 1475 cm^3/rev with the new nomenclature. The volumetric efficiency of the device is the ratio of the actual mass of ingested air into the device divided by the theoretical mass of air that would fill the fixed geometric volume of the device per revolution.

$$\eta_v = \frac{m_a}{\rho_{a,i} \cdot V_d}$$

where η_v is the volumetric efficiency, m_a is the actual air mass ingested, $\rho_{a,i}$ is the inlet air density, and V_d is the geometric volume of displacement per revolution in the positive displacement device (Equation from SAE J1723, 1995; SAE International, 1995).

The actual performance is affected by many things in the design including the ductwork feeding and exhausting the device, the inlet and outlet port design, and the rotor design features.

The isentropic efficiency of the device is quantified effectively by the thermal rise across the device compared to a completely isentropic compression process. The relationship is as follows:

$$\eta_T = \frac{T_{inlet} \cdot \left(\frac{P_{outlet}}{P_{inlet}}\right)^{\left(\frac{\gamma-1}{\gamma}\right)} - T_{inlet}}{T_{inlet} - T_{outlet}}$$

where η_T is the isentropic efficiency of the device, T_{inlet} and T_{outlet} are the inlet and outlet absolute temperatures, P_{inlet} and P_{outlet} are the inlet and outlet absolute pressures, and γ is the specific heat ratio of the air pumped through the device (Equation from SAE J1723, 1995; SAE International, 1995).

The efficiency varies with the speed and pressure ratio of the device and is typically assessed on a map similar to the following (Figure 13).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto113
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

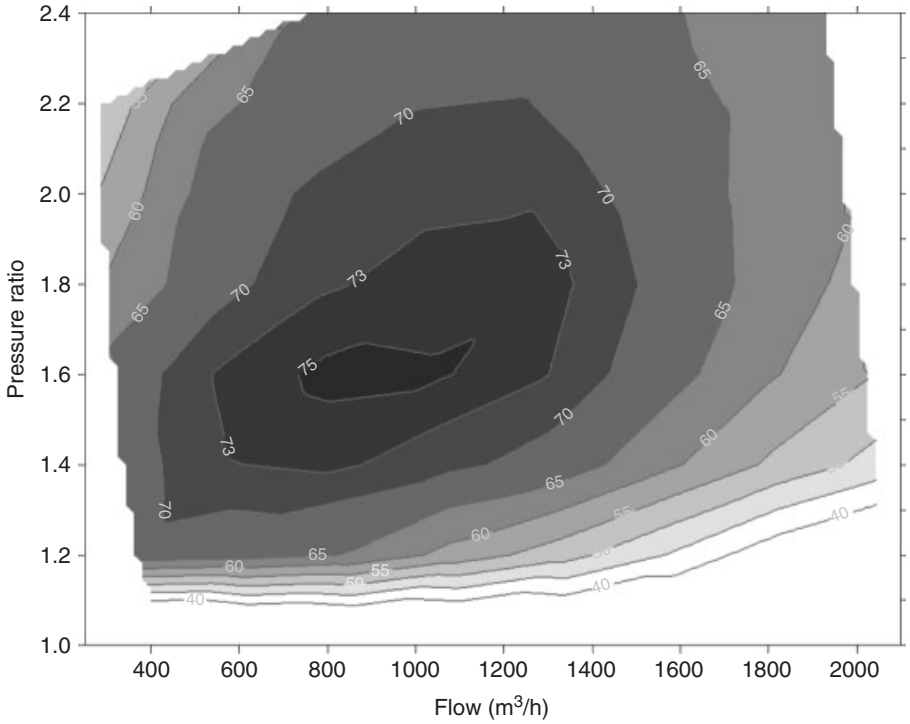

Figure 13. Isentropic compressor efficiency. (Reproduced by permission of Eaton Corporation.)

The actual isentropic efficiency in the final application also is affected by many variables, differing from the standardized in the test environment including duct geometry and atmospheric conditions. Within the device, the thermal efficiency is affected by inlet and outlet port geometry, rotor design, and particularly internal leakage within the device.

4 ENGINE MATCHING

Internal combustion engines are available in a wide range of sizes to fit many applications. Even considering the scope of this encyclopedia is limited to automotive engine design applications, once you consider the global market the variety is still vast. Engine displacements can range from a few hundred cubic centimeters for A-segment mini-cars dominant in Asia-Pacific markets to seven or more liters in J-segment sport utility vehicles (SUVs) and full-sized heavy-duty pickup trucks. This range of engine displacements coupled with the range of maximum engine speeds creates a spectrum of applications for potential supercharging. A supercharger needs to be matched to the application providing the desired mass air flow for the application. Figure 14 shows a typical relationship between engine displacement and the Eaton TVS supercharger displacement.

The range of the supercharger displacement for a variety of engine sizes is affected by primarily pulley ratio selection and bypass strategy.

4.1 Drive systems

The main drive system for a supercharger is either a belt drive or a gear drive. Belt drives are far more common than gear drives because of the ease of packaging and lower cost of integration. Gear drive systems would effectively require that the supercharger be integrated in either the front crank or cam system or the rear of the engine and require significant integration in the base engine design. While a gear drive system would be a more mechanically efficient solution, a belt drive approach allows the supercharger to be treated more like an accessory allowing the device to be mounted further away from the main engine rotating shaft systems, thus a majority of the OEM supercharger applications are driven via belt drive. Figure 15 shows a couple of types of belt routing.

Supercharged OEM engines are utilizing micro-V belts for supercharger drive systems for noise, efficiency, and durability. Depending on the application, the V belt/pulley system may range from a 3 V/groove system to a 12 V/groove system or even larger depending on the size

of the engine and supercharger. The peak power required to drive a supercharger can range from 5 to 150 kW for engines ranging from 0.5 to 7.0 L of displacement. Although this work is effectively recovered in positive pumping work during the intake stroke of the engine, the supercharger pulley and belt still need to be able to transmit this power. In addition to the width of the belt, the belt wrap angle is another key consideration in applying the supercharger to the application. A greater belt wrap angle increased the force transmission before the transition from static to dynamic friction in the belt/pulley interface. Most supercharger applications have belt wrap angles in excess of 180° to minimize the required belt width and handle the torque requirements to drive the device (Figure 16).

4.2 Dual boosting configurations

1. While superchargers can be used as single boosting devices in a particular application, it is possible to use superchargers in conjunction with turbochargers to change the operating characteristics of the system and increase the power density of the application. Figure 17 shows the air routing for a super-turbo application.

The theory of operation is that the supercharger provides the benefit of quick transient response during low engine speed when the exhaust energy is low. At intermediate engine speeds, a controller starts to bypass the supercharger and both boosting devices work in concert. Then, at the highest engine speeds, the supercharger is completely bypassed and typically clutched out, whereas the turbocharger handles the boosting duties alone. This type of application could allow the use of a more cost-effective waste-gated turbocharger compared to the relatively more expensive variable geometry turbochargers (VGTs) on the market nowadays.

An alternative configuration is a turbo-super arrangement where the turbocharger is placed in advance of the supercharger. The schematic of this system is shown in Figure 18.

In this application, the supercharger multiplies the boost provided by the turbocharger by the supercharger's pressure ratio. As the supercharger is a positive displacement device, the pressure ratio across the device is constant regardless of the inlet pressure. This configuration also allows for quick transient manifold pressure increases, such as the super-turbo configuration.

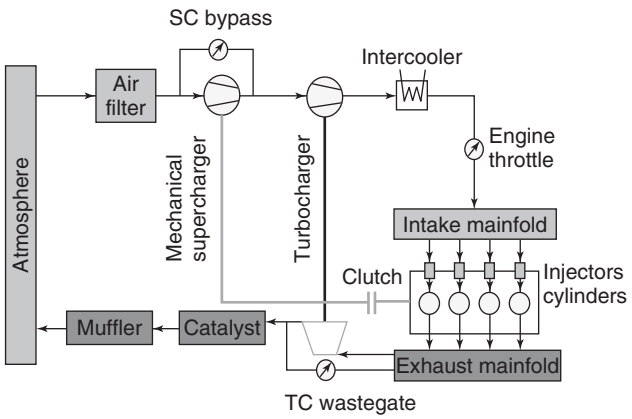

Figure 17. Supercharger–turbocharger configuration. (Reproduced by permission of Eaton Corporation.)

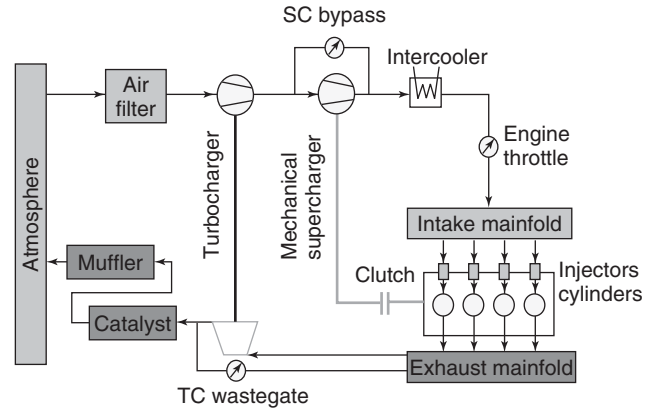

Figure 18. Turbocharger–supercharger configuration. (Reproduced by permission of Eaton Corporation.)

4.3 Bypass configurations

Bypass circuits are required to be used in supercharged induction systems when the engine does not require the mass flow rate that the supercharger is capable of generating. The bypass circuit can be used to control the manifold pressure to the appropriate pressure ratio level and the mass air flow sensor output allows the engine control unit (ECU) to determine the correct fueling rate. Typically, a supercharger is completely bypassed for BMEP load levels of 10 bar or less and the engine operates effectively naturally aspirated. The bypass circuit either can be an external loop outside of the supercharger itself or can be integrated directly in to the supercharger. Figure 19 shows a pneumatic bypass actuator and an integrated bypass butterfly valve on the left side of the model.

Bypass actuators are typically either pneumatic or electrically actuated throttles. The pneumatic actuators are proportionally balanced to close the bypass valve as the intake manifold pressure approaches atmospheric pressure,

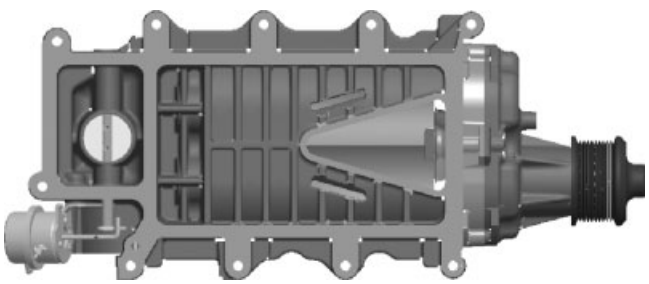

Figure 19. Integrated bypass configuration. (Reproduced by permission of Eaton Corporation.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto113
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

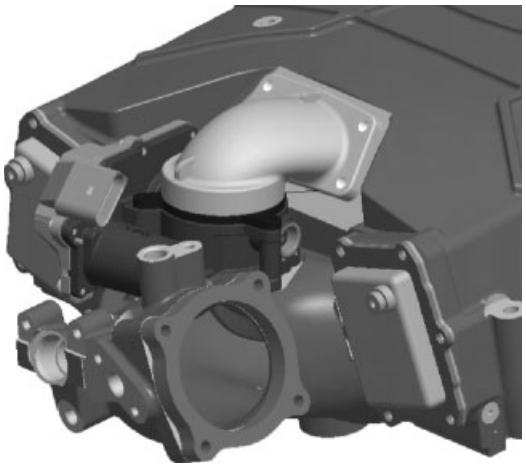

Figure 20. External bypass configuration. (Reproduced by permission of Eaton Corporation.)

which is in relationship to the main intake throttle's position. While the approach is very cost effective, it does not allow for manipulation of the boost profile in an active bypass control scenario. One way to use an active bypass control approach is to bleed excessive boost pressure to maintain a flat brake-torque level at higher engine speeds to control loads to drivetrain components. In addition, this also allows for a slightly larger supercharger than the application may require to further increase low speed torque levels and enable more aggressive down speeding for improved fuel economy. Figure 20 shows an integral bypass circuit coupled with an electric actuator in a complete upper manifold system.

Pressure drop in the bypass circuit is a key consideration for parasitic loss control during bypassed operation. Optimization techniques such as computational fluid dynamics (CFD) analysis are often utilized to minimize the losses associated with flow in bypass circuits (Figure 21).

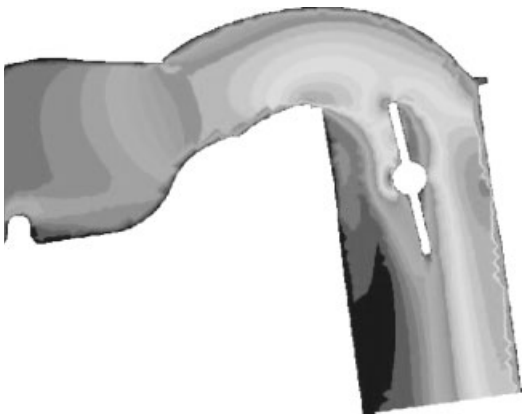

Figure 21. Bypass flow optimization. (Reproduced by permission of Eaton Corporation.)

4.4 Supercharger efficiency

The volumetric and isentropic efficiencies of a supercharger in application are controlled by the design characteristics of the supercharger itself and the way that it is applied to an engine. In this chapter, it is assumed that the engine manufacturers understand the effects of ductwork upstream and downstream of the device, as well as the charge air cooling strategy on overall engine performance. Focus is placed on the device itself in this discussion of supercharger efficiency.

The roots type supercharger has typically been characterized as a devise most suitable for low pressure ratio applications, but the resultant performance characteristics of the device can be drastically altered with careful design. This gives the ability to adjust the performance to the needs of the application. The characteristics that have the greatest effect on the isentropic and volumetric efficiency are the number of rotor lobes, lobe helix angle, outlet port geometry, rotor length, and rotor diameter. All these characteristics are interrelated. As shown in the following example, if you fix the number of lobes, the diameter, and the twist but vary the length of the rotor, then helix angle changes (Figure 22).

These parameters can be tuned to optimize the performance of the device for a particular application. For example, a super-turbo application will have significantly different optimal supercharger characteristics that a supercharger only application with this former preferring a greater volumetric efficiency at low engine speeds whereas the later prefers greater isentropic efficiency through a broad speed range. Another application, like supercharging a diesel engine, may desire higher pressure ratios that increased isentropic efficiency can enable. Tools such

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

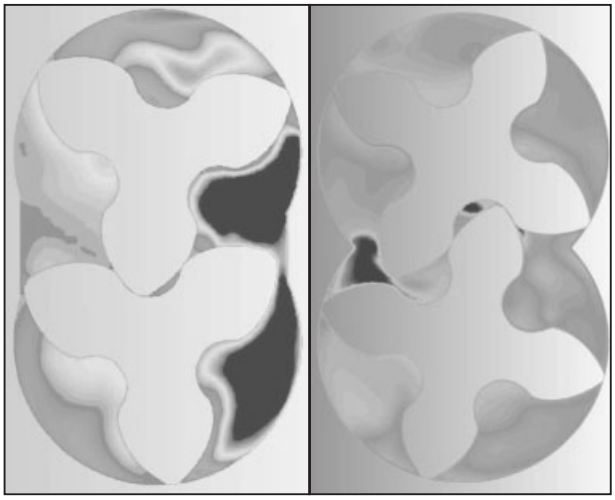

Figure 23. CFD device comparison. (Reproduced by permission of Eaton Corporation.)

as CFD can be utilized to virtually assess the effects of variable on the desired performance of the device (Figure 23).

The optimization of the design can have a dramatic effect on the performance characteristics of the device. Figure 24 shows a comparison of equal displacement superchargers with an optimization of volumetric efficiency at low speed.

The impact on performance varies with pressure ratio and speed, giving the designer the ability to push the high efficiency area of operation around the supercharger map. Figure 25 shows the effect of helix angle on isentropic efficiency at 1.4 and 1.8 pressure ratio operating conditions.

With optimization possibilities, we can target low speed volumetric efficiency for compound boosting applications, higher pressure ratio operation for compression ignition, and higher speed efficiency for supercharged only optimization (Figure 26).

The developments in this area of supercharger development have effectively changed the way that engine and vehicle manufacturers should think about traditional supercharging.

4.5 Supercharged performance

The ultimate goal of engine boosting is to efficiently increase the power/torque density of a specific engine application. With optimization of the engine, the use of charge air cooling, and appropriate selection of the boosting device, significant increases in power density can occur for a given engine displacement. Figure 27 compares the change in power and torque as the result of adding at 1900 cc/rev supercharger with an intercooler to a gasoline 6.2 L V-8 application. In this application example, there is a 50% increase in brake torque over most of the operating speed range compared to the naturally aspirated engine and a 46% increase in peak power (Figure 27).

Traditionally, power density levels of 75 kW/L have been considered well optimized for a boosted engine, but with proper design of the entire engine levels up to, or beyond, 150 kW/L can be feasible.

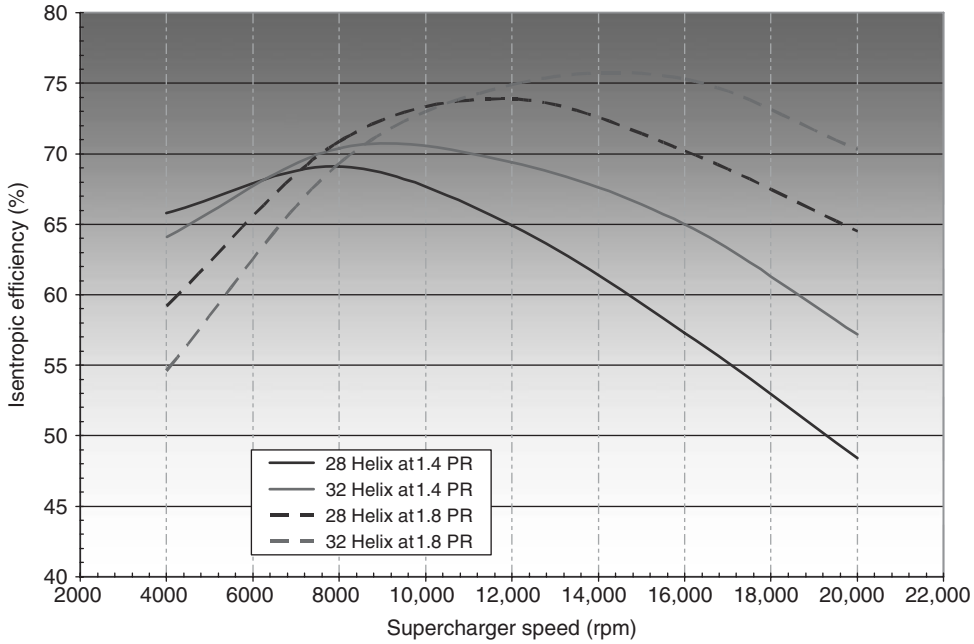

Figure 25. Isentropic efficiency versus helix angle. (Reproduced by permission of Eaton Corporation.)

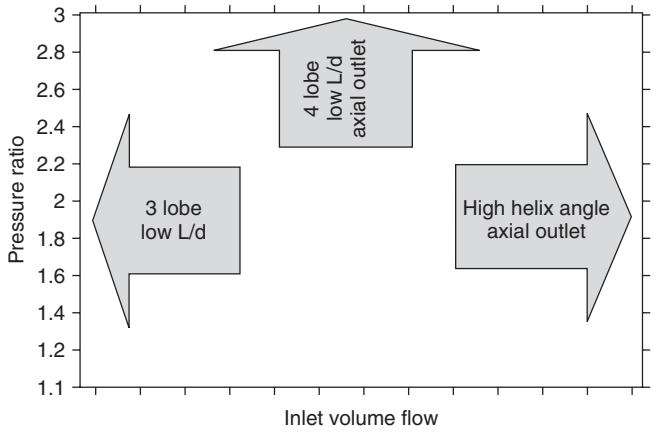

Figure 26. Device function optimization. (Reproduced by permission of Eaton Corporation.)

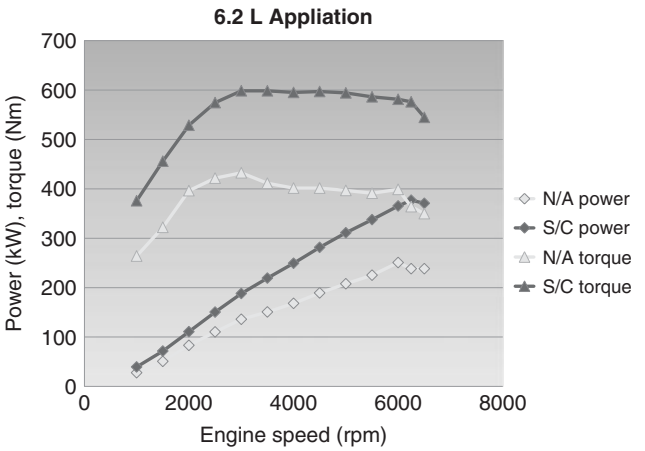

Figure 27. Power density optimization. (Reproduced by permission of Eaton Corporation.)

An additional benefit of mechanical supercharging is the transient impact of performance. Given the direct mechanical connection between the supercharger and engine, boost response is significantly faster than devices that are passively coupled. The following example shows manifold pressure response from 900 rpm with a wide open throttle (WOT) step input at 0 s in first gear (Figure 28).

The effect on vehicle response from a stop light or during the initiation of a passing maneuver is very noticeable. In addition, the transient torque rise rate allows for applications to be geared to run slower during typical cruise conditions to reduce frictional losses in the entire powertrain, yet provide acceptable performance for quick acceleration. This technique is called *Down-Speeding* in the industry.

The transient response of a supercharger can be exploited when coupled in a compound boosting system, such as a super-turbo configuration. This combination of devices gives quick transient response while continuing to maintain the highest pressure ratio capability and maintaining altitude compensation inherent with turbocharging. Figure 29 shows

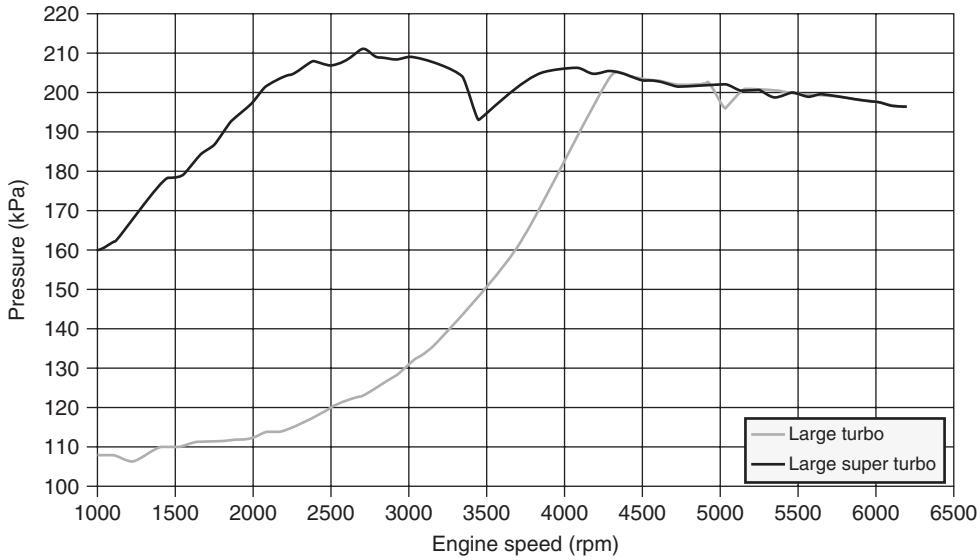

Figure 29. Compound boosting response. (Reproduced by permission of Eaton Corporation.)

the manifold pressure during a 1060 rpm/s WOT transient acceleration.

Finally, one performance area that may not initially come to mind when thinking about supercharging is emissions performance for diesel applications. As regulations around the world continue to tighten allowable emissions for automotive transportation, there may be a technology opportunity for supercharging that had not previously been required. With diesel applications using technology such as oxidation catalysts, the cold-start emissions start to have the same concerns that they have been for many years on gasoline engines. The following test data compares diesel engine boosting between superchargers and turbochargers. This particular test had both systems tuned to produce the same BMEP levels. The test cycle is the first 75 s on US FTP 75 (Figure 30).

The exhaust temperature entering the catalysts of the test systems is typically 50°C higher is the supercharged system compared to the turbocharged system with the same exhaust temperature in the manifold collector (Figure 31).

The key to cold-start emissions performance is the time it takes the catalysts to reach acceptable conversion

efficiency, which is typically between 200 and 250°C operating temperature. With appropriate exhaust energy available, the catalyst "light-off" time can be substantially improved with a supercharged system (Figure 32).

Another interesting area of comparison is particulate matter levels during transient load steps leveraging the responsiveness of the air mass availability in a supercharged application. In the testing that follows, the control of the turbocharged system was optimized for either "Best Smoke Control" or "Best Torque Rise" system response. The port is for a 10–90% load step at 1500 rpm engine speed. The plot shows the BMEP, exhaust opacity, and the combustion AFR. The first thing to note is that the load, as expected, responds quickly allowing for leaner AFR levels during the transient. This promotes leaner operation in the supercharged configuration resulting in lower peak exhaust opacity during the event (Figure 33).

As technology and regulations move forward, the future could be a very interesting time for supercharged engines.

Fundamental Chemical Kinetics

Charles K. Westbrook and William J. Pitz
Lawrence Livermore National Laboratory, Livermore, CA, USA

1 INTRODUCTION

Combustion in an internal combustion engine provides the energy to propel a vehicle. Combustion efficiency has economic implications such as miles per gallon of fuel consumed. Combustion in the engine also produces emissions of toxic chemicals and greenhouse gases that affect the environment. Ultimately, all of these factors are results of the specific chemical reactions as well as the rates and chemical pathways of those reactions that control the fuel combustion, all of which we call *fundamental chemical kinetics*.

Within a single engine cycle, chemical kinetics determines the rate and time of ignition, overall combustion rate, flame interaction with combustion chamber walls and piston rings, production of soot and other hydrocarbon emissions, and formation and emissions of other pollutants such as oxides of nitrogen (NO_x) and greenhouse gases, especially carbon dioxide (CO_2). Modeling of chemical kinetics of combustion has become an important tool (Westbrook *et al*., 2005) in engine research, and this chapter provides an overview of some of the fundamental aspects of chemical kinetics, with special attention on the types of fuel molecules that are characteristic of fuels used in modern vehicles. The same kinetic principles are important in combustion processes in spark-ignition (SI), diesel, and homogeneous charge, compression ignition (HCCI) engines as well as in aircraft gas turbine engines.

2 BASIC CHEMICAL KINETICS

Chemical kinetics of hydrocarbon combustion is complex, from initial fuels through stable and radical intermediate species to final products. The goal of combustion is to produce water (H_2O) and carbon dioxide (CO_2), as these products release the greatest possible amount of heat and do the most practical work.

It is convenient to write this combustion process as a single global reaction, using heptane for illustration

$$C_7H_{16} + 11\ O_2 \rightarrow 7\ CO_2 + 8\ H_2O \qquad (1)$$

The overall combustion rate of most hydrocarbons has a strong dependence on temperature, which can be simulated ideally as an Arrhenius expression:

$$\text{Rate} = A\ \exp\left(\frac{-E_a}{RT}\right) \qquad (2)$$

where T is the temperature, R is the universal gas constant, Ea is an activation energy, and A is a constant. The factors A and Ea would have different values for different fuels or reactants.

This type of expression has been used many times (Westbrook and Dryer, 1981) to provide approximate rates of overall reactions. However, the actual combustion of the hydrocarbon fuel does not take place via such a single, global reaction, and such simplified expressions are limited in their predictive capabilities. It is necessary to describe the reaction progress more accurately to gather insight into the details of the combustion process.

Combustion of a hydrocarbon fuel really takes place one atom at a time, removing atoms from the fuel, steadily taking apart the fuel, and building final products. Every step has its own rate, depending on the pressure and temperature of the environment in which the combustion is taking place. Depending on the size and structure of the fuel molecule, hundreds or even thousands of intermediate chemical species can be produced. Species interact via elementary chemical reactions, many of which proceed via complex excited states. For any specific fuel, it is possible to collect all the chemical species and elementary reactions involved in the combustion of that fuel into a chemical kinetic reaction mechanism that can be used as a computational tool to analyze combustion properties of that fuel.

Rates of elementary reactions are taken from many sources. Some particularly important reaction rates have been measured in laboratory experiments, and some reaction rates can be calculated from fundamental theoretical approaches (Wagner, 2002; Zador *et al*., 2011). Once the chemical species, elementary reactions, and reaction rates are assembled into a reaction mechanism, it is then "validated" or tested by comparing the computed results using the mechanism with results from laboratory experiments. Often, mechanism validation uses a variety of experimental problems such as laminar flame speeds, ignition delay measurements, and experiments in plug-flow reactors, stirred reactors, and engine tests to establish a "comprehensive" kinetic mechanism (Westbrook and Dryer, 1980, 1984) that has wide applicability and confidence that its numerical predictions will be as accurate as possible.

Recent kinetic modeling is focusing on large fuel molecules, as most transportation fuels consist mainly of such fuel molecules (Battin-Leclerc, 2008; Curran *et al*., 1998, 2002; Dagaut and Gail, 2007; Dagaut *et al*., 2007; Dagaut and HadjAli, 2009; Glaude *et al*., 2010; Herbinet *et al*., 2008, 2010; Oehlschlaeger *et al*., 2009; Ramirez *et al*., 2011; Ranzi *et al*., 2005, 2009; Westbrook *et al*., 2009, 2011a,b). Practical transportation fuels, especially gasoline, diesel fuel, and jet fuel, contain significant amounts of so many molecules that it is impossible to include kinetic models for all of them. The current solution for this dilemma is to include models for some of the most important components of the hydrocarbon fuel, expecting that simulations using such a selective "surrogate mechanism" (Farrell *et al*., 2007; Pitz *et al*., 2007a, 2007b; Pitz and Mueller, 2011; Colket *et al*., 2007; Violi *et al*., 2002) can produce results that will be approximately the same as the behavior of the real fuel.

3 BASIC CLASSES OF REACTIONS

Combustion is best characterized as a chain reaction, in which chain carriers are active radicals, highly reactive species such as H and O atoms, OH, HO_2, and CH_3. Small radical species have a collective identity as a "radical pool," which is a way of representing the overall reactivity of a hydrocarbon system. Radicals react primarily by removing H atoms from the fuel in "H-atom abstraction" reactions. The products of abstraction reactions react further, producing additional radical species that continue the overall combustion process. Some radicals participate in "chain-branching" reactions, which increase the total number of available radical species, further increasing the rate of H-atom abstraction reactions. Chain branching can produce an explosive growth in the number of radical species and the rate of heat release, leading to ignition. At the same time, other radical recombination reactions can reduce the number of radical species, mediating or reversing the effects of chain branching.

The most important chain-branching reaction (Westbrook and Dryer, 1980, 1984) in combustion is between H atoms and molecular oxygen:

$$H + O_2 = O + OH \tag{3}$$

consuming one radical H and producing two new radicals, O and OH. Other elementary chain-branching reactions include

$$O + H_2 = H + OH \tag{4}$$

and

$$CH_4 + O = CH_3 + OH \tag{5}$$

Another reaction of H atoms with O_2 that is important in converting H atoms to HO_2 radicals is

$$H + O_2 + M = HO_2 + M \tag{6}$$

where M represents the total concentration of all species in the reactive mixture and is needed to conserve energy and momentum in this type of reaction.

It is impossible to overstate the importance of Reaction (3) in combustion chemistry. In models for flame propagation, high temperature ignition, or explosions, Reaction (3) contributes more to the observed rate of overall reaction than most of the other reactions combined. H atoms are highly diffusive and reactive and abstract H atoms from fuel molecules, and many other reactions produce new H atoms.

The importance of Reaction (3) has many implications. Any fuel that produces H atoms will generate high overall reaction rates, as the H atoms provide so much chain branching. For example, ethane as a fuel is unusually reactive, because every H-atom abstraction by a radical X from ethane leads to the ethyl radical (C_2H_5)

$$C_2H_6 + X = C_2H_5 + HX \tag{7}$$

$$C_2H_5 + M = C_2H_4 + H + M \tag{8}$$

and ethyl immediately produces H atoms by Reaction (8).

In contrast, methane (CH_4) produces low levels of H atoms, as H-atom abstraction from methane produces methyl radicals (CH_3), which react slowly without producing H atoms:

$$CH_4 + X = CH_3 + HX \tag{9}$$

As a result, methane combustion is unusually slow compared to combustion of other hydrocarbon fuels, because its main radical does not produce H atoms. Methane and ethane are special cases, as each leads to a single, unique product radical; larger hydrocarbon fuels lead to a mixture of H and CH_3 radicals, reacting at overall rates that are intermediate between those of methane and ethane (Westbrook, 1986).

It is easy to identify chain branching that occurs in a single reaction such as Reactions (3), (4), or (5), but sometimes chain branching occurs over a sequence of reactions. For example, during the intermediate temperature reaction of many hydrocarbons, a sequence of reactions occur for a fuel RH

$$RH + HO_2 = R + H_2O_2 \tag{10}$$

$$R + O_2 + M = Q + HO_2 \tag{11}$$

where Q is a stable intermediate species. These steps maintain the number of radicals and build up the concentration of hydrogen peroxide (H_2O_2). Once H_2O_2 decomposes in Reaction (12), the group of Reactions (10–12) collectively provides chain branching, with a net increase in the radical pool of two OH radicals.

$$H_2O_2 + M = OH + OH + M \tag{12}$$

However, the O–O bond is not easy to break, so it breaks into two OH radicals only when the temperature approaches 1000 K, when it decomposes rapidly. When Reactions (10) and (11) take place at temperatures *above* 1000 K, Reaction (12) proceeds rapidly and the chain branching is immediate. If these reactions take place at temperatures *below* 900 K, then the chain branching is delayed until the temperature reaches 1000 K, when multiple OH radicals are finally liberated, a result called *degenerate chain branching* (Griffiths and Barnard, 1995). Degenerate branching is a major component in so-called low temperature chemistry (LTC) and the negative temperature coefficient (NTC) of ignition. Diesel, SI, and HCCI engines all start to ignite at temperatures below 900 K, so degenerate chain branching is important in all three engine environments.

4 CHEMICAL STRUCTURE OF FUELS

Historically, most transportation fuels have been produced by refining petroleum liquids. In recent years, alternative fuels from other geological sources and biosources have begun to appear in automotive fuels, but their fundamental chemical kinetics are very similar to the kinetics of petroleum-based fuels. Gasoline, diesel fuel, and jet fuel contain measurable levels of hundreds or even thousands of different species. In order to characterize these fuels, it is useful to divide the fuel components into a small number of characteristic fuel classes, summarized in Figure 1.

The relative amounts of components in these classes of fuels are summarized in Figure 2. Gasoline is highest in amounts of branched alkanes and aromatics, fuel structures that resist engine knock; however, diesel fuels are high in *n*-alkanes and cycloalkanes, components that ignite rapidly. Diesel and jet fuels are low in aromatic compounds, as smoke and soot production are particularly troublesome in diesel and jet engines and aromatics are precursors for soot.

5 REACTION PATHWAYS

Overall reaction pathways that convert fuel to intermediates and products depend on the molecular structure of the fuel and the temperature and pressure of the reactive mixture. Two main routes are taken by nearly every hydrocarbon fuel, outlined in Figure 3.

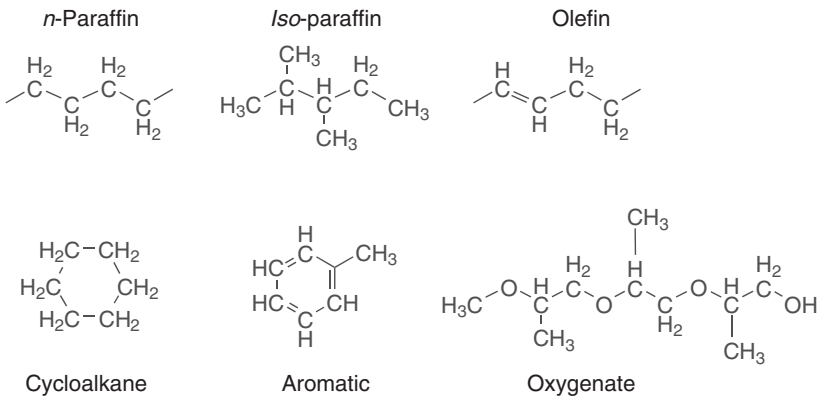

Figure 1. Structural classes of components in petrochemical fuels, with examples for each class.

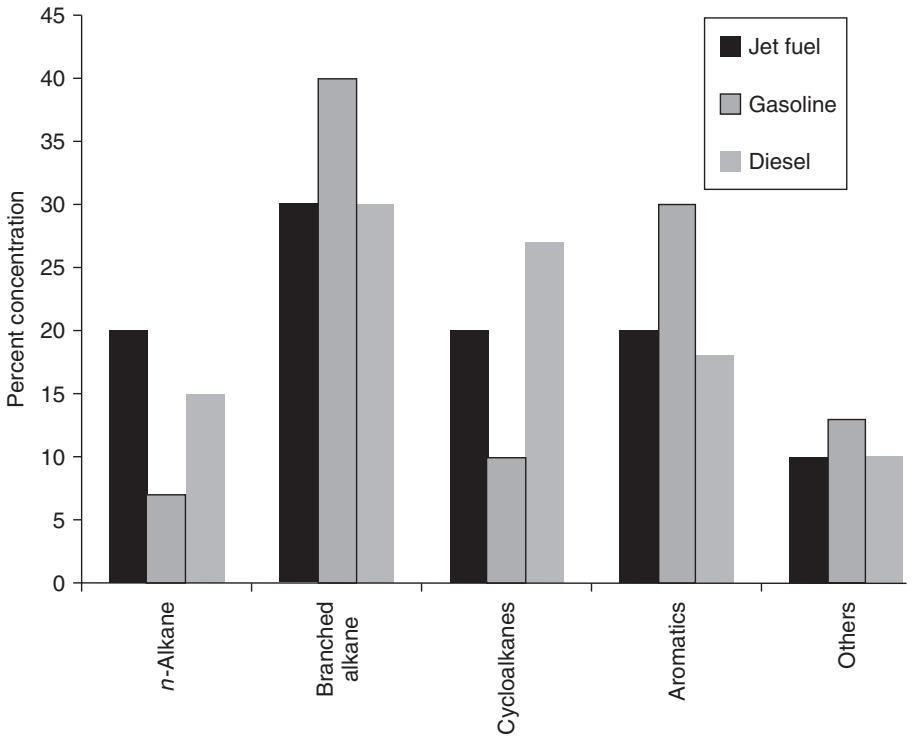

Figure 2. Fractions of fuel classes found in common gasoline, diesel fuel, and jet fuel.

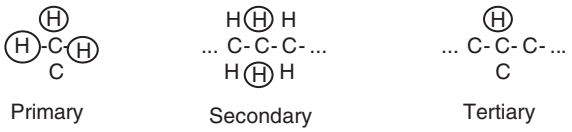
Stable hydrocarbon molecules are consumed primarily by reactions with radical species. There are different types of C–H bonds in hydrocarbon molecules, differences that determine which H atoms are abstracted from each molecule. These distinctions also play a major role in establishing the effects of molecular structure on low temperature alkylperoxy radical isomerization reactions.

The major bond types are primary, secondary, and tertiary C–H bonds, and their bond strengths and rates of H-atom abstraction reactions depend on the number of other C atoms bonded to the C atom involved in the C–H bond. These bonds are shown below:



Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

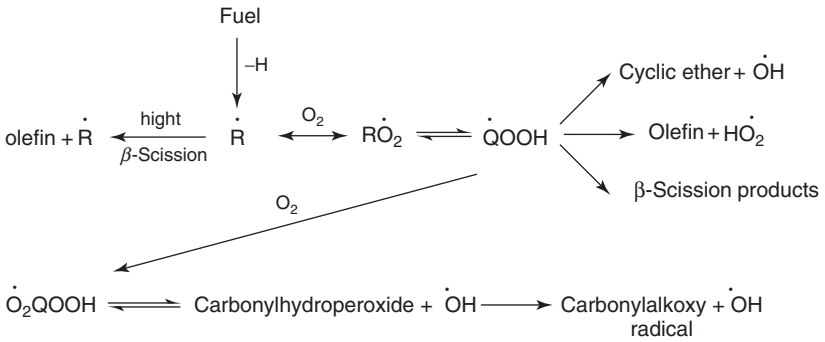


Figure 3. Reaction pathways, showing high temperature and low temperature routes.

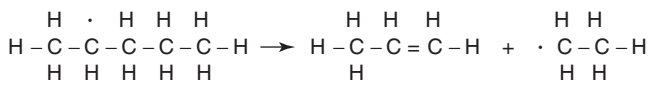
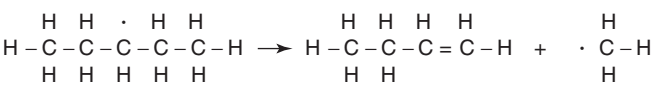
In the primary C–H bond, the C atom is bonded to only one other C atom, while in the secondary C–H bond the C atom is bonded to two other C atoms. Tertiary C–H bonds involve a C atom that has three other C atoms bonded to it. Primary C–H bonds are strongest at 101 kcal/mol, secondary C–H bonds next at 98.5 kcal/mol, and tertiary C–H bonds are weakest at 96.5 kcal/mol, so it is easiest to abstract H atoms from tertiary sites and most difficult to abstract them from primary C–H sites.

Virtually every fuel first reacts by losing an H atom to a radical, leaving a fuel radical R as a product. Subsequent reactions of that product depend on the reacting gas temperature and pressure, and on the structure of the radical species itself. At relatively high temperatures, the radical decomposes, producing smaller species. For example, decomposition of a 2-pentyl radical from *n*-pentane proceeds as



(13)

producing propene (C_3H_6) and an ethyl (C_2H_5) radical. The ethyl radical then produces ethene (C_2H_4) and H atoms (Reaction 8). Abstraction of the H atom in *n*-pentane at the "2" site therefore accelerates the overall rate of reaction since it leads to H atoms. In contrast, the 3-pentyl radical has a different impact because its products are different,

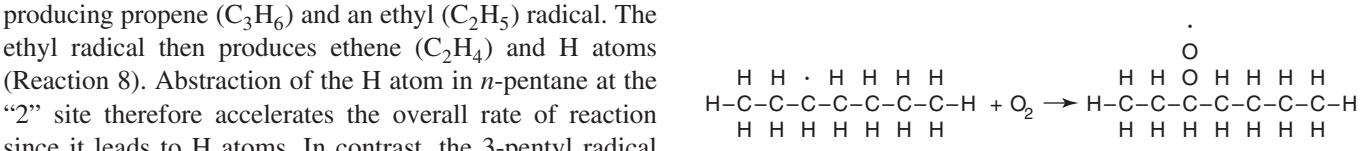


(14)

specifically 1-butene and methyl radicals, and production of methyl radicals decelerates the overall rate of reaction. Decomposition of the 1-pentyl radical is also decelerating, as it produces two stable C_2H_4 species and a methyl radical. For *n*-pentane, abstraction of the four H atoms at the 2-sites leads to H atom production, and abstraction of the eight H atoms at the 1-sites and 3-sites leads to methyl radicals. The fact that the three pentyl radicals decompose to different products demonstrates the necessity of accounting for "site-specific H-atom abstraction" from hydrocarbon fuels. Mixtures of accelerating and decelerating H-atom abstraction pathways are a common feature of most hydrocarbon fuels, and high temperature ignition delay times of most alkanes are very similar (Westbrook *et al*., 2001; Smith *et al*., 2005).

6 LOW TEMPERATURE REACTION PATHWAYS

Under low temperature conditions, the dominant reaction pathway for radicals R, shown in Figure 3, is addition of molecular oxygen to produce an alkylperoxy radical species RO_2, illustrated below for a 3-heptyl radical, producing a 3-heptylperoxy radical.



(15)

The equilibrium for this $R + O_2 = RO_2$ reaction is a strong function of temperature; the rate of the addition reaction producing RO_2 is effectively independent of temperature, while the decomposition reaction producing $R + O_2$ has large activation energy. The reaction proceeds rapidly toward RO_2 at lower temperatures (i.e., $T \leq 750$ K), but at higher temperatures this reaction becomes kinetically balanced, and, as the temperature increases further, RO_2 becomes very unstable and decomposes rapidly. The temperature at which the RO_2 becomes unstable is about

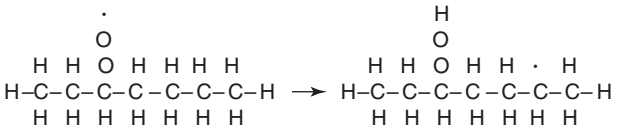
Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

800 K and the equilibrium has shifted almost completely to $R + O_2$ by the time the temperature reaches 850–900 K.

Production of RO_2 species initiates a sequence of reactions that are collectively called *alkylperoxy radical isomerization reaction pathways*, *low temperature oxidation*, or *cool flame chemistry*. At temperatures where the RO_2 species is relatively stable, its primary reaction involves H-atom transfer from within the RO_2 species to the O–O• site in the radical.

This process can be shown, following Reaction (15):



(16)

This product is identified as QOOH in Figure 3, and it is named by specifying the location of the OOH group and the location of the remaining radical site, so the product in Reaction (16) is $C_7H_{14}OOH3\text{-}6$ with the OOH at the 3-site and the radical at the 6-site. Reaction (16) is commonly called an *RO_2 isomerization reaction* or *alkylperoxy radical isomerization*.

The example shown in Reaction (16) describes a process where the O–O• radical "reaches" to take an H atom located three carbon atoms away from the C atom hosting the O–O• group. In chemical terms, this reaction proceeds by forming a seven-membered transition state ring including the O–O group, its host carbon, the three additional C atoms down the molecule chain, and the H atom attached to that target C atom. Three major factors affect the rate of this H-atom transfer: the type of C–H bond being broken (i.e., primary, secondary, or tertiary bond), the number of atoms in the transition-state ring, and the number of equivalent H atoms available at similar sites. It is easy to form transition-state rings with six or seven atoms in the ring but difficult to form transition-state rings with four or five atoms or rings larger than seven atoms.

The QOOH species is a pivotal point, with QOOH having a choice of four or five possible consumption pathways. It can decompose back to the RO_2 reactant, and it can decompose by breaking the O–O bond, producing OH and a cyclic ether species.

$$C_7H_{14}OOH3\text{-}6 \rightarrow cycC_7H_{14}O3\text{-}6 + OH \qquad (17)$$

Reaction (16) can produce a different QOOH, specifically $C_7H_{14}OOH3\text{-}4$, by transferring the H atom from the adjacent C atom, leading to an olefin and HO_2.

$$C_7H_{14}OOH3\text{-}4 \rightarrow 3\,C_7H_{14} + HO_2 \qquad (18a)$$

Another important reaction pathway for fuel radicals R is a direct reaction with O_2:

$$3\,C_7H_{15} + O_2 \rightarrow 2\,C_7H_{14} + HO_2 \qquad (18b)$$

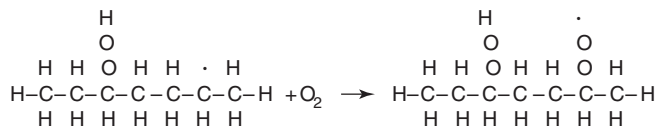
which is equivalent to Reactions (16) and (18a) in reactants and products but with a different rate because it proceeds by a different chemical process (Sheng *et al.*, 2002; Zador *et al.*, 2011).

Finally, if the QOOH abstracts the H atom two sites away, the result can be

$$C_7H_{14}OOH3\text{-}5 \rightarrow C_2H_5CHO + 1\,C_4H_8 + OH \qquad (19)$$

All these reaction sequences begin with one radical R in Reaction (15) and lead to stable smaller species plus one new radical, namely OH in Reactions (17) and (19) or HO_2 in Reactions (18a) and (18b). Therefore, all these pathways are chain-propagation pathways and cannot contribute to chain branching and ignition at low temperatures.

A final reaction pathway for QOOH does lead to low temperature chain branching and is the most important part of low temperature kinetics. Shown in Figure 3, QOOH can add a second O_2 at its radical site, in general terms a reaction $QOOH + O_2 = O_2QOOH$. In the example being used, this makes $C_7H_{14}OOH3\text{-}6O_2$:



(20)

The O_2QOOH species can then react by decomposing back to $QOOH + O_2$ reactants, or by internally transferring another H atom via a reaction analogous to Reaction (16). That product species then decomposes to smaller fragments and two OH radicals, providing low temperature chain branching. Both Reactions (15) and (20) are very sensitive to temperature, and increasing the temperature to about 850–900 K makes both reactions proceed back, toward the $R + O_2$ and $QOOH + O_2$ sides, terminating the low temperature alkylperoxy radical isomerization reaction pathway and ending the low temperature chain branching.

Fuel ignition at low temperatures can be illustrated in Figure 4 for ignition at 3 bar pressure of stoichiometric *n*-heptane/air at initial temperatures of 700 and 850 K, as well as stoichiometric 3-methyl hexane.

The computed results for *n*-heptane at 700 K show no appreciable heat release or temperature increase for the first 8 ms. During this 8 ms, radical species are produced from the fuel and O_2, but there are not enough radicals to consume a significant amount of fuel. Heptyl radicals

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

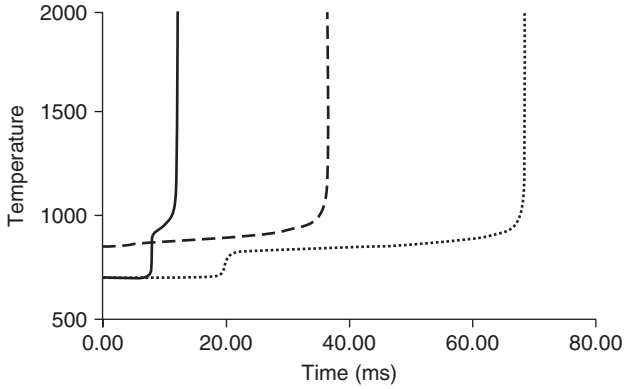


Figure 4. Computed ignition delay of stoichiometric *n*-heptane/air at 3 bar pressure, initial temperature 700 K (solid curve), 850 K (dashed curve), and 3-methyl hexane at 3 bar pressure and initial temperature 700 K (dotted line).

produced from the fuel react by addition to O_2 to produce $C_7H_{15}O_2$ radicals, which then isomerize to produce QOOH species. Enough of these QOOH species add a second O_2 to produce chain branching via Reaction (20), leading to low temperature ignition. This chain branching and ignition produces the rapid rise at 8 ms in temperature from 700 to about 900 K in Figure 4. At 900 K, the equilibrium in the heptane versions of Reactions (15) and (20) has shifted dynamically toward $R + O_2$ and $QOOH + O_2$, stopping the low temperature chain branching and the heat release. The temperature then goes through another slow growth stage for 4 ms longer until it reaches about 1000 K. At this point, the accumulated H_2O_2 decomposes rapidly into OH (i.e., Reaction 12), and this sudden flood of new OH radicals provides enough degenerate chain branching to drive the system to its final ignition phase at about 12 ms. The phenomenon shown for the mixture initially at 700 K in Figure 4 is called a *two-stage ignition*, with the first stage ignition at 8 ms and the second stage at 12 ms. The first-stage ignition is also called a *cool flame* or *low temperature* ignition.

The second case for *n*-heptane in Figure 4 has an initial temperature of 850 K. This temperature is at the high end of the low temperature regime, so this mixture experiences virtually no low temperature reactivity because the equilibrium for Reactions (15) and (20) is already favoring $R + O_2$ and $QOOH + O_2$. Low levels of radical species consume fuel slowly, while Reactions (10) and (11) build the levels of H_2O_2 (which is relatively inert because the temperature is still below 1000 K and H_2O_2 cannot decompose). When the temperature finally reaches 1000 K, decomposition of the accumulated H_2O_2 produces large amounts of OH and provides chain branching, producing the ignition at 36 ms seen in Figure 4.

It might seem counterintuitive that the mixture initially at 700 K ignites more rapidly (12 ms) than the mixture initially at 850 K (36 ms), but this is a very tangible demonstration of the impact of the low temperature kinetics regime on overall hydrocarbon ignition. The limited temperature interval over which this unusual chain branching pathway is active means that mixtures that pass through this temperature interval will have a "headstart" on the path to ignition. The mixture initially at 850 K does not experience any low temperature reactions because its initial temperature is above the low temperature reaction region. Not all fuels possess this reaction pathway; if we replace *n*-heptane by another heptane isomer, specifically 2,2,3-trimethyl butane, at an initial temperature of 700 K, which is certainly within the range of low temperature reactivity for many fuels, the latter shows no low temperature reactivity and no first-stage ignition, and the total ignition delay is very long, about 1 s rather than 12 ms. This different behavior is due to the specific molecular structure of 2,2,3-trimethyl butane, particularly the fact that all but one of its 16 H atoms are bound at primary sites in the fuel molecule, strongly inhibiting alkylperoxy radical isomerizations like Reaction (16), so it does not produce a first-stage ignition and its approach to 1000 K and the degenerate branching ignition remains very slow. The more reactive *n*-heptane has an octane number (ON) of 0 while 2,2,3-trimethyl butane has an ON of 112 (Lovell, 1948); *n*-heptane has a great deal of low temperature reactivity, while 2,2,3-trimethyl butane has virtually none, and the principal reason for the difference is that *n*-heptane has many H atoms located at secondary sites while 2,2,3-trimethyl butane has most of its H atoms located at primary sites.

One additional curve is plotted in Figure 4, showing the computed temperatures for another heptane isomer (3-methyl hexane) at an initial temperature of 700 K. This fuel shows a two-stage ignition, the first stage at about 20 ms and the final ignition at about 68 ms. The first stage is later and shows less temperature increase than the first stage for *n*-heptane, so 3-methyl hexane requires a longer time than *n*-heptane to reach the decomposition temperature of H_2O_2. The results for 3-methyl hexane are somewhat intermediate between those for *n*-heptane and 2,2,3-trimethyl butane, and the ON for 3-methyl butane is also intermediate at 52 (Westbrook *et al*., 2002; Silke *et al*., 2005).

7 PRIMARY REFERENCE FUELS

We noted earlier that the rate of RO_2 isomerization in Reaction (16) depends on the type of bond that must be broken to transfer an H atom from a bond with a C atom to a bond with the O–O• group. Three fuel molecules for which

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

nearly all of the H atoms are located at primary sites are *iso*-octane (2,2,4-trimethyl pentane), *iso*-cetane (2,2,4,4,6,8,8-heptamethyl nonane), and 2,2,3-trimethyl butane discussed earlier. *Iso*-octane has 18 H atoms, with 15 located at primary C–H sites, two at secondary sites, and one at a tertiary site. *Iso*-cetane has a total of 34 H atoms, with 1 at a tertiary site, 6 at secondary sites, and 27 at primary sites, and 2,2,3-trimethyl butane has 15 primary H atoms out of a total of 16 H atoms. Nearly all of the RO_2 isomerizations in these fuels require difficult internal abstraction of an H atom from primary sites, and all of them experience slow ignition delays. In Figure 5, the computed ignition delay times are plotted as functions of initial temperature for stoichiometric fuel/air mixtures at 13 bar pressure for *iso*-octane and *iso*-cetane, as well as results for *n*-heptane and *n*-hexadecane at the same conditions.

For the *n*-alkanes, the results in Figure 5 show that, from about 940 to 800 K, the ignition delay time actually becomes shorter (i.e., more reactive) as the temperature decreases, an NTC of reactivity that reflects the amount of low temperature combustion (LTC) that occurs as a result of the molecular structure of the fuel. The existence of an NTC region for a given fuel means the fuel will have two-stage ignitions for a range of initial temperatures. The strong NTC behavior for the *n*-alkanes is shown clearly, and the extents of NTC behavior for the *iso*-alkanes can be seen to be dramatically less than for the *n*-alkanes. Overall, the *n*-alkanes react much more rapidly than the *iso*-alkanes, especially in the NTC or low temperature oxidation region.

In a diesel engine, with no spark plug to ignite the fuel/air mixture, the liquid fuel must vaporize and mix with air quickly enough so that it can find a flammable condition for autoignition. The first mixtures of fuel and air that are able to ignite are quite fuel-rich (Dec, 1997) and are usually within the NTC region. To guarantee efficient operation, the fuel must encourage autoignition, and from Figure 5 it is clear that *n*-alkane fuels ignite rapidly. Diesel engines define the ignitability of their fuel by its cetane number (CN), which has an upper and a lower limit that serve as reference points. The CN of greatest ignitability is for *n*-hexadecane, with a defined CN of 100, and the low CN, slow-to-ignite reference fuel is *iso*-cetane, with a reference CN of 15. The correlation of the amount of low temperature kinetics with CN is very clear.

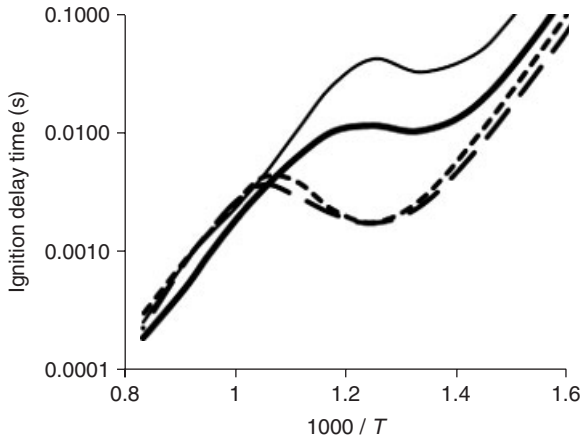

Figure 5. Computed ignition delay times at 13 bar pressure for stoichiometric fuel/air mixtures for *iso*-octane (thin solid line), *iso*-cetane (thick solid line), *n*-heptane (short dashed line), and *n*-hexadecane (long dashed line).

In the case of gasoline reference fuels in SI engines, the process that reflects relative autoignition fuel properties is the onset of knocking behavior. The problem of engine knock has a long history, and the relationship between ignition rate and fuel structure had been understood in phenomenological terms since the early 1920s (Midgley, 1923), making it possible to define reference fuels and a scale of knocking tendency (Lovell, 1948). This is the ON scale, with low values of ON indicating a high rate of autoignition and tendency to knock, while high values indicate low reactivity with low amounts of NTC behavior. *n*-Heptane has the defined low value of ON = 0 and *iso*-octane has the high value of ON = 100. These pairs of reference fuels, *iso*-cetane (CN = 15) and *n*-cetane (CN = 100) for diesel fuel, and *n*-heptane (ON = 0) and *iso*-octane (ON = 100) for gasoline, are the primary reference fuels (PRFs).

For both pairs of PRFs, assessing the ON or CN of an unknown fuel sample is done by finding the mixture of the reference fuels that shows the same autoignition behavior as that of the fuel in question. Experimentally, the comparisons are carried out under carefully specified conditions in a special test engine, a time-consuming process that is also quite expensive. Recent advances in chemical kinetic mechanisms for the PRFs (Westbrook *et al*., 1991, 2011b) have made it possible to do these comparisons between PRF mixtures and test fuels on the computer using detailed kinetic reaction mechanisms, which not only saves time and money but also provides a unique view into the fundamental chemistry that controls autoignition of these complex fuels.

Autoignition rates of the PRFs shown in Figure 5 are virtually identical at temperatures above 950 K, regardless of molecular structure, so the distinctions that affect both CN and ON are the differences in their amounts of low temperature alkylperoxy radical kinetics over the temperature range from 650 to 900 K. Both highly reactive PRFs, *n*-heptane and *n*-hexadecane, are long chains of secondary C–H bonds that are relatively easy to abstract and support extensive amounts of low temperature via alkylperoxy

radical kinetics and ignite easily. Both highly reactive PRFs, *n*-heptane and *n*-hexadecane, have long chains of C-H groups with H atoms that are relatively easy to abstract. As a result, both support extensive amounts of low temperature alkylperoxy kinetics and ignite readily.

8 BIOFUELS

Modern technology has been experimenting with biofuels for many years. The first diesel engine was demonstrated by its inventor, Rudolf Diesel, at the Paris Exposition of 1898; it burned peanut oil, making that the first biodiesel fuel. The motivation for using that fuel was that France had access to very large quantities of peanuts and peanut oil from its colonies in North Africa, so the opportunity of a country using whatever plant and plant oil resources it possesses has always been an important part of biofuel choice.

In recent years, liquid transportation biofuels have taken two pathways, one using small fuel molecules for use in SI engines as supplements or replacements for gasoline, and the other using larger fuels derived from plant oils, animal fats, and now including oils from algae to use in diesel engines. Significant amounts of research have examined a variety of energetic small molecules, including hydrogen and a number of small alcohols, for use in SI engines. Alcohols including methanol (CH_3OH), ethanol (C_2H_5OH), and *n*-butanol (*n*-C_4H_9OH) have been studied experimentally and in kinetic modeling as promising liquid fuels. Reliable kinetic reaction mechanisms have been developed for all of these potential small-molecule transportation fuels, and those mechanisms have been used to examine a wide range of combustion and engine properties. For the most part, these fuels are reliable, efficient supplements to gasoline and can be used in neat form without serious impacts on engine operations including overall combustion, and the detailed chemical kinetics of these small biofuels are quite well understood, although some material compatibility issues remain. Low temperature kinetics are unimportant for these small fuel molecules, and they have correspondingly high ONs.

Principal biodiesel fuels today (Graboski and McCormick, 1998) are produced from soybean oils and rapeseed (canola) oils, soy biodiesel fuel in the United States and rapeseed biodiesel fuel in Europe. Most vegetable oils do not burn conveniently in diesel engines, but a simple process called *transesterification* can convert the triglyceride vegetable oils into smaller, alkyl ester structures that burn much more efficiently. When the reagent for transesterification is methanol, the alkyl ester is a methyl ester, which is the case for most biodiesel fuels. This process is illustrated in Figure 6, showing that the initial triglyceride and three methanol molecules produce three methyl ester molecules and one glycerol molecule.

Both soy methyl ester (SME) and rapeseed methyl ester (RME) consist (>99%) of the same five distinct species, whose molecular structures are shown in Figure 7. Four of the species are in a single family, including methyl stearate, $C_{17}H_{35}(CO)OCH_3$, which is saturated with no C=C double bonds; methyl oleate, $C_{17}H_{33}(CO)OCH_3$, with one C=C double bond; methyl linoleate, $C_{17}H_{31}(CO)OCH_3$, with two C=C double bonds; and methyl linolenate, $C_{17}H_{29}(CO)OCH_3$, with three C=C double bonds. The fifth major component of biodiesel fuel is methyl palmitate, $C_{15}H_{31}(CO)OCH_3$, saturated like methyl stearate but with only 16 C atoms in the linear carbon chain. These components are also named as shown in the figure, with methyl stearate denoted as (C18:0), indicating a carbon chain with 18 C atoms in the continuous chain and zero double bonds in that chain. C18:1, C18:2, and C18:3 indicate carbon chains of the same length as methyl stearate, but with one, two, and three C=C double bonds in the chain. Methyl palmitate is denoted as C16:0 for its chain length of 16 C atoms and no C=C double bonds.

One important implication of the relative simplicity of the composition of biodiesel fuel is that, unlike petroleum-based fuels, it is possible to construct kinetic mechanisms that contain *all* of the components of the fuel. The amounts

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

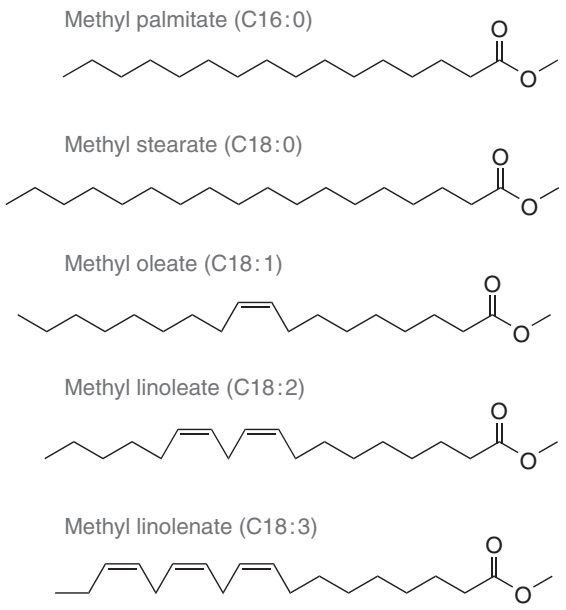

Figure 7. Structural diagram for the five primary components in most biodiesel fuels.

of each of the five components in SME can vary slightly, but the fractions are approximately 0.08 of C16:0, 0.04 of C18:0, 0.25 of C18:1, 0.55 of C18:2, and 0.08 of C18:3. The corresponding components in RME are 0.04 of C16:0, 0.01 of C18:0, 0.60 of C18:1, 0.21 of C18:2, and 0.14 of C18:3. The largest component in SME is C18:2 with two C=C double bonds, and the largest component in RME is C18:1 with one C=C double bond; these differences make a significant impact on the performance of these fuels in diesel engines.

Another interesting feature of biodiesel fuel is the components *not* present in the fuel. Most important, no aromatic species are present in biodiesel fuel, and aromatics are principal chemical precursors to soot production. The absence of aromatics in biodiesel fuels limits soot emissions, relative to emissions from conventional diesel fuel. Another benefit is that, unlike most hydrocarbon species in conventional diesel fuel, each component of soy biodiesel fuel contains two oxygen atoms from the ester group; it has been shown experimentally (Miyamoto *et al*., 1998) and in kinetic simulations (Westbrook *et al*., 2006) that oxygen atoms in the fuel reduce soot production in diesel combustion.

The most common use of biodiesel fuel is to blend it with conventional diesel fuel. Petroleum-based diesel components in these blended fuels will certainly include substantial amounts of aromatics, so blended diesel fuel will still produce soot, but the oxygen content in the biodiesel portion will help reduce the soot being produced by the blend.

9 EFFECTS OF C=C DOUBLE BONDS ON LOW TEMPERATURE REACTIVITY

Most past kinetic analyses have focused on saturated hydrocarbon fuels without C=C double bonds and applies equally to conventional hydrocarbons and to the saturated components of biodiesel fuel, methyl stearate and methyl palmitate. However, the kinetic situation changes for the other biodiesel components with one, two, and three C=C double bonds. Computed results for ignition delay time for methyl linoleate and methyl stearate, at exactly the same conditions as those in Figure 5 for the conventional fuel PRF mixtures, show that the two double bonds delay the ignition of methyl linoleate by a factor of at least two, relative to the ignition time of methyl stearate, with almost all of the differences found in the low temperature, cool flame region.

As the only kinetic and molecular structure feature that is different for these two fuels is the inclusion of two C=C double bonds in methyl linoleate, we must look at the kinetic features of double bonds to understand how they affect the ignition rates.

The structure of a chain molecule in the immediate vicinity of a C=C double bond is illustrated on the left, with a saturated chain without a C=C double bond on the right,

```
    H H  H  H  H  H H  H                H H  H  H H H  H  H
... –C–C–C–C=C–C–C–C–... ....C–C–C–C-C–C–C–C –...
    H H  H     H  H H                  H H  H  H H H  H  H
```

or, labeled in a more instructive way

```
    s s  a  v  v  a s  s                s s  s  s s s  s  s
... –C–C–C–C=C–C–C–C –... ... –C–C–C–C-C–C–C–C –...
    s s  a     a  s s                   s s  s  s s s  s  s
```

The "s" represents a conventional secondary C–H bond, which is relatively weak (98.5 kcal/mol) and is the main feature of the saturated carbon chains in methyl stearate, methyl palmitate, and *n*-alkane hydrocarbon molecules. When a C=C double bond is inserted into the chain, three changes occur. First, two H atoms are replaced by the double bond. Second, the two H atoms that remain bonded to the C atoms in the double bond become much more strongly bound to them by a "vinylic" C–H bond (indicated by the "v," 109 kcal/mol). Third, the four H atoms bound to atoms adjacent to the double bond become bound much less strongly than in secondary bonds at much weaker C–H bonds called *allylic* C–H bonds ("a" above, 88 kcal/mol).

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

H atoms at allylic sites are much easier to abstract than those at secondary sites, and very much easier to abstract than H atoms at primary or vinylic sites, so H-atom abstraction occurs preferentially at these allylic sites. Intuition might then predict that O_2 addition should occur easily at these sites, leading to enhanced low temperature reactivity and faster ignition. However, this does not occur. The allylic radical site remains a weak location for any atom to remain bound for very long, so although O_2 is indeed added quickly to these allylic sites, the allylic RO_2 does not remain long enough to initiate the subsequent H-atom transfer. In chemical terms, the addition rate of Reaction (15) is fast at the allylic sites, but the dissociation rate of the reverse direction of Reaction (15) is extremely fast for allylic sites. Easy abstraction of allylic H atoms actually slows the overall rate of fuel oxidation in the low temperature regime, and the net result is a retarded rather than advanced ignition. Additional C=C double bonds lead to more nonproductive allylic sites in these methyl ester fuel molecules, further retarding ignition, and this is reflected by the steadily decreasing ignition rate for these molecules with more C=C double bonds.

We note that the same impact of adding C=C double bonds into a long carbon chain discussed earlier is a factor in conventional hydrocarbon fuel molecules, so the CNs of *n*-alkane fuels will be reduced when a double bond is inserted into that fuel. Most experimental studies of olefin CNs have examined 1-olefins, but 1-olefins provide only one C atom with two allyl H atom sites, which is only half the effect of the C=C double bonds in these biodiesel fuels. At the same time, on the basis of data from Murphy *et al*. (2004), CNs for 1-olefins are lower than values for *n*-alkanes with the same number of C atoms by significant amounts. For example, the CN values for *n*-octane, 1-octene, and 2-octene are 64, 41, and 43, respectively; for *n*-undecane and 1-undecene they are 79 and 65; for *n*-dodecane and 1-dodecane they are 80 and 71; for *n*-tetradecane and 1-tetradene they are 93 and 79; and for *n*-hexadecane and 1-hexadecene they are 100 and 84. The inhibiting effect of the C=C double bond and the resulting allyl radicals in the unsaturated species clearly has an effect on CN, which is consistent with the effects described here for the reduction in CN from methyl stearate to methyl oleate of 101 to 59, especially when we remember that, in methyl oleate, the C=C double bond is in the middle of the carbon chain and there are four H atoms at allylic sites, while the double bond is at the end of the chain for most available data in conventional hydrocarbon chains. Clearly, more information is needed on other olefins of hydrocarbons.

10 IGNITION OF BIODIESEL FUEL

The CN for soy biodiesel fuel is 47, which is acceptable for use as a "neat" fuel in the United States but too low for use in much of Europe, which requires a somewhat higher CN. Values of CN for individual components are 101 for methyl stearate, 59 for methyl oleate, 38 for methyl linoleate, and 23 for methyl linolenate, so the addition of each C=C double bond to methyl stearate reduces the CN by a considerable amount, with the largest impact seen for the addition of the first C=C double bond. The value of CN for methyl palmitate, with a carbon chain two atoms shorter than that of methyl stearate, is 86, showing the effect of a smaller chain length on CN.

A realistic combustion environment for simulations of diesel-like ignition is the jet-stirred reactor (JSR), commonly used in many research laboratories for basic chemical kinetics studies (Dagaut and Gail, 2007; Dagaut *et al*., 2007; Dagaut and HadjAli, 2009). The JSR provides a realistic simulation of diesel ignition, particularly if operated at elevated pressure (e.g., 50 bar) and fuel-rich conditions ($\phi = 2$ or 3), as diesel engines ignite under fuel-rich, high pressure conditions.

Reactivities of the components in biodiesel fuel are shown in Figure 8, with the fractional fuel consumptions (or conversions) plotted against the mixture temperature. A separate curve is shown for each component in biodiesel fuel, at conditions that are stoichiometric with 0.2% fuel, diluted by helium, at atmospheric pressure and a reactor residence time of 1.5 s. The two saturated components, namely methyl stearate and methyl palmitate, start reacting at 500 K. Both curves rise rapidly as the temperature of the reactor is increased to about 600 K, where these components show nearly equal conversions of about 0.7 or 70% consumption, due primarily to low temperature oxidation reactions. Both curves decrease significantly between 600 and 750 K to a minimum of about 25% conversion and then

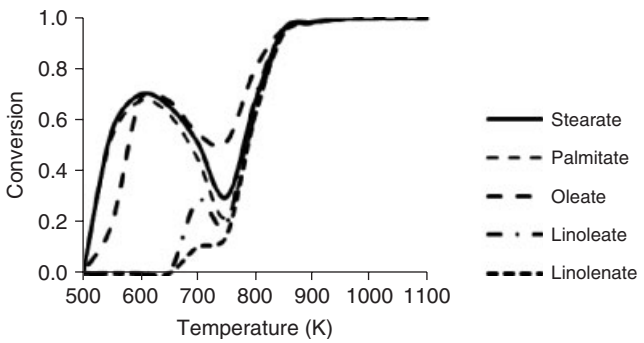

Figure 8. Simulated JSR conversion of each soy biodiesel component as individual fuel.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto114
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

increase to 100% conversion for temperatures above 875 K. Both saturated components show considerable amounts of NTC behavior from 600 to 750 K, and, above 750 K, their reactivity increases rapidly.

Methyl oleate, with one C=C double bond, is less reactive under JSR conditions than either of the saturated components. It shows significant NTC behavior, but not as much as the saturated components, and the oleate begins to react at temperatures slightly higher than the stearate or palmitate. Methyl linoleate is much different from the first three components; it does not begin to react until about 650 K and shows minor NTC behavior. Methyl linolenate is even less reactive at lower temperatures, shows no NTC behavior except for a slight inflection point in its conversion curve at 700 K, and is completely burned to products, like the other components, above 875 K. This group of fuels reacts in the same order at their CN values of 101, 86, 59, 38, and 23.

When the five components are combined into a single fuel with relative fractions characteristic of soy biodiesel, using the same conditions as those for Figure 8, the full SME biodiesel simulation results can be seen in Figure 9. Conversions of all five components are shown, and it is clear that, when combined into a fuel, they all burn at very much the same rates over the entire temperature range. The conversion curve for the mixture, with its CN of 47, falls neatly into line with the five separate component conversion curves in Figure 8, between methyl oleate (CN = 59) and methyl linoleate (CN = 38).

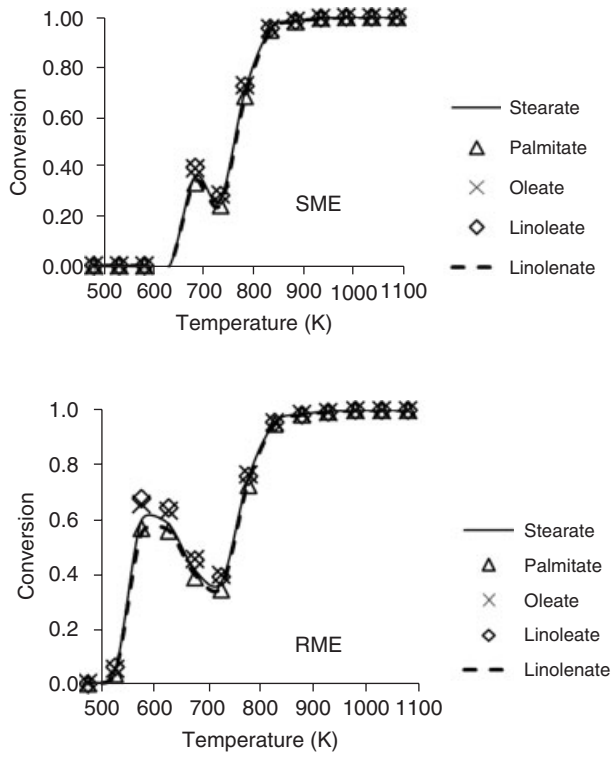

Figure 9. JSR simulations for soy methyl ester and rapeseed methyl ester fuels.

For comparison, a JSR simulation was carried out with the initial composition of RME fuel, with CN = 54. Its primary component is methyl oleate, with only one C=C double bond, and comparisons of the RME behavior in Figure 9 with the component curves in Figure 8 and the SME mixture in Figure 9 show that not only is the RME more reactive than SME but it also comes close to the computed behavior of the single-component methyl oleate, with CN = 59. These observations demonstrate that the JSR simulations are able to rank the single-component fuels and the composite SME and RME fuels in the same order as their known CN values and reproduce the effects of mixing their relative concentrations in a consistent way.

11 OTHER BIODIESEL FUELS

Many other biodiesel fuels have the same major components as RME and SME. The same chemical kinetic model used to simulate soy and rapeseed biodiesel kinetics can be used to study biodiesel fuels made by transesterification from sunflower oil, safflower oil, linseed oil, Jatropha oil, cottonseed oil, corn oil, olive oil, palm oil, and peanut oil, as well as oils from beef tallow. The CNs of these fuels range from 39 for linseed oil methyl ester to 62 for palm oil methyl ester. Chemical kinetic analysis easily explains these extreme values and reactivities in terms of their relative compositions of the five major components. That is, palm oil has 46% of the saturated component methyl palmitate and 40% of methyl oleate, which has one C=C bond, leading to its high CN value. In contrast, linseed oil methyl ester has virtually no saturated, high CN components, and includes 54% methyl linolenate, the component with CN = 23, leading to a CN value for the linseed oil methyl ester fuel of only 39. In fact, linseed oil methyl ester biodiesel fuel is the only common plant-derived biodiesel fuel that cannot be used in most diesel engines without CN-improving additives.

A final example shows that the hydrocarbon reference fuel scale and the biodiesel fuel CN ratings are internally consistent and calibrated to the same CN scale. This is illustrated in Figure 10, showing two diesel PRF mixtures of CN20 and CN60 and three different biodiesel fuels, namely beef tallow methyl ester, peanut oil methyl ester, and linseed oil methyl ester. This illustration uses a JSR environment at 50 bar pressure, with 200 ppm (parts per million) fuel at an equivalence ratio of 2, diluted in Helium,

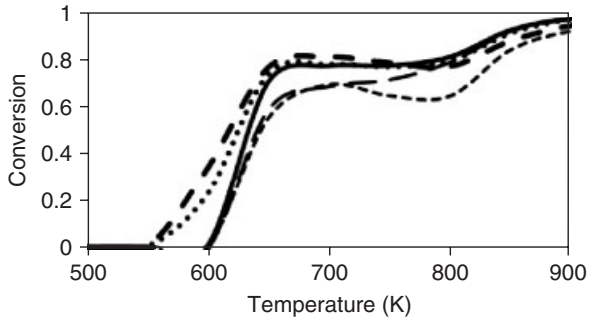

Figure 10. JSR simulations at 50 bar pressure, $\phi = 2200$ ppm fuel in O_2, diluted in He, 0.05 s residence time. Fuels are CN60 (dashed curve), beef tallow methyl ester (CN58, dotted curve), peanut oil methyl ester (CN54, solid curve), linseed oil (CN39, long dashes curve), and CN20 (short dashes curve).

and a residence time of 0.05 s. The CN60 and the beef tallow methyl ester curves are very close together over the entire temperature range and have CN values of 60 and 58, respectively. The least reactivity in Figure 10 is for CN20, and the biofuel closest to CN20 is the curve for linseed oil methyl ester, which has CN = 39. Peanut oil methyl ester, with CN = 54, is more reactive than linseed oil but less reactive than the beef tallow fuel with CN = 58, and all the differences between beef tallow methyl ester and peanut oil methyl ester are at the lowest temperatures of the calculations.

The differences between the biodiesel fuel reactivities, which are due to differences in the amounts of C=C double bonds in the carbon chains, can be related directly to the differences in reactivity of the PRF mixtures, which in turn are due to differences in the relative number of primary, secondary, and tertiary C–H bonds in the saturated hexadecane isomers of the PRF diesel fuels.

12 CONCLUSION

This chapter has described the major features of the chemical kinetics of combustion of transportation fuels and how the size and structures of those fuels control the rate of their oxidation reactions and heat release. Particular attention has been given to the kinetics of large hydrocarbon and biodiesel molecules that are common to SI and diesel engines, where the sizes of the fuel molecules present some unique challenges for kinetic analysis. The key to understanding these processes is to view them as chain reactions, so identification of the main chain-branching reactions leads naturally to a coherent picture of steady combustion in burners and flames, and quenching and autoignition in SI, HCCI, and diesel engines. Examples have been used to illustrate the overall principles involved in chemical kinetics, and special attention has been given to low temperature kinetics, which play important roles in many practical combustion problems.

Fundamental Combustion Modes

Ronald D. Matthews
The University of Texas, Austin, TX, USA

1 CATEGORIES OF ENGINES AND CORRESPONDING MODES OF COMBUSTION

In general, three types of engines are used in passenger cars and heavy-duty vehicles. The spark ignition (SI) engine is the most widely used engine in the world in passenger cars, primarily because it is the lowest cost option for simultaneously meeting performance expectations and standards imposed regarding fuel economy and emissions. The SI engine is by far the most dominant engine in the US passenger car and light-duty truck market. The diesel engine is used in some passenger cars and light-duty trucks, extensively so in Europe, and in almost all heavy-duty trucks. The gas turbine, primarily mentioned for completeness, was last used in a passenger car built by Chrysler in 1963, for the only consumer test of gas turbine-powered cars. However, the gas turbine is used in all of the tanks in the US military, and they are the dominant engine in air transportation applications. Although the gas turbine is not of much practical importance from the perspective of on-road automotive engineering, the idealization of the combustion process in a gas turbine will appear in the "combustion phase diagrams" to be discussed later in this chapter.

These three types of engines are characterized by three different modes of combustion. The homogeneous charge SI engine has a premixed flame. The combustion process in a diesel engine is dominated by a diffusion, or non-premixed, flame. The combustion process in a gas turbine can be idealized as a "perfectly stirred reactor." In a premixed flame, the fuel and air are uniformly mixed on the molecular scale but are separated from the products of combustion by a thin flame sheet. In a diffusion flame, the fuel and air are separated, must diffuse in opposite directions, and form a flame zone in the vicinity of the stoichiometric zone between the fuel and the air, with the rate of heat release controlled by the diffusion or mixing process. In a perfectly stirred reactor, the fuel, air, and products of combustion are homogeneously and instantaneously mixed on the molecular scale as reaction proceeds.

These three modes of combustion are not the complete set of the potential modes under which fuel and air can react under engine-type conditions. An important fourth mode is volumetric energy release. During volumetric energy release, the fuel and air are mixed on a molecular scale but combustion appears to be initiated throughout the volume by a rapidly developing kinetically controlled ignition process. Knock in SI engines is characterized by this mode of combustion. Volumetric combustion also occurs in a less premixed form during the "premixed burn" phase of diesel combustion and is a dominant mode of combustion in many forms of low temperature compression ignition combustion being explored worldwide for the fuel efficiency potential it offers

[e.g., homogeneous charge compression ignition (HCCI) combustion].

2 TURBULENT PREMIXED FLAMES

For the conditions within internal combustion engines, all of these fundamental modes of combustion are complicated by the presence of turbulence. The effects of turbulence on premixed flame propagation are discussed in this section. As already noted, turbulent premixed flames are the dominate mode of combustion within homogeneous charge SI engines. This section discusses a unified way to view and categorize turbulent premixed flames relevant to SI engines—a view that also shows how perfectly/well-stirred flames relevant to gas turbines fit into the picture. In addition, the effects of the critical parameters controlling the turbulent premixed flame front propagation speed are discussed. The overall discussions provide understanding of the nature and speed of turbulent premixed flames under various conditions, and which conditions are most relevant to SI engines.

As background to this topic, it is first useful to discuss the laminar premixed combustion process. Envision a premixed flame propagating in a well-insulated tube under laminar plug flow conditions in the absence of buoyancy. This laminar premixed flame can be held at a stationary position within the tube by flowing the reactants into the tube at the correct velocity: the "unstretched laminar flame speed," S_L, which depends upon the reactant composition, temperature, and pressure (as discussed in Section 2.3.1). If this premixed laminar flame is traversed with composition and temperature probes, where it must be noted that this laminar premixed flame is extremely thin, the resulting measurements will yield results similar to those presented in Figure 1. As the flame is approached from the reactant side, one notes that the fuel begins to disappear and intermediate hydrocarbons and molecular hydrogen are observed. Further into the flame, the intermediate hydrocarbons are oxidized to form CO and the molecular hydrogen is oxidized, eventually, to form water. Further through the flame, the CO is oxidized to form CO_2 in a relatively slow but highly exothermic reaction.

If the approach flow is turbulent rather than laminar, the central question is: how does the turbulence affect the laminar flame structure and chemistry? Understanding the interactions between turbulence and laminar combustion has been a central theme of combustion research for more than 30 years (e.g., Lancaster *et al*., 1976; Mattavi, Groff, and Matekunas, 1979). This need eventually led to methods for quantitatively categorizing various regimes within which turbulence would have specific effects on the combustion process. The Damkohler number versus turbulent Reynolds number diagram developed by Abraham, Williams, and Bracco (1985) is the subject of Section 2.1. Borghi's (1985) combustion phase diagram, and modifications thereof, is the subject of Section 2.2. Section 2.3 covers the elements of a physically based model of turbulent premixed flame propagation to provide the reader a physical understanding of flame propagation in SI engines, including stratified charge SI engines. In addition, the overall SI engine combustion system is discussed in Spark Ignition Combustion.

2.1 The Damkohler number versus turbulent Reynolds number diagram

Abraham, Williams, and Bracco (1985) made a breakthrough in understanding the interaction between turbulence and laminar flame-type combustion in homogeneous charge SI engines by constructing a diagram of a Damkohler number, Da_Λ, versus the turbulent Reynolds number, Re_Λ, as illustrated in Figure 2.

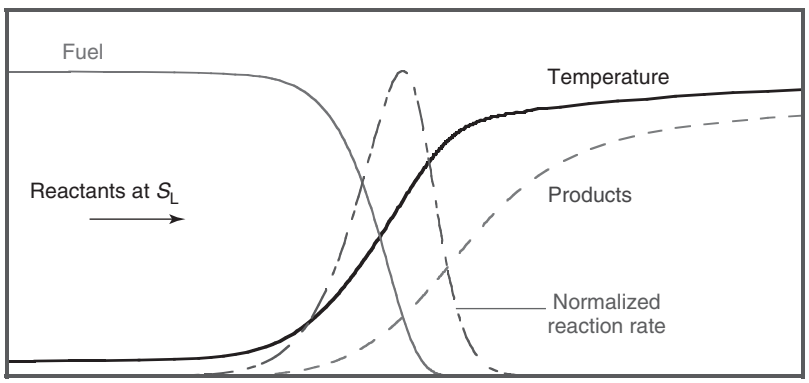

Figure 1. Temperature, composition, and reaction rate distributions through a premixed laminar flame.

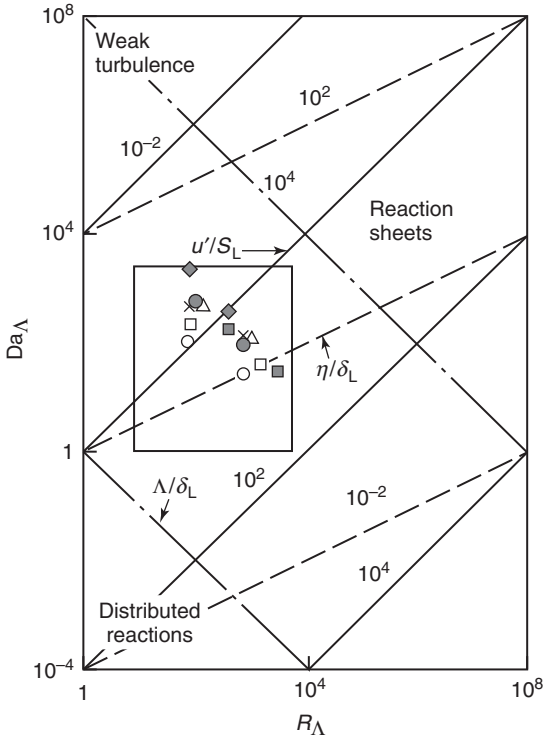

Figure 2. The $Da_\Lambda - Re_t$ diagram. (From Abraham, Williams, and Bracco, 1985. Copyright © SAE International. Reprinted with permission.)

Of the various Damkohler number definitions that exist, the Damkohler number chosen by Abraham, Williams, and Bracco (1985) for construction of Figure 2 is defined as the ratio of the characteristic turnover time of a turbulent eddy of the size of the integral length scale, $\tau_t = L_i/u'$, to the characteristic residence time in a laminar flame, $\tau_L = \delta_L/S_L$,

$$Da_{L_i} = Da_\Lambda = \frac{\tau_t}{\tau_L} = \frac{L_i}{u'}\frac{S_L}{\delta_L} \tag{1}$$

where u' is the root mean square (RMS) of the turbulent velocity fluctuations (the turbulence intensity), L_i or Λ is the integral length scale size of the spectrum of turbulent eddy sizes, S_L is the unstretched laminar flame speed, and δ_L is the laminar flame thickness. Abraham, Williams, and Bracco note that this Damkohler number can be perceived as an inverse measure of the influence of the turbulent processes on the chemical processes occurring in the flame. The Reynolds number they used is defined as

$$Re_t = R_\Lambda = \frac{u' L_i}{\nu} \tag{2}$$

where ν is the laminar kinematic viscosity. The integral length scale is the size of the largest turbulent eddies in the flow field.

Within Figure 2, Abraham, Williams, and Bracco identify two limiting regimes of turbulent combustion, reaction sheets, and distributed reactions (Williams, 1984, 1985), as originally suggested by Damkohler (1947). In the reaction sheet regime, the propagating flame front is wrinkled and convoluted by the turbulence but the turbulence does not affect the combustion chemistry; $\tau_L \ll \tau_t$. In the distributed reaction regime, pockets of fuel plus air and other pockets of combustion products are randomly mixed throughout the combustion zone.

Damkohler's original suggestion for the division separating these two limiting regimes of turbulent combustion was that $\Lambda/\delta_L = 1$, so this line is shown in Figure 2 (also shown is a parallel line for $\Lambda/\delta_L = 10^4$). A more recent suggestion, now known as the Klimov–Williams criterion (Klimov, 1963; Williams, 1976), $\eta/\delta_L = 1$, where η is the Kolmogorov scale of turbulence, is also shown in Figure 2 (included are parallel lines for the ratio with values of 10^{-2} and 10^2). The Kolmogorov scale of turbulence is the smallest size of turbulent eddies in the flow field.

Within the reaction sheet regime, turbulent flames are wrinkled laminar premixed flames. The structure of the wrinkled laminar flame depends upon the location within the reaction sheet regime on the $Da_\Lambda - Re_t$ diagram. For cases when $u'/S_L \ll 1$, the Damkohler number is very large (via Equation 1), turbulence is weak (as indicated in Figure 2), and wrinkling of the flame front by turbulence is gentle. This is a subregime that is not encountered under engine operating conditions. At higher turbulence intensities, flame front wrinkling is pronounced but a single continuous reaction sheet can still be identified. For even higher turbulence intensities, the turbulence wrinkles the flame so severely that adjacent areas of the wrinkled flame collide, cutting off pockets of unburned mixture, and forming "multiply connected" reaction sheets. In Figure 2, Abraham, Williams, and Bracco include a suggested boundary between the single sheet and multiple sheet subregimes, $u'/S_L = 1$ (Klimov, 1975, 1983), but they note that this boundary is quite uncertain.

By making some estimates, Abraham, Williams, and Bracco (1985) also imposed a rectangle that represented the operating envelope of homogeneous charge SI engines (the inset of Figure 2). Here, it should be noted that most of this rectangle lies within their multiply connected reaction sheet regime ($u'/S_L \geq 1$) although, again, they pointed out that this boundary criterion was quite uncertain.

The combustion phase diagram developed by Abraham, Williams, and Bracco (1985) only included one of the

four modes of combustion, turbulent premixed flames, but was an important advance in our understanding of the interaction between turbulence and flame chemistry. They began this process by examining several prior relationships for the turbulent burning velocity (S_T) within the reaction sheet regime. In general, these prior relationships allowed solution for S_T as a function of the RMS of the turbulent velocity fluctuation (i.e., the turbulence intensity u') and the unstretched laminar flame speed (S_L). They concluded that the various models tended to agree that S_T/S_L depends on u'/S_L within the reaction sheet regime, but there was significant controversy over the form of the functional dependence. They further concluded that multidimensional models of premixed charge combustion within the reaction sheet regime needed to account for the turbulent flame structure "because the burning velocity and the flame surface area are the principle parameters that affect the pressure history" for homogeneous charge SI engines.

2.2 Borghi's combustion phase diagram

Our understanding of the interaction between turbulence and combustion was also significantly advanced by Borghi (1985), who developed the premixed combustion "phase diagram" that is provided in Figure 3a, following the modifications made by Peters (1986). This diagram includes

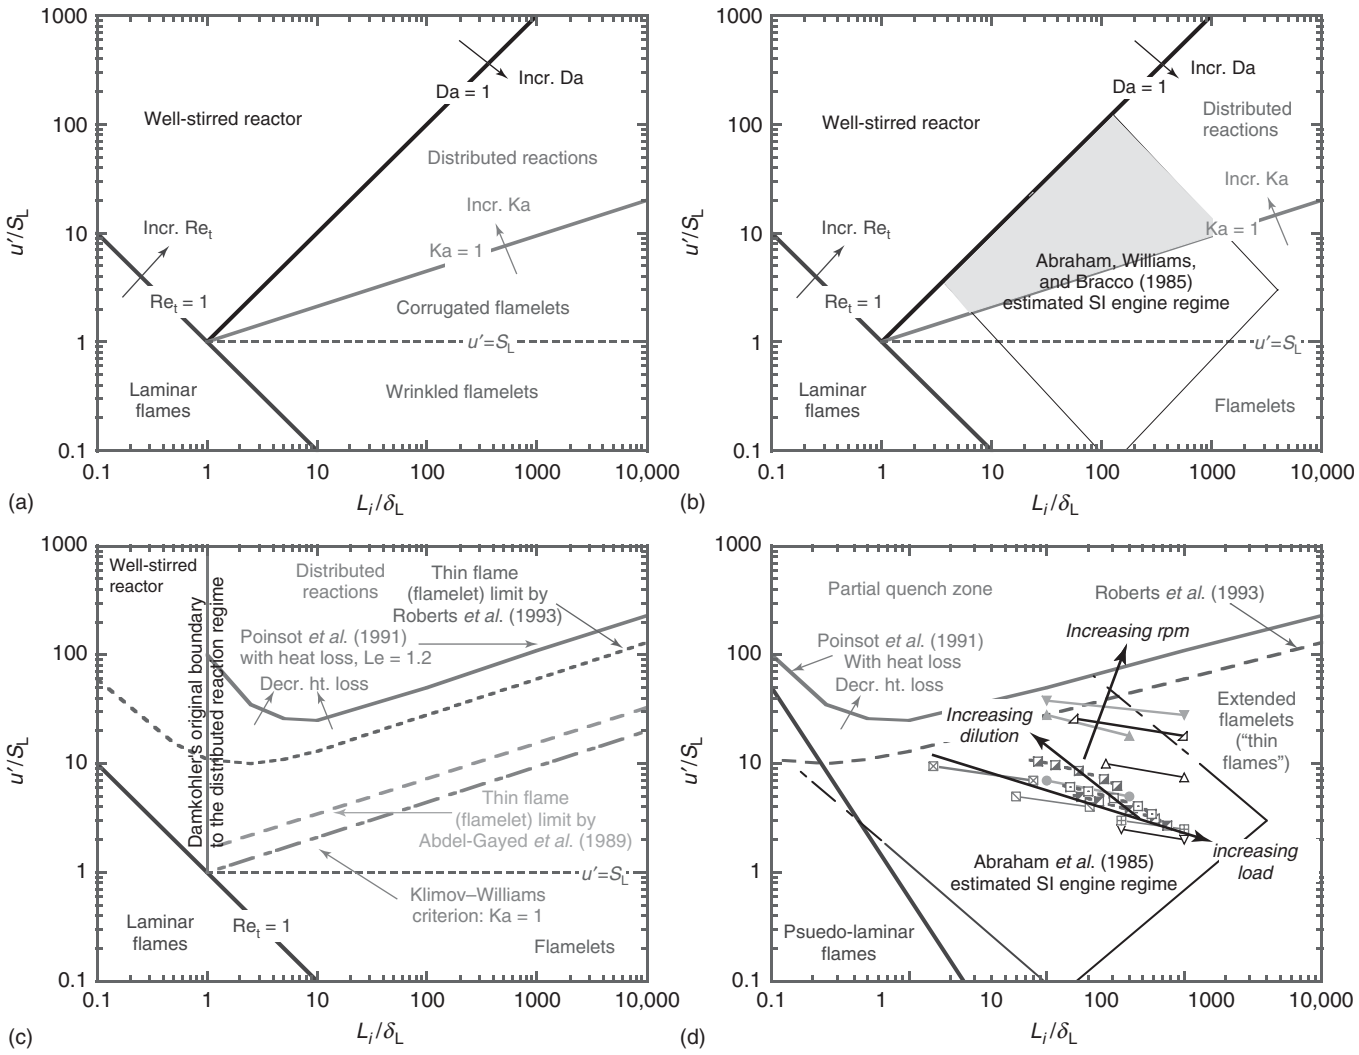

Figure 3. (a) Borghi's (1985) premixed combustion phase diagram with Peters' (1986) nomenclature. (b) Borghi's (1985) diagram with the estimated engine-operating regime from Abraham, Williams, and Bracco (1985) superimposed. (c) Borghi diagram showing shifting thoughts over the border between the flamelet and the distributed reaction regimes of turbulent premixed combustion. (d) Borghi diagram as modified by Poinsot, Veynante, and Candel (1991) and with the estimated engine operating regime from Abraham, Williams, and Bracco (1985) with the more recent engine operating results from Matthews *et al*. (1996) and Dai *et al*. (1998).

the turbulent Damkohler number and the turbulent Reynolds number that were the basis for the Abraham, Williams, and Bracco (1985) $Da-Re_t$ diagram discussed in Section 2.1. Here, the turbulent Damkohler number was defined as the ratio of a characteristic time for turbulence to a characteristic time for the reactions within the flame or, in other words, the ratio of the time scale for turbulent mixing to the time scale for reaction. Thus, this Da is essentially the equivalent of the Da used by Abraham, Williams, and Bracco (1985), discussed in Section 2.1. However, the Borghi diagram adds additional parameters that, in turn, allow division of turbulent premixed combustion into additional categories.

The Borghi combustion phase diagram is a rearrangement of the $Da_\Lambda - Re_t$ diagram, but uses the ratio of the turbulence intensity to the unstretched laminar flame speed, u'/S_L, as the abscissa rather than Re_t and the ratio of the turbulence integral length scale to the unstretched laminar flame thickness, L_i/δ_L, as the ordinate rather than Da_Λ. That is, Borghi identified two of the parameters appearing within the $Da_\Lambda - Re_t$ diagram as the most important parameters for dividing combustion into various regimes, with Da_Λ and Re_t becoming dividing lines between combustion regimes. Borghi also added the Karlovitz number, Ka (a measure of flame "stretch"), as a new parameter for dividing the regimes. The Karlovitz number that appears in Figure 3 is the ratio of the characteristic residence time within a laminar flame, t_F, to the time scale for dissipation of turbulence kinetic energy in the smallest (Kolmogorov) scale eddies, t_D:

$$\mathrm{Ka} = \frac{t_F}{t_D} = K\frac{\delta_L}{S_L} \tag{3}$$

where K is the flame stretch rate. Therefore, as used in Figure 3a, a large Ka ($\mathrm{Ka} > 1$) means that the flame is thick and/or the unstretched laminar flame speed is low (both of which could be caused by dilution with recirculated exhaust gas) and/or the flame stretch rate is high (Section 2.3.2). The flame falls within the laminar flamelet regime (corrugated and wrinkled flamelets; $\mathrm{Ka} < 1$) when the flame is thin and/or the unstretched laminar flame speed is high and/or the flame stretch rate is low.

Borghi's diagram in Figure 3 divides the regimes of turbulent premixed combustion into four categories based on the various parameters: laminar flames (whenever $Re_t < 1$), well-stirred reactors ($Re_t > 1$ and $Da < 1$), distributed reactions ($Re_t > 1$, $Da > 1$, and $Ka > 1$), and two types of laminar flamelets ($Re_t > 1$, $Da > 1$, and $Ka < 1$): (i) wrinkled flamelets ($u' < S_L$) and (ii) corrugated flamelets ($u' > S_L$). The well-stirred reactor in this diagram is similar to the perfectly stirred reactor mentioned in Section 1 except that mixing between the reactants and products is not perfect, but this regime is still an idealization of combustion in a gas turbine. In premixed combustion, laminar flamelets are flames for which the flame thickness is smaller than the smallest length scale of the turbulent flow (the Kolmogorov scale, η). In the wrinkled flamelet regime, the thin flame is only moderately wrinkled by the turbulent flow whereas the flame front is much more strongly wrinkled in the corrugated flamelet regime.

Figure 3b shows the Borghi diagram with the estimated engine-operating regime by Abraham, Williams, and Bracco (1985) superimposed (the thin-lined diamond with upper part lightly shaded in gray). According to this estimate of the engine operating regime, much of engine operation falls within the flamelet regime but much also falls within the distributed reaction regime. However, it must be noted that this estimate of the engine-operating regime relied on estimates of the turbulence intensity, integral length scale, and laminar flame thickness. More importantly, they note that "the sufficient condition for the presence of the distributed reaction regime is not satisfied in engine combustion" where they identified this condition as $L_i \ll \delta_L$ (the largest scale of the turbulent eddies must be much smaller than the laminar flame thickness). Thus, the addition of the Karlovitz number to the Borghi diagram shows that the lightly shaded gray part of the original engine-operating regime defined by Abraham, Williams, and Bracco (1985) can be eliminated by their conclusion that distributed reactions do not occur within SI engines.

Figure 3c illustrates how additional research resulted in further shifts and new definitions for the border between the flamelet and the distributed reaction regimes of turbulent premixed combustion. Several aspects of this figure are notable. First, Damkohler originally placed the border between well-stirred reactors and distributed reactions at $L_i/\delta_L = 1$ and $u'/S_L > 1$. More importantly, the border between the flamelet and the distributed reaction regime moved because of the results of additional research. In 1989, Abdel-Gayed, Bradley, and Lung argued that this border should occur at $\mathrm{Ka} = 1.64$ rather than at the Klimov–Williams criterion of $\mathrm{Ka} = 1.0$. Soon after that, Poinsot, Veynante, and Candel (1991) performed direct numerical simulations of flame/vortex interactions using the full Navier–Stokes equations and a simplified chemistry model to predict flame quenching by isolated vortices. Their formulation included non-unity Lewis number, non-constant viscosity, and heat losses so that the effect of flame stretch, flame curvature, transient dynamics, and viscous dissipation could be accounted for. Their results showed that flame fronts are much more resistant to quenching by vortices than previously expected. Their results also showed that strain is not the only important parameter

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto115
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

determining flame/vortex interaction. Heat losses, flame curvature, viscous dissipation, and transient dynamics had significant effects, especially for small scales, and they strongly influence the boundaries of the combustion regimes. It was found that the Klimov–Williams limit to the flamelet regime underestimates the size of the flamelet regime by more than an order of magnitude. Roberts *et al*. (1993) performed measurements, combined with concepts proposed by Poinsot, Veynante, and Candel (1991), in order to infer the "thin flame limit," which indicates when laminar flamelet theories become invalid, since quenching allows hot products and reactants to coexist (i.e., distributed reactions are possible). Their experiments included vortex core diameters as small as the flame thickness. Their main conclusion was that small vortices are less effective at quenching a flame than was previously believed. Therefore, the inferred regime within which thin flame (laminar flamelet) theories are valid extends to a turbulence intensity that is more than an order of magnitude larger than that which was previously predicted. Their results also indicated that micromixing models, which assume that the smallest eddies exert the largest strain on a flame, are not realistic. They found that the measured vortex Karlovitz number that is required to quench a flame is not constant but decreases by a factor of 4 as the vortex size increases from one to five flame thicknesses.

As noted previously, the well-stirred reactor regime identified in the upper left of Figure 3c is an idealization of the combustion process in a gas turbine. Although satisfactory agreement can be obtained between this type of model for combustion in a gas turbine and experimental data (Swithenbank, Poli, and Vincent, 1973), there are strong limitations to the well-stirred reactor approach (e.g., Kuo, 1986). However, because gas turbines are not used in the automotive market, gas turbine-type combustion will not be discussed any further. The interested reader is referred to Lefebvre (1983), Treager (1979), Mattingly (1996), and Turns (2000).

Figure 3c is the Borghi combustion phase diagram as modified by Poinsot, Veynante, and Candel (1991) via the direct numerical simulations discussed above. They defined an "extended flamelet" as a regime in which the reactants and products are separated by a thin reaction zone that is laminar-like but does not necessarily have the structure of a laminar flame. They chose to examine quenching because "If the local stretch induced by the turbulent flow … is sufficiently large and the flame is quenched at a given location, combustion stops in the vicinity of this point and fresh reactants will diffuse into the products without burning. Combustion ceases to take place in thin sheets and the flamelet concepts (laminar or extended) become less adequate. Therefore, quenching in a turbulent premixed flame determines the limit between two essentially different behaviors (i.e. flamelets or no flamelets)." Thus, in Figure 3, Poinsot, Veynante, and Candel replaced the distributed reaction regime (Figure 3c) with the "partial quench zone." Their DNS results also resulted in the boundary between the extended flamelet and partial quench zones illustrated in Figure 3, where the position of this boundary depends upon the heat loss from the flame.

Figure 3d includes an overlay of the engine-operating regime estimated by Abraham, Williams, and Bracco (1985) and the results of a more recent examination of engine-operating regimes for typical current technology homogeneous charge SI engines by Matthews *et al*. (1996) and the extension of this work by Dai *et al*. (1998). These latter results, represented by the data symbols in the plot, relied upon a well-calibrated quasi-dimensional engine model (including a calibrated turbulence model) to extract u'/S_L and L_i/δ_L throughout the combustion process of a 4.6 L V8 SI engine (Matthews *et al*., 1996) and both a 1.6 L and a 2.0-L four-valve I4 SI engine (Dai *et al*., 1998) over a range of operating conditions. The base operating conditions for these engines were 1500 rpm, 2.62 bar brake mean effective pressure (BMEP), stoichiometric, no exhaust gas recirculation (EGR), and minimum spark advance for best torque (MBT) spark timing. These investigations examined the effects of engine speed, load, and dilution with both excess air and recirculated exhaust gas. Only one parameter was varied at a time. In Figure 3d, the beginning of combustion is the far left point on each curve or line with the far right data point on that same curve or line as the end of combustion. The three curves (rather than straight lines) were generated by examining not just the beginning and end of combustion but a series of states between these two extremes. More importantly, as the engine speed increases the lines for each operating speed shift up and to the right; as the load increases the lines shift down and to the right, and as the mixture becomes more diluted the curves shift up and to the left. Only the last stages of combustion for the V8 at 5500 rpm, stoichiometric, and for the 1.6-L inline 4 at 9000 rpm, rich, appear to be outside of the engine-operating regime originally estimated by Abraham, Williams, and Bracco (1985). More details are available in the original papers (Matthews *et al*., 1996; Dai *et al*., 1998).

One conclusion that must be drawn from Figure 3d is that Abraham, Williams, and Bracco (1985) estimated the engine-operating regime fairly well, especially given that the "engineering tools" available for aiding such estimates have progressed significantly since they made their estimate. Their lower limit Reynolds number appears to have been a bit too conservative but their upper limit Reynolds number was quite accurate, except for some

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

engines operating at high engine speeds especially with a low load and/or with high dilution.

The most important conclusion to be drawn from Figure 3d is that flames within SI engines fall within the laminar flamelet regime of turbulent premixed combustion for most, or perhaps all, operating conditions. In this regime, the dominant effects of turbulence are to stretch and wrinkle the flame. Within the flamelet regime, the reactions are sufficiently fast that the burned gases and the unburned gases can be considered as separated by very thin flamelets, and the local structure of the flamelets is essentially that of a laminar flame. In other words, the dominant effects of turbulence on the premixed flame are to wrinkle and stretch the flame surface while the inner flame structure is not significantly altered by the turbulent flow field. The significance of the flamelet assumption is that it decouples the chemistry from the turbulence and, thereby, reduces the problem of modeling premixed turbulent combustion to the description of flame surfaces: the flame propagates locally at the instantaneous stretched laminar flame speed but the global turbulent flame propagates faster than the corresponding laminar flame because the flame surface area is increased by flame wrinkling. This means that the mass burning rate of the flame ($\dot{m}_b$) can be expressed as

$$\dot{m}_b = \rho_u u_L A_T = \rho_u I_o S_L A_T \tag{4}$$

where ρ_u is the unburned reactant (i.e., fuel–air-diluent mixture) density, u_L is the local instantaneous stretched laminar flame propagation speed, and A_T is the total (i.e., turbulent) surface area of the flame. Furthermore, u_L in Equation 4 is given by $I_o S_L$, where I_o is the flame stretch parameter, discussed more in Section 2.3.2, and S_L, as already defined, is the unstretched laminar flame speed discussed in Section 2.3.1.

Figure 4 illustrates the wrinkled laminar flame. Turbulent eddies over the full range of sizes from the integral length scale on the large end of the spectrum to the Kolmogorov scale on the small end, interact with the surface of the flame and, thereby, wrinkle and stretch the very thin flame. This variety of eddy sizes produces concave wrinkles in the flame surface of various sizes. Each local flamelet then propagates normal to the local flame surface at the local, instantaneous, stretched laminar flame speed, u_L. In turn, the small-scale concave wrinkles tend to become annihilated by the local flame propagation process while any large-scale convex wrinkles (portions of the flame not recently impacted by large eddies) tend to grow larger. Thus, the range of flame wrinkling scales differs somewhat from the range of turbulent eddy sizes. In addition, the flame wrinkling process continues as the flame propagates through the turbulent flow field. However, if one could freeze the flow and the reactions and probe any local flamelet to measure the local, instantaneous composition and temperature profiles of the very thin flamelet, this would yield results very similar to those shown in Figure 1 for the unstretched laminar premixed flame except that the local flamelet would be propagating normal to the flame surface at a somewhat different speed: u_L rather than S_L.

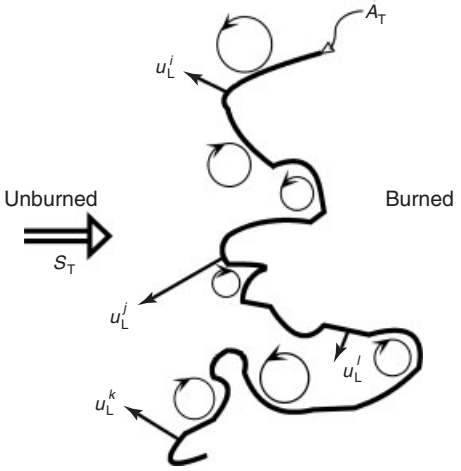

Figure 4. Snapshot illustration of turbulent premixed flame propagation. The turbulent approach flow has mean velocity S_T, the flame propagates normal to the local surface at velocity u_L (the superscript indicates that u_L is dependent upon the location along the instantaneous flame surface), and the total (turbulent) flame surface area is A_T.

2.3 Turbulent premixed flame speed

Several SI engine combustion models rapidly took advantage of the flamelet assumption, such as the coherent flamelet model (e.g., Cheng and Diringer, 1991; Boudier *et al*., 1993; Duclos, Veynante, and Poinsot, 1993) and the fractal flame model (e.g., Matthews and Chin, 1991; Chin *et al*., 1992; Zhao, Matthews, and Ellzey, 1993, 1994). Such models must (i) determine the instantaneous unstretched laminar flame speed S_L, (ii) quantitatively describe the effects of flame stretch on the local laminar flame speed (e.g., via I_o), and (iii) account for the increase in flame surface area caused by the turbulence. Each of these requirements is discussed in the following sections.

2.3.1 The unstretched laminar flame speed

As just noted, engine models that take advantage of the flamelet assumption must calculate the instantaneous

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto115
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

unstretched laminar flame speed. The unstretched laminar flame speed is a thermochemical property of a premixed reactive mixture. It depends upon the composition of the reactants (including the fuel, the air, and the amount of exhaust residual and/or EGR that may be present), the reactant temperature, and the system pressure.

The unstretched laminar flame speed, S_L, can be predicted using detailed kinetics models of the type discussed in Fundamental Chemical Kinetics (or appropriate simplified kinetics models if available) in conjunction with a suitable one-dimensional flame simulation code. Somewhat surprisingly, few codes are available for predicting this fundamental quantity. Perhaps the most widely used is PREMIX (Kee *et al*., 1985). PREMIX calls a very accurate code, as a subroutine, for calculation of the transport properties (TRANFIT, Kee, Warnatz, and Miller, 1983) since these transport properties have a significant influence on the flame propagation rate. Obviously, the results are also highly dependent upon the accuracy of the kinetics mechanism. Accurate high temperature kinetics mechanisms (i.e., schemes that are suitable for predicting flame propagation) are available for methane (which closely resembles natural gas), propane, and a variety of other hydrocarbons and alcohols, but not for gasoline. However, a kinetics mechanism is available for primary reference fuel (PRF) blends that can be used to predict the unstretched laminar flame speeds of various simulated gasolines. Unfortunately, such predictions are highly consumptive of computational time, since the time requirement increases roughly with the square of the number of species involved (Westbrook and Dryer, 1984). For methane, perhaps the simplest accurate detailed kinetics mechanism consists of 57 reactions and 25 species (Kee *et al*., 1985), while a recent detailed kinetics model for iso-octane (Curran *et al*., 1996) consists of 3445 elementary reactions and 805 species.

Although challenging, one method of determining S_L for engine simulation codes and accounting for the effects of pressure, unburned gas temperature, equivalence ratio, and residual gas fraction plus EGR on S_L is to use a laminar flame speed code to generate extensive tables of S_L for a broad range of conditions. These tables can then be called from the engine simulation code as a "laminar flame speed library."

An alternative approach is to predict the unstretched laminar flame speed using experimentally derived empirical correlations. Before introducing an example of an unstretched laminar flame speed correlation, it is first necessary to define a few symbols and terms. The unburned gas temperature, T_u, is the temperature of the reactants ahead of the flame in the unburned zone. The residual mass fraction, f, is the fraction of the mixture trapped within the cylinder at intake valve closing that consists of exhaust products remaining in the cylinder from the previous cycle. The equivalence ratio, ϕ, sometimes called the fuel/air equivalence ratio, is defined via

$$\phi \equiv \frac{F/A}{(F/A)_s} = \frac{(A/F)_s}{A/F} = \frac{1}{\lambda} \tag{5}$$

In the definition of ϕ, F/A is the actual fuel/air mass ratio, $(F/A)_s$ is the stoichiometric fuel/air mass ratio, A/F and $(A/F)_s$ are their respective reciprocals, and λ is the excess air ratio. For stoichiometric mixtures (no excess air, no excess fuel), $\phi = 1.0$, while for lean mixtures $\phi < 1.0$ and for rich mixtures $\phi > 1.0$.

Perhaps the most widely used empirical correlations for the unstretched laminar flame speed were developed at MIT (Metghalchi and Keck, 1980, 1982; Milton and Keck, 1984; Rhodes and Keck, 1985). This empirical correlation is valid for $0.7 < \phi < 1.6$, $0.4 < P < 12$ atm, $350 < T_u < 550$ K, and residual mass fractions (including EGR) up to 30% and is

$$S_L = S_L^o \left(\frac{T_u}{298}\right)^a \left(\frac{P}{1.0}\right)^b [1 - 2.06 f^{0.77}] \tag{6}$$

where the cylinder pressure P must be in atmospheres, the reference pressure is 1.0 atmosphere, and S_L^o is the unstretched laminar flame speed at the reference state of 298 K, 1 atm, with no dilution by residual or EGR ($f = 0$). S_L^o is empirically related to the equivalence ratio via

$$S_L^o = B_m - B_\phi (\phi - \phi_m)^2 \tag{7}$$

where the constants B_m, B_ϕ, and ϕ_m are given in Table 1 for four fuels.

For propane, iso-octane, and methanol, coefficients a and b in Equation 6 are empirically related to the equivalence ratio via

$$a = 2.18 - 0.8(\phi - 1) \tag{8}$$

Table 1. Coefficients for use in the empirical equations for the unstretched laminar flame speed.

Fuel	ϕ_m	B_m (cm/s)	B_ϕ (cm/s)
Methanol	1.11	36.9	140.5
Propane	1.08	34.2	138.7
Iso-octane	1.13	26.3	84.7
Reference gasoline	1.21	30.5	54.9

Metghalchi and Keck (1980, 1982), Milton and Keck (1984), and Rhodes and Keck (1985).

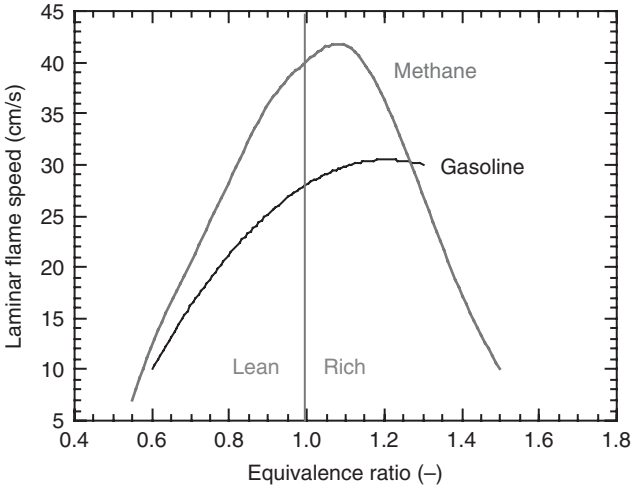

Figure 5. The effects of equivalence ratio on the unstretched laminar flame speeds of methane and gasoline at a pressure of 1 bar with a reactant temperature of 298 K. These results are from correlation equations obtained by fits to experimental data; gasoline from Metghalchi and Keck (1982); methane from Andrews and Bradley (1972).

$$b = -0.16 + 0.22(\phi - 1) \tag{9}$$

while for a reference gasoline, a and b are the following functions of equivalence ratio:

$$a = 2.4 - 0.271\phi^{3.51} \tag{10}$$

$$b = -0.357 + 0.11\phi^{2.77} \tag{11}$$

Using correlations such as these, the effects of equivalence ratio on the unstretched laminar flame speed are illustrated in Figure 5. The unstretched laminar flame speed is highest for a somewhat rich mixture not only for methane and the reference gasoline but also for all hydrocarbons. The same correlations can be used to show the effects of pressure, unburned gas temperature, and exhaust residual fraction plus EGR. An example is provided in Figure 6, which shows that the unstretched laminar flame speed decreases as the system pressure increases. This is caused by a falloff of chemical kinetic rates with increasing pressure. However, in spite of the pressure falloff of the combustion chemistry, the mass burning rate given by Equation 4 increases with increasing pressure because it is also a function of the density of the unburned mixture, and the effect of pressure on density increases faster with increasing system pressure (linearly) than the effect of the pressure falloff of the chemical kinetic rates.

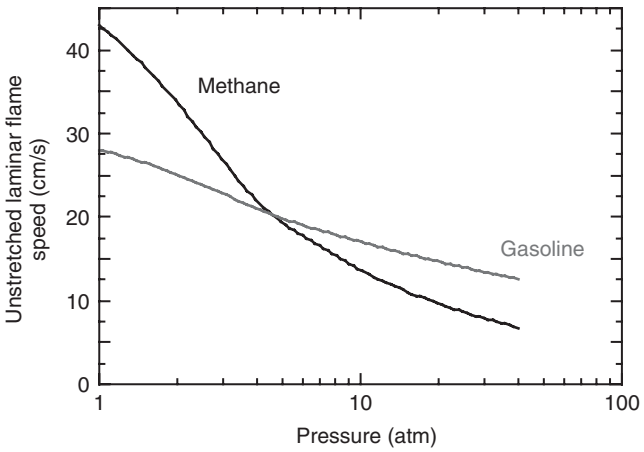

Figure 6. The effects of pressure on the unstretched laminar flame speeds of methane and gasoline for stoichiometric mixtures with a reactant temperature of 298 K. These results are from correlation equations obtained by fits to experimental data; gasoline from Metghalchi and Keck (1982); methane from Andrews and Bradley (1972).

2.3.2 *The effects of flame stretch on the laminar flame speed*

In general, flame expansion and turbulence strain slow down a laminar flame. These effects may be quantified via

$$u_L = I_o S_L \tag{12}$$

where u_L is the stretched laminar flame speed and I_o is the dimensionless flame stretch parameter.

Chung and Law (1988) showed that the flame stretch parameter is a function of the flame stretch rate (K), assuming a relatively small effect of stretch on the flame speed:

$$I_o = \frac{u_L}{S_L} = 1 - \left[\frac{1}{\mathrm{Le}} - \left(\frac{1}{\mathrm{Le}} - 1\right)\frac{E_A}{2\overline{R}T_{ad}}\right] \times \frac{D}{S_L^2}K - q_{rad}\frac{E_A}{2\overline{R}T_{ad}} \tag{13}$$

where $\overline{R}$ is the universal gas constant, Le is the Lewis number (the ratio of the thermal diffusivity to the mass diffusivity, α/D) of the deficient reactant (the fuel diffusing through the air), E_A is the global activation energy, T_{ad} is the adiabatic flame temperature, K is the flame stretch rate, and q_{rad} is the radiation heat loss from the flame. Assuming negligible heat loss from the flame via radiation (an excellent assumption for homogeneous charge SI engines), a Lewis number of approximately 1, and a Prandtl number

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto115
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

(Pr = ν/α) of approximately 1 yields (Chin *et al.*, 1992):

$$I_o = \frac{u_L}{S_L} = 1 - \frac{\nu}{S_L^2}K \tag{14}$$

where ν is the laminar kinematic viscosity in the unburned gases. The flame stretch rate is composed of two additive components (Chung and Law, 1988):

$$K = K_E + K_S \tag{15}$$

where K_E is the flame stretch rate associated with flame expansion or large-scale curvature of the flame and K_S is the stretch rate associated with turbulence strain in the small scale wrinkles.

For a spherical flame, as is normally assumed for flame propagation in a homogeneous charge SI engine in quasi-dimensional engine simulations, Law (1988) showed that

$$K_E = \frac{2}{r_f}\frac{dr_f}{dt} = \frac{2}{r_f}\left[\frac{\rho_u}{\rho_b}S_L\right] \tag{16}$$

where r_f is the flame radius, the rate of change of the flame radius is equal to the terms within the square brackets if the flame thickness is much smaller than the flame radius, and ρ_u and ρ_b are the densities in the unburned and burned zones, respectively.

Turbulence strain can be expressed as the lifetime of an eddy of the size of the Taylor microscale, λ:

$$K_S = \frac{u'}{\lambda} \tag{17}$$

Various investigators (Herweg and Maly, 1992; Chin *et al.*, 1992; Abdel-Gayed and Bradley, 1985, Abdel-Gayed, Bradley, and Lau, 1988) used this expression in combination with relationships for the Taylor microscale of turbulence, the integral length scale, the turbulence intensity, and the laminar kinematic viscosity to derive various, but similar, relationships for turbulence strain in their quasi-dimensional engine models with the form:

$$K_S = C_S\sqrt{\frac{\varepsilon}{\nu}} \tag{19}$$

where ε is the rate of dissipation of turbulence kinetic energy:

$$\varepsilon = \frac{(u')^3}{L_i} \tag{20}$$

and the constant, C_S, varied from 0.157 (Abdel-Gayed and Bradley, 1985) to 0.430 (Chin *et al.*, 1992) depending upon the theory used to derive the constant. In spite of the factor of 3 difference in the flame stretch rates due to turbulence strain, it was found (Wu *et al.*, 1993) that there was little effect on the burning rate predictions of a quasi-dimensional engine model for a stoichiometric propane/air mixture. More significant effects might be found for dilute mixtures and/or engine designs and operating conditions that produce high turbulence intensities.

No experimental data for engines is available for directly validating these flame stretch submodels, but all have a common form (when the Lewis and Prandtl numbers are both assumed to be 1.0) and differ only in magnitude.

2.3.3 *Turbulent premixed flame speed*

Under engine-like conditions, a turbulent flame will burn approximately 10 times faster than the corresponding laminar flame, primarily because of the increase in flame surface area caused by the turbulence. A relationship between the turbulent flame speed and the unstretched laminar flame speed is (e.g., Turns, 2000)

$$S_T = S_L\frac{A_T}{A_L} \tag{21a}$$

where S_T is the turbulent flame speed, S_L is the unstretched laminar flame speed, A_T is the total (turbulent) surface area of the wrinkled flame, and A_L is the surface area of a smooth laminar flame with the same mean radius as the turbulent flame. However, Equation 21a is more accurately written as

$$S_T = u_L\frac{A_T}{A_L} = I_oS_L\frac{A_T}{A_L} \tag{21b}$$

Equation 21b accounts for the additional effects of turbulence strain and flame curvature, both of which modify the unstretched laminar flame speed as discussed in the previous section, generally in a manner that decreases it compared to a laminar flame that is flat and not subjected to strain by a turbulent flow field. While these flame curvature and turbulence strain effects are important and decrease the turbulent flame speed, they do not overcome the turbulent flame speed increase induced by turbulent wrinkling of the flame. Thus, overall a turbulent flame burns faster than the corresponding laminar flame because of the dominant effect of the increase in surface area of the flame due to wrinkling of the flame front by the turbulent eddies.

The variety of turbulent premixed combustion models, such as those noted previously (e.g., Cheng and Diringer, 1991; Matthews and Chin, 1991; Chin *et al.*, 1992; Herweg and Maly, 1992; Boudier *et al.*, 1993; Duclos, Veynante, and Poinsot, 1993; Zhao, Matthews, and Ellzey, 1993,

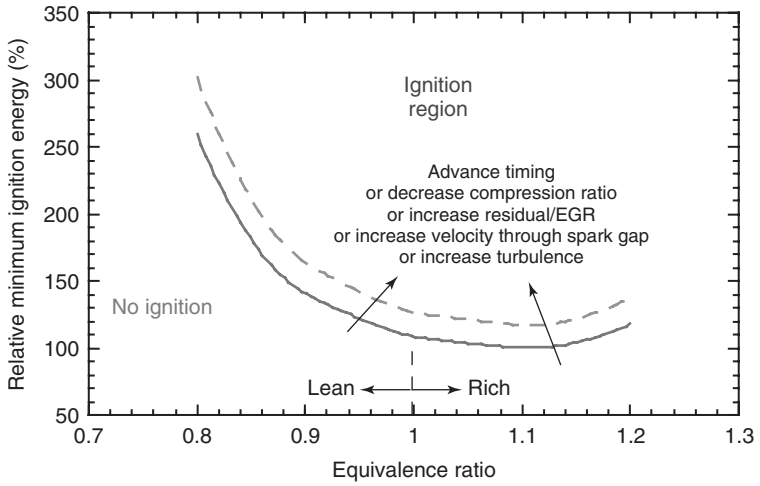

Figure 7. Effects of the equivalence ratio and other parameters on the energy required to achieve ignition. Figure generated from equations presented by Ballal and Lefebvre (1974).

1994), indicate that there are a wide variety of methods used to account for the increase in flame surface area due to wrinkling of the flame front by the turbulent flow field (the A_T/A_L term in Equation 21b).

2.3.4 *Effects of stratification*

An advanced, higher efficiency, spark-ignition engine concept involves using a fuel/air mixture with an equivalence ratio that is stratified (i.e., varies spatially) in the engine cylinder rather than a homogeneous premixed charge. Stratification is achieved by appropriate timing of fuel injection directly into the cylinder. The goal of this approach is to use the quantity of fuel injected to control load, rather than throttling the intake charge, and achieve overall lean operation at part load conditions. The net effect is an engine with significantly improved part load fuel efficiency. For optimal combustion, these stratified charge engines seek to place a stoichiometric or somewhat rich mixture near the spark plug at the time of spark with the mixture becoming progressively leaner away from the spark plug. The reason that it is important to produce a nearly stoichiometric mixture near the spark gap at the time of ignition is illustrated in Figure 7. This figure shows that stoichiometric and somewhat rich mixtures are much easier to ignite than lean mixtures, producing more stable ignition and combustion of a stratified and overall lean fuel–air mixture.

As the flame propagates through this mixture after ignition, it is evident from the laminar flame speeds in Figure 5 that the flame in the stratified environment will initially propagate relatively fast, and that the flame speed will decrease as the flame encounters increasingly lean mixtures away from the spark plug. In general, the turbulence intensity also decays throughout the combustion process, which further decreases the burning rate as the flame propagates through a stratified charge. This slowing of the combustion rate in the leaner mixtures can lead to combustion instabilities, one of the major design challenges for commercializing this approach for improving engine efficiency.

However, modeling such a turbulent, premixed, stratified charge is relatively straightforward. As noted above, for the homogeneous charge turbulent premixed flame, the modeler must account for the local instantaneous effects of flame stretch, flame wrinkling, and the unstretched laminar flame speed, which varies only because of the rapidly changing cylinder pressure and unburned gas temperature. For the turbulent, premixed, stratified charge engine, the modeler must also account for the local, instantaneous effects of the equivalence ratio on the unstretched laminar flame speed.

3 MIXING CONTROLLED COMBUSTION

Section 2 of this chapter pertained to the mode of combustion that is most relevant to SI engines. In diesel engines, the rate of heat release by the combustion process is dominated by mixing of the fuel with the air, both of which are separated by a flame front. This is classically called a diffusion, or non-premixed, flame, which is marked by separation of the fuel from the air, even under laminar conditions and with a gaseous fuel. In a diffusion flame, the fuel molecules diffuse toward the air, and the "air molecules"

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto115
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

diffuse toward the fuel, with both diffusion processes driven by concentration gradients. Thus, in a diffusion flame the mass burning rate is limited by the rate of mixing of the fuel and air. That is, diffusion flames are "mixing controlled."

The subject of mixing controlled combustion in a fuel jet is best introduced by first examining a nonreacting laminar jet of a gaseous fuel issuing into quiescent ambient oxidizer (such as air). The following assumptions will be used (Turns, 2000):

- The molecular weights of the fuel and oxidizer are equal. This assumption, combined with ideal gas behavior and constant pressure and temperature, yields uniform density throughout the flowfield.
- Transport of species is via binary diffusion governed by Fick's law.
- Momentum and species diffusivities are constant and equal (thus, the Schmidt number = Sc = $\nu/D = 1.0$, where ν is the momentum diffusivity (kinematic viscosity) and D is the species or mass diffusivity).
- Only the radial diffusion of momentum and species is important; axial diffusion is neglected (thus, the solution will only be valid some distance downstream from the nozzle exit).

Given these assumptions, the governing equations are as follows:

1. *Continuity (conservation of mass)*:

$$\frac{\partial v_x}{\partial x} + \frac{1}{r}\frac{\partial (v_r r)}{\partial r} = 0 \tag{25}$$

2. *Conservation of axial momentum*:

$$v_x \frac{\partial v_x}{\partial x} + v_r \frac{\partial v_x}{\partial r} = \nu \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_x}{\partial r}\right) \tag{26}$$

3. *Conservation of species*:

$$v_x \frac{\partial Y_\mathrm{f}}{\partial x} + v_r \frac{\partial Y_\mathrm{f}}{\partial r} = D \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial Y_\mathrm{f}}{\partial r}\right) \tag{27}$$

where x is the axis along the centerline of the jet, r is the radial direction, v_x is the velocity in the direction that is parallel to the jet axis, v_r is the velocity perpendicular to the jet axis, ν is the kinematic viscosity, D is the molecular diffusion coefficient, and Y_f is the mass fraction of the fuel. Furthermore, because there are only two species in this simplified analysis,

$$Y_\mathrm{f} + Y_\mathrm{ox} = 1 \tag{28}$$

where Y_ox is the mass fraction of the oxidizer.

The boundary conditions along the jet centerline ($r = 0$) are

$$v_r(x, 0) = 0 \tag{29a}$$

$$\frac{\partial v_x}{\partial r}(x, 0) = 0 \tag{29b}$$

$$\frac{\partial Y_\mathrm{f}}{\partial r}(x, 0) = 0 \tag{29c}$$

Moreover, at large radii,

$$v_x(x, \infty) = 0 \tag{30a}$$

$$Y_\mathrm{f}(x, \infty) = 0 \tag{30b}$$

Finally, at the jet exit it is assumed that the axial velocity, v_e, and fuel mass fraction, $Y_\mathrm{f,e}$, are uniform across the jet:

$$v_x(0, r \le R) = v_\mathrm{e} \tag{31a}$$

$$Y_\mathrm{f}(0, r \le R) = Y_\mathrm{f,e} = 1$$

where R is the radius of the jet nozzle. Elsewhere in the plane of the nozzle exit

$$v_x(0, r > R) = 0 \tag{31b}$$

$$Y_\mathrm{f}(0, r > R) = 0$$

The solution for the fuel mass fraction distribution is

$$Y_\mathrm{f} = \frac{3}{8\pi}\frac{v_\mathrm{e}\pi R^2}{D}\frac{1}{x}\left[1 + \frac{\left\{\left(\frac{3}{16}\right)(\rho_\mathrm{e} v_\mathrm{e} R)\frac{1}{\mu}\frac{r}{x}\right\}^2}{4}\right]^{-2} \tag{32a}$$

where ρ_e is the density at the jet exit and μ is the dynamic viscosity. Equation 32a may be rewritten as

$$Y_\mathrm{f} = \frac{3}{8\pi}\frac{\dot{V}_\mathrm{f,e}}{D}\frac{1}{x}\left[1 + \frac{\zeta^2}{4}\right]^{-2} \tag{32b}$$

where $\dot{V}_\mathrm{f,e}$ is the volumetric flow rate of fuel at the jet exit and

$$\zeta \equiv \left(\frac{3\rho_\mathrm{e} J_\mathrm{e}}{16\pi}\right)^{1/2}\frac{1}{\mu}\frac{r}{x}$$

where J_e is the momentum flow at the jet exit:

$$J_\mathrm{e} = \rho_\mathrm{e} v_\mathrm{e}^2 \pi R^2$$

A solution for the fuel and oxidizer mass fraction profiles resulting from Equations 28 and 32a as a function of radial distance from the jet centerline is illustrated in Figure 8. The

DOI: 10.1002/9781118354179.auto115
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

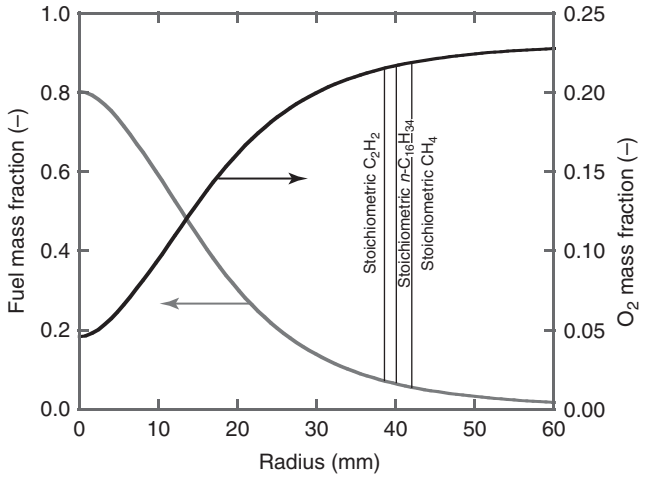

Figure 8. Fuel and molecular oxygen mass fraction profiles through a nonreacting laminar jet of fuel issuing into quiescent air through a 10-mm diameter nozzle at 10 cm/s. These profiles are for a plane that is 7.5 nozzle diameters downstream from the jet exit.

impacts of fuel and oxidizer diffusion are clearly evident. The radius at which the fuel/air mixture is stoichiometric at an axial distance of 75 mm is also illustrated for three different fuels by the vertical lines near methane (CH_4, H/C atom ratio = 4.0), *n*-hexadecane ($C_{16}H_{34}$, a primary reference fuel for Cetane number tests, H/C = 2.125), and ethyne (more commonly called acetylene, C_2H_2, H/C = 1.0). The results in Figure 8 illustrate that the stoichiometric contour is near the outer boundary of the jet and that fuel type will affect the radial location of this contour.

Figure 9 illustrates the locus of radii at which a stoichiometric mixture is located for the *n*-hexadecane and air example, with all other conditions being the same as for Figure 8. This stoichiometric surface is of interest because this is approximately where the flame would be located if the mixture were ignited. Fuel would diffuse from the inside and oxidizer from the outside to the flame at the stoichiometric surface.

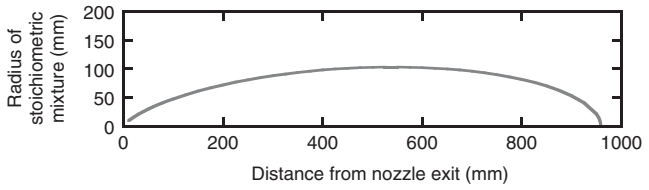

Figure 9. Radius at which a stoichiometric mixture of *n*-hexadecane and air is located for a nonreacting laminar jet of fuel (*n*-hexadecane) issuing into quiescent air; same conditions as Figure 8.

Taking the next step and extending this solution to the case of a reacting laminar jet is more difficult because of the following reasons:

- Constant density and viscosity should no longer be assumed.
- The species conservation equation will have a source/sink term.
- A species conservation equation will need to be employed for a minimum of three species (fuel, oxidizer, and product) and more than three species (e.g., fuel, O_2, N_2, CO_2, and H_2O) if increased accuracy is desired.
- Because the solution will be very sensitive to the transport properties, the Schmidt number should no longer be assumed equal to 1.0.
- An energy conservation equation must be included in the set of governing equations, and it will also include a source/sink term due to the chemical reactions.

However, a solution for a laminar jet diffusion flame has been developed (Turns, 2000) from which Figure 10 was derived. This solution is highly simplified because only three species were considered and various other simplifying assumptions were made. Among the assumptions is that chemical kinetics are infinitely fast, such that the flame is an infinitesimally thin surface at which the fuel and oxidant disappear and the products appear. This is the "flame sheet approximation," which is somewhat analogous to the thin flame (flamelet) assumption used for premixed turbulent flames. The solution shown in Figure 10 demonstrates that the fuel and oxidant disappear at the flame front (see Figure 10c) and that the "product" is formed at the flame front and diffuses away in both directions.

Figure 10 presents an illustration of this simple type of laminar diffusion flame: a laminar gaseous fuel jet issuing from a nozzle into quiescent ambient air. This illustrates a few essential features of mixing-controlled combustion. The type of diffusion flame shown in Figure 10 is highly idealized relative to actual diesel combustion, but is representative of the type of combustion that can occur in a diesel engine in a fuel jet issuing from an orifice of a fuel injector during the fuel injection phase of combustion. (See Diesel and Diesel LTC Combustion and Dec, 1997, for detailed discussion of combustion in diesels.) The flame will be located along the stoichiometric contour that is shown in Figure 9. Fuel diffuses radially away from the jet centerline to the flame front while the oxidizer diffuses in the opposite direction from the ambient gas to the flame front.

To proceed further and develop a simulation of a turbulent diffusion flame, the question again arises as to how

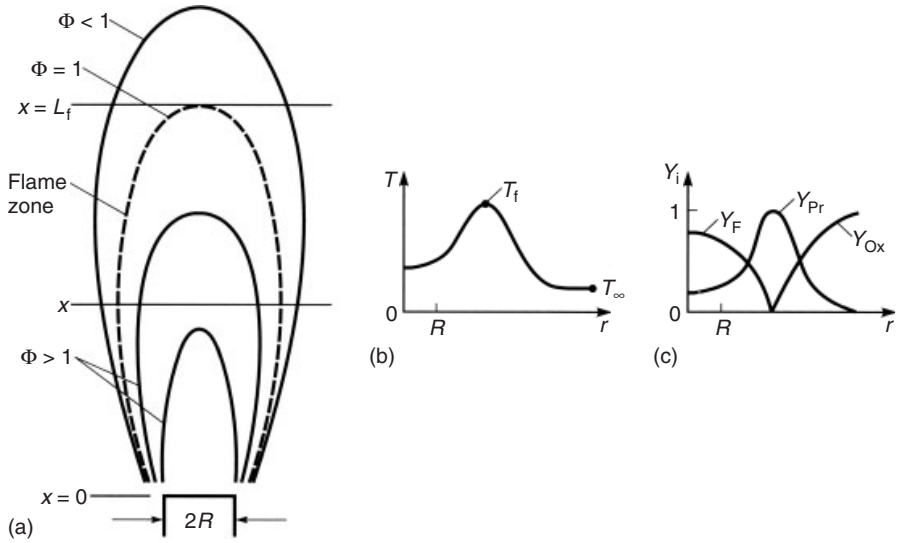

Figure 10. (a–c) Illustration of a simple laminar jet diffusion flame with a gaseous fuel. (Reproduced with permission from S.R. Turns, *An Introduction to Combustion* (Turns, 2000). © The McGraw-Hill Companies, Inc.)

the turbulence affects the combustion process. Turbulence increases the transport of momentum, species, and thermal energy and increases (wrinkles) the flame surface area (although for diffusion flames, unlike premixed flames, the flame surface area does not appear as an independent parameter). Again, various models have been developed to account for wrinkling of diffusion flames and the other effects of turbulence. An example of a gaseous jet turbulent diffusion flame is provided in Figure 11, which shows the diffusion flame location at various instants in time superimposed on top of each other and the minimum and maximum extent of the diffusion flame.

Here, it should be noted that the diesel-type diffusion combustion process is also complicated by several other factors that include the injected fuel being a liquid rather than a gas, the surrounding air being not only not quiescent but also a turbulent flowfield with potentially high velocities, and the process being transient rather than a steady state diffusion flame. Further discussions of the details of diesel combustion are provided in Diesel and Diesel LTC Combustion along with conceptual models for diesel combustion as it occurs in an engine.

It should also be noted that mixing-controlled combustion can play a role in hydrocarbon emissions from SI engines. These emissions are primarily due to fuel that emerges after peak pressure from places it collected during the engine cycle, such as deposits, oil layers, and—especially—crevices. This unburned fuel emerges when the cylinder pressure falls sufficiently low during the expansion stroke, and/or during "exhaust blowdown," and/or during the exhaust stroke. Whether this protected fuel eventually completely or partially oxidizes or does not react at all depends upon mixing with the hot products of combustion before they cool too much. Liquid fuel films on the cylinder walls, cylinder head, and top of the piston in port-injected SI engines, direct injected SI engines, and diesels can also produce mixing controlled combustion, leading to both hydrocarbon and soot emissions.

4 VOLUMETRIC ENERGY RELEASE

Volumetric energy release refers to a mode of combustion that differs significantly from the three modes introduced in the previous sections (premixed, diffusion, and well stirred). In this mode of combustion, reactants reach temperature, pressure, and mixture conditions that enable a spontaneous rapid oxidation process, basically an autoignition process. Examples of autoignition volumetric combustion include knock in SI engines, the ignition and premixed burn process in diesel engines, and the combustion process in high efficiency engines under development that employ various forms of low temperature combustion (LTC) [e.g., HCCI, controlled autoignition (CAI), and premixed charge compression ignition (PCCI)]. The volumetric energy release mode of combustion is dominated by chemical kinetic reaction rates. For high reactivity fuels (high Cetane number or low Octane number), the autoignition typically occurs in two stages. The first stage is initiated and controlled by low-to-intermediate temperature ($<$1000 K) hydrocarbon oxidation chemistry. During this stage, fuel is partially broken down and energy is released. This first stage helps raise the temperature toward approximately 1000 K, at which point "high temperature kinetics" kicks in and dominates the second stage of ignition. The ignition process rapidly progresses from here to a high heat release phase. For low reactivity fuels (high Octane number and low Cetane number), the low-to-intermediate temperature oxidation chemistry first stage of ignition is either not present or not nearly as significant for many relevant conditions. In this case, the ignition process takes longer for the same conditions and progresses directly into the high temperature kinetics phase when temperatures reach approximately 1000 K. Ignition processes and relevant chemical kinetics are discussed in detail in Fundamental Chemical Kinetics.

Knock in SI engines can be used as an example of this combustion mode. As the flame in a SI engine propagates away from the spark plug, the burned mixture behind the flame has a much higher temperature than the unburned mixture in front of the flame. Since both the burned and unburned mixtures can be treated as mixtures of ideal gases, they can be described by the ideal gas equation of state. Thus, the high temperature in the burned volume increases the pressure in the burned zone. This produces a pressure wave that propagates at the speed of sound, which is much faster than the turbulent flame speed. Therefore, the pressure increases throughout the combustion chamber essentially uniformly. This combustion-induced increase in pressure of the unburned "end gases" (the reactive mixture ahead of the flame front), together with the increase in pressure resulting from the upward motion of the piston, increases the temperature of the end gases. Because the rate of chemical reaction of the end gases generally increases strongly with increasing temperature, if the ignition delay time of the end gases (the time required for the reactions to reach an energy liberating phase, which is a function of the fuel type, the mixture composition, and the temperature history of the end gases) is less than the time required for the flame to reach the farthest point in the combustion chamber (which is primarily a function of engine design and engine speed), autoignition will occur in the unburned gases. Owing to inhomogeneities, all of the end gas does not autoignite simultaneously, but nearly so. This results in more-or-less a volumetric release and an energy release rate that can be much higher than for the normal flame propagation process. If sufficient energy is released during the autoignition reactions, a strong acoustic wave is developed, which reverberates in the combustion chamber yielding the audible sound that is called *knock*. Because knock can rapidly damage an SI engine, avoidance of knock is one of the primary factors limiting the design of SI engines.

In short, knock is the result of a "horse race" between the residence time of the unburned mixture ahead of the flame and the autoignition delay time. Knock is most likely to occur for conditions that either promote the reactivity of the unburned mixture (i.e., decrease the autoignition delay time) or decrease the flame propagation rate (i.e., increase the end gas residence time).

It has been shown that knock in SI engines is a result of low-to-intermediate temperature reactions involving alkanes, especially long straight chain alkanes (Cernansky *et al*., 1986; Westbrook, Pitz, and Leppard, 1991; Westbrook and Pitz, 1991, 1993; Leppard, 1992; Chevalier *et al*., 1992; Curran *et al*., 1995, 1996; Roberts, Matthews, and Leppard, 1996), with other hydrocarbon species essentially "soaking up" energy and/or active radicals.

The same kinds of reactions and chemical species are responsible for the autoignition process in diesel engines. In the case of diesels, the autoignition process is a more readily apparent two-stage ignition process, as previously described, that results from the autoignition characteristics of diesel fuel—a low reactivity fuel compared to gasoline.

For LTC approaches, much if not all of the cylinder undergoes volumetric energy release. To successfully achieve HCCI one must get the fuel vaporized and partially premixed with air prior to the autoignition chemistry reaching the point of autoignition. Gasoline vaporizes easily but does not autoignite easily whereas diesel fuel vaporizes slowly but autoignites easily. Based on the very different autoignition and vaporization characteristics of gasoline and diesel fuel, two very different overall approaches to LTC have arisen and are often referred to as HCCI [or gasoline compression ignition (GCI)] and

diesel LTC. Ideally, for GCI a premixed charge of gasoline and air is inducted into an engine with a sufficiently high compression ratio to allow the entire cylinder contents to autoignite in rapid succession. However, to prevent the rate of pressure rise from being too excessive (leading to engine damage, similar to engine knock), the mixture is rarely truly homogeneous as the name HCCI implies. Stratification of the fuel–air mixture and of the temperature can be used to help slow the rate of progression of the combustion and broaden the load range capability of HCCI. In addition, charge dilution with excess air or EGR is used to slow down and spread out the heat release rate. Development of practical means of controlling the heat release rates and time of autoignition are primary development challenges for HCCI engines.

In the case of diesel LTC, there are two typical pathways (e.g., Dec, 2009) used. One is to inject the diesel fuel very early to allow time for vaporization and mixing of this low volatility fuel, but the ignition delay—which is inherently short for high Cetane fuels—must be stretched out via the relatively low oxygen concentration associated with high EGR rates. The EGR must also be aggressively cooled to further increase the delay in autoignition. Decreased compression ratio and late intake valve closing (which decreases the effective compression ratio while maintaining the expansion ratio) have also been used to increase the autoignition delay. High emissions of unburned hydrocarbons due to spray overpenetration/wall wetting have been reported, and control of combustion phasing (e.g., the crank angle at which peak pressure occurs) as the engine speed and load change remains a challenge. The second pathway used to attain diesel LTC involves fuel injection near or after top-dead-center compression. This pathway to diesel LTC provides better control over combustion phasing but the autoignition delay must still be "stretched out" to allow sufficient time for fuel evaporation and mixing. This is again accomplished via high levels of EGR. However, in this case, some of the heat release at the end of combustion often still occurs via mixing controlled combustion. As a result, care must be taken to ensure that NO*x* and PM emissions are controlled to low levels without inducing excessive unburned hydrocarbon and CO emissions. These remain as research challenges.

In summary, LTC is, in essence, controlled knock (Foster, 2012). For all LTC approaches, some inhomogeneity or stratification is essential so that the entire mixture within the combustion chamber does not all autoignite simultaneously resulting in excessive heat release rates and, thereby, excessive pressure rise rates. Instead, conditions must be generated such that a few locations autoignite, releasing sufficient energy to induce other regions to autoignite, which then induce other regions to autoignite. Thus, rather than flame propagation, LTC seems to involve propagation of autoignition, but this is not fully understood as yet. The desired stratification may be due to inhomogeneity in mixture composition or temperature, which will control the degree to which the autoignition reactions progress locally toward the energy liberation phase. Control of ignition timing and heat release rates, extending the load range capability, and avoidance of conditions that generate high levels of various emissions remain challenges for achieving the brake-specific fuel consumption potential of LTC (Dec, 2009).

The interested reader is referred to Spark Ignition Combustion for further details on spark-ignition combustion and knock, to Diesel and Diesel LTC Combustion for details on diesel combustion and diesel LTC, and Advanced Compression-Ignition Combustion for Ultra-Low NO_x and Soot for details on advanced gasoline compression ignition forms of LTC (e.g., HCCI).

5 MIXED COMBUSTION MODES

Engines have mixed modes of combustion more often than not. A few brief examples may be illustrative. Combustion in a SI engine is a premixed flame propagation process in which preflame reactions will occur in the end gases as already discussed, possibly progressing to the energy-liberating stage called *knock* (volumetric energy release). In addition, as already discussed, under the right conditions the fuel/air mixture that is hidden from the combustion process in crevices and deposits can emerge after peak pressure during the expansion stroke where it can become involved in a diffusion oxidation process—related to but probably not a diffusion flame. This is because the chain of reactions will not have sufficient time to reach an energy-liberating stage before exhaust valve opening with the consequent sudden decrease in pressure and temperature that will freeze the reactions. Another mixed combustion mode that can occur in both port-injected and direct-injected gasoline engines is due to "wall films"—films of liquid gasoline on the cylinder walls, piston top, and/or cylinder head. The flame can pass over such wall films without consuming them because the rate of evaporation is controlled by the surface temperature rather than by the gas temperature. As the wall film evaporates, it can take part in a diffusion-controlled combustion process that resembles a pool fire. The pool fires lead to emissions of particulate matter, and evaporation of the remaining wall film too late in the cycle produces hydrocarbon emission problems (e.g., Stanglmaier, Li, and Matthews, 1999; Li *et al*., 1999, 2000, 2001; Huang, Matthews, and Ellzey, 2001a; Huang

et al., 2001b, Alger *et al*., 2001; Steeper and Stevens, 2000; Stevens and Steeper, 2001; Warey *et al*., 2002).

Combustion in diesel engines occurs in multiple phases after autoignition. The first is dominated by a rapid volumetric energy release referred to as the *premixed combustion phase*. This is followed next by a quasi-steady very rich premixed flame embedded within a turbulent diffusion flame, which in turn is located in the vicinity of the mean stoichiometric mixture region zone surrounding the fuel jet for the remainder of the injection event (see Diesel and Diesel LTC Combustion and Dec 1997). After the end of fuel injection, mixing controlled combustion continues as pockets of fuel and air mix and burnout in the final stages of diesel combustion. If fuel during injection impinges and collects on walls, pool fires similar to those already discussed for gasoline engines can occur.

The diesel-fueled LTC combustion process briefly introduced in the previous section is dominated by a staged volumetric energy release process followed, in the last stage of combustion, by mixing controlled combustion of rich regions. Another recent approach to LTC is reactivity-controlled compression ignition (RCCI), in which a low reactivity fuel, such as gasoline, is port-injected to yield a nearly homogeneous charge while a more reactive fuel, such as diesel, is direct-injected to provide control over the combustion "phasing" (e.g., Inagaki *et al*., 2006; Kokjohn *et al*., 2009). In RCCI, the ignition process, which is controlled by the more reactive fuel, starts a volumetric energy release process, which is followed by a currently unknown but likely combination of volumetric energy release and premixed flame propagation through the mixture of the less reactive fuel with air (Kokjohn *et al*., 2011).

Solving Combustion Chemistry in Engine Simulations

Norbert Peters and Heinz Pitsch
RWTH Aachen University, Aachen, Germany

1 INTRODUCTION

Combustion in engines depends critically on the appropriate choice of the fuel to be used—its chemical and physical properties as well as its availability, sustainability, and cost. Under these limiting conditions, liquid hydrocarbons derived from fossil fuels will continue to play a major role for the foreseeable future. However, readily available biofuels such as ethanol must also be considered as an alternative. Especially, blends of different fuels will gain importance for fuel-flexible engine operation in the future. The tendency to auto-ignite is an inherent property of all long-chain hydrocarbons or oxygenated fuels under high pressure and temperature conditions, as they occur in engines. When it occurs as an undesired event in the end gas of spark-ignition (SI) engines, it may lead to engine knock and may damage the engine. In diesel (or compression-ignition, CI) engines, auto-ignition is desired, as it occurs at a well-controlled time delay after injection to initiate the combustion process. SI engines, in order to avoid engine knock, are operated with high octane number (ON) fuels. The ON (defined as the percentage of isooctane in a mixture of isooctane and *n*-heptane that has in a reference experiment the same auto-ignition characteristics as the considered fuel) characterizes the auto-ignition behavior of gasoline fuels, such that low ON fuels are readily ignitable and high ON fuels are difficult to ignite. For CI engines, the desired auto-ignition properties are quite different. Ignition properties of diesel fuels are characterized by the cetane number (CN). A high CN (defined as the percentage of normal cetane in a mixture of normal cetane and isocetane that has in a reference experiment the same auto-ignition characteristics as the considered fuel) stands for a fuel that is easily ignitable (short ignition delay time), whereas a low CN characterizes a fuel with a long ignition delay time. *N*-Heptane, for instance, has a CN of 56, which is close to that of diesel fuel.

As it is impossible to represent the chemical composition of commercial fuels in their full complexity, surrogate fuels containing only a few chemical components are often used in numerical simulations. These components are chosen by their ability to reproduce the performance of the commercial fuel with respect to ignition, combustion, and pollutant formation, provided that a detailed chemical kinetics are available for them. A simple example for SI engines is primary reference fuels (PRF), which are a binary blend of *n*-heptane and isooctane. On the basis of such a surrogate fuel, for example, the laminar burning velocity—needed for the prediction of turbulent combustion in gasoline engines—can be calculated. Another example to be shown later is the use of *n*-heptane as a diesel surrogate for

ISBN: 978-0-470-97402-5

the prediction of auto-ignition, combustion, and pollutant formation in a CI engine. The short ignition delay time of *n*-heptane is due to a particular group of reactions active at low temperatures. Those reactions will be discussed in detail later.

The chapter is outlined as follows: at first, one-step global kinetics are introduced and the resulting ignition delay time and thermal runaway is illustrated. This serves as a basis for a critical discussion of the Livengood–Wu integral, which is often used for the prediction of auto-ignition in engines. Then, as an example for elementary kinetics, the low temperature part of an *n*-heptane mechanism is presented. It is reduced to a four-step mechanism, from which the low temperature ignition delay time can be calculated analytically.

Chemical effects that appear in models for SI-engines are discussed next. While detailed chemistry has been used in models for the sparking process only recently, it enters into combustion models for turbulent flame propagation, such as the extended coherent flame model (ECFM) and the G-equation model, through the way it determines the laminar burning velocity. Chemical effects are also responsible for engine knock and preignition events leading to "super-knock" in super-charged SI engines.

In diesel or CI engines, chemistry plays a crucial role at all stages: auto-ignition at the premixed stage, combustion at the nonpremixed, diffusion-controlled stage, and finally, for pollutant formation. As an example of combustion and pollutant formation in a CI engine, an early application of the flamelet model is presented.

2 ONE-STEP GLOBAL KINETICS: AUTO-IGNITION

As mentioned in the previous section, auto-ignition is a desired and necessary step in CI engines, where it initiates combustion after the fuel has been injected into the compressed high temperature air (with or without exhaust gas recirculation, EGR), and it is an undesired side effect in SI engines, where it may occur in the yet unreacted mixture ahead of the propagating premixed flame front potentially leading to engine knock. Auto-ignition before spark timing is called *preignition* and may even lead to the so-called super-knock events that may damage the engine and must be avoided.

The chemical process of auto-ignition in engines may best be understood by considering a homogeneous charge in an adiabatic system at variable volume. Using a one-step reaction

$$\text{Fuel} + \text{Oxygen} \rightarrow \text{Products} \qquad (1)$$

one may assume a first-order reaction with respect to the fuel to one obtain the reaction rate

$$\omega = B\left(\frac{\rho Y_F}{W_F}\right)\left(\frac{\rho Y_{O_2}}{W_{O_2}}\right)\exp\left(-\frac{E}{\mathcal{R}T}\right) \qquad (2)$$

Here, B is the frequency factor, ρ the density, and Y_i and W_i the mass fractions and the molecular weights of fuel and oxygen, respectively. The temperature (in degrees Kelvin) is denoted by T, $\mathcal{R}$ is the universal gas constant, and E the activation energy. Assuming this rate expression, the frequency factor B and the activation energy E are adjustable constants for a given fuel. For instance, using auto-ignition measurements in a counterflow configuration over a liquid surface, Seshadri, Humer, and Seiser, 2008 have deduced activation temperatures $T_a = E/\mathcal{R}$ for pure fuels, but also for jet and diesel fuels (Table 1). As auto-ignition under these conditions is governed by high temperature kinetics, these numbers are valid only if the initial temperature exceeds a value of typically 1000 K.

For illustration, we will first discuss the case of homogeneous combustion in a constant volume combustion chamber assuming adiabatic conditions, for simplicity. For the case of a homogeneous mixture having at $t = 0$ the temperature T_0, the temperature will increase at first slowly, then rapidly, if the assumed one-step reaction is exothermic. This is called *thermal runaway*. As the activation temperature is much larger than the initial temperature T_0, the exponential term is dominating in the rate expression in Equation 2 showing that the rate is very sensitive to temperature changes. To simplify the analysis, one may, therefore, only retain the effect of temperature changes and neglect the consumption of the reactants during the time of thermal

Table 1. Activation temperatures and frequency factors obtained from auto-ignition measurements in stagnation point flows.

Fuel	Chemical symbol	$T_a\,[K]$	$B\,[m^3/(mol \cdot s)]$
n-Heptane	C_7H_{16}	25 800	4.65×10^{10}
n-Octane	C_8H_{18}	19 500	1.66×10^{8}
n-Decane	$C_{10}H_{22}$	15 300	3.08×10^{6}
n-Dodecane	$C_{12}H_{26}$	15 200	2.68×10^{6}
n-Hexadecane	$C_{16}H_{36}$	14 800	1.77×10^{6}
isooctane	C_8H_{18}	30 600	2.18×10^{12}
Cyclohexane	C_6H_{12}	28 500	7.48×10^{11}
Methylcyclohexane	C_7H_{14}	29 000	5.79×10^{11}
o-Xylene	C_8H_{10}	28 000	8.95×10^{10}
JP-10	$C_{10}H_{16}$	26 000	4.63×10^{10}
JP-08	$C_{11}H_{21}$	29 600	6.08×10^{11}
Diesel	$C_{14.7}H_{26.8}$	25 000	6.57×10^{9}

runaway. For a variable volume chamber, setting the mass fractions of the fuel and the oxidizer equal to their initial values $Y_{F,0}$ and $Y_{O_2,0}$, one obtains the temperature equation as

$$\rho\, c_v \frac{dT}{dt} = \frac{p}{V}\frac{dV}{dt} + Q_v B \frac{\rho Y_{F,0}}{W_F}\frac{\rho Y_{O_2,0}}{W_{O_2}} \exp\left(-\frac{E}{\mathcal{R}T}\right) \quad (3)$$

where p is the pressure. The volume of the vessel changes with time as $V(t)$. The heat capacity c_v and the heat of reaction Q_v at constant volume are assumed constant and will be evaluated at the initial condition $T = T_0$. In the case of a constant volume explosion, the density is also constant and the first term on the r.h.s. vanishes. This case will be considered first.

Using the method of large activation energy asymptotics (Peters, 1992), p. 55), Equation 3 can be solved analytically for the case $dV/dt = 0$ to obtain the temperature as a function of time

$$T = T_0 - \frac{\mathcal{R}T_0^2}{E}\ln\left(1 - \frac{t}{t_I}\right) \quad (4)$$

This equation shows that T tends to infinity when t approaches t_I, thus illustrating the thermal runaway. The ignition delay time t_I, defined as the time at which thermal runaway occurs in the adiabatic constant volume vessel, is then determined as

$$t_I = \frac{\mathcal{R}T_0^2}{E}\frac{c_v}{\rho_0 Q_v B}\frac{W_F W_{O_2}}{Y_{F,0}Y_{O_2,0}} \exp\left(\frac{E}{\mathcal{R}T_0}\right) \quad (5)$$

It is noteworthy that in a plot of the logarithm of t_I over $1/T_0$, the so-called Arrhenius diagram, one obtains a nearly straight line with a positive slope equal to the activation temperature $T_a = E/\mathcal{R}$. Values for T_a and frequency factors B are given in Table 1 for different fuels.

During the compression stroke in an engine, the background temperature changes continuously. Thermal runaway is then an effect superimposed on this varying background temperature. A popular procedure to estimate the ignition time t_{ign} resulting from both the background temperature change and the thermal runaway is the use of the Livengood–Wu integral (Livengood and Wu, 1955) defined by

$$\int_0^{t_{ign}} \frac{1}{\tau(T(t), p(t))}\, dt = 1 \quad (6)$$

where $\tau(T(t), p(t))$ is the homogeneous ignition delay time evaluated at temperature $T(t)$ and pressure $p(t)$, and $T(t)$ and $p(t)$ are the in-cylinder temperature and pressure at time t considering the background compression. The auto-ignition delay time at different initial temperatures can be evaluated from detailed chemical kinetics, but will in the following, for illustration purposes, be taken from the analytic solution, Equation 5.

A correct prediction of homogeneous auto-ignition with changes of the background temperature because of compression would have to include the unsteady change of volume dV/dt in the temperature Equation 3. To illustrate this, we have performed such a simulation using a simple kinematic piston displacement model for a supercharged SI engine with a compression ratio of 12, a stroke of 94.6 mm, a bore of 86 mm, and a connecting rod of 152.2 mm. The intake temperature was 107 °C and the intake pressure was 2 bar. Global low temperature kinetics for *n*-heptane were used with $B = 1.86 \cdot 10^{11}$ m^3/(mol s), $E/\mathcal{R} = 22\,732$ K, and

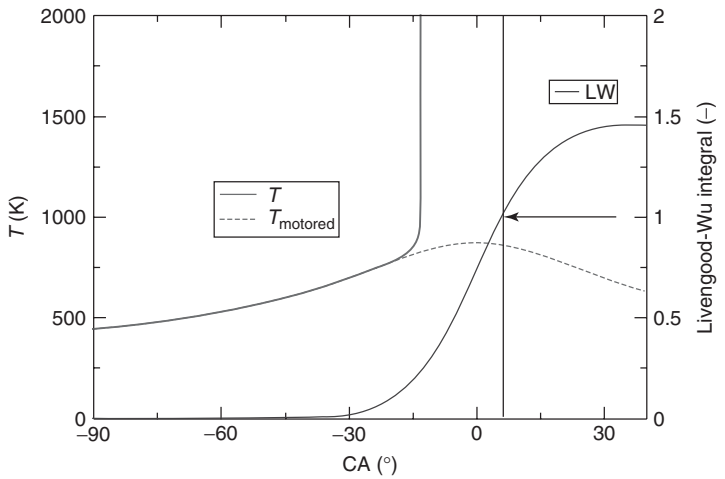

Figure 1. Illustration of auto-ignition calculated from Equation 3 and from the Livengood–Wu integral and the solution of Equation 3.

$Q_v/c_v = 4824$ K kg/kmol. The thermal equation of state with the molecular weight of air was used.

The temperature of the simulation is shown in Figure 1 for motored conditions and for the case of homogeneous auto-ignition calculated numerically from Equation 3 at 3000 rpm. As the source term in Equation 3 is not limited at equilibrium conditions, the temperature increases without limit, just as in Equation 4. In addition, the Livengood–Wu integral evaluated with t_I from Equation 5 is shown, thereby considering only the background temperature changes. The time (in terms of deg. CA) when it crosses unity corresponds then to this prediction of auto-ignition. There is a noticeable difference between the two calculations illustrating the limitations in using the Livengood–Wu integral without considering thermal runaway.

3 DETAILED CHEMICAL KINETICS, THEIR REDUCTION AND TABULATION

Detailed chemical mechanisms for transportation fuel surrogates have been developed in the past. However, these mechanisms often consist of many thousands of elementary reactions and species, and are, therefore, impractical for engine simulations. Starting from an early account (Peters and Rogg, 1993) on how to reduce detailed chemical mechanisms in combustion by steady-state analysis, many groups have proposed reduction procedures (Pepiot-Desjardins and Pitsch, 2008; Lu and Law, 2006; Zeuch *et al.*, 2008; Løvås, 2009; Sun *et al.*, 2010; Lu, Ju, and Law, 2001; Lu and Law, 2006). As even reduced mechanisms often still contain too many chemical species and reactions, a further step to reduce the computational effort is to tabulate the resulting chemical source terms. An algorithm called in situ adaptive tabulation (ISAT) was developed in the context of transported probability density function (PDF) methods (Pope, 1997). As those methods are in general too expensive to be used in engine calculations, more specific tabulations have been proposed (Jay and Colin, 2011; Mittal and Pitsch, 2013).

For the example of *n*-heptane (C_7H_{16}, denoted as F), which often serves as a surrogate fuel for auto-ignition and combustion in diesel engines, we show in Table 2, taken from Ref. (Peters *et al.*, 2002), those reactions that are rate determining for the low temperature and the high temperature branch of auto-ignition. Calculated ignition delay times are shown in Figure 2 for several pressures in an Arrhenius diagram. The low temperature branch (on the right) and the high temperature branch (on the left) have a positive slope in this diagram. The intermediate branch is the so-called negative temperature coefficient (NTC) branch typical for diesel fuels. In an engine, the background pressure changes because of compression, as low temperature auto-ignition chemistry is occurring. This will impact the prediction of the auto-ignition time as discussed earlier. However, the general principles of mechanism reduction, as demonstrated in the following, will remain valid.

Assuming steady state (thus, canceling the species when adding two reactions) of the heptyl radical C_7H_{15} (denoted as R), we obtain by adding reaction 1 to reaction 4

$$\text{(I)}\quad \mathrm{F} + 2\mathrm{O_2} = \mathrm{RO_2} + \mathrm{HO_2} \tag{7}$$

where the heptyl peroxide radical $C_7H_{15}O_2$ is denoted by RO_2. Similarly, adding reaction 3 to reaction 4, we obtain

$$\text{(II)}\quad \mathrm{F} + \mathrm{OH} + \mathrm{O_2} = \mathrm{RO_2} + \mathrm{H_2O} \tag{8}$$

Table 2. The most important reactions for low temperature auto-ignition of *n*-heptane (C_7H_{16}).

Number	Reaction						
1	C_7H_{16}	+	O_2	→	C_7H_{15}	+	HO_2
2	C_7H_{16}	+	HO_2	→	C_7H_{15}	+	H_2O_2
3	C_7H_{16}	+	OH	→	C_7H_{15}	+	H_2O
4	C_7H_{15}	+	O_2	→	$C_7H_{15}O_2$		
5	$C_7H_{15}O_2$			→	$C_7H_{14}O_2H$		
6	$C_7H_{14}O_2H$	+	O_2	→	$O_2C_7H_{14}O_2H$		
7	$O_2C_7H_{14}O_2H$			→	$HO_2C_7H_{13}O_2H$		
8	$HO_2C_7H_{13}O_2H$			→	$OC_7H_{13}O_2H$	+	OH
9	$OC_7H_{13}O_2H$			→	$OC_7H_{13}O$	+	OH
10	$OC_7H_{13}O$			→	CH_2O	+	$C_5H_{11} + CO$
11	C_5H_{11}			→	C_2H_4	+	C_3H_7
12	C_3H_7	+	O_2	→	C_3H_6	+	HO_2
13	$2HO_2$			→	H_2O_2	+	O_2
14	H_2O_2	+	(M)	→	2OH	+	(M)

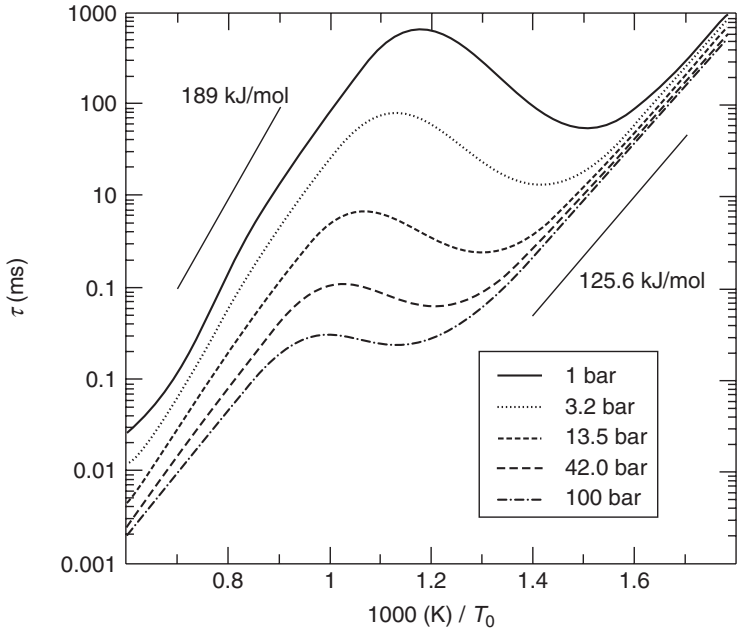

Figure 2. Ignition delay time of *n*-heptane as a function of the initial temperature T_0.

If we, furthermore, assume steady state for all intermediates up to ketohydroperoxide $OC_7H_{13}O_2H$ (denoted as KET), we obtain by adding reactions 5–8

$$\text{(III)}\quad RO_2 + O_2 = \text{KET} + OH \tag{9}$$

Finally, by adding reactions 9–12, we obtain by the same procedure

$$\text{(IV)}\quad \text{KET} + O_2 = P + OH + HO_2 \tag{10}$$

where P is the sum of the stable species CH_2O, CO, C_2H_4, and C_3H_6.

The four-step global mechanism I–IV illustrates the low temperature chain branching mechanism: by oxygen addition to the fuel, two OH radicals are formed in reactions III and IV, whereas only one OH radical is consumed in reaction II. The mechanism may be used to determine the low temperature ignition delay time, t_1, analytically (Peters *et al.*, 2002)

$$t_1 = \frac{\ln\,(Y_F/\varepsilon)}{(k_5(T)k_9(T))^{1/2}} \tag{11}$$

Here, Y_F is the mass fraction of the fuel and $k_5(T)$ and $k_9(T)$ the reaction rate coefficients (in s^{-1}) of reactions 5 and 9 as a function of temperature, respectively, and ε is proportional to the ratio of the reaction rate of reaction 1 to the rate coefficient of reaction 9

$$\varepsilon = \frac{k_1(T)Y_{O_2}}{k_9(T)} \tag{12}$$

In a similar way, the ignition delay time of the high temperature branch shown in Figure 2 may be determined analytically. Here, only the reactions 2, 13, and 14 are rate determining, as shown in Peters *et al.*, (2002). From these analytic solutions, the activation energies of the two branches are determined and are shown in Figure 2. The corresponding activation energies 125.6 and 189 kJ/kmol may be converted into activation temperatures as 15 179 and 22 732 K. The latter is to be compared to the value of 25 800 K (valid for the high temperature branch) given in Table 1.

4 CHEMICAL EFFECTS IN SI ENGINES

As a simple model for SI, heat deposition by the electrical spark may be modeled as a localized region of very high temperature. As the heat diffuses out, it forces the formation of radicals, which then initiate a self-sustained laminar, later turbulent premixed flame. Early examples for modeling SI are the Arc-and-Kernel tracking ignition model (AKTIM) (Duclos and Colin, 2001; Colin, Benkenida, and Angelberger, 2003) and the discrete particle ignition kernel (DPIK) model (Tan and Reitz, 2006). Chemistry enters into

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto116
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

these models through an expression for the laminar burning velocity.

A more detailed model that uses elementary chemistry is the spark channel ignition monitoring (Spark CIMM) model (Dahms *et al*., 2009). Here, the stratified mixture close to the spray in a direct-injection gasoline engine is monitored during the spark duration by tracing ignition kernels arising from the spark using fictitious particles that can lead to the formation of quasi-laminar flame kernels. Auto-ignition is modeled by adding a spark energy deposition source term to the unsteady flamelet equations, which consider the detailed ignition and combustion chemistry, as will be discussed later.

The early flame kernel development occurring after SI is typically modeled by spherical flame propagation. The turbulent flame that develops thereafter can be modeled, for instance, by the G-equation model (Peters, 1999; Dekana and Peters, 1999; Tan and Reitz, 2003; Tan, Kong, and Reitz, 2003) or the ECFM (Colin, Benkenida, and Angelberger, 2003; Candel and Poinsot, 1990; Duclos and Zolver, 1998). From the G-equation model, the turbulent burning velocity s_T was derived by Peters (1999) and can be written as Peters (2000)

$$s_T = s_L + v' \cdot [-\alpha\,\mathrm{Da} + \sqrt{(\alpha\,\mathrm{Da})^2 + 4\alpha\,\mathrm{Da}}\,] \qquad (13)$$

where $\alpha = 0.195$ and $\mathrm{Da} = s_L l/(v' l_F)$. This equation shows that in addition to the turbulence intensity v' and the integral length scale l, also the laminar burning velocity s_L and the flame thickness l_F enter into the expression. Therefore, approximations or tabulations of the laminar burning velocity and of the laminar flame thickness are needed as a function of initial temperature, pressure, and equivalence ratio. They can be constructed for gasoline fuels fairly easily on the basis of elementary reaction mechanisms, which are available for surrogate fuels.

A more controversial subject in SI-engine simulations is the prediction of engine knock. While Colin, Benkenida, and Angelberger (2003) considered the time evolution of a fictitious species with a source term based on a correlation with the ignition delay time τ_I, Bradley and Kalghatgi (2009), Kalghatgi and Bradley (2012), and Peters, Kerschgens, and Paczko (2013) based their prediction on the Livengood–Wu integral (1955) discussed earlier. Here, approximations of ignition delay times of surrogate fuels for gasoline were used. Furthermore, in Peters, Kerschgens, and Paczko (2013), a framework was developed for the prediction of the probability for a localized detonation, which leads to "super-knock" (Kalghatgi and Bradley, 2012). The prediction is based on a combination of the detonation diagram proposed in Bradley et al., (2002) and Gu, Emerson, and Bradley, 2003) with a refined theory of turbulence (Wang and Peters, 2006, 2008). Here, approximated ignition delay times for PRF surrogates are used, but also their derivative with respect to the temperature is needed.

5 CHEMICAL EFFECTS IN CI ENGINES

Owing to the different combustion process in CI engines as compared to SI engines, the influence of chemical kinetics becomes even more important. In CI engines, the diesel fuel is injected directly as a liquid spray into a hot environment composed of compressed air with or without recirculated exhaust gas. Atomization and evaporation occurs very rapidly resulting in a highly stratified mixture of gaseous fuel and oxidizer with local fuel–air equivalence ratios ranging from very lean to very rich mixtures. The part of that mixture, which is within the flammability limits, then auto-ignites first. This is called the *premixed burn stage* and is associated with a large heat release rate. The remaining part of the mixture burns in the following in a nonpremixed, diffusion-controlled stage. During this stage, soot is formed in the rich part of the mixture. As mixing with the surrounding oxidizer continues, most of the soot is oxidized, whereas NO_x is formed in the lean to stoichiometric part of the mixture as the temperature increases.

There are several models used nowadays for the computational fluid dynamics (CFD) modeling of ignition, combustion, and pollutant formation in CI engines based on detailed chemistry. Direct integration of the chemistry at every grid point of the mesh based on the mean values of all scalar variables may appear the most straightforward, although it ignores all scalar fluctuations and turbulence closure. Other models are the characteristic time (CTC) and the representative interactive flamelet (RIF) model. The CTC model (Kong, Han, and Reitz, 1995) is a local exchange model where the change of the mass fraction Y_i is modeled as

$$\frac{\mathrm{d}Y_i}{\mathrm{d}t} = -\frac{Y_i - Y_i^*}{\tau_L} \qquad (14)$$

Here, Y_i^* is the local and instantaneous thermodynamic equilibrium value of mass fraction Y_i and τ_L the CTC to achieve such equilibrium (Kong, Han, and Reitz, 1995). The CTC τ_L is the sum of a laminar timescale derived from a global reaction rate and a turbulent timescale that is proportional to the integral timescale of turbulence. The RIF model will be presented in more detail later.

Singh, Reitz, and Musculus (2006) have compared the direct integration, the CTC, and the RIF models. Depending

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto116
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

on the engine operation point, the heat release rates predicted by the three models differ in time (in terms of deg. CA) and their peak value, but no specific trend could be deduced. While the implementation of detailed chemistry by direct integration is probably the most expensive, the CTC and the RIF models solve chemistry "on the fly."

The RIF model uses a flamelet code (cf. Figure 3), where the mixture fraction Z is the independent variable. This is defined as m_1, the mass of the fuel (subscript 1), divided by the mass of fuel and oxidizer (subscript 2)

$$Z = \frac{m_1}{m_1 + m_2} \tag{15}$$

Denoting stoichiometric mixture fraction as Z_{st}, fuel is deficient and the mixture is called *fuel lean* for $Z < Z_{st}$. Similarly, if $Z > Z_{st}$, oxygen is deficient and the mixture is called *fuel rich*. There is a unique relation between Z and the local fuel-to-air equivalence ratio ϕ

$$\phi = \frac{Z}{1-Z}\frac{(1-Z_{st})}{Z_{st}} \tag{16}$$

The flamelet model is based on the assumption of a thin reaction zone. Then, the flamelet structure is to leading order described by the one-dimensional time-dependent equations

$$\begin{aligned} \rho\frac{\partial T}{\partial t} - \rho\frac{\chi_{st}}{2}\frac{\partial^2 T}{\partial Z^2} &= \sum_{i=1}^{n}\frac{h_i}{c_p}\omega_i + \frac{\dot{q}_R}{c_p} + \frac{1}{c_p}\frac{\partial p}{\partial t} \\ \rho\frac{\partial Y_i}{\partial t} - \rho\frac{\chi_{st}}{2}\frac{\partial Y_i}{\partial Z^2} &= \dot{\omega}_i \quad i = 1, 2, \ldots, k \end{aligned} \tag{17}$$

Here, h_i is the specific enthalpy, ω_i the chemical source term of species i, c_p the heat capacity at constant pressure, and $\dot{q}_R$ the radiative heat loss. Furthermore,

$$\chi_{st} = 2D\left(\frac{\partial Z}{\partial x_\alpha}\right)^2_{st} \tag{18}$$

is the instantaneous scalar dissipation rate at stoichiometric conditions, where D is the thermal diffusivity and x_α are the spatial coordinates. It has the dimension $1/s$ and may be interpreted as the inverse of a CTC. It acts as a prescribed parameter in Equation 17, representing the influence of convection and diffusion normal to the surface of the stoichiometric mixture. In the limit $\chi_{st} \to 0$, the equations for a homogeneous reactor are obtained.

Models in nonpremixed turbulent combustion are often based on the presumed shape PDF approach. This requires the knowledge of the Favre mean mixture fraction $\tilde{Z}$ and its variance $\tilde{Z}''^2$ at each position $\mathbf{x}$ and time t. Then, a suitable

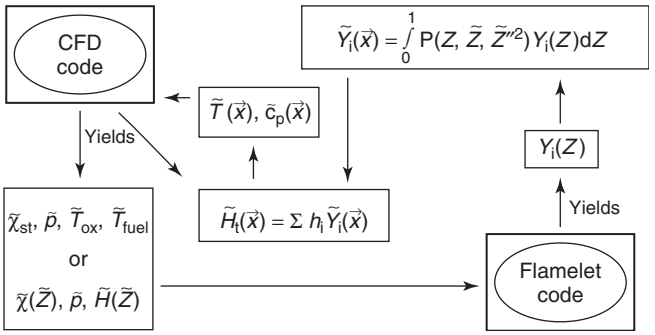

Figure 3. Code structure of the representative interactive flamelet concept.

two-parameter probability density function is "presumed" in advance, thereby fixing the functional form of the PDF by relating the two parameters in terms of the known values of $\tilde{Z}$ and $\tilde{Z}''^2$ at each point of the flow field. As in a two-feed system, the mixture fraction Z varies between $Z = 0$ and $Z = 1$; the beta function PDF is widely used for the function $P(Z, \tilde{Z}, \tilde{Z}''^2)$ referred to in Figure 3. More details about the beta function PDF are given in Peters (2000).

The solution of the flamelet equations provides the local flame structure in terms of species mass fractions as function of mixture fraction. Most importantly, this model allows for the use of detailed chemical kinetics, which is a prerequisite for accurate simulations of auto-ignition and pollutant formation. However, the solution of the flamelet equations requires further consideration. For stationary problems, the time dependence in these equations is often neglected. Then, the flamelet equations can be solved and the solutions can be tabulated as function of the governing parameters, in the standard formulation only the scalar dissipation rate. However, the time dependence of the flamelet equations becomes important in diesel engines, because ignition is a temporal process and because of the time-varying pressure and scalar dissipation rate. These parameters, therefore, have to be specified in the solution of the flamelet equations in a time-accurate manner from a CFD solution, which in itself requires the solution of the flamelet equations. In the RIF model, both CFD and flamelet equations are, therefore, solved simultaneously and interactively. The CFD solver then provides at each time step domain-averaged values of the flamelet parameters, stoichiometric scalar dissipation rate, and pressure; the solution of the flamelet equations together with the presumed PDF of mixture fraction provides the Favre-averaged density and mass fraction fields in the CFD domain (Peters, 2000; Barths, Pitsch, and Peters, 1999; Barths, Hasse, and Peters, 2000). The calculation procedure is schematically shown in Figure 3.

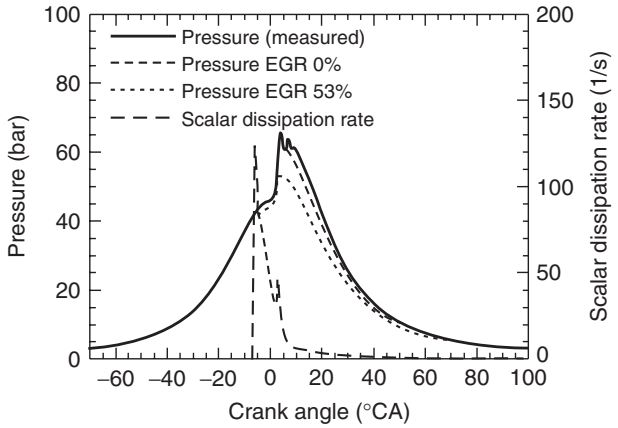

Figure 4. Calculated pressure compared with experiments for 0% EGR (From Pitsch, Barths, and Peters, 1996. Copyright © 1996 SAE International. Reprinted with permission.)

An early example of the application of the RIF model was presented by Barths, Pitsch, and Peters (1999), Pitsch, Barths, and Peters (1996), where it was used to predict ignition, soot, and NO_x, all with a detailed chemical kinetic model, for a Volkswagen DI 1.9l engine that was fueled with *n*-heptane and operated at varying levels of EGR. Exemplary results from the simulations are given in Figures 4 and 5 and show that ignition delay, pressure, NO_x, and soot are predicted with good accuracy. More recently, in an application by Cummins Inc., the RIF model has served as the central ingredient for the design process of modern CI engines (Eckerle and Stanton, 2006).

6 SUMMARY

In this chapter, we have given a few examples that show how global and elementary kinetics can be used in numerical combustion simulations of SI and CI engines. There are, of course, many details to be considered in order to make their implementation successful. However, by replacing commercial fuels by appropriate surrogates and by reducing the detailed kinetic models for these surrogates appropriately, CFD calculations can be performed within reasonable compute times. A further reduction comes from tabulating either source terms or properties such as ignition delay times and burning velocities. Thereby, one now is able to capture many of the effects for which chemistry is responsible in engine combustion.

NO_x Formation and Models

Craig T. Bowman

Stanford University, Stanford, CA, USA

1 INTRODUCTION

The principal nitrogen oxides emitted from automotive engines are nitric oxide (NO) and nitrogen dioxide, collectively referred to as NO_x. A variety of strategies for reducing nitrogen oxide emissions from these engines have been implemented in modern engines and include both in-cylinder strategies and after-treatment strategies. The focus of this chapter is on in-cylinder NO_x reduction; after-treatment strategies are the subject of Gas Aftertreatment Systems. The concepts underlying in-cylinder NO_x emissions by reduction may be understood in terms of the reaction mechanisms for the formation and removal of NO_x in the engine combustion process.

In the following sections, the current state of understanding of the gas-phase reaction mechanisms for nitrogen oxide chemistry in combustion processes is discussed. The discussion is separated into two parts—mechanisms for nitrogen oxide formation and mechanisms for nitrogen oxide removal—recognizing that in engine combustion processes these mechanisms may be coupled.

2 REACTION MECHANISMS FOR NITRIC OXIDE FORMATION

NO is the primary nitrogen oxide emitted from automotive engines. The principal route to NO formation in automotive engine combustion is oxidation of molecular nitrogen present in the combustion air or in the fuel (some natural gas contains up to 10% by volume of N_2). In addition, nitrogen-containing additives in the fuel can contribute to NO formation in the engine. NO may be formed from N_2 by three reaction mechanisms: (i) the thermal NO mechanism, (ii), the prompt NO mechanism, and (iii) the N_2O mechanism. In spark-ignition and compression ignition engines, the dominant NO formation process is the thermal mechanism. All three mechanisms are described in Sections 2.1–2.3. The mechanism for the formation of NO from nitrogen additives in the fuel is discussed in Section 4.

2.1 Thermal NO formation mechanism

Three reversible reactions comprise the thermal NO formation mechanism:

$$O + N_2 \rightleftharpoons NO + N \qquad \text{(R1)}$$

$$N + O_2 \rightleftharpoons NO + O \qquad \text{(R2)}$$

Table 1. Rate coefficient expressions for reactions (R1)–(R3)[a].

Reaction	A	B	C(K)
(R1) $O + N_2 \rightarrow NO + N$	1.81×10^{14}	0	−38,400
(R2) $N + O_2 \rightarrow NO + O$	9.0×10^{9}	1	−3,270
(R3) $N + OH \rightarrow NO + H$	1.08×10^{14}	−0.2	0

Units: cm^3, mol, s.
[a]Data compiled from Baulch *et al*. (2005).

$$N + OH \rightleftharpoons NO + H \qquad (R3)$$

The temperature-dependent rate parameters for reactions (R1)–(R3) have been measured over a wide temperature range. The rate-controlling reaction for thermal NO formation is the slow reaction $O + N_2 \rightarrow NO + N$ (R1). The rate coefficient expressions for (R1)–(R3), in the form $AT^B \exp[-C/T(K)]$, are available in Baulch *et al*. (2005) and are tabulated in Table 1.

The primary parameters governing thermal NO formation can be determined using an equation for the maximum NO formation rate. This equation may be derived from (R1)–(R3) by invoking as quasi-steady-state approximation for N-atoms neglecting back reactions,

$$\frac{d(N)}{dt} = k_1(O)(N_2) - k_2(N)(O_2) - k_3(N)(OH) \approx 0$$

In molar concentration units, the maximum NO formation rate may then be expressed,

$$\left[\frac{d(NO)}{dt}\right]_{max} = 2k_1(O)(N_2) \times \left\{\frac{1 - (NO)^2/K(O_2)(N_2)}{1 + k_{-1}(NO)/[k_2(O_2)k_3(OH)]}\right\} \qquad (1)$$

where $K = (k_1/k_{-1})(k_2/k_{-2})$ is an equilibrium constant for the reaction $N_2 + O_2 \rightleftharpoons 2NO$.

At engine combustion conditions, the characteristic time for NO formation is very much greater than the characteristic time for fuel oxidation. Hence, to a reasonable approximation, the values for (O), (O_2), (N_2), and (OH) and the temperature used to evaluate the rate parameters, k_1–k_3, in Equation 1 may be assumed to be their respective equilibrium values in the burned gas. For combustion of lean and stoichiometric fuel–air mixtures, $k_3(OH)_{eq} \ll k_2(O_2)_{eq}$, so that Equation 1 may be approximated by,

$$\left[\frac{d(NO)}{dt}\right]_{max} = 2k_1(O)_{eq}(N_2)_{eq} \qquad (2)$$

When $(O)_{eq}$ is related to $(O_2)_{eq}$ by the equilibrated reaction, $\frac{1}{2}O_2 \rightleftharpoons O$, then Equation 2 may be expressed,

$$\left[\frac{d(NO)}{dt}\right]_{max} = 1.70 \times 10^{17} T^{-\frac{1}{2}} \exp\left[-\frac{69750}{T(K)}\right] \times (O_2)_{eq}^{\frac{1}{2}}(N_2)_{eq} mol/cm^3/s^1 \qquad (3)$$

The strong dependence of the thermal NO formation rate on the post-combustion gas temperature and the somewhat weaker dependence on the O_2 concentration in the burned gas, $(O_2)_{eq}$, are evident in Equation 3. Methods for reducing NO_x emissions from automotive engines, where NO is produced mainly by the thermal mechanism, are directed toward reduction of the NO formation rate rather than by enhancing the NO removal rate, which is very slow at typical engine combustion temperatures. From Equation 3, it can be seen that modification of the combustion process, such as exhaust gas recirculation or controlling spark or fuel injection timing, to reduce the maximum burned gas temperatures, the availability of oxygen, or both will reduce the NO formation rate and, hence, NO_x emissions.

Also evident from Equation 3 is that the amount of NO formed is dependent on time, especially the time at which the burned gas temperature is high. A characteristic time for NO formation in lean and stoichiometric fuel–air mixtures may be defined as

$$\tau_{NO} \equiv \frac{1}{\frac{d(NO)}{dt} \cdot \frac{1}{(NO)_{eq}}} \qquad (4)$$

Combining Equations 3 and 4, together with an expression for the equilibrium constant of $N_2 + O_2 \rightleftharpoons 2NO$, yields

$$\tau_{NO} = \frac{8 \times 10^{-16} T \exp[58300/T(K)]}{\sqrt{P}} \qquad (5)$$

2.2 Prompt NO formation mechanisms

Measurements of NO concentrations near the flame zones of hydrocarbon–air and hydrogen–air premixed flames and on the air side of hydrocarbon diffusion flames show that maximum NO formation rates exceed those given by Equation 1. Three mechanisms for this accelerated NO formation have been identified: (i) superequilibrium O and OH concentrations that accelerate the rates of the thermal NO mechanism; (ii) a reaction sequence, shown in Figure 1, that is initiated by reactions of hydrocarbon radicals, present in and near the reaction zone, with molecular nitrogen

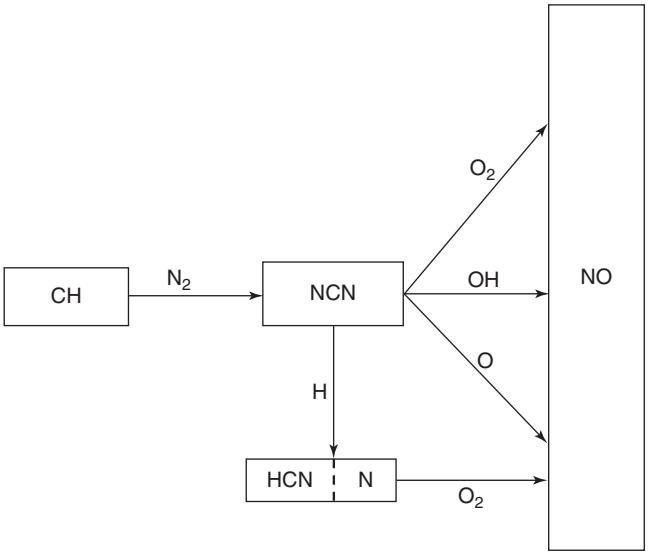

Figure 1. Reaction path diagram showing the principal pathways leading to prompt NO formation.

(Fenimore, 1970); and (3) reaction between the nitrogen-containing radical NNH and O atoms (Bozzelli and Dean, 1995; Harrington *et al*., 1996), present in the burned gas.

The relative importance of the three mechanisms of prompt NO formation depends on the combustion conditions. Acceleration of NO formation via the thermal mechanism by superequilibrium O and OH concentrations can be important in non-premixed flames, in stirred reactors for lean fuel–air mixtures, and in low pressure premixed flames. For near stoichiometric and rich premixed hydrocarbon–air flames and for hydrocarbon–air diffusion flames, prompt NO formation occurs primarily by the reaction sequence shown in Figure 1. Mechanism 3 has been proposed as an important source of NO in lower temperature flames (Bozzelli and Dean, 1995).

Rate coefficient expressions for the prompt NO reaction pathways shown in Figure 1 are available from Vasudevan *et al*. (2007) and Lin and coworkers (2005, 2007, 2009) and are tabulated in Table 2. Of particular importance are the rates of the prompt NO initiation reaction,

$$CH + N_2 \longrightarrow NCN + H \qquad (R4)$$

and the subsequent reactions of NCN to form NO via (R5)–(R7).

$$NCN + O_2 \longrightarrow NCO + NO \qquad (R5)$$

$$NCN + OH \longrightarrow HCN + NO \qquad (R6)$$

$$NCN + O \longrightarrow CN + NO \qquad (R7)$$

Table 2. Rate coefficient expressions for reactions (R4)–(R8).

Reaction	A	B	C (K)	References
(R4)	6.03×10^{12}	0	−11150	Vasudevan *et al*. (2007)
(R5)	3.80×10^{9}	0.51	−12377	Zhu and Lin (2005)
(R6)	4.71×10^{10}	0.44	−2013	Zhu, Nguyen, and Lin (2009)
(R7)	2.55×10^{13}	0.15	+17	Zhu and Lin (2007)

Units for A: cm^3, mol, s.

An alternative precursor species for NCN formation, C_2O, via the following reaction pathway has been proposed by Williams and Fleming (2007) and Konnov (2009).

$$C_2O + N_2 \longrightarrow NCN + CO \qquad (R8)$$

At this time, the importance of this pathway for prompt NO formation has not been established. Furthermore, reaction pathways for C_2O formation in flames are uncertain and accurate expressions for the rate coefficient of (R8) are not currently available.

2.3 Mechanism for NO formation from N_2O

Wolfrum (1972) suggested that NO can also be formed from N_2 by a reaction sequence involving the formation of N_2O by the three-body recombination reaction (M = any collision partner),

$$O + N_2 + M \longrightarrow N_2O + M \qquad (R9)$$

and subsequent reaction of the N_2O to form NO via,

$$N_2O + O \longrightarrow NO + NO \qquad (R10)$$

The formation of NO by the N_2O mechanism increases in importance as the fuel–air ratio decreases, as the burned gas temperature decreases, or as pressure increases. The N_2O mechanism would be the most important under conditions where the NO emissions are relatively low, as for example, in lean premixed gas turbine combustors (Malte and Pratt, 1974) or in homogeneous charge compression ignition (HCCI) engines.

3 REACTION MECHANISM FOR NO FORMATION FROM NITROGEN IN THE FUEL

Conventional distillate fuels used in spark-ignition and compression ignition engines contain very little nitrogen, although organic nitrogen-containing compounds are used as additives. These compounds typically are high molecular weight amines that are added in amounts ranging from a few tens to a few hundred parts per million. While it is likely that organic nitrogen additives at these levels will not be significant contributors to NO_x emissions from these engines, for the purpose of completeness, the chemical pathways for amine conversion to NO will be presented.

Figure 2 shows these reaction pathways. In the figure, ammonia is used as a surrogate amine compound. Ammonia will react with small radicals present in the hot combustion products in a sequential process leading, eventually to N atoms. The N atoms will react with oxygen-containing species (O_2 and OH) to form NO. Some N atoms will react with NO present in the burned gas to reduce it to N_2. An intermediate nitrogen species, HNO, also can contribute to NO formation, via the pathway shown in Figure 2. The competition between the NO-forming and NO-reducing reaction pathways determines the net amount of NO formed by this process. In oxygen-containing combustion products and for low levels of the nitrogen additive, the conversion of the fuel–N to NO is nearly quantitative (Bowman, 1991).

4 REACTION MECHANISMS FOR NO_2 AND N_2O

4.1 Mechanism for formation and removal of NO_2

Measured NO_2 emissions from spark-ignition engines are relatively small; however, in diesel engines, NO_2 can be 10–30% of the total NO_x emissions (Heywood, 1988). Measurements of NO and NO_2 in premixed and diffusion flames show that there are relatively large NO_2/NO ratios near the flame zone (Merryman and Levy, 1975; Drake *et al*., 1987). The gas-phase reaction mechanism for the formation and removal of NO_2 in combustion is well known. The principal NO_2 formation pathway is

$$NO + RO_2 \longrightarrow NO_2 + RO \qquad \text{(R11)}$$

In this reaction, RO_2 is a peroxy radical and the R is an H atom or an alkyl group. In low temperature regions of

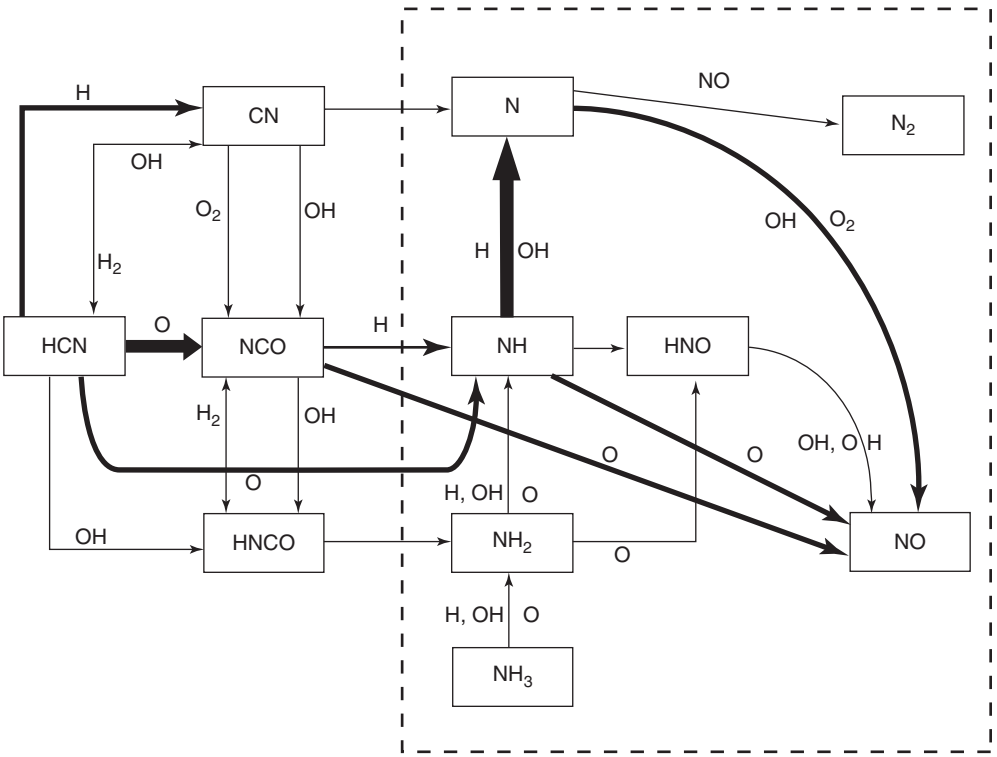

Figure 2. Reaction path diagram for oxidation of NH_3 and HCN in flames.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto117
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

flames, RO_2 is relatively stable and it can react with NO formed in higher temperature regions and be transported by diffusion to lower temperature regions. The NO_2 formed in (R11) is converted back to NO via

$$NO_2 + H \longrightarrow NO + OH \quad \text{(R12)}$$

$$NO_2 + O \longrightarrow NO + O_2 \quad \text{(R13)}$$

At elevated temperatures ($T > 1500$ K), NO_2 removal by (R12) and (R13) is rapid because of the presence of high radical concentrations in the combustion products. Typical lifetimes of NO_2 in combustion products at 1500 K are less than 10 ms. Persistence of NO_2 in the engine exhaust is likely due to quenching by mixing with cooler fluids.

4.2 Mechanism for formation and removal of N_2O

N_2O emissions from automotive engines are not currently regulated, however N_2O is a greenhouse gas and, as such, N_2O emissions are of interest. In current light-duty gasoline engines with three-way catalysts, N_2O is formed primarily in the catalyst and N_2O emissions are dependent on the sulfur content of the fuel. N_2O can also be formed as a by-product in diesel engines equipped with SCR NO reduction systems. Direct in-cylinder production of N_2O in current engine designs should be very small; however, as noted in Section 2.3, in-cylinder N_2O formation will increase at the elevated pressures and lean-burn conditions found in some HCCI engines.

The dominant gas-phase N_2O formation reaction in non-nitrogen containing fuels is (R9). The primary N_2O removal steps in combustion products are

$$N_2O + H \longrightarrow N_2 + OH \quad \text{(R14)}$$

$$N_2O + O \longrightarrow N_2 + O_2 \quad \text{(R15)}$$

$$\longrightarrow NO + NO \quad \text{(R10)}$$

The rate parameters for these reactions are known fairly accurately at combustion temperatures (Baulch *et al.*, 2005). For temperatures above 1500 K, the lifetime of N_2O in combustion products is less than 10 ms.

5 REBURN MECHANISM FOR NO REMOVAL FROM COMBUSTION PRODUCTS

Reburning is the name given to a reaction process for NO removal in combustion products by reaction with small hydrocarbon radicals to form cyano species. The reburn reaction pathways are active in fuel-rich regions, such as found in diffusion flames, where these cyano species react preferentially to form N_2. The final levels of NO emitted from hydrocarbon–air flames are the balance of NO formation via the reaction pathways described in Section 2 and NO removal via reburn.

A reaction path diagram for NO reburn in methane combustion, due to Miller, Durant, and Glarborg (1998), is shown in Figure 3. The important reaction pathways, in so far as reburn is concerned, are the reactions of the radicals CH_3 and HCCO with NO to produce cyano species. Figure 3 also shows the reaction pathways for these radicals from hydrocarbon fuel species.

The specific elementary reaction steps that participate in the reburn process include

$$CH_3 + NO \longrightarrow HCN + H_2O \quad \text{(R16a)}$$

$$CH_3 + NO \longrightarrow H_2CN + OH \quad \text{(R16b)}$$

and

$$HCCO + NO \longrightarrow HCN + CO_2 \quad \text{(R17a)}$$

$$HCCO + NO \longrightarrow HCNO + CO \quad \text{(R17b)}$$

At elevated temperatures, the reaction of NO with CH will contribute to NO removal via

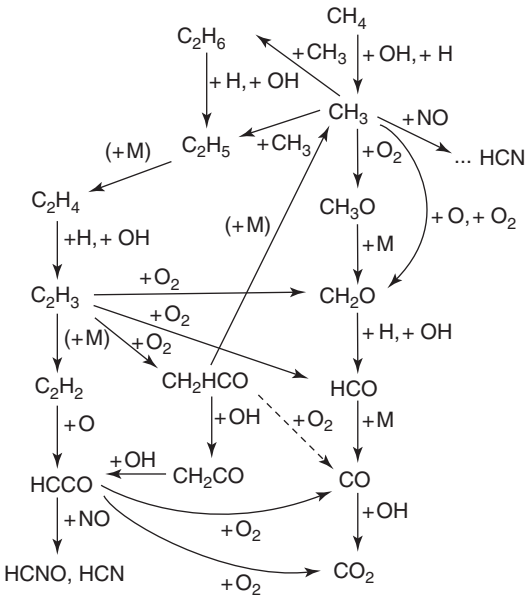

Figure 3. Reaction path diagram for NO reburn in CH_4 combustion. (Reproduced with permission from Miller, Durant, and Glarborg (1998). © The Combustion Institute.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto117
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

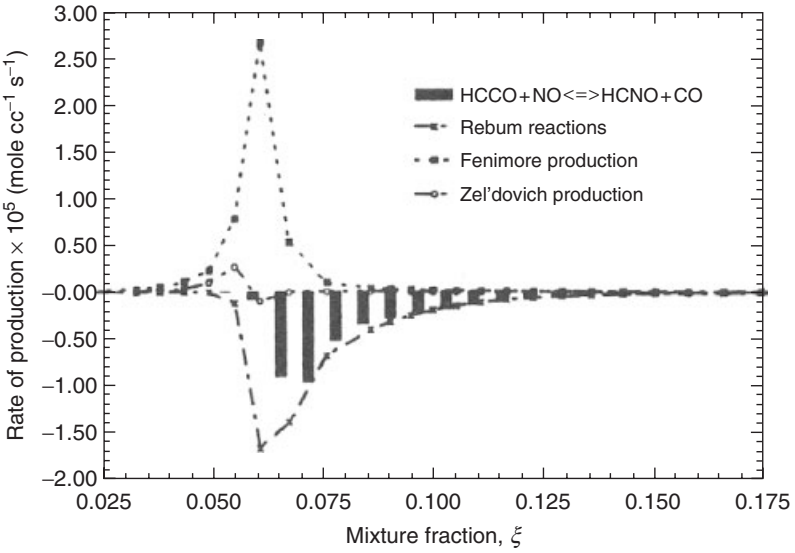

Figure 4. Contributions of reactions to NO reburn in an atmospheric pressure diffusion flame. (Reproduced with permission from Marro, Pivovarov and Miller (1997). © The Combustion Institute.)

$$CH + NO \longrightarrow HCN + O \qquad (R18)$$

Subsequent reaction of the HCN produced in (R16a), (R17a), and (R18) occurs via the reaction pathways shown in Figure 2. Under fuel-rich conditions, the pathways leading to N_2 is favored. The H_2CN formed in (R16b) dissociates to produce HCN via

$$H_2CN \longrightarrow HCN + H \qquad (R19)$$

and, therefore, contributes to the $NO \rightarrow HCN \rightarrow N_2$ process.

The HCNO formed in reaction (R17b) reacts primarily via

$$HCNO + O \longrightarrow HCO + NO \qquad (R20)$$

$$HCNO + OH \longrightarrow HCOH + NO \qquad (R21)$$

$$HCNO + H \longrightarrow HNCO + H \qquad (R22)$$

Reactions (R20) and (R22) effectively regenerate the NO removed in reaction (R17b) and, hence, are ineffective in removing NO. The HNCO produced in reaction (R22) will react with O, H, or OH to produce amine species (NH, NH_2), HNO or NCO, that may react to form NO, N_2O, or N_2.

The rate parameters for key reactions in the reburn processes, (R16a), (R16b), (R17a), and (R17b), from Miller, Durant, and Glarborg (1998), are

$$k_{16} = 0.3T^{3.52} \exp[-1990\ \mathrm{K/T}]\ \mathrm{cm^3/mol/s}$$

$$k_{17a} = 1.45 \times 10^{16} T^{-0.968} \exp[-326\ \mathrm{K/T}]\ \mathrm{cm^3/mol/s}$$

$$k_{17b} = 1.17 \times 10^{11} T^{0.65}\ \mathrm{cm^3/mol/s}$$

Figure 4 shows calculated contributions of reburn and NO formation reactions in an atmospheric pressure CH_4–air diffusion flame (Marro, Pivovarov, and Miller, 1997). The vertical axis shows the NO formation (>0) and removal (<0) rates. The horizontal axis is mixture fraction, ξ defined as $\xi \equiv$ initial CH_4 mass flow rate/total (CH_4 + air) mass flow rate, the Fenimore production is due to the prompt NO mechanism and Zeldovich production is due to the thermal NO mechanism, described in Sections 2.2 and 2.1, respectively. NO removal by reburn occurs on the fuel-rich side of the flame. The HCCO + NO reaction plays a major role in the reburn process in this flame, with the remainder of the reburn occurring through CH_x + NO reactions.

6 CONTRIBUTIONS OF MECHANISMS TO NO EMISSIONS FROM COMBUSTION PROCESSES

In this section, representative contributions to NO production of the NO formation and removal mechanisms described earlier are presented for combustion of methane and air. Figure 5 shows the calculated contributions of the thermal, prompt, and N_2O mechanisms to NO formation in a one-dimensional, premixed, laminar CH_4–air flame at

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto117
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

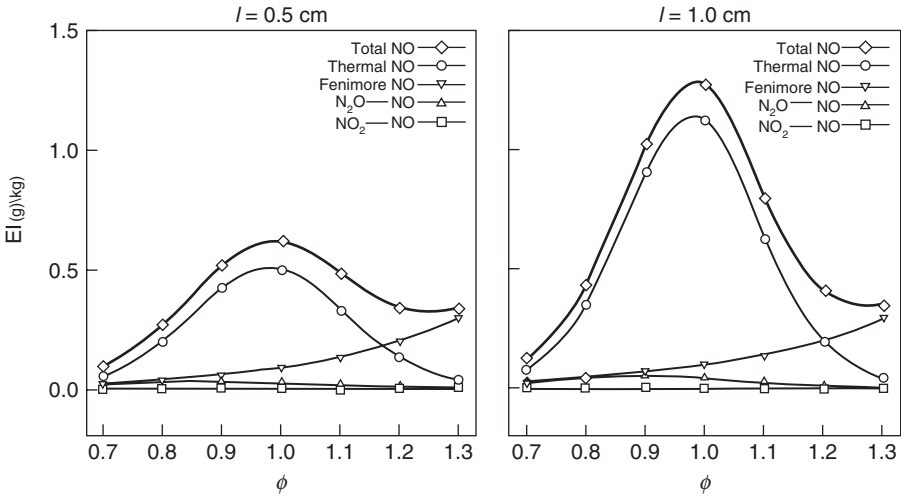

Figure 5. Contributions of mechanisms to NO formation in a premixed laminar CH_4–air flame at atmospheric pressure for various fuel–air equivalence ratios. Two positions above the burner surface, l, are shown. (Reproduced with permission from Nishioka *et al*. (1994). © The Combustion Institute.)

atmospheric pressure as a function of fuel–air equivalence ratio, ϕ, defined as

$$\phi \equiv \frac{n_{\text{fuel}}/n_{O_2}}{(n_{\text{fuel}}/n_{O_2})_{\text{stoichiometric}}}$$

at two axial locations, l, in the flame, measured with respect to the burner surface (Nishioka *et al*., 1994). The NO levels are reported in terms of an emission index, EI_{NO}, (g NO/kg CH_4).

From Figure 5, it can be seen that for lean and stoichiometric mixtures ($\phi \leq 1$), the thermal NO mechanism is the dominant source of the NO produced in the flame. The prompt NO mechanism, labeled here as Fenimore NO, increases in importance as ϕ increases. For values of $\phi > 1.2$, the prompt NO mechanism is the dominant source of NO. For these particular flame conditions, the N_2O mechanism contributes only a small amount of NO production and, then, only for the leanest mixtures.

Figure 6 shows the calculated contributions of the thermal, prompt, and N_2O formation mechanism and the NO reburn mechanism to total NO production in laminar CH_4–air diffusion flames at pressures of 1 and 40 bar (Hewson and Bollig, 1996). The vertical axis is the NO production rate (kmol NO/m^3/s) and the horizontal axis is the mixture fraction, z (which is equivalent to ξ). Mixture fraction may be viewed as a normalized fuel–air ratio, ranging from 0 for pure air to 1 for pure fuel. The z-value corresponding to a stoichiometric CH_4–air mixture

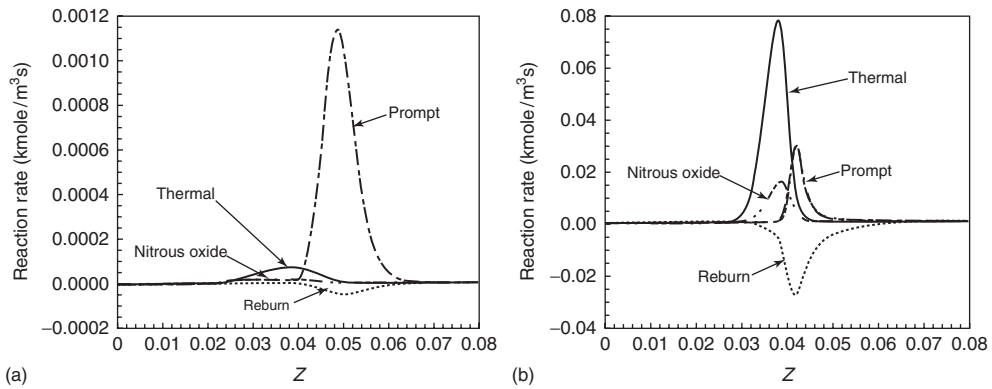

Figure 6. Contributions of mechanisms to NO formation and removal in a laminar CH_4–air diffusion flame at pressures of 1 bar and 40 bar. (Reproduced with permission from Hewson and Bollig (1996). © The Combustion Institute.)

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto117
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

is $z = 0.055$. Values of $z < 0.055$ correspond to the air side of the flame, whereas values of $z > 0.055$ correspond to the fuel side.

From Figure 6, it can be seen that the relative contributions for the different NO formation and removal mechanisms depend on pressure and on the location in the flame. At a pressure of 1 bar, the prompt NO mechanism is the dominant source of NO, with the maximum rate of NO formation occurring near the stoichiometric mixture fraction, $z = 0.055$, that is, near the location of the flame. At this pressure, there are minor contributions to NO formation from the thermal and N_2O mechanisms, with the maximum NO formation rates occurring on the air side of the flame. At the elevated pressure, the relative contribution of the N_2O mechanism to NO formation increases, due mainly to the fact that the rate of (R9) increases as P^3, whereas the rates of (R1) (thermal NO) and (R4) (prompt NO) increase as P^2. NO removal by reburn reaction pathways increases with increasing pressure. Hence, accurate predictions of NO emissions in high pressure diffusion flames, such as occur in diesel engines, require consideration of all three NO formation mechanisms and the reburn NO removal mechanism.

7 CONCLUDING REMARKS

This article has summarized the current understanding of the gas-phase reaction mechanisms and rate parameters for nitrogen oxide formation and removal in combustion. At this time, detailed reaction mechanisms for predicting NO, NO_2, and N_2O emissions are available in the literature (e.g., Miller and Bowman, 1989; Konnov, 2009) and also on the internet (e.g., http://www.me.berkeley.edu/gri_mech/).

Fuel Introduction

Rolf Reitz[1], Lyle Pickett[2], and Mario Trujillo[1]

[1] *University of Wisconsin–Madison, Madison, WI, USA*
[2] *Sandia National Laboratories, Albuquerque, NM, USA*

1 INTRODUCTION

Fuel is the lifeblood of the internal combustion engine and various fuel introduction methods are used to mix the fuel with air in the correct proportions for optimal combustion. A key consideration is to be able to vaporize the liquid fuel in the short time available in each engine cycle, and this generally requires that the fuel be finely atomized during the mixing process. Owing to the importance of fuel injection and spray processes in IC engines, many review articles and books have been written on these topics and are available for further study (Reitz and Bracco, 1986; Stiesch, 2003; Reitz, 2006; Jiang *et al*., 2010). Excellent reference books include Challen and Baranescu (1998) for diesel engine fuel injection and Heywood (1988) for carbureted and manifold injection gasoline engines.

This section provides a review of the fundamental processes involved in the introduction of fuels into the combustion chamber. We begin with a brief discussion of various types of spray nozzles and those commonly used in engine applications. Fuel introduction strategies are discussed in Section 2, ranging from classical intake manifold fuel introduction using carburetors to modern port fuel injection (PFI) fuel injectors, with discussion of fuel film and deposit effects. These are followed by a review of direct in-cylinder fuel introduction, with consideration of issues relevant for spark-ignition and diesel engines. Experimental findings on fundamental spray processes, such as the effect of air entrainment on spray penetration and vaporization, injector nozzle, injection timing and fuel effects on combustion, oil dilution, and engine wear are then discussed. In addition, the effect of fuel sprays interactions with the in-cylinder airflows is discussed.

An in-depth understanding of fundamental spray processes is required for successful modeling of engines. Thus, Section 3 reviews current theories of atomization, drop breakup, collision and coalescence, vaporization, drag and deformation, turbulent diffusion, and spray/wall impingement processes. The final section of this chapter is devoted to discussion of new computational tools that are currently under development for improved understanding of spray processes.

1.1 Types of sprays

Sprays are used in many applications, including the process industries (e.g., spray drying, spray cooling, and powdered metals), treatment applications (e.g., humidification and gas scrubbing), coating applications (e.g., surface treatment, spray painting, and crop spraying), medicinal and printing applications, combustors (e.g., burners, furnaces, rockets, and gas turbines), and automotive diesel and gasoline engines. Generally, the liquid to be sprayed is injected

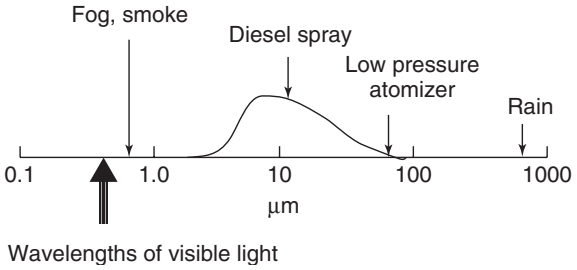

Figure 1. Drop sizes in various applications.

at a high velocity through a small orifice, and atomization is the process whereby the liquid is broken up into droplets (Lefebvre, 1989). Atomization influences spray vaporization rates because, in the form of small droplets, the total surface area of the injected liquid is increased. In automotive engine applications, fast vaporization is desirable for good fuel–air mixing (Heywood, 1988).

The trajectories of the injected spray drops formed by atomization are governed by the momentum of the drops, drag forces, and interactions between the drops and the surrounding gas, as discussed later. Practical atomizers generate sprays with a distribution of drop sizes, with average drop diameters ranging from a few micrometers to as large as 0.5 mm (Reitz, 2005). The smaller drops in the spray vaporize fast, if there is adequate mixing with surrounding air, to form combustible mixtures. Therefore, the rate of atomization and mixing ultimately controls the ignition process in combustion systems. On the other hand, large drops carry most of the mass and momentum of the injected liquid and these drops are able to penetrate into the high pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown in Figure 1.

1.1.1 Pressure atomizers

Pressure atomizers are used to produce solid cone or hollow cone sprays, which can be classified as low or high pressure sprays. In solid cone (or full cone) sprays, the injected liquid is concentrated along the spray axis and, with high injection pressures, can provide high spray penetration, such as is required in direct-injection diesel engines where injection takes place near top dead center (TDC) into a high gas density environment (Figure 2a, b). Low pressure solid cone sprays may be used for early injections when chamber gas densities are low and where low spray penetration is favored to prevent spray wall impingement. In pressure atomizers, the chamber gas density, injection pressure, and nozzle hole diameter control the momentum exchange between the spray and the ambient gases and the resulting spray drop size (Hiroyasu, Kadota, and Arai 1980).

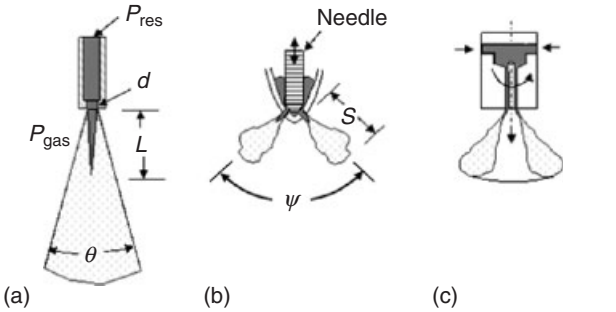

Figure 2. Pressure atomizers (a) plain orifice, solid cone (b) multihole, diesel, or asoline direct injection, and (c) swirl nozzle, hollow cone.

In hollow cone sprays, a swirling flow is setup within the nozzle passage, yielding a spray whose central axis region can be relatively free of drops, giving wide spray dispersal (Figure 2c). The air core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays and has been proposed for some gasoline direct-injection engines. However, precautions are needed for use in transient applications because the atomizer can dribble at start-up and shut down when the air core is not fully formed.

In the plain orifice nozzle (Figure 2a), the liquid emerges at a velocity related to the theoretical limit

$$U_f = \frac{C_d}{C_a} \cdot \sqrt{2 \cdot \frac{P_f - P_a}{\rho_f}} \qquad (1)$$

where P is the pressure, ρ is the density, and the subscripts f and a signify fuel or charge-gas (ambient) density ("res" and "gas" in Figure 2), respectively. In addition, C_a is the orifice area contraction coefficient and C_d is the orifice discharge coefficient, the ratio of which lowers the actual injection velocity from the ideal Bernoulli velocity by accounting for flow losses due to friction and cavitation effects within the nozzle. An intact liquid core of length L may exist somewhat downstream of the nozzle exit (Figure 2a), depending on upstream cavitation and turbulence. As the spray emerges, it develops a conical shape with spray angle, θ. High pressure spray injection is intermittent and is required to start and stop quickly without dribble between injections. This is accomplished by means of a needle valve that is actuated by a cam and spring system in older mechanical "jerk" pump systems or by electromagnetic solenoids or piezo stacks in modern electronic injectors. These latter approaches permit the duration and injection pressure to be varied independently of each other and engine speed.

1.1.2 *Other atomizers*

Other atomizer designs are found in combustion applications, as described by Lefebvre (1989). The most common atomizer types include the pressure atomizers described in Figure 2 and rotary, twin-fluid (air assist, air blast, and effervescent), flashing, electrostatic, vibratory, and ultrasonic atomizers. Group hole nozzles have also been proposed for internal combustion engine applications (Kim *et al*., 2009). In this case, each nozzle hole of the showerhead nozzle (Figure 2b) is replaced by a pair of smaller converging or diverging holes. In the converging nozzle case, the impinging jets create unstable liquid sheets that help break up the liquid to produce the sprays.

Air assist and air blast are twin-fluid atomizers that use airflows to aid the liquid breakup. However, they require a source of compressed air, and this introduces significant complexity and cost in automotive applications.

A common feature of the above-mentioned nozzle designs is that atomization is enhanced by reducing the liquid jet diameter or liquid sheet thickness and by arranging for a high relative velocity between the liquid and gas flows. For the common pressure atomizer, this can be achieved by increasing the injection pressure, and indeed, injection pressures exceeding 2000 bar are being introduced in modern diesel engines.

2 FUEL DELIVERY IN AUTOMOTIVE ENGINES

For automobile applications, specific fuel introduction technologies are most common. Figure 3 summarizes these different methods for injecting fuel, dependent on the type of engine. Fuel may be introduced and mixed with air before entering the engine cylinder, or it may be injected directly into the cylinder. The characteristics of fuel sprays produced by each of these technologies are reviewed in this section.

2.1 Fuel introduction systems

2.1.1 *Carburetor*

A carburetor blends fuel and air by creating a subatmospheric pressure environment to draw liquid fuel from the tank into the engine's intake system. As shown in the upper left schematic, intake air is directed through a venturi contraction, which increases the velocity and reduces local pressure, thereby creating a vacuum to pull fuel into the air stream. Typically, a single carburetor is used to mix fuel and air before dividing the prepared charge toward multiple cylinders, but multiple carburetors with separate intake manifolds are also utilized. Modern passenger cars

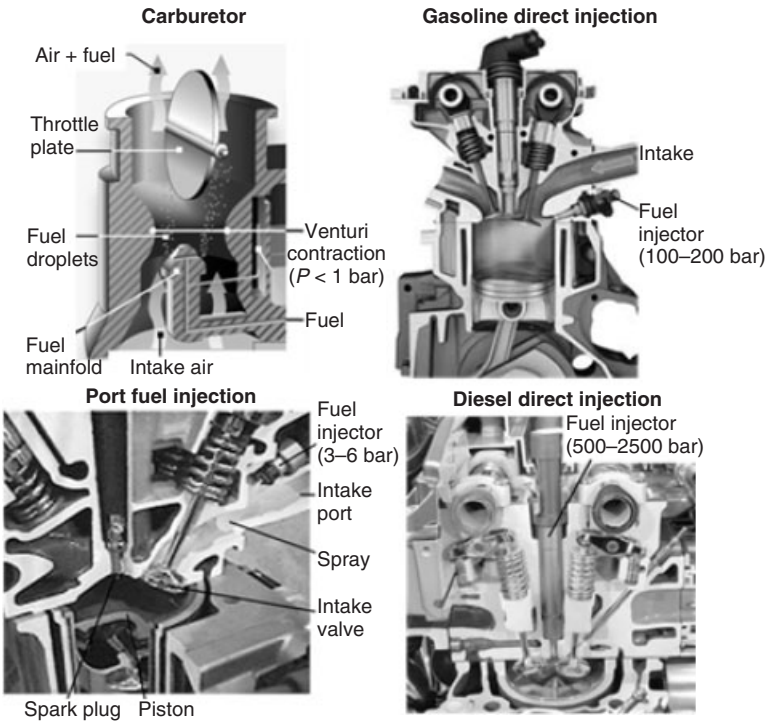

Figure 3. Schematics and cutaways of various fuel introduction systems representative of common automobile technology. Fuel injector location and other engine components are labeled, along with typical fuel injection absolute pressure.

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118

no longer use carburetor fueling but carburetors are still very common in small utility engines.

When fuel is ejected from the fuel manifold, only a small portion of the fuel vaporizes upstream of the throttle plate, as typical for large, poorly atomized droplets. Large droplets with diameters in the range 25–100 μm or larger are typical (Heywood, 1988). Significant liquid fuel impacts the throttle plate and throttle-body walls, forming a liquid film (Heywood, 1988). The liquid film vaporizes as air continuously flows into the engine. Because the fueling system and conditions within the carburetor are poor for vaporization, high volatility fuels such as gasoline are required for this type of engine.

Fueling rates within the carburetor are adjusted automatically when the airflow rate increases or decreases as dictated by the throttle plate position. As the airflow rate increases, the velocity at the venturi contraction increases and the pressure decreases, thereby increasing the fueling rate. While this type of fueling adjustment is functional and simple because it requires no fuel pressurization (i.e., a fuel pump), it is imprecise over the large operating range of engine. Consequently, carburetors were replaced with pressurized, electronically controlled fuel injectors of type shown in Figure 2b or c. A single fuel injector positioned at the throttle body came to be known as a single-point, central-fueling, or throttle-body injector, as engine fueling is performed at a single input location. While the throttle-body injection system is not shown schematically in Figure 3, the PFI system, discussed in Section 2.1.2, bears similarities.

2.1.2 *Port injection*

PFI systems deliver fuel very close to the intake of each cylinder of an engine, as shown in Figure 3. The injector is modestly pressurized and controlled by an electronically activated needle valve to open and close at the proper timing for the cycle of that particular cylinder. The injection duration is varied depending on the engine power requirement, with typical injection durations ranging from 1.5 to 10 ms (Heywood, 1988). As one fuel injector is required for each cylinder, this system is also known as *multipoint fuel injection*.

Similar to carburetor fueling, the port injection fuel spray mixes with intake air before being ingested into the cylinder. The fuel spray is directed toward the valve of the intake port. Droplet atomization and vaporization is improved compared to a carburetor for several reasons. First, the spray shape is actively designed to mix with intake air and minimize wetting of the intake port. Droplets may even be ingested directly into the cylinder during the intake cycle, particularly when the intake valve is open, with in-cylinder droplets amounting to 10–20% of the fueling at some conditions (Peters, 1982). Second, higher fuel injection pressure forms smaller droplets that are easier to atomize. Third, the intake port and valve are warmer because of the proximity to the cylinder combustion chamber, which naturally vaporizes more fuel. Vaporization is also enhanced by the backflow of hot residuals into the intake (Heywood, 1988). Despite the improved vaporization, substantial fuel films are still formed along the intake port and valve and must be vaporized by the flow of incoming air.

2.1.3 *Direct cylinder injection*

Two different variants of injection technology to introduce fuel directly into the engine cylinder and combustion chamber are shown in Figure 3. Gasoline direct injection from the side of the cylinder is shown at the upper right. Diesel direct injection from the cylinder center is shown at the lower right. As with other technologies, variants for gasoline and diesel direct injection exist. For example, gasoline injection with centrally mounted orientation has been implemented; as has diesel injection from the side. Other variants may include indirect, prechamber injection, but these technologies have now generally been superseded by direct injection.

The design for a direct-injection gasoline nozzle is typically a 5–8 hole pattern with a somewhat narrow "umbrella" or included angle between sprays (ψ in Figure 2b). Gasoline injectors with an annular swirl pattern such as that shown in Figure 2c are also common. The optimum hole number and included angle is dependent on the injector location relative to the cylinder and to the timing of injection. As depicted in Figure 3, a gasoline spray may be injected early in the cycle with the piston near bottom dead center (BDC) and the intake valve open. The spray fills the combustion chamber as it penetrates across the chamber and mixes with in-cylinder gases. Although there is some distance between the injector and opposing cylinder wall, allowing vaporization, liquid droplets may impact the cylinder liner or the advancing piston. Wall wetting may be undesirable because of oil dilution and other concerns, demonstrating the care that must be taken when designing a direct-injection fueling system. The location of the fuel cloud relative to the spark plug is another consideration.

Gasoline direct-injection fuel pressures are higher than that of PFI systems. One reason for this is that the fuel pressure must exceed in-cylinder pressures that become elevated during the compression cycle. Higher injection pressure also promotes atomization and allows shorter

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

fueling intervals to deliver the same mass. In general, gasoline direct-injection systems will experience significant variation of the in-cylinder charge-gas properties because of the huge pressure and temperature variations experienced during intake, compression, exhaust, and so forth, as well as mixing with different exhaust gas residuals. The spray development and vaporization will strongly depend on the in-cylinder conditions and flow patterns during injection.

As opposed to gasoline injection systems where fuel is injected early in the cycle and later ignited with a spark plug, diesel injection timing typically occurs slightly before full compression (TDC). Because the piston is in close proximity to the fuel injector at TDC, diesel injectors are designed with an open included angle ($\psi \approx 140-150^{\circ}$) to direct each plume mainly in the radial direction. The number of spray plumes/nozzle holes varies, but 5–8 is typical. As the charge-gas pressure and temperature are quite high at TDC compression, evaporation of liquid fuel is enhanced and low volatility (high boiling point temperature) fuels such as diesel or biodiesel mix and evaporate without serious wall wetting and fuel film formation. Rapidly mixing fuel with dense charge gases is enhanced by very high fuel injection pressure, which Figure 3 shows may exceed 2000 bar. As depicted in Figure 1, diesel sprays are finely atomized with smaller droplet sizes. Mixing, vaporization, ignition, and completion of combustion occur in only a few crank angle degrees near TDC, also aided by the high injection pressure and high rate of fuel delivery. Injection durations may be as short as 0.2 ms, extending to approximately 3 ms. Multiple injection events during a single cycle are also widely used.

2.2 Spray penetration fundamentals

Given that different injection systems deliver fuel into much different charge gas environments, either within the intake system or directly into the cylinder, it is helpful to understand how various injector and ambient conditions will affect spray penetration, mixing, and vaporization. A simple example of measurements depicting the effect of different injection timings, wherein the spray would mix with quiescent gases at different density and temperature, is given in Figure 4 for single-orifice sprays. The spray liquid- and vapor-phase spray tip penetrations (S, in Figure 2b) are shown at conditions typical for near-TDC diesel injection, as well as injection at 20° before TDC. For both conditions, the rate of injection has a top-hat shape (bottom curve) and the injection duration is the same. With increasing time after the start of injection (ASI), the liquid and vapor phases

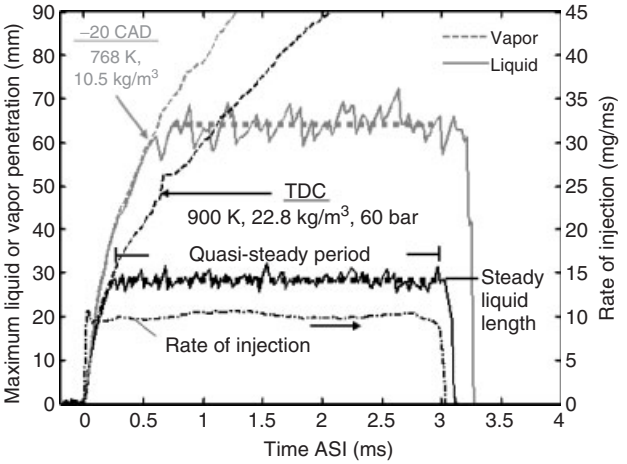

Figure 4. Measured vapor- and liquid-phase axial penetrations at near-TDC (black) and early-injection (gray) conditions. Rate of injection at right axis. Ambient: 0% O_2 at temperature and density given. Injector: 0.181 mm orifice diameter, 110 MPa pressure, and #2 diesel fuel. (Reproduced with permission from Pickett *et al.*, 2009. © L.M. Pickett, S. Kook and T.C. Williams, Sandia National Laboratories.)

of the spray penetrate together. The spray penetrates more slowly into a high density environment. As hot gases are entrained into the spray, the liquid phase eventually reaches an axial position where the liquid is vaporized completely. The vapor phase continues to penetrate downstream, but the liquid phase fluctuates about a mean "quasi-steady" position throughout the duration of injection, as indicated in the figure. This maximum liquid penetration distance is defined as the quasi-steady liquid length (LL) or simply the LL. Note that the LL more than doubles, comparing TDC to −20 CAD injection timing.

When describing spray penetration, note the importance of distinguishing between liquid- and vapor-phase penetrations. The overall penetration will always be described by the vapor-phase penetration, and if upstream of the LL, the liquid- and vapor-phase penetrations are the same.

2.2.1 *Overall penetration and mixing*

With guidance from fundamental measurements such as that shown in Figure 4, empirical formulas and analytical solutions have been developed to predict overall penetration. Naber and Siebers (1996) derived an analytical solution, relating a nondimensional penetration time ($\tilde{t}$) to a nondimensional axial penetration distance ($\tilde{S} = \tilde{x}$) as:

$$\tilde{t} = \frac{\tilde{S}}{2} + \frac{\tilde{S}}{4} \cdot \sqrt{1 + 16 \cdot \tilde{S}^2} + \frac{1}{16} \cdot \ln\left(4 \cdot \tilde{S} + \sqrt{1 + 16 \cdot \tilde{S}^2}\right) \quad (2)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$\tilde{t} = t \cdot \sqrt{\frac{\rho_a}{\rho_f}} \frac{a \cdot \tan(\theta/2)}{\sqrt{C_a} \cdot d_0} \cdot U_f \quad (3)$$

$$\tilde{S} = \tilde{x} = x \cdot \sqrt{\frac{\rho_a}{\rho_f}} \frac{a \cdot \tan(\theta/2)}{\sqrt{C_a} \cdot d_0} \quad (4)$$

where t is the time, x is the axial distance from the injector, d_0 is the orifice diameter, θ is the full spreading angle, and the constant a has a value of 0.66–0.75. In the near-field limit of a spray, Equation 2 has an $\tilde{S} = \tilde{t}$ dependency, and in the far-field limit, an $\tilde{S} = \tilde{t}^{0.5}$ dependency. Expectations for the effect of injector and charge-gas conditions follow from Equations 1–4. For example, penetration rate increases with the increasing fuel injection pressure or nozzle diameter and decreases with the increasing spreading angle or charge-gas density.

2.2.2 *Liquid-phase penetration*

Without considering atomization and breakup processes directly, an understanding of the penetration and mixing of the spray also can be used to explain the maximum liquid penetration. For example, Siebers (1999) showed that LL predictions were in good agreement with measurements when assuming mixing-limited vaporization. Estimates for mixing, or an average fuel–ambient mass ratio at a particular axial distance, come from Equations 2–4 as:

$$\frac{F}{A} = \frac{2}{\sqrt{1 + 16 \cdot \tilde{x}^2} - 1} \quad (5)$$

Then, assuming perfect mixing and liquid–vapor equilibrium, the fuel–ambient ratio $(F/A)_{liq}$ by mass where complete vaporization is expected is determined to be that when the enthalpy change in the ambient gas entrained into the spray matches the energy required to heat and vaporize the liquid fuel at the local equilibrium temperature. $(F/A)_{liq}$ depends on the charge-gas temperature and density, as well as the particular fuel properties and fuel temperature. Combining terms from Equations 4 and 5, and recognizing the need for a constant to account for local conditions at the center of the spray, the equation to predict the steady LL is (Siebers, 1999):

$$LL = 0.62 \cdot \sqrt{\frac{\rho_f}{\rho_a}} \cdot \frac{\sqrt{C_a} \cdot d_0}{\tan(\theta/2)} \sqrt{\left(\frac{2}{(F/A)_{liq}} + 1\right)^2 - 1} \quad (6)$$

Exploration of the dependency of Equation 6 on charge-gas conditions and fuel type provides insight about the different injection technologies utilized in automobile applications. Figure 5 shows the predicted maximum liquid penetration length if fuel from a single-orifice nozzle is injected into gas at certain crank angles before TDC. This calculation assumes that there is no wall impingement, that is, that the gas medium is infinite. As such, there is no interaction between neighboring spray plumes. The predictions shown are for single-orifice nozzle of 0.181-mm diameter, typical of production fuel injectors. The charge-gas conditions are calculated based on polytropic compression of gases initially at 340 K and 1 bar at BDC. The top axis shows the charge temperature and density at a given crank angle. Charge density is indicated because overall (vapor) penetration depends on density, rather than pressure (Naber and Siebers, 1996).

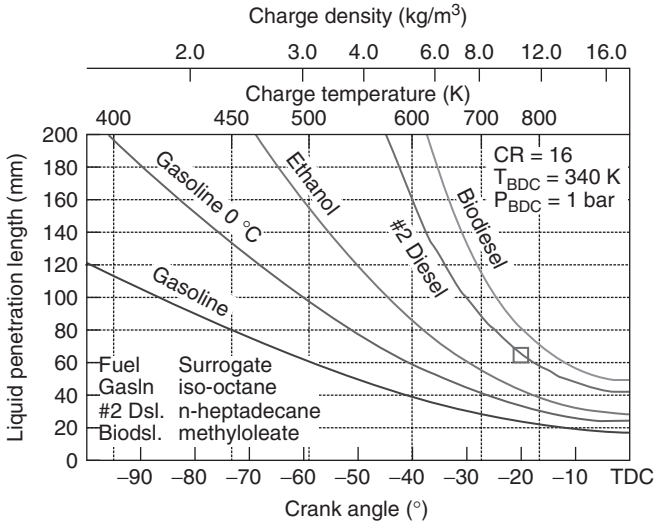

Figure 5. Predicted liquid penetration length when injecting various types of fuel at different timings before top dead center based on Equation 6 (Siebers, 1999) for single-orifice 0.181 mm nozzle at 95°C, unless indicated. Single-component surrogate fuels (lower left) are used to represent realistic fuels. Charge density and temperature at the time of compression are given on the top axis, resulting from bottom center conditions and compression ratio (CR) indicated at upper right.

Figure 5 also shows that the LL depends strongly on fuel type. Fuels with a high boiling point temperature, such as #2 diesel and biodiesel, have a longer liquid penetration than fuels with a low boiling point temperature, such as gasoline. In this calculation, the thermodynamic properties of single-component surrogate fuels are used to provide representative $(F/A)_{liq}$ for realistic fuels. For instance, *n*-heptadecane has a boiling point temperature that corresponds to the 90% distillation temperature point for #2 diesel, and methyl oleate is one of the major components for soy methyl ester biodiesel. The use of these surrogates has been justified by past comparison with experimental

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

data (Siebers, 1999). For example, the measured LL for the same conditions of Figure 4 is shown as a square symbol, falling right in line with the #2 diesel predictions in Figure 5.

The very strong effect of charge-gas temperature and density is also evident in Figure 5. Injecting #2 diesel and biodiesel before approximately −40 CAD results in LLs that exceed 100 mm, which is much larger than the bore radius of a typical heavy-duty diesel engine. Wall wetting, fuel film formation, and oil contamination are expected, particularly for biodiesel, as the predictions show that the LL of biodiesel is 15–50% higher than that of diesel with more significant differences at earlier injection timing. As such, one can appreciate why diesel fuels are typically injected only near TDC. On the other hand, the high volatility gasoline produces much shorter LLs, remaining well below 100 mm for injections as early as −90 CAD. At −90 CAD, where the expected charge temperature and density are much lower, approximately 410 K and 1.7 kg/m^3, respectively. Clearly, gasoline evaporates quite effectively, consistent with the practice for injection of gasoline even at BDC.

With reference to the gasoline results, we also show the effect of fuel temperature or the use of ethanol as an alternative to gasoline. Simulating a cold engine start at winter conditions, the gasoline temperature was changed from 95°C, a warm engine coolant temperature, to 0°C. The LL increases by 50–70%, suggesting a far greater likelihood for wall wetting at cold-start conditions. If significant fuel remains as a film along the wall and does not vaporize during compression and reach the spark plug, the engine will misfire during cold start. The predicted LLs for ethanol are also much higher than that of gasoline, by more than a factor of two. Curiously, the boiling point temperature is lower for ethanol compared to iso-octane, the gasoline surrogate fuel. However, the heat of vaporization is factor of 2.7 higher for ethanol than for iso-octane. Therefore, ethanol requires more entrainment of hot charge gases to reach the point of complete evaporation. As a result, ethanol has a longer LL than that of gasoline. Fuel and fuel temperature dependencies on LL obviously deserve attention for the injector and engine design.

While the perspective of overall and maximum liquid-phase penetration for a single spray is helpful because of the basic understanding it affords, actual injection systems coupled with gas flows that are highly variable and turbulent require deeper analysis. In the following sections, we describe spray modeling as applied to computational fluid dynamics (CFD) simulations.

3 THEORIES OF ATOMIZATION, DROP BREAKUP AND SPRAY PROCESSES

Engine sprays are multidimensional, multiphase, multicomponent, turbulent, compressible, reactive flows. The length scales of the smallest drops in the spray are of the order of a few micrometers (Figure 1) and their lifetimes are tens of microseconds. However, IC engine physical dimensions and timescales are of the order of centimeters and tens of milliseconds. This three to four orders of magnitude range disparity of scales necessitates that submodels be formulated for processes that are too small to be resolved in practical CFD. These processes include atomization and drop breakup, drop collision and coalescence, vaporization, drag and deformation, turbulent diffusion, and wall impingement, as discussed in this section.

The basic governing equations are the continuity (mass conservation), momentum (Navier–Stokes equations), energy, turbulence [normally the Reynolds averaged Navier–Stokes (RANS) $k-\epsilon$ equations] equations, and equations of state (ideal gas law). Assumptions include the use of the ideal gas law, Fick's law of mass diffusion, and others, depending on the details of the model. The discrete droplet model (DDM) (Dukowicz, 1980) method is widely used by researchers and also in commercial engine CFD codes to model the gas–liquid flow interactions. The gas phase is treated as continuous and described by the conventional Eulerian formulation. The liquid phase is treated as consisting of discrete particles and is described using the Lagrangian approach, in which liquid droplets are represented as assemblages of particles using the DDM method. The Lagrangian description of the particles avoids numerical diffusion and allows individual attributes, such as particle size, velocity, and position, to be statistically assigned to each particle. Mass, momentum, and heat transfer between the gas and liquid phases is accounted for with source terms that describe unresolved physical processes using submodels. Some important spray models are discussed next.

3.1 Governing equations

3.1.1 Gas phase

The motion of a gas-phase flow is described using the Navier–Stokes equations. The gas mixture consists of multiple species, and the continuity equation for species k is

$$\frac{\partial(\rho Y_k)}{\partial t}+\frac{\partial(\rho Y_k U_j)}{\partial x_j}=\frac{\partial}{\partial x_j}\left[\rho D\frac{\partial Y_k}{\partial x_j}\right]+\dot{\omega}_k+\dot{\rho}_k^{\mathrm{s}} \quad (7)$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

where Y_k is the mass fraction of species k, ρ is the total mass density of the mixture, t is the time, x_j is the Cartesian position, and U_j is the fluid velocity. D is the single diffusion coefficient with the assumption of Fick's law diffusion. $\dot{\omega}_k$ and $\dot{\rho}_i^{\mathrm{s}}$ are source terms because of chemical reaction and spray evaporation/condensation, respectively. Summing Equation 7 over all species yields the continuity equation for the gas phase:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho U_j)}{\partial x_j} = \dot{\rho}^{\mathrm{s}} \tag{8}$$

The momentum equations for the gas-phase are

$$\frac{\partial (\rho U_i)}{\partial t} + \frac{\partial (\rho U_i U_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j} + F_i^{\mathrm{s}} + F_i^{\mathrm{b}} \tag{9}$$

where p is the pressure and τ is the viscous stress tensor:

$$\tau_{ij} = \mu \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} - \frac{2}{3} \frac{\partial U_k}{\partial x_k} \delta_{ij} \right) \tag{10}$$

where μ is the dynamic viscosity, δ is the Kronecker delta, and F_i^{s} is a source term due to spray drop drag forces. F_i^{b} is the gravitation body force equal to ρg.

The energy conservation equation can be expressed in terms of sensible energy, e, which is the specific internal energy exclusive of chemical energy, as

$$\frac{\partial (\rho e)}{\partial t} + \frac{\partial (\rho e U_j)}{\partial x_j} = -p \frac{\partial U_j}{\partial x_j} + \frac{\partial J_j}{\partial x_j} + \dot{Q}^{\mathrm{s}} + \dot{Q}^{\mathrm{c}} \tag{11}$$

The heat flux vector J is the sum of contributions because of heat conduction and enthalpy diffusion:

$$J_j = -K \frac{\partial T}{\partial x_j} - \rho D \sum_{k=1}^{N_s} h_k \frac{\partial Y_k}{\partial x_j} \tag{12}$$

$\dot{Q}^{\mathrm{s}}$ and $\dot{Q}^{\mathrm{c}}$ are source terms because of spray and chemical reaction, respectively, and N_{s} is the total number of species. Assuming an ideal gas, the state equation is used to relate pressure and density:

$$p = \rho R T \sum_{k=1}^{N_s} \frac{Y_k}{W_k} \tag{13}$$

where W_k is the molecular mass of the kth species.

3.1.2 Liquid phase

The liquid-phase interactions with the gas-phase flow are complicated two-way couplings. For example, turbulence modifies the dispersed drops behavior, which, in turn, modifies turbulence produced by the drops. When the particle number density is sufficiently large, the effect of the particle–particle interactions (e.g., collisions and coalescences) must be considered.

The locally homogeneous flow (LHF) model neglects the slip effect between the liquid and gas phases, which are assumed to be in dynamic and thermodynamic equilibrium (Crowe, Sommerfeld, and Tsuji, 1998). This is the limiting case with infinitely small droplets. To consider the effects of the finite rate transport between the phases, various separated flow (SF) models have been proposed, including the DDM. In the DDM, the spray is represented by a finite number of parcels of identical drops. The motion and transport of these droplet groups are tracked and the effects of the liquid phase on the gas phase are considered by introducing appropriate spray source terms into the governing equations of the gas phase. This approach assumes that after primary breakup the droplets are small enough to be viewed as point sources. Thus, the spray dynamics can be described by the spray equation (Williams, 1958), where the spray is represented by a droplet distribution function, f:

$$f = f(\mathbf{V}_{\mathrm{d}}, r_{\mathrm{d}}, T_{\mathrm{d}}, y, \dot{y}; \mathbf{x}, t) \tag{14}$$

where $\mathbf{x}$, $\mathbf{V}_{\mathrm{d}}$, r_{d}, and T_{d} are the spatial location, velocity, equilibrium radius (the radius that the droplet would have if it was spherical), and the temperature of the droplet, respectively. y and $\dot{y}$ monitor the distortion of the drop from the spherical shape and its time rate of change. The droplet distribution function is defined such that $f \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\dot{y}$ is the probable number of droplets per unit volume at position $\mathbf{x}$ and time t with velocity in the interval $(\mathbf{V}, \mathbf{V} + \mathrm{d}\mathbf{V})$, radii in the interval $(r_{\mathrm{d}}, r_{\mathrm{d}} + \mathrm{d}r_{\mathrm{d}})$, temperature in the interval $(T_{\mathrm{d}}, T_{\mathrm{d}} + \mathrm{d}T_{\mathrm{d}})$, and distortion parameters in the intervals $(y, y + \mathrm{d}y)$ and $(\dot{y}, \dot{y} + \mathrm{d}\dot{y})$. The first moment of f is the number density of the droplets:

$$n = \int f \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\dot{y} \tag{15}$$

The second moment about radius r_{d} is the liquid volume fraction θ or liquid macroscopic density ρ'_1:

$$\theta = \int \frac{4}{3} \pi r^3 f \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\dot{y}$$

$$\rho'_1 = \int \frac{4}{3} \pi r^3 \rho_{\mathrm{d}} f \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\dot{y} \tag{16}$$

The time evolution of f is obtained by solving the spray equation:

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

$$\frac{\partial f}{\partial t} + \nabla_{\mathbf{x}} \cdot (f\mathbf{V}_{\mathrm{d}}) + \nabla_{\mathbf{V}} \cdot (f\mathbf{F}) + \frac{\partial}{\partial r_{\mathrm{d}}}(f\dot{r}_{\mathrm{d}}) + \frac{\partial}{\partial T_{\mathrm{d}}}(f\dot{T}_{\mathrm{d}}) + \frac{\partial}{\partial y}(f\dot{y}) + \frac{\partial}{\partial \dot{y}}(f\ddot{y}) = \dot{f}_{\mathrm{coll}} + \dot{f}_{\mathrm{bu}} \tag{17}$$

where $\mathbf{F}$, $\dot{r}_{\mathrm{d}}$, $\dot{T}_{\mathrm{d}}$, and $\ddot{y}$ are the time rates of change of the drop's velocity, radius, temperature, and oscillation velocity $\dot{y}$, respectively. The terms on the right-hand side account for collision and coalescence and drop breakup effects on the distribution function. With f solved for, the effects of the liquid phase on the gas phase are modeled with the source terms in the conservation equations (Equations 8, 9, and 11), namely,

$$\dot{\rho}^{\mathrm{s}} = -\int 4\pi r_{\mathrm{d}}^2 \dot{r}_{\mathrm{d}} \rho_{\mathrm{d}} f \, \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\ddot{y} \tag{18}$$

$$\mathbf{F}^{\mathrm{s}} = -\int \left(\frac{4}{3}\pi r_{\mathrm{d}}^3 \mathbf{F}' + 4\pi r_{\mathrm{d}}^2 \dot{r}_{\mathrm{d}} \mathbf{V}_{\mathrm{d}} \right) \rho_{\mathrm{d}} f \, \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\ddot{y} \tag{19}$$

$$\dot{Q}^{\mathrm{s}} = -\int \left\{ \frac{4}{3}\pi r_{\mathrm{d}}^3 \left[C_{\mathrm{p,l}} \dot{T}_{\mathrm{d}} + \mathbf{F}' \cdot \left(\mathbf{V}_{\mathrm{d}} - \widetilde{\mathbf{U}} - \mathbf{u}' \right) \right] + 4\pi r_{\mathrm{d}}^2 \dot{r}_{\mathrm{d}} \left[e_{\mathrm{l}}\left(T_{\mathrm{d}}\right) + \frac{1}{2}(\mathbf{V}_{\mathrm{d}} - \widetilde{\mathbf{U}})^2 \right] \right\} \times \rho_{\mathrm{d}} f \, \mathrm{d}\mathbf{V}_{\mathrm{d}} \mathrm{d}r_{\mathrm{d}} \mathrm{d}T_{\mathrm{d}} \mathrm{d}y \mathrm{d}\ddot{y} \tag{20}$$

where $\mathbf{F}' = \mathbf{F} - \mathbf{g}$.

3.2 Atomization models

In the primary breakup process, the liquid exiting the injector nozzle disintegrates into filaments and drops because of interaction with the surrounding gas, as depicted in Figure 6. In spite of decades of research, the details of the breakup process are not well understood, partially due to the fact that the optically dense region near the nozzle exit cannot be resolved easily experimentally. Instabilities on the liquid–gas interface are thought to be a major driving force for the breakup process. Recent high resolution X-ray spray visualization experiments and direct numerical simulations (DNS)s (Section 4) provide some support for the existence of instabilities that lead to surface waves and their role in the breakup process.

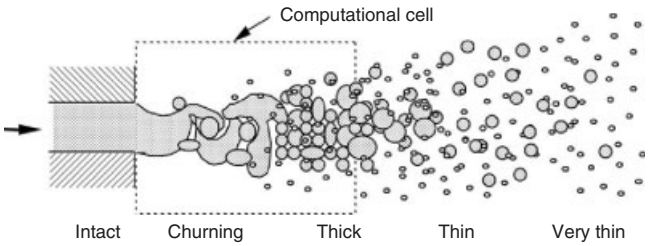

Figure 6. Schematic diagram of jet breakup regimes.

In practical engine CFD simulations, the atomization process occurs on length scales that are below the scale of resolution of the computational mesh, as depicted in Figure 6. In this case, initial conditions for the drop distribution function parameters in the DDM at the injector nozzle exit must be supplied using submodels. The necessary parameters include the injection velocity and initial drop sizes and trajectories. The injection velocity or injection rate shape can be determined from detailed injector flow dynamic simulations that account for needle movement and cavitation processes (Lee and Reitz, 2010). However, in engine codes, simpler phenomenological nozzle flow models such as that of Sarre, Kong, and Reitz (1999) are often used with a measured injection rate shape. In this model, the nozzle discharge coefficient ratio in Equation 1 is modeled as

$$C_{\mathrm{d}}/C_{\alpha} = C_{\mathrm{V}} = \left(K + \mathrm{frict}\ \frac{L}{D} + 1 \right)^{1/2} \tag{21}$$

where the friction factor frict and inlet loss coefficient K are determined from tabulated data.

3.2.1 Primary breakup

The breakup process has been modeled using wave instability models, such as the hybrid Kelvin–Helmholtz (KH) and Rayleigh–Taylor (RT) models of Beale and Reitz (1999). The KH model is based on a linearized analysis of the stability of the surface of a cylindrical liquid jet or sheet to perturbations, η, as depicted in Figure 7.

These linear stability analyses lead to dispersion equations that include the physical and dynamical parameters of the liquid jet or sheet and the surrounding gas, and which relate the growth rate of unstable waves to their wavelength. Curve fits of numerical solutions have been generated by Reitz (1988) for the maximum growth rate, Λ_{KH} (Λ in Figure 7), and the corresponding wavelength, Ω_{KH} (Ω in Figure 7), for jets as

$$\Lambda_{\mathrm{KH}} = \frac{9.02 r_{\mathrm{d}} (1 + 0.45\mathrm{Z}^{0.5})(1 + 0.4\mathrm{T}^{0.7})}{(1 + 0.865\mathrm{We}_{\mathrm{air}}^{1.67})^{0.6}} \tag{22}$$

$$\Omega_{\mathrm{KH}} = \frac{0.34 + 0.38\mathrm{We}_{\mathrm{air}}^{1.5}}{(1 + \mathrm{Z})(1 + 1.4\mathrm{T}^{0.6})} \sqrt{\frac{\sigma}{\rho_{\mathrm{l}} r_{\mathrm{d}}^3}} \tag{23}$$

where the gas Weber number is $\mathrm{We}_{\mathrm{air}} = \rho U_{\mathrm{rel}}^2 r_{\mathrm{d}}/\sigma$, and the Ohnesorge number is $\mathrm{Z} = \mathrm{We}_{\mathrm{d}}^{1/2}\mathrm{Re}_{\mathrm{l}}^{-1}$. U_{rel} is the relative

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

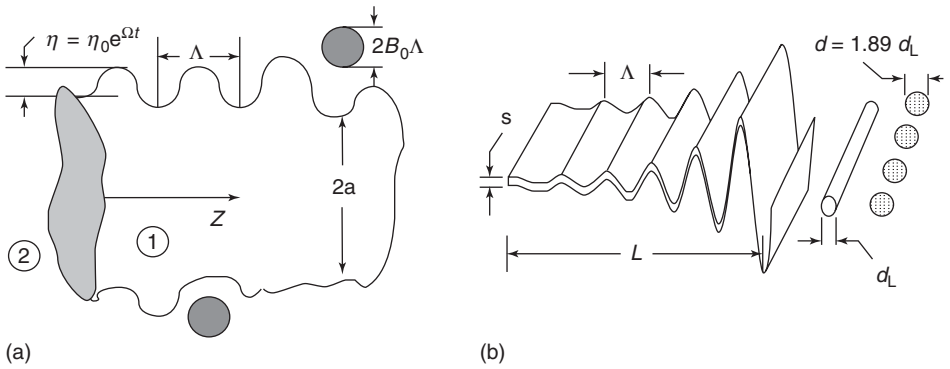

Figure 7. Schematic diagrams depicting surface wave-induced breakup of (a) liquid jets or "blobs" and (b) liquid sheets.

velocity between the gas and the droplet and σ is the surface tension. The droplet Weber number is $We_d = \rho_l U_{rel}^2 r_d/\sigma$, the liquid Reynolds number is $Re_l = \rho_l |\mathbf{U}_{rel}|^2 r_d/\mu_{l,}$ and T is the Taylor number $T = We_{air}^{1/2} Z$.

The KH model is implemented by postulating that a parent drop with radius r_d breaks up from a liquid jet of diameter $d_L = 2a$ to form new droplets with radius $r_{d,c}$ determined by (Reitz, 1988):

$$r_{d,c} = B_0 \Lambda_{KH} \tag{24}$$

as depicted in Figure 7a, where B_0 is a model constant. The rate of change in the radius of the parent droplet or liquid blob is described by

$$\frac{dr_d}{dt} = \frac{r_d - r_{d,c}}{\tau_{KH}} \tag{25}$$

where the breakup timescale τ_{KH} is

$$\tau_{KH} = \frac{3.726 B_1 r_d}{\Omega_{KH} \Lambda_{KH}} \tag{26}$$

where B_1 is a second model constant.

The RT model describes the growth of instabilities associated with deceleration of the injected drops. The frequency of the fastest growing wave, Ω_{RT} (Ω in Figure 7), and its corresponding wavelength, Λ_{RT} (Λ in Figure 7), are given by (Beale and Reitz, 1999)

$$\Omega_{RT} = \sqrt{\frac{2}{3\sqrt{3\sigma}} \frac{[-a_d(\rho_l - \rho)]^{1.5}}{\rho_l + \rho}} \tag{27}$$

$$\Lambda_{RT} = 2\pi \Omega_{RT} \sqrt{\frac{3\sigma}{-a_d(\rho_l - \rho)}} \tag{28}$$

where a_d is the droplet acceleration. When the predicted wavelength is less than the droplet diameter, the RT waves are assumed to grow on the surface of the droplet and the wave growth time is tracked. When it reaches the RT breakup timescale $\tau_{RT} = C_\tau/\Omega_{RT}$, the drop is assumed to break up. The radii of the new droplets are computed using

$$r_{d,c} = 2 C_{RT} \Lambda_{RT} \tag{29}$$

where C_τ and C_{RT} are additional model constants. Beale and Reitz (1999) applied the RT model to the decelerating drops beyond a liquid breakup length that is proportional to the distance, $L \sim t_{BK} U_{mean}$ (Figure 2).

Other liquid breakup and atomization models have been proposed that consider drop deformation processes such as the Taylor analogy breakup (TAB) model of O'Rourke and Amsden (1987), as described in Section 3.2.2.

3.2.2 *Droplet breakup and drag*

When the relative velocity between the drop and the surrounding gas is high, the drop deforms, which also influences its drag coefficient. The drop drag coefficient was related empirically by Liu, Mather, and Reitz (1993) to the magnitude of the drop deformation using

$$C_d = C_{d,sphere}(1 + 2.632y) \tag{30}$$

where $C_{d,sphere}$ is the drag coefficient of a spherical drop and y is the drop distortion parameter that is proportional to the displacement of the drop's surface from its equilibrium position divided by the drop's radius. $y = 0$ represents the lower limit of a sphere and $y = 1$ the upper limit of a flat disk, as shown in Figure 8a.

y can be computed using the TAB model of O'Rourke and Amsden (1987) or the similar droplet deformation and breakup (DDB) model of Ibrahim, Yang, and Przekwas (1993). The TAB model assumes that a liquid drop is analogous to a spring–mass system (analogy of Taylor,

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

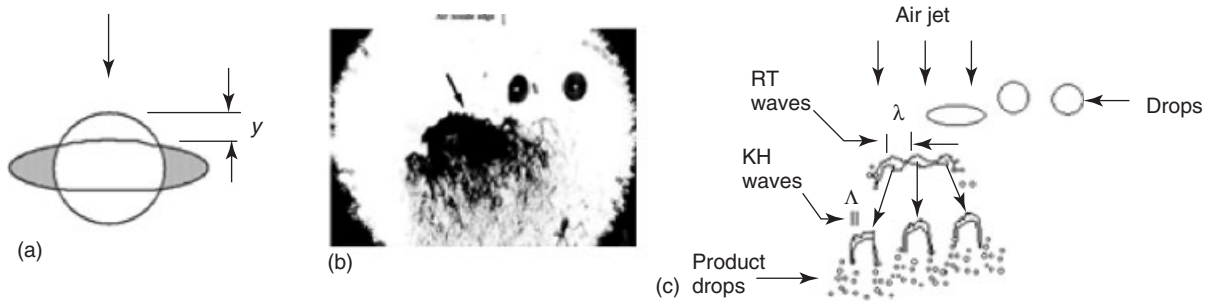

Figure 8. Schematic diagram of (a) drop deformation leading to breakup and (b) photograph of 170 mm diesel fuel drops deflected and broken up by 250 m/s air jet. Monodisperse drop stream enters from right, and the air jet is oriented vertically downward. RT waves are indicated by arrow. (c) Proposed KH–RT drop breakup mechanisms. (Reprinted from Atomization and Sprays, Vol. 6, Hwang, S.S., Liu, Z., and Reitz, R.D., Breakup Mechanisms and Drag Coefficients of High Speed Vaporizing Liquid Drops, pp. 353–376, Copyright (1996), with permission from Begell House, Inc.)

1963), and drop breakup occurs when the amplitude of the drop oscillation $y = 1$. The drop distortion parameter is given as

$$\ddot{y} = -5\frac{\mu_l}{\rho_l}\frac{\dot{y}}{r_d^2} - \frac{8\sigma y}{\rho_l r_d^3} + \frac{2}{3}\frac{\rho}{\rho_l}\frac{U_{rel}^2}{r_d^2} \tag{31}$$

where U_{rel} is the relative velocity between the gas and the drop. As can be seen in Figure 8b, in the case of high speed drop breakup, the flattened drop disintegrates into a shower of drops. Hwang, Liu, and Reitz (1996) proposed that the breakup is due to KH and RT instabilities (Figure 8c), as discussed for jet breakup earlier.

3.3 Models of other spray processes

3.3.1 *Turbulent dispersion models*

In most DDMs, the drop moves according to its velocity, $\frac{d\mathbf{x}_d}{dt} = \mathbf{V}_d$, and its acceleration is

$$\frac{d\mathbf{V}_d}{dt} = \frac{\mathbf{F}_d}{m_d} = D_d(\mathbf{U} - \mathbf{V}_d) + \mathbf{g} \tag{32}$$

where the drag function $D_d = \frac{3}{8}\frac{\rho|\mathbf{U}-\mathbf{V}_d|}{\rho_d r_d}C_d(\mathrm{Re}_d)$ and the drag coefficient are given by Amsden *et al.* (1985) as

$$C_d = \begin{cases} 24\mathrm{Re}_d^{-1}\left(1 + \mathrm{Re}_d^{2/3}/6\right), & \mathrm{Re}_d < 1000 \\ 0.424, & \mathrm{Re}_d \geq 1000 \end{cases} \tag{33}$$

The drop Reynolds number is $\mathrm{Re}_d = \frac{2\rho r_d|\mathbf{U}-\mathbf{V}_d|}{\mu_{air}(\widehat{T})}$, where the average temperature $\widehat{T} = (T + 2T_d)/3$, and the gas instantaneous velocity $\mathbf{U}$ seen by the droplet is $\mathbf{U} = \widetilde{\mathbf{U}} + \mathbf{u}''_d$, where $\widetilde{\mathbf{U}}$ is the mean gas velocity.

Turbulence effects are modeled by a turbulent dispersion model, which provides the gas turbulent velocity, $\mathbf{u}''_d$. Each component of $\mathbf{u}''_d$ is randomly chosen from a Gaussian distribution with standard deviation, $\sigma = \sqrt{2k/3}$. $\mathbf{u}''_d$ is chosen once every turbulence correlation time t_{turb}, which is the minimum of an eddy breakup time and a time for the droplet to penetrate an eddy (Gosman and Ioannides, 1981).

3.3.2 *Drop collision and coalescence models*

The seminal drop collision model of O'Rourke (1981) considers collisions between drop parcels located in the same computational cell. The collision frequency of a pair of particles is

$$\nu = \frac{N_{mp}}{V_{cell}}\pi(r_{lp} + r_{mp})^2|\mathbf{V}_{lp} - \mathbf{V}_{mp}| \tag{34}$$

where the subscripts mp and lp denote the more populous and less populous droplet parcels, respectively, N is the number of drops in the parcel, and V_{cell} is the volume of the numerical cell. The probability that the more numerous particles undergo n collisions with the smaller number of particles is assumed to follow a Poisson distribution, and the probability of no collision is $P_0 = e^{-\nu\Delta t}$, where Δt is the computational time step. A random variable is selected to determine whether the collision event will occur or not. Another independent random number YY in the interval (0,1) is used to calculate the collision impact parameter $b = YY^{1/2}(r_{lp} + r_{mp})$, which determines the collision outcome by comparing it with the critical impact parameter b_{cr}

$$b_{cr} = (r_{lp} + r_{mp})\{\min[1, 2.4(\gamma^3 - 2.4\gamma^2 + 2.7\gamma)/\mathrm{We}_{lp}]\}^{1/2} \tag{35}$$

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

with $\gamma = r_S/r_L$, and the Weber number of the larger drop parcel $We_{lp} = \rho_d |\mathbf{V}_{lp} - \mathbf{V}_{mp}| r_{lp}/\alpha(\overline{T}_d)$. For the Weber number, the mean temperature $\overline{T}_d = \frac{r_{mp}^3 T_{d,lp} + r_{mp}^3 T_{d,mp}}{r_{lp}^3 + r_{mp}^3}$ and the liquid surface tension coefficient $\alpha(\overline{T}_d) = \frac{\overline{T}_d - T_{cr}}{T_0 - T_{cr}} \alpha_0$.

When $b < b_{cr}$, coalescence occurs, otherwise each collision is assumed to be a grazing collision. In the case of a coalescence collision, the droplet number of the new parcel is adjusted and the properties of the new parcel are determined from mass and momentum conservation laws. Improvements have been made to the O'Rourke model to account for other collisions outcomes, such as satellite drop formation and drop shattering by Munnannur and Reitz (2007).

As the O'Rourke model only considers collision events between groups of identical droplets (parcel) that are located in the same computational cell, the outcome of the model depends on mesh size. To remove mesh dependency, Munnannur and Reitz (2009) proposed a radius-of-influence (ROI) collision model. The ROI model considers potential collision between every pair of droplet parcels whose distance $D_{lp,mp}$ is smaller than the maximum of their influence radii, R_{lp} and R_{mp}, where R_p is the distance of the colliding drops, and l and m can travel at their current velocities in one numerical time step:

$$D_{lp,mp} \leq \max(R_{lp}, R_{mp}) \tag{36}$$

The collision frequency is then computed as:

$$\nu = \frac{N_{mp}}{V_{col}} \pi (r_{lp} + r_{mp})^2 |\mathbf{V}_{lp} - \mathbf{V}_{mp}| \tag{37}$$

The collision volume V_{col} is based on the radii of influence:

$$V_{col} = \frac{4}{3} \pi (R_{lp} + R_{mp})^3 \tag{38}$$

Thus, the influence of mesh topology is removed and the collision events only depend on the droplet parcel distribution in space. Other elements of the ROI model are similar to those of the O'Rourke model.

3.3.3 *Drop vaporization*

Assuming a single composition and homogeneous distribution of temperature inside the droplet, the rate of droplet radius change due to evaporation is given by the Frossling correlation (Faeth, 1983):

$$r_d = \frac{dr_d}{dt} = -\frac{\rho D}{2\rho_d r_d} B_m Sh_d \tag{39}$$

where Sh_d is the Sherwood number for mass transfer:

$$Sh_d = (2.0 + 0.6\ Re_d^{1/2} Sc_d^{1/3})\ \frac{\ln(1 + B_m)}{B_m} \tag{40}$$

with Schmidt number $Sc_d = \frac{\mu_{air}(T)}{\rho D}$. D is the fuel vapor diffusivity and $B_m = \frac{Y_{F,s} - Y_{F,\infty}}{1 - Y_{F,s}}$ is the Spalding mass transfer number, with $Y_{F,s}$ and $Y_{F,\infty}$ the fuel vapor mass fraction at the droplet's surface and at the outer boundary of the film surrounding the droplet. The surface mass fraction $Y_{F,s}$ is computed from the Clausius–Clapeyron equation:

$$Y_{F,s}(T_d) = \frac{1}{1 + \frac{W_{air}}{W_F} \left[\frac{p}{p_v(T_d)} - 1\right]} \tag{41}$$

where W_F is the molecular weight of fuel vapor, and W_{air} is the local average molecular weight of all species except fuel vapor. p is the local pressure and p_v is the equilibrium fuel vapor pressure.

The rate of droplet temperature change is determined from the energy equation:

$$\frac{4}{3} \rho_d \pi r_d^3 C_l \dot{T}_d - 4\rho_d \pi r_d^2 \dot{r}_d L(T_d) = 4\pi r_d^2 \dot{Q}_d \tag{42}$$

where C_l is the liquid specific heat, $L(T_d)$ is the latent heat of vaporization, and $\dot{Q}_d$ is the rate of heat conduction to the droplet surface per unit area and is computed using the Ranz–Marshall correlation (Faeth, 1983):

$$\dot{Q}_d = \frac{k_{air}\ (\widehat{T})\ (T - T_d)}{2r_d}\ Nu_d \tag{43}$$

where the Nusselt number Nu_d is

$$Nu_d = \left(2.0 + 0.6 Re_d^{1/2} Pr_d^{1/3}\right) \frac{\ln(1 + B_m)}{B_m} \tag{44}$$

and the Prandtl number $Pr_d = \frac{\mu_{air} C_p}{k_{air}}$, C_p is the local specific heat at constant pressure, and k_{air} is the thermal conductivity coefficient of air.

Ra and Reitz (2009) have developed a more accurate model that considers transient heat transfer inside the droplet. Instead of assuming a uniform droplet temperature, the droplet surface temperature $T_{d,s}$ is computed from a heat and mass transfer balance at the interface between the droplet and surrounded gas when the droplet size is larger than a preset critical value. The energy balance at the interface is written as

$$4\rho_d \pi r_d^2 \dot{r}_d L(T_{d,s}) = 4\pi r_d^2 (Q_i + Q_d) \tag{45}$$

where Q_i is the energy flux from inside the droplet to the surface. It is modeled as a convective heat transfer process with internal circulation considered and written as

$$Q_i = \frac{k_l}{\delta_e}(T_d - T_{d,s}) \quad (46)$$

where k_l is the liquid thermal conductivity. δ_e is the unsteady equivalent thickness of the thermal boundary layer and calculated from the effective thermal diffusivity:

$$\delta_e = \sqrt{\pi \alpha_{eff} t} = \sqrt{\pi \chi \alpha_l t} \quad (47)$$

where $\chi = 1.86 + 0.86 \tan h[2.225 \log_{10}(Pe_l/30)]$ and Pe_l is the Peclet number of the droplet. Q_d is also computed from the droplet surface temperature $T_{d,s}$ from

$$Q_d = \frac{k_{air}\ (\widehat{T})\ (T - T_{d,s})}{2r_d}\ Nu_d \quad (48)$$

As the effective heat transfer coefficient for the outer heat flux is coupled with the vaporization rate, the surface temperature of the droplet must be determined by solving the two equations iteratively.

Other evaporation models have been proposed that consider multicomponent fuel effects. These include continuous multicomponent models (Lippert and Reitz, 1997), discrete multicomponent models (Ra and Reitz, 2009), and discrete/continuous multicomponent models (Yang and Reitz, 2010), which have been developed and applied to IC engine simulations.

3.3.4 *Spray/wall impingement*

Spray wall impingement is important for both PFI and DI engines. Fuel wall films in the intake ports can cause an undesirable fuel delivery delay and an associated fuel metering error in PFI engines. In wall-guided *direct-injection-spark-ignition* (DISI) engines, the fuel is directly injected into a specially designed piston bowl and the spray impingement is used to generate an optimal stratified mixture. In diesel engines, spray wall impingement may lead to unacceptable unburned hydrocarbon (UHC) and/or soot emission, as well as low fuel efficiency. Therefore, an accurate spray/wall interaction model is important in engine simulations.

The outcome of a drop impingement event depends on the properties of the drop, the wall surface roughness conditions, and the details of the gas boundary layer in the near-wall region. If the wall temperature T_w is less than the liquid boiling temperature T_B, a collision of a drop on the solid surface may result in sticking, bouncing, spreading, or splashing, as described by Bai and Gosman (1995). The stick regime occurs when the impact energy is low and the wall temperature is below the pure adhesion temperature T_{pa}. The impinging drop adheres to the solid surface or coalesces with any liquid film existing on the surface. As the Weber number is increased, drop rebound can occur from the wall or liquid film, and the velocity and direction of the rebounding drop is often determined from experimental and analytical correlations (Naber and Reitz, 1988).

The spreading regime occurs at higher incident drop Weber numbers. Here, the drop spreads on the wall surface for a dry wall or merges with the liquid wall film on impact for a wet wall. When a train of drops impacts the wall surface, the time between multidrop impacts, or the impact frequency, must be considered. A splashing regime occurs at higher incident Weber numbers because of the development of a crown instability, which leads to secondary atomization of the impinging drop and/or wall film. The criterion for splash is

$$E^2_{splash} = \frac{We}{\min\ (H_f/d_d, 1) + Re_d^{-1/2}} > E^2_{splask,\ crit} \quad (49)$$

where H_f is the thickness of the liquid film and the drop Reynolds number is based on the velocity normal to the surface and $E^2_{splash,crit} = 3330.0$ (O'Rourke and Amsden, 2000). Liquid films can also be modeled using a two-dimensional thin film assumption that includes consideration of fuel vaporization (Stanton and Rutland, 1998).

3.4 Modeling applications

Two applications are briefly discussed as examples of current CFD spray modeling capabilities based on the spray models discussed in the previous sections. The first considers steady vaporizing, noncombusting sprays injected in a constant-volume chamber. Simulations that use coarse meshes and large time steps are of interest in applications to reduce the computer time needed for engine simulations. However, coarse meshes can result in inaccurate predictions of mass, momentum, and energy transfer between the spray drops and the combustion chamber gas, or poor prediction of droplet breakup and collision and coalescence processes. Accordingly, the spray models discussed earlier have been proposed to address these deficiencies, including use of an unsteady gas jet model to improve momentum transfer predictions in underresolved regions of the spray near the injector nozzle (Figure 6), a vapor particle model to minimize numerical diffusion effects, and a radius of influence drop collision model to ensure consistent collision computations on different meshes (Shi, Ge, and Reitz 2011;

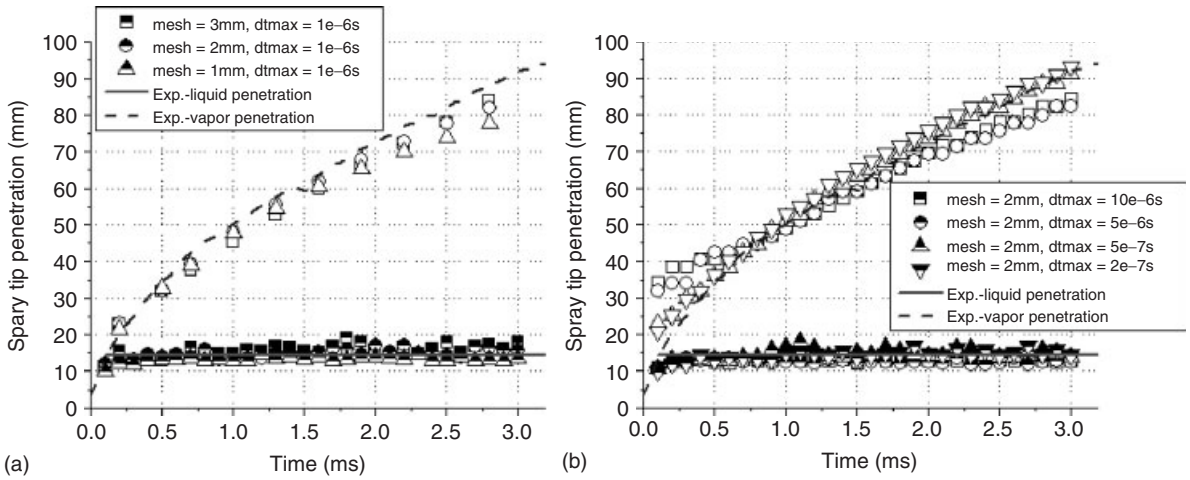

Figure 9. (a) Mesh and (b) time step independency of predicted vapor and liquid penetrations. Experimental data of Naber and Siebers (1996) and Pickett (2007). Diesel fuel injection, nozzle diameter 257 μm, injection pressure 1370 bar, gas temperature 1000 K, and gas density 58.6 kg/m^3.

http://www.springer.com/engineering/mechanical+eng/book/978-0-85729-618-4).

3.4.1 *Spray penetration predictions*

As discussed in Figure 4, spray penetration is an important process in direct injection engines, and thus accurate predictions are critical for CFD modeling. Wang, Ge, and Reitz (2010) combined the above models with KH–RT breakup models to improve the consistency of drop breakup predictions. A modified mean collision time model was also proposed to reduce the time step dependency of droplet collision predictions. The models were implemented into the KIVA CFD code (Amsden, 1997), and the results were found to demonstrate independence with respect to both mesh sizes and time steps, as shown in Figure 9. The vapor penetration and LL predictions agree well with the experiments of Naber and Siebers (1996) and Pickett (2007), even when various numerical grids are used whose mesh sizes vary by a factor of 3 (order of magnitude in cell volume), and with almost two orders of magnitude variations in time steps.

3.4.2 *Engine fuel–air mixing predictions*

A second example application of spray modeling in CFD simulations considers the single-cylinder optical light-duty diesel engine experiments simulated by Dempsey *et al*. (2012). The engine and injector geometry are summarized in Table 1, and a schematic of the engine is shown in Figure 10. A production, high pressure, solenoid-driven, common-rail Bosch CRIP2.2 fuel injector

Table 1. Engine and injector specifications for Figure 12.

Engine geometry

Bore/stroke (mm)	82.0/90.4
Displacement (cc)	4.77
Compression ratio	16.7
Squish height (mm)	0.88

Injector geometry
Bosch common rail CRIP2.2

Sac volume (mm^3)	0.23
Number of holes	7
Hole diameter (mm)	0.14
Included angle (deg)	149
Tip protrusion (mm)	2.1
Hole protrusion (mm)	0.3

	Baseline	*Current*
Engine speed (rpm)	1500	1500
Intake charge (Mole fraction)	O_2: 0.10 N_2: 0.81 CO_2: 0.09	N_2: 1.0
Intake temperature (K)	372	300
Intake pressure (bar)	1.5	1.5
Injection fuel (mg)	8.8	8.8
Fuel rail pressure (bar)	860	860
Global equivalence ratio	0.3	N.A.
Start of injection (° ATDC)*	–23.6	–23.6
Injection duration (° CA)	4.5	4.5
Swirl ratio	2.2	2.2

was centrally mounted in the cylinder head and features seven equally spaced holes with nominal nozzle hole diameter of 0.14 mm. The piston top is constructed from fused silica but retains the production piston geometry, featuring a reentrant bowl design and piston crown valve cutouts, as seen in the numerical mesh shown in Figure 11. Full 3D simulation results were used to initialize sector mesh simulations.

The engine was operated with pure nitrogen intake and thus under noncombusting conditions to allow equivalence ratio measurements using a toluene fluorescence diagnostic. The near-TDC temperature and density of a baseline combusting operating condition were closely matched by maintaining the same intake charge mass flow rate and lowering the intake temperature to account for the lower specific heat of the pure N_2 charge. The operating conditions for the baseline combusting case and the nonreacting case are shown in Table 1.

A comparison of the measured (Figure 12a) and predicted (Figure 12b) equivalence ratio fields is shown in Figure 12. The predictions show only one-seventh of the chamber as symmetry is assumed about each of the seven fuel jets from the nozzle. It can be seen that rapid mixing is observed in the head of the injected spray jets in the region above the bowl, with peak equivalence ratios near 2.0. This is well captured by the simulation where the peak equivalence ratio in the head of the jet is ∼2.1. It is also seen that the simulations adequately predict the bulk effects of swirl motion for this engine on the fuel spray.

4 DIRECT NUMERICAL SIMULATIONS OF ATOMIZATION

As described in Section 3.2, the physics of the liquid breakup process are still poorly understood. Accordingly, recent efforts to predict the atomization process, not through

modeling, but directly from a fully resolved simulation of the underlying equations or a DNS have commenced (Tryggvason, Scardovelli, and Zaleski 2011; Shinjo and Umemura, 2010, 2011a,2011b). DNS is enabled through a combination of improvements in numerical methods coupled with increases in computational power and the proliferation of massively parallel computing. The field is relatively young, with the first review been reported by Gorokhovski and Herrman (2008), which summarized work that appeared in the literature as far back as 2004. Owing to its recent inception and its potential impact into a variety of industrial applications, it is attracting an increasing number of research efforts and progress is being made at an accelerated pace.

An important aspect to note from recent DNS studies of atomization, for instance Shinjo and Umemura (2011b), is the significant level of computational power required. Under the traditional Lagrangian–Eulerian model approach, the number of cells (n) often used nowadays is around $O(10^5)$ and $O(10^6)$, whereas the DNS calculations are $O(10^9)$. Hence, the computational expense, which at best scales as $n\log(n)$, is approximately three to four orders of magnitude larger. The cost is also reflected in both memory usage and disk space. In addition, owing to the numerical constraints on time step size, for example, the Courant–Fredricks–Lewy (CFL) condition, the computational burden is further exacerbated. Nevertheless, the level of physical detail offered by DNS is well beyond any conventional spray treatment through simulation or experiments. It provides a complete inside view of the dense region of the spray, which, at this point, has not been possible. Equally as important, DNS offers a means of model testing that is significantly superior to all experimental validation exercises to date (provided the equations solved are an accurate reflection of the physics). All quantities calculated in a DNS can be interrogated and postprocessed for detailed comparison against models. Issues regarding the density of the spray plume, which have proved difficult to overcome in experimental diagnostic techniques, are simply nonexistent and irrelevant in DNS. Moreover, quantities such as local Weber numbers that cannot be obtained directly from experiments are available from DNS data sets.

Owing to the potential benefits arising from the use of DNS data in model validation, as well as in studies of the physics of atomization, it is important to recognize the challenges faced by the numerical solution of the governing equations. As opposed to single-phase flows, the presence of a gas–liquid interface poses significant numerical difficulties and continues to be an active area of research. In what follows, a brief review is given of the main numerical methods used in atomization simulations followed by a

Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

description of the latest simulation results. Most of the work that has been performed thus far consists of the advection of a gas–liquid interface under incompressible and isothermal flow conditions (both gas and liquid), where phase change is absent.

4.1 Numerical methods

Owing to the numerous topological changes undergoing in a typical atomization scenario, all numerical methods presently employ an implicit interface representation strategy. This essentially implies that the underlying computational mesh remains stationary, and the treatment avoids numerical stability issues (e.g., negative Jacobians) inherent in interface tracking methods, where the mesh points follow the interface. Under this strategy, the more common methods are the volume of fluid (VoF) (Hirt and Nichols, 1981), level set (Osher and Sethian, 1988), and hybrid schemes (Sethian and Smereka, 2003). These are summarized in the following subsections. More extensive reviews can be found in Tryggvason, Scardovelli, and Zaleski (2011) for the VoF approach and Osher and Fedkiw (2003) for the level set method.

4.1.1 Volume-of-fluid

The central part of the method is the transport of a volumetric liquid fraction, α, often referred to as the *color function*. If we define an indicator function as

$$I(\mathbf{x},t)=\begin{cases}1 & x\in \text{ the liquid phase}\\ 0 & x\in \text{ the gas phase}\end{cases} \tag{50}$$

the liquid fraction corresponding to a given computational cell, Ω_k, becomes

$$\alpha_k=\frac{1}{|\Omega_k|}\int_{\Omega_k} I(\mathbf{x},t)\mathrm{d}\forall \tag{51}$$

The VoF method is essentially composed of two steps. In the first step, the gas–liquid interface or free surface is reconstructed from the liquid fraction field. In the second step, this geometric construction is used to solved a transport equation for α, for instance

$$\frac{\partial\alpha}{\partial t}+\nabla\cdot(\alpha\mathbf{u})=0 \tag{52}$$

where $\mathbf{u}$ is the local liquid velocity. To date, a multitude of VoF methods have been presented with the first ones being reported by Debar (1974) and Hirt and Nichols (1981). In these works, interfacial cells, that is, cells where $0<\alpha<1$, were treated such that the interface was formed from line segments oriented parallel to either coordinate axis (SLIC, simple line interface). This low order geometric reconstruction was then used in the advection of fluid across computational cells. Owing to problems arising from erroneous generation of liquid bodies ejected from the liquid domain, floatsam or jetsam, improved reconstruction methods have been presented. For instance, the SLIC algorithm allowed piecewise linear segments to be arbitrarily oriented with respect to the coordinate axes (PLIC, piecewise linear interface) (Youngs, 1982) and provided an improvement over previous methods. A representation of both PLIC and SLIC methods is shown in Figure 13 adapted from the work of Rider and Kothe (1998).

A key parameter in the correct reconstruction of the interface arises from the accurate calculation of the interface normal, which can be directly linked to the slope of the interface. A number of methods have arisen to compute this quantity including the method of Youngs (1982), ELVIRA (efficient least-squares volume-of-fluid interface reconstruction algorithm) by Pilliod and Puckett (2004), and the least-squares fit method by Scardovelli and Zaleski (2003), as well as a number of other alternatives and combinations as discussed within these articles and in the text by Tryggvason, Scardovelli, and Zaleski (2011). Once the interface is reconstructed, it is employed in the solution of Equation 52, written in integral form as

$$\left(\frac{\alpha_k^{n+1}-\alpha_k^n}{\Delta t}\right)\mathrm{d}V=\int_{\partial\Omega_k}\alpha\mathbf{u}\cdot\mathbf{n}\mathrm{d}s \tag{53}$$

The key difficulty is ensuring that the geometrical information employed in the interface reconstruction is appropriately used in the calculation of volumetric mass fluxes. Due to this limitation, it is challenging to employ a broader range of mesh types, for instance, unstructured meshes.

Owing to the geometrical complexity of these previous schemes, alternatives to the entire interface reconstruction have been proposed within the VoF framework. Some of these are discussed by Gopala and van Wachem (2008). Among these alternatives, one approach, which has received increasing attention in recent years (Kissling *et al.*, 2010; Rusche, 2002), is based on adding a compressive term to the transport equation for α. This is the approach that characterizes the numerical treatment in the open source VoF code interFOAM, which forms part of the openFOAM libraries. In integral form, Equation 52 can be modified according to

$$\int_{\Omega_k}\frac{\partial\alpha}{\partial t}\mathrm{d}V+\sum_{f\in\partial\Omega_k}(\alpha_\mathrm{f}\varphi_\mathrm{f})=-\sum_{f\in\partial\Omega_k}(\varphi_{rf})[\alpha(1-\alpha)]_\mathrm{rf} \tag{54}$$

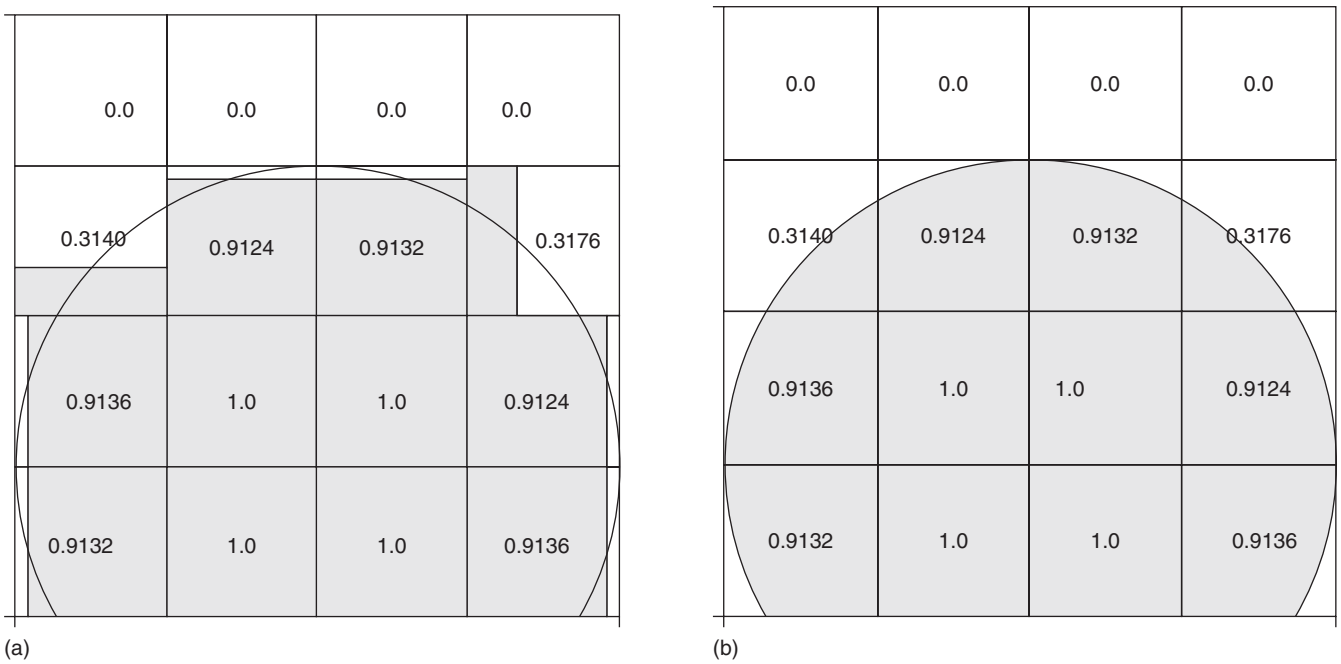

Figure 13. Shaded regions correspond to reconstructed liquid region for both the (a) SLIC and PLIC (b) methods. The PLIC method allows for a more realistic and accurate representation of the interface. Numbers in cells denote volume fractions. (Adapted from Rider and Kothe, 1998. © Elsevier.)

where the subscript f denotes each face associated with cell Ω_k and the flux φ is given by $u_f \cdot S_f$, where S_f is the vector area of a given face and u_f is the cell-centered projected velocity on the face. The compressive flux term appears on the right-hand side of this expression. A limiter is used in the evolution for α, such that the compressive flux is only active in the neighborhood of the interface. Its effect is to maintain the interface sharp by mitigating numerical diffusion. This solver has been tested against a variety of canonical advection test cases, for example, Zalesak notched disk and dynamic problems (e.g., sloshing and single droplet splashing) leading to results that range between first and second order in the L_1 error norm. The accuracy of the calculations are comparable to the coupled level set and volume-of-fluid (CLSVoF) of Sussman and Puckett (2000), the VoF method (SOVoF) of Pilliod and Puckett (2004), and the various VoF schemes studied in Gopala and van Wachem (2008).

4.1.2 *Level set methods*

A perhaps more popular approach in the direct simulation of multiphase flows with severe topological changes is the use of the level set method. Under this approach (Osher and Fedkiw, 2003), a level set function, ϕ, is solved as a Lagrangian invariant, namely

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = 0 \tag{55}$$

This function is then directly used to track the gas–liquid interface, which is generally denoted as the iso-surface corresponding to $\phi = 0$, that is, the zero level set. Hence, regions where ϕ is less than zero are typically interpreted as corresponding to a liquid phase, and similarly regions where ϕ is greater than zero pertain to the gas phase. In addition, the level set function is initialized and periodically maintained to be equal to a distance function to the interface, that is, $\phi(x) = |\mathbf{x} - \mathbf{x}_f|$, where $\mathbf{x}_f$ is the closest interfacial point to $\mathbf{x}$. This distance function property has been shown to help in the preservation of accuracy (Sussman, Smereka, and Osher 1994) as the level set field is evolved.

A variety of methods have been presented on the most efficient and accurate ways to calculate this equation. In fact, much of the literature on this topic does not even address our atomization problem but emphasizes the numerical issues in solving Equation 55. This continues to be an active area of research, which will eventually translate to better and more efficient methods for simulating the liquid breakup problem. The latest methods using this approach (Nave, Rosales, and Seibold 2010; Czajkowski and Desjardins, 2011; Yan and Osher, 2011) report an impressive order of accuracy with second-order behavior in

Encyclopedia of Automotive Engineering, Online © 2014 John Wiley & Sons, Ltd.

DOI: 10.1002/9781118354179.auto118
Also published in the *Encyclopedia of Automotive Engineering* (print edition) ISBN: 978-0-470-97402-5

the calculation of interfacial curvature. This last parameter is particularly important in the calculation of surface tension forces, which govern the breakup behavior for sufficiently small droplets or ligaments.

4.1.3 *Momentum calculation in atomization calculations*

Due to the presence of both gas and liquid phases and the significant changes in material properties, special care has to be given to the solution of momentum, which is derived in Chang *et al*. (1996), yielding

$$\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) = -\nabla P + \nabla \cdot [\mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T)] + \rho \mathbf{g} + \int_\Gamma \sigma \delta(\mathbf{x} - \mathbf{x}_s)\kappa \mathbf{n} \qquad (56)$$

where the conservative form is presented here and Γ is the gas–liquid interface. For atomization calculations, the surface tension force is particularly important in governing the formation of the resulting droplet population. This force is represented by the last term in Equation (56), where the Diract delta function, δ, is used to isolate the surface tension effects to the interface location $\mathbf{x}_s$. The local curvature and interface normal are, respectively, given by κ and $\mathbf{n}$. Two common approaches exist in the literature for implementing the surface tension into a numerical discretization of Equation (56), namely the continuous surface force method (Brackbill, Kothe, and Zemach 1992) and the continuous surface stress method. Both of these are elaborated in detail in Tryggvason, Scardovelli, and Zaleski (2011).

For VoF methods, the viscosity and density are generally expressed as a weighted function of the liquid fraction α,

$$\mu(\mathbf{x}_\kappa) = \mu_l \alpha(\mathbf{x}_\kappa) + \mu_g(1 - \alpha(\mathbf{x}_\kappa)) \quad \text{and}$$
$$\rho(\mathbf{x}_\kappa) = \rho_l \alpha(\mathbf{x}_\kappa) + \rho_g(1 - \alpha(\mathbf{x}_\kappa)) \qquad (57)$$

where $\mathbf{x}_k$ corresponds to the spatial location for a given cell. Similarly, in level set methods, these material properties are smoothed over the interface using hyperbolic functions that essentially spread the interface over one or two grid cells. Recent methods have advocated the use of sharp interface strategies, which implies that the above relatively smooth transition in material properties, for instance Equation 57, occurs abruptly. A closer look at these strategies generally reveals that such an exact approach is often voiced but rarely strictly enforced. The final solution of Equation (56) for atomization simulations is often exercised using the classical projection methods introduced by Chorin (1968) or the PISO algorithm (Issa, 1985), where a predictor step is followed by a solution of a pressure Poisson equation to ensure the velocity field at the new time level is divergence free. The stability of the solution is restricted by CFL and capillary timescale constraints (Galusinski and Vigneaux, 2008).

4.2 Simulating atomization

As discussed earlier, this is a fast changing field that has received an increasing amount of attention over recent few years. Gorokhovski and Herrmann (2008) presented a review of the state of the art at that time. Since then, the size of the calculations and the degree of detail afforded by them has notably increased. One of the recurring themes in their reviews is that many of the calculations presented have not reported a systematic grid study in which key properties, such as drop size distribution, could be analyzed. This measure will show directly whether adequate grid resolution has been achieved by demonstrating convergence of the calculated drop size distribution with increasing grid resolution. Many of the calculations were categorized as underresolved DNS, and it was noted that most of the calculations did not provide quantitative comparisons against experimental findings. Similar arguments can be made nowadays with respect to the newer studies reported. In fact, grid studies and numerical convergence on the prediction of interfacial disturbances and subsequent ligament/droplet formation continue to be an area of research need.

In a series of articles, Shinjo and Umemura (2010, 2011a,2011b) have reported results on some of the largest atomization calculations to date. Their study focused on the qualitative and quantitative characteristics of a liquid jet undergoing breakup after being injected into a quiescent domain. Three cases were reported in terms of increasing bulk Weber number, $We = (\rho_l U^2 D/2)/\sigma$, namely $We = 1270$ with 400×10^6 cells, $We = 3530$ with 1.16×10^9 cells, and $We = 14{,}100$ with 6.0×10^9 cells. A snapshot of the gas–liquid interface colored by axial velocity is shown in Figure 14 corresponding to these three cases. The results clearly indicate an increase in the population of small droplets with increasing Weber number. From the role of the Weber number, which is a measure of the stability of a liquid body to atomization, this is an expected result. Moreover, the authors provide substantial evidence for the manner in which atomization takes place. It begins with instabilities in both the liquid jet tip and the liquid core, which grow and breakup into ligaments, which subsequently break into smaller droplets. This is in agreement with observed experimental findings and provides a reassuring notion used in the development of atomization models.

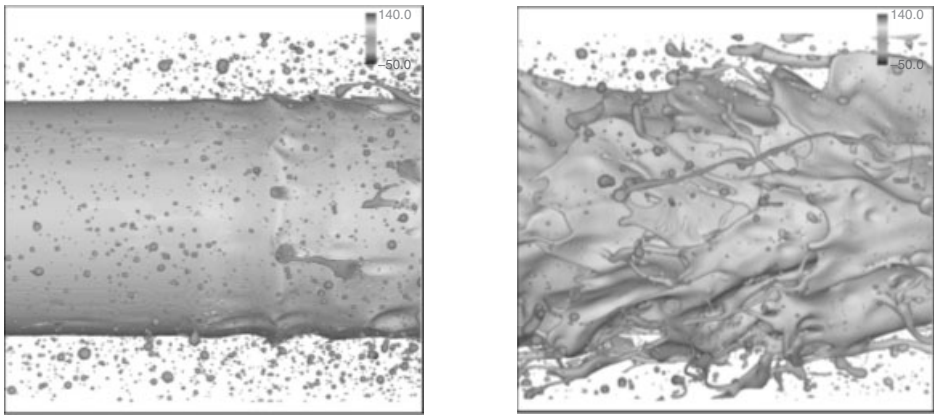

Figure 15. Gas–liquid interface of the jet core displayed in Figure 14 showing the growth of instabilities and subsequent formation of ligaments and droplets. Early time shown in (a) and later time in (b). Colored by axial velocity. (Adapted from Shinjo and Umemura, 2011b. © Elsevier.)

In their latest article, Shinjo and Umemura (2011b) report a study on the breakup characteristics of the liquid core of the jet. These are shown in Figure 15, at two different times. Through a detailed viscous boundary layer analysis of this core region, the authors conclude that the Tollmien–Schlichting (TS) mode is responsible for breakup. Moreover, the authors provide a convincing picture of the physical mechanisms leading to atomization. Initially, the liquid jet tip is deformed because of aerodynamic forcing into the shape of a mushroom head (Figure 14). The deformation proceeds leading to growth of instabilities and formation of ligaments that are periodically stripped from the head. These ligaments subsequently undergo stretching and droplet formation. Downstream of the mushroom head region, a recirculation system is established in the flow field, which entraps small atomized drops. The TS instabilities take some time to develop in the core; however, once they are formed, they are convected into the jet tip, further destabilizing the liquid head. The recirculation flow region also aids in accelerating the growth of the TS waves.

The effect of global Weber number on the resulting droplet population in an atomization calculation has also been reported in the work of Trontin *et al.* (2010), where a liquid sheet having a thickness of δ is exposed to a classical homogenous isotropic turbulent flow field, which is allowed to decay. The sheet is surrounded above and below by gas regions. The gas-to-liquid density and viscosity ratio is one. The authors report that with small Weber number $\mathrm{We} = (\rho_1 U^2 D/2)/\sigma$ of 0.2, the initial disturbance does not result in the atomization of the liquid sheet. With increasing Weber number (We = 2), the sheet atomizes into larger droplets accompanied by small satellite droplets. With even larger Weber number, the atomization intensifies producing a larger population of small droplets. Time histories of the turbulent energy indicate that the maximum deviation from

the corresponding single-phase configuration occurs for the We = 2 case, where the oscillations of the larger droplets grow and persist for relatively long times.

The effect of density ratio, which is particularly important in pressurized combustion applications, has been studied in the simulations reported by Herrmann (2011). The effect of varying this ratio is analyzed by considering two cases having $\rho_l/\rho_g = 10$ and 100, respectively, while keeping the momentum flux ratio, crossflow and jet Weber numbers, and crossflow and jet Reynolds number constant. A snapshot of these two cases is shown in Figure 16, where the higher liquid density case exhibits more penetration and appears to bend less in the direction of the crossflow. The results also indicate a decrease in mean drop size with increasing density ratio and a change in the location where atomization takes place. For the higher liquid density case, the formation of droplets occurs closer to the injector. This also impacts the droplet velocity distribution in the crossflow direction, where the higher density case has a significantly lower mean component.

To ease the burden of computation, Gorokhovski and Herrmann (2008) and Herrmann, 2011 introduce Lagrangian elements to represent small-scale liquid structures that are nearly spherical. It is the resolution of these structures that requires the greatest computational power, and hence their translation into a Lagrangian–Eulerian representation provides significant relief on the computational burden. Moreover, the atomization process for these elements is practically complete; hence, full resolution of their dynamics is not completely necessary. A snapshot of this hybrid treatment is shown in Figure 17. Similar approaches have also been reported by Tomar *et al*. (2010), where in their case the underlying simulation is based on the VoF method. They also provide a mechanism in which the Lagrangian droplets are transferred to a VoF description based on the proximity to the gas–liquid interface. This effectively allows for both Lagrangian droplet formation produced by the atomization process and coalescence, in cases where the droplets merge back into the VoF resolved liquid domain.

4.3 DNS summary and future challenges

As pointed out by Shinjo and Umemura (2010) and earlier by Gorokhovski and Herrmann (2008), level set formulations can result in the formation of fictitious droplets on the order of the grid spacing. This imposes a constraint on the grid density to ensure that the spectrum of breakup processes occurring in atomization calculations is fully resolved. With increasing Weber number and the associated shift to smaller droplet populations as evidenced in Figure 14, it becomes increasingly difficult to obey this constraint. It is primarily this fact that establishes a ceiling

on the global Weber number that can be solved in DNS manner. Up to this point, grid studies consider mostly the final droplet population as a measure of convergence. While this is definitely an important point, it leaves other important characteristics such as the growth of instabilities and the process leading to the breakup of fine ligaments undetermined. Much work remains to be done in this aspect. A particularly sensitive topic is the breakup characteristics under various degrees of grid resolution using numerical schemes other than the level set method of Shinjo and Umemura (2010) or Gorokhovski and Herrmann (2008) and Herrmann, (2011).

On the basis of experience involving canonical advection tests using both level set and VoF methods, we found that the errors increase with increasing interfacial curvature. This implies that as the gas–liquid interface becomes increasingly corrugated during the atomization process, the level of error attributed to advection increases substantially. This is illustrated exercising the augmented level set method (Nave, Rosales, and Seibold 2010; Anumolu and Trujillo, 2011), where both the level set function and its gradient are transported in semi-Lagrangian manner. The order of the method is reported as being fourth order locally and to perform better than fifth order weighted essentially nonoscillatory (WENO) schemes. We have confirmed this convergence rate, but only found it to be the case for objects that were relatively smooth. Objects having levels of curvature above a specified threshold show a worsening level of convergence rate. Results are shown in Figure 18 corresponding to the advection of a spherically harmonic shape defined as

$$\phi = \sqrt{(x - x_o)^2 + (y - y_o)^2} - (r + A\cos(4H\theta));$$
$$\theta = \tan^{-1}\left(\frac{y - y_o}{x - x_o}\right) \text{ with } \theta \in \left[-\frac{\pi}{2}, \frac{\pi}{2}\right] \tag{58}$$

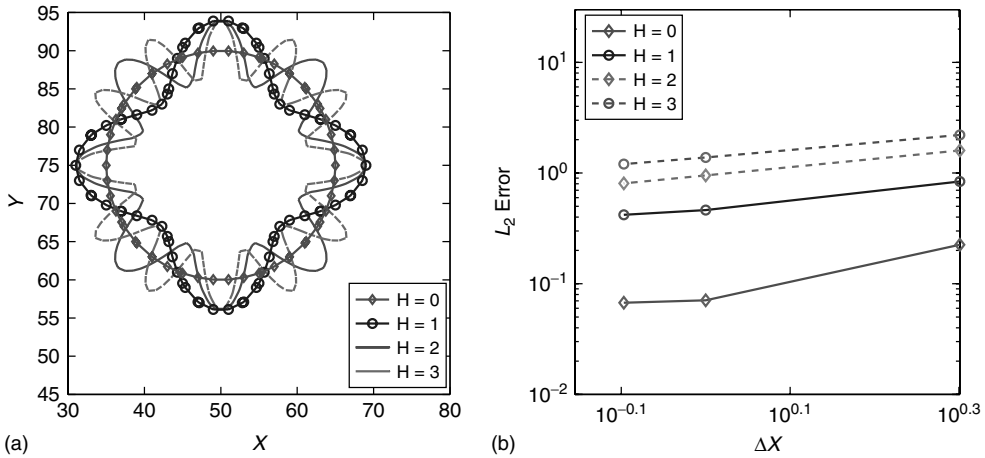

Figure 18. Advection test corresponding to the transport of a spherically harmonic object (a) with increasing levels of interfacial curvature. L_2 error norms are shown on the accompanying plot (b).

under the advection of a circular flow field

$$\mathbf{u} = (u, v); u = \frac{\pi}{314}(50 - y); v = \frac{\pi}{314}(x - 50) \quad (59)$$

The results clearly indicate that increasing local curvature leads to an increase in the L^2 norm of the error by approximately an order of magnitude (convergence rates are approximately the same). Again, the implications are that the fine structures in an atomization calculation are especially vulnerable to this type of error. In addition, we believe that they are also prone to errors in the prediction of the dynamics of breakup, that is, the two-phase momentum calculations. Although at this time, evidence for this idea has not yet been provided.

Compared to the state of the art of atomization a decade ago, significant improvements in computational power and methods over recent 4–6 years have given birth to a new field, namely DNS of atomization. With the level of detail available in these large calculations, it has become possible to interrogate the physical processes taking place in the dense part of the spray region—an area that has been largely unexplored. These calculations remain challenging, not only in terms of computational demands but also more importantly in controlling and understanding the propagation of errors that can easily overwhelm the entire atomization prediction. Hence, a significant aspect of the research over the next few years will undoubtedly be targeted at minimizing the error. In addition, it is expected that computational models based on Lagrangian–Eulerian or partially resolved Eulerian–Eulerian approaches, as well as hybrid schemes, will be presented as alternative strategies for calculating atomization. These models should have the benefit of having DNS data available for detailed comparisons. This is an unprecedented step and marks a turning point in the development of such models, where before only experiments could be used.

Another route in the DNS approach is the implementation of phase change, as well as other future improvements, to make the simulation approach capable of representing all of the relevant physics occurring in realistic fuel injection configurations, for example, diesel sprays. While the phase change and cavitation capability has been reported within the context of implicit interface capturing methodologies limited to small domains (Lee and Son, 2011; Huang and Zhang, 2007), future improvements including a comprehensive and generalized treatment of the thermodynamics, in particular the interfacial conditions at high pressures remain as challenges. These generalizations are required in the adequate treatment of the two-phase flow processes occurring in various engine configurations. It is reasonable to expect that another decade will have to pass, before the full integration of these effects will have become mature within the framework of implicit interface capturing technologies.

Please note that the abstract and keywords will not be included in the printed book, but are required for the online presentation of this book which will be published on Wiley Online Library (http://onlinelibrary.wiley.com/). If the abstract and keywords are not present below, please take this opportunity to add them now.

The abstract should be a short paragraph of between 150–200 words in length and there should be 5 to 10 keywords

Abstract: This chapter reviews the fundamental processes involved in the introduction of fuels into the engine. Spray nozzles commonly used in engine applications are summarized, together with fuel introduction strategies ranging from classical carburetor intake manifold fuel introduction to modern port fuel injection (PFI) fuel injectors. Issues relevant for direct in-cylinder fuel introduction spark-ignition and diesel engines are also reviewed. The effects of air entrainment on spray penetration and vaporization, together with injector nozzle, injection timing and fuel effects on combustion, oil dilution, and engine wear are also discussed. In addition, the effect of fuel spray interaction with in-cylinder airflows is discussed. Current models of fundamental spray processes in engines are reviewed, including models for atomization, drop breakup, drop collision and coalescence, vaporization, drag and deformation, turbulent diffusion, and spray/wall impingement processes. This chapter concludes with a discussion of new computational tools that are currently under development for improved understanding of spray processes.

Keywords: sprays; fuel injection; atomization; breakup; penetration; vaporization; DNS modeling

In-Cylinder Flow

Jacques Borée[1] and Paul C. Miles[2]

[1] *ISAE-ENSMA, Futuroscope Chasseneuil, France*
[2] *Sandia National Laboratories, Livermore, CA, USA*

1 INTRODUCTION

> "An automobile engine, even at present, represents (at least from a fluid mechanical point of view) an accumulation of a century of practice and just a little science"
>
> John L. Lumley

As pointed out by Gosman (1986) in his treatise "Flow Processes in Cylinders", in-cylinder flows in automotive engines have far greater importance than merely the efficient filling and emptying of the cylinder. These flows are essential to the fuel–air mixing process, both through bulk transport by the mean flow and through the small-scale mixing by the turbulent eddies, which subsequently allows molecular diffusion to rapidly complete the intermingling of fuel and air on a molecular scale. The scaling of the turbulent flow structure—an expression we will use to encompass the mean, bulk flow structures as well as the turbulence—with engine speed is the fundamental reason that engines are able to run efficiently even as engine speed changes by an order of magnitude. In spark ignition (SI), predominantly premixed engines, the near proportionality of the turbulent flame speed to the turbulent fluctuating velocity is what allows the oxidation process to be completed in shorter times at high engine speeds, while in non-premixed or partially premixed compression ignition (CI) engines burn duration is shortened by the analogous increase in turbulent mixing rates. Turbulent mixing is also important in homogeneous charge CI combustion regimes, where the temperature inhomogeneities created by turbulent transport from the boundary layers act to smooth the heat release, preventing excessive pressure rise rates.
